Direct measurements of the radiation component of electrical conductivity, taken under irradiation conditions, have been published. Figs. 2 and 3 give the results of measurements of the electrical conductivity as a function of temperature on quartz[72] and potassium iodide[4], both of which are wide-gap materials. It is evident that the radiation component of the conductivity vanishes at ~140° for both quartz and monocrystalline potassium iodide.

Barry and Roberts[73] found that the rate of the synthesis of methanol from carbon monoxide and hydrogen over zinc oxide (in a flow system at atmospheric pressure) is increased by a factor of 2–3 by gamma radiation at 160–230°, whereas above 230° the radiation has no effect.

The decomposition of methanol on zinc oxide[74] is also markedly accelerated by gamma radiation provided the temperature is below 400°. Above this temperature no radiation effect could be detected.

A peculiar difference in the effect of radiation on the activity of *n*- and *p*-type semiconductors was noted in the same paper[74]. With zinc oxide (an *n*-type semiconductor) the rate of decomposition of methanol was increased by irradiation, but with chromium oxide (a *p*-type semiconductor) the opposite effect was observed under otherwise identical experimental conditions. Evidently, this effect is due to some specific feature of the methanol decomposition mechanism, in conjunction with the electronic structure of the catalysts. As the authors point out, the effect of the radiation decays rapidly when the catalyst is shielded from the source of radiation. There is an interesting "saturation" effect, or some kind of limit to the effect of radiation on the catalytic activity of zinc oxide and chromium oxide samples of different initial activity. The radiation–catalytic activity of the samples of zinc oxide and chromium oxide found to be most active in the ordinary catalytic reaction was independent of the radiation dose. On the other hand, the radiation–catalytic activity of low-activity zinc oxide could be made to approach the activity of the most active zinc oxide sample in the non-irradiated state at high enough doses. This observation is consistent with the hypothesis put forward by Coekelbergs and coworkers[22], according to which radiation can have no effect on a semiconductor already carrying a maximum concentration of current carriers.

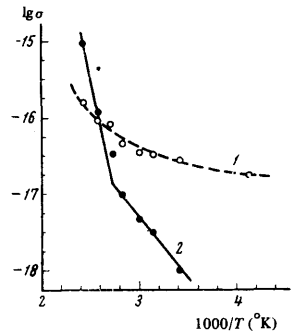

Figure 2. Temperature dependence of the logarithm of the electrical conductivity of crystalline potassium iodide[4]: *1*) not irradiated; *2*) exposed to X-rays.

The radiation–catalytic oxidation of carbon monoxide on alumina[75] under the influence of X-rays has been studied by the dynamic method over the temperature range 23–400°. The effect of irradiation was to increase the reaction rate at temperatures up to 300°.

It has been shown that the activation energy of the reaction is zero in the temperature range 80–300°. At temperatures above 300°, however, the activation energy is 18 kcal mole^{-1}, i.e. is almost indistinguishable from the activation energy of the thermal reaction (Fig. 4).

Spitsyn and coworkers[76–83] have studied catalytic reactions at very high temperatures using radioactive catalysts. These systems are much more complex and specific, because the source of radiation in this case is a radioactive isotope of one of the elements in the crystal lattice of the catalyst. They found that the catalytic activity of sodium and magnesium sulphates and of tricalcium phosphate containing ^{35}S, ^{45}Ca, and ^{32}P towards the dehydration of cyclohexanol and isopropanol increases with the specific radioactivity of the catalyst and with the intensity of β-radiation. The introduction of radio-isotopes into the catalyst led in some cases[76,77] to a fall (100–120 deg) in the optimum temperature for the reaction. According to the authors[14,80,81], these effects can be explained by the charging of the sample.

It must be stressed that the catalytic activity of radioactive catalysts is very dependent on the method of preparation. Spitsyn ascribes[83] to this effect the discrepancy between the results obtained in his laboratory and those of Krohn and Smith[84].

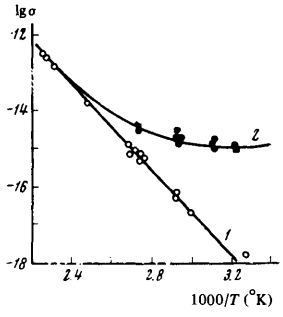

Figure 3. Temperature dependence of the logarithm of the electrical conductivity of quartz[72]: *1*) not irradiated; *2*) exposed to radiation.

In another series of papers[85-88] Spitsyn and coworkers discuss the dehydration of n-decanol and the isomerisation of dec-1-ene over aluminium oxide at 250–450° under the influence of various types of radiation: X-rays, gamma rays, and radiation from a nuclear reactor. The highest increase in reaction rate (a factor of 2–3) was obtained using X-rays. Irradiation with gamma rays and with neutrons lowered the catalytic activity of the alumina: according to the authors, this is explained by the annihilation of active centres on the catalyst surface. The rate of isomerisation was increased by irradiation with sources of all types except gamma rays from ^{60}Co, which caused a decrease in the rate of isomerisation of dec-1-ene. A decrease in the optimum temperature was found also on adding ^{137}Cs as a radioactive impurity. The effect of radiation decreased on raising the temperature of the catalytic reaction, obviously as a result of "annealing" of the radiation defects. The same effect of temperature on the radiation-catalytic activity was found by Maxim and coworkers[89] in their work on the oxidation of carbon monoxide on nickel oxide containing 2.5% of lithium in the presence of radiation. With catalysts of relatively low initial activity and conductivity, and at low reaction temperatures, irradiation had a drastic effect on both the catalytic activity and the electrical conductivity of the system.

Thus, existing data indicate that changes in catalytic activity during radiation-catalytic processes are usually relatively minor, they are most likely to be found at low temperatures, and they vanish completely at high temperatures.

2. Low-temperature Radiation-Catalytic Reactions

This group of reactions includes, mainly, radiation-catalytic reactions in the adsorption layer, which are carried out at low temperatures, where the rate of the normal catalytic reaction is negligible. In this case the radiation effect is all-important, because the ionising radiation is the only source of energy available to low-temperature radiation-catalytic reactions. The "Arrhenius" activation energy for these reaction is usually almost zero.

The most characteristic feature of these reactions is the transfer of the energy absorbed by the solid to molecules adsorbed on its surface. The transfer of energy supplied by the ionising radiation from the solid to the adsorbed molecules is confirmed by a fund of experimental evidence, according to which the radiation-chemical yield of heterogeneous reactions (calculated for the adsorbed species) is well in excess of the corresponding radiation-chemical yield for the homogeneous reaction.

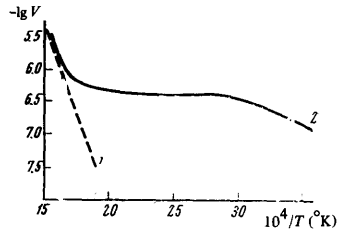

Figure 4. Logarithm of the catalytic activity of Al_2O_3 (V) against reciprocal temperature for the oxidation of carbon monoxide[75]: *1*) dark reaction; *2*) exposed to radiation.

We must stress that the radiation-chemical yields of heterogeneous catalytic reactions are very difficult to compute, because of the need to know the distribution of the energy absorbed by the system between the catalyst and the adsorption layer, the mechanism of transfer of the absorbed energy, etc. With radiation-catalytic reactions in the adsorption layer it can be assumed that the energy of the ionising radiation is absorbed by the solid and by the adsorbate in proportion to their electron fractions. In practice, the radiation-chemical yield of a reaction involving the adsorbate can be defined in two ways: the radiation-chemical yield referred to the energy absorbed by the whole system, i.e. solid and adsorbate, and the radiation-chemical yield referred to the energy absorbed by the adsorbate only, G_{ads}‡. The latter does not reflect the true significance of the radiation-chemical yield. However, a comparison of G_{ads} with the corresponding radiation-chemical yield for the homogeneous radiolysis (G_{hom}) leads to some definite conclusions on the role of the solid in the radiation-catalytic reaction and on the ways in which energy absorbed in the bulk of the solid can be transferred to molecules adsorbed on its surface. Radiation-chemical yields per 100 eV of energy absorbed by the whole system are termed G_{tot}, as in a number of other investigations[22]. Large values of this yield (upwards of 100) are evidence that a chain mechanism may be present. The radiation-chemical yield G_{tot} is a measure of the extent to which the radiation energy absorbed by the whole system is utilised.

The chemical nature, and in particular the electronic properties of the solid, play an important role in the energy transfer process. Some solids can accelerate chemical

‡ This quantity is sometimes termed G_{gas} in the foreign literature[22].

processes on their surface, i.e. they are radiation catalysts and they provide an effective medium for the energy transfer; other solid are altogether lacking in these properties. The earliest investigations of the role of the catalyst in the energy transfer process were aimed at the heterogeneous radiolysis of alkanes. Allen and coworkers[90-94] studied the influence of gamma radiation on the low-temperature reactions of pentane adsorbed on silica gel, alumina, magnesium oxide, and various molecular sieves. The relationship between the radiation-chemical yield of hydrogen and the electron fraction of pentane adsorbed on solid surfaces led the authors to propose an energy transfer effect between the solid and molecules adsorbed on its surface. The energy transfer was assumed to be confined to the first adsorbed layer, the rate of the heterogeneous reaction in all other layers being the same as that for the homogeneous reaction.

A large number of products, of different composition, have been detected during the radiation-induced conversion of pentane in the adsorbed state, the most abundant being hydrogen and decane isomers. In contrast to the homogeneous radiolysis of pentane, the yields of unsaturated hydrocarbons were quite low and the yields of isomerisation products were high, suggesting that the selectivity of the reaction had been changed. The radiation-chemical yields were dependent on catalyst composition and (for catalysts of a given composition) on the particle size. Fig. 5 shows the dependence[91] of radiation-chemical yield on the coverage of the adsorbent surface. Radiolysis measurements on NaCoX molecular sieve failed to detect any hydrogen formation on this catalyst.

However, the curves of Fig. 5 relate to the formation of free hydrogen, and may be significantly distorted by radiation-induced hydrogen chemisorption, known to occur to different extents on different solids[95-97].

The authors discuss these results from the standpoint of electronic ideas, the energy transfer process being treated as the motion and recombination of free electrons and holes formed by irradiation.

Topchiev and his coworkers[98-102] studied the heterogeneous radiolysis of heptane adsorbed on aluminium silicate, chromate, molybdate, and other oxide catalysts under the influence of gamma radiation. The reaction was investigated both at room temperature and at liquid nitrogen temperature. The composition of the heterogeneous radiolysis products of heptane differed from the composition of the homogeneous radiolysis products; the heterogeneous catalytic reaction gave fewer unsaturated hydrocarbons and a greater proportion of isomerisation products, again showing that the selectivity of the process had changed. The investigation included a study of the effect of coverage on the reaction rate. The transfer of energy from the solid to the adsorbed molecules, first established by Allen, was confirmed in this work. It was also shown that the rate of radiolysis of hydrocarbon adsorbed in excess of monolayer coverage was the same as the rate of the homogeneous reaction[99]. The rate of the heterogeneous radiolysis of heptane fell steeply at high doses (of the order of 5×10^8 rad); one possible explanation is rapid polymerisation of the resulting unsaturated compounds.

Hentz[103] studied the effect of radiation on the reactions of isopropylbenzene adsorbed on microporous alumina-silica. The following species were detected among the decomposition products: hydrogen, methane, propene, propane, isobutane, benzene, isopropylcyclohexane, etc. The reaction was found to be more specific than the radiation-induced decomposition of liquid or gaseous isopropylbenzene. Thus, the yield of benzene was higher in the presence of the catalyst, the formation of unsaturated hydrocarbons was inhibited, the amount of isomerisation products increased, and isopropylcyclohexane could not be detected in the absence of the catalyst. The radiation-chemical yields of all products decreased at higher doses of absorbed radiation. By studying the dependence of the individual yields on the electron fraction of the particular adsorbate the author concluded that the mechanism of benzene formation is different from that of all the other products. Whereas the yield of methane increased slowly with the electron fraction of isopropylbenzene (in the low-coverage region), and the yield of hydrogen fell, the yield of benzene went through a sharp maximum at 1% coverage of the surface. This behaviour was ascribed to saturation of the centres most active towards dealkylation. In the light of the peculiar relationship between the benzene yield and coverage, and of the high radiation-chemical yields in the presence of the solid, the author concludes that the energy absorbed by the solid is transferred to the adsorbed molecules and is converted into the energy needed to activate the chemical reaction.

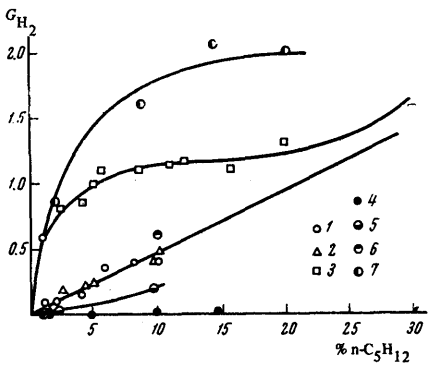

Figure 5. Hydrogen yield as a function of n-pentane adsorbed (wt.%)[91]: *1*) SiO_2 (100 μm); *2*) SiO_2 (62 μm); *3*) SiO_2 (0.02 μm); *4*) Fe_2O_3 (less than 44 μm); *5*) attapulgite (1 μm); *6*) montmorillonite (5 μm); *7*) silica gel.

There have been several recent reports of the effect of radiation on the reactions of inorganic and organic compounds adsorbed on various substrates. The yields are invariably higher than those of the corresponding homogeneous reactions.

The heterogeneous radiolysis of carbon dioxide has been studied by a number of workers. Thus, Coekelbergs and coworkers[104] investigated the radiation-chemical decomposition of carbon dioxide adsorbed on alumina, silica gel, and magnesium oxide under the influence of gamma radiation from ^{60}Co, beta radiation from ^{90}Sr, and X-rays. Energy transfer from the solid to the adsorbed molecules was confirmed in every case. With alumina, the ratio G_{ads}/G_{tot} increased very markedly at lower surface coverages. The radiation-chemical yields remained constant in the temperature range 25-300°, and the nature of the radiation also had little effect.

Other workers[105] studied this reaction on silica gel, alumina, and various semiconductors. The radiation-chemical activity was higher with intrinsic semiconductors than with n- or p-type semiconductors. Changes in dose rate over the range 0.28–3.18 Mrad h^{-1}, and temperature increase up to 180°, had no effect on the radiation-catalytic process.

Sutherland and coworkers[106] studied the rate of radiolysis of carbon dioxide adsorbed on silica gel as a function of the dose of radiation, of the concentration of adsorbed molecules, of the catalyst preparation conditions, and of the water content in the silica gel. The high radiation-chemical yields of carbon monoxide were ascribed to energy transfer from the sorbate to the sorbent (sic.).

One of the earliest papers from Coekelbergs' laboratory[107] discusses the decomposition of nitrous oxide at 80°, with formation of nitrogen and oxygen, in the presence of silica gel or alumina and under the influence of fission products. The microporous sorbents were found to increase the ratio G_{ads}/G_{hom} by a factor of 3–10. Nitrogen fixation was also investigated (at 25 atm and 80°, in the presence of fission products). The total amount of fixed nitrogen was defined as the sum of the oxides $NO_2 + N_2O_3 + N_2O_5$. The reaction was shown to be strongly influenced by the presence of microporous solids, especially silica gel.

Coekelbergs and coworkers[108] studied the synthesis of ammonia on alumina at atmospheric pressure under the influence of beta rays from ^{90}Sr and gamma rays from ^{60}Co: the former had little effect, but in the presence of gamma radiation the yield of ammonia was proportional to the dose of radiation, independent of hydrogen pressure, but dependent on the pressure of nitrogen. The activation energy in the range 200–600°K was found to be ~0.5 kcal $mole^{-1}$, with a radiation-chemical yield G_{ads} of 100–500 molecules. This high value of G_{ads} is ascribed to the transfer of the energy absorbed by the solid to the adsorbed molecules. Ammonia synthesis occurred on one grade of alumina only: no reaction was observed on the other alumina samples, or on silica gel, magnesium oxide, and zinc oxide.

Thus, the most marked effect of ionising radiation on the reactions of adsorbed molecules is found with solids of the insulator type, which have also been most extensively investigated. Semiconductors have been studied in a few isolated cases in this context, metals hardly at all.

The radiation-catalytic activity of solids with different gap widths (insulators, semiconductors, and metals) was first investigated under otherwise identical experimental conditions by Zhabrova and her coworkers[109,110], who chose cyclohexane in the adsorption layer as their experimental system. Irradiation was by fast electrons and by gamma rays from ^{60}Co. The most active catalysts were found to be insulating oxides (silica gel, alumina-silica, and alumina), whereas metals and low-gap semiconductors (such as zinc oxide, cuprous oxide, nickel oxide, and active carbon) did not develop catalytic activity on irradiation. The radiation-chemical yield of hydrogen was studied as a function of surface coverage of silica gel by cyclohexane (Fig. 6), and it was found that the extent of reaction of cyclohexane with formation of hydrogen increases with decrease of coverage. A possible energy transfer mechanism from the solid to the adsorbed molecules was put forward on the basis of the band theory of the solid state. It must be stressed, however, that in this work the radiation-catalytic activity was determined merely from the amount of hydrogen evolved. Hence, the quantitative data for the radiation-chemical activity of the various solids obtained in this work may be in error by the extent to which hydrogen is adsorbed on these solids.

This deficiency was overcome in a study by the same authors[111-114] of the radiation-catalytic reactions of methanol adsorbed on solids with forbidden gaps of different width. In this work the radiation-catalytic activity was determined for all the main reaction products: hydrogen, formaldehyde, and ethylene glycol. The highest radiation-chemical yields G_{ads} were obtained with insulators (high energy gap materials). Thus, with silica gel the parameter G_{ads} exceeded the corresponding radiation-chemical yield for the homogeneous radiolysis of methanol by over a factor of 10. Significant radiation-catalytic activity was found also in alumina, alumina-silica, and potassium fluoride, whereas semiconducting oxides had lower activity. Metals, active carbon, and graphite showed no radiation-catalytic activity.

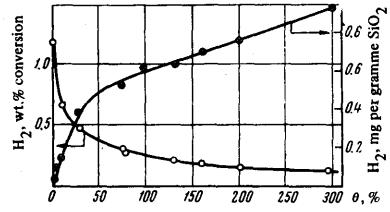

Figure 6. Amount of hydrogen formed and percentage conversion of cyclohexane against coverage of a silica gel surface by cyclohexane[110].

The fact that the radiation-chemical yields of the products of the heterogeneous radiolysis of methanol are much higher on the surface of insulators and some semiconductors than the radiation-chemical yields of the corresponding homogeneous reaction suggests that these solids are able to transfer the energy absorbed from the ionising radiation to molecules adsorbed on their surface. This is evidently not the case for the other group of solids (platinum, palladium, cuprous oxide, nickel oxide, active carbon, and graphite).

Rabe and coworkers[115] studied the radiolysis of azoethane adsorbed on silica gel. Only the gaseous decomposition products were monitored, consisting mainly of nitrogen (with small amounts of hydrogen and methane). The higher yield of nitrogen (as compared with the homogeneous reaction) is explained by assuming that the radiant energy absorbed by the solid is used in the chemical decomposition of the adsorbed azoethane. A more recent communication by the same authors[116] describes the radiolysis of azoethane adsorbed on different solids: silica gel, magnesium oxide, zinc oxide, nickel oxide, titanium dioxide, alkali metal halides, and graphite. The conclusion is that, as in the radiation-catalytic decomposition of cyclohexane and methanol, the strongest tendency to transfer absorbed energy from the solid to molecules adsorbed on the surface is found in insulators. Some semiconductors have a weak effect, others have practically none. The relative radiation-catalytic activity of solids towards the radiolysis of azoethane is illustrated in Fig. 7 as plots of amount of nitrogen formed against surface coverage of the solids by azoethane. With the exception of magnesium oxide, the amount of nitrogen increased monotonically in every case with surface coverage. With magnesium oxide the relationship was more complicated, with maxima at

different coverages for the various products. The radiation-chemical yield of the decomposition products of azoethane decreases with increasing dose of total absorbed radiation.

Sorokin and coworkers[117-119] made a detailed study of the decomposition of ammonia adsorbed on various zeolite surfaces, and found that when the Na form of the zeolite is used the radiant energy absorbed by the solid is transferred to the adsorbed ammonia molecules. The yield of hydrazine—the main radiolysis product of ammonia—expressed in terms of the energy taken up by the adsorbed ammonia was considerably higher than the corresponding yield for the radiolysis of liquid or gaseous ammonia. The radiation-chemical yields of products increased at lower surface coverages of the zeolite by ammonia, and the ratio of hydrazine to hydrogen increased, showing that the selectivity of the process had changed. No energy transfer was observed on irradiating ammonia adsorbed on zeolite in the Ca form.

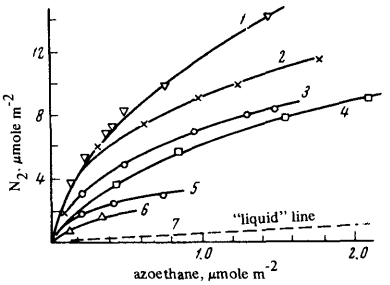

Figure 7. Nitrogen evolved against adsorption of azoethane on various solid surfaces[115]: *1*) SiO_2 (5.9 Mrad); *2*) KI (2 Mrad); *3*) NaF (2 Mrad); *4*) NaCl (2 Mrad); *5*) LiF (2 Mrad); *6*) SiO_2 (1.5 Mrad); *7*) homogeneous radiolysis ("liquid" line).

The influence of the ions present in the zeolite structure on the radiation-catalytic properties of the system has been noted also in the radiolysis of pentane[93] and cyclohexane[120] in the adsorption layer.

The radiolysis of water adsorbed on silica gel has been studied by Krylova and Dolin[121]. The high radiation-chemical yield of hydrogen (calculated on the basis of the energy taken up by the adsorbed water only) is explained by postulating that the adsorbed molecules can acquire additional energy from the solid. The effect of adsorbed water on the ESR spectrum of silica gel irradiated at −196° supports the energy transfer hypothesis. Carbon dioxide was detected among the radiolysis products: according to the authors, this is the result of interaction between traces of residual organic matter on the silica gel surface and oxidising agents formed during the radiolysis of water. More rigorous purification of the silica gel surface from traces of organic compounds lowered the radiation-chemical yield of the radiolysis products of water.

As was pointed out above, there is ample evidence[110,113,116] that, in contrast to ordinary catalysis, the solids most active in radiation-catalytic processes are insulators and wide-gap semiconductors. The dependence of catalyst activity upon the width of the forbidden gap for radiation-catalytic and ordinary catalytic reactions is shown in Figs. 8 and 9. Fig. 8, which refers to the radiation-catalytic decomposition of methanol, shows that semiconductors and insulators behave as active catalysts if their forbidden gap is 4 eV wide or more. We note that the acid-base properties of the solids do not appear to play an important part in radiation-catalytic processes: it can be seen from Fig. 8 that insulators with acidic properties (SiO_2, Al_2O_3) are as effective as basic insulators (MgO, CaO) towards the radiation-catalytic reactions of methanol.

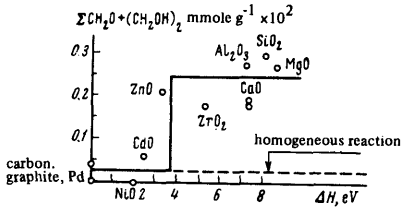

Figure 8. Radiation-catalytic activity of solids as a function of forbidden gap width[122].

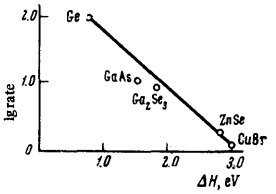

Figure 9. Activity of semiconductor catalysts as a function of forbidden gap width[123].

In contrast to radiation catalysis, the activity of the catalyst in ordinary oxidation-reduction catalysis decreases as the width of the forbidden gap increases[123].

Coekelbergs and coworkers[16] have shown theoretically that large qualitative and quantitative changes in catalytic activity can be obtained even at low radiation intensities in the case of insulators. On the other hand, only minor changes in activity are possible (even at high radiation intensities) in the case of "good" semiconductors. This behaviour is sometimes found also with radiation-catalytic chain reactions. Thus, the radiation-chemical yield for the polymerisation of ethylene (in terms of the energy absorbed by the whole system) is 20–50 times higher on silica gel, alumina, or zeolites than in the homogeneous reaction. The lowest catalytic activity was that of the semiconductor zinc oxide, whereas active carbon actually inhibited the reaction.

The rate of the radiation-catalytic polymerisation of acrylonitrile and methyl methacrylate at −78° increased by an order of magnitude in the presence of magnesium oxide and some *p*-type semiconductors[125], whereas *n*-type semiconductors were less effective. The polymers obtained by this reaction had a high molecular weight, a high density, and a stereoregular structure.

A group of workers[126,127] has studied the radiation-induced graft polymerisation of methyl methacrylate and styrene on powdered magnesium oxide and Aerosil (SiO_2). The rate of the reaction was found to depend on the monomer concentration in the adsorption layer. The high radiation-chemical yield of the reaction is ascribed by the authors to transfer of the energy absorbed by the catalyst to the surface.

The radiation-catalytic synthesis of higher carboxylic acids from ethylene and carbon dioxide has been achieved in the presence of an insulator (alumina)[128,129]. The consumption of ethylene, related to the total energy absorbed, was $G_{(-C_2H_4)} = 10^3$. The carboxylic acids contained approximately 100 molecules, i.e. the yield of radiation-induced polymerisation centres was about 10. The catalyst appears to act not only by increasing the initiation efficiency but also by partly suppressing the chain-breaking step. In the absence of radiation the reaction did not take place, even on adding free-radical initiators.

The radiolysis of heptane in the adsorption layer on alumina above 150° is also stated to be a chain reaction[101].

Kohn has made a detailed study of the radiation-catalytic oxidation of approximately 70 different hydrocarbons on silica gel and alumina[130]. The radiation-chemical consumption of oxygen was often very high, with $G_{(-O_2)} \simeq 100$, suggesting the possibility of chain reactions. The yield of reaction products was independent of temperature, and increased on lowering the oxygen pressure. According to the author, existing views on the mechanism of chain growth on the surface for "dark" heterogeneous reactions cannot explain the growth of chains during the radiation-catalytic oxidation of hydrocarbons. Radiation-catalytic chain reactions are characterised by a very high radiation-chemical yield (on the basis of total absorbed energy). One possible explanation is more effective chain initiation at the surface of an irradiated solid, coupled with a lower mobility of the growing molecules in the adsorption layer of a solid surface. The latter effect can inhibit the rate of chain breaking. Also, the "orientation" of the molecules on the surface of a solid can influence the mechanism of chain growth, and sometimes leads to the formation of stereoregular polymers[125] as in the case of thermal heterogeneous polymerisation.

3. Possible Mechanism and Electronic Steps in the Radiation-induced Transformation of Adsorbed Molecules

As was stated above, in radiation-catalytic processes the radiant energy absorbed by a wide-gap solid can be transferred to chemisorbed molecules, the result being a radiation-chemical yield G_{ads} of reaction products much greater than the corresponding yield for homogeneous radiolysis.

Early workers used the statistical approach to explain the main features of energy transfer[98,102]. According to others[131], the radiation-catalytic activity of solids is determined by their specific heat, the more active catalysts having relatively low specific heats. These ideas have not been confirmed experimentally. Various reaction schemes involving surface hydrogen atoms are considered in a series of investigations of the radiation-catalytic activity of silica gel. One such scheme was proposed by Sutherland and Allen[94] in order to account for the selectivity of the heterogeneous radiolysis of pentane on the surface of silica gel and on NaHX molecular sieve:

$$SH \rightsquigarrow S + H \quad (1)$$

$$H + C_5H_{12} \rightarrow C_5H_{11} + H_2 \quad (2)$$

$$C_5H_{11} + C_5H_{11} \rightarrow C_{10}H_{22} \quad (3)$$

where SH is a surface compound with Si-OH groups.

In the liquid-phase radiolysis the yield of decane is 1/2, consisting almost entirely of isomeric decanes. If silica gel is used the yield of decane becomes 2/3, of which 1/6 is n-decane and the remaining 5/6 are a mixture of isomers. With NaHX at low coverages, a higher ratio of decane isomers to normal decane is obtained.

According to Sutherland and coworkers[106], during the heterogeneous radiolysis of carbon dioxide on silica gel energy is absorbed also by surface Si-OH groups, which then interact with adsorbed molecules. It must be noted, however, that schemes involving OH groups of the silica gel are usually supported only by indirect evidence. Strelko and Suprunenko[132] observed the formation of $\cdot C_6H_6D$ and $\cdot C_6H_7$ radicals during isotope exchange between the hydrogen atoms of benzene adsorbed on silica gel and partially deuteriated OH groups, under the influence of ionising radiation.

Unambiguous proof of the participation of silica gel surface groups in radiation-catalytic reactions of organic compounds obviously requires a study of hydrogen exchange between the surface groups and the reacting molecules during the radiolysis.

On the other hand, studies of the radiation-catalytic reactions of methanol on silica gel have shown unequivocally that surface hydrogen atoms are not involved in the reaction, since the radiation-catalytic activity of silica gel is not affected when the hydrogen ions of OH groups are replaced by calcium ions[136].

Electronic models are widely used to explain the features of energy-transfer phenomena in radiation-catalytic reactions.

Caffrey and Allen[91], in their work on the heterogeneous radiolysis of pentane on silica gel and on molecular sieves, discussed a possible mechanism for the transfer of absorbed energy from the solid to adsorbed molecules, involving the recombination of electrons with positive charges localised on adsorbed molecules. The authors postulated the formation of a pentyl radical.

ESR studies of the radiation-catalytic reactions of cyclohexane[110] revealed the formation of adsorbed $\cdot C_6H_{11}$ radicals and the appearance of paramagnetic centres on the surface of the insulating oxides and fairly-wide-gap semiconductors which catalyse this reaction. No adsorbed $\cdot C_6H_{11}$ radicals or paramagnetic centres were observed with semiconductors lacking radiation-catalytic activity towards the reaction. The cyclohexane was assumed to be adsorbed on an excess charge carrier (hole) with formation of a positively charged molecule of cyclohexane. Recombination of an electron from the conduction band can take place on this charged molecule, and the recombination energy, determined by the width of the forbidden gap, is localised on the adsorbed molecule and enables it to decompose. There is a high probability that the decomposition is accompanied by the formation of free radicals, but the composition of the radiation-catalytic decomposition products of cyclohexane is so complicated that it was not possible to compare the amounts of products and radicals formed and to establish the role of the latter in the overall process.

The mechanism of the radiation-catalytic transformation of methanol has been studied in greater detail[111-113]. Irradiation of methanol adsorbed on insulators and on semiconductors showing radiation-catalytic activity leads to the formation of adsorbed $\cdot CH_2OH$ radicals and much smaller

amounts of·CHO and·CH_3. A typical ESR spectrum of irradiated methanol adsorbed on silica gel is shown in Fig. 10. In order to characterise the role of adsorbed radicals, the amounts of radicals and of radiation–catalytic decomposition products of methanol were compared in a special series of experiments. The results (Fig. 11) show the variation of the numbers of resulting ethylene glycol molecules (upper curve) and·CH_2OH radicals (lower curve) with the dose of radiation absorbed. It can be seen that the two curves deviate in the region of high absorption, evidently due to radical recombination at high concentration, whereas in the low-absorption region the curves are close together. This suggests that·CH_2OH radicals are intermediate products in the formation of ethylene glycol. Analogous investigations of the role of·CHO radicals[122] showed that these are not intermediates, but they probably arise by the decomposition of formaldehyde under the influence of radiation.

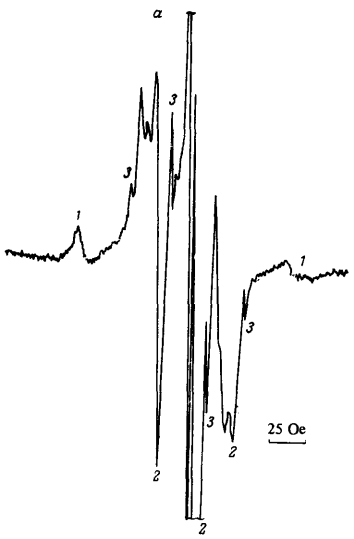

Figure 10. ESR spectrum[113] of methanol adsorbed on silica gel and irradiated at −196° (dose: 10 Mrad): *1*)·CHO radical; *2*)·CH_2OH radical; *3*)·CH_3 radical.

The correlation between the radiation–catalytic activity of solids in the heterogeneous radiolysis of methanol and their electronic properties (forbidden gap width), and also the correlation with the appearance of adsorbed radicals, justify the assumption that the heterogeneous radiolysis of methanol involves both electronic and radical steps, and that the energy transfer process is associated with the motion and recombination of excess charge carriers generated in the solid by the radiation. From the experimental results, the following scheme was put forward for the radiation–catalytic conversion of methanol adsorbed on solid surfaces:

$$\text{T solid} \rightsquigarrow \text{T solid} \oplus \ominus$$
$$CH_3OH \oplus \longrightarrow \underset{\text{chem.ads.}}{CH_3OH^+}$$
$$\underset{\text{chem.ads}}{CH_3OH^+} + \ominus \longrightarrow \dot{C}H_2OH + \dot{H}$$
$$\dot{C}H_2OH + \dot{C}H_2OH \longrightarrow (CH_2OH)_2$$
$$\dot{C}H_2OH \longrightarrow CH_2O + \dot{H}$$
$$\dot{H} + \dot{H} \longrightarrow H_2$$

Under the influence of radiation, excess non-equilibrium charge carriers (electrons and holes) are formed in the solid. Methanol molecules adsorbed on the surface interact with these carriers, and since alcohols have electron-donating properties we may assume that the methanol molecules interact with holes. As in the case of cyclohexane, an adsorbed positively charged methanol molecule acts as a recombination centre for an excess electron from the conduction band. Recombination of a pair of charges liberates an amount of energy equal to the width of the forbidden gap minus the height of the energy level of the chemisorbed molecule. If this energy is high enough (≥4 eV), an atom of hydrogen is eliminated from the methanol molecule with formation of a·CH_2OH radical. Recombination of the·CH_2OH radicals produces ethylene glycol molecules, and dissociation of these radicals produces formaldehyde molecules. A hydrogen molecule is formed by the recombination of two hydrogen atoms.

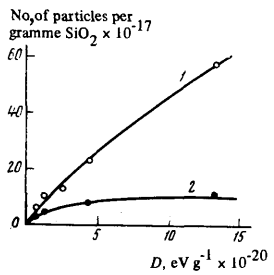

Figure 11. Number of·CH_2OH radicals and of ethylene glycol molecules (expressed as CH_2OH particles) as a function of dose absorbed; surface coverage of silica gel 30% at −196°:[113] *1*) $(CH_2OH)_2$; *2*)·CH_2OH.

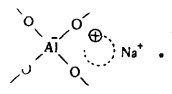
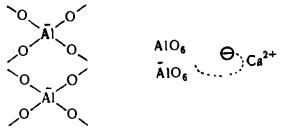
A similar energy transfer scheme involving the recombination of excess current carriers, but with the participation of intermediate charged centres, has been proposed from a study of the heterogeneous radiolysis of ammonia on zeolites[117]. By using the ESR method it was shown that hydrazine is formed through the recombination of $\dot{N}H_2$ radicals. As the number of $\dot{N}H_2$ radicals on the surface increases, the number of paramagnetic centres falls (Fig. 12). In order to explain the mechanism of heterogeneous radiolysis, the ESR spectra of ammonia adsorbed on sodium and calcium zeolites were investigated[119], and it was concluded that the paramagnetic entities obtained by gamma irradiation of these two types of zeolite are different. In the Na form the radiation-induced catalytic centres are, according to the authors, of the *V*-centre type, and are similar to the centres formed by irradiation of silica gel containing alumina:



Irradiation of the Ca-form, on the other hand, is said to produce paramagnetic F-centres consisting of excess electrons localised on Ca–O bonds. According to the authors, these centres have the structure



In both forms of zeolite, the energy absorbed in the bulk of the solid must be re-evolved during recombination of the electrons and holes. In the presence of adsorbed ammonia molecules, which have a high affinity for positive charge because of the unshared electron pair on the nitrogen atom, a donor–acceptor bond is formed between the molecule and the surface. In the case of the Na-form, the holes formed by irradiation reinforce the bond between the ammonia molecule and the surface. On the other hand, with the Ca-form the electrons localised at the surface weaken the bond between the ammonia molecule and the surface, and energy transfer by electron–hole recombination has a low probability. As required by this model, the zeolite in the Ca-form was found to be inactive towards the heterogeneous radiolysis of ammonia.

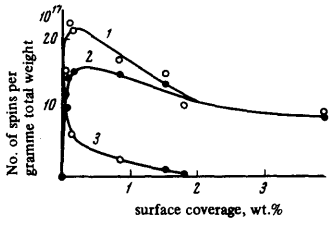


Figure 12. Effect of surface coverage on the concentration of radicals[119]: *1*) total concentration; *2*)·NH_2 radicals; *3*) paramagnetic centres in the zeolite.

Similar recombination mechanisms for the energy transfer process are proposed in other investigations of the radiation–catalytic reactions of organic molecules, recently published[103,117,134]. In most of the schemes put forward a molecule of the organic compound, adsorbed on the surface, acts as the recombination centre for excess current carriers. Intermediate paramagnetic F- and V-centres, formed in the solid during irradiation by capture of an electron or a hole at various defects, are not usually postulated. Yet, these centres must play an important part in processes involving prior irradiation of the catalyst. They stabilise the free current carriers, and thus give rise to "long-lived" excitation in the solid (the "memory" effect). On the other hand, it was shown in a number of investigations that the presence of impurities or other structural defects in the catalyst is relatively unimportant when irradiation is applied during the reaction. For example, the radiation–catalytic activities of silica gel and of alumina–silica containing 10% of alumina were found to be the same in the radiolysis of methanol[111] and of isopropylbenzene[134]. A sample of spectroscopically pure silica gel, containing less than 10^{-4}% of aluminium, had the same radiation–catalytic activity as a sample of silica gel of SMKh grade, containing a significant amount of alumina[122]. Thus, most workers (with the exception of Sorokin[117]) assume that energy transfer in dielectrics involves free charge carriers, and that localised charge carriers (if they are formed) play a minor part. It would appear that direct trapping of excess carriers by adsorbed molecules is the basic process in the radiation–catalytic reactions of adsorbed molecules.

4. Role of the Bulk and Surface of Solids in the Energy Transfer Process

As stated above, the most commonly held view of the energy transfer process involves the recombination of excess non-equilibrium charge carriers formed in the bulk of the solid under the influence of radiation. However, the extent to which these excess carriers from the bulk are used in the radiation–chemical reaction at the surface is still uncertain.

Under these conditions, the radiation-induced chemical reactions of adsorbed molecules offer some insight into the physical processes taking place in the bulk of the solid exposed to ionising radiation. This approach was used by Zhabrova and coworkers[122,135,136], who studied the radiolysis of methanol in the presence of two of the most active radiation catalysts—silica gel and alumina—with different surface-to-volume ratios. The silica gel samples, prepared by the hydrothermal method[137,138], had identical chemical compositions but different specific surface areas and globule diameters D. In the first series of experiments the amount of methanol adsorbed on the samples was the same (0.17 mmole g^{-1}). This amount was sufficient to give monolayer coverage on the sample with the smallest specific surface (20 m^2 g^{-1}), but on the large-area samples the coverage was only a few per cent.

Table 1. Influence of specific surface area and globule diameter of silica gel on the radiation–catalytic decomposition of methanol. Temperature 20°C, dose rate of gamma radiation 1.3×10^{16} eV g^{-1} s^{-1}, dose 10^{20} eV g^{-1}.

Specific surface area S, m^2 g^{-1}	Globule diameter D, Å	Surface coverage θ, %	Amount of products formed, mmole g^{-1} $\times 10^2$		G_{ads}, mmole per 100 eV		Extent of conversion, mole %	
			CH_2O	$(CH_3OH)_2$	CH_2O	$(CH_3OH)_2$	CH_2O	$(CH_3OH)_2$
20	1400	100	0.22	0.12	220	120	1.5	0.8
50	550	51	0.19	0.14	190	140	1.1	0.8
100	270	25.5	0.14	0.10	140	100	0.8	0.6
150	180	17	0.14	0.12	140	120	0.8	0.7

360	75	7.1	0.21	0.12	210	120	1.2	0.7
390	70	6.4	0.21	0.16	210	160	1.2	0.9
540	50	4.7	0.18	0.17	180	170	1.7	1.0
620	40	4.1	0.18	0.18	180	180	1.1	1.0
640	40	4	0.16	0.17	160	170	0.9	1.0
800	30	3.2	0.24	0.18	240	180	1.4	1.0

The results, summarised in Table 1, show that the radiation–chemical yields of products are almost constant for all the samples. Since the methanol undergoes radiation–catalytic reactions only by virtue of the energy transferred from the solid, it is obvious that for a given dose the same amount of energy has been transferred from the bulk to the surface of all the samples examined. The fact

that the energy transferred is independent of the globule diameter of the silica gel and of the surface coverage is evidence that the diffusion of carriers from the bulk to the surface is not rate-limiting, and that the adsorbed alcohol molecules have a fairly large affinity for charge carriers (holes). An analogous series of experiments with alumina samples gave similar results.

In another series of experiments, the adsorption of methanol on the surface of the various samples was varied so as to give a constant surface coverage of 50% of a monolayer. The effect of changing the adsorption of methanol on the surface of one of the samples was also studied. The variation of the radiation-chemical yields of formaldehyde and ethylene glycol with surface concentration of methanol on the silica gel is shown in Fig. 13.

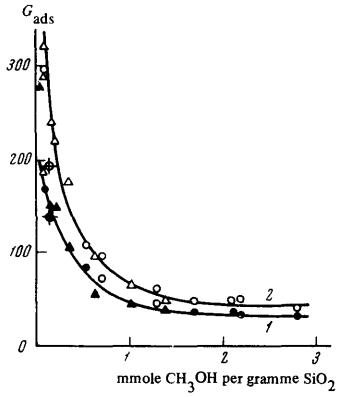

Figure 13. Radiation-chemical yields of oxygen-containing products against adsorption of methanol on the surface of silica gel[136]: *1*) $(CH_2OH)_2$; *2*) CH_2O.

As the Figure shows, the radiation-chemical yields (and therefore also the extents of conversion of the methanol, which are proportional to the yields) for silica gels of different surface areas but constant coverage, and the values for different coverages of the same specimen, all lie on the same curve. The mean of the radiation-chemical yields obtained in the series of experiments of Table 1 also lies on the same curve. For a given dose of absorbed radiation, the highest radiation-chemical yields G_{ads} were obtained on samples with the lowest amount of adsorbed methanol. As the adsorption of methanol was increased, the radiation-chemical yields of both products fell. Thus, this work has shown that the extent of conversion of adsorbed methanol in a radiation-catalytic reaction is determined only by the relationship between the amount of methanol and the number of excess current carriers formed in the bulk of the solid (SiO_2 or Al_2O_3), whereas the specific surface area, the pore size and globule diameter, and the extent of coverage of the surface have no effect on the reaction.

Since all the free charge carriers are effectively captured on adsorbed molecules, irrespectively of the surface coverage, these results justify the conclusion that all or practically all the excess carriers formed in the bulk of the solid are used in the radiation-catalytic process. The values of G_{tot} and G_{ads} (from the sum of the oxygen-containing products), determined from the initial slopes of the kinetic curves, are set out in Table 2. It can be seen that the mean value of G_{tot} for silica gel is 4.4. According to electrophysical measurements[2], the average energy of formation of a pair of charge carriers for a number of insulators is 20 eV. Since this value can be equated to the width of the forbidden gap for insulators, we conclude that the yield of pairs of carriers per 100 eV of energy absorbed in a dielectric of the SiO_2 type should lie between 4 and 5. This agrees satisfactorily with the experimental value of 4.4, thus providing a further argument in favour of the hypothesis that practically all the excess carriers formed in the bulk of a dielectric take part in the radiation-chemical process at the surface.

Table 2. G_{ads} and G_{tot} for the radiation-catalytic conversion of methanol on silica gel at different surface coverages[135].

Coverage, %	G_{ads}, molecules per 100 eV	G_{tot}, molecules per 100 eV
3.8	1970	4.8
17.5	370	4.2
53	120	4.2
100	70	4.4

Further indirect evidence for this conclusion comes from other investigations. Thus, Rojo and Hentz[134] found that the yield of benzene (measured from the initial slope of the kinetic curve) is 4 in the decomposition of isopropylbenzene on silica gel previously irradiated at −196°. In the radiation-catalytic dealkylation of adsorbed isopropylbenzene at room temperature the yield G_{tot} was 2. However, this quantity was determined at a relatively high dose (not from the initial portion of the kinetic curve at low doses), and might therefore be too low. According to the authors, the capture efficiency of current carriers by adsorbed molecules is close to 100%.

Rabe and coworkers[115] obtained curves of the yield of radiolysis products against surface coverage of various solids by azoethane (Fig. 7). In every case (except magnesium oxide) the yield of radiolysis products of azoethane increased with surface coverage up to monolayer coverages, whilst the reaction rate decreased. The authors suggest that the excited species generated in the solid by the radiation have a fairly large radius of action, and that the adsorbed molecules must compete for the energy transferred from the solid.

Thus, the conclusion that the excess current carriers generated in the bulk of the solid are fully utilised in radiation-chemical processes at the surface appears to be generally applicable to all solids of the dielectric type.

It is evident from a survey of published data that the use of ionising radiation in heterogeneous catalysis has opened a new field for the study of electronic factors, which allows the role of free and of localised carriers in the elementary acts of catalytic reactions to be identified, and can suggest ways of controlling these processes.

The use of ionising radiation provides a test of various propositions of the electronic theory of catalysis, and it allows us to formulate new theoretical problems and to extend the range of experimental approaches to the study of elementary acts in catalysis and chemisorption.

The ability of adsorbed molecules to act as "traps" for electrons and holes in competition with other traps (impurities and structural defects on solid surfaces) has been demonstrated by the use of ionising radiation.

It has been amply demonstrated that the creation of charge carriers in insulators and semiconductors often leads to the formation of various kinds of charged and free-radical species on the surface, which play an important part in catalytic and chemisorption processes.

The mechanism of radiation–catalytic reactions is often closely dependent on the transfer of energy absorbed by the solid to molecules adsorbed on the surface. The energy transfer problem is also very relevant in ordinary catalytic reactions, but the elementary mechanism of transfer, involving the motion of electric charges, can differ in the two cases. The width of the forbidden gap is an important consideration in catalysts for ordinary oxidation–reduction reactions. This factor is of major importance also in radiation–catalytic reactions. However, in contrast to ordinary catalysis, the most active catalysts in radiation catalysis are solids with a wide forbidden gap.

It has been shown in a number of systems that the increase of radiation–catalytic activity with gap width stems from the recombination mechanism for the interaction of a charged adsorbate–hole complex and an electron arriving from the conduction band. Hence a comparison of the forbidden gap with the energy required to break various bonds in the reacting molecule is particularly relevant. This comparison suggests some principles for the selection of radiation–active catalysts.

The study of the nature of catalytically active centres, their structure, the role of free carriers, and the extent to which these take part in the elementary steps of catalytic reactions is greatly assisted by the use of ionising radiation —a powerful agency for altering the concentration electrical charge carriers and for localising carriers on intrinsic defects of the surface.

An analogy has been observed between the active centres formed by conventional methods of catalyst preparation and the active centres of the radiation-induced defect type.

Thus, we may conclude that further developments in the relatively young science of radiation–catalytic processes are vital to the understanding of elementary acts in catalysis.

Inositol Phosphatides—Structure, Biochemistry, Synthesis

B.A.Klyashchitskii, S.D.Sokolov, and V.I.Shvets

Progress made during the past 10-12 years in establishing the structure, elucidating the biological role, and synthesising the inositol phosphatides—a class of phospholipids—is discussed. The first part considers problems involved in establishing the structure of mono-, di-, and tri-phosphoinositides, mannosides of phosphatidylinositol, and more complicated "inositide" complexes. The second part deals with the biochemistry of inositol phosphatides, in particular the properties and functions specific to phosphoinositides. The problems and successes in the synthesis of phosphoinositides are discussed in the last part. A large amount of experimental information is used to show the complexity of the selective protection of the hydroxy-groups in myoinositol with the aim of obtaining initial compounds for the synthesis of inositol phosphatides. Work done during recent years is shown to open up a path to the synthesis of optically active phosphoinositides of natural structure. A list of 114 references is included.

CONTENTS

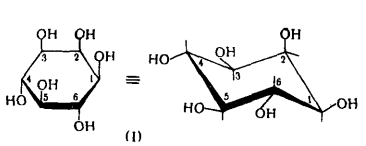
I. Introduction 345
II. Components and structure of inositol phosphatides 345
III. Biochemistry of inositol phosphatides 348
IV. Synthesis of inositol phosphatides 349

I. INTRODUCTION

The inositol phosphatides are among the most important examples of phospholipids. The presence of phosphoinositides in Nature was first pointed out by Anderson[1], who isolated them from tubercle bacilli. It has now been found that phosphoinositides are present in plants, various animal organs, and micro-organisms: they have been found in soya beans[2], kidney beans[3], milk[4], the brain[5], the liver, kidneys, and other sources[6]. Two reviews have been published dealing in some measure with problems of the structure and synthesis of inositol phosphatides[6,7]. As our knowledge of these compounds becomes deeper and broader, new aspects of their biological role and chemical properties are continually opening up, showing the extraordinary importance of these compounds in the life of various organisms. The present review deals briefly with recent work on the chemistry and the biochemistry of the inositol phosphatides.

II. COMPONENTS AND STRUCTURE OF INOSITOL PHOSPHATIDES

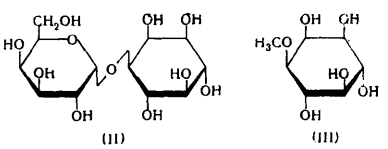
A structural unit of all inositol phosphatides is myoinositol (MI) (I), the only inositol present in Nature in the form of phosphate derivatives[8].



(I)

Myoinositol is widely distributed in Nature, both in the free and in the combined form. It has been found, for example, in rubber latex[9], sperm plasma[10], and sugar beet[11]. It occurs in these sources together with galactin[12], 1-*O*-α-*D*-galactopyranosyl- (1*R*)-myoinositol (II). (Here and subsequently the configuration in asymmetrically substituted derivatives of myoinositol is given in Angyal's notation[13]).

Mention must be made also of such natural myoinositol compounds as (+)-bornesitol[14] or 1-*O*-methyl-(1*R*)-myoinositol (III), α-*D*-galactopyranosyl-(1→6)-α-*D*-galactopyranosyl-(1→1)-myoinositol[15], isolated together with galactin from the roots of the pea, and various myoinositol mannosides, the structure of which will be discussed below.



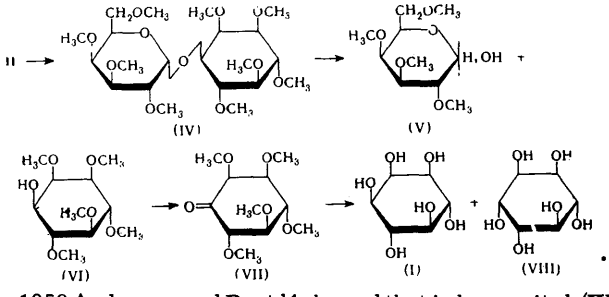
(II) (III)

Sugars and amines must be noted among other components of inositol phosphatides, besides the phosphates, glycerol, and fatty acids usually met in their hydrolysis products. Not long ago many investigators regarded sugars and amines as "impurities" in inositol phosphatides, and endeavoured to remove them by chromatographic and chemical methods of purification[16]. Such "purification" probably resulted frequently in breakdown of the complicated native inositol phosphatide molecule[17]. Anderson[18] showed in several papers that mannose is present in inositol-containing glycolipids of tubercle bacilli. Arabinose and galactose have been found in purified phosphoinositides of soya-beans[19] and lipids of groundnuts[20]. D-Glucose, combined with myoinositol by a glycosidic bond, has been isolated also from the glycolipids of acid-stable bacteria[21]. In 1965 Galanos and Kapoulas worked out a technique for isolating lipid fractions[22], on the basis of which they suggested that lipids, including inositol phosphatides, are present in vegetable and animal tissues as complicated triesters of phosphoric acid[23]. Sugars may also be components of these "triester complexes".

Nitrogen bases also are effective components of inositol phosphatides. Thus aminoethanol has been detected in inositol phosphatides from groundnuts[20], and soya-beans, and in the glycolipid of acid-resistant bacteria. Choline, aminoethanol, and serine may form part of the "triester complexes"[22,23]. Amino-acids—L-ornithine[24], hydroxylysine, asparagine, glutamine, glycine, alamine, etc.—have been observed in many inositol phosphatides[3]. Thus inositol phosphatides containing glutamic and aspartic acids, valine, leucine, threonine, and isoleucine have been isolated from wool fat[25].

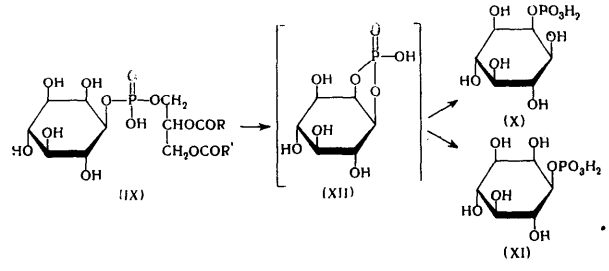
In 1956 the structure of the simplest inositol phosphatides had still not been established; in particular, such an important question as the point of addition of phosphate to myoinositol was obscure[6]. Most workers considered that the phosphate residue was bound to an axial 2-hydroxyl of the myoinositol, since hydrolysis of inositol phosphatides yielded the 2-phosphate.

In 1953 Kabat et al.[12] had established that in galactin (II) a galactopyranose residue was combined by means of an α-glycosidic bond with the 1-hydroxy-group of myoinositol. Methylation of (II) with dimethyl sulphate gave nonamethylgalactin (IV), hydrolysis of which in 0.5 *N* hydrochloric acid yielded 2, 3, 4, 6-tetramethyl-D-galactose (V) and the pentamethyl ether of myoinositol (VI). The latter was oxidised with chromium trioxide to myoinosose (VII), reduction of which followed by demethylation gave both myinositol (I) and (–)-inositol (VIII), which proved the structure given here for galactin (II):



In 1958 Anderson and Post[14] showed that in bornesitol (III) the 1-hydroxy-group of myoinositol had been methylated.

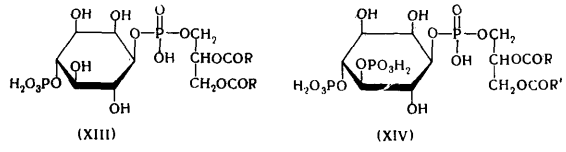
In contrast to these natural compounds of myoinositol, it was very difficult to establish the position of the myoinositol–phosphate bond in phosphoinositides, owing to migration of the phosphate residue during hydrolysis of the natural lipids. The myoinositol molecule (I), having a plane of symmetry through positions 2–5, is optically inactive, but introduction of a substituent into position 1, 3, 4, or 6 should result in the appearance of optical activity. In 1959 several papers were published[26–28] which showed that the hydrolysis of natural phosphoinositides, e.g. phosphatidylinositol (IX), yields a mixture of 2– and 1-phosphates of myoinositol (X) and (XL), which are formed by phosphate migration under conditions of hydrolysis, with intermediate formation of a cyclic ester (XII):



Since the myoinositol 1-phosphate obtained (XI) was optically active, the intermediate cyclic phosphate (XII) should be optically active, which would have been impossible if the myoinositol in the natural compound (X) had been phosphorylated in position 2. This demonstrated that the phosphate residue in natural phosphoinositides is attached to the $C_{(1)}$ atom of the myoinositol molecule.

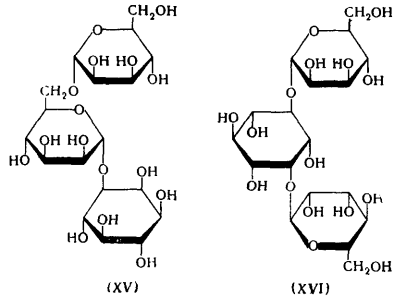
This was confirmed in another paper[27]: glycerylphosphorylinositol, isolated from cow's liver ($[\alpha]_D^{25}$ –13.5° for the cyclohexylammonium salt) yielded after periodate oxidation the optically active glycolaldehydemyoinositol phosphate ($[\alpha]_D^{25}$ –13.2° for the cyclohexylammonium salt: i.e. the main contribution to the optical activity of the natural compound is made by the asymmetrically substituted myoinositol 1-phosphate). Thus in galactin (II), bornesitol (III), and phosphoinositides of soya-beans[29], liver[30], and other sources, myoinositol is substituted in the (equatorial) position 1.

During recent years several major laboratories (those of Ballou, Hawthorne, Dawson, etc.) have been conducting intensive research into polyphosphoinositides possessing great metabolic activity and important biological functions. The structures (XIII) and (XIV) have been established[31–33] for di- and tri-phosphitides:



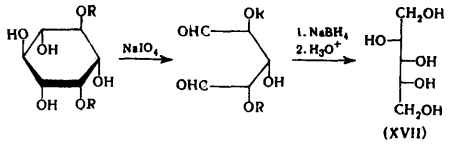
Periodate oxidation of myoinositol triphosphate, isolated from products of the alkaline hydrolysis of the triphosphoinositide of bull's brain, with subsequent reduction and dephosphorylation, gave D-iditol. Similarly, D-threitol was obtained from the diphosphate[32]. From this it was established that the triphosphoinositide was the 4,5-diphosphate of 1-phosphatidyl-(1S)-myoinositol (XIV), and the diphosphoinositide the 4-phosphate of 1-phosphatidyl-(1S)-myoinositol (XIII)[33].

Certain glycolipids of acid-resistant bacteria belong to an interesting class of inositol phosphatides. Anderson showed that these lipids contain a compound of myoinositol with two molecules of mannose, which was termed manninositose[34]. In 1960 Vilkas and Lederer[35] hydrolysed completely methylated manninositose, and obtained an equimolecular mixture of tri- and tetra-*O*-methylmannoses, while periodate oxidation showed the 1→6 bonding of the two mannose residues. On the basis of these results the structure (XV) was assigned to manninositose. This structure was even confirmed by synthesis[36], but in 1964 Lee and Ballou[37], in a brilliant paper on the myoinositol mannosides from the glycolipids of *Mycobacterium tuberculosis* and *Mycobacterium phlei*, showed it to be untenable, and established the structure of manninositose (XVI) and the pentamannoside of phosphatidylmyoinositol.



Exhaustive periodate oxidation of dimannosylmyoinositol with subsequent reduction of the polyaldehydes with sodium tetrahydroborate and acid hydrolysis of the reduction products yielded arabitol (XVII) (the D-configuration was established for (XVII) in the case of the pentamannoside of

myoinositol) and glycerol (from carbon atoms 4, 5, and 6 of the mannoses) in the proportions 1 : 2:

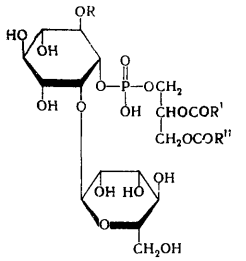


(XVII)

Exhaustive methylation of the dimannoside of myoinositol followed by methanolysis led to the formation of two moles of 2, 3, 4, 6-tetra-*O*-methylmannose per mole of 1, 3, 4, 5-tetra-*O*-methylmyoinositol. The structure of the latter was confirmed also by the nuclear magnetic resonance spectra. The α-glycosidic bonds in the dimannoside of myoinositol were established from the signal of the anomeric proton in the n.m.r. spectrum of this compound.

The phosphatidic acid residue in mannosides of phosphatidylmyoinositol should be present in position 1 of the myoinositol ring, since only this can explain the formation on periodate oxidation from the same products as in the oxidation of myoinositol dimannoside. Thus the glycolipid from *Mycobacterium tuberculosis* is 1-phosphatidyl-2, 6-di-*O*-α-D-mannopyranosyl-(1S)-myoinositol (XVIII)[37]. The presence of mannose residues on both sides of the phosphate–myoinositol bond explains the stability of the phosphate diester bridge to alkaline hydrolysis and the unusual stability of intact glycolipids in hot acetic acid (absence of free hydroxyls on the myoinositol ring carbon atoms adjacent to the phosphate bond).

The structure of the myoinositol monamannoside isolated from *Mycobacterium tuberculosis* was proved by exhaustive methylation followed by methanolysis and identification of the resulting pentamethylmyoinositol by comparison with all four possible isomers in gas–liquid chromatography[38]. It was established that the mannose was bound to the 2-hydroxyl of the myoinositol, i.e. that the intact lipid has the structure (XIX):

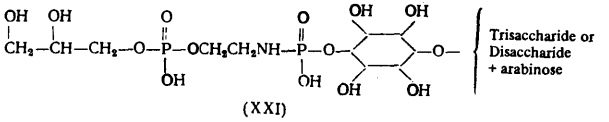


(XVIII: R = α-D-mannopyranosyl); (XIX: R = H); (XX: R = α-D-mannopyranosyl-(1 → 2)-*O*-α-D-mannopyranosyl-(1 → 6)-*O*-α-D-mannopyranosyl-(1 → 6)-*O*-α-D-mannopyranosyl).

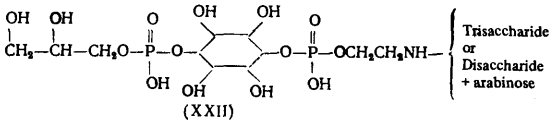
The biosynthesis of phosphatidylmyoinositol dimannoside is probably accomplished by the stepwise glycosylation of phosphatidylmyoinositol, firstly at position 2 and then at position 6 [39].

Complete structures were later established also for the tri-, tetra-, and hexa-mannosides of phosphatidylmyoinositol[40]. Thus the pentamannoside was proved to have the structure 1-phosphatidyl-2-*O*-α-D-mannopyranosyl-6-[*O*-α-D-mannopyranosyl-(1 → 2)-*O*-α-D-mannopyranosyl-(1 → 6)-*O*-α-D-mannopyranosyl-(1 → 6)-*O*-α-D-mannopyranosyl)]-(1S)-myoinositol (XX). Pangborn and McKinney[41] have recently shown that, in the serologically active phosphoinositides of *Mycobacterium tuberculosis*, the ratio of fatty acids to phosphorus is 3 : 1 or 4 : 1; palmitic and tuberculostearic acids were found most frequently among the fatty acids, while little stearic and oleic acids were found. The authors assume that the "excess" acids can be esterified by any free hydroxyls (one or two) in the myoinositol or mannose residues. The same conclusion was reached by Brennan and Ballou[42], who studied the biosynthesis of several mannosylphosphatidylmyoinositols catalysed by intracellular fractions of *Mycobacterium phlei*. They included the three substances which they obtained among the dimannophosphoinositides. The ratio of fatty acids to phosphorus in these compounds was 4 : 1, 3 : 1, and 2 : 1.

Great interest attaches to establishing the structure of the intact complicated lipid complexes which are assumed to be present in animal and plant organisms. One of the first attempts to penetrate the structure of the complicated "inositide complex" was the hypothesis of approximate structures of the inositol phosphatide from groundnuts (XXI and XXII)[6,20]:

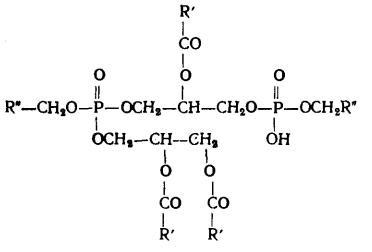


(XXI)

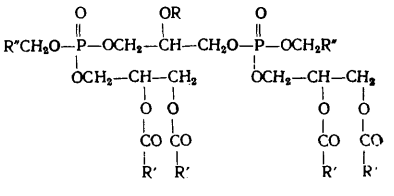


(XXII)

Several authors consider that natural lipid complexes are triesters of phosphoric acid. This view was first expressed by Collins[43], who suggested the possible structures (XXIII) and (XXIV) for such complexes (R = H). Unfortunately, only a few papers have yet been published on the study and structure of lipid "triester complexes". Sinha and Gaby[44] investigated the lipo-amino-acid complexes from *P. aeruginosa*, and regarded these compounds as triesters of phosphoric acid having the structure (XXIV), with R = OCCH(NH$_2$)R‴, the R′ being residues of fatty acids, and R″ residues of nitrogen bases:



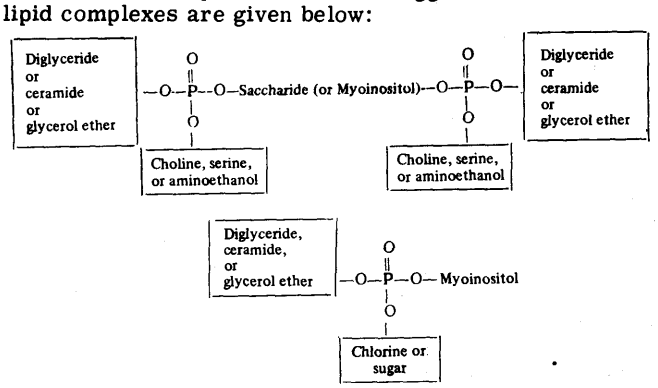
(XXIII)



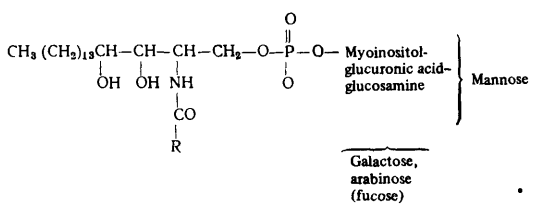
(XXIV)

As already remarked, Galanos and Kapoulas[4,22,23] developed a technique for isolating lipid complexes from natural sources, and proposed several structures for such complexes, in which myoinositol is an important component. They consider that "triester complexes" are actually present in animal and vegetable tissues, while individual phospholipids are merely products of their degradation during isolation from natural sources. These authors note especially the role of myoinositol in stabilising

the "triester complexes". Some suggested structures for lipid complexes are given below:



A series of papers was published by Carter [45] on the isolation from plant seeds of phytoglycolipids containing myoinositol. A study of the degradation products of the phytoglycolipid led to the proposed structure [46]



In 1966 as phingolipid containing dihydrosphingosine, myoinositol, and mannose was isolated from the micro-organisms *Torulopsis utilus* [47].

Further work on the isolation, structure, and synthesis of complicated triester lipid complexes should finally settle the question of their presence in animal and vegetable tissues and their structure.

III. BIOCHEMISTRY OF INOSITOL PHOSPHATIDES

The biochemistry of inositol phosphatides, as members of the class of phospholipids, has been a subject for research in many laboratories, and is quite widely represented in individual papers, reviews, and monographs (e.g. Hawthorne's review [48]). The present Section will survey work done in recent years on properties and functions characteristic of inositol phosphatides.

Phosphoinositides, together with other phospholipids, form structural components of cells. An increased content of inositol phosphatides is found in the cells of certain tissues. Thus the percentage content of inositol phosphatides (and sphingomyelin) in the cells of the lens of the human eye is considerably higher than in other tissues of the body, where lecithin predominates in the phospholipid fraction [49]. It has been suggested that inositol phosphatides have some specific function as structural components of cell membranes in the filaments of the lens of the human eye. Myoinositol labelled with ^{14}C is actively incorporated into the cytoplasmic membranes of the fungus *Neurospora crassa* [50], where it was found that cytoplasmic membranes containing protease were relatively impoverished in lecithin and enriched in inositol phosphatides. Structural integration of protease particles was disturbed in mutants of *N. crassa* grown on a medium containing an insufficient quantity of myoinositol.

Much work has recently been done on the properties of monomolecular films of various phospholipids, which in some measure simulate biological membranes. Studies have been made of the hydrolysis by phospholipase A of monolayers [51] of lecithin, phosphatidyl-aminoethanol, and phosphatidylinositol all labelled with ^{32}P. The change in the surface potential of the film served as a measure of the degree of decomposition of the lipid. Loss of radioactivity by the film on hydrolysis was due to escape of the lyso-compound of the film. Physicochemical and biochemical study of enzymatic hydrolysis in the presence of calcium ions showed the lowest rate of hydrolysis to occur in films of ^{32}P-phosphatidylinositol, which possesses the highest affinity for Ca^{2+}.

Several workers have isolated enzymes specific to inositol phosphatides. Hawthorne [52] isolated from the guinea-pig a phosphoinositideinositolphosphohydrolase which acted on mono-, di-, and tri-phosphoinositides without hydrolysing other phospholipids. Enzymatic hydrolysis yields a diglyceride and inositol phosphates; no inorganic phosphate was detected. English et al. [53] isolated an enzyme termed myoinositolkinase. Myoinositol 1-phosphate was detected among the reaction products.

Inositol phosphatides take part in such important processes in the cell as the change in size of the mitochondria and active transport through the membrane [54]. A "contractile" protein, which was responsible for contraction of the mitochondria on the addition of adenosine triphosphate and magnesium ions, lost its activity on extraction with solvents which remove lipids. The active component was a phosphatidylinositol at a concentration of 10^{-6} M. Other lipids do not possess such activity [55]. In a study of the metabolism of the phosphoinositide complex in the salivary gland of the cat on electrical stimulation, Gaut et al. [56] concluded that increased metabolic activity occurred in the phosphoinositide complex, and they suggested that a phosphoinositide combined with a membrane protein may play an active part in transport processes in the cell. Lipo-amino-acids, in which considerable interest has recently been shown, may also be involved in active transport through the membrane. It is suggested [57], for example, that the synthesis of antibodies involves the formation of a lipo-amino-acid complex on or in the cell membrane, by means of which the amino-acid enters the cell. These complexes may, perhaps, take part in protein synthesis. They may well have the structure of triesters of phosphoric acid [23]. Phosphatidylinositol has been detected in the lipid portion of phosphatidopeptides from lamellae and chloroplasts of the bean. The stability of phosphatidopeptides to acid hydrolysis and their infrared spectra indicate a lipid–peptide ester link [3].

An active part in transport through the membrane is suggested also for the polyphosphoinositides found in various organs and tissues. The metabolism of the phosphoinositide complex of brain was first investigated by Brockerhoff and Ballou [39,58], who showed the path of biosynthesis from monophosphoinositide by phosphorylation to di- and tri-phosphoinositides. Adenosine triphosphate may be the donor of the phosphate group. Later work [59] has confirmed that the incorporation of ^{32}P-orthophosphate into the diphosphoinositide of mitochondrial fractions from the liver is diminished by inhibitors of oxidative phosphorylation. Dephosphorylation takes place together with phosphorylation in the inositide complex, so that a metabolic process is occuccring:

$$\text{Monophosphoinositide} \rightleftharpoons \text{diphosphoinositide} \rightleftharpoons \text{triphosphoinositide}$$

Perhaps this may also explain the biochemical role of the inositide complex in the transport of cations [60].

The extraordinarily high metabolic activity of the inositide complex and its participation in active transport through the membrane have been discussed in many papers during the past three years. Hawthorne[61], studying the place of synthesis of the diphosphoinositides of rat liver, found that they were synthesised mainly in plasmic membranes. He even demonstrated the synthesis of polyphosphoinositides *in vitro* catalysed by a homogenate of rat brain[62]. The high metabolic activity of phosphoinositide complexes is explained by the presence of polyphosphoinositides in them. Freyss et al[63] showed a high rate of metabolism of inositol phosphatides compared with other phospholipids, when studying the metabolism of various phospholipids in the brain of the rat, and Nicolas[64] reached the same conclusion, having established a more rapid loss of radioactivity by the inositol phosphatides of myelin labelled with 1-^{14}C-acetate, compared with cerebrosides, phosphatidyl-aminoethanol, and other lipids.

The biochemistry of other inositol phosphatides is also unusual. Inositol monophosphatides containing residues of two different fatty acids, isolated from the lipid fractions of horse brain, are found[65] to be blood anticoagulants. Bacterial glycolipids possess serological activity. Phosphatide antigens of several mycobacteria have been identified as mannosides of phosphatidylinositol[66]. They fix complement in a serum containing antibodies against tubercle bacilli. The glycolipids of acid-stable bacteria are very toxic: an adult mouse is killed 5–8 days after the injection of 5–10 μg. The cause of death is not yet clear. The injection of certain lipid fractions of tubercle bacilli produces immunisation of animals, increasing, for example, the lifetime of a mouse which has been inoculated with virulent tubercle bacilli. Detailed information on the biological role and functions of the glycolipids of acid-resistant bacteria will be found in Lederer's review[67].

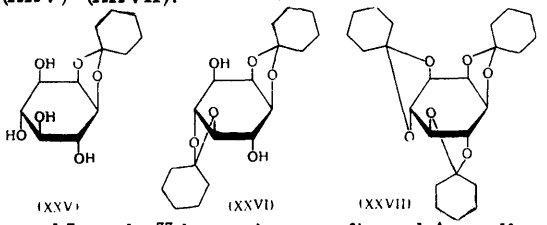
Many papers have been published also on the biosynthesis and the metabolism of myoinositol[68-70]. It has been established that myoinositol plays a part in cellular morphogenesis, lipid synthesis and transport, the transport of ions and hormones through cell membranes, and other important vital processes[71]. A detailed account of the biochemistry of myoinositol has been given in a recent review by Posternak[72].

IV. SYNTHESIS OF INOSITOL PHOSPHATIDES

Besides a biochemical study, many laboratories are occupied with synthetic investigations on the inositol phosphatides. Phosphoinositides themselves—in particular their main component, myoinositol—provide a wide field of activity for organic chemists. The urgent requirements of biochemistry and biology also lead to synthetic investigations on phospholipids. For example, Collins[43] regards the synthesis of triesters of phosphoric acid, the structure which he suggested, as having great value in confirming their presence in Nature and in studying their properties. In fact, the isolation of such labile substances from natural sources requires colossal amounts of labour, and ultimately does not yield quantities sufficient for a systematic study of their properties and biological activity. A similar opinion is held by Ballou[37,38].

A comprehensive study of the chemistry of myoinositol is being made in Angyal's laboratory. This work is of great value for the synthesis of inositol phosphatides. The myoinositol molecule (I) contains six hydroxyls, five of which are equatorial, while one, in position 2, is axial. The myoinositol molecules have the chair form, as has been confirmed by X-ray examination[73]. This structure creates fundamental difficulties in the synthesis of inositol phosphatides in which myoinositol is combined with phosphate in position 1. Various protective groups for the hydroxyls have been studied, but until recently none of them has enabled a protected myoinositol to be prepared with a free 1-hydroxyl, a key intermediate in the synthesis of inositol phosphatides. Isopropylidene protection was used in the early work, and with its help methyl ethers of myoinositol were synthesised in low yields[74].

Subsequently cyclohexylidene derivatives of myoinositol, prepared in good yield by reaction with cyclohexanone, have come to be employed. Angyal[75,76] has prepared mono-, di-, and tri-cyclohexylidene derivatives of myoinositol (XXV)–(XXVII):

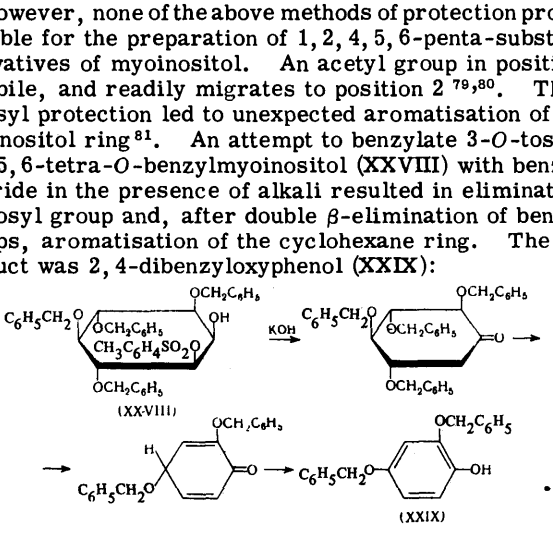


(XXV) (XXVI) (XXVII)

Mager and Ionesku[77] have since confirmed Angyal's observation that acetals are first formed at *cis*-hydroxyls (*ae*), and only then at *trans*-hydroxyls (*ee*). Angyal and Tate[78] have synthesised myoinositol 4- and 5-monophosphates and 1,4-, and 1,6-, and 4,5-diphosphates from cyclohexylidene derivatives of myoinositol.

Further efforts were directed at the selective protection of the 2-hydroxy-group in 1,4,5,6-tetra-substituted derivatives of myoinositol, which are easily obtained from 1,2-cyclohexylidenemyoinositol (XXV). It was shown that several substituents occupy the 3-equatorial position preferentially, whereas others do not display such selectivity. Thus the acetylation[79], tosylation[80], benzylation, and methylation[81] of the tetra-substituted derivatives take place selectively at position 3, whereas tetrahydropyranyl protection is not selective[82]. It was suggested[81] that reactions involving a transition state (etherification, substitution by an S_N2 mechanism) take place preferentially at position 3 owing to great steric hindrance at position 2. Rapid reactions (substitution by an S_N1 mechanism) are less sensitive to steric hindrance, and therefore occur non-selectively.

However, none of the above methods of protection proved suitable for the preparation of 1,2,4,5,6-penta-substituted derivatives of myoinositol. An acetyl group in position 3 is labile, and readily migrates to position 2[79,80]. The use of tosyl protection led to unexpected aromatisation of the myoinositol ring[81]. An attempt to benzylate 3-*O*-tosyl-1,4,5,6-tetra-*O*-benzylmyoinositol (XXVIII) with benzyl chloride in the presence of alkali resulted in elimination of the tosyl group and, after double β-elimination of benzyl groups, aromatisation of the cyclohexane ring. The final product was 2,4-dibenzyloxyphenol (XXIX):

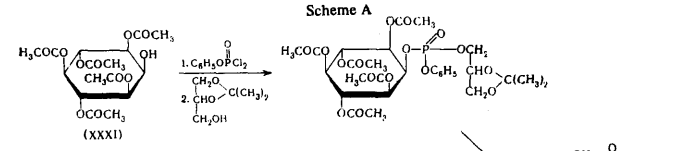


(XXVIII) (XXIX)

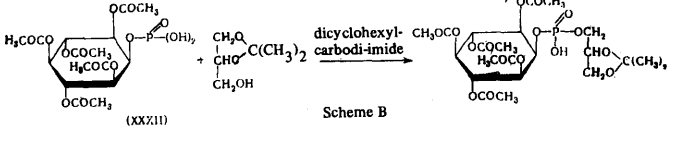
In 1966 the preparation was reported of DL-1,2,4,5,6-penta-*O*-benzylmyoinositol[83], which serves as a convenient intermediate for the synthesis of racemic inositol phosphatides. In this synthesis Gigg used allyl protection, previously employed in the chemistry of carbohydrates[84]. Allyl protection was introduced selectively in position 3 of 1,4,5,6-tetra-*O*-benzylmyoinositol, the product was then benzylated at position 2, and after isomerisation of the allyl group into propenyl the latter was removed by acid hydrolysis. Finally, Angyal[85] has recently shown that 1-benzyl-2,3,4,5,6-penta-acetylmyoinositol can be obtained by the acetolysis of 1,4,5,6-tetrabenzylmyoinositol, owing to steric hindrance to acetolysis of the benzyl group at position 1. Hydrogenolysis of the product yielded 1,2,4,5,6-penta-acetylmyoinositol. All this work shows how complicated and interesting is the problem of the selective protection of the hydroxy-groups in myoinositol.

The first synthesis of a product of the hydrolysis of inositol phosphatides—myoinositol 2-monophosphate—was accomplished in 1949 by Iselin[86], by the reduction of scyllo-mesoinosose penta-acetate with subsequent phosphorylation with diphenyl phosphorochloridate and removal of the protective groups. As already remarked in Section II, it was thought at that time that the phosphate in inositol phosphatides was attached to the $C_{(2)}$ atom of the myoinositol molecule. Only after ten years did Davies and Malkin[87] and at the same time Ellis and Hawthorne[88] synthesise 1-glyceryl-2-myoinositol phosphate (XXX) by different methods: the former by the reaction of 1,3,4,5,6-penta-*O*-acetylmyoinositol (XXXI) with phenyl phosphorodichloridate and 1,2-isopropylideneglycerol (Scheme A); and the latter by condensing (XXXII), the 2-phosphate of (XXXI), with 1,2-isopropylideneglycerol in the presence of dicyclohexylcarbodi-imide (Scheme B).

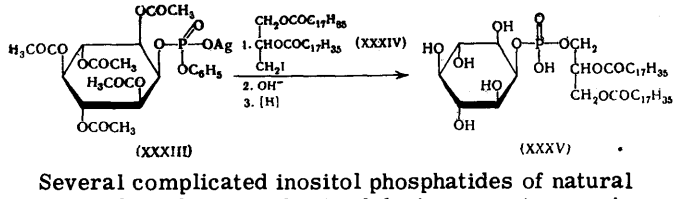
Scheme A



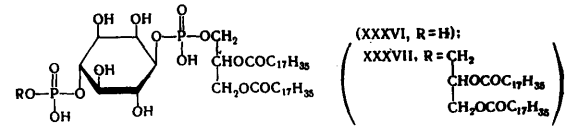
Scheme B



Davies and Malkin[89] also obtained the inositol phosphatide (XXXV) by condensing the silver salt of a protected 2-phosphate of myoinositol (XXXIII) with the iodide of 1,2-distearoylglycerol (XXXIV), but it subsequently became clear that the product did not have the natural structure:

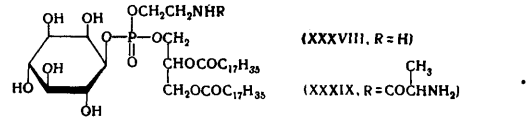


Several complicated inositol phosphatides of natural structure have been synthesised during recent years in Preobrazhenskii's laboratory. Thus Preobrazhenskii, Shvets, et al.[90] prepared the 1,4-diphosphoinositides (XXXVI) and (XXXVII) by condensing 1,2:4,5-dicyclohexylidenemyoinositol (XXVI) with phosphoryl chloride and 1,2-distearoylglycerol:



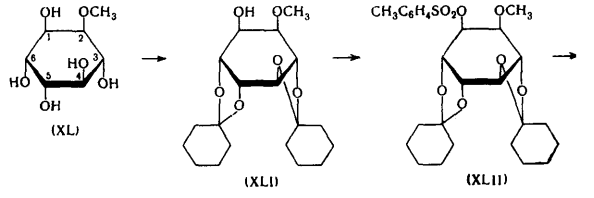
These compounds may be fragments of more complicated lipid complexes.

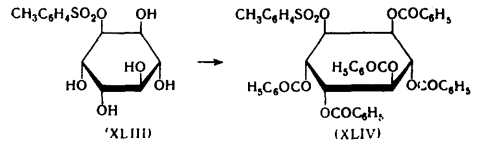
The same workers[91] were the first to obtain inositol phosphatides having the structure of triesters of phosphoric acid (XXXVIII), and simulating a possible bond between the lipid and the amino-acid moieties in lipo-amino-compounds (XXXIX):



Unfortunately, all the inositol phosphatides described were isolated in the optically inactive, racemic form. In natural phosphoinositides the myoinositol molecule is asymmetrically substituted in the equatorial 1-position, and hence possesses optical activity. This has been demonstrated both for simple inositol phosphatides[26-30] and for the complicated complexes. It has been established[92], for example, that brain triphosphoinositide has the structure 2,3-di-*O*-acylglyceryl-1-[(1′*S*)-myoinositol 1′,4′,5′-triphosphate].

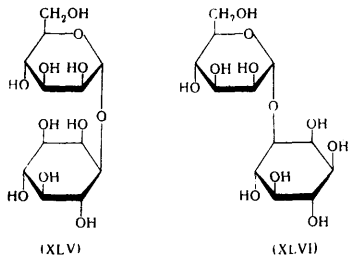
In practice the problem of synthesising optically active inositol phosphatides has still not been solved. It is true that Ballou[29] reported in 1959 the synthesis of optically active myoinositol 1-phosphate, which can serve as intermediate for the synthesis of optically active inositol phosphatides. The starting material in this synthesis was galactin (II), which was completely benzylated by Kuhn's method; methanolysis with 1% hydrochloric acid led to cleavage of the α-glycosidic bond in nonabenzylgalactin, the resulting 1,2,4,5,6-penta-*O*-benzylmyoinositol was phosphorylated with diphenyl phosphorochloridate in the free 3-position, and after removal of protective groups the optically active myoinositol 1-phosphate was obtained[93]. Gero[94] has recently suggested a different route to this optically active compound, starting from quebrachitol, 2-*O*-methyl-(−)-inositol (XL). 3,4:5,6-Di-*O*-cyclohexylidenequebrachitol (XLI) was obtained[73] from (XL), and then converted into 3,4:5,6-di-*O*-cyclohexylidene-2-*O*-methyl-1-*O*-tosyl-(−)-inositol (XLII). After elimination of the methyl group with boron trichloride in dichloromethane at −80°C the unstable 1-*O*-(−)-inositol (XLIII) was obtained. This was benzoylated, and optically active myoinositol 1-phosphate could be obtained from the final products, 2,3,4,5,6-penta-*O*-benzoyl-1-*O*-tosyl-(−)-inositol (XLIV), after removal of the tosyl group, inversion of the 1-hydroxyl, and phosphorylation:





(XLIII) (XLIV)

However, optically active naturally occurring compounds—galactin and quebrachitol—were used as starting materials in these syntheses[93,94]. Purely chemical methods of obtaining optically active 1-*O*-substituted myoinositols have not yet been developed because of the great difficulty of separating the resulting racemic mixtures into optical isomers. The only example of such a separation is the work of Angyal and Shelton[95] on the synthesis of 1-*O*-α-D-mannopyranosylmyoinositols—(XLV) and (XLVI)—and α-D-mannopyranosyl-(1→6)-*O*-α-D-mannopyranosyl-(1→1)-myoinositol (XV). Mannosylmyoinositol was obtained by the Königs-Knorr reaction from 1,4,5,6-tetra-*O*-acetylmyoinositol and tri-*O*-acetyl-α-D-mannopyranosyl bromide, the low yield (4.5%) being explained by large steric hindrance. Mannosylmyoinositol is easily separated into two diastereomers—1*S* (XLV) and 1*R* (XLVI)



(XLV) (XLVI)

These diastereomers could have served as starting material for the preparation of optically active 1-*O*-substituted derivatives of myoinositol, but the low yield gives no grounds for regarding this work as a practical route to optically active phosphoinositides. The same workers[95] synthesised galactin in 2.1% yield by the Königs-Knorr reaction. In this case the diastereomers were separated by seeding with crystals of natural galactin.

During recent years great successes have been achieved in studying the chemistry and the biochemistry of inositol phosphatides. The structure of several "inositide complexes" has been elucidated, and methods have been developed for isolating them from vegetable and animal tissues. Inositol phosphatides undoubtedly play an important part in the most intimate processes in the cell. But the structure of many complicated phosphoinositides, their complexes with amino-acids and proteins, and the biological role of such compounds have hitherto formed subjects of hypothetical assumptions. Although there are considerable achievements in the chemistry of inositol phosphatides, in the synthesis of complicated lipid complexes simulating possible natural structures, the problem of preparing optically active phosphoinositides, which are of the greatest interest for biology, is still unsolved. The synthesis of these compounds will probably be accomplished in the near future.

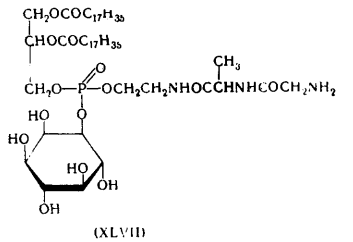
---o0o---

Many papers on the structure, biochemistry, and synthesis of inositol phosphatides have been published while the manuscript was being prepared for press.

Scamark et al.[96] have shown for the first time that 1-*O*-(D-glycerylphosphoryl)-(1*S*)-myoinositol is present as a normal component in biological tissues, not as a degradation of complicated phosphoinositides. They isolated this compound from the prostate gland and the epididymis of rats, and from bull and ram semen. Di- and tri-phosphoinositides have been isolated from baking yeast (*Saccharomyces cerevisiae*)[97].

The detection of mannophosphoinositides in various species of bacteria indicates the close phylogenetic and taxonomic relations of these species. Mannophosphoinositides have been isolated from *Propionibacterium shermanii*[98], *Streptomyces sioyaensis*[99], *Corynebacterium xerosis*[100], and others[101,102]. Ballou and Brennan[103] have continued to study the biosynthesis of mannophospjoinositides of *Mycobacterium phlei*. The enzymatic acylation of dimannophosphoinositides is discussed in the same paper. The high metabolic activity of phosphoinositides is confirmed in several papers. A tracer is incorporated into the phosphatidylinositol in *Nocardia polychromogenes* eight times as rapidly as into a cardiolipin[104]. Nakatani et al.[105] have investigated the incorporation of inorganic phosphate *in vitro*. Phosphorus-32 is incorporated more rapidly into phosphatidylinositol than into lecithin (in the coronary artery of the bull, for example, by factors of 4.9–5.3). It has been shown[106] that acetylcholine stimulates cleavage of the phosphodiester bond in the phosphoinositides of the guinea-pig brain. Enzymes specific to phosphoinositides continue to be studied. Thus Lee and Huggins have reported on the structure[107], purification, and properties[108] of triphosphoinositidephosphomonoesterases from rat kidneys. The role of phosphoinositides and complicated inositide complexes in organising the membranes of the nervous system is discussed from the point of view of evolution in Kreps's book[109].

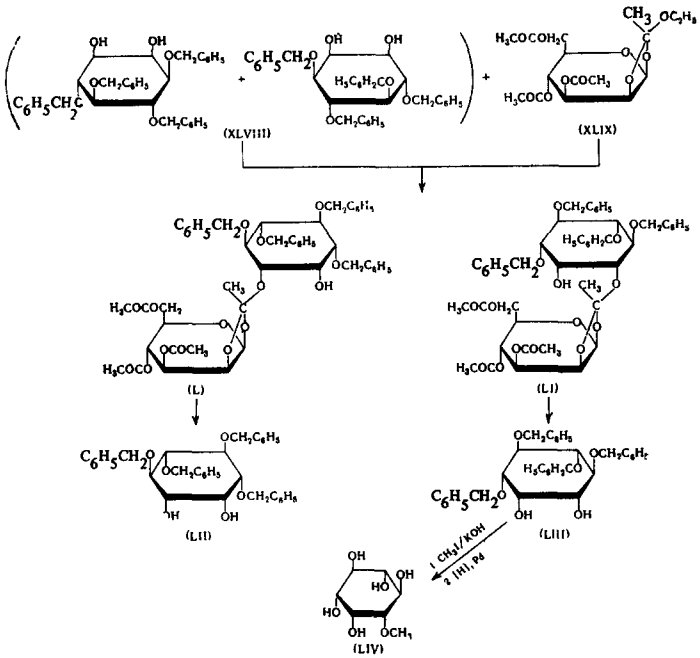
N. A. Preobrazhenskii's school enjoys a leading position in synthetic investigations on the inositol phosphatides. In 1968 Preobrazhenskii, Zhdanovich, Lyutik, et. al.[110] synthesised *O*-[α-(α′β-distearoyl)glycerylphosphoryl-(1-myoinositol)]-*N*′-(glycylalanyl)amino-ethanol (XLVII), the simplest phosphatidopeptide, which is a model of possible structures for the phosphatidopeptide fractions from tissues of brain, liver, etc. The same workers[111] have reported the synthesis of a monophosphoinositide containing the phosphatidyl residue in position 1, the starting material being 1,2,4,5,6-penta-*O*-acetylmyoinositol[85]. Preobrazhenskii, Tarusova, Kozlova, et al. have investigated[112] the benzoylation of 1,2 : 4,5-dicyclohexylidenemyoinositol (XXVI), and have shown that position 3 in the myoinositol is benzoylated preferentially.



(XLVII)

Continuing his previous work[94] aimed at obtaining optically active phosphoinositides, Géro[113] has synthesised 1,2,4,5,6-penta-*O*-benzoyl-(1*S*)-myoinositol, using quebrachitol as starting material. Unfortunately, the optical isomer which he has obtained does not yield phosphoinositides of natural structure, in which the phosphatidyl residue is bound[26-30] to the (1*S*)-position in myoinositol.

Preobrazhenskii and the present Reviewers [114] have recently developed a method for separating racemic asymmetrically substituted myoinositols via diastereomeric orthoesters with carbohydrates, which enables both optically active isomers to be isolated in optically pure form. 1,4,5,6-Tetra-*O*-benzylmyoinositol (XLVIII) was subjected to transesterification with 3,4,6-tri-*O*-acetyl-1,2-*O*-ethylorthoacetyl-β-D-mannopyranose (XLIX), the resulting diastereomeric orthoesters (L) and (LI) were separated by crystallisation and chromatography, and 1,4,5,6-tetra-*O*-benzyl-(1*S*)-myoinositol (LII) and its (1*R*)-enantiomer (LIII) were isolated from the separated orthoesters (L) and (LI) by mild acid hydrolysis. The first complete synthesis of (−)-bornesitol (LIV) has been accomplished from the (1*R*)-enantiomer.



The possibility of separating various asymmetrically substituted myoinositols into enatiomers opens up a path to the synthesis of optically active phosphoinositides of natural structure.

Complexes of Molecular Nitrogen

Yu.G.Borod'ko and A.E.Shilov

The review deals with problems associated with the formation and structure of complexes of molecular nitrogen with transition metal compounds, metals, and other active species. Nitrogen interacts very weakly with acceptors of the type BF_3 but is capable of forming more stable systems (of the type of diazo-compounds) with species having both acceptor and donor properties (CH_2, CH, O).

On the surface of metals (nickel, palladium, platinum), nitrogen forms complexes with the linear configuration of the fragment M-N≡N.

A large number of stable complexes (nitrogenyls), also with a linear configuration of the M-N≡N fragment and analogous to the carbonyls and diazo-compounds, have been obtained recently with compounds of iron(II), ruthenium(II), osmium(II), cobalt(I), rhodium(I), iridium(I), and nickel(0). In addition, dinitrogenyl compounds $L_n M(N_2)_2$ and dinuclear complexes M-N≡N-M are known.

In nitrogenyl compounds nitrogen behaves as a π-electron acceptor ligand and therefore donor ligands stabilise the $M-N_2$ bond in the complex and acceptor ligands weaken it.

The method of synthesis of nitrogenyl complexes, their properties, and the mechanism of their formation have been examined. The possibility of the involvement of dinuclear complexes in nitrogen fixation under mild conditions is discussed.

The bibliography includes 121 references.

I. INTRODUCTION

In the last three years the chemistry of a new class of coordination compounds, complexes of molecular nitrogen with transition metal compounds, has arisen and has been developing vigorously. Although the first such complex was synthesised as late as 1965, at the present time dozens of similar compounds are known and some of them are surprisingly stable. By analogy with the carbonyls, it has been suggested that they be called nitrogenyl complexes.

It is noteworthy that, even before the preparation of these complexes, hypotheses were put forward concerning the possibility of the coordination of molecular nitrogen and the probable structure of the complexes. The great interest in the complexes of molecular nitrogen is due to the fact that they are probably intermediates in reactions involving the binding of molecular nitrogen, in particular in biological nitrogen fixation. Chemisorption and hydrogenation of nitrogen on the surface of various metals are closely associated with the formation of the complexes.

Studies in recent years have shown that molecular nitrogen is capable of interacting not only with transition metals and their compounds but also with a number of other active species in the gas phase and in solution, the reactions being to a considerable degree related. Therefore such investigations are also included in the review.

The range of studies involving the formation of the complexes and reactions of molecular nitrogen under mild conditions has been rapidly developing recently and it is likely that new reviews will be necessary in the near future.

II. PHYSICOCHEMICAL PROPERTIES OF MOLECULAR NITROGEN

Table 1 lists certain physicochemical characteristics of molecular nitrogen. It is readily seen that the nitrogen molecule has very high dissociation energies and ionisation potentials and exhibits an appreciable quadrupole moment and polarisability.

Table 1. Physicochemical properties of molecular nitrogen

Interatomic distance r_e	1.0975 Å
Quadrupole moment	-1.4×10^{-26}
Anisotropy of the polarisability ($\alpha_{\parallel} - \alpha_{\perp}$)	0.696×10^{-24} cm^3
Ionisation potential	367 kcal mole^{-1}
Electron excitation energy	
$^1\Sigma_g^+ \rightarrow {}^3\Sigma_u^+$	142 kcal mole^{-1}
$^1\Sigma_g^+ \rightarrow \Pi_g$	196 kcal mole^{-1}
Dissociation energy ($^1\Sigma_g^+$)	225 kcal mole^{-1}
Vibration frequency (gas)	2331 cm^{-1}
Anharmonicity constant	0.006
Rotational constant	1.9983
Solubility:	
in water (20°C)	1.7×10^{-2} cm^3 cm^{-3}
in benzene (20°)	1.11×10^{-1} cm^3 cm^{-3}

The inertness of molecular nitrogen is attributed to the high stability of the first bond to be dissociated in the N_2 molecule. The energy of this bond amounts to about 130 kcal mole^{-1},[1] which greatly exceeds the corresponding values for other multiple bonds. For example, in acetylene the dissociation of the first bond requires only 53 kcal mole^{-1}.[1] Pauling[1] explains the deviation from linearity of the variation of the dissociation energy of the nitrogen–nitrogen bond with increasing bond order (Fig. 1) by the lower repulsion energy of the unshared electron pair in molecular nitrogen compared with the N=N and N–N bonds.

The positions of the upper filled and lower unfilled molecular levels of the interacting molecules play a significant role in the formation of the complexes, since they determine the donor–acceptor properties of the interacting species.

Let us now consider the system of molecular orbitals of the N_2 molecule. Eight molecular orbitals are formed from the eight sp^3 orbitals of the two nitrogen atoms. The sequence of the filled molecular orbitals of the nitrogen molecule ($^1\Sigma_g^+$) with increasing energy (Fig. 2) is as follows: $1\sigma_g^2$, $1\sigma_u^2$, $2\sigma_g^2$, $2\sigma_u^2$, $1\pi_u^4$, and $3\sigma_g^2$. The highest filled level is the bonding $3\sigma_g$ level, since ionisation of N_2 results in the formation of the N_2^+ ion ($^2\Sigma_g^+$) by removal of a $3\sigma_g$ electron[2,3]. It is noteworthy that, in contrast to N_2, the upper filled 3σ level of carbon monoxide is of the non-bonding type[4] and this is precisely the reason for the significant difference between N_2 and CO as ligands in complex formation (see pp. 360 and 367).

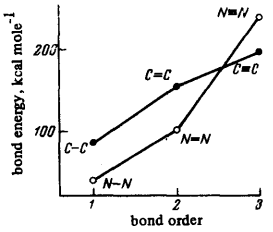

Figure 1. Dependence of the energy of the nitrogen–nitrogen and carbon–carbon bonds on bond multiplicity.

The removal of electrons from bonding orbitals weakens the nitrogen–nitrogen bond while their removal from antibonding orbitals strengthens the bond. In diatomic molecules this affects the interatomic distances and frequencies of the stretching vibrations.

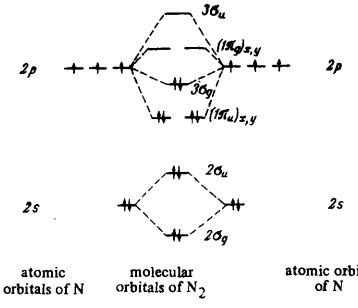

Figure 2. Molecular orbitals of N_2 (arbitrary scale).

The ionisation potentials, interatomic distances, and vibration frequencies (Table 2) confirm the sequence of molecular orbitals presented in Fig. 1. The removal of an electron from the strongly antibonding $2\sigma_u$ level leads to a decrease in the interatomic distance and an increase in the vibration frequency, while the removal of $3\sigma_g$ and $1\pi_u$ electrons greatly weakens the N≡N bond. The $3\sigma_g$, $1\pi_u$, and $2\sigma_u$ molecular orbitals of nitrogen are located relatively close to one another and small changes in interatomic distance can alter the sequence of these levels[5].

The ionisation potential of N_2 is 360 kcal mole^{-1}† and the dissociation energy of N_2^+ remains fairly high (201 kcal mole^{-1}). The electron affinity of molecular nitrogen, which characterises the position of the lower unfilled level,

† All the energy values quoted in the review without a reference were taken from Ref. 9.

is important. In this connection studies[6,7] on the scattering of slow electrons by molecular nitrogen, which showed that electrons with energies of 53 kcal mole^{-1} collide inelastically with N_2, are of interest. The observed low-energy resonance is probably associated with the excitation of the short-lived virtual negative ion N_2^- ($^2\Pi_g$), the potential energy minimum of which is higher by 34 kcal mole^{-1} than the lowest vibrational state of N_2($^1\Sigma_g^+$).[8] These data lead to the conclusion that in the excited state N_2 possesses considerable electron affinity.

Table 2. Physical constants of N_2 in various electronic states*

	N_2			N_2^+		
	$^1\Sigma_g^+$	$^3\Sigma_u^+$	$^1\Pi_g$	$^2\Sigma_g$	$^2\Pi_u$	$^2\Sigma_u^+$
Interatomic distance r, Å	1.09			1.12	1.17	1.07
Vibration frequency ν_e, cm^{-1}	2358			2207	1902	2419
Dissociation energy D_e, kcal mole^{-1}	225	83	138	201		
Ionisation potential of the N_2 molecule ($^1\Sigma_g^+$), kcal mole^{-1}	360 ($3\sigma_g$); 390 ($1\Pi_u$); 430 ($2\sigma_u$)					

* The interatomic distances and the vibration frequencies have been taken from Ref. 5 and the ionisation potentials from Ref. 3.

We may note that in carbon monoxide, which is isoelectronic with respect to nitrogen, resonance is observed at an electron energy of about 39 kcal mole^{-1}. The dissociation energy of "hot" nitrogen molecules in long-lived states is greatly reduced (Table 2).

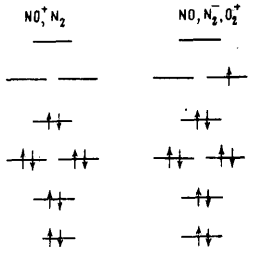

Figure 3. The system of molecular orbitals of NO^+ and N_2 and of NO, N_2^-, and O_2^{2+} (arbitrary scale).

In order to obtain some idea about the weakening of the nitrogen–nitrogen triple bond in the N_2^- ion, we shall compare the dissociation energies of the isoelectronic molecules NO^+ and N_2, and also NO, N_2^-, and O_2^+ (Fig. 3). The dissociation energy of NO^+ is 252 kcal mole^{-1}. The introduction of an electron into the antibonding $1\pi_g$ orbital reduces the strength of the nitrogen–oxygen bond and the dissociation energy of NO is 152 kcal mole^{-1}. The dissociation energy of the O_2^+ molecule, isoelectronic with NO and N_2^-, is 153.5 kcal mole^{-1}. Assuming that in the transition from N_2 to N_2^- the dissociation energy diminishes in proportion to the energy change on going from NO^+ to NO, we obtain about 140 kcal mole^{-1} for the dissociation energy of the N_2^- ion. On the basis of this value, it is possible to estimate the electron affinity (EA) of N_2 from the following cycle:

$$\begin{aligned} &N_2 + e \rightarrow N_2^- && +EA,\\ &N_2^- \rightarrow N^- + N && -140 \text{ kcal mole}^{-1},\\ &N^- \rightarrow N + e && -1 \text{ kcal mole}^{-1},\\ &N + N \rightarrow N_2 && +225 \text{ kcal mole}^{-1},\\ &\overline{EA = -84 \text{ kcal mole}^{-1}}. \end{aligned}$$

Thus, in accordance with this estimate, the affinity of the nitrogen molecule for an electron is a large negative quantity. The electron affinity obtained and the ionisation potential of the N_2 molecule show that the ionic states N_2^+ and N_2^- are difficult to achieve on energetic grounds, i.e. reactions with complete electron transfer

$$N_2 + D \rightarrow N_2^- + D^+$$
$$N_2 + A \rightarrow N_2^+ + A^-$$

are very unlikely (here D is an electron donor and A an acceptor).

III. REACTIONS OF N_2 WITH NON-METAL DERIVATIVES

Several examples of non-elastic collisions of N_2 with the molecules of other gases are known at present.

1. Collision Complexes in the Gas Phase

In a mixture with carbon dioxide, H_2, and other gases under a pressure of several tens of atmospheres, nitrogen absorbs infrared radiation. Then the spectrum of the gaseous mixture shows both the frequency corresponding to the fundamental vibration of N_2 and the sum and difference frequencies with the colliding molecules. Such vibrational transitions are due to the simultaneous excitation of the two interacting molecules by a single light quantum[10].

In an inelastic collision the electrical charges of the molecules are redistributed, as a result of which vibration frequencies corresponding to forbidden transitions appear in the infrared spectrum. Thus Fahrenfort and Ketelaar[11] observed absorption bands at 2331, 2995, and 4670 cm^{-1} in the spectrum of a mixture of N_2 with CO_2. The last two are combination frequencies:

$$\nu(N_2) + \nu'(CO_2) = 2331 + 2349 = 4680 \text{ cm}^{-1},$$
$$\nu(N_2) + \nu''(CO_2) = 2331 + 667 = 2998 \text{ cm}^{-1}.$$

It has been shown experimentally that the intensity of infrared absorption corresponding to simultaneous transition in a complex of two molecules is proportional to the pressures of both mixture components, i.e. the transitions occur in bimolecular collisions.

Under normal conditions, the lifetime of collision complexes should not exceed 10^{-13} s, since the interaction energy of the components of the complex is very low.

2. Interaction of Molecular Nitrogen with Water, Hydrogen Chloride, and Boron Trifluoride

Van der Waals forces play a significant role in the formation of "collision complexes" of molecular nitrogen. However, it has been shown[12] that the formation of complexes as a result of exchange interactions, similar to hydrogen bonding, is possible. In the study of the broadening

of the rotational lines of the R- and P-branches of the rotational vibrational bands of water, hydrogen chloride, and methane in a mixture with different gases, it was found[12] that the effect of the gases in the broadening of the water and hydrogen chloride lines increases in the sequence He, Ar, O_2, and N_2. N_2 is almost twice as effective as argon, although the effect of argon and nitrogen on the methane molecule is almost the same (Table 3).

Table 3. Collisional broadening cross-sections (10^{-16} cm^2) of molecules[12] with Ar and N_2

Molecule	λ, nm	Ar	N_2
H_2O	1.45	41 (30) *	85 (32)
HCl	1.7	62 (50)	116 (53)
CH_4	1.7	50 (28)	50 (30)

* The gas-kinetic cross sections are indicated in brackets.

The difference in the broadening effects of argon and molecular nitrogen on the rotational lines of water and hydrogen chloride has been attributed to the formation of the hydrogen bonds N_2...HCl and N_2...HOH.

In order to investigate the donor–acceptor interaction of nitrogen with powerful acceptors, the infrared spectra of mixtures of nitrogen with boron trifluoride were investigated[13]. A change in the contour and integral intensities of the $\nu_2(A'')$ and $\nu_3(E)$ bands of boron trifluoride, corresponding to an increase in the moment of inertia and the dipole moment of the B–F bond in the BF_3 molecule, were observed.

Table 4. Electro-optical parameters $\partial\mu/\partial Q$ and the dipole moments μ_{B-F} of boron trifluoride mixed with various gases[13]

Gas	$\partial\mu/\partial Q$, CGSU/cm^{-1} g$^{-1/2}$	$10^{18}\mu_{B-F}$, CGSE
BF_3 *	101.5	1.7
BF_3+He **	103	1.75
BF_3+H_2 (D_2)	104.5	1.77
BF_3+Ar	111	1.9
BF_3+N_2	116.5	2.0

* The pressure of BF_3 was in all cases 20–30 mmHg.
** The pressure of the gas interacting with BF_3 was 70 atm.

Compared with other gases (helium, hydrogen, deuterium, and argon), nitrogen has the greatest effect on the integral intensity and the dipole moment of the B–F bond; argon is the next most effective gas in this respect (Table 4).

The increase of the moment of inertia and of the polarity of the B–F bond in mixtures of boron trifluoride with argon and nitrogen is evidence of the formation of donor–acceptor molecular complexes in which N_2 behaves as an electron donor by virtue of its unshared electron pair or the π electrons of the triple bond and BF_3 behaves as an acceptor by virtue of the unfilled $2p_z$ orbital of boron. The complexes of boron trifluoride with argon were known even earlier[14].

It is noteworthy that the intensities $\mathcal{I}\nu_2$ and $\mathcal{I}\nu_3$ vary little in the nitrogen pressure range 1–70 atm and therefore a very low concentration of the complexes is formed even at high pressures.

Evidently, by itself donor–acceptor interaction, even with powerful acceptors such as boron trifluoride, leads to the formation of complexes with only a very weak bond, i.e. nitrogen may be regarded as a very weak base.

So far there is no information about the structure of the unstable donor–acceptor complexes of molecular nitrogen in the gas phase.

3. Interaction of Nitrogen with Carbenes and Related Species

Organic diazo-compounds and diazonium salts may be arbitrarily regarded as complexes of molecular nitrogen with carbenes and aryl cations respectively[15]. Nitrous oxide (N_2O) and hydrazoic acid (HN_3) may be included among these compounds. In fact the interatomic distance r_{NN} and the stretching vibration frequency $\nu(N_2)$ in these compounds are close to the corresponding values in molecular nitrogen. The C–N_2, O–N_2, and HN–N_2 fragments have a linear configuration‡ (which, as will be shown below, is characteristic of the complexes of nitrogen with metals and their compounds).

The C–N_2, O–N_2, and HN–N_2 bonds are fairly stable: thus in diazomethane $D(H_2C-N_2)$ = 21 kcal mole^{-1} [16] and in nitrous oxide $D(O-N_2)$ = 40 kcal mole^{-1}. The higher energy of the bond of N_2 with carbenes (and the related species O, NH, etc.) and aryl cations, compared with "pure" acceptors such as BF_3, can be accounted for by the additional interaction of the antibonding N_2 orbital and the unshared pairs of p electrons in CH_2, O, or NH. In diazonium salts this role is fulfilled by the π electrons of the aromatic ring, which explains the higher stability of aromatic diazonium salts compared with the aliphatic salts.

It has been shown recently that in many cases the decomposition of diazo-compounds may be reversible. This confirms that it is valid to regard these compounds as "complexes" of molecular nitrogen.

It is now known that certain species are capable of reacting with nitrogen to form diazo-compounds, the process involving a small activation energy. Thus the oxygen atom formed in the singlet state by the photolysis of ozone reacts with N_2 to form N_2O.[17–19] The yield of nitrous oxide varies significantly with reaction conditions: in the gas phase it is only 0.01%,[17] in liquid nitrogen it is 7%,[18] and in solid nitrogen it reaches 35%.[19] This increase in the yield is accounted for by the fact that the energy of the excited N_2O molecule formed in the reaction between N_2 and O is more readily eliminated in the condensed phase.

Moore and Pimentel[20] observed in 1964 the reaction of methylene with N_2 in the solid nitrogen matrix at 20°K. In the photolysis of $CH_2{}^{15}N^{14}N$ in solid molecular nitrogen[14] the infrared spectrum of the products showed, in addition to the absorption bands at 2053 and 2072 cm^{-1}, which are

‡ A cyclic form, as in diazirine $H_2C\langle{}^{N}_{N}\rangle$, is also known. However, linear diazomethane is thermodynamically more stable.

due to the $\nu(N{\equiv}N)$ vibrations in $CH_2{}^{15}N^{14}N$ and $CH_2{}^{14}N^{15}N$ respectively, a band at a frequency of 2096 cm^{-1}, corresponding to the $\nu(N{\equiv}N)$ vibrations in $CH_2{}^{14}N^{14}N$.

The light diazomethane is formed in the reaction

$$CH_2{}^{15}N^{14}N \rightleftarrows CH_2 + {}^{15}N^{14}N \rightleftarrows CH_2{}^{15}N^{14}N$$

$$CH_2 + {}^{14}N^{14}N \rightarrow CH_2{}^{14}N^{14}N$$

It may be supposed that in this case "hot" CH_2 species formed in the photolysis of diazomethane react with nitrogen.

The reaction of methylene with molecular nitrogen in the gas phase was first observed and investigated in detail by Shilov and coworkers [15,21,22]. Both diazomethane and keten, diazirine, and phenylcyclopropane, subjected to photolysis or pyrolysis in an atmosphere of labelled $^{15}N_2$, were employed as sources of methylene in these investigations. In all cases the formation of linear diazomethane ($CH_2{}^{15}N_2$) molecules was observed; the isomeric cyclic diazirine did not form. It was shown that both singlet [$CH_2(s)$] and triplet [$CH_2(t)$] methylene are capable of interacting with nitrogen, the activation energies for the reactions of $CH_2(s)$ and $CH_2(t)$ being respectively about 8 and 16 kcal $mole^{-1}$. Here we may note that, although these quantities are in fact small, they nevertheless exceed the activation energy for the formation of nitrogen complexes with transition metals and their compounds (see p.369). Among the carbenes investigated, methylene proved to be the more active with nitrogen. The rates of the reactions of $(CF_3)CH$ and $(CN)CH$ with N_2 are lower at least by a power of ten than that of CH_2. The remaining carbenes investigated, CH_3CH, C_5H_4, and $CHCOOC_2H_5$, do not react with nitrogen at an appreciable rate.

Recently it was shown that the CH radical [23] and the C atom [24] are also capable of reacting with molecular nitrogen.

An interesting case of the formation of a diazo-compound in the reaction of nitrogen with benzenesulphenium ($C_6H_5S^+$) was recently described [25]. This reaction (if the data are correct) is the first and so far unique example of a reaction of nitrogen with non-metal derivatives in solution at room temperature and at atmospheric pressure of nitrogen. Although the reaction product was not identified, the authors noted that it is capable of entering into the azo-coupling reaction. This suggests that a diazonium salt is formed.

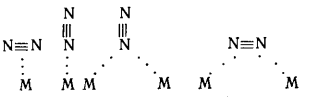
IV. COMPLEXES OF N_2 ON THE SURFACE OF METALS

In the reaction of N_2 with metals there is rapid reversible low-temperature chemisorption and slow high-temperature chemisorption [26]. Surface complexes of molecular nitrogen are then formed together with surface nitrides. Measurements of the heat of chemisorption show that the values of ΔH_{ads} vary in the range between −2 and −20 kcal $mole^{-1}$.

It has been established [27] that several states of chemisorbed nitrogen molecules are realised in the chemisorption of N_2 on the surface of tungsten purified in an ultrahigh vacuum. In one of these states (molecular) nitrogen is completely desorbed at 300°K, while in the other it is desorbed only above 1100°K. If the initial nitrogen is a mixture of $^{14}N_2$ and $^{15}N_2$, the gas desorbed above 1100°K contains $^{14}N^{15}N$. Kinetic studies showed that the desorption of some of the molecules is a second-order process and that of others is a first-order process with respect to the concentration of N_2 on the surface. This finding has been explained [27] by the existence on the surface of both "atomic" (i.e. evidently nitride) nitrogen and its "molecular" form. Possibly isotopic $^{14}N^{15}N$ molecules are formed in the decomposition of the four-membered surface complexes

The possibility of the existence of four-membered nitrogen rings, stabilised by complex formation with transition metals, was demonstrated theoretically in a recent paper [28].

Several structures may be put forward for the surface complexes of molecular nitrogen in low-temperature chemisorption, for example:



So far there has been no direct experimental evidence for the structure of the surface complexes and various authors put forward different considerations in favour of one or other of the structures given above.

By analogy with the bonds of other unsaturated molecules with metals, it may be assumed [29] that the M–N_2 bond forms via the filled π or σ orbitals of N_2 and the free p orbitals of the metal (donor–acceptor interaction) and also the unshared pairs of d electrons of the metal and the antibonding orbitals of N_2 (dative interaction). In this treatment it is of course assumed that the behaviour of the d levels of the surface metal atoms is equivalent to that of free metal atoms.

It may be expected that the polarity of the M–N_2 bond in the surface complex will be different for different metals depending on the relative contributions of the dative and donor–acceptor bonds. In most cases the charge of N_2 should then be negative. It has been shown electrochemically [30,31] that nitrogen undergoes cathodic polarisation on cobalt, copper, silver, and iron. The authors believe that this is associated with the cathodic reduction of the nitrogen molecule: N_2^- ions are formed on the surface of porous metallic films.

Eischens and Jacknow [32], who investigated the chemisorption of N_2 on nickel, observed infrared absorption in the region of 2196 cm^{-1}. With the aid of the $^{14}N_2$ and $^{15}N_2$ isotopes, they showed that this absorption is due to the stretching vibration of the N≡N bond, the frequency of which is greatly reduced compared with that in gaseous nitrogen. The authors believe that the vibration of the N_2 molecule is active in the infrared spectrum because of the formation of the complex Ni–N≡N. Subsequently the infrared spectra of N_2 chemisorbed on different metals (nickel, cobalt, palladium, platinum, iridium) were investigated by other workers [15,33,34,120].

To elucidate the structure of the surface Ni–N_2 complex, molecular nitrogen $^{14}N^{15}N$ was employed [35] (see p. 364). Analysis of the contours of the observed absorption bands of the isotopic molecules $^{14}N^{14}N$, $^{14}N^{15}N$, and $^{15}N^{15}N$ confirmed the linear structure of the complex. In the same study the enthalpy of formation of the complex, Ni + N_2 ⇌ Ni–N_2, was measured and found to be −9.2 kcal $mole^{-1}$ for a surface coverage $\Theta \simeq 0.05$ and −5 kcal $mole^{-1}$ for $\Theta \simeq 0.2$.

According to the data of Eischens and Jacknow [32] and Chernikov and Borod'ko [36], the Ni–N_2 complex is sensitive to molecular hydrogen: when hydrogen is admitted to the system comprising nickel and N_2, the nitrogen absorption band is displaced to higher frequencies, up to 2260 cm^{-1} and then up to 2275 cm^{-1}. Under the action of argon and krypton, the absorption band is displaced towards lower

frequencies[36], to 2170 and 2080 cm^{-1} respectively. It follows from these data that, on being chemisorbed on nickel, hydrogen and the inert gases alter the state of the surface of the metal and the strength of the nickel–nitrogen bond. The direction of the displacement of the vibration frequency of the N≡N bond shows that H_2 behaves as an electron acceptor and argon and krypton behave as electron donors (see p. 365).

The surface complexes of N_2 with palladium and platinum were investigated by van Hardeveld and van Montfoort[34]. Since the extinction coefficients of the bands corresponding to the ν(N≡N) vibration of nitrogen chemisorbed on nickel, palladium, and platinum are similar, one may conclude that the structure of the N_2 complexes with palladium and platinum is also linear.

It is interesting that the complex formation is influenced by the dimensions of the palladium and platinum crystallites: N_2 complexes are formed on particles with effective diameters in the range 15 Å $< d_{eff} <$ 70 Å. Virtually no complexes are formed on metal particles with $d >$ 200 Å and the amount formed on particles with $d <$ 10 Å is very small. These features of the surface nitrogen compounds distinguish them from individual coordination compounds containing a nitrogen molecule as the ligand.

Table 5. Effect of chemisorption on the stretching vibration frequencies of N_2 and CO

Compound	$\nu(N\equiv N)_{ads}$, cm^{-1}	$(\nu_{gas}-\nu_{ads})/\nu_{gas}$	Compound	$\nu(N\equiv N)_{ads}$, cm^{-1}	$(\nu_{gas}-\nu_{ads})/\nu_{gas}$
Ni—N_2	2204	0.055	Ni—CO	2033	0.051
Pd—N_2	2260	0.031	Pd—CO	2085	0.027
Pt—N_2	2230	0.041	Pt—CO	2071	0.034

Carbon monoxide, which is isoelectronic with nitrogen, is also known to form linear complexes on the surface of metals. Comparison of the ν(N≡N) and ν(C≡O) stretching vibration frequencies (Table 5) shows that the reduction of the ν(N≡N) frequency of chemisorbed nitrogen from its frequency in the gas phase is greater than the corresponding shift for carbon monoxide. This is probably associated with the different nature of the upper filled levels of N_2 and carbon monoxide, namely the $3\sigma_g$ orbital of N_2 is bonding and the $3\sigma_g$ orbital of carbon monoxide is non-bonding[4]. While the formation of the π bonds, by which the electron density is displaced to the antibonding orbitals of N_2 and carbon monoxide, lowers the stretching vibration frequencies, the formation of σ bonds has different effects[37] on the N≡N and C≡O bond strengths and hence the ν(N≡N) and ν(C≡O) frequencies. In the coordination of N_2 the formation of a σ bond leads to an electron shift from the bonding $3\sigma_g$ orbital and an additional lowering of the ν(N≡N) frequency, while in the case of carbon monoxide the formation of a σ bond is associated with a decrease of electron density in the non-bonding 3σ orbital§.

§ Carbon monoxide in the gas phase is characterised by absorption at 2146 cm^{-1} in the infrared spectrum, while in the complex BH_3...CO (formed via a σ bond) the ν(C≡O) vibration frequency is 2164 cm^{1}. Possibly this is due to the fact that the 3σ(CO) level is weakly antibonding.

In the interaction of carbon monoxide with transition metals the displacement of the ν(C≡O) frequency is a result of the superposition of two opposed effects, and the fact that ν(C≡O) is reduced on complex formation is evidence that the π dative component makes a greater contribution to the bond with the transition metal than the σ donor component. For the nitrogen molecule, both types of interaction lead to a decrease of frequency. Therefore, in contrast to carbon monoxide, in the case of N_2 one should always expect a bathochromic shift of the ν(N≡N) frequency on complex formation[37].

V. COMPLEXES OF NITROGEN WITH TRANSITION METAL COMPOUNDS (NITROGENYLS)

1. SYNTHESIS AND CHEMICAL PROPERTIES OF NITROGENYLS

Nitrogenyl Complexes of Ruthenium

$[RuN_2(NH_3)_5]X_2$. This, the first of the known complexes of molecular nitrogen with transition metal compounds, was obtained by Allen and Senoff[38] in 1965 by the reaction of $RuCl_3$ with hydrazine hydrate in aqueous solution; it is then possible to isolate from the solution the saltlike compounds $[RuN_2(NH_3)_5]X_2$ (X = Cl^-, Br^-, I^-, or BF_4^-). Subsequently the same complexes were obtained by the action of hydrazine hydrate on other ruthenium(III) and ruthenium(IV) salts and in the reaction of sodium azide with aquopentammineruthenium(III) methanesulphonate[39].

The complexes $[RuN_2(NH_3)_5]X_2$ were also obtained when all the ligands, except nitrogen, were substituted by ammonia[40] in the non-saltlike complexes $RuN_2Cl_2(H_2O)THF$ (see p. 361)[THF = tetrahydrofuran (Ed. of Translation)], by passing nitrogen[41] into an aqueous solution of $[Ru(NH_3)_5H_2O]Cl_2$, and by the action of ammonia[42] and zinc dust on $RuCl_3.3H_2O$.

The salts of pentammineruthenium nitrogenyls have been isolated in a crystalline state. They are thermally stable and relatively stable in aqueous solutions, but, under the action of a number of compounds, molecular nitrogen may be displaced by other ligands[39].

The infrared spectra of the complexes show an absorption band in the region 2105–2167 cm^{-1} (Table 6), which corresponds to the N≡N stretching vibration, and in the electronic spectra there are absorption bands with maxima at 221 and 463 nm.

According to the data of Allen and Senoff[38], under the action of $NaBH_4$ nitrogen in the complex may be reduced to ammonia either completely or, as stated subsequently[39], partially. However, these results were not confirmed[40]. It has been established by mass-spectrometric analysis that ammonia in the product of the reaction of $[Ru^{15}N_2(NH_3)_5]X_2$ with $NaBH_4$ is not enriched in labelled $^{15}NH_3$ in excess of the natural content, i.e. N_2 in the complex is not reduced.

It also proved impossible to reduce the nitrogen in the complex by reducing agents such as $CrCl_2$, EtMgBr, $Na_2S_2O_4$, and zinc and hydrochloric acid[40]. Allen and coworkers[38,39] and subsequently Chatt and coworkers[45] stated that, under the action of sulphuric and hydrochloric acids, only part of the coordinated nitrogen in the nitrogenyl complex is evolved in the form of N_2 (i.e. the coordinated nitrogen reacts at least partially with the acid), but these results appear very doubtful, particularly in view of

the negative findings of Borod'ko et al.[40] in the study of the reduction of a nitrogenyl complex¶.

$RuN_2Cl_2L_3$ (L = H_2O, NH_3, Py, THF, etc.). These complexes were the first to be obtained directly from molecular nitrogen. They are formed[40,43,44] by the reduction of $RuCl_3$ and $RuCl_3OH$ with amalgamated zinc in the presence of nitrogen in tetrahydrofuran (THF). The yield of the nitrogen complex increases with the N_2 pressure and becomes almost quantitative at pressures in excess of 40–60 atm.

* The vibration frequencies ν(N≡N) of the crystalline complex due to Davydov splitting.
** The vibration frequency of the Davydov component with maximum intensity.

The composition of the complex obtained in tetrahydrofuran solution corresponds to the formula $RuN_2Cl_2(H_2O)_2THF$. This complex is thermally much less stable than the pentammine and decomposes slowly with evolution of hydrogen even at room temperature. It has been established[40,44] that, when the complex is acted upon by bases (ammonia, pyridine, ethylenediamine, etc.), the ligands at the ruthenium atom are substituted with retention of part of the nitrogen in the coordination sphere. A whole series of $RuN_2Cl_2L_3$ with different ligands L were obtained in this way, which permitted certain conclusions about the nature of the ruthenium–nitrogen bond. It again proved impossible to reduce the nitrogen in the complex by various reducing agents.

¶ In fact, recently Chatt and coworkers[46,47] found that the results of earlier studies[38,39,45] showing the reduction of N_2 in the complex and also the interaction of nitrogenyl complexes with acids are erroneous, due to the presence of large amounts of hydrazine as an impurity in the complex obtained by Allen's method.

Other Complexes of Nitrogen with Ruthenium Compounds

It has been established[44,48] that nitrogen is coordinated to ruthenium when $RuCl_3$ is reduced by reducing agents such as C_2H_5MgBr, C_6H_5MgBr, $TiCl_3$, Na_2S_2, and Na_2S. The complexes formed under these conditions were not isolated but there are indications that in some cases they contain ligands other than those discussed above. Thus, when sulphides are used, the complexes probably contain sulphur together with nitrogen.

$RuN_2(PPh_3)_3H_2$. It has been found[49] that nitrogen forms a complex on interaction with the ruthenium compound having the hypothetical formula $Ru(PPh_3)_4H_2$. This complex was isolated[50] after the reaction of $(PPh_3)RuHCl$ with $AlEt_3$ in the presence of nitrogen in ether. The complex corresponds to the formula $RuN_2(PPh_3)_3H_2$. It is sensitive to air and is stable in an atmosphere of nitrogen at room temperature.

Dinitrogenyl complex of ruthenium(II). The interaction of *cis*-$[Ru(en)_2N_3N_2]^+$ with HNO_2 yielded a complex containing two nitrogen molecules in the coordination sphere of ruthenium in the *cis*-position[51]. The reaction takes place according to the equation
cis-$[Ru(en)_2N_3N_2]^+ + HNO_2 \rightarrow$ *cis*-$[Ru(en)_2(N_2)_2]^{2+} + N_2O$.
The infrared spectrum of the complex shows two absorption bands at 2220 and 2190 cm^{-1}. In aqueous solution the dinitrogenyl complex decomposes irreversibly with formation of *cis*-$[Ru(en)_2H_2ON_2]^{2+}$; the product of this reaction was isolated as the tetraborate [ν(N≡N) = 2130 cm^{-1}].

Osmium Complexes

Ammine nitrogenyls. The first complexes of nitrogen with osmium compounds were obtained[52] by the reaction of hydrazine with osmium compounds such as K_2OsCl_6, $OsCl_4$, $OsCl_3OH$, i.e. a reaction analogous to that whereby ruthenium nitrogenyls are synthesised by the method of Allen and Senoff. If is interesting that, in contrast to ruthenium compounds, the formation of several complexes of molecular nitrogen with osmium was observed in this case. Subsequently it was established[53,54] that the main product is the analogue of pentammineruthenium nitrogenyl $[OsN_2(NH_3)_5]X_2$ with ν(N≡N) at 2012 cm^{-1} in the infrared spectrum. The less stable dinitrogenyl complex $[Os(N_2)_2(NH_3)_4]X_2$ probably forms at the same time.

In a recent communication[55] the synthesis of the dinitrogenyl complex of osmium by another method was described. When nitrous acid acts on an aqueous solution of $[OsN_2(NH_3)_5]X_2$, a crystalline product is formed, whose composition corresponds to the formula $[Os(N_2)_2(NH_3)_4]X_2$ (X = Cl^-, Br^-, or I^-) according to elemental analysis. The infrared spectrum of this compound shows absorption bands at 2120 and 2175 cm^{-1}, which is evidence of the *cis*-configuration of this dinitrogenyl complex.

In the crystalline state the complex $[OsN_2(NH_3)_5]X_2$ is exceptionally stable: it decomposes above 200°C. In aqueous solution the evolution of nitrogen is catalysed by various metal ions (Ag^+, Cu^{2+}).[56] The thermal decomposition of the complex in aqueous solution is inhibited by carbon monoxide[57]. This is probably due to the binding of catalytically active species into inactive carbonyls.

Other Complexes of Osmium with Molecular Nitrogen

Nitrogenyl complexes of osmium have been obtained[44] directly from molecular nitrogen in the reduction of $OsCl_3OH$ by amalgamated zinc in tetrahydrofuran solution. Examination of the vibration spectra of the reduction products led to the conclusion that several nitrogen-containing complexes are formed. The complexes were not identified but it may be supposed that they are similar in composition to the ruthenium complexes formed under analogous conditions†.

Dinuclear Complexes of Ruthenium and Osmium

It has been stated[58] that the formation of a complex in which two metal atoms are linked to nitrogen is possible. The dinuclear ruthenium complexes are formed when the pentammineruthenium nitrogenyl $[RuN_2(NH_3)_5]X_2$ reacts with the aquopentammine complex $[Ru(NH_3)_5H_2O]X_2$. In aqueous solution the complex $[(NH_3)_5RuN_2Ru(NH_3)_5](BF_4)_4$ has an intense absorption band at 262 nm.

The formation of dinuclear complexes in aqueous solutions is an equilibrium process: when the concentration of $\{[Ru(NH_3)_5]_2N_2\}^{4+}$ is reduced, the complex dissociates into the mononuclear nitrogenyl and $[Ru(NH_3)_5H_2O]^{2+}$.

It has been suggested[56] that the decomposition of $[OsN_2(NH_3)_5]^{2+}$ in the presence of silver(I) and copper(II) salts takes place via the intermediate formation of the complexes $[(NH_3)_5OsN_2Cu]$ and $[(NH_3)_5OsN_2Ag]$.

Nitrogenyl Complexes of Iron

The complexes of nitrogen with iron compounds are of interest, since their formation in the enzyme systems of nitrogen-fixing bacteria probably constitutes the first stage in the biological fixation of nitrogen.

A complex of a dihydride derivative of iron(II) with nitrogen was synthesised by Sacco and Aresta[59] by the reaction of N_2 with $FeH_2[P(C_6H_5)_2R]_3$ (R = ethyl or butyl). A yellow crystalline complex, decomposing at 80°C with evolution of nitrogen and hydrogen, was then isolated. The complex is diamagnetic and is characterised by an intense absorption band in the infrared at 2055–2060 cm^{-1}. The interaction of this complex with triethylaluminium gave the compound $FeH_2N_2[P(C_6H_5)_2R]_2$, whose infrared spectrum shows a band at a frequency of 1989 cm^{-1}, which has been assigned[59] to the stretching vibrations of the nitrogen–nitrogen bond.

The formation of nitrogen complexes with iron compounds, produced by the action of N_2 on low-valence derivatives of iron, has also been described[60]. Thus the reaction of nitrogen with the iron(0) complex of cyclooctadiene or with tris-π-allyliron in the presence of phosphines yields nitrogen-containing complexes (a band at 2038 cm^{-1} is observed in the infrared spectrum), which, however, could not be isolated in a pure state.

Complexes of Nitrogen with Cobalt Compounds

The formation of complexes of molecular nitrogen with cobalt compounds has been described[61–65]. Yamamoto et al.[61] obtained the cobalt complex at atmospheric nitrogen pressure by the reaction of cobalt(III) acetylacetonate with ethoxydiethylaluminium in the presence of triphenylphosphine in ether or toluene. In accordance with the results of elemental analysis, the formula $CoN_2(PPh_3)_3$ was ascribed to the yellow crystals isolated from the solution. In the absence of air the complex is comparatively stable, but decomposes with evolution of nitrogen at 80°C.

A nitrogenyl complex of cobalt was also obtained by Misono and coworkers[63,64] by the action of nitrogen on a hydride derivative of cobalt. The hydride was synthesised by passing H_2 into a mixture of cobalt(III) acetylacetonate, triphenylphosphine, and tri-isobutylaluminium in ether at 10°C. In the interaction of this hydride solution with nitrogen the colour of the former changes from yellow to red and orange crystals can be isolated from the reaction mixture; their infrared spectrum shows absorption at 2088 cm^{-1}. Evidently this complex is identical with that obtained by Yamamoto and the reaction involves the displacement of hydrogen by nitrogen from cobalt hydride. It was concluded[63,64] that the product of the reaction with nitrogen is a mixture of $CoN_2(PPh_3)_3$ and $CoHN_2(PPh_3)_3$.

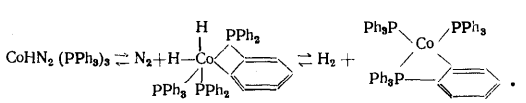
The Italian workers Sacco and Rossi[65,66] stated that nitrogen reacts reversibly with the trihydride complex of cobalt to form a cobalt(I) nitrogenyl complex:

$$CoL_3H_3 + N_2 \rightleftarrows CoHN_2L_3 + H_2.$$

where L = PPh_3 or PPh_2Et. This complex consists of orange crystals, which are fairly stable in air and soluble in non-polar solvents. An intense absorption band at 2080–2084 cm^{-1} in the infrared spectrum of the complex corresponds to the stretching vibrations of the nitrogen. The complex is diamagnetic; in accordance with the formula quoted, 1.5 moles of gas consisting of nitrogen and hydrogen in the proportions $N_2 : H_2 = 2 : 1$ are evolved per mole of the complex in its decomposition at 100–150°C.

Since the complex of Sacco and Rossi is very similar in its properties to the complex obtained by the Japanese workers[61–64], it may be supposed that the two are identical. Indeed X-ray diffraction analysis showed[67] that the complex obtained by a similar procedure[61] has the formula $CoHN_2(PPh_3)_3$. In a recent study by NMR Misono and coworkers[68] obtained further confirmation that this complex contains a hydride hydrogen atom and therefore the previously proposed formula[61] $CoN_2(PPh_3)_3$ may be regarded as erroneous.

The study of the isotope exchange of deuterium with the complex showed[69] that not only the hydride hydrogen atom but also the hydrogen atoms in the *ortho*-positions of the phenyl ring of triphenylphosphine participate in the reaction, possibly according to the mechanism



The complex $CoHN_2(PPh_3)_3$ reacts reversibly with H_2, ethylene, and ammonia with displacement of nitrogen[62]; it reacts irreversibly with carbon monoxide to form a carbonyl[70], and also with carbon dioxide to form the formate complex[71] $CoHCO_2(PPh_3)_3$.

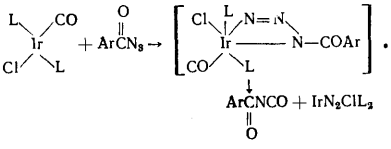
The cobalt nitrogenyl complex catalyses the hydrogenation of ethylene[72], the oxidation of triphenylphosphine to triphenylphosphine oxide, and the dimerisation of ethylene and propene[73].

† Recently a number of nitrogenyl complexes of osmium(II) of the type $OsN_2X_2(PR_3)_3$, where X = Cl or Br, were obtained[121] by the method of Borod'ko et al.[44]

The Nitrogenyl Complexes of Indium(I)

Collman and Kang[75] synthesised the complex $IrN_2Cl(PPh_3)_2$ by the reaction of azides with the carbonyl complex of iridium. The band at 2105 cm^{-1} in the infrared spectrum of this complex corresponds to the N≡N stretching vibrations. The complex is stable in the crystalline state at room temperature, but its solutions in chloroform and toluene decompose slowly with evolution of nitrogen.

A study of the mechanism of the formation of the complex IrN_2L_3 showed[75] that the reaction takes place in the coordination sphere of iridium without liberation of N_2 and CO molecules into the solution. The reaction also yields the isocyanate:



The Nitrogenyl Complex of Rhodium(I)

Using a procedure similar to that employed in the synthesis of the iridium complex of N_2, the analogous N_2 complex of rhodium(I) $RhN_2Cl(PPh_3)_2$ was synthesised[76]. A band at 2152 cm^{-1} in the infrared spectrum of the complex corresponds to the N_2 vibrations. The complex is less stable than its iridium analogue. Although in the solid state (yellow crystals) the complex remains unchanged at room temperature in the absence of air, its solutions in chloroform, benzene, or toluene decompose rapidly with evolution of nitrogen

Complexes of Nickel(0)

The first nitrogen complex of zerovalent nickel was synthesised in 1968[77]. This is a dinuclear complex which is formed on mixing nickel acetylacetonate with trimethylaluminium in the presence of nitrogen and tricyclohexylphosphine. The reaction proceeds according to the equation

$$2Ni(acac)_2+4(C_6H_{11})_3P+4Al(CH_3)_3+N_2\longrightarrow N_2[Ni(P(C_6H_{11})_3)_2]_2+ +4(CH_3)_2Al(acac)+4CH_3.$$

The yield of the complex, which consists of dark red crystals, reaches 40%.

In benzene solution the dinuclear complex dissociates reversibly to the mononuclear complex $NiN_2[P(C_6H_{11})_3]_2$ and $Ni[P(C_6H_{11})_3]_2$. The infrared spectrum of the mononuclear nitrogenyl shows absorption at 2028 cm^{-1}, which has been assigned to the vibration of the N≡N bond.

Nitrogen Complexes of Manganese(II)

It has been stated[78] that oxygen, carbon monoxide, and nitrogen combine reversibly with manganese(II) compounds forming 1 : 1 adducts. In contrast to all the mononuclear nitrogenyl complexes known hitherto, the infrared spectrum of the adduct with nitrogen does not contain a band in the region 2000–2200 cm^{-1}. It is surprising that the infrared spectrum of the carbon monoxide complex also lacks a band corresponding to the CO vibration. This finding is so unusual, that its validity appears questionable.

---o0o---

Thus several methods are known at present for the synthesis of complexes containing molecular nitrogen in the coordination sphere of the metal and the complexes can be obtained both by the addition of molecular nitrogen and by indirect methods, in which nitrogen is formed directly in the coordination sphere of the metal.

The coordination of molecular nitrogen can occur at the instant of the reduction of transition metal salts (as in the synthesis of carbonyls) by the substitution of ligands in certain low-valence metal derivatives, and by direct interaction with coordination-unsaturated systems.

Although considerable advances have in fact been achieved in the synthesis of nitrogenyl complexes, many features of these compounds still remain obscure. For example, the failure to synthesise the complex by one of the standard methods may imply either that the complex is unstable or that the method is unsuitable for the given compound.

2, THE STRUCTURE OF THE COMPLEXES AND THE NATURE OF THE M–N_2 CHEMICAL BOND

X-Ray Diffraction Analysis of Nitrogenyls

At present only two compounds have been analysed by X-ray diffraction: $[RuN_2(NH_3)_5]X_2$,[79,80] and $CoHN_2(PPh_3)_3$.[67] The ruthenium complexes crystallise with a cubic lattice containing four molecules per unit cell. Bottomley and Nyburg[79,80] showed that the ruthenium ion is surrounded octahedrally by nitrogen atoms [r(Ru–N) = 2.10 Å], molecular nitrogen is coordinated to the two metals almost linearly, and the distance between two adjacent nitrogen atoms in the RuNN fragment is 1.12 Å. While the linear coordination of the N_2 molecule has been established unambiguously, the interatomic r(Ru–N) and r(N–N) distances have been determined only approximately due to the statistically disordered arrangement of the molecules in the lattice.

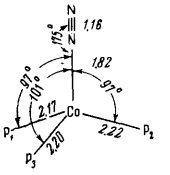


Figure 4. The structure of $CoHN_2(PPh_3)_3$.

The $CoHN_2(PPh_3)_3$ crystals were obtained[67] in two modifications, one of which is not susceptible to accurate analysis, while the other (it is noteworthy that subsequently it could not be synthesised again) has the structure of a distorted trigonal bipyramid (Fig. 4).

It should be noted that both in the cobalt complex and probably in the ruthenium nitrogenyl the M–N–N fragment is not rigorously linear. The Co–N–N angle is[67] 175° ± 4°.

In the nitrogenyl complexes of ruthenium and cobalt the r(N–N) bond length is greater than in the nitrogen molecule in the gas phase [r(N≡N) = 1.097 Å]. However, it is

significantly smaller than the nitrogen–nitrogen interatomic distance in azo-compounds; therefore it can be assumed that the multiplicity of the nitrogen–nitrogen bond in $[RuN_2(NH_3)_5]X_2$ and $CoHN_2(PPh_3)_3$ is close to three.

Infrared Absorption Spectra of Nitrogenyl Complexes

Infrared spectroscopy has found wide application in the identification and study of nitrogenyl complexes. As a result of the coordination of the N_2 molecule, an intense absorption band due to the stretching vibrations of the NN bond appears in the spectrum (2000–2200 cm^{-1}).

The vibration frequency of the N≡N bond in the nitrogen molecule is known to be 2331 cm^{-1}, while those of the N=N bonds in azo-compounds are in the range 1400–1600 cm^{-1}.[81,82] Thus the frequency range of the NN bond vibrations in nitrogenyl complexes (Table 6) corresponds to a bond order close to 3, in agreement with the X-ray diffraction studies.

Group-theoretical Analysis of the NN Bond Vibrations in Nitrogenyl Complexes

In principle molecular nitrogen can form with transition metals complexes having different structures (I)–(X) (Fig. 5). [So far compounds of types (I), (III), and (IX) have been synthesised.] On the basis of the local symmetry of these models, it is possible to determine under what conditions the nitrogen–nitrogen bond stretching vibrations will be active in the infrared absorption spectrum.

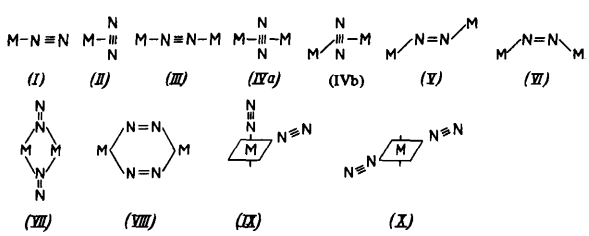

Figure 5. Possible structures of the nitrogen complexes.

The results of such analysis are presented in Table 7, which shows (fifth and sixth columns) that nitrogen–nitrogen bond vibrations in complexes of the type (I), (II), (IVb), (VI), and (VII)–(X) are active in the infrared spectrum, while the vibrations of complexes of the type (III), (IVa), and (V) are inactive. It should be noted that this conclusion was obtained on the assumption that in dinuclear complexes the ligands of both metal atoms and the metal atoms themselves are the same. On the other hand, when the ligands or the metal atoms are different, the symmetry is decreased and the stretching vibrations of the NN bond may be active in the infrared spectrum.

Spectra of Nitrogenyl Complexes Containing Nitrogen Isotopes

The validity of the assignment of the absorption bands in the range 2000–2200 cm^{-1} (Table 6) to the stretching vibrations of the N≡N bond is unambiguous, particularly since the replacement of $^{14}N{\equiv}^{14}N$ by $^{15}N{\equiv}^{15}N$ or $^{14}N{\equiv}^{15}N$ results in a decrease of the vibration frequency by 60–70 cm^{-1} or 30–35 cm^{-1} respectively, which agrees well with the calculated isotopic shift[40,43,44,49,52,54]. The ability to synthesise nitrogenyl complexes containing nitrogen-29 only, made it possible in some cases to establish the structure of the $M-N_2$ fragment.

Table 7. Types of stretching vibrations of the nitrogen–nitrogen bonds active in the infrared spectrum

Structure	Symmetry point group	Complete representation	Types of vibrations active in infrared spectrum	ν_s (NN)	ν_{as} (NN)

IX	C_{2v}	$4A_1+A_2+3B_1+B_2$	$4A_1+3B_1+B_2$	A_1	B_1
X	D_{2h}	$2A_g+B_{2g}+B_{3g}+2B_{1u}+2B_{2u}+2B_{3u}$	$2B_{1u}+2B_{2u}+2B_{3u}$	—	B_{1u}

The spectra of ruthenium complexes containing $^{14}N^{14}N$ and $^{14}N^{15}N$ have been investigated[40,44]. The activity of the NN bond vibrations in the infrared spectrum may be evidence of the formation of complexes of type (I) or (II) (Fig. 5). If the complexes have the linear structure (I), then there are two equally probable possibilities of the coordination of nitrogen-29: either $Ru-{}^{14}N{\equiv}{}^{15}N$ or $Ru-{}^{15}N{\equiv}{}^{14}N$, and the $\nu(N{\equiv}N)$ vibration frequencies may differ by 3–10 cm^{-1}. For the structure of type (II), the band in the RuN_2 spectrum should of course not be split. Analysis[44] of the observed spectrum of the complex $RuN_2Cl_2(NH_3)_3$ showed that the absorption band corresponding to $\nu(^{14}N{\equiv}^{15}N)$ results from superposition of two bands with a splitting of 4–6 cm^{-1}. Hence it was concluded that the Ru–N≡N fragment is linear. Similar results were obtained[40] also for pentamminenitrogenylruthenium, in agreement with X-ray diffraction data[79,80]. The N≡N stretching vibration frequencies of the complexes $[RuN_2(NH_3)_5]I_2$ containing nitrogen isotopes proved to be as follows:

$$\left.\begin{array}{ll}[Ru(NH_3)_5N^{14}{\equiv}N^{14}]I_2 & 2132\\ [Ru(NH_3)_5N^{14}{\equiv}N^{15}]I_2 & 2098\end{array}\right\}\Delta\nu{=}4\ cm^{-1}$$

$$\left.\begin{array}{ll}[Ru(NH_3)_5N^{15}{\equiv}N^{14}]I_2 & 2094\\ [Ru(NH_3)_5N^{15}{\equiv}N^{15}]I_2 & 2060\ cm^{-1}\end{array}\right\}$$

The force constants (10^6k, cm^{-2}) of the bonds in the Ru–N≡N fragment were calculated from these experimental values[40]: $k_{NN} = 29.3$, $k_{RuN} = 5.5$, and $k_{NN,RuN} = 1.2$.

It is interesting that these force constants of the bonds in the Ru–N≡N fragment of the nitrogenyl complex proved to be close to the corresponding force constants for the diazo-group C–N≡N in diazomethane[83]: $k_{NN} = 27.7$, $k_{CN} = 7.97$, and $k_{CN,NN} = 1.5$.

In the infrared spectra of the crystalline complexes $CoHN_2(PPh_3)_3$ [84] and $FeH_2N_2(PPh_3)_3$ [85] the half-widths of the bands due to the vibrations of the $^{14}N{\equiv}^{14}N$, $^{14}N{\equiv}^{15}N$, and $^{15}N{\equiv}^{15}N$ bonds are the same, the half-width amounting to

5–6 cm^{-1}. Thus one may conclude that the band corresponding to the $^{14}N\equiv{}^{15}N$ vibration in the complexes is not split. When the iron compounds are dissolved in toluene, the absorption bands corresponding to the N≡N vibration become appreciably broader (up to 16 cm^{-1}) (Fig. 6).

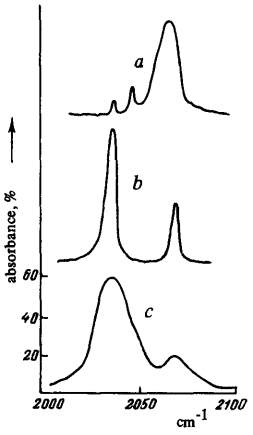

Figure 6. Absorption bands associated with the stretching vibrations of the N≡N bond in $FeH_2N_2(PPh_3)_3$: *a*) crystalline $FeH_2N_2(PPh_3)_3$; *b*) crystalline product containing $FeH_2(^{14}N^{15}N)(PPh_3)_3$ and $FeH_2(^{14}N^{14}N)(PPh_3)_3$; *c*) spectrum of a mixture of $FeH_2(^{14}N^{15}N)(PPh_3)_3$ and $FeH_2(^{14}N^{14}N)(PPh_3)_3$ in toluene solution at 10°C.

To account for the results obtained[85], it has been suggested that association complexes are formed in the crystals.

Borod'ko et al.[54] have quoted the vibration frequencies of a series of pentammineosmium nitrogenyls with different nitrogen isotopes in the range 60–3700 cm^{-1} and have given the assignments of these bands. The Os–N≡N fragment is characterised by three absorption bands corresponding to $\nu(NN) = 2010–2034$ cm^{-1}, $\nu(Os–N_2) = 500–518$ cm^{-1}, and $\delta(OsNN) = 245$ cm^{-1}.

Absorption Band Intensities $\mathcal{J}(N\equiv N)$

The integral intensity of the absorption band corresponding to the stretching vibration of the N≡N bond can be used to assess the structure of the $M–N_2$ fragment. In the case of linear coordination of the type M–N≡N the nitrogen–nitrogen bond is appreciably polarised and probably in all nitrogen complexes with a linear structure the intensity $\mathcal{J}(N\equiv N)$ will be high. By analogy with the π-complexes of symmetrical olefins and acetylenes, one may expect that the intensity $\mathcal{J}(N\equiv N)$ in the spectra of π-complexes of the type $M-\overset{N}{\underset{N}{\|}}$ will be very low.

Table 8, where the intensities for a number of nitrogenyls are listed, shows that $\mathcal{J}(N\equiv N)$ varies in the range $2.7 \times 10^4–8.5 \times 10^4$ litre $mole^{-1}$ cm^{-2}, which is characteristic of the intensities of the stretching vibrations of nitrogenyls known to have a linear structure and also of carbonyls. Hence one may conclude that the linear structure M–N≡N obtains in the complexes $[OsN_2(NH_3)_5]X_2$, $RhN_2Cl(PPh_3)_2$, $IrN_2Cl(PPh_3)_2$, and $Fe_2H_2N_2(PPh_3)_3$.

It is interesting that the surface complexes of nitrogen on metallic nickel, palladium, and platinum appear to have $\mathcal{J}(N\equiv N)$ intensities similar to those quoted above.

Table 8. Integral intensities of the bands due to the stretching vibrations of the N≡N bond

Compound	$\nu_{(N\equiv N)}$, cm^{-1}	$\mathcal{J}_{(N\equiv N)}$, 10^4 litre $mole^{-1}$ cm^{-2}	Refs
$FeN_2H_2(PPh_3)_3$	2066	4.9	85
$[RuN_2(NH_3)_5]Br_2$	2106	2.9	54

$[OsN_2(NH_3)_5]^{2+}$	2030	8.5	54
$RhN_2(PPh_3)_2Cl$	2152	3.4	37
$IrN_2(PPh_3)_2Cl$	2095	2.7	37

Dependence of the $\nu(N\equiv N)$ Frequency on the Radii of the Anions and the Nature of the Ligands

The N≡N bond stretching vibration frequency in the salts $[RuN_2(NH_3)_5]X_2$ and $[OsN_2(NH_3)_5]X_2$ depends on the anion X^-: the greater the ionic radius of the anion the higher is the vibration frequency[87] (Fig. 7). This relation may be due to the fact that, as the radius of the X^- anion decreases, the effective electrostatic field strength increases. Accordingly there is an increase in the contribution of the more polar structure (b) which is characterised by a lower $\nu(N\equiv N)$ vibration frequency:

$$\underset{(a)}{L_5M–N\equiv N} \longleftrightarrow \underset{(b)}{L_5M=\overset{+}{N}=\overline{N}}$$

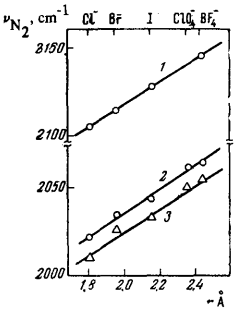

Figure 7. Dependence of the stretching vibration frequency $\nu(N\equiv N)$ on the radius of the anion: 1) $[RuN_2(NH_3)_5]X_2$; 2) and 3) $[OsN_2(NH_3)_5]X_2$. The variation of the frequencies of the two components of $\nu(N\equiv N)$, due to Davydov splitting, is shown for the osmium complex.

In the series of non-saltlike compounds of the type $RuN_2Cl_2L_3$ the N≡N stretching vibration frequency depends on the nature of the ligand L: the frequency falls with increasing basicity of the ligand[40] (Table 9). Misono et al.[87] who investigated the compounds $CoHN_2L_3$ in which L = $P(p\text{-}CH_3C_6H_4)_3$, $P[(C_6H_5)_2C_2H_5]_3$, $P(n\text{-}C_4H_9)_3$, or $P(C_2H_5)_3$ arrived at a similar conclusion; this dependence is evidence

of a significant contribution of the d_π–p_π interaction in the formation of the M–N_2 bond. Under the influence of donor ligands, the contribution of structure (b) falls.

It also follows from the work of Misono et al.[87] that the steric factor plays a major role in the formation of nitrogen complexes. Thus nitrogen complexes are not formed with $P(C_6H_5)_2H$ and $P(C_6H_5)_2CH_3$ and only the compound $CoHL_4$ (L = phosphine) is produced. Thus in the more bulky phosphines (PPh_3, $PPh_2C_2H_5$, etc.) one coordination site is occupied by molecular nitrogen because it is inaccessible to the phosphine molecule, although the metal–phosphine bond is probably stronger than the metal–nitrogen bond.

Table 9. Variation of the stretching vibration frequency ν(N≡N) of ruthenium nitrogenyls $RuN_2Cl_2L_3$ with the basicity of the ligand (L)

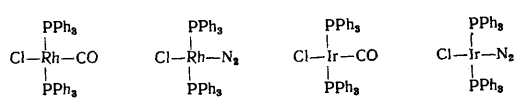
$RuN_2Cl_2L_3$	
ligand (L),	ν (N≡N), cm^{-1}
$3H_2O$	2163
$2H_2O \cdot THF$	2153
$(CH_3)_2NCHO$*	2123
C_5H_5N *	2115
$2NH_3 \cdot H_2O$	2090
$3NH_3$	2080
$C_2H_4(NH_2)_2$	2085

* The number of ligands was not determined.

On the basis of the infrared absorption spectra of the square complexes $IrN_2(PPh_3)_2Cl$ and $IrCO(PPh_3)_2Cl$, Collman et al.[88] concluded that molecular nitrogen is a more powerful π-electron acceptor than carbon monoxide. This conclusion is based on the fact that in the formation of the complex the ν(N≡N) stretching vibration frequency falls more than does ν(C≡O) relative to the corresponding vibration frequencies of the gaseous N_2 and CO molecules. Collman et al.[88] do not take into account the fact that in the formation of the CO complex the ν(C≡O) stretching vibration frequency may actually increase, since the upper filled molecular orbital 3σ(CO) is non-bonding (see p. 360).

In fact, in agreement with the qualitative quantum-chemical treatment, carbon monoxide gives rise to stronger σ and π bonds with a transition metal atom than does molecular nitrogen, i.e. CO is a stronger "π-acid" than N_2.

The study of the nitrogen complexes of rhodium(I) and iridium(I)



showed[37] that the ν(M–Cl) stretching vibration frequency is higher by 12–15 cm^{-1} for the *trans*-position with respect to N_2 than for the *trans*-position with respect to CO (Table 10). Since the replacement of the CO molecule by N_2 does not alter the kinematic parameters of the complexes, the masses of molecular nitrogen and carbon monoxide being the same, the difference in the ν(M–Cl) frequencies is undoubtedly due to the difference in the M–Cl bond strengths.

Electron transfer from CO or N_2 via the σ bond to the hybrid ($d_{z^2} + p_z + s$) orbital of the metal hinders the formation of the M–Cl bond (which is the reason for the *trans*-effect).

Dependence of the ν(N≡N) Frequency on the Nature of the Metal

Since the nature of the ligand has a very significant influence on the vibration frequency of the N≡N bond, it is useful to compare the frequencies only for complexes having the same structures and the same ligands. Table 11 lists the values of the ν(N≡N) frequencies for certain nitrogenyl complexes of ruthenium(II), osmium(II), rhodium(I), and iridium(I). Evidently on going from complexes of metals with 4*d* electrons to those of metals with 5*d* electrons, the ν(N≡N) frequency is reduced by 60–90 cm^{-1}, while the ν(M–N_2) frequency is increased by 18 cm^{-1}.

Table 10. Stretching vibration frequencies ν(N≡N), ν(C≡O), and ν(M–Cl) in the square complexes of rhodium(I) and iridium(I)

Compound	ν (N≡N), cm^{-1}	ν (C≡O), cm^{-1}	ν (M–Cl), cm^{-1}
$RhN_2Cl(PPh_3)_2$	2152	—	315
$RhCOCl(PPh_3)_2$	—	1967	304
$IrN_2Cl(PPh_3)_2$	2095	—	329
$IrCOCl(PPh_3)_2$	—	1955	315

Probably the nitrogenyls of the transition elements in the lower periods have a structure close M=N=N, since with increase in the principal quantum number, there is an increase in the overlap of the molecular orbitals and therefore the d_π–p_π interaction is stronger (see p. 367).

Table 11. Dependence of the stretching vibration frequencies ν(N≡N) and ν(M–N) on the nature of the metal

Compound	ν (N≡N), cm^{-1}	ν (M–N_2), cm^{-1}	Compound	ν (N≡N), cm^{-1}
$[RuN_2(NH_3)_5]Cl_2$	2102	500	$RhN_2Cl(PPh_3)_2$	2152
$[OsN_2(NH_3)_5]Cl_2$	2012	518	$IrN_2Cl(PPh_3)_2$	2095

Kinetic studies of the breakdown of nitrogenyl complexes confirm an increase in the strength of the M–N_2 bond on transition to metals in the lower periods. Thus the Os–N_2 bond energy in $[OsN_2(NH_3)_5]^{2+}$ is not less than 39 kcal $mole^{-1}$,[57] while in the corresponding ruthenium cation $D(Ru-N_2)_2 \simeq$ 25 kcal $mole^{-1}$. In the complex $RuN_2Cl_2THF(H_2O)_2$ the energy of the RuN_2 bond amounts to 22 kcal $mole^{-1}$.[95]

Other Results Obtained by Vibrational Spectroscopy

In the infrared spectra of $[OsN_2(NH_3)_5]X_2$ crystals the absorption band corresponding to the ν(N≡N) frequency results from the superposition of a number of components[37,53,54]. Thus in the spectrum of $[OsN_2(NH_3)_5]Cl_2$ the asymmetric band splits into three components: at 2012, 2022, and 2033 cm^{-1}. At the same time the infrared spectra of solutions of the complex in H_2O and D_2O are characterised by a single symmetrical absorption band at a frequency of 2030

cm^{-1}. In the spectra of the corresponding ruthenium complexes, both in the crystalline state and in aqueous solution, there is a single line. The splitting of the $\nu(N\equiv N)$ band of osmium nitrogenyls has been explained[37,54] by the resonance interaction of the translationally non-equivalent molecules in the unit cell of the crystal (the Davydov effect). In view of the splitting, it was concluded that the crystals of osmium nitrogenyls, in contrast to the ruthenium compounds, have a lattice with a lower symmetry than cubic.

In the spectra of the crystalline compounds $FeH_2N_2(PPh_3)_3$ and $FeH_2N_2(PPh_2Et)_3$ the absorption bands corresponding to the N≡N stretching vibrations are split into three components[85] (Fig. 6) which are displaced towards lower frequencies by 65–70 cm^{-1} when $^{14}N_2$ is replaced by $^{15}N_2$. In the spectra of crystals containing a mixture of the isotopic molecules $[FeH_2{}^{14}N^{14}N(PPh_3)_3]$ and $[FeH_2{}^{14}N^{15}N(PPh_3)_3]$ the band corresponding to the isotope present at a low concentration is not split, while that corresponding to the isotope at a high concentration is split.

These results show that the splitting of the infrared band due to the N≡N stretching vibrations is due to the resonance interaction of the translationally non-equivalent molecules in the unit cell of the crystals[86]. Due to the statistical distribution of the isotopic molecules containing nitrogen-28 and nitrogen-29 with different $\nu(N\equiv N)$ vibration frequencies, in the mixed crystals the resonance conditions are not realised and the Davydov components are absent.

The occurrence of Davydov splitting and the presence of three $\nu(N\equiv N)$ components shows that $FeH_2N_2(PPh_3)_3$ and $FeH_2N_2(PPh_2Et)_3$ crystallise with a lattice whose symmetry is lower than cubic and the number of molecules in the unit cell of the crystals is not less than three. Probably this effect can also account for the splitting associated with the stretching vibration of the N≡N bond in the crystalline complex $CoHN_2(PPh_3)_2$ into two components[66] with frequencies of 2101 and 2087 cm^{-1}.

The frequencies of the first and second overtones of the stretching vibration of the N≡N bond in the complex $[OsN_2(NH_3)_5]Br_2$ have been observed[57] at 3998 and 5904 cm^{-1}. The calculated anharmonicity constant X_e of the N≡N bond vibration in the complex is about 0.0125, while for gaseous nitrogen $X_e \simeq 0.0063$. According to an approximate estimate based on the convergence of the vibrational levels, the energy of the NN bond in the complex is about 120 kcal $mole^{-1}$. Unfortunately the accuracy of this estimate is low and the error is unknown. At the same time such a sharp increase of bond energy compared with the nitrogen molecule is not surprising, since the dissociation of the NN bond in the complex should result in the formation of a strong Os≡N bond. The range of values of the M≡N bond energies for various metals in the gas phase is 96–145 kcal $mole^{-1}$.[89] Thus the reduction of the N≡N bond energy in the complex should indeed be appreciable.

Raman Spectra. $\{[Ru(NH_3)_5]_2N_2\}(BF_4)_4$ and $[Ru(NH_3)_5N_2](BF_4)_2$

It has been shown[58] that in the infrared spectrum of the dinuclear complex $\{[Ru(NH_3)_5]_2N_2\}^{4+}$ there is no absorption characteristic of the stretching vibration of the N≡N bond. In view of this finding, a symmetrical structure was postulated[58], in which the N≡N molecule behaves as a bridge ligand.

Study of the Raman spectra of the crystalline tetrafluoroborate salt of this complex[90], containing $^{14}N_2$ and $^{15}N_2$, showed that the spectrum includes intense bands at frequencies of 2100 and 2030 cm^{-1} for the light and heavy nitrogen respectively. Therefore these lines should be assigned to the stretching vibration of the nitrogen–nitrogen bond {belonging to the symmetry type A_{1g}, which is allowed in the Raman spectrum and forbidden in the infrared spectrum [see Fig. 5 and Table 7, structure (III)]} and the order of this bond is close to three.

It should be noted that the formation of the complex with the linear structure Ru–N≡N–Ru leads to a decrease of the vibration frequency of the N≡N bond compared with the mononuclear complex. Thus the Raman spectrum of $[Ru(NH_3)_5N_2](BF_4)_2$ shows an intense line at 2133 cm^{-1}, while in the dinuclear complex the vibration frequency falls to 2100 cm^{-1}.

The Nature of the M–N_2 Bond

Even before the synthesis of the first complexes of molecular nitrogen with transition metal compounds, the question of the possibility of their formation and of the nature of their chemical bond was discussed. Orgel[91] compared transition metal carbonyls with the nitrogenyls, which were hypothetical at the time. According to Orgel, electron transfer from the σ orbital of N_2 to the metal and from the metal to the antibonding π orbital of N_2 leads to the transition of the neutral N_2 molecules to an excited state identical with the highest states of the $n-\pi$ transition. For N_2, the energy of the $n-\pi$ transition is 7.3 eV, while in the case of carbon monoxide the energy is 6 eV, the energies of the $\pi-\pi$ transitions for the two molecules being 6–8 and 7–8 eV respectively. Hence it was concluded that the configuration $M-\overset{N}{\overset{\|}{N}}$ is more favoured compared with M–N≡N than is $M-\overset{C}{\overset{\|}{O}}$ compared with M–C≡O.

However, all the transition metal nitrogenyls known at the present time and also the surface complexes of nitrogen evidently have a linear structure like the carbonyls and diazo-compounds. As already mentioned, this has been established by X-ray diffraction analysis and by infrared and Raman spectroscopy.

Furthermore examination of the experimental data for the nitrogenyl complexes permits the following preliminary generalisations: (1) molecular nitrogen complexes are formed by compounds of transition metals in lower oxidation states, which have unshared pairs of d electrons; (2) the contribution of the $d\pi-p\pi$ interaction is significant in the formation of the M–N_2 bond, N_2 behaving as a π-electron acceptor ligand; (3) donor ligands enhance the stability of molecular nitrogen complexes and π-acceptors reduce it‡; (4) other conditions being equal, the complexes of metals in the lower Periods of the Periodic System are more stable than those in the higher Periods; (5) the nitrogenyl complexes known at the present time are diamagnetic, i.e. stable complexes are probably formed with metals in low-spin states.

‡ This explains the finding that each new N_2 molecule weakens the M–N_2 bond and polynitrogenyl complexes are less stable than mononitrogenyl complexes. We may also note that this distinguishes polynitrogenyls from polycarbonyls, many of which are very stable. Probably this is because carbon monoxide is not only a powerful π-electron acceptor ligand but also a much stronger σ-electron donor than nitrogen (see p. 360). Therefore the introduction of several CO molecules does not alter significantly the electron density at the metal.

We may note that N_2 complexes have been obtained for compounds of ruthenium and osmium [metals in Periods (V) and (VI)] with ligands which give rise to both weak (H_2O, NH_3, C_4H_8O, etc.) and strong (PR_3, H) crystal fields. For metals of Period (IV) (iron, cobalt, and nickel), covalent nitrogenyl complexes have been obtained (and these are probably the most stable) with ligands giving rise to a powerful field. This is evidently because low-spin states of metals of Periods (V) and (VI) are realised with both types of ligand, while for iron, cobalt, and nickel compounds spin-paired states can be obtained only with strong-field ligands.

It is striking that the electron shells of the metals in the complexes $FeH_2N_2(PPh_3)_3$ and $CoHN_2(PPh_3)_3$ are isoelectronic, as in the carbonyls $FeH_2(CO)_4$, $CoH(CO)_4$, and $Ni(CO)_4$, and in the nitrogenyls the number of outer electrons (18) corresponds to an inert gas shell. The number of electrons in $NiN_2[P(C_6H_{11})_3]_2$ is two less, but the complex may also include a solvent molecule with an electron pair.

Probably the stabilising effect of hydride bonds can be explained by the fact that nitrogen is a powerful electron donor. For a carbonyl hydride, this is illustrated by its acid dissociation in solution:

$$CoH(CO)_4 \rightleftarrows H^+ + [Co(CO)_4]^-.$$

We shall now examine the scheme of the molecular orbitals for the cation $[OsN_2(NH_3)_5]^{2+}$ shown in Fig. 8 (for clarity the energy scale has been extended).

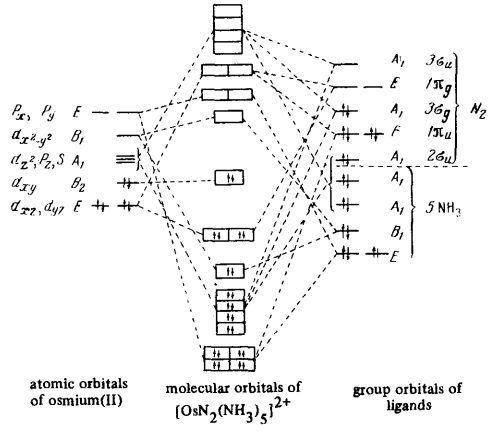


Figure 8. The system of molecular orbitals of $[OsN_2(NH_3)_5]^{2+}$ (arbitrary scale).

The $[OsN_2(NH_3)_5]^{2+}$ cation belongs to the point group C_{4V} and therefore the distribution of the atomic orbitals of osmium(II) corresponds to splitting in a tetragonal field. The ammonia molecules, which are σ-electron donors, are taken into account by the introduction of five groups of σ-orbitals. By taking into account the symmetry and the distribution of the osmium(II) and N_2 levels, it is seen that in the formation of the complex osmium cations there is, on the one hand, electron transfer from the bonding atomic orbitals of osmium of the type $E(d_{XZ}, d_{YZ})$ to the lower antibonding molecular orbital of nitrogen $(1\pi_g)_{XZ,YZ}$ and, on the other hand, the filled molecular orbitals of nitrogen of the type $A_1(3\sigma_g, 2\sigma_u)$ are capable of donating electrons to the antibonding hybrid osmium orbital $(d_{Z^2} + p_Z + s)$.

Fig. 9 gives a conventional representation of these two components of the metal–molecular nitrogen bonds in the complex $[OsN_2(NH_3)_5]^{2+}$ both for a linear and a non-linear configuration of the fragment. Fig. 9 shows that the overlapping of the orbitals is greater for the linear configuration of the $Os-N_2$ fragment, since in this case a dative bond is formed as a result of the overlapping of two pairs of orbitals, $d_{XZ}-(1\pi_g)_{XZ}$ and $d_{YZ}-(1\pi_g)_{YZ}$ in the mutually perpendicular planes xz and yz. In the π-complex with C_{2V} symmetry both dative and donor–acceptor interaction is less intense due to the smaller degree of overlapping of the orbitals.

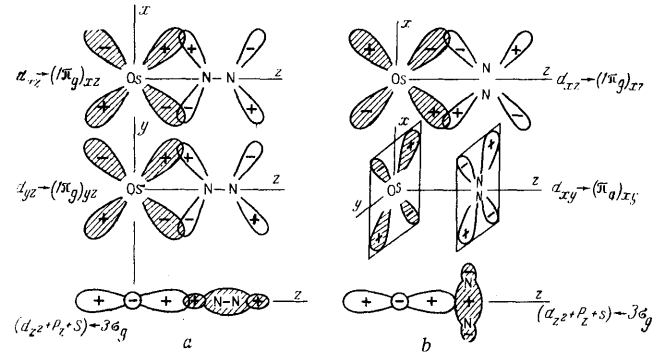

Figure 9. The overlapping of molecular orbitals in $[OsN_2(NH_3)_5]^{2+}$: *a*) for the linear coordination of molecular nitrogen, i.e. Os–N≡N (C_{4V}); *b*) for the π-complex (C_{2V}).

According to the principle of overlapping and orientation, the complex has the structure in which the overlap integrals are a maximum. Therefore it is evident that the complex with C_{4V} symmetry should be more stable than the complex with C_{2V} symmetry.

The hypothetical $Fe-N_2$ fragment, consisting of a neutral iron atom and a coordinated nitrogen molecule, has been examined quantum-chemically[92] for the two possible structures Fe–N≡N and Fe–$\overset{N}{\underset{N}{\|}}$. On the basis of the calculation, it was concluded[92] that the linear coordination of nitrogen is to be preferred and the charge distribution for the Fe–N′≡N″ model was obtained (Table 12). In this calculation the orbital energies calculated by the Hartree–Fock–Roothaan method were used as the diagonal elements of the effective Hamiltonian. As a result, the N_2 molecule was found to have an overall positive charge, i.e. nitrogen behaves as a donor in relation to the metal atom.

If the diagonal elements are approximated by the ionisation potentials of the valence states[93], one obtains for the linear model M–N′≡N″ (where M = Fe or Ru) a different charge distribution (Table 12), which agrees qualitatively with the experimental data concerning the π-electron acceptor properties of N_2 as a ligand.

Population analysis of the M–N and N–N bonds shows[93] that the contribution of the π-electron component to the metal–nitrogen bond is greater than that of the σ-electron

component, and the σ-components of the nitrogen–nitrogen bond in the coordinated and free N_2 molecules are almost indistinguishable. (The population of the bond may serve to some extent as a characteristic of its strength.)

Table 12. The atomic charges and electron populations for the fragment M–N′≡N″

Compound	Population of M–N′ bond		Population of N′–N″ bond		Atomic charges			Refs.
	σ-component	π-component	σ-component	π-component	M	N′	N″	
Fe—N′≡N″	0.433	0.254	0.845	0.746	—0.43	1.01	—0.58	92
	0.215	0.302	0.829	0.561	0.485	—0.188	—0.297	93
Ru—N′≡N″	0.255	0.313	0.832	0.590	0.426	—0.150	—0.276	93
N≡N			0.785	0.875				93

* The interatomic distances (Å) used in the calculation by Vinogradova et al.[93] were as follows: $r(Fe–N) = 1.8$; $r(N–N) = 1.16$; $r(Ru–N) = 1.9$.

3. THE MECHANISM OF THE FORMATION OF MOLECULAR NITROGEN COMPLEXES

Nitrogen is still an unusual ligand in the chemistry of coordination compounds and therefore it is interesting to examine how it becomes coordinated. There are very few data on this problem. The mechanism of the interaction of nitrogen in the reduction of $RuCl_3.nH_2O$ in tetrahydrofuran has been investigated in greatest detail[94,95]. As already stated, the main product of this reaction is $RuN_2Cl_2(H_2O)_2THF$; a certain amount of $RuN_2Cl_2(H_2O)_3$ is also formed. The study of the reaction kinetics led to the conclusion that nitrogen reacts with the coordination-unsaturated species RuL_5 formed as an intermediate in the reduction. The RuL_5 species may be coordinated not only to nitrogen but also to any other compound L′ present in the solution. For example, L′ may be water. The dependence of the yield of the nitrogenyl complex on nitrogen pressure is consistent with the mechanism

$$RuCl_3 \cdot nH_2O \xrightarrow{Zn} RuCl_2L_3$$

$$RuCl_2L_3 \begin{cases} \xrightarrow[N_2]{k_2} RuN_2Cl_2L_3, \\ \xrightarrow[L']{k_3} RuCl_2L_3L'. \end{cases}$$

The study of the exchange of molecular nitrogen with the nitrogen in the coordination sphere of ruthenium nitrogenyls[94,95] confirmed that nitrogen interacts with the coordination-unsaturated species RuL_5. It was established that the exchange of molecular nitrogen involves substitution by a dissociative mechanism of S_N1 type:

$$\begin{gathered} RuN_2L_5 \underset{k_2}{\overset{k_1}{\rightleftarrows}} RuL_5 + N_2, \\ RuL_5 + L' \xrightarrow{k_3} RuL_5L'. \end{gathered} \qquad (1)$$

In accordance with this mechanism, the exchange reaction takes place only in the thermal decomposition of the nitrogenyl complex. The application of the method of steady-states to mechanism (1) leads to the following expression for the rate of decomposition:

$$\frac{dz}{dt} = \frac{k_1k_2(a-z)L'}{k_2N_2 + k_3L'} = k_{eff}(a-z) \qquad (2)$$

where $z = [RuL_5L']$ and a is the initial $[RuN_2L_5]$. According to Eqn. (2), the decomposition of the nitrogenyl complex in an atmosphere of nitrogen is a first-order reaction, $1/k_{eff}$ varying linearly with the nitrogen pressure. The addition of water slows down the nitrogen exchange in the complex. It is reasonable to conclude that water competes with nitrogen in the reaction with RuL_5. The ratio of the rate constants (k_2/k_3) for the reactions of N_2 and H_2O with RuL_5 was determined from the kinetic data. The ratio is independent of temperature and equal to about 3.1. Tetrahydrofuran competes much less strongly than water. The results suggest that the difference in the reactivities of nitrogen and water is determined mainly by steric factors and the activation energy for the reaction of N_2 with RuL_5 is close to zero. Thus it has been shown[94,95] that nitrogen is coordinated only by a dissociative mechanism (S_N1) and not by an S_N2 mechanism (in contrast, for example, to the coordination of carbon monoxide) and that the rate constant for the reaction with a coordination-unsaturated compound is very high.

It may be supposed that the coordination of nitrogen in the reaction

$$[Ru(NH_3)_5H_2O]^{2+} + N_2 \rightarrow [RuN_2(NH_3)_5]^{2+} + H_2O$$

in aqueous solution at atmospheric nitrogen pressure[41] takes place by a similar mechanism. The kinetics of this reaction have been investigated recently[96] and the rate constants for the formation of the mono- and di-nuclear pentammineruthenium nitrogenyls have been measured, but the possibility of a dissociative mechanism was not discussed at all. Nevertheless it may be supposed that the water molecule in the aquopentammine-complex is weakly bound to the ruthenium atom and the following equilibrium exists in aqueous solution:

$$[Ru(NH_3)_5H_2O]^{2+} \rightleftarrows [Ru(NH_3)_5]^{2+} + H_2O$$

and the $[Ru(NH_3)_5]^{2+}$ ion interacts with molecular nitrogen.

Sacco and Aresta[59] obtained the complex $FeH_2N_2L_3$ (where $L = PPh_2Et$) in the reaction of N_2 with the iron dihydride compound FeH_2L_3. It was noted that the complex is formed readily not only in solution but also in the solid state. Here too nitrogen probably adds to the five-coordinated iron compound FeH_2L_3, which, however, is stable in this case. Further studies should show how general is the conclusion that nitrogen is incapable of reacting by an S_N2 mechanism.

4. COMPLEXES OF MOLECULAR NITROGEN AS INTERMEDIATES IN REDUCTIVE NITROGEN FIXATION

Several types of nitrogen reduction reactions with formation of ammonia or its derivatives are known at present.

The Formation of Nitrides in the Reaction of Nitrogen with Metals

Metals usually react with nitrogen at a high temperature; even lithium and the alkaline earth metals (calcium, strontium, and barium), which are known to form nitrides at room temperatures, react extensively with nitrogen only on heating. In many cases the necessity for severe reaction conditions is probably not due so much to the inertness of nitrogen as to the formation on the surface of oxide, nitride, etc. films; on clean surfaces nitrogen reacts with the metal at a high rate. Thus, if the reaction of lithium with ethyl bromide is carried out in nitrogen, the excess of lithium is converted into the nitride[97] at 30°C. Studies on the chemisorption of nitrogen on tungsten[27] and molybdenum[98] show that nitrogen is atomised (i.e. evidently forms surface nitrides) at a low temperature.

Heterogeneous-Catalytic Hydrogenation of Nitrogen

This process, which has been known for a long time and is widely used in technology, is carried out under comparatively severe conditions in the presence of metals such as iron, ruthenium, and osmium. Without considering this process in detail, to which numerous monographs and reviews have been devoted (see, for example, Kiperman[99]), we may note that for this process too the state of the catalyst surface is very important: on a clean iron surface, the synthesis of ammonia[100] takes place even at 80°C, albeit slowly.

Reduction of Nitrogen in Solutions

In 1964 Vol'pin and Shur[101] discovered a new nitrogen reduction reaction in hydrocarbon and ethereal solutions under the action of reducing agents such as organometallic compounds, metal hydrides, and metals [C_2H_5MgBr, Mg + MgI_2, C_6H_5Li, Al(iso-Bu)$_3$, etc.] in the presence of transition metal derivatives [$TiCl_4$, $(C_2H_5)_2TiCl_2$, $FeCl_3$, VCl_4, etc.]. A large number of examples of this reaction were subsequently observed in several studies[102,103].

The reaction takes place under very mild conditions, for example at room temperature and atmospheric nitrogen pressure. The reaction products yield ammonia on hydrolysis[101] and are probably nitride derivatives[104], although in most cases their structure is still unknown. It is interesting that in some cases the hydrolysis results also in the formation of aromatic amines[102]. Usually the yield of ammonia after the hydrolysis of the reaction products is smaller than or close to the stoichiometric value when calculated relative to the transition metal but titanium tetrachloride is a catalyst for the formation of aluminium nitride[105] (at least in the system Al–$AlBr_3$–$TiCl_4$).

In an attempt to simulate the biological fixation of molecular nitrogen, various workers investigated the reduction of nitrogen in aqueous solutions by powerful reducing agents in the presence of transition metal compounds, and some of them reported[106-108] the formation of small amounts of ammonia. These results could not, however, be reproduced[109].

Enzymic Fixation of Molecular Nitrogen

This extremely important biological process is carried out by many micro-organisms. Recently the mechanism of this reaction has been vigorously investigated and particularly important results have been obtained after the successful isolation of active cell-free extracts from the nitrogen-fixing bacteria. Without going into the details of these investigations (see the appropriate reviews[110,111]), we may note the following principal features of the mechanism of the biological fixation of nitrogen: (1) the reaction constitutes the reduction of nitrogen with intermediate formation of ammonia; (2) the enzymic system consists of two main components; one of them activates the nitrogen molecule and the other is responsible for electron (or hydrogen atom) transfer to the activated nitrogen molecule; metal atoms (iron and molybdenum) participate in both these processes; adenosinetriphosphoric acid, which is converted into adenosinediphosphoric acid and phosphate during the reaction, also plays an important role; (4) the part of the enzymic system activating the nitrogen is deactivated by carbon monoxide and hydrogen.

---o0o---

Bearing in mind that metals or their compounds participate in all nitrogen reduction reactions, it is reasonable to suppose that the first stage involves the formation of an N_2 complex with the metal. In some of the earlier studies[15,29,101,112,113,114] it was also believed that the formation of a nitrogen complex is an essential intermediate stage in nitrogen fixation. The discovery of nitrogen complexes and the study of the complex-formation reactions have confirmed this view. Indeed, one may note in the first place that systems in which N_2 complexes are formed resemble those in which nitrogen is hydrogenated or reduced.

In many cases nitrogen complexes with ruthenium, osmium, cobalt, and iron compounds are formed in solution under the same conditions and under the action of the same reagents as the nitride derivatives in the reduction of nitrogen. Some examples are presented in Table 13.

Table 13. Examples of systems in which different products are formed with N_2

System	Nitrogen-containing product	Refs.
$RuCl_3$+EtMgBr+N_2	nitrogen complex	43
$FeCl_3$+EtMgBr+N_2	nitride derivative	95
Co (acac)$_3$+$AlEt_2OEt$+PPh_3+N_2	nitrogen complex	60—62
Ni (acac)$_3$+Al (iso-C_4H_9)$_3$ + N_2	nitride derivative	119

Ruthenium(II) complexes are formed in an aqueous medium and in the presence of oxygen, which explains why water is not an inhibitor of the biological fixation of nitrogen. Further reduction of nitrogen in the complexes formed in the first stage may consist in the formation of an "azo-complex" with two metal atoms:

$$M' + N_2 \rightarrow M'-N\equiv N,$$
$$M'-N\equiv N + M'' \rightarrow M'-N=N-M''.$$

The double bond –N=N– is further reduced to ammonia derivatives. A model for this mechanism of the biological fixation of nitrogen was proposed by Parshall[112], who considered the reduction of diazo-compounds (as analogues of the nitrogen molecule in the complex) in the presence of a hydride derivative of divalent platinum.

However, the formation of complexes is not a sufficient condition for the activation of nitrogen for further reactions. Indeed, the known nitrogenyl complexes are very stable with respect to nitrogen reduction reactions in the coordination sphere of the metal. As already pointed out, the reports[38,39] of the reduction of nitrogen in the ruthenium complex under the action of sodium borohydride were not subsequently confirmed[40].

In other nitrogenyl complexes nitrogen is also not reduced under the action of the usual reducing agents[46,47]. It can of course be supposed that the intermediate complexes in the reduction of nitrogen differ in structure from the stable nitrogenyls; for example, they could have the structure of the π-complex type $M-\overset{N}{\underset{N}{\|}}$. However, it is more likely that the reason lies in the necessity for a definite combination of properties in the metals comprising the complexes in order that the catalytic process may take place.

To establish what complexes can be intermediate in the catalytic reduction of nitrogen, it is necessary to bear in mind the exceptional stability of the first bond dissociated in the N_2 molecule (about 130 kcal mole^{-1}) and, on the other hand, the instability of the remaining two bonds. The addition of one H_2 molecule to a nitrogen molecule with formation of the di-imide N_2H_2 is endothermic to the extent of 49 kcal mole^{-1},[115] whereas the hydrogenation of acetylene to ethylene, for example, takes place with the evolution of 42 kcal mole^{-1}. Therefore the hydrogenation of nitrogen via the intermediate formation of free N_2H_2 is impossible under mild conditions. For this reason, the reaction involving "incorporation" in the M–H bond is unlikely for nitrogen:

$$M{-}H + N_2 \rightarrow M{-}N{=}N{-}H$$

This could be regarded as two-electron reduction (such a reaction might be put forward by analogy with the hydrogenation of acetylenes and olefins). Hence it is not surprising that nitrogen is not hydrogenated on the usual catalysts active in the hydrogenation of other unsaturated compounds.

In order to reconcile the ease of reduction of nitrogen in biological systems with the apparent necessity for the intermediate formation of di-imide (or its derivative), it has been suggested[116] that the formation of N_2H_2 is accompanied by a coupled reaction involving an energy gain, so that the overall free energy of the reaction decreases and the formation of N_2H_2 becomes possible.

However, in the formation of nitrogen complexes with transition elements there is a possibility, in principle, of another reduction pathway, not involving intermediate compounds with an N=N double bond.

In mono- and di-nuclear nitrogenyl complexes the order of the bond between the nitrogen atoms remains close to three. If the dinuclear complex is now acted upon by a two-electron reducing agent X_2, then two bonds in the nitrogen fragment may dissociate at once with formation of a hydrazine derivative as a result of the additional transfer of two electrons from the metal atoms constituting the complex:

$$M'\cdots N{\equiv}N\cdots M'' + X_2 \rightarrow \begin{matrix} & X & X & \\ & \diagdown & \diagup & \\ M' & & N{-}N & M'' \end{matrix}$$

Thus the intermediate formation of a dinuclear complex with molecules of nitrogen subsequently allows the four-electron reduction to a hydrazine derivative in one stage§.

The overall addition of two H_2 molecules to N_2 with formation of hydrazine in aqueous solution is endothermic only to the extent of 8 kcal mole^{-1}. Reducing agents only a little stronger than H_2, for example sodium dithionate, are capable of providing sufficient energy for the reduction of nitrogen to hydrazine or its derivatives. It is then necessary to remember that the metals comprising the complex must themselves be relatively powerful one-electron reducing agents. Furthermore, the complexes must not be too stable, since an increase in bond strength in the complex corresponds to a greater energy expenditure in its subsequent reduction.

In Vol'pin–Shur reactions these conditions are evidently fulfilled. Indeed in the presence of powerful reducing agents such as aluminium, RMgX, LiR, etc. transition metal compounds are reduced to low states of oxidation, becoming fairly powerful reducing agents. Since intermediate nitrogen complexes have not been detected in these reactions so far, their stability is probably low.

From this standpoint, it is not surprising that stable N_2 complexes of ruthenium, osmium, etc. cannot be reduced. The $M{-}N_2$ dissociation energy in these complexes reaches tens of kcal mole^{-1} and the capacity for electron transfer is low: osmium(II) and ruthenium(II) in these compounds are weaker reducing agents than H_2.

On the basis of the above considerations alone, three cases of the interaction of a metal or its compound (M) with an N_2 molecule have been examined[117]:

1. M is a very powerful reducing agent capable of transferring an electron to the N_2 molecule or forming a covalent bond by complete dissociation of one of the bonds in the nitrogen molecule in the absence of d_π–p_π interaction. The reduction potential of M in such a reaction must be not less than 2.5 eV. Even atomic hydrogen does not react with nitrogen, since the energy of the $H{-}N_2$ bond is negative. It may be supposed that a reaction of this kind takes place with lithium and certain other metals. Further addition of M to $M{-}N_2$ will occur very readily with the final formation of a nitride. At low temperatures M cannot be a catalyst for a reducing agent weaker than itself (for example H_2), since this would necessitate the expenditure of a large amount of energy on the dissociation of the M–N bond in the nitride. The reaction is of course impossible in an aqueous medium.

2. M is a weak reducing agent. The bond with nitrogen is formed mainly as a result of d_π–p_π interaction; the bond order in N_2 remains close to three. The formation of ruthenium(II) and osmium(II) complexes probably approaches this type. These complexes and the dinuclear complexes $M'N_2M''$ are formed readily but further reduction of nitrogen requires the use of a reducing agent almost as strong as for free nitrogen. The reaction largely terminates with formation of complexes stable to reduction.

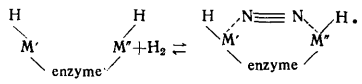
3. The intermediate case. The energy of the formation of the complexes M'N and $M'N_2M''$ includes a considerable contribution from d_π–p_π interaction, and at the same time M and M'' are comparatively powerful reducing agents capable of transferring one electron to an acceptor molecule. It is in fact in this case that we have the possibility of catalysis in the presence of M' and M'' of the reduction of molecular nitrogen by a reducing agent more powerful than M' and M'', although the reaction may of course terminate with formation of nitrides containing the M' and M'' atoms. The Vol'pin–Shur reaction and heterogeneous hydrogenation may be assigned to this case.

When a reducing agent active in an aqueous medium (of the type of sodium hydrosulphite) and with a reduction potential of about −0.2 eV is employed, the catalytic reaction can be achieved only for definite values of the reduction potential of M' and M'' and for definite strengths of the N_2–catalyst bond in the complex. These conditions are probably realised in the biological fixation of nitrogen, where M' and M'' are respectively both Fe atoms or Fe and Mo atoms present as constituents of the enzymes and forming a dinuclear complex with nitrogen in the course of fixation. It may be supposed[58] that the role of ATP in nitrogen fixation consists in its participation in the formation of hydride derivatives of molybdenum or iron.

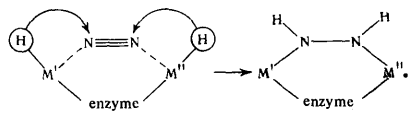
There are grounds for believing that in the biological fixation of nitrogen cyclic complexes with molybdenum and iron atoms linked by the enzyme molecule are formed, in contrast to the familiar "azo-complexes". Because of the

§ In principle one cannot exclude the possibility also of the six-electron reduction $M'\ldots N{\equiv}N\ldots M'' + X_2 \rightarrow M'{=}N{-}X + X{-}N{=}M''$. However, such a reaction, which cannot be regarded as a single elementary process, appears to be less likely.

more favourable entropy factor, this should lead to a higher concentration of the intermediate "azo-complex" and a correspondingly higher rate of reaction than in the case of the linear complex:



Further four-electron reduction can be readily represented, for example, as double "incorporation" in the M–H bond:



The formation of *cis*-dideuterioethylene[118] in the reduction of acetylene by the enzymic nitrogen-fixing system in D_2O provides indirect confirmation of the cyclic structure of the intermediate complex.

Further studies will show to what extent this hypothesis is correct.

---o0o---

As already stated, nitrogenyl complexes with the compounds of seven metals of Group VIII of the Periodic System (iron, ruthenium, osmium, cobalt, rhodium, iridium, and nickel) have been isolated and characterised at the present time. There is no doubt that other transition metals are also capable of forming complexes with N_2 in a low-valence state. Although it may be supposed that the chemistry of nitrogenyls will prove to be less elaborate than the chemistry of the related more stable carbonyls, it will evidently undergo much further development. Probably it will be possible to isolate stable nitrogenyls of many metals (for example, platinum compounds), but unstable complexes with a low heat of formation, which can be observed at a low temperature and a high nitrogen pressure, will prove even more numerous.

The problem of the structure of the complexes is very interesting: it is still obscure whether we are dealing with π-complexes of N_2 or compounds with a structure analogous to that of the carbonyl bridge compound $\begin{matrix} M \\ N\equiv N \\ M \end{matrix}$, etc.

So far very little is known about dinuclear complexes of the type M–N≡N–M, which are of particular interest as possible intermediates in nitrogen reduction reactions. The mechanism of such reactions still requires serious revision and development. Evidently, it is possible to bind N_2 catalytically via unstable complexes (possibly by a process of the type of biological nitrogen fixation) or to synthesise other nitrogen-containing compounds (except ammonia).

It may be hoped that the development of the low-temperature chemistry of molecular nitrogen will lead to the creation of new highly effective catalytic systems and will thereby give rise to the discovery of new industrial methods for the binding of atmospheric nitrogen.

Reactivity of Sulphides

I.S.Chaus and I.A.Sheka

The characteristic features of the interaction of metal sulphides in sintering, fusion, and coprecipitation from their solutions are discussed in this review. It is shown that the formation of solid substitutional solutions at elevated temperatures is due to the similarity of the effective radii of the metals, determined taking into account the degree of covalence of the M-S bond. It has been found that, as the composition of the reacting sulphides becomes more complicated, their miscibility increases and that the greater the similarity of the ionic radii of the metals the easier the formation of solid solutions of the sulphides when the latter are coprecipitated from solution. The bibliography incorporates 213 references.

I. INTRODUCTION

Sulphides have been attracting the attention of inorganic and analytical chemists for a long time because their low solubility and in most cases a characteristic colour make them suitable for qualitative and quantitative analyses. However, more thorough investigation of the conditions for their isolation from complex solutions and also of the properties of the pure sulphides synthesised showed that changes in the acidity of the solution, which is the decisive factor in their precipitation, is insufficient for quantitative separation. The attempts to prevent coprecipitation by adding to the solution before precipitation various organic and inorganic complex-forming agents were unsuccessful in most cases. The interest in sulphides in the last decade is due to the fact that they, and chalcogenides in general, have semiconductor properties[1-5] and, since their melting points are high, they can be successfully employed up to 800–900°C. Their high stability to thermal dissociation at elevated temperatures in the absence of oxidising agents makes it possible to employ sulphides as constructional materials in the preparation of pure substances.

The vigorous development of the rare-metals industry, which is based mainly on the processing of polymetallic sulphide ores, also requires a more complete study of the chemical behaviour of sulphides.

The reason for the high reactivity of sulphides probably consists in the fact that for most sulphides the heat of the atomisation of sulphur is much higher than that of the metal and therefore polymers are frequently formed[6-8]. The positive electronegativity difference indicates the polarisation of the sulphide sulphur[8,9], which should also enhance the reactivity of the sulphides.

The interaction of these compounds is complicated by the presence in them of three types of bond: covalent, metallic, and ionic. The considerable ionic character of the bonds is typical for the sulphides of alkali and alkaline earth metals and lanthanides. The bonds in the sulphides of B group metals are covalent and those in the transition metal sulphides are of the covalent-metallic type[2,3,6,10-12].

The structures of the crystalline sulphides are various but most of them are highly symmetrical with close packing of the sulphide sulphur or the metal[13,14]. It has been noted[14] that structures of this type are deficient in the metal.

Furthermore, many sulphides tend to form two or more polymorphic modifications, the stability of which is determined not only by the temperature but also by the presence of another sulphide (sometimes even in insignificant amounts).

Thus the reactivity of sulphides should depend on the nature of the bond, the type of lattice, the dimensions of the atoms or ions of the metals whose compounds interact, and their polarising capacity.

It has now been established that sulphides interact with formation of solid solutions and complex sulphides. Nevertheless, so far there is no information which would make it possible to predict the nature of the interaction of simple sulphides.

II. INTERACTION OF SULPHIDES AT ELEVATED TEMPERATURES

1. The Formation of Solid Solutions

According to general hypotheses, the formation of solid solutions of metals or chemical compounds is observed when the crystals belong to the same or similar structural types, when the difference between the lattice constants and the radii of the interacting atoms are small, and when the chemical properties of the metals or the types of chemical bonds are also similar[15]. The failure of any one of the above conditions leads to the formation of a narrow range of solid solutions or their complete absence.

In their interpretation of experimental results, investigators usually compare either atomic or ionic radii (depending on the data obtained), without taking into account as a rule the type of bond. Thus Flahaut et al.[14] based their discussion of data for the formation of the solid solutions of the sulphides of aluminium, gallium, and indium, on the one hand, and magnesium, manganese, zinc, and cadmium, on the other, on the similarity of the atomic radii, and for the sulphides of the lanthanides and magnesium, the calcium subgroup metals, manganese, and lead on the similarity of the ionic radii. However, the bond in lanthanide sesquisulphides[16,17], and in the majority of sulphides in general, has considerable covalent character.

Table 1, which lists the available information about the existence of solid solutions in sulphide systems, shows that the difference between atomic radii cannot account for the formation of the more extensive region of solid solutions of gallium sulphide with Cu_2S than for the corresponding solid solutions with Ag_2S. This applies equally to the systems Cu_2S–Ag_2S, Ga_2S_3–MnS, etc. On the other hand,

germanium and tin sulphides form a continuous series of solid solutions, other conditions being equal. The above examples show that, using atomic or ionic radii alone, it is impossible to account for the presence or absence of a solid solution in the given system.

Table 1. Regions of existence of solid solutions in sulphide systems.

System	Difference between radii,%			Solubility, mole %	Type of lattice of solid solution	Refs.
	ionic	atomic	effective			
B_2S_3—BeS	41.2	19.4	—	nil	—	14

In_2S_3—Cu_2S	4.2	18.0	—	less than with Ga_2S_3	—	18
In_2S_3—Ag_2S	19.0	8.3	—	ditto	—	18
Y_2S_3—MgS	26.0	11.1	—	up to 23 (Y_2S_3)	cubic	14, 20 21
Y_2S_3—CaS	0.0	8.6	—	up to 5 (Y_2S_3)	cubic	14, 20 21, 22
Y_2S_3—SrS	16.3	16.5	—	very narrow range if any	—	14, 20
Y_2S_3—BaS	20.0	26.0	—	nil	—	14, 20
Y_2S_3—MnS	14.1	27.2	—	up to 23 (Y_2S_3)	cubic	14, 20, 21
Y_2S_3—PbS	20.0	3.3	—	up to 5 (Y_2S_3)	cubic	21
Cu_2S—Ag_2S	15.0	11.0	13.0	nil	—	23, 24
ZnS—MnS	7.7	1.5	2.0	0–52 (MnS)	hexagonal	25
CdS—MnS	11.6	10.7	12.9	continuous series	hexagonal	
Ag_2S—PbS	14.4	17.2	—	0.4 (Ag_2S at 700°C) 3.0 (PbS at 605°C)	—	26
Ag_2S—Bi_2S_3	3.0	20.9	—	4.0 (Bi_2S_3 at 615°C)	—	26
PbS—Bi_2S_3	9.1	4.4	—	9 (Bi_2S_3 at 800°C) 3 (Bi_2S_3 at 400°C)	—	26
GeS—SnS	4.0	11.4	—	continuous series	ortho-rhombic	27
ZnS—FeS	4.5	0.0	6.8	up to 16 (FeS)		28
FeS—($TiS \cdot TiS_2$)	12.4	16.9	4.7		NiAs, CdI_2 type	29
CoS—($TiS \cdot TiS_2$)	13.8	15.9	11.1		CdI_2 type	29
NiS—($TiS \cdot TiS_2$)	14.5	11.5	14.2		CdI_2 type	29

Therefore it is difficult to agree with the statement [14, 20] that the occurrence of a wide range of solid solutions is possible in systems where the ionic radii of the metals differ by 27–28%.

The presence of a covalent bond should reduce the miscibility of sulphides, since this entails the mutual substitution not of metal atoms or ions but of groups of the type $M_xS_y^{n(\pm)}$. However, since sulphide sulphur tends to form its own lattice, it may be supposed that in its formation the sulphur incorporated in a species of the type $M_xS_y^{n(\pm)}$ can also serve as a "constructional material". Therefore formally the dimensions of this species may be described by the radius of the metal.

The determination of the effective charges of the elements in sulphides showed that the ionic character of the bond differs appreciably for various metals and lies in the range 30–60%. [6,12] This value is fairly appreciable in calculations designed to establish the similarity of ionic or atomic radii of metals and therefore a correction allowing for it must be introduced. Hence we calculated "effective" radii (Table 2) defined as the sum

$$\frac{q \cdot r_{M^{n+}}}{n} + \left(1 - \frac{q}{n} \cdot r_{M\cdot}\right)$$

where n is the valence of the metal, q its effective charge in the sulphide, and $r_{M\cdot}$ and $r_{M^{n(\pm)}}$ are the atomic or ionic radii.

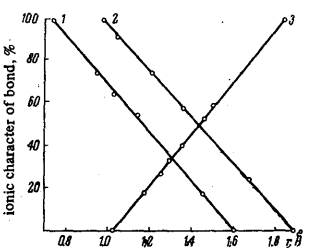
The validity of the calculations is confirmed by the fact that the calculated effective radii for both the cations and sulphide sulphur lie satisfactorily on the straight line drawn through the values of the ionic and atomic radii (Figure).

Table 2. "Effective" radii of metals in sulphides.

Sulphide	Effective radius, Å	Sulphide	Effective radius, Å	Sulphide	Effective radius, Å
Cu_2S	1.18	BaS	1.95	FeS	1.06
Ag_2S	1.35	ZnS	1.16	CoS	1.12
MgS	1.11	CdS	1.31	NiS	1.09
CaS	1.47	MnS	1.14	Al_2S_3	1.00
				Ga_2S_3	1.22

Comparison of the metal radii obtained in this way with the experimental values for gallium in Ga_2S_3 shows (Table 1) that they differ by not more than 9.8%. The following series of compounds with increasing size of the region of solid solutions of gallium sulphide with certain metal sulphides has been constructed on the basis of the calculated data: $Cu_2S > ZnS > MnS > CdS > MgS > Ag_2S$; it agrees satisfactorily with the experimental series [14,18,19]:

$$Cu_2S > ZnS > MnS \geqslant CdS \geqslant Ag_2S > MgS$$



Variation of the effective radius with the ionic character of the bond for sodium (curve *1*), magnesium (curve *2*), and sulphur (curve *3*) in their compounds.

Some deviation observed in the case of Ag_2S is evidently due to the fact that the range of existence of the solid solution in this system has been established only approximately. We believe that the solubility of Ag_2S in Ga_2S_3 should be less than 12 mole %.

The above hypothesis agrees well with the results of studies on systems consisting of FeS, CoS, NiS, and TiS. $.TiS_2$, [29] where the empirical series based on the range of existence of solid solutions—FeS ≫ CoS > NiS—agrees with the series based on the difference between the effective radii of the metals (Table 1). The calculation of the radii was made on the basis of the titanium radius in TiS, which is of decisive importance in this case. The sulphides CrS, VS, and MnS are even less capable of forming solid solutions with $TiS.TiS_2$.

Because of the lack of data on the effective charges of the metal and sulphur in lanthanide sesquisulphides, it is unfortunately impossible to make a similar comparison for their interaction woth the sulphides of magnesium, manganese, lead, and calcium subgroup metals[14,20,21]. However, the available effective charges for the latter compounds explain why in the experimental series based on the size of the solid solution regions–MgS > MnS > CaS > PbS > SrS > BaS–manganese sulphide occupies an intermediate position and strontium and barium sulphides altogether fail to form solid solutions or the solid solutions are formed only over a narrow range.

The introduction of the concept of the "effective" radius of the metals in sulphides permits the elimination of the contradictions existing in the literature. As an example, one may quote the data of Flahaut and coworkers[20], who failed to explain why the solid solution region in the systems Y_2S_3–MgS or Y_2S_3–MnS is greater than in the system Y_2S_3–CaS, although the ionic radii of calcium and yttrium are almost the same.

It is noteworthy that sulphide sulphur forms a close-packed sublattice with octahedral and tetrahedral vacancies, which are occupied by metals in a definite sequence. Since the dimensions of these sites are smaller than those of the majority of metals, a polarisation effect occurs when the vacancies are filled. Analysis of the data obtained shows that the formation of solid solutions should be most complete when the high symmetry of the crystals is further increased or maintained. This inturn is possible when the dimensions of the metals undergoing mutual substitution and the bond types are similar. Indeed the solid solutions obtained in the vast majority of cases crystallise in the cubic or hexagonal system (Table 1). The high symmetry of the crystals in the formation of solid solutions is also due to the tendency of the sulphide sulphur to give rise to its own intrinsic sub-lattice. Therefore the factors leading to its distortion alter the energy of the crystal, in consequence of which it becomes less stable. Conversely, if the addition of another sulphide favours the formation of an undistorted sulphur sublattice, miscibility is observed even when the initial substances differ considerably in symmetry type. As an example, one may quote the studies of Hahn et al.[18], who observed that the addition of small amounts of copper or silver sulphide stabilises the zinc blende structure, which is unstable for gallium sulphide at 900°C. An exception is the system GeS–SnS in which a continuous series of solid solutions is formed. However, X-ray diffraction studies showed that these sulphides form two types of solid solutions, on the basis of GeS and SnS.[27]

Since the nature of the chemical bond in sulphides is variable, the charges of the metal and sulphur should alter on formation of solid solutions. This favours an increase or decrease of the covalent character of the bond and a simultaneous deviation of the metal radii from those in the initial compounds. These changes are small, since mixed crystals are formed only when the type of chemical bond and dimensions of the metals in the initial sulphides are similar. Indeed, when aluminium sulphide is added to zinc sulphide, the Al–S interatomic distance decreases, while in the systems MS–L_2S_3 (L = lanthanide) the L–S distance increases. In the first example the addition of a more ionic compound (Al_2S_3) leads to an increase in the latter of the covalent bond character, as a result of which the interatomic distance Al–S is reduced. The addition of Ga_2S_3 to ZnS, the ionic character of the bond of which is similar, scarcely changes the Ga–S distance. The lack of data on charge distribution in lanthanide sulphides precludes an analogous comparison, but the increase of the L–S distance suggests that the covalent bond character in L_2S_3 is smaller than in the MS compounds investigated.

Apart from the systems described, some results in the literature cannot be arranged systematically in a similar manner because of the lack of essential data[30,31].

The miscibility of sulphides increases greatly when one of the system components is a double sulphide. Thus the sulphides of bismuth and lead are almost immiscible, but 1.7 and 10 mole % PbS dissolves in $AgBiS_2$ at 200°C and 615°C respectively. Bismuth sulphide forms mixed crystals with $AgBiS_2$, in which the maximum Bi_2S_3 content is 16 mole %, and 14 mole % $AgBiS_2$ dissolves in PbS at 195°C.[26] It is believed that the increased miscibility of the components is due to the replacement of Ag^+ and Bi^{3+} by $2Pb^{2+}$ with formation of a cubic structure. The replacement in $AgBiS_2$ of silver by thallium, the dimensions of which are closer to those of lead and bismuth, leads to the formation of a continuous series of solid solutions in the system PbS–$TlBiS_2$.[32] The lower miscibility of PbS and $AgBiS_2$ is probably due not only to the greater difference between the dimensions of the metal atoms but also the inadequate homogenisation of mixtures of the systems. The regions of solid solutions in the systems $CuGaS_2$–ZnS and $AgGaS_2$–ZnS correspond respectively to 40 and 5–10 mole % ZnS.[33] The investigators concerned believe that the smaller solid solution region in the system with $AgGaS_2$ is not due to steric hindrance to the replacement of silver by zinc but is caused by the greater departure of the unit cell from the pseudocubic form. The spinels $MgIn_2S_4$, $CrIn_2S_4$, $MnIn_2S_4$, $CdIn_2S_4$, and $CoIn_2S_4$ form with In_2S_3, and $ZnAl_2S_4$ with Al_2S_3, an almost unlimited region of solid solutions[14,34]. An exception is $CaIn_2S_4$. It has been noted that in the region rich in MS solid solutions are not formed[14]. This phenomenon is probably due to the fact that the lattice constants of the spinel and the trivalent metal sulphide differ less than for the sulphide MS.

$PbSnS_2$ forms a two-sided solid solution with the initial components in which the region of homogenisation corresponds to about 30–53 mole % PbS.[35-37] The existence of a more extensive region of solid solutions of $PbSnS_2$ with SnS than with PbS can be accounted for by the similarity of their lattice constants.

According to X-ray diffraction data, the thiochromate spinel systems $ZnCr_2S_4$–$CdCr_2S_4$ and $FeCr_2S_4$–$CdCr_2S_4$ form a continuous series of solid solutions, due to the similarity of the atomic radii of zinc, cadmium, and iron[28].

Complete miscibility of the components is also observed in the systems Ag_3AsS_3–Ag_3SbS_3 and Ag_8GeS_6–Ag_8SnS_6.[38,39] It can be supposed that in the system Ag_8SnS_6–Ag_8SiS_6, whose compounds are isomorphous, unlimited miscibility should be observed.

The ready formation of solid solutions with complex sulphides and the unlimited miscibility of the components suggest that in the compounds described the metals are not divided into cations and anions but are distributed statistically in the tetrahedral and octahedral vacancies in the sulphur sublattice.

As mentioned above, solid solutions of simple sulphides are formed when the crystal structures, chemical bond type, and the effective radii of the metals undergoing mutual substitution are similar. As the composition of the compounds becomes more complicated, the above criteria lose their value. For double sulphides, the following factor evidently limits the miscibility: the dimensions of the vacancies in the sulphur sublattice do not exceed 0.76 Å,[13] while the effective radii of the majority

of metals are much greater and therefore the incorporation of the latter leads to the deformation of the lattices and the polarisation of sulphur. The formation of a double sulphide is favoured by a high temperature and the unsaturation of the chemical affinity of the sulphide sulphur. At the same time the constant of the sulphur sublattice increases, which creates favourable conditions for a freer substitution of the metals. This is also facilitated by the absence of acid radicals from many double sulphides of the type $[M_2S_4]^{2-}$, $[MS_6]^{8-}$, etc.

2. The Formation of Complex Sulphides

Systematic studies of sulphide systems at high temperatures were carried out by Flahaut, Hahn, and their coworkers. The most complete studies have been made on complex sulphides formed by mono-, tri, or di-valent metals with the general composition $M^IM^{III}S_2$, where M^I = Li, Na, K, Rb, Cs, Cu, or Ag and M^{III} = B, Al, Ga, In, P, V, As, Sb, Bi, Cr, Ti, Fe, or Ni.[3,18,26,40,41,64-66,70,72-75,79,97,114,183,199-206] Some investigators are inclined to attribute to the above compounds the formula $M^I_2M^{III}_2S_4$ in order to draw an analogy with the double sulphides $M^{II}M^{III}_2S_4$, where M^{II} = Cu, Mg, Ca, Sr, Ba, Zn, Cd, Hg, Mn, Fe, Co, Ni, Pb, Yb, Sm, or Eu and M^{III} = B, Al, Ga, In, Y, La, Ce, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Ti, Zr, As, Sb, Bi, Cr, Fe, Co, or Ni.[3,14,19,21,22,26,42,44,46-63].

The chemical stability of the sulphides described in relation to acids and alkalis is much greater than that of the individual compounds. Thus, whereas Al_2S_3, Ga_2S_3, and Cr_2S_3 are readily hydrolysed in moist air, $Li_2Ga_2S_4$, $Li_2In_2S_4$, $Rb_2Ga_2S_4$, $Cs_2Ga_2S_4$, $Rb_2In_2S_4$, and $Cs_2In_2S_4$ are not decomposed by water[64-66] and $Na_2Ga_2S_4$ and $K_2In_2S_4$ form hydrates. The double sulphides $MBiS_2$ (M = alkali metal) are stable in relation to water and $CuAlS_2$ is actually stable in relation to dilute hydrochloric acid at normal temperatures.

Many of the sulphides quoted above are not decomposed at high temperatures, which permits their purification by recrystallisation from a melt of halide salts with the same cation M,[48] or with the acid of gas-transport reactions[46,48]. The stability of the compounds formed by the interaction of the sulphides of zinc subgroup metals and gallium increases on going from double sulphides containing mercury to those with zinc and from the double sulphides with aluminium to those with indium, but it is lower than the stability of the analogous oxygen compounds.

Sokolov[67] proposed an empirical rule to determine whether the formation of compounds in binary sulphide systems is possible; it assumed that the reactions occur when the interatomic distance between the anion and the complex-forming cation in the crystalline state is smaller than the distance between another cation and the anion. However, in many systems mutual coordination of the initial compounds is observed as a function of their relative amounts (for example, $4Cu_2S.Na_2S$ and $Cu_2S.9Na_2S$). The above deficiencies make it difficult to extend the rule to many sulphide systems and therefore it will not be employed in the present review.

There exist three types of sulphide crystal lattices: chalcopyrite, spinel, and salt-like.

Double sulphides containing mono- and tri-valent metals crystallise with a chalcopyrite structure, the position of the atoms corresponding to a distorted tetragonal zinc blende structure with a statistical distribution of the metals. According to the data of Hahn et al.[19], many simple sulphides tend to undergo tetrahedral coordination, but this is prevented when the metal : sulphur ratio is greater or smaller than unity. This obstacle is eliminated in the interaction of two sulphides ($M_2S + M_2S_3$) which form compounds with a zinc blende structure and the corresponding electron distribution. This increase in the symmetry of double sulphide crystals is probably caused (as was observed in the formation of solid solutions) by the tendency of sulphur to form its own sublattice. In most cases the metals in the compounds differ in their radii, charges, and polarisation properties and therefore the formation of a wurtzite or zinc blende structure is different. The chalcogenides of mono- and tri-valent metals frequently have the chalcopyrite structure, in which there is an ordered arrangement of the metals in accordance with their properties.

The spinels include double sulphides, the composition of which is described by the formula $M^{II}M^{III}_2S_4$; they have the wurtzite or zinc blende structures. The high symmetry of the crystals is caused, on the one hand, by the tendency of sulphide sulphur to form its own lattice and, on the other hand, by the presence in most metals of a filled d level, as a result of which they tend to form with non-metals covalent bonds with sp^3 orbitals and a tetrahedral configuration[19]. Spinels are divided into normal and inverse depending on the distribution of the metal in the vacancies of the sulphide sulphur lattice. In the first type M^{II} atoms are distributed in tetrahedral vacancies and M^{III} atoms in octahedral vacancies, while in the second type M^{II} and M^{III} occupy simultaneously both octahedral and tetrahedral sites. This phenomenon is due to the relative ionic radii of the metals[51]. Depending on whether the radius of M^{II} is greater or smaller than that of M^{III}, the normal or inverse spinel is formed. However, this rule, as well as the rule designed to determine the lattice energy, the polarisation of sulphur, or the relative bond energies, is not always obeyed in practice. For example, at normal temperatures the "thiogallate structure"[19] resembles that of β-Cu_2HgI_4, but at higher temperatures it undergoes a transition to a zinc sulphide lattice with a statistical distribution of the metals.

Furthermore, indium, tin, and lanthanides form sulphides with the composition M_3S_4. X-Ray diffraction and magnetic studies of these compounds confirmed the existence in them of di- and tri-valent metals, so that the phase can be regarded as the spinel $M^{II}M^{III}_2S_4$.[52,68,69]

Taken together the above data lead to the conclusion that double sulphides with the composition $M^IM^{III}S_2$ or $M^{II}M^{III}_2S_4$ are formed only in those cases where the initial sulphides M^I_2S, $M^{II}S$, and $M^{III}_2S_3$ crystallise in a system of high symmetry and the polarisation properties of the metals are very weak.

The polarisation of sulphide sulphur by metals in the formation of double sulphides has attracted much attention[19,51]. Indeed the radii of covalent or ionic sulphur are much greater than those of oxygen and therefore, under the action of multicharged ions, sulphur should be considerably polarised. Compairson of the polarising capacities of zinc subgroup and Group III metals shows that, on going from zinc to mercury, there is a tendency for metals to be polarised, while on going from indium to boron there is a considerable increase in the polarisability of sulphur. Thus both in the transition from indium to boron and from zinc to mercury the electron density in double sulphide crystals will deviate to the maximum extent from that for wurtzite or zinc blende, which in turn will tend to loosen the structure and ultimately will in general lower the

stability of the double sulphide. This factor readily accounts for the stability and the possibility of the formation of double sulphides with the compositions discussed. Thus so far, it has proved impossible to obtain the spinels MAu_2S_4 (M = Mg, Zn, Cu^{II}, Ti^{II}, Sn^{II}, Pb, Mn^{II}, or Fe^{II}), and also the compounds $MgAl_2S_4$, $CuAl_2S_4$, $FeAl_2S_4$, $CoAl_2S_4$, and $NiAl_2S_4$, which have been described for indium. The sulphides of elements in the lowest state of oxidation (VS, SnS, TiS, Ti_2S_3, etc.) also fail to form spinels with trivalent metals [29,51,55,70].

Triple sulphides with the composition Cu_2ZnSnS_4, Cu_2CdSnS_4, and Cu_2HgSnS_4 have the zinc blende structure and the compound $CuZn_2GaS_4$, the existence of which has not been quite convicingly demonstrated as yet, crystallises in the hexagonal system [33,71]. It is interesting to note that the analogous compound Cu_2FeSnS_4 has been described as a mineral.

Crystallographic studies of the sulphide $CuPS_2$ showed that this compound crystallises with a würzite lattice and its structure is analogous to that of $CuBS_2$, where sulphur and boron or copper atoms are believed to alternate [203].

On the basis of the above data, one may conclude that the statistical distribution of metals in the vacancies of the sulphur lattice is more likely than the salt-like structure. Thus the data quoted do not justify the classification of the compounds described above as salt-like, which means that they cannot be approached from the standpoint of the acid–base theory. Therefore one can hardly agree with the statement [64] that potassium thioindate can be regarded as the salt of the dibasic acid $H_2In_2S_4$. The absence of salt-like properties in these compounds is confirmed by the following data. If CuV_2S_4 is regarded as a salt, then copper should be replaced by other metals. In fact the attempts to replace copper by zinc, cadmium, or mercury proved to be unsuccessful [3,72,73]. Rüdorff and Stegemann [74] established that the formation of $K_2Cr_2S_4$ is much more difficult than the formation of $Na_2Cr_2S_4$. On the basis of the chemical and crystallographic properties of potassium thiochromite, it was concluded that its lower stability is due to the different polarising properties of the alkaline metals, which is hardly ever observed for salt-like compounds. When the sulphide $Na_2Fe_2S_4$ is treated with a solution of a silver salt, the silver replaces not only the sodium but also part of the iron [75].

Only a few compounds have been classified as salt-like double sulphides with the composition $M^{II}M^{III}S_2$ or $M^{II}M^{III}_2S_4$. Bokii et al. [76] and Betekhtin [77] suggest that the sulphides of trivalent arsenic, antimony, and bismuth be regarded as salts containing complex ions of the type $[ES_3]^{3-}$. However, as stated above, crystallographic study of such bismuth compounds showed that they have a structure of the sodium chloride type with a statistical distribution of the metal atoms. $SrAs_2S_4$, which crystallises with a zinc blende structure, evidently belongs to sulphides of the same type [73]. Furthermore, the double sulphides $Ag_{24}Sb_2S_{15}$, Ag_9SbS_6, Ag_5SbS_4, Ag_3SbS_3, and $Ag_2Sb_{12}S_{19}$, which occur in nature as minerals, cannot be readily regarded as derivatives of the corresponding acids. The behaviour of $PbBi_2S_4$, which crystallises in the orthorhombic systems with layers of bismuth and sulphur having the composition BiS_2^-, is somewhat unusual [78]. Alkali metal thioarsenites and thioantimonites may be classified as salt-like compounds.

The elements of the arsenic subgroup are known to form compounds in which they are present in the anionic form. On this basis, one might expect that in the interaction with sulphides the metal components of which tend to form cations, thio-salts should be formed. However, arsenic, antimony, and bismuth do not form double sulphides having the composition $M^{II}M^{III}_2S_4$ with metals of the calcium subgroup, zinc, beryllium, the iron-group metals, etc [73]. It is striking that As_2S_3, Sb_2S_3, and Bi_2S_3 crystallise in a system of lower symmetry (orthorhombic and monoclinic) than the other trivalent metal sulphides mentioned above. At the same time the products of their interaction with Cu_2S and Ag_2S crystallise with a lattice of the chalcopyrite type. Similiar phenomena were observed also for other sulphides, which leads to the conclusion that an increase in the symmetry of the low-symmetry crystals is possible only when two metal atoms, of different valence, can replace zinc atoms in the zinc blende structure without appreciable distortion of the latter. X-Ray diffraction studies of sodium and potassium thiochromites [74,79] led to the conclusion that –Cr–S–Na–S–Cr– layers in hexagonal positions form a close-packed structure of the sodium chloride type. The formation in this structure of CrS_2^- units permits the classification of these compounds as salt-like. It is interesting to note that the group of double sulphides with the composition $MNaS_2$ (M = Nd, Sm, Eu, Gd, Tb, Dy, Ho, or Er) have been assigned to this type of thio-compound [60].

Table 3. Composition of double sulphides containing Group IV elements.

ES_3^{2-}		ES_4^{4-}	ES_6^{8-}	$E_2S_5^{2-}$
Li_2SiS_3	$CaSiS_3$	Li_4SiS_4 Cd_2GeS_4 $La_4[GeS_4]_3$	Cu_8SiS_6	$Na_2Ge_2S_5$
Cu_2SiS_3	Cu_2SnS_3	Cu_4SiS_4 Hg_2GeS_4 $Ce_4[GeS_4]_3$	Ag_8SiS_6	$CaSi_2S_5$
Na_2GeS_3	K_2TiS_3	Mg_2SiS_4 Mn_2SiS_4 $Pr_4[GeS_4]_3$	Ag_8GeS_6	
Cu_2GeS_3	$SrTiS_3$	Ca_2SiS_4 Mn_2GeS_4 $Nd_4[GeS_4]_3$	Ag_8SnS_6	
$PbGeS_3$	$BaTiS_3$	Ca_2GeS_4 Pb_2SiS_4 $Sm_4[GeS_4]_3$		
K_2SnS_3	$BaZrS_3$	Ca_2SnS_4 Pb_2GeS_4 $Gd_4[GeS_4]_3$		

The sulphide of tetravalent elements form a series of compounds [39,61,70,75,80–96], which can be regarded as the salts of the corresponding acids (Table 3).

Comparison of X-ray diffraction data show that only the thio-compounds of silver crystallise in the cubic system [39,44], which is characteristic of simple compounds. The structure of double sulphides belongs to a system of lower symmetry—orthohombic and even monoclinic—but for the majority of sulphides it has not been elucidated at all.

Sulphides containing elements of the titanium subgroup and copper(I) are dimorphous. The existence of the anions $[SiS_3]^{2-}$ or $[SiS_4]^{4-}$ has been proved only for Li_2SiS_3 and Ca_2SiS_4. [80]

The presence in certain double sulphides of anions, the formal correspondence between these compounds and the usual salt-like compounds, the great tendency of Group IV elements to form anions, the low symmetry of the crystals of many of the compounds, and the more ready hydrolysis of Li_4SiS_4 and Ca_2SiS_4 compared with Li_2SiS_3 and $CaSiS_3$ permit the classification of these compounds as salt-like. Their greater basicity than that of salts of the corresponding oxygen acids can be accounted for by the greater size of sulphide sulphur compared with oxygen. However, the data quoted above do not explain the coordination of four, and even less so six, atoms (ions) of sulphur by silicon, germanium, and tin, the increase in crystal symmetry on going from double sulphides containing copper to those with manganese, the occurrence of hexagonal packing of

sulphide sulphur in Mn_2SiS_4 and Mn_2GeS_4 with the metal atoms distributed among the tetrahedral and octahedral vacancies, the decrease of reactivity in the series $SiS_2 > GeS_2 > SnS_2$, the acid properties increasing in the same sense, and the relatively high miscibility of silver thiostannate and thiogermanate over the entire concentration range, although the dimensions of the ions $[GeS_6]^{8-}$ and $[SnS_6]^{8-}$ should differ considerably.

The above group of compounds is located at the boundary between complex sulphides, which are typical for mono- or di- and tri-valent elements, and the thio-salts of metals of Groups V–VII. The complex sulphides containing alkali and alkaline earth metals and Group IV metals should probably also be classified as thio-salts. This conclusion is confirmed by data for the interaction between titanium or zirconium sulphides, on the one hand, and elements of the calcium subgroup and magnesium, on the other. Since the acid properties of zirconium disulphide are not very pronounced, a metal with very marked basic properties is required for the formation of a double sulphide. Among the metals enumerated above, barium has the most basic properties and this is why only $BaZrS_3$ is formed. Evidently the reaction with alkali metals will proceed much more readily, and hafnium sulphide will behave similarly. Titanium disulphide has more marked acid properties and therefore it forms two compounds—$SrTiS_3$ and $BaTiS_3$. The stability of the above sulphides increases from double compounds containing zirconium to those containing titanium. The findings described above agree well with data [70,95] showing the absence of interaction of TiS_2 with ZnS, CdS, HgS, MnS, FeS, and NiS.

These results are in conflict with the statement [95] that compounds of the type ABS_3 have a structure consisting of ions packed into groups $(AS_3)_n$, in which the radii of the ions A and S should not differ too much. The species B is disregarded. However, this explanation is not entirely satisfactory, since it is impossible to understand the reason for the higher reactivity of the sulphides of calcium subgroup metals with TiS_2 than with ZrS_2 or TaS_2.

Group V elements in the normal state of oxidation yield two series of double sulphides, which may be regarded as derivatives of mono- and tri-basic acids (Table 4). The compounds BPS_4 and $AlPS_4$ are isomorphous, crystallising in the orthorhombic system with formation of infinite chains, as in the case of SiS_2, aluminium and phosphorus being linked to one another via sulphur and each being surrounded by sulphur atoms distributed tetrahedrally. Monosubstituted sodium, silver, and thallium thiophosphates are polymeric [97]. X-Ray diffraction study of sulvanite [86,98] Cu_3VS_4 and infrared spectroscopic study of ammonium thiovanadate in solutions [101] showed the existence of the tetrahedra $[VS_4]^{3-}$, which are distributed as in β-K_2SO_4. In view of the short Cu–V interatomic distance in the crystal lattice, it is believed [86] that there is a bond between copper and vanadium. The diamagnetism of Cu_3VS_4, its low electrical conductivity at elevated temperature, and the fact that even part of the vanadium cannot be replaced by chromium, manganese, iron, cobalt, and nickel suggest the formula $Cu_3^{+}V^{5+}S_4^{2-}$. The diamagnetism of the sulphide Tl_3NbS_4 leads to the assignment of the formal valencies to the elements in the compound: $Tl_3^{+}Nb^{5+}S_4^{2-}$. As a result of the considerable asymmetry in the distribution of cations about sulphur, these ions are strongly polarised. Estimation of the degree of polarisation by calculating the electrostatic field confirmed that this energy constitutes a considerable part of the total lattice energy, which is greater than for the zinc blende structure. It is interesting to note that the analogous arsenic compound Cu_3AsS_4 has a covalent As–S bond, in contrast to sulvanite [86].

When vanadium in sulvanite is replaced by niobium and tantalum, which have greater atomic dimensions, the stability of the thio-compounds increases and the colour weakens, which can be accounted for by less intense polarisation of the elements.

Table 4. Composition of double sulphides containing Group V elements [76,86,97–100].

	ES_4^{3-}		ES_3^{-}
Cu_3VS_4	K_3VS_4	Tl_3VS_4	$(NaPS_3)_x$
Cu_3NbS_4	K_3NbS_4	Tl_3NbS_4	$CuVS_3$
Cu_3TaS_4	K_3TaS_4	Tl_3TaS_4	$CuTaS_3$
Cu_3AsS_4	BPS_4	$AlPS_4$	$(AgPS_3)_x$
Cu_3SbS_4			$(TlPS_3)_x$

The compound $CuTaS_3$ crystallises in the orthorhombic system, in which tantalum is surrounded octahedrally by six sulphur atoms with six bonds and a Cu–Ta metallic bond is present [86]. Similar double sulphides with thallium and potassium have been less investigated. In view of the isomorphism of K_3VS_4 and K_3TaS_4, it is believed that these compounds are also salt-like, but some investigators deny the isomorphism of KVS_3 and K_3VS_4 [sic], since in this case the tetrahedra should be combined in a different way.

The data quoted show that the double sulphides described above, containing Group V elements in the highest state of oxidation, are similar to the oxygen-containing compounds and may be classified as thio-salts containing the ions $[ES_3]^{-}$ or $[ES_4]^{3-}$. The compounds exhibit different stabilities towards moisture, acids, and alkali. Thus, while sodium, boron, and aluminium thiophosphates readily undergo complete hydrolysis in moist air, K_3VS_4 hydrolyses only after dissolution; $(TlPS_3)_X$ and $(AgPS_3)_X$ are oxidised only with nitric acid on heating, and sulvanite Cu_3VS_4 occurs as a mineral. It has been noted that the compounds Tl_3ES_4 (E = V, Nb, or Ta) are sparingly soluble in water [86]. The melting points of these double sulphides are in the range 300–500°C. Studies on the electrical conductivity of the sulphides suggest that they are semiconductors.

The data for the interaction of the sulphides of lanthanides (L_2S_3) and aluminium or gallium with formation of compounds having the composition $AlL^{III}S_3$ (L^{III} = La, Ce, Pr, Nd, Sm, Gd, or Y), $GaL^{III}S_3$ (L^{III} = La or Y) [102,103], and $YInS_3$ [103–105] are insufficient for their assignment to any of the classes described above. Most of them crystallise in the hexagonal system ($YInS_3$ crystallises in the orthorhombic system). With certain component ratios, glasses are produced. The compounds are stable towards water, alkalis, weak mineral and organic acids, and organic solvents [104]. It is suggested that a covalent–ionic bond is present in the molecule of the sulphide $ML^{III}S_3$. [105] In accordance with the type of crystal lattice and composition, the sulphides $FePS_3$, $CoPS_3$, and $NiPS_3$ may be included among these compounds [106].

Apart from the classes of compounds described above, there is much information in the literature concerning the existence of compounds with more complex chemical compositions (Table 5). The ratios of the initial sulphides in these compounds range mainly from unity to five. However, in some cases fractional ratios occur, for example

in $5Na_2S.2Fes$, $5Cu_2S.2Na_2S$, $5PbS.4Sb_2S_3$, and $2L_2S_3.3GeS_2$, where L is a lanthanide [40,83,107-110], reaching nine in only a few cases, namely in $9Na_2S.Cu_2S$. [107,108]. Their crystal structures are also different, but the most characteristic feature of all of them is the absence of acid and basic groups.

Table 5. Composition of complex sulphides obtained by the thermal method.

Composition of compound	No. of valence electrons	Composition of compound	No. of valence electrons	Composition of compound	No. of valence electrons	Composition of compound	No. of valence electrons

Thus Flahaut et al. [111] and then Ballsstracci [112,113] obtained and investigated by X-ray diffraction compounds with the general formula $M_2S.5Al_2S_3$, when M = Li, Cu, or Ag, $Ag_2S.5L_2S_3$ (L = La, Ce, Pr, Nd, Sm, Gd, Tb, or Dy), and $3Cu_2S.L_2S_3$ (L = Tb, Dy, Ho, Er, Tm, Yb, Lu, or Y). They showed that aluminium-containing double sulphides crystallise with a spinel type of lattice, in which the monovalent metals and one fifth of aluminium are distributed in a random fashion among the tetrahedral vacancies. In the sulphide $Ag_2S.5L_2S_3$ the metal atoms are distributed statistically among the vacancies of the sulphide sulphur lattice.

Copper and iron sulphides interact with formation of the compounds Cu_5FeS_4 ($5Cu_2S.Fe_2S_3$), $CuFeS_2$ ($Cu_2S.Fe_2S_3$), and $CuFe_2S_3$ ($CuS.2FeS$), where the metal atoms in the crystal lattice occupy tetrahedral sites in a spinel type structure with a close-packed sulphide sulphur lattice [40,114].

The double sulphide Ba_2ZnS_3, [115] to which the incorrect composition $BaZnS_2$ was initially attributed [66] (this probably applies also to $SrZnS_2$), crystallises in the orthorhombic system. The Zn–S and Ba–S distances in this compound are almost equal to those in the initial sulphides, which also throws doubt on their salt-like structure. X-Ray diffraction confirmed the existence in the system PbS–Bi_2S_3 of double sulphides with the composition $Pb_2Bi_2S_5$ and $Pb_4Bi_2S_7$. [73,116] It has been established that the $Pb_2Bi_2S_5$ structure contains extensive regions of the zinc sulphide type [117].

Double sulphides with the composition MCu_4S_3 (M = K or Rb), which crystallise in the tetragonal system [118-120], have been described. The lattice consists of layers of –S–Cu–S–Cu–S– units, in which sulphur atoms form an almost regular tetrahedron. Copper is displaced from this tetrahedron into the layer formed by the alkali metal atoms. It is present in these compounds in the mono- and di-valent forms, but occupies identical positions regardless of valence, the layers constituting an integral whole and bearing a negative charge, i.e. $[Cu_4S_3]^-$.

Many of the sulphides listed in Table 5 have the sphalerite or zinc blende structure with a statistical distribution of metal atoms. This suggests that the compounds may be derived from the zinc sulphide structure, where the zinc sites are occupied by other metals and sulphide sulphur forms its own more or less distorted lattice. Goodman [121] and also Koshkin [122] believe that the chalcopyrite lattice of semiconductor compounds of the type $A^IB^{III}C_2^{VI}$, $A_2^IB^{IV}C_3^{VI}$, and $A^{II}B^{IV}C_3^{VI}$ resembles the sphalerite lattice, the difference being that the metal chalcopyrite sublattice contains atoms of two types. With a statistical distribution of metal atoms, the lattice of the three component compounds does not differ from that of sphalerite. The retention of the lattice properties in more complex sulphides suggests that the above hypotheses can be extended to the compounds under discussion.

However, the crystal-chemical properties of zinc sulphide requires that the following conditions be fulfilled. Since in the crystal lattice of the double sulphide the two metals must occupy at least two zinc positions, the number of valence electrons of the metal should be a multiple of four and the overall polarising capacity of the metals should be close to that of zinc in ZnS. Table 5 shows that all the compounds may be divided into two groups in accordance with the composition of the initial simple sulphides.

The first group includes the sulphides with metals having even or odd valences (for example $Cu_2S.Ag_2S$, $Li_2S.5Al_2S_3$, $GeS_2.2MS$, etc). The total number of valence electrons of the metals is a multiple of four. The data explain why in the sulphide systems where the metals have even or odd valences the initial components form only combinations in which the total number of valence electrons of the metals is a multiple of four and which have the composition $M_2S.M_2S_3$, $3M_2S.M_2S_3$, $M_2S.3M_2S_3$, and $M_2S.5M_2S_3$. The numbers of valence electrons in the molecules of the complex compounds are respectively 8, 12, 20, and 32, while the numbers corresponding to the compositions $2MS.M_2S_3$, $4M_2S.M_2S_3$, $M_2S.4M_2S_3$, and $M_2S.6M_2S_3$ are 10, 14, 14, 26, and 38 respectively. Therefore their existence is less likely.

A number of compounds with metals having different valences, where, as in the preceding case, the total number of valence electrons of the metals is a multiple of four, approach closely in their properties the sulphides of the above type. The thiospinels $M^{II}S.M_2^{III}S_3$, $3MS.K_2S$, and $3MS.In_2S_3$ should be included among them. As a rule, their crystals show high symmetry. Probably the combinations of these two factors is in fact decisive for the existence of compounds of this kind.

It is interesting to note that an increase in the complexity of the composition of sulphides of this type, for

example $Cu_2S.MS.SnS_2$ (M^{II} = Zn, Cd, or Hg), or $M^I_2S.M^{III}_2S_3.2M^{IV}S_2$ (M^I = Cu or Ag; M^{III} = Al, In, or Cr; M^{IV} = Ti, Zr, Hf, or Sn)[71,123] does not infringe the principle that the number of valence electrons of the metals must be multiple of four.

The second group includes complex sulphides consisting of elements with even and odd valences, the sum of the valence electrons of the metals of the coordinated sulphides being a multiple of four, for example $MS.2M_2S_3$, $2MS.M_2S_3$, etc., despite the different coordinating capacities of sulphides of this class.

Comparison of the available literature data shows that the coordination number of the simple sulphides combined in the complex depends on the position of the metals in the Periodic System; it increases with the atomic number of the complex-forming metal. As an example, one may quote the double sulphides which include Group I elements: $Na_2Mn_2S_4 \rightarrow K_2Mn_3S_4$; $Na_2Cu_3S_3 \rightarrow K(Rb)Cu_4S_3$; $M_2S.Bi_2S_3$ (M = Li, Na, or K) $\rightarrow Rb_2.3Bi_2S_3$; $Na_2S.Cr_2S_3 \rightarrow K_2S.2Cr_2S_3$; $Cu_2S.Bi_2S_3 \rightarrow Ag_2S.3Bi_2S_3$; etc. It has been noted that rubidium and bismuth sulphides do not form $Rb_2S.Bi_2S_3$. Thus, as the atomic number of the coordinating metal increases, the composition of stable double sulphides becomes more complicated.

III. INTERACTION OF SULPHIDES IN PRECIPITATION FROM AQUEOUS SOLUTIONS

As in fusion, the interaction of sulphides in their precipitation from solution reduces to the formation of solid solutions or double compounds, but the process itself takes place in a more complicated manner. This is because, apart from the conditions for the formation of solid solutions or complex sulphides described in the preceding sections, other factors influencing the process are the solubility of the sulphides (which varies within a wide range), the state of the metal in the initial solution, the stability of its complexes, and the presence of other substances which affect the formation of colloidal and crystalline particles.

For example the particular modification of cadmium sulphide obtained when it is precipitated from solutions depends both on the temperature and the composition of the initial salt[124].

One must agree with Feigl's view[7] that the above phenomena cannot be described solely in terms of the law of mass action or the solubility products. One of the main factors which influence the interaction of sulphides is the concentration in the solution of hydrogen sulphide and sulphide ions. This effect determines conditions for the formation of the precipitate and the acquisition of a charge by the latter. When the amount of hydrogen sulphide is insufficient, metal atoms are adsorbed on the surface of the precipitate by virtue of their high affinity for sulphur, and create a positive charge, while in the presence of an excess of hydrogen sulphide a negative charge is produced. In their discussion of the effect of hydrogen sulphide on coprecipitation, Kolthoff and coworkers[125,126] concluded that hydrogen sulphide and its ions favour the interaction of sulphides because their concentration is higher on the surface of the precipitate than in solution, which has been confirmed by the studies of Rudnev and Malofeeva[127-131]. The removal of hydrogen sulphide from the surface of the solid reduces or altogether suppresses the reactivity of the sulphides precipitated. The capacity for coprecipitation is partially or completely restored after repeated addition to the washed precipitate of water containing hydrogen sulphide. Therefore it is believed that the presence of hydrogen sulphide or its ions on the surface of the sulphide is an essential but not a decisive factor in coprecipitation. This hypothesis is confirmed by the studies of Vachnadze[132], which show that the existence of the compounds In_2S_3 and $MInS_2$ is determined by the relative amounts of In and M^I and not of the sulphide sulphur and indium, and also by the ion exchange between the sulphide precipitate and solution in the absence of adsorbed hydrogen sulphide. In the latter case the experiments were performed on columns containing freshly prepared sulphides of zinc, cadmium, and lead with solutions of copper, lead, manganese, cobalt, nickel, zinc, cadmium, and thallium(I) salts or the sulphides of iron, zinc, lead, cadmium, copper, and silver with solutions of mercury(II), copper(II), and silver salts[133-135]. It was shown that in all the experiments only copper was fully precipitated, while other ions either did not undergo quantitative exchange or their exchange was not consistent with the solubility products. It was noted that the exchange is retarded as the concentration of the precipitating metal in solution is reduced regardless of the solubility products of the sulphides, probably because diffusion of the metal ions through the layer of the corresponding sulphides is difficult. It is interesting to note that the rate of exchange with the less soluble cadmium sulphide is much higher than with the more soluble zinc sulphide, while complete exchange between As_2S_3 and silver ions is not achieved in practice. It is believed that in this case the double sulphide Ag_3AsS_3 is formed and is not decomposed by the excess silver ions. Mercury is precipitated in the form of the compounds xHgS.yHgHal$_2$. There is no ion exchange between zinc sulphide and arsenic, germanium, and indium salts, but the degree of precipitation of indium from solutions containing all the above metals increases under analogous conditions, while that of germanium falls[136], which we believe to be related to the formation of solid solutions of indium and arsenic sulphides or double sulphides. The investigators concerned have correctly noted that the absence of a rigorous relation between the results and the solubility products of the sulphides can be explained by the low reliability of the solubility products and the lack of data for their variation with the size of the precipitated crystals and the particular modification of the sulphide. Indeed, according to data in handbooks[137], the solubilities quoted for the same sulphide differ by 2–6 powers of ten. The results show that the suggestions by Ruff and Hirsch[138] to use as the criterion of the possibility of separation the ratio $SP_1 : SP_2 = K$, where SP_1 and SP_2 are the solubility products of the sulphides to be separated, is erroneous. For high values of K, the sulphides should be separated quantitatively and equilibrium should be attained rapidly. It has now been established that NiS ($SP = 10^{-21}$–10^{-28}) coprecipitates most readily with SnS_2, Bi_2S_3, and FeS, whose solubility products are smaller, and K for Bi_2S_3 is 10^{44}, while MnS ($SP = 10^{-15}$) is most readily coprecipitated with SnS_2 and HgS, where $K = 10^{28}$, the extent of coprecipitation with sulphides whose solubility products are much higher being appreciably less. Nor can one agree with the view put forward by Troitskii[139], who accounts for deviations of this kind by adsorption or by the presence in the precipitate of impurities more soluble than the element coprecipitated.

Many investigators noted long ago that the sorption capacity of the sulphides precipitated from solutions is different in the presence of organic compounds, where were therefore used to suppress coprecipitation[140-142]. The reason for this phenomenon is the interaction of the

oppositely charged colloidal particles of the organic substance and the sulphide sol with possible formation of chemical compounds [143,144]. Sulphides react most fully with triphenylmethane dyes and certain azine dyes, whereby it is possible to prevent completely the coprecipitation of metals with sulphides. This is also favoured by the formation of stable complexes of the coprecipitating metal with the organic compound.

The study of the sorption capacity of a group of sulphides, using as an example the dye Neutral Red, showed that the sorption capacity of bismuth, antimony, mercury, and tin sulphides increases with time, that of arsenic and lead sulphides decreases, and that of copper, silver, and cadmium sulphides remains unchanged [143,145]. The authors believe that this is due to a change in the state of aggregation of the sulphides. However, the results of studies on the coprecipitation of gallium subgroup metals with copper, cadmium, mercury(II), and thallium(I) sulphides and with Bi_2S_3 showed [146,147] that the attempts to extend these findings to the coprecipitation of metals were unsuccessful. Similar results were obtained in the study of the effect of the surface area of the sulphides formed and their charge on their reactivity [145,148,149].

It may be supposed that the degree of coprecipitation should be a minimum in the presence of organic substances and when organic sulphur-containing substances, which do not produce sulphide ions in the solution, are employed. Ion exchange can be successfully used to concentrate elements forming sparingly soluble sulphides.

The interaction of metal salts and hydrogen sulphide may take place via the formation of normal (MS), acid $[M(HS)_2]$ and mixed ($M^{I}SM^{II}$) compounds [150,151]. Furthermore, it is also complicated by the presence in the inner sphere of the complex cation of coordinated water and hydrogen sulphide, which are capable of forming stable hydrogen bonds [152-155].

Thus the data obtained by investigators attempting to find the physical causes of coprecipitation [138,139,156-160] yielded convincing proof of one of the first hypotheses put forward by Feigl [7,161], namely that the reason for the interaction between sulphides is the coordination unsaturation of sulphide sulphur, as a result of which the formation of solid solutions and double sulphides is possible. Physical factors merely increase or decrease the degree of coprecipitation but are not decisive for the reactivity of sulphides. Their interaction with formation of double compounds must be determined by the thermodynamic quantities which include in the first place the affinity of the metals for sulphur, the latter decreasing with enhancement of the non-metallic properties of the elements in the series Zn > Mn > (Co) > Cd > Cu > (Ni) > Fe > Rb > Sn > Ag > Sb > Bi. [162] Furthermore, as pointed out by Yatsimirskii [163], stable thio-salts are formed in those cases where the sulphides have pronounced electrostatic and covalent characteristics.

All the findings described above suggest that the most reliable results can be obtained only by employing the method of physicochemical analysis in combination with crystallographic hypotheses concerning the structure of the above class of compounds. The application of physicochemical analysis to coprecipitation processes, which was first justified by Rudnev and Malofeeva, permitted a deeper understanding of this phenomenon. However, we believe that, when phase diagrams are plotted, a somewhat arbitrary procedure is employed. Usually coprecipitation is studied under conditions excluding the deposition of an independent phase consisting of one of the sulphides. Therefore in the formation of complex compounds the ratio of the amounts of the metals in the precipitate is smaller than in the solution. As the equivalence point is approached, the degree of coprecipitation diminishes due to the decomposition by the medium of the double sulphide formed and the difficulty of attaining the true state of equilibrium because of the rapid precipitation of the solid phase. Therefore the coprecipitation curve obtained by plotting $M:M_1$ (solution) against the degree of precipitation of M(%) will describe the interaction processes only when a single stable complex sulphide is formed (Table 6). When several compounds exist in the system, the curves will reflect only the most stable compound, which is not the case when the results are represented by plots of $M:M_1$ (precipitate) against $M:M_1$ (solution). Therefore in order to avoid an incorrect interpretation of the results, experimental data should always be represented by plots of the latter type.

Table 6. Comparison of the results of interaction studies of sulphides on the basis of different plots.

System	Interaction of sulphides based on different plots		Refs
	$M:M_1$ (soln.)–degree of precipitation, %	$M:M_1$ (soln.)–$M:M_1$ (ppt.)	
Tl_2S — Re_2S_7	$TlReS_4$	$2Tl_2S\cdot Re_2S_7$—$3Tl_2S\cdot Re_2S_7$	127, 165

Tl_2S — PdS	$TlPd_2S_3$	$Tl_2S\cdot 4PdS$	164

The conclusions based on the results of the study of systems by the method of continuous variations alone are not sufficiently convincing, since this procedure involves the continuous variation of the amount of solid phase, which affects the degree of precipitation. This can probably account for the discrepancy between the results obtained in the study of the system Tl_2S–PbS by a thermal method, which indicates very limited miscibility [32], and by precipitation of the sulphides, which indicates unlimited miscibility of the solid solutions [164].

In connection with the formation in the system of several complex compounds or solid solutions and compounds, the method of preparation of double sulphides in the presence of a large excess of the coprecipitating metal is valid only if the formation of a single double sulphide has been proved. If the interaction takes place in a complex manner, the preparation of a stoichiometric sulphide requires the use of an acceptable excess, a more suitable acidity of the solution, or fusion.

1. Formation of Solid Solutions

A general defect of the studies relevant to this section is the lack of a rigorous proof of the individuality of the solid phases formed, as was the case in the fusion of the sulphides. Therefore sometimes, when the precipitation of solid solutions during coprecipitation is postulated, a clear distinction is not established between this process and the formation of double sulphides.

The possibility of the formation of a solid solution in the study of coprecipitation in the sulphide systems of zinc and manganese, cadmium and manganese, cadmium and mercury, manganese and mercury, and cobalt and tin was pointed out at an early stage by Feigl[7,161], who called such products "*misch*-sulphides", but this was disputed by Ruff and Hirsch.

The study of the interaction of the sulphides of indium and tin(IV), arsenic(III), bismuth, and cadmium[168,174] indicates the formation of solid solutions, the range of existence of which are various. The results have been explained by the similarity of the atomic radii and the crystallographic parameters, assuming the bonds in the sulphides to be covalent. However the conclusion[174] that "... with increase in the difference between the atomic radii of the metals replacing one another, the miscibility of the components in molecular solid solutions steadily diminishes" is controversial, since in reality similar degrees of coprecipitation have been obtained for pairs of metals differing appreciably in their radii.

The study of the interaction under similar conditions of the sulphides of gallium and tin(IV), copper(II), zinc, and cadmium[175-178] showed that the range of existence of the solid solutions depends on the similarity of the ionic radii of the metals and the ionic character of the metal–sulphur bond. Furthermore, it was established that the degree of precipitation of gallium is determined also by the concentrations of the metals in the initial solution when their relative amounts are kept constant. This is due to the concentration gradient of the coprecipitating element near the surface of the precipitate, caused by its rapid deposition. The subsequent equalisation does not have an appreciable influence on the process, since it is now determined by the diffusion coefficient of the coprecipitating metal in the solid phase. As an example, one may quote on the dissolution of indium coprecipitating with tin disulphide in hydrochloric acid of various concentrations, where it was established that, as the precipitate dissolves, the indium to tin ratio increases from 0.4 for the first portion to 0.8 when the precipitate has completely disappeared. The results suggest that, when solid solutions are formed, coprecipitation will be most complete in dilute solutions, since under these conditions a high degree of dispersion of the sulphide precipitate is maintained for a longer period. This creates favourable conditions for the system to approach a state of equilibrium. Indeed the degree of precipitation of gallium with zinc and copper sulphides increases as the concentration of the elements in the initial solution is reduced. Thus the above property of sulphide systems may serve as one of the criteria for the determination of the cause underlying the interaction of sulphides during their isolation from solution.

The results of the study of the interaction in the systems Tl_2S–As_2S_3 and Tl_2S–As_2S_5, where the existence of a limited region of solid solutions in the first system (100–62 mole % As_2S_3) and its absence in the second was demonstrated, confirm the conclusion of a significant role of metal ion dimensions in the process under discussion. The data concerning the unlimited miscibility in the systems Tl_2S–Sb_2S_3, Tl_2S–Sb_2S_5, and Tl_2S–SnS require revision, since the dimensions of the metal species differ appreciably from one another[179].

The lack of information about the ionic character of the bond for most of the sulphides described hinders the use of effective radii in the discussion of experimental data.

Thus in the formation of solid solutions of sulphides precipitated from solution the conditions established in the systems are not as severe as in fusion and therefore the degree of mutual replacement of the metals is less complete. This can probably explain the finding that in the region of solid solutions, even when the atomic or ionic radii and crystal chemical parameters are similar, the ratio of the metals in the precipitate does not exceed 1 : 0.1 (10%)[180,181].

The data on the effects of temperature on the interaction between sulphides in the formation of solid solutions are contradictory. Some workers believe that an increase of temperature reduces the degree of coprecipitation in the case of crystalline precipitates but has not effect if the sulphide is amorphous, while others think that it has no effect at all or increases the degree of coprecipitation[178,182,212].

The degree of coprecipitation of the metal depends to a considerable degree on the concentration of acid in the initial solution. This is because a decrease of acidity favours the precipitation of the second sulphide in consequence of secondary processes. In such cases the reason for the coprecipitation of the metal may be inferred only from X-ray diffraction data. Therefore sulphide systems must be studied under conditions such that the degree of coprecipitation is less than 100%. Then the formation of an independent or so called "colloidal" phase of the coprecipitating sulphide becomes impossible. The formation of the "colloidal" phase complicates the comparison of the conditions for the formation of solid solutions and double sulphides and the determination of the relations governing such processes. Evidently this can account for the discrepancy between the views of various workers on the effect of temperature and acidity of the medium on coprecipitation. The determination of the type of interaction of the sulphides from the chemical analysis of the solid phase precipitated is also doubtful[168].

Comparison of the data concerning the impurity content in minerals consisting of simple sulphides[183] confirms our earlier conclusion that the amount of impurities in compounds with a cubic lattice is much greater than for the same substances with a hexagonal lattice. Thus up to 26% of iron, 5% CdS, and 5.36% HgS have been found in cubic zinc sulphide, while in hexagonal zinc sulphide [the CdS content is (? Translator)] up to 8% and HgS was not detected. Manganese and zinc sulphides, which have similar effective radii and crystallise in the cubic system, contain a large number of metals at high concentrations. The impurities most frequently encountered are iron, copper, zinc, and manganese, which is probably due to the intermediate position of these metals in the series of effective radii.

An increase [decrease ? (Ed. of Translation)] in the content of isomorphous impurities in the series $Bi_2S_3 > Sb_2S_3 > As_2S_3$ takes place in parallel with the variation of the reactivity of the sulphides. This suggests that in this case complex sulphides and not solid solutions are formed.

The isomorphous substitution of elements in double sulphides can be followed most fully for compounds of the type $M_xE_yS_z$, where M^I = Cu or Ag, E^{III} = As, Sb, or Bi, $x = 1$ or 3, $y = 1$ or 3, and $z = 2$, 3, or 5. As the ratio M : E increases, there is an increase in the symmetry of the crystals of the complex sulphides, the impurity content, and the degree of mutual substitution of the E elements, but the degree of isomorphous substitution of the M elements diminishes.

Thus comparison of the relations obtaining in the formation of solid solutions formed by the fusion of sulphides or their precipitation from aqueous solution shows that in all cases the interaction in the systems is more complete when the radii of the metals corrected for the ionic charac-

ter of the M–S bond are similar and the crystal symmetry is high.

2. Formation of Complex Sulphides

There is less information about the interaction of sulphides during their precipitation from solutions (Table 7) than in the case of their heat treatment.

Hexavalent molybdenum and tungsten form thio-salts of the type $M^{I}_{2}ES_4$ derived from the corresponding acids H_2ES_4.[195,207-211] Infrared spectroscopic studies of the double sulphides in solutions and in the crystalline state showed that the existence of a tetrahedral configuration of sulphur atoms around the metal $[ES_4]^{n-1}$ is characteristic of elements in Groups V and VI, for which the existence of E=S double bonds has been demonstrated. The characteristic frequency of the E–S stretching vibrations is in the range 400–500 cm^{-1} [101,166,194]. Other elements, including rhenium(VII), do not form ions of this type, and therefore investigators [195,196] rejected the possibility of the formation of the thio-salts $KReS_4$ and $TlReS_4$. The absence of the E=S double bonds [194,197] in $[AsS_4]^{3-}$ and $[SbS_4]^{3-}$ also throws doubt on the salt-like nature of these compounds.

Table 7. Composition of double sulphides obtained by co-precipitation from solution [127,129,130,164,165,167-171,173,176-179,184-193,213].

$2Bi_2S_3 \cdot 3Ga_2S_3$	30						
$2Bi_2S_3 \cdot Ga_2S_3$	18						

Apart from the double sulphides quoted in Table 7, a number of others, where the metals are in an unusual valence state, have been described in the literature. These include $TlSnS_2$, $TlMoS_2$, $TlIn_2S_3$, $TlGeS_2$, $Tl_3Sb_2S_2$, Tl_3Ir_3S, $TlRh_2S_4$, $TlRu_2S_6$, $TlPd_2S_3$, $TlPtS_3$, $InGe_3S_5$, and ZnS.GaS.[166,198] According to data derived by physico-chemical analysis, the inflections in the coprecipitation curves reflect only the ratio of the metals in the compound formed. The sulphur content is determined by chemical analysis preceded by washing and drying of the precipitate, which can lead to a change in its composition. Indeed formulae for certain sulphides can be written assuming the metal to be present in different valence states, for example, $TlSnS_2$–$Tl_2S.SnS.SnS_2$, $TlIn_2S_3$–$Tl_2S.2InS.In_2S_3$, $InGe_3S_5$–$InS.2GeS.GeS_2$, etc. All the simple sulphides quoted here are obtained as a rule at elevated temperatures.

A general feature of the compounds listed in Table 7 is the fact that the sum of the valence electrons of the metal is a multiple of four (for the majority of the sulphides). As for the double sulphides obtained by the thermal method, these can be divided into two similar groups: metals with even or odd and mixed valences having analogous properties. It is interesting to note that some of the compounds listed have also been obtained by the thermal method, for example $Cu_2S.In_2S_3$, $Ag_2S.In_2S_3$, $Tl_2S.In_2S_3$, $ZnS.Ga_2S_3$, etc.

The results quoted show that, in their interaction, simple sulphides tend to form definite compounds regardless of the method used. The acid–base properties of the simple sulphides are not of decisive importance for their reactivity.

Methods of Synthesis of β-Substituted Furan Derivatives

L.D.Krasnoslobodskaya and Ya.L.Gol'dfarb

The review describes the methods of synthesis of β-substituted furan derivatives. Particular attention was devoted to the methods based both on furan itself and its α-monosubstituted derivatives. This approach to the problem arises from the fact that at the present time compounds of the furan series, for example furfural, furan, silvan, etc. are readily available and are manufactured on a commercial scale. The bibliography includes 202 references.

I. INTRODUCTION

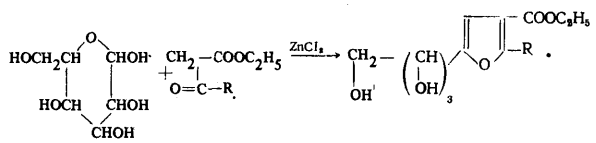
The most important distinctive feature of the furan system consists in its vigorously defined mode of interaction with electrophilic and nucleophilic agents: in all cases, when at least one α-position in the ring is free and the second α-position is not substituted by a very active group, for example a keto-group, the new substituent enters the α-position whatever its nature [1]. This gave rise to a definite trend in the development of the chemistry of furan. As a result α-mono- and αα'-di-substituted furan derivatives constitute so far the main bulk of the synthesised and investigated compounds of the furan series. At the same time many β-substituted derivatives have been obtained by an "indirect" method involving, in particular, the ring closure of the corresponding open-chain derivatives, which are frequently not readily available. However, it is evident that the interest in β-substituted furan derivatives will increase, since they are often encountered in natural products and sometimes exhibit physiological and other activity different from that of the isomeric compounds with substituents in the α-positions. As an example, one may quote the importance of the position of the nitro-group as a factor responsible for antibacterial activity [2].

II. METHODS OF SYNTHESIS OF TRI- AND TETRA-SUBSTITUTED FURAN DERIVATIVES

Since tri- and tetra-substituted furan derivatives (mainly tri-substituted) are the starting materials in the synthesis of β-mono-, 2,3-di-, and 2,4-di-substituted furan derivatives, it is desirable to describe in the first place the general methods for the preparation of these compounds.

1. Syntheses Based on Aliphatic β-Dicarbonyl Compounds

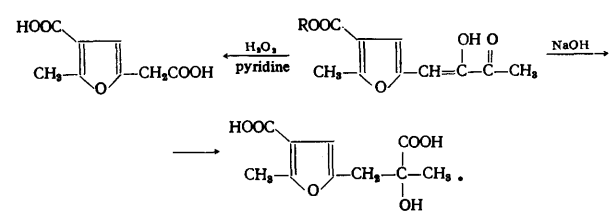
α-Substituted esters of furan-3-carboxylic acid (II) have been obtained by the reaction of acetoacetic ester, benzoylacetic ester, or the ester of acetonedicarboxylic acid with aldoses (I):[3,4]



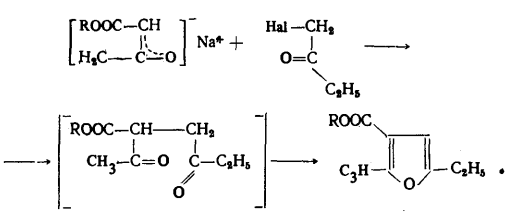
(I) (II)

Compound (II, R = CH_3) has been oxidised with potassium permanganate to 5-methylfuran-2,4-dicarboxylic acid and with periodic acid to the ester of 2-formyl-5-methylfuran-carboxylic acid.

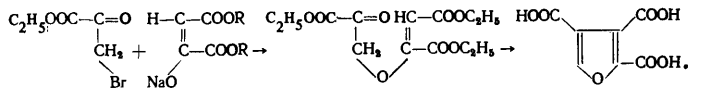
Recently Dalton [5] showed that, when compound (II) is heated in an ethanolic solution of hydrogen chloride, an α-diketone is formed. Under the action of hydrogen peroxide, the diketone is converted into 2-carboxymethyl-5-methylfuran-4-carboxylic acid, while in the presence of alkali it undergoes a benzilic acid rearrangement:



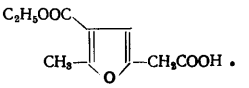
Tri-substituted furan derivatives are also obtained in the interaction of sodioacetoacetic ester and similar compounds with α-halogeno-ketones:[6-8]



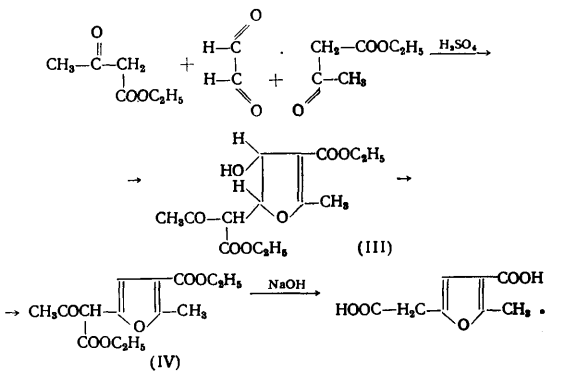
At the same time there are reactions regarded as examples of the interaction of an α-halogenocarbonyl compound with the sodio-derivative of a β-dicarbonyl compound via the oxygen atom. For example, Reichstein[9] described the reaction of the sodio-derivative of the oxaloacetic ester with monobromopyruvic acid, which was converted into furan-2,3,4-tricarboxylic acid:



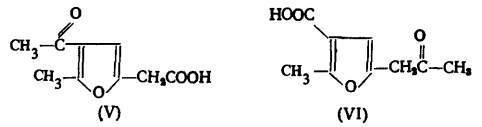
If the process proceeded via a 1,4-dicarbonyl compound, as suggested by Sutter[10], the reaction product would have been furan-2,3,5-tricarboxylic acid. When the acetoacetic ester is heated with the disodium salt of succinic acid in acetic anhydride, the monoethyl ester of 4-carboxy-5-methylfuran-2-acetic acid is formed:



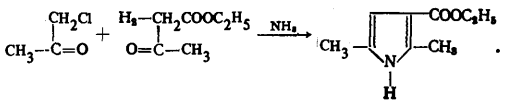
This synthesis was achieved for the first time by Fittig[11] and then by Reichstein and Grüssner[12]. Patent data published in 1959 show[13] that 4-carboxy-5-methylfuran-2-acetic acid can also be obtained by the condensation of acetoacetic ester with glyoxal in an acid medium:



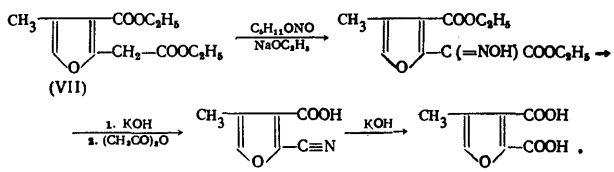
It has been shown that the process takes place via stages involving the formation of compounds (III) and (IV). The Fittig reaction was repeated in 1963 with acetylacetone by Suverkropp and Wynberg[14], who obtained 4-acetyl-5-methylfuran-2-acetic acid (V), which was then converted by decarboxylation into 3-acetyl-2,5-dimethylfuran. It proved to be identical with the product formed in the acylation of 2,5-dimethylfuran[15]. It is noteworthy that the structure of the isomeric 5-acetonyl-2-methylfuran-3-carboxylic acid (VI) was previously incorrectly attributed to compound (V):[16]



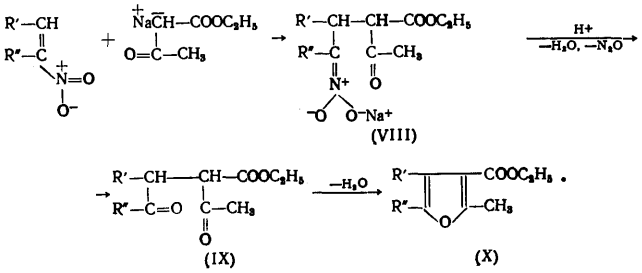
The syntheses of Feist[17] and Benary[18] are very close to the reactions of the sodio-derivatives of β-dicarbonyl compounds with α-halogeno-ketones. They consist in the interaction of β-dicarbonyl compounds with α-halogeno-ketones[17] or with α-chloroacetaldehyde[18] in ammonia. These reactions usually result in a mixture of pyrrole and furan derivatives, the relative amounts of which depend on the nature of the β-dicarbonyl compound employed. Thus, when acetoacetic ester is used, pyrrole derivatives are mainly obtained (the Hantzsch reaction):



With acetonedicarboxylic acid, the formation of the furan derivative (VII) predominates[17,19]. Starting with compound (VII), Rinkes[20] and Reichstein[19] achieved almost simultaneously the synthesis of 4-methylfuran-2,3-dicarboxylic acid, which can be illustrated by the following scheme:



Boberg and Schultze[21] synthesised a number of tri- and tetra-substituted furan derivatives by the reaction of sodioacetoacetic ester with α-nitro-olefins:

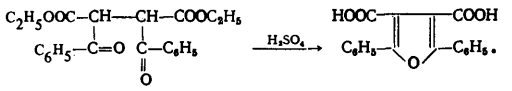


The sodium salt of the nitronic acid (VIII) underwent the Nef reaction under the influence of cold mineral acid[22] and was converted via the 1,4-dicarbonyl compound (IX) into esters of furan-3-carboxylic acid (X). By hydrolysing compound (X) and decarboxylating the acid, it is possible to obtain 2,3,5-trisubstituted furan derivatives.

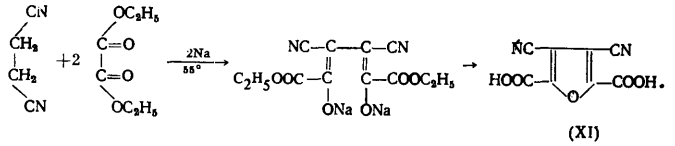
2. Syntheses from Saturated and Unsaturated 1,4-Diketones and 1,4-Keto-alcohols

The oldest method for the preparation of furan derivatives from aliphatic compounds is the cyclodehydration of the dienol forms of 1,4-diketones. As early as 1884, Bayer and Perkin[23] converted dibenzoylsuccinic ester into

2,5-diphenylfuran-3,4-dicarboxylic acid by refluxing for 20 h with 30% sulphuric acid:



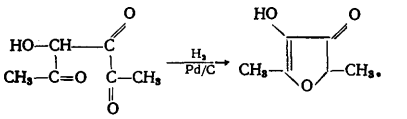
3,4-Diacetyl-2,5-dimethylfuran was obtained similarly by the action of hydrochloric acid on tetra-acetylethane [24,25]. In 1941 Trefil'ev and Lifanov [26] repeated this synthesis using hydrobromic acid. Subsequently an American patent was published, in which the preparation of the acid (XI) according to the scheme



(XI)

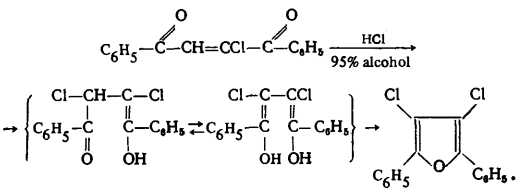
was described [27].

In 1956 Hoffmann and Eugster [28] synthesised the principal aromatic components of the pineapple fruit—3-hydroxy-2,5-dimethyl-4,5-dihydrofuran-4-one (XII):

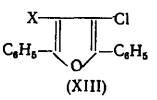


(XII)

The synthesis of tetrasubstituted furan derivatives from unsaturated 1,4-diketones was investigated in detail by Lutz and McGinn [29] using dibenzoylethylenes. They assumed that probably ring closure precedes the addition of the reagent in the 1,4-positions favouring cyclisation. Both *cis*- and *trans*-dibenzoylchloroethylenes react with hydrogen chloride in 95% alcohol forming 3,4-dichloro-2,5-diphenylfuran:



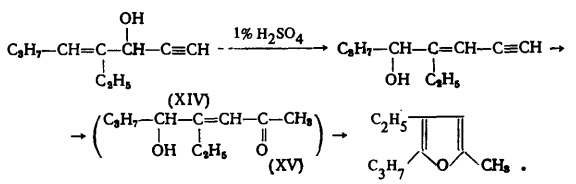
The reaction of *cis*-dibenzoylchloroethylene with acetyl chloride or acetic anhydride in the presence of sulphuric acid yields chloro- or acetoxy-furans (XIII):



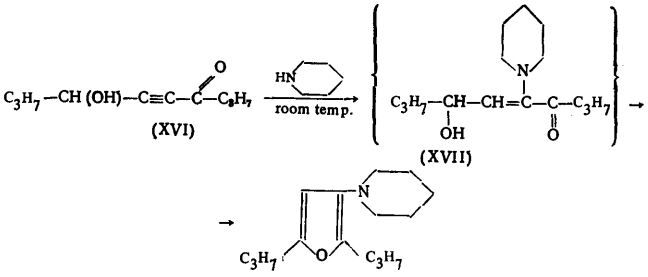
(XIII)

where X = Cl or $CH_3C(=O)-O-$.

Heilbron et al. [30] showed that enyne alcohols (XIV) are cyclised into a furan system during distillation with 1% sulphuric acid, probably via an intermediate keto-alcohol (XV):

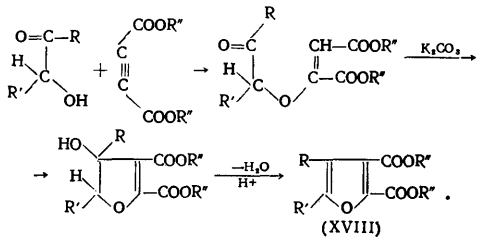


Cyclisation also takes place when piperidine is allowed to act upon the keto-alcohol (XVI), evidently also via an ethylenic 1,4-keto-alcohol (XVII):[31]



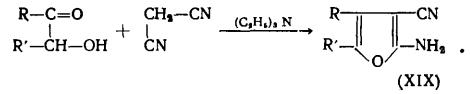
3. Other Syntheses of Aliphatic Compounds

Furan derivatives with the structure (XVIII) have been obtained by the condensation of the esters of acetylene-dicarboxylic acid with an α-hydroxy-ketone [32]:



(XVIII)

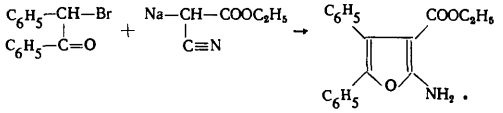
In 1966 Gewald [33] stated that the dinitrile of malonic acid readily reacts with α-hydroxy-ketones in the presence of bases, forming 2-amino-3-cyanofurans (XIX):



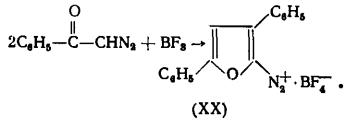
(XIX)

4-Acetyl-2-amino-3-cyano-5-methylfuran, analogous to compounds (XIX), had been synthesised earlier [34] from the dinitrile of malonic acid and 3-chloroacetylacetone. In contrast to the unsubstituted 2-aminofuran, these amino-furans are relatively stable. Only compounds (XIX) with a free α-position are sensitive to oxygen.

2-Amino-3-ethoxycarbonyl-4,5-diphenylfuran was obtained by the reaction of α-bromodeoxybenzoin with the sodio-derivative of cyanoacetic ester in ethanol [35]:



The first compound with a diazo-group in the furan ring, 2,4-diphenylfuran-5-diazonium fluoroborate (XX), was synthesised in 1963 by Reid and Bodenstedt [36], who allowed benzoyldiazomethane to react with boron trifluoride-ether:



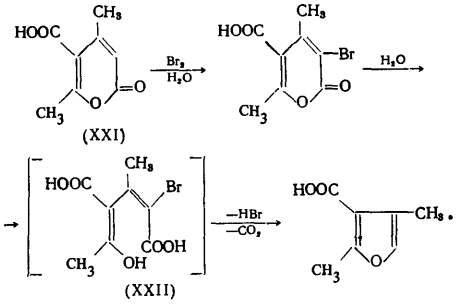
(XX)

It is noteworthy that the mechanisms of most of the reactions described above have an inadequate basis and the equations quoted must be regarded as only approximate.

The syntheses involve certain difficulties: frequently mixtures difficult to separate are formed and the yields of the desired products are as a rule low.

4. Syntheses from Other Cyclic Systems

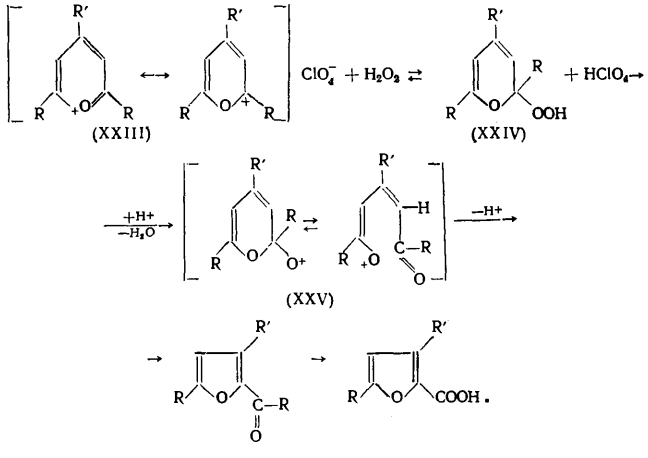
In his study of the bromination of α-pyrone derivatives Feist observed [37] that in some cases the reaction can be used to synthesise furan compounds. According to the suggested mechanism, dimethylcoumalic acid (XXI) gives rise to 2,4-dimethylfuran-3-carboxylic acid, probably via the intermediate (XXII):



(XXI)

(XXII)

In 1960 Balban and Nenitzescu [38] published a paper in which the synthesis of trialkyl-substituted furan derivatives from pyrylium salts is proposed. Earlier only one similar case of the contraction of the pyran ring in the hydrolysis of 2,4,5,6-tetraphenylpyrylium bromide had been described [39]. It was found [38] that, under the action of hydrogen peroxide, the readily available trialkylpyrylium perchlorates (XXIII) are converted into 3,5-dialkyl-2-acylfurans. These ketones were oxidised to the corresponding 3,5-dialkylfuran-2-carboxylic acids, whereby their structure was confirmed:



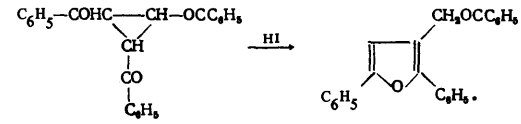
(XXIII)

(XXIV)

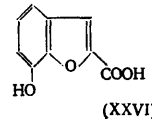
(XXV)

In this reaction the α-position of the pyran ring is subjected to nucleophilic attack by hydrogen peroxide and this gives rise to the peroxy-analogue of the pseudo-base (XXIV), which decomposes under the action of the acid formed. The formation of the furan ring favours the irreversible stabilisation of the cation (XXV).

Certain trisubstituted furan derivatives can be obtained from cyclopropane derivatives. For example, when concentrated hydriodic acid is allowed to act on *cis*- and *trans*-tribenzoylcyclopropanes, 2,5-diphenyl-3-phenylacetylfuran is formed [40]:

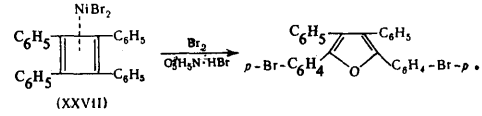


Furan-2,3,5-tricarboxylic acid was obtained from 7-hydroxycoumarone-2-carboxylic acid (XXVI) by oxidation with hydrogen peroxide in an alkaline solution [41]. In compound (XXVI) the benzene ring becomes sensitive to oxidation by virtue of the presence of the hydroxy-group, but the furan ring is stable [42] with respect to the action of hydrogen peroxide in an alkaline medium, particularly when it contains a carboxy-group:



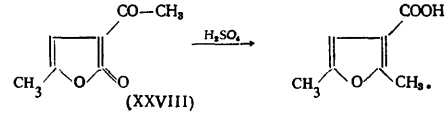
(XXVI)

Comparatively recently it has been established [43] that substituted furans may be obtained in high yield from the nickel bromide complex of tetraphenylcyclobuta-1,3-diene (XXVII) by treatment of the latter with bromine in the presence of pyridine hydrobromide which had been kept in moist air:



(XXVII)

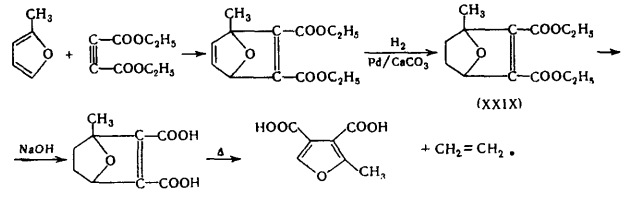
βγ-Unsaturated α-acyl-lactones can be readily converted into furancarboxylic acids. For example, 2,5-dimethylfuran-3-carboxylic acid is obtained smoothly from α-acetylangelicalactone (XXVIII):[44]



(XXVIII)

5. Preparation from α-Monosubstituted Furan Derivatives by Successive Diene and Retrodiene Syntheses

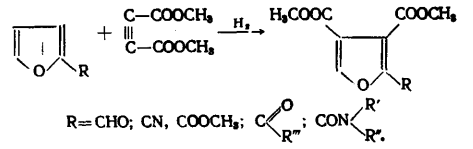
Adler and Rickert [45] showed that the adduct obtained by the addition of the diester of acetylenedicarboxylic acid to silvan can be partially reduced with hydrogen over a palladium catalyst. The product (XXIX) is converted into 2-methylfuran-3,4-dicarboxylic acid on hydrolysis and heating (retrodiene synthesis):



(XXIX)

Similarly the corresponding 2,3,4-trisubstituted furan derivatives were obtained from 1-acetamido-1-(fur-2′-yl)-ethane [46] and the acetal of furfural [47]. Recent investigations [48,49] revealed the capacity of furan derivatives substituted in the α-position by electron-acceptor groups to

react as dienes with the dimethyl ester of acetylenedicarboxylic acid:

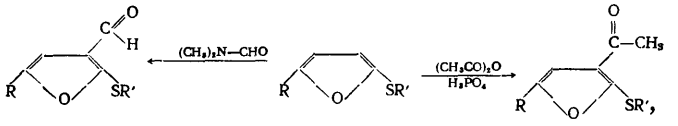


The method of consecutive diene and retrodiene syntheses is used[50] to identify the α- and β-furyl residues in natural products since furan-3,4-dicarboxylic acid is formed from mono-β- or $\beta\beta'$-disubstituted derivatives[51,52] as a result of the reactions described above, while mono-α-derivatives yield trisubstituted furan.

6. Substitution Reactions of α-Monosubstituted Furan Derivatives

The vast majority of known trisubstituted furan derivatives have been obtained by the electrophilic substitution of readily available mono-α-substituted furans: silvan, furfural, and pyromucic acid and its esters. It is generally known that, regardless of its nature, a new substituent enters into the second α-position in the ring of an α-monosubstituted furan. The possibility of further substitution in the β-position depends on the type of substituents already present in the α- and α'-positions and on the nature of the attacking reagents.

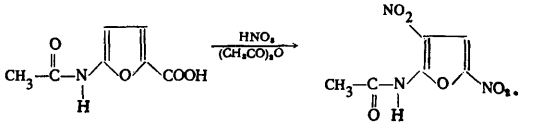
If the α-positions of the ring are substituted by two identical electron-donor groups, the introduction of a third substituent, although possible, is hindered as a result of the competing reaction involving the opening of the furan ring or the displacement of one of the existing groups by the attacking reagent[53]. For example, 2,5-dimethylfuran may be nitrated[54], chloromercurated[55], sulphonated[56], and acylated[7] in the β-position, but it does not undergo the Gattermann–Koch reaction[57]. In this case the ring is opened and acetonylacetone is formed. For furan derivatives with two electron-donor non-identical substituents in the α-position, only isolated examples of the introduction of β-substituents are known, since the reaction is usually accompanied by the opening of the furan ring. Examples are the acylation and formylation of 2-alkyl-5-alkylthiofurans (XXX).[58] The new substituent occupies the β-position adjacent to the alkylthio-group:



(XXX)

where R and R′ = alkyl.

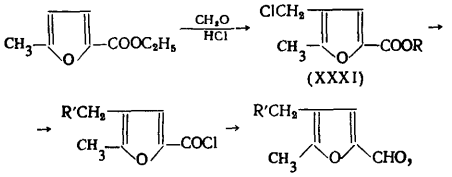
Examples of the formation of trisubstituted furan derivatives when the α- and α'-positions of the ring are occupied by different electronegative groups are encountered rarely; in the main they occur with compounds having two identical electron-acceptor groups. For example, the diethyl ester of furan-2,5-dicarboxylic acid can be mercurated[59] and chlorinated[60] but not brominated[61–63]. Furan-2,5-dicarboxylic acid is inert with respect to reagents such as aqua regia, fuming nitric acid, bromine, and concentrated sulphuric acid[55]. The greatest number of β-substitution reactions is known for $\alpha\alpha'$-disubstituted furans in which one group is an electron donor and the other an electron acceptor. These are mainly substituted esters of furan-2-carboxylic acid[64–77]. The work of Sasaki[78] on the nitration of 2,5-disubstituted furan derivatives with substitution should be mentioned:



The replacement of the carboxy-group by a nitro-group takes place with best yields in the case of electron-donor groups in the α'-position of the furan ring.

The introduction of two substituents into the furfural molecule[79] or silvan molecule[56,80,81] has been described, but such cases are rare; they include, in particular, the syntheses[82,83] of 4,5-dibromofurfural and 2-acetyl-4,5-dibromofuran in one stage using aluminium chloride without solvent. Under the conditions of the bromination of furfural[84] or its acylal[85,86] in a solvent without aluminium chloride, 5-bromofurfural is formed. Apart from the procedures described above, there are also others leading to trisubstituted furans, for example from 3,4-disubstituted[87,88], 2,3-disubstituted[88,89], and 2,4-disubstituted[79,90,91] derivatives, but these are of limited applicability.

A series of papers dealing with the synthesis of new tri- and tetra-substituted furan derivatives via the reactions of groups already present in the furan ring have been published. Among these one should mention the investigation of Mndzhoyan et al. of the synthesis of the chloroacetyl-, β-chloropropionyl-, and p-nitrobenzoyl-amides of 4,5-disubstituted furan-2-carboxylic acid[95] and of the preparation of the ethyl ester of 4-chloromethyl-5-methylfuran-2-carboxylic acid[67] (XXXI) and its conversion into 4,5-dimethylfuran-2-aldehyde[68], 5-bromoethyl-4-chloromethylfuran-2-carboxylic acid[92], 2-dimethylaminoethyl ester of 4-benzyl-5-methylfuran-2-carboxylic acid[92], and 4-benzyl-5-methylfuran-2-aldehyde[94], from which the nitrile, amide, and amine were obtained:



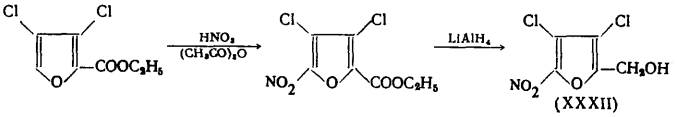
(XXXI)

where R = H or C_2H_5 and R′ = H or C_6H_5.

Janda and coworkers[96,97] synthesised the methyl ester (XXXI) from 5-acetylsilvan and replaced the chloromethyl group by an aldehyde group.

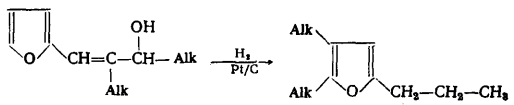
In a study of the possibility of the allyl rearrangement in certain tetrasubstituted furans, for example in 3,4-dichloromethyl-2,5-dimethylfuran under the action of sodium cyanide, Novitskii et al.[98] obtained certain new tetrasubstituted furans. They also synthesised[99] a number of trisubstituted furans.

Michels[100] described the conversion of the ester of 3,4-dichlorofuran-2-carboxylic acid into the alcohol (XXXII):

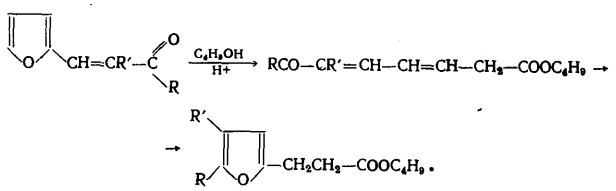


(XXXII)

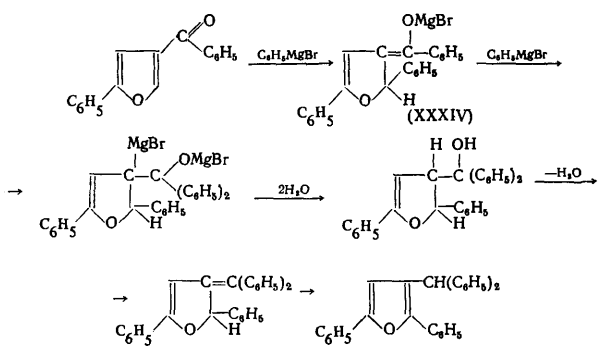
There exist patent data[101] concerning the synthesis of trialkylfurans (XXXIII) by a procedure involving a catalytic hydrogenation stage over platinum:



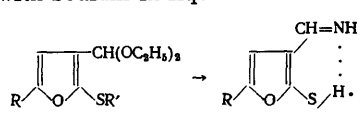
Esters of 4,5-dialkylfuran-2-propionic acids were obtained from fur-2-ylalkenones by acid-catalysed alcoholysis[102]:



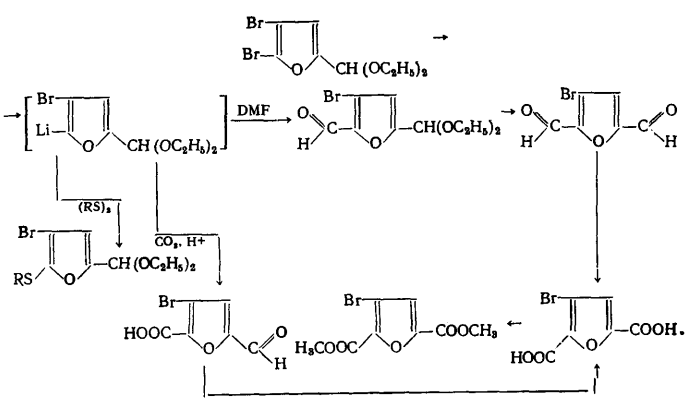
An example of the synthesis of a trisubstituted furan from a 2,4-disubstituted derivative, 4-benzoyl-2-phenylfuran, has been described[103]. In this case probably one phenylmagnesiumbromide molecule adds initially to the 1,4-positions of the conjugated system and the second molecule to the double bond of compound (XXXIV):



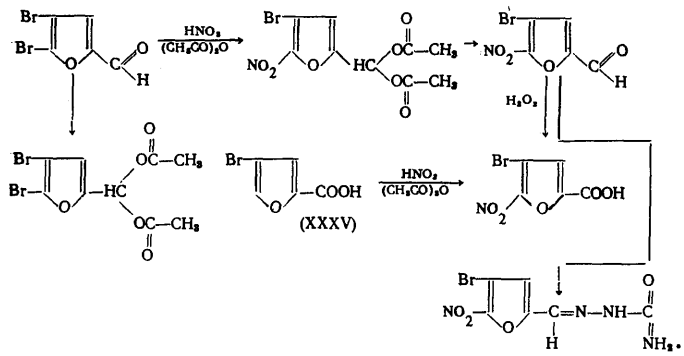
Like the corresponding acetals of the thiophen series[104], the acetals of 5-alkyl-2-alkylthiofuran-3-aldehydes are converted[105] into 5-alkyl-2-mercaptofurfurylideneimines on treatment with sodium in liquid ammonia:



By virtue of the inertness of the acetalised aldehyde group to the action of butyl-lithium, it proved possible to synthesise from 4,5-dibromofuran-2-aldehyde[82,83] the previously unknown sulphides, dialdehydes, and diesters with a bromine atom in the β-position of the ring[106]:



New nitro-derivatives, which may prove of interest as antibacterial agents, were also obtained by the substitution of a bromine atom in the α-position by a nitro-group[106]. The substitution of bromine in the α-position[84,107] by a nitro-group in the furan series is not always possible.



It is noteworthy that the present authors were able to nitrate the acid (XXXV) with formation of 4-bromo-5-nitrofuran-2-carboxylic acid. Judging from the literature data[72], in the nitration of compound (XXXV) the furan ring cleaves to form bromofumaric acid.

III. METHODS OF SYNTHESIS OF MONO-β-SUBSTITUTED FURAN DERIVATIVES

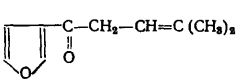
The information about the preparation of β-monosubstituted furan derivatives is extremely limited; this is undoubtedly because of the difficulties associated with their synthesis. In fact up to 1933 not a single mono-β-substituted furan had been obtained. Only isolated cases of the introduction of a substituent in the β-position of an unsubstituted furan molecule were described. When furan is alkylated with propene in the presence of boron trifluoride-ether, a very small amount of the isomeric mono-β-alkyl derivative is formed together with the α-isomer[108]. By alkylating furan with isobutene and pentene in the presence of phosphoric acid on kieselguhr, it is possible to obtain[109] β-alkylfurans with acceptable yields, but containing an admixture of α-isomers. It is interesting to note that 2-t-butylfuran isomerises[109] over this catalyst to 3-t-butylfuran. Nevertheless these data have no value when the aim is to synthesise β-monosubstituted furans.

We shall now examine the methods available at present for the preparation of β-monosubstituted furan derivatives.

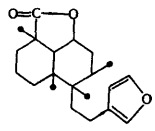
1. Isolation from Natural Products

The first known 3-monosubstituted furan, furan-3-carboxylic acid, was not synthesised but was isolated from plants[110,111]. The principal component of perilla oil is 3-furyl isopentyl ketone[112,113]. The oil also contains 3-(4'-methylpent-3'-enyl)furan[113,114]. Each year there is an increase in the number of β-monosubstituted furan derivatives discovered as constituents of natural materials[50,115-118].

In 1962 a ketone with the following structure was obtained from perilla oil[119]:

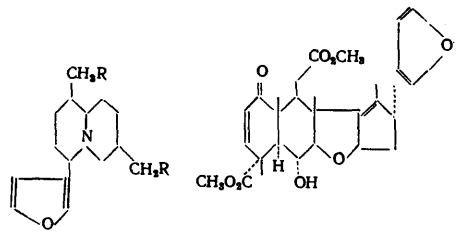


The following structure has been proposed for marrubiin, which incorporates a non-condensed 3-substituted furan ring[120]:

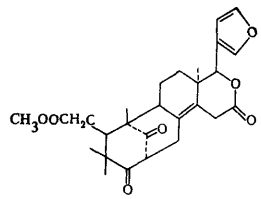


The structure of this compound was confirmed[121] by additional data.

It is suggested[122,123] that the β-furyl residue is a structural component of the castoramine molecule and "nimbinic acid", to which the following structures are attributed respectively:

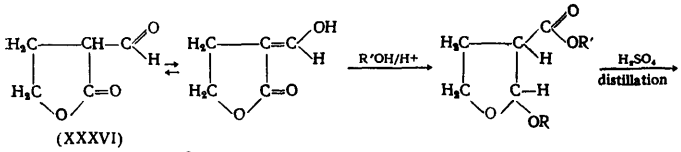


The following structure has been assigned to mexicanolide, a natural lactone[124]:

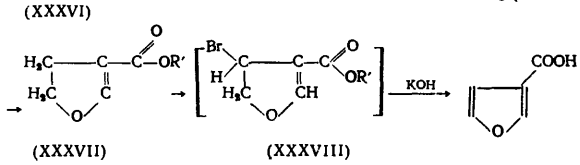


2. Cyclisation of Aliphatic Compounds

There are very few examples of the preparation of β-monosubstituted furan derivatives by direct ring closure of aliphatic compounds. The method of synthesis of furan-3-carboxylic acid, proposed fairly recently, is interesting. α-Formyl-γ-butyrolactone (XXXVI) is obtained from the readily available γ-butyrolactone formed[125] by the dehydration of butane-1,4-diol and subsequent condensation with formic ester[44]:

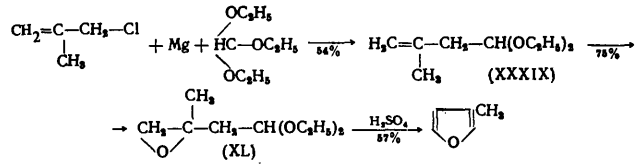


(XXXVI)

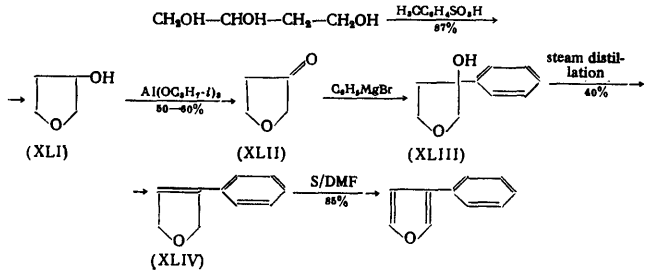


(XXXVII) (XXXVIII)

The rearrangement[44] of this lactone to the ester of 4,5-dihydrofuran-3-carboxylic acid (XXXVII) and bromination[126] of the latter by *N*-bromosuccinimide leads to an unstable product (XXXVIII), which is converted by treatment with aqueous alkali into furan-3-carboxylic acid with 58% yield[126]. A convenient three-stage synthesis of 3-methylfuran has been described[127]. The diethyl acetal of 3-methylbut-3-enal (XXXIX), formed by the reaction of methylallyl chloride, magnesium, and orthoformic ester, is converted by oxidation with perphthalic acid into the epoxide (XL), the hydrolysis of which yields 3-methylfuran:



Wynberg[128] synthesised 3-phenylfuran from 1,2,4-trihydroxybutane:



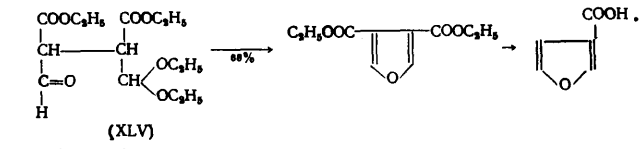
Compounds (XLI), (XLII), and (XLIII) were obtained for the first time by Yur'ev and Korobitsyn[129,130].

The last stage in the conversion of 3-phenyl-2,5-dihydrofuran (XLIV) into 3-phenylfuran, in 2–3% solution of sulphur in dimethylformamide, requires special attention. When 3-hexyl-2,5-dihydrofuran is treated similarly[128] with a solution of sulphur in dimethylformamide, the expected results are not achieved. This method is particularly interesting, since the attempt[128] to prepare 3-phenylfuran from 3-phenylfuran-2-carboxylic acid, synthesised by a standard method[131], proved unsuccessful.

3. The Removal of Two or One Substituents from Tri- and Di-substituted Furan Derivatives

The structure of furan-3-carboxylic acids isolated from a natural product was confirmed in 1932 by Reichstein[132], who obtained it by the decarboxylation of furan-2,3-dicarboxylic acid (see p. No. 401). A year later Reichstein prepared it[133] by the decarboxylation of furan-3,4-dicarboxylic acid. When furantetracarboxylic acid is heated to 270°C, furan-2,3,4-tricarboxylic and furan-3,4-dicarboxylic acids are formed. On heating with copper in quinoline, the latter yields furan-3-carboxylic acid.

Gilman showed[134] that furan-3-carboxylic acid can be obtained by the decarboxylation of furan-2,4-dicarboxylic acid. In connection with the development[135] of a relatively simple method for the synthesis of furan-3,4-dicarboxylic acid, consisting in the cyclisation of the diethyl ester of 2-diethoxymethyl-1-formylsuccinic acid (XLV), there arose the possibility of the direct synthesis[136] of furan-3-carboxylic acid:

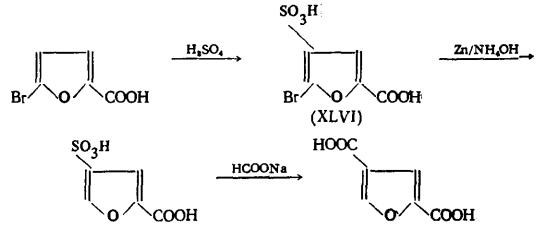


(XLV)

Probably this method is the most convenient preparative procedure.

3-Methylfuran has been obtained[19,20] by the decarboxylation of 4-methylfuran-2,3-dicarboxylic acid and also 3-methylfuran-2-carboxylic acid[131,137,138].

3-Nitrofuran was prepared by Rinkes[65] from 5-methyl-4-nitrofuran-2-carboxylic acid. Its decarboxylation yielded[77] 2-methyl-3-nitrofuran, which was oxidised to 4-nitrofuran-2-carboxylic acid, the latter being decarboxylated to 3-nitrofuran in 18% yield. Furan-3-sulphonic acid was also obtained[139] by the elimination of substituents from the α-positions of a trisubstituted furan, namely 5-bromo-4-sulphofuran-2-carboxylic acid (XLVI). The latter was synthesised for the first time by Hill and Palmer[140] by treating 5-bromofuran-2-carboxylic acid with fuming sulphuric acid. However, they did not establish which of the two β-positions was substituted by the sulpho-group. The structure of the acid (XLVI) was confirmed by Gilman[69] by means of reactions leading to the formation of the known furan-2,4-dicarboxylic acid:

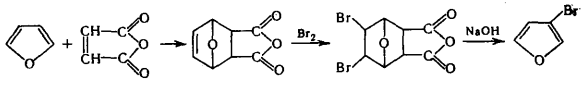


Treatment of compound (XLVI) with an equimolar amount of bromine by a standard method[141] yielded 2,5-dibromofuran-3-sulphonic acid[139], which was converted into furan-3-sulphonic acid by Hills method[140].

β-Halogenofurans may be obtained[53,142] by the removal of three halogen atoms from tetrahalogenofurans. However, this method cannot be regarded as convenient because of the difficulty of synthesising the starting materials and because the reaction products are obtained in low yields. 3-Bromofuran and 3-chlorofuran were obtained[143] from 4,5-dibromo-, 4,5-dichloro-, and 3,4-dichloro-furan-2-carboxylic acids by the action of zinc in aqueous ammonia followed by decarboxylation in quinoline in the presence of copper.

Certain doubts have been expressed about the method of preparation of 3-bromofuran[144]. They concerned the reproducibility of the yields in the bromine elimination stage. Consequently Gronowitz and Sorlin suggested that 3-halogenofuran, namely 3-iodofuran, be obtained from furan-2-carboxylic acid via 3-chloromercurifuran (see p. 397).

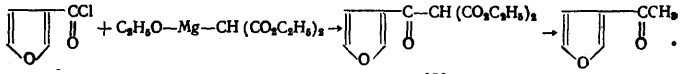
There exist also other indirect methods for the introduction of a halogen into position 3 of the furan ring, for example by the bromination of the adduct of furan and maleic anhydride[145]:



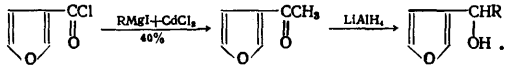
4. Syntheses Based on Furan-3-carboxylic Acid

Among the β-derivatives of furan, furan-3-carboxylic acid is the most readily available and the most frequently used starting material in various syntheses. The preparation from it of 2,4-disubstituted furan derivatives is described below (see p. 399). The syntheses of a number of β-monosubstituted furan derivatives, consisting in the conversion of the carboxy-group, will be examined here. Gilman obtained[134] furan-3-aldehyde by the Rosenmund reduction of the chloride of furan-3-carboxylic acid and the reduction of furan-3-aldehyde by the Wolff–Kishner method gave 3-methylfuran. Monosubstituted β-ketones, individual representatives of which are encountered in natural products[112,113,119], remained inaccessible for a very long time. Information[146] about their preparation included no data concerning the experimental conditions and the constants and analyses of the desired products. This made it difficult for other investigators to repeat the syntheses[147].

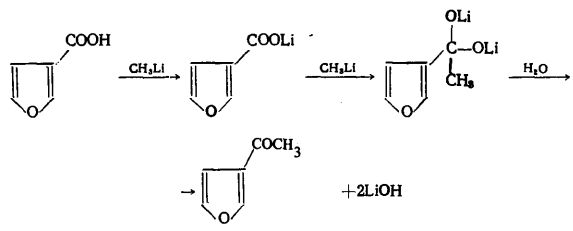
Kubota and Naya[148] obtained in 1956 3-acetylfuran in 86% yield by the Reynolds method[149] from the chloride of furan-3-carboxylic acid:



In 1959 Grunanger and coworkers[150] synthesised in low yields a number of alkyl 3-furyl ketones by the reaction of the chloride of furan-3-carboxylic acid with organocadmium compounds. The ketones were reduced to the corresponding alcohols in high yields:

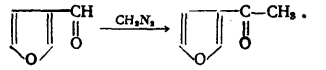


Somewhat later Gronowitz and Sorlin[147] obtained 3-acetylfuran from furan-3-carboxylic acid by Tegner's reaction[151] consisting in the interaction of methyl-lithium with carboxylic acids:

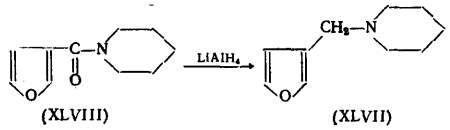


The constants of 3-acetylfuran (a crystalline compound) and its semicarbazone, quoted in these papers, agree, but differ from the data of Gilman et al.[146], who described 3-acetylfuran as liquid.

The work of Capuano[152], which has hardly any preparative value for the synthesis of 3-acetylfurans because its yield is too low, should also be mentioned:



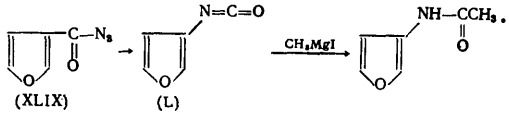
In connection with studies on the alkaloids of the yellow lily, *N*-(fur-3′-ylmethyl)piperidine (XLVII) was synthesised[136] by the reduction of *N*-(3-furoyl)piperidine (XLVIII):



(XLVIII) (XLVII)

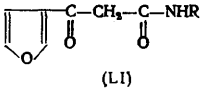
The history of one synthesis based on furan-3-carboxylic acid, namely the preparation of 3-acetamidofuran, is interesting. When this investigation was undertaken[153], the author could hardly suppose that subsequently it might prove to be of value for the demonstration of the structure

of a natural product. It was found that, when *N*-acetyl-D-glucosamine and *N*-acetyl-D-galactosamine, which form part of the polysaccharides of chitin and cartilage, were treated[154] with a solution of sodium carbonate, furan compounds were formed, one of which is 3-acetamidofuran. Its structure was confirmed[155] synthetically by repeating the Burtner synthesis[153]. Furan-3-carboxylic acid was converted into its chloride in 60% yield. Under the conditions specified by Naegeli and Stefanovitsch[156], the latter reacted with sodium azide to give 3-furoyl azide (XLIX) in 80% yield. Subsequently this azide was subjected to the Curtius rearrangement and was converted in 60% yield into the isocyanate (L), from which 3-acetamidofuran was obtained in 41% yield by the action of methylmagnesium iodide:



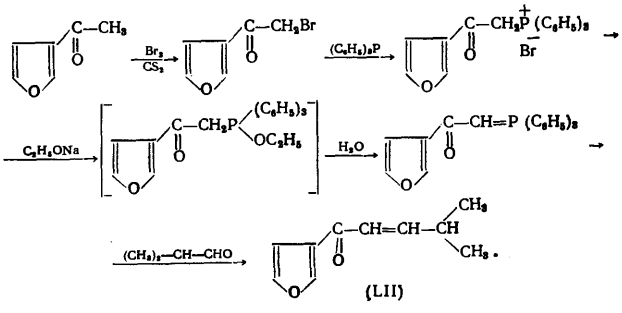
(XLIX) (L)

Starting from furan-3-carboxylic acid, Wul'fson and Kolchin[157] synthesised the substituted amides (LI) of 3-furoylacetic acid:



(LI)

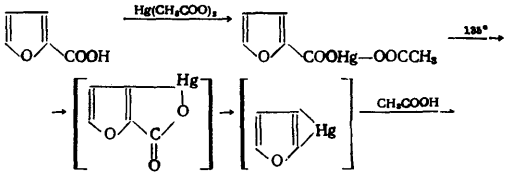
The synthesis of the ketone (LII) should also be mentioned[158]:

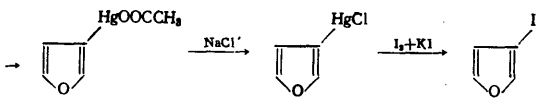


(LII)

5. Syntheses Based on Furan-2-carboxylic Acid

In 1933 Gilman and coworkers[53] showed that the reaction of mercuric chloride with the sodium salt of pyromucic acid results in decarboxylation, the chloromercuri-group entering the furan ring. When mercuric acetate is allowed to act on pyromucic acid under the conditions described by Pesci[159] with subsequent pyrolysis of the resulting mixed salt, 3-acetoxymercurifuran is obtained instead of the expected 2-acetoxymercurifuran. Thus here we are dealing with the *ortho*-rearrangement characteristic of aromatic mercury salts, although the reaction is in this case more complex and its mechanism cannot be regarded as established:





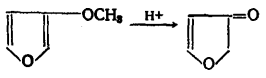
This synthesis is interesting because it permits the introduction of a substituent into the β-position of the furan ring, while leaving the α-positions free. In furan-3-carboxylic acid the carboxy-group cannot be replaced by the chloromercuri-group. The yield of 3-chloromercurifuran amounts to 15%, which was recently comparatively confirmed by other investigators[147,160], 3-Chloromercurifuran is an infusible compound insoluble in all solvents, which can be converted by treatment with an aqueous solution of iodine and potassium iodide into 3-iodofuran in 46% yield. Gilman also noted[53] that the attempt to prepare 3-acetylfuran by the action of acetyl chloride on 3-chloromercurifuran was unsuccessful. Gilman characterised 3-iodofuran as a much more stable compound than 2-iodofuran; it was shown that the iodine in this compound is not very labile. 3-Iodofuran did not react even with activated magnesium or lithium and underwent only partial exchange for the metal when acted upon by a sodium–potassium alloy.

The reactions of 3-chloromercurifuran were investigated in greater detail fairly recently by Gronowitz and Sorlin[147,160], who found that it is impossible to obtain 3-substituted furan derivatives by treating 3-chloromercurifuran with bromine, thiocyanogen, or acetyl chloride in benzene solution. In bromination experiments it was impossible to isolate the reaction products but it was established that the substitution takes place at a carbon–hydrogen bond and not an organometallic bond. Treatment with thiocyanogen gave a low yield of a mixture of 2- and 3-isomers in proportions of 4 : 1, which the authors also explained by the competition of reactions at the C–H bond in the active α-position and the C–Hg bond at the β-position in the ring. The product of the interaction of 3-chloromercurifuran with acetylchloride in benzene is 2-acetylfuran (yield 17%). Consequently 3-substituted furan derivatives can be obtained from 3-chloromercurifuran only by reaction with iodine and, as established by Bak et al.[161], with deuterium chloride.

The fact that in some cases an electrophilic agent attacks the reactive α-position of the five-membered heterocyclic compound more readily than the organometallic bond in the β-position was first discovered in the thiophen series. Namely, Gronowitz found[144] that, when 3-thienyl-lithium was acted upon by cadmium chloride and zinc chloride with subsequent treatment with acetyl chloride, a mixture of 55% of 2-acetylthiophen and 31% of 3-acetylthiophen was obtained.

Gronowitz and Sorlin also confirmed[147] and improved Gilman's results; in experiments designed to synthesise 3-iodofuran it proved possible to increase the yield from 46 to 75%; the scope of syntheses based on 3-iodofuran was also extended. In particular, it was shown that the iodine atom in 3-iodofuran is not as inert as was suggested by Gilman. It is sufficiently labile to undergo exchange for lithium in the reaction with alkyl-lithium in ethereal solution at −70°C. This permits the synthesis of new 3-substituted furan derivatives. When carbon dioxide, *NN*-dimethylformamide, and dimethyl disulphide were allowed to react with this organolithium compound, furan-3-carboxylic acid (yield 72%), furan-3-aldehyde (yield 38%), and fur-3-yl sulphide (yield 75%) were obtained respectively. Furthermore, it was shown[147] that, in contrast to 2-bromo- and 2-iodo-furan[162], 3-iodofuran

reacts with sodium methoxide in methanol in the presence of copper(II) oxide, forming 3-methoxyfuran in 65% yield. 3-(2*H*)-furanone (LIII) was synthesised by the acid hydrolysis of 3-methoxyfuran [163]:



(LIII)

The reaction of 3-iodofuran with copper cyanide in quinoline gave [147] 3-cyanofuran in 50% yield.

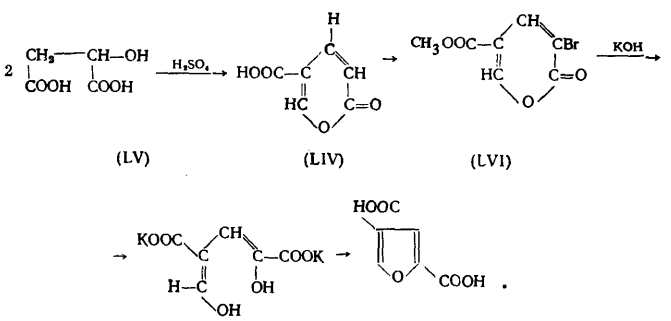
IV. METHODS OF SYNTHESIS OF 2,4-DISUBSTITUTED FURAN DERIVATIVES

The methods discussed below are mainly used to obtain 2,4-disubstituted furan derivatives.

1. Cyclisation of Certain Aliphatic Compounds

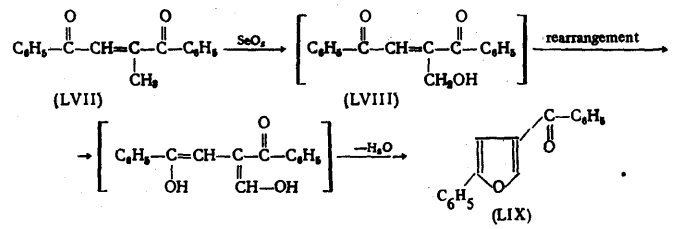
2,4-Disubstituted furans of various types are difficult to obtain, since the second electrophilic substituent usually enters the α'-position in the ring, forming 2,5-disubstituted furans regardless of the directing capacity of the group already present in the α-position. Only one rather difficult to explain case is known where in the reaction of isopropyl chloride with furfural in the presence of aluminium chloride the alkyl group enters the β'-position [79,164,165] (yield of 4-isopropylfurfural 11%). However, this is not a typical example and there is no doubt that it cannot be classified as a general method for the synthesis of 2,4-disubstituted furan. Usually, in order to obtain 2,4-disubstituted furans as well as the mono-3-substituted derivatives and 2,3-disubstituted derivatives, it is necessary to use rather inefficient "indirect" procedures. One of these is cyclisation by a suitable method of selected aliphatic compounds, the synthesis of which is often associated with considerable difficulties. We shall quote as an example the synthesis of furan-2,4-dicarboxylic acid [134] from malic acid via coumalic acid.

There exist also other methods [41] for the preparation of this acid, but they are used more rarely. Gilman [134] obtained coumalic acid (LIV) from malic acid (LV) by Pechman's synthesis [166], consisting in the treatment of malic acid with sulphuric acid; the acid (LIV) was then obtained in 60% yield. The methyl ester of the acid was further converted by the Feist reaction [167] into the ester of bromocoumalic acid (LVI) in 65% yield and the latter into furan-2,4-dicarboxylic acid in 50% yield:



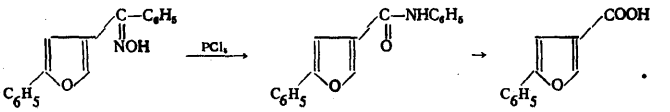
(LV) (LIV) (LVI)

The cyclisation of 1,2-dibenzoylprop-1-ene (LVII) in its oxidation with selenium dioxide also leads [168] to a 2,4-disubstituted furan—4-benzoyl-2-phenylfurfuran. The authors [168] suggest that initially the methyl group at the double bond is oxidised to an alcoholic group and the ketone (LIX) is formed from the alcohol (LVIII) as a result of a prototropic rearrangement with subsequent elimination of water:

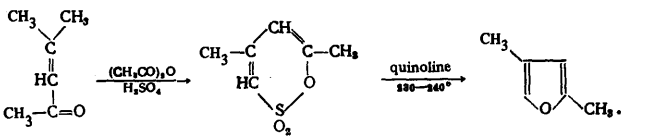


(LVII) (LVIII) (LIX)

The same workers [168] achieved the Beckmann rearrangement of the ketone oxime, which leads to 5-phenylfuran-3-carboxylic acid, a compound otherwise difficult to obtain:

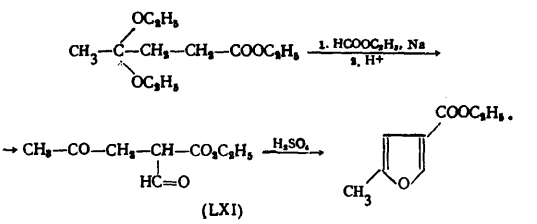


In 1948 Morell proposed [169] a novel synthesis of 2,4-disubstituted furans consisting in the heating of 3,5-dimethylsultone (LX) in quinoline. However, in view of the low availability of compound (LX) (low yields), this method can hardly be regarded as preparative:



(LX)

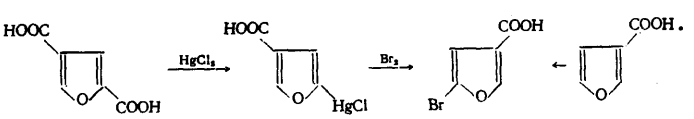
The synthesis of 5-methylfuran-3-carboxylic acid from levulinic acid [170] consists in the condensation of the diethyl ketal of levulinic acid with formic ester and subsequent cyclisation of the ester (LXI) by treatment with sulphuric acid:



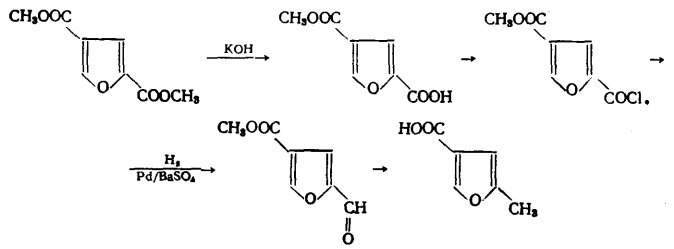
(LXI)

2. Reactions of Furan-2,4-dicarboxylic Acid

Despite the difficulties in its preparation, furan-2,4-dicarboxylic acid is regarded as the most readily available in the series of 2,4-disubstituted furans. A number of other 2,4-disubstituted derivatives were obtained by the conversion of its carboxy-groups. For example, by selective substitution of the α-carboxy group by a chloromercuri-group, Gilman and Burtner synthesised [134] 2-bromofuran-4-carboxylic acid in order to confirm the structure of the product formed on bromination of furan-3-carboxylic acid:

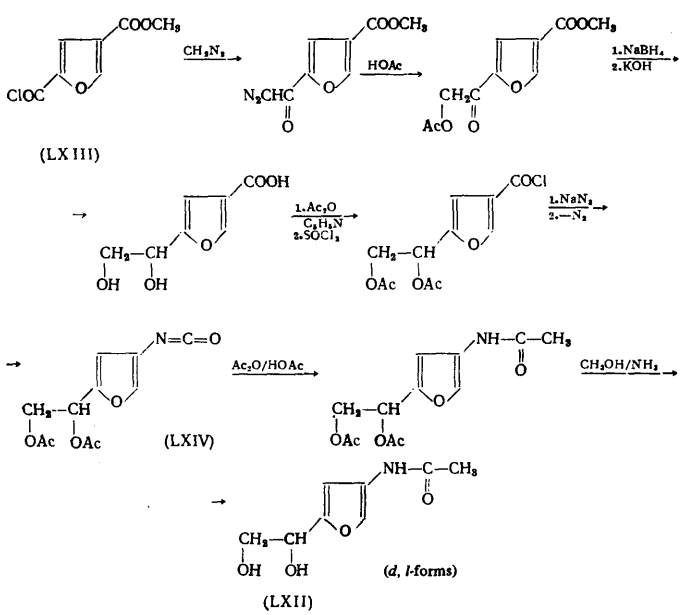


5-Methylfuran-3-carboxylic acid was also obtained[171] from furan-2,4-dicarboxylic acid:



This method is based on the more ready hydrolysis of the ester group of the diester in the α-position.

The difficulties which must be overcome in the synthesis of 2,4-disubstituted furans may be demonstrated by means of the following example: in order to confirm[154] the structure of "chromogen III" (LXII), isolated from natural products (chitin and the polysaccharides of cartilage), it was necessary to undertake a seven-stage synthesis. The seven stages, starting with malic acid and proceeding via coumalic and furan-2,4-dicarboxylic acids to the chloride of 4-methoxycarbonylfuran-2-carboxylic acid (LXIII), were described earlier[171]. Further stages[154] are illustrated by the following scheme:



In this synthesis the isocyanate (LXIV) was converted into 3-acetamido-5-diacetoxyethylfuran by a standard method[172] —by the action of a 1:1 mixture of acetic anhydride and acetic acid.

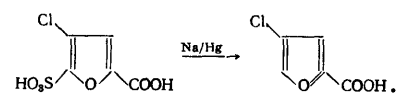
3. Electrophilic Substitution Reactions in the Series of Furans Substituted in the β-Position by *Meta*-directing Groups

Reactions of this kind are extremely rare. In 1933 Gilman[134] formulated the directing rule operating when a substituent enters the furan ring with an electronegative group in the β-position. For the nitration and bromination of furan-3-carboxylic acid and also furan-3-aldehyde as examples, it was shown that the site of substitution is the further removed α-position in the ring, as a result of which 2,4-disubstituted furans are produced.

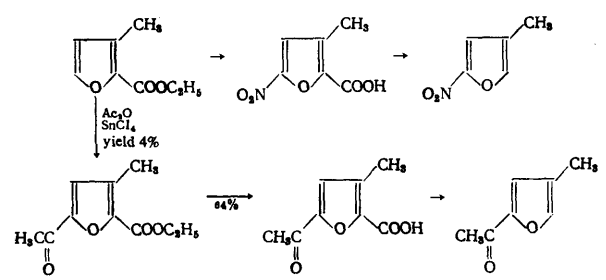
4. Elimination of One Substituent from Trisubstituted Furans

Probably the most widely used procedure employed in the synthesis of 2,4-disubstituted furans is the removal of certain groups, usually halogen atoms[62,69-71,73,74] and a carboxy-group[41,81,173] from trisubstituted furans. The reagents most often used to eliminate halogen atoms are zinc in acetic acid, alcoholic ammonia, or aqueous ammonia solutions, and sodium amalgam.

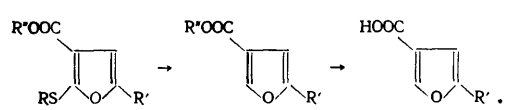
An example of the synthesis of a 2,4-disubstituted furan, namely 4-chlorofuran-2-carboxylic acid, by the elimination[70] of a sulpho-group has also been described:



It is noteworthy that 4-methyl-2-nitrofuran[81] and 2-acetyl-4-methylfuran[173] were obtained via a trisubstituted derivative starting with the relatively readily available 2,3-disubstituted derivative:

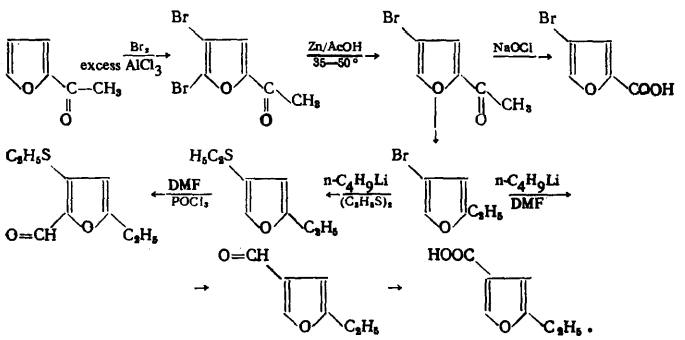


Recently a series of 2,4-disubstituted furans were prepared[58,174] by the elimination of a sulphide group from trisubstituted furans with the aid of Raney nickel:



The authors of the present review demonstrated for the first time the possibility of eliminating sulphide sulphur from furan derivatives by Raney nickel with preservation of the ring double bonds in the synthesis of 2,3-disubstituted furans[175] and proposed a method for the selective elimination of a bromine atom from the α-position in 2-acetyl-4,5-dibromofuran with zinc in acetic acid[176]. Under the conditions discovered, the keto-group and the bromine atom in the β-position do not undergo any changes. We were unable to find any literature data concerning the possibility of the elimination of a halogen atom from the furan ring while retaining the carbonyl group. Usually the latter, in particular in an aldehyde, is reduced to an alcoholic or a methyl group under the action of zinc in acetic acid[177] (a modification of the Clemmensen reaction).

Only Lutz and coworkers mention in one of their communications [178] the elimination by zinc in acetic acid of two bromine atoms from 3-(ω-dibromoacetyl)-2,5-diphenylfuran with retention of the keto-group. 2-Acetyl-4-bromofuran, which we obtained, is a key compound for the synthesis of many 2,4-disubstituted furans (bromides, sulphides, etc.):

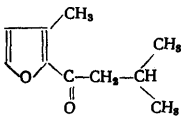


V. METHODS OF SYNTHESIS OF 2,3-DISUBSTITUTED FURAN DERIVATIVES

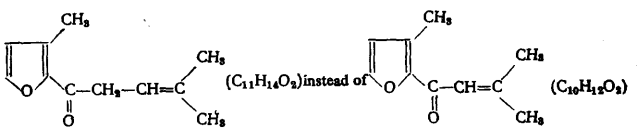
The known 2,3-disubstituted furans were obtained from certain natural products, by the cyclisation of aliphatic compounds into a furan system, the conversion of the carboxy- or methyl groups in 2-methylfuran-3-carboxylic and 3-methylfuran-2-carboxylic acids, by the elimination of one substituent from trisubstituted furans, mainly by the decarboxylation of acids, and by substitution of the available β-monosubstituted furans, mainly 3-methylfuran.

1. Isolation from Natural Products

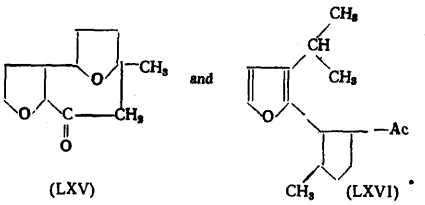
Most of the furan compounds encountered in nature are terpenoids [179]. Together with mono-β-substituted derivatives, a number of 2,3-disubstituted furans were isolated from natural products: 2-isovaleroyl-3-methylfuran [180],



"naginata ketone", and others. The "naginata-ketone" was detected for the first time in the essential oil of *Elsholtzia oldhami* by Fujita [181], who incorrectly attributed to it the structure

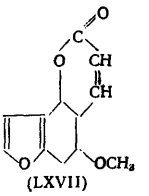


as established by Naves and Ochsner [182]. The structures of ipomeamarone [183] (LXV) and pelargone [184] (LXVI) from the essential oil of *Bourbon geranium*, which are also 2,3-disubstituted furan derivatives, were likewise elucidated:

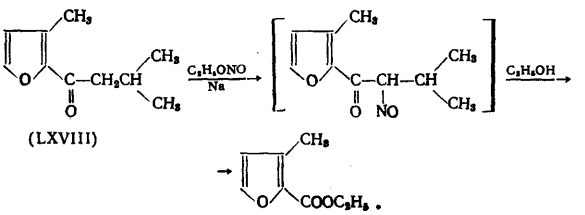


Isomaltol, isolated for the first time from bread by Back [185] and obtained recently by Hodge and coworkers [186] by appropriate treatment of lactose, is also a 2,3-disubstituted furan, namely 3-hydroxyfur-2-yl methyl ketone, as shown by Fischer and coworkers [187].

A substance called isobergaptene (LXVII) was isolated from the roots of *Pimpinella saxifraga* [188]. Its oxidation with hydrogen peroxide in alkaline solution gave furan-2,3-dicarboxylic acid:

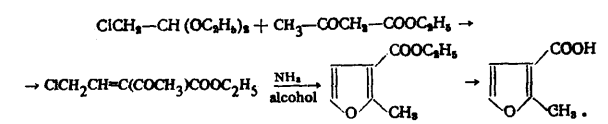


When ethyl nitrite and sodium were allowed to react with isobutyl 3-methylfur-2-yl ketone (LXVIII), isolated from the essential oil of a member of the labiatae (*Elsholtzia Cristata wild*), the ketone decomposed with formation of the ester of 3-methylfuran-2-carboxylic acid [137]:



2. Cyclisation of Aliphatic Compounds into the Furan System

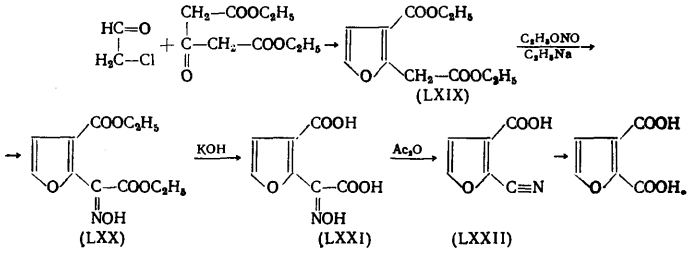
There exist several methods of synthesis for 2-methylfuran-3-carboxylic acid. The method of Plancher and Albini [189] is inconvenient, since the interaction of chloroethylideneacetoacetic ester with alcoholic ammonia was carried out in a sealed tube; the authors did not state the yield:



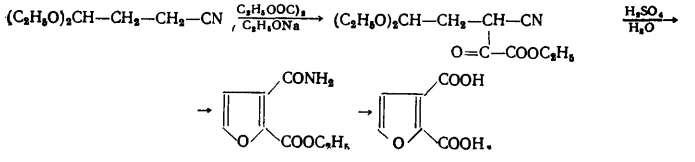
Benary [18] obtained the ester of this acid as an admixture with the ethyl ester of 2-methylpyrrole-3-carboxylic acid by the reaction of chloroacetaldehyde with acetoacetic ester in an ammoniacal medium. Gilman, who repeated the study [89], notes that the yield of 2-methylfuran-3-carboxylic acid is 40%.

There is also mention [69,96] of other methods of synthesis of the acid. As a rule, they consist of many stages and

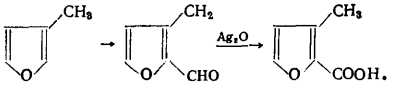
reduce to the decarboxylation of 5-methylfuran-2,4-dicarboxylic acid. Reichstein [132] also used the Benary method to prepare furan-2,3-dicarboxylic acid. He synthesised in 18% yield the ethyl ester of 3-ethoxycarbonylfuran-2-acetic acid (LXIX) by the condensation of chloroacetaldehyde with the diethyl ester of acetonedicarboxylic acid in the presence of ammonium hydroxide. Further reactions of the ester (LXIX) reduced to the synthesis of the oxime (LXX) and its subsequent conversion via compound (LXXI) and the nitrile (LXXII) into furan-2,3-dicarboxylic acid:



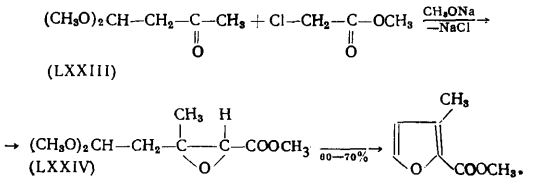
Later furan-2,3-dicarboxylic acid was obtained [170] from 4,4-diethoxybutyronitrile [190]:



As already mentioned above, 3-methylfuran-2-carboxylic acid was obtained for the first time from the natural ketone (LXVIII). Reichstein synthesised this acid from 3-methylfuran [90]:



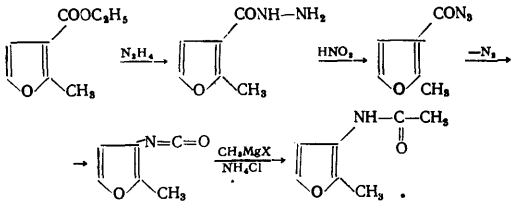
In 1956 Burness [131,138] proposed a new synthesis for 3-methylfuran-2-carboxylic acid whereby the latter became quite readily available. In this procedure the starting compound is the dimethyl acetal of formylacetone (LXXIII), which is converted quantitatively by the Darzens method, by the reaction with methyl monochloroacetate, into the glycidic ester (LXXIV), the distillation of which at 160°C leads to the methyl ester of 3-methylfuran-2-carboxylic acid:



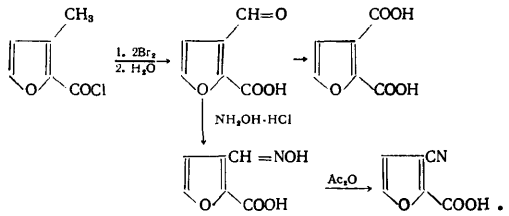
3-Phenylfuran-2-carboxylic acid was obtained similarly [138].

3. Reactions of 2-Methylfuran-3-carboxylic and 3-Methylfuran-2-carboxylic Acids

Although 2-methylfuran-3-carboxylic acid is essentially rather difficult to obtain, certain important studies have been carried out on its basis. Here we shall mention the synthesis [153] of 3-acetamido-2-methylfuran:

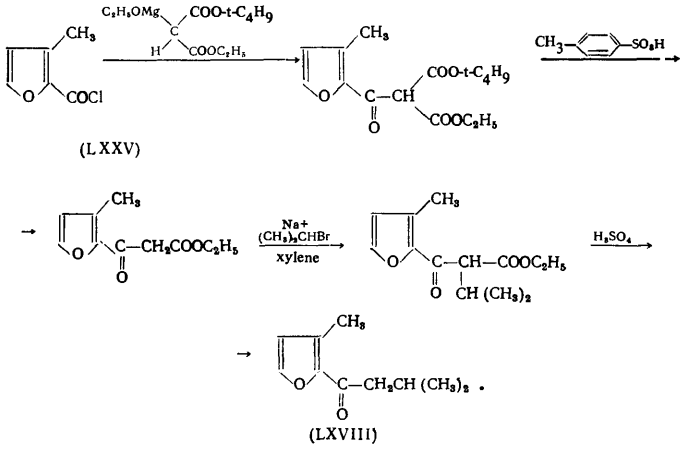


The isomeric 3-methylfuran-2-carboxylic acid has been much more widely used as a starting material for a wide variety of reactions. Asahina and Murayama [137], who obtained 3-methylfuran-2-carboxylic acid for the first time, synthesised from it certain 2,3-disubstituted furans. By the reaction of two moles of bromine with the chloride of this acid in direct sunlight at 130°C and subsequent hydrolysis, they obtained 3-formylfuran-2-carboxylic acid. On oxidation with silver oxide, the latter yielded furan-2,3-dicarboxylic acid:



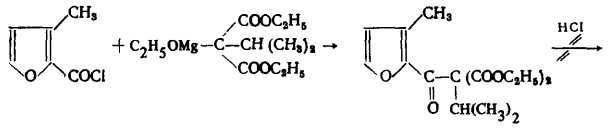
3-Cyanofuran-2-carboxylic acid was synthesised from the aldehydo-acid via the oxime.

In recent years there has been a considerable increase of interest in 3-methylfuran-2-carboxylic acid as a starting material. Ketones detected in natural products have been prepared from it. In 1963 Finan and Forthergill [191] synthesised the "Elsholtzia ketone" (LXVIII) in 50% yield using the acid chloride (LXXV) as the starting material:

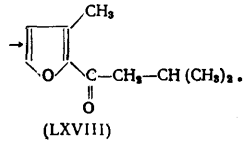


The attempts [191] to modify somewhat this synthesis in connection with data [192] concerning a new method for the preparation of the "perilla ketone" proved to be fruitless. Following the procedure of the Japanese investigators but using the acid chloride (LXXV) instead of the chloride of furan-3-carboxylic acid, Finan and Fothergill [191] condensed the acid chloride with the ethoxymagnesium derivative of

the diethyl ester of α-isopropylmalonic acid, but the ester (LXXVI) could not be cleaved to yield the ketone (LXVIII):

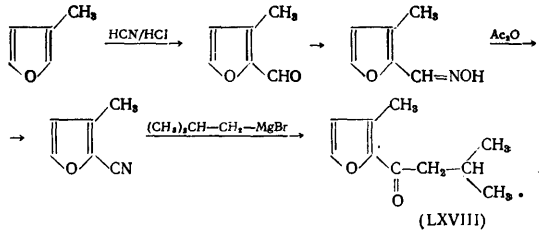


(LXXV) (LXXVI)



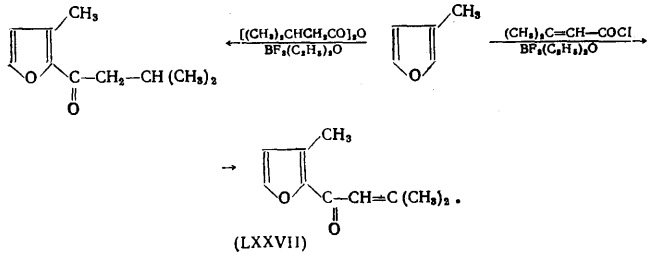
(LXVIII)

This finding is consistent with the observations of some workers [193,194], who showed that on treatment with an acid the diethyl esters of alkylated α-acylmalonic acid are not split with the formation of ketones. The structure of the "Elsholtzia ketone" (LXVIII) was confirmed for the first time in 1931 by Reichstein, who obtained it from 3-methylfuran in a low yield by the following procedure [90]:



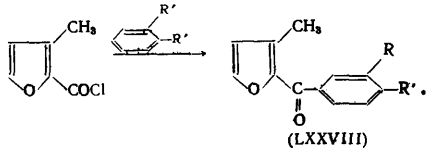
(LXVIII)

We may also mention here the formation of this ketone [173] in 30% yield when 3-methylfuran, which has become quite readily available, is acted upon by the anhydride of isovaleric acid. Some of its homologues have been synthesised similarly. The same workers obtained the "naginata ketone" (LXXVII) in 40% yield [195]:



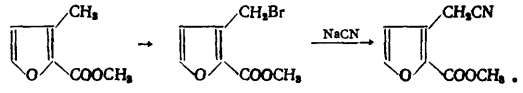
(LXXVII)

Leditschke [196] synthesised the hitherto unknown aryl 3-methylfur-2-yl ketones (LXXVIII) by the acylation of aromatic hydrocarbons with the chloride of 3-methylfuran-2-carboxylic acid:



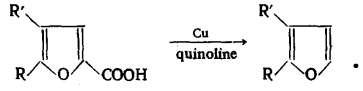
(LXXVIII)

Fairly recently the methyl ester of 3-bromomethylfuran-2-carboxylic acid was obtained [197] in a satisfactory yield by the reaction of *N*-bromosuccinimide with the methyl ester of 3-methylfuran-2-carboxylic acid in the presence of a radical-reaction initiator:

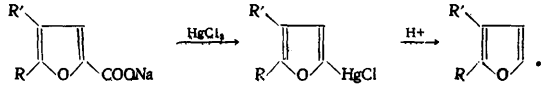


4. Elimination of One Substituent from Trisubstituted Furan Derivatives

The syntheses of 2,3-disubstituted furans from trisubstituted derivatives reduce to the reductive elimination of a halogen atom from certain trisubstituted furans [73,89] and decarboxylation [65,67,69,79,80,88,89,96,134,198–200] of the corresponding furan-2-carboxylic acid:



In the decarboxylation the authors [134] employed a method involving the intermediate replacement of the carboxy-group by a chloromercuri-group, which was subseqently eliminated by treatment with acid:



5. Substitution Reactions of Certain β-Monosubstituted Furan Derivatives

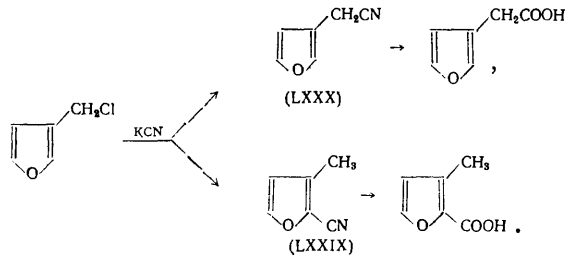
Until Gilman formulated the directing rule for mono-β-substituted furans in reactions involving the introduction of an electrophilic substituent into the ring [134,201], there existed only one example of reactions of this kind: the formylation [90] of 3-methylfuran by the Gattermann–Koch method. Having somewhat extended the number of mono-β-substituted furan derivatives, Gilman showed [134] that, when the existing β-group is *ortho*, *para*-directing in the benzene series, the new substitutent is directed to the adjacent α-carbon atom, forming 2,3-disubstituted furan; on the other hand, if the β-group is *meta*-directing, the new group forms a 2,4-disubstituted furan.

Gilman achieved the nitration of 3-methylfuran [134] and the chloromercuration of 3-methylfuran [201] and 3-isopropylfuran [79] with formation of the corresponding 2,3-disubstituted furans.

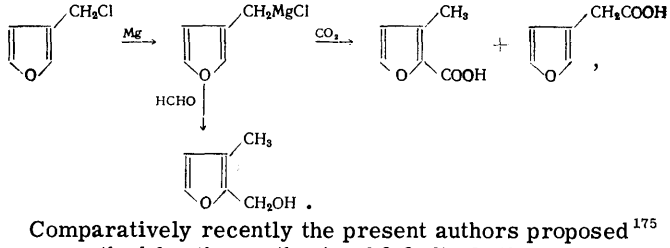
In view of the ready availability of 3-methylfuran, recently electrophilic substitution reactions with this compound have been carried out again, namely acylation [173] and bromination [197]. When 3-methylfuran was brominated with one mole of *N*-bromosuccinimide without a radical-reaction initiator, 2-bromo-3-methylfuran was obtained. When the amount of the brominating agent was varied, then, depending on the presence or absence of a radical-reaction initiator, various bromination products were obtained: with bromine either in the α-position of the furan ring or in the methyl group.

Sherman and Amstutz [202] made an interesting observation, namely that 2,3-disubstituted furan is formed as a result of the allyl rearrangement of certain β-monosubstituted furans of 3-chloromethylfuran under the action of

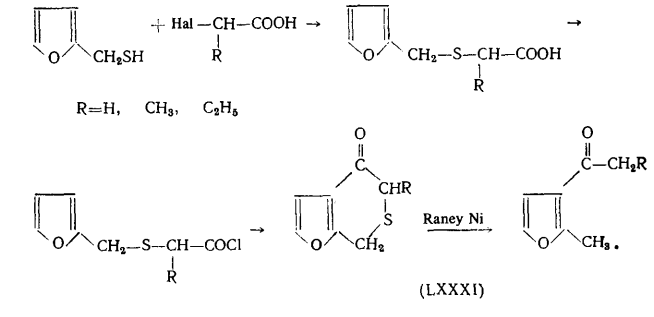
an aqueous solution of potassium cyanide and of fur-3-yl-methylmagnesium chloride under the action of carbon dioxide and formaldehyde. In the first case the product of the allyl rearrangement—3-methyl-2-furonitrile (LXXIX) —is formed only as an impurity in the main product fur-3-ylacetonitrile (LXXX):



In the second case the main product is 3-methylfuran-2-carboxylic acid (90% yield) or 3-methylfurfuryl alcohol (33% yield) is obtained as the sole product:



Comparatively recently the present authors proposed[175] a new method for the synthesis of 2,3-disubstituted furans —allyl 2-methylfur-3-yl ketones. It consists in the formation from the readily available 2-substituted furans of bicyclic condensed systems with a "bridge" between the second and third positions in the furan ring incorporating a sulphur atom in one of the units. This unit, separated from the ring by carbon atoms, is eliminated in the next stage by Raney nickel. The elimination of sulphite sulphur from the side chain by Raney nickel takes place without appreciable reduction of the furan ring to the tetrahydrofuran derivative:



In the course of the synthesis of 2,3-disubstituted furans a new condensed bicyclic compound (LXXXI) was obtained and some of its properties were investigated.

N-Vinyl Compounds of the Pyrrole Series

M.F.Shostakovskii, G.G.Skvortsova, and E.S.Domnina

The review deals with the methods of synthesis and reactivities of *N*-vinyl derivatives of pyrrole, indole, and carbazole. Their chemical properties have been compared with one another and also with those of aryl vinyl ethers and enamines. Since the reactions of *N*-vinyl pyrroles have been inadequately investigated, all the principal chemical properties of this series will be considered—mainly with *N*-vinylindole as an example, this compound having been most thoroughly investigated by the authors of the review. The bibliography includes 201 references.

CONTENTS

I. Introduction 407

IV. Charge-transfer complexes based on pyrrole, indole, carbazole, and their vinyl halogen-containing derivatives 415

I. INTRODUCTION

Heterocyclic compounds containing a nitrogen atom in the ring are extremely widely distributed in nature as alkaloids, vitamins, and pigments, and play a very important role in biological processes [1,2]. Many compounds with an indole ring exhibit high pharmacological activity [3].

In recent years unsaturated *N*-heterocyclic compounds have been attracting attention because of their high and unusual reactivity. The vinyl derivatives of pyrrolidone and various other lactams are already used in the plastic and synthetic fibres industry, electronic engineering, and medicine and have been frequently described [4,5]. Among the *N*-vinyl compounds, *N*-vinylindole remained completely uninvestigated for a long time. The introduction into the indole molecule of a vinyl group conjugated via the nitrogen atom with the π-electrons of the double bonds of the benzopyrrole system opens up a path to the synthesis of more complex compounds, including macromolecular compounds. This gives rise to great potential possibilities for the synthesis of new antimicrobial and medicinal preparations, organic semiconductors, and thermally and electrically insulating coatings.

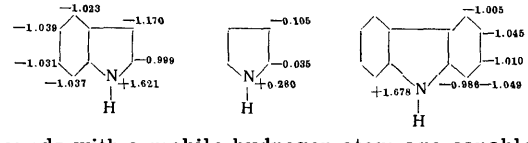
The information in the literature about the chemistry of the parent compound of this series, *N*-vinylpyrrole, is very limited. Only the problem of the preparation and polymerisation of *N*-vinylcarbazole is discussed. Furthermore, the available published data on the *N*-vinyl compounds of pyrrole and its benzo-derivatives have not so far been compiled.

II. METHODS OF SYNTHESIS OF *N*-VINYLPYRROLES

Vinyl derivatives of nitrogen-containing heterocycles may be synthesised in different ways. The methods for their preparation can be divided into several groups in accordance with the reaction on which their synthesis is based: (1) direct vinylation; (2) dehydration of β-hydroxyethyl derivatives of heterocycles; (3) dehydrohalogenation of halogenoethyl derivatives of heterocycles.

1. Direct Vinylation

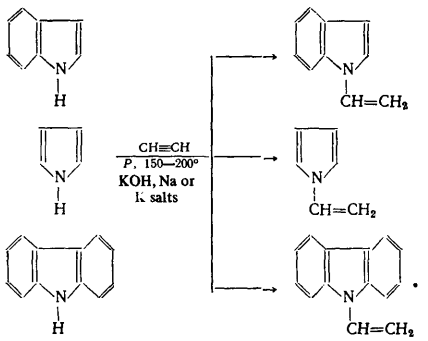
As a result of π-electron conjugation, the electron density at the nitrogen atom in pyrrole, indole, and carbazole molecules is transferred to the ring, which leads to considerable polarisation of the N–H bond. This effect may be regarded as the main reason for the enhanced mobility of the hydrogen atom attached to the nitrogen atom. Recent theoretical calculations confirmed the presence of an excess positive charge at the nitrogen atom of pyrrole systems [1,6]:



Compounds with a mobile hydrogen atom are capable of interacting with acetylene to form vinyl derivatives [7]. The vinylation reaction is based on the work of Favorskii [8], who showed that alcohols add to substituted acetylenes with formation of vinyl ethers. Shostakovskii [9], Prilezhaeva [10], Kalabina [11], and Sidel'kovskaya [12,13] extended this reaction to mercaptans, phenols, lactams, and thiono-amides. Foreign studies in this field have been carried out by German chemists led by Reppe [14,15] and a number of American [16,17] and Japanese [18,19] scientists.

The available literature data show that the vinylation of amino-compounds is more complex than that of alcohols, phenols, and mercaptans. Recently Chekulaeva [20] reviewed the information about the reactions of acetylene with amines and ammonia and described the principal laws governing these reactions. Primary and secondary aliphatic amines react with acetylene in the presence of alkalis, forming resins [14]. The replacement of alkali by zinc or cadmium salts leads to the synthesis of unstable vinylamines [15,20]. Stable products are obtained when heterocyclic imino-compounds are vinylated. The methods of their preparation have been described systematically in individual sections of review articles [14–16,21–23] and also in monographs [5,24].

Usually the interaction of compounds of the pyrrole series with acetylene takes place at elevated temperatures and a pressure of 15–20 atm in the presence of basic catalysts. The latter are alkali metal salts of the compounds vinylated and also substances which are capable of substituting by an alkali metal the hydrogen of the imino-group in the pyrrole molecule:



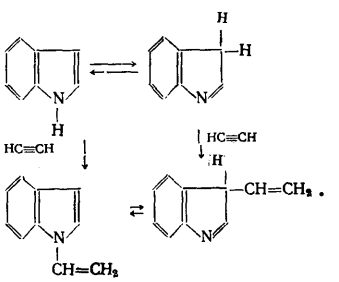
Sodium and potassium hydroxides or alkoxides are frequently employed [15,25] and alkali metals less so [26]. The catalyst is also treated with promoting agents, which make it possible to carry out the reaction at lower pressures and temperatures, accelerate the main vinylation process, and increase the yield. Agents of this kind which have been employed are zinc oxides [27,28], powdered zinc [29,30], and zinc carbonate, phosphate, and sulphide [31]. Sometimes small amounts of ammonia, pyridine, or quinoline are added to the reaction mixture in order to accelerate the reaction [31,32]. The catalyst usually consists of three parts of potassium hydroxide and one part of zinc oxide and is added in an amount of 3–4%. The reaction is normally performed in solution or in suspension. It is very important to carry out the process in an organic solvent which dissolves the vinylated compound, for example benzene, toluene, cyclohexane, methylcyclohexane, decalin, and dimethylcyclohexanol [33]. Acetylene is diluted with nitrogen, carbon dioxide, or methane in proportions of 2 : 1. The reaction lasts 4–5 h. Carbazole is also vinylated at 180°C in the presence of sodamide and calcium carbide in ligroin [34]. *N*-vinylcarbazole is synthesised in high yields at 200°C in ethyl vinyl ether solution [35].

In the reaction of an equimolar mixture of technical fluorine and carbazole with acetylene at a pressure of 39 atm and 195°C in toluene in the presence of potassium hydroxide and added quinoline, Karpukhin and Levchenko [36,37] obtained in 61% yield a mixture of vinyl derivatives containing 45% of *N*-vinylcarbazole.

Pyrrole and its benzo-derivative are also vinylated in the gas phase at atmospheric pressure and a temperature of 250–320°C, but the yield of products is much lower than in the vinylation in the aqueous phase [38,39]. Pyrrole vapour has been vinylated with acetylene over the Fe/K_2CO_3 catalyst at 300°C and a pressure of 300–500 mm. [15] In 1962 a new method was proposed for the synthesis of *N*-vinylpyrrole [40] by allowing gaseous acetylene and pyrrole to come into contact at 150–350°C with a catalyst consisting of an MgO carrier impregnated with 5–15% KOH.

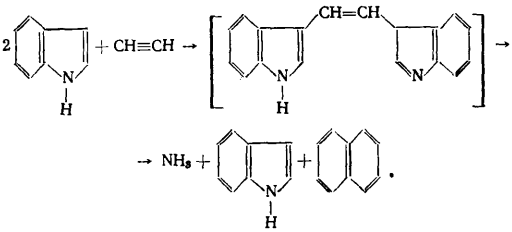
The information about the synthesis of *N*-vinylindole is very limited. Indirect indications of the possibility of the preparation of *N*-vinylindole by analogy with *N*-vinylcarbazole and *N*-vinylpyrrole appeared for the first time in the 1930's in a number of patents [29,28,41]. Reppe [27] describes the synthesis of *N*-vinylindole by the reaction of indole with acetylene under pressure in the presence of 2% KOH at 150–160°C for 70 h. In the 1950's Kawasaki [42] noted that an increase in the amount of KOH and of temperature to 180°C and the use of a potassium salt of indole instead of potassium hydroxide reduces the duration of heating to 4–5 h. *N*-Vinylindole was also synthesised by passing a mixture of indole and acetylene vapours over an iron catalyst at 300°C. [15]

Shostakovskii et al. [43], who studied the vinylation of indole, showed that this is a complex process, since under the conditions of this reaction not only indole itself but also its tautomeric form—pseudoindole—can exist. Nowadays it is no longer surprising that indole and pyrrole are protonated both at nitrogen and carbon. This is indicated by preliminary data obtained in the study of the ionisation of these compounds [44]. One cannot exclude the possibility that both tautomeric forms of indole, which have active hydrogen atoms in positions 1 and 3, can react with acetylene to form *N*-vinylindole and pseudovinylindole by the mechanism



The latter is probably formed as a result of the migration of the vinyl group in the *N*-vinylindole molecule under the conditions of the reaction.

Shostakovskii et al. [43] assumed that the high-boiling compound which they isolated is formed as a result of the interaction of both tautomeric forms of indole with an acetylene molecule. On heating it decomposes into ammonia, indole, and naphthalene:

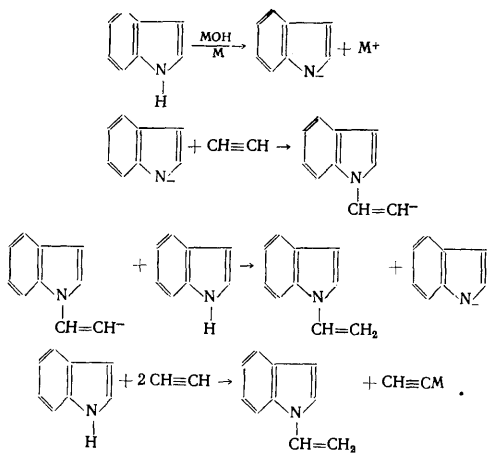


Later Domnina, Skvortsova, and coworkers investigated the reaction of indole with acetylene under pressure in order to drive the reaction towards the optimum degree of formation of one of the tautomeric forms—*N*-vinylindole. They showed that the yield of the latter compound is significantly improved when the reaction is carried out in toluene or dioxan with small amounts of water (about 10%). The solvent favours the ionisation of the initial component and an increase of the concentration of acetylene in the reaction mixture. Potassium hydroxide (about 30%) and sodium hydroxide have been recommended as catalysts [45]. The variation of the yield of *N*-vinylindole with the concentration of potassium hydroxide, the amount of water, temperature, and the duration of the vinylation of indole has been investigated [46]. A decrease of the concentration of potassium hydroxide to 25% lowers the yield of *N*-vinylindole almost by a factor of two. Heating above 220°C leads to thermal polymerisation of the vinylation product. The best result, with the yield of *N*-vinylindole reaching 90% of theoretical, was achieved when indole was allowed

to react with acetylene at 180°C in the presence of 5.5% of metallic potassium [47]. The process takes 30 min. An increase of the duration of the reaction leads to enhanced tar formation.

When the potassium salt of indole is used as a catalyst, the vinylation takes place under the same conditions, the yield of *N*-vinylation reaching up to 88%. The replacement of potassium hydroxide by metals (sodium, lithium, and their salts) proved to be less effective, since the process had to be carried out at a higher temperature (up to 220°C), which results in the polymerisation of the *N*-vinylindole formed.

By analogy with other cyclic imines [48], the mechanism of the vinylation of indole can be represented as follows:



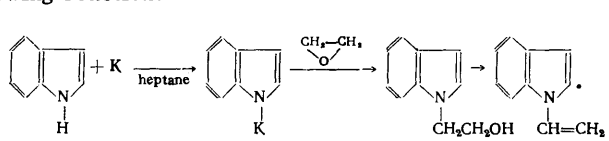
This is confirmed by the synthesis of *N*-vinylindole from potassium indolate when the latter reacts directly with acetylene.

The method of synthesis of *N*-vinyl derivatives of the pyrrole series by direct vinylation has many advantages: the process consists of a single stage, the yields are high, and in many cases the starting material is readily available. However, experiments at elevated pressures and temperatures are complicated by the risk of explosion of acetylene. Therefore in many countries other methods for the introduction of the vinyl group into heterocyclic compounds are being developed together with studies designed to widen the scope of the syntheses based on acetylene, and these are considered below.

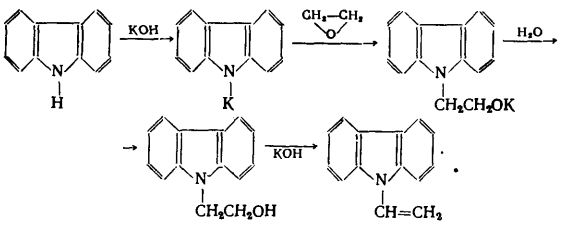
2. Dehydration of β-Hydroxyethyl Derivatives of Heterocyclic Compounds

Carbazole derivatives are dehydrated at a reduced pressure and an elevated temperature, frequently in the presence of potassium hydroxide. In a few cases acid catalysts are employed (potassium hydrogen sulphate, sulphuric acid, acetic anhydride, or alumina).

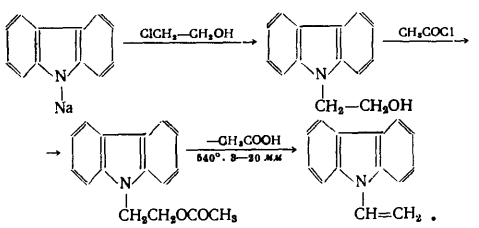
Japanese investigators [49] synthesised *N*-vinylindole from potassium indolate and epoxyethane in 40.5% yield by the following reaction:



They obtained *N*-vinylpyrrole similarly in 23.6% yield. Other workers [50–52] synthesised *N*-vinylcarbazole by the dehydration of *N*-(β-hydroxyethyl)carbazole using the reaction



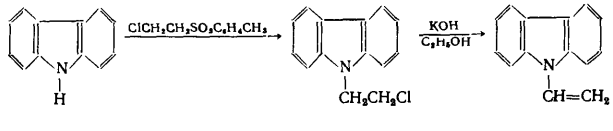
Sometimes the sodium salt of carbazole is used instead of the potassium salt [50,53]. The hydroxy-derivative obtained from the salt and ethylenechlorohydrin is treated with an excess of acetic acid, acetyl chloride, or acetic anhydride and then pyrolysis of the resulting acetate yields *N*-vinylcarbazole:



Lopatinskii et al. [54] obtained *N*-vinylcarbazole in 70–75% yield by the dehydration of *N*-(β-hydroxyethyl)carbazole with 10% potassium hydroxide at 250–270°C. In order to obtain β-hydroxyethyl derivatives, they also used the interaction of halogenocarbazoles with epoxyethane [55,56]. In a recently proposed method [57] *N*-vinylcarbazole and its 3-chloro- and nitro-derivatives are synthesised by the vacuum pyrolysis of the corresponding *N*-(α-acetoxyethyl)-carbazoles, which are readily obtained by the addition of vinyl acetate to carbazoles in solution in aliphatic ketones in the cold in the presence of solid alkalis [58]. The process can be carried out in a single stage without the isolation of the intermediates. The yields of *N*-vinylcarbazoles reach 65–80% of theoretical [59]. In its efficiency the method surpasses all other known methods for the preparation of 3-chloro-*N*-vinylcarbazoles.

3. Dehydrohalogenation of Halogenoethyl Derivatives of Heterocyclic Compounds

The elimination of hydrogen halides from the corresponding α- and β-halogenoethyl derivatives of nitrogen-containing heterocycles is achieved by the action of bases (potassium hydroxide, sodium ethoxide and methoxide, pyridine, sodamide, trimethylamine). Clemo and Perkin [60] obtained *N*-vinylcarbazole and *N*-vinyl-1,2,3,4-tetrahydrocarbazole by the elimination of hydrogen chloride from *N*-(β-chloroethyl)carbazole with alcoholic alkali at 50–60°C:



N-(β-chloroethyl)carbazole is synthesised by the reaction of β-chloroethyl *p*-toluenesulphonate with carbazole in acetone solution in the presence of alkali.

Lopatinskii and Zherebtsov[61] discovered the conditions for the conversion of 3-chloro-, 3,6-dichloro-, 3-bromo-, and 3,6-dibromo-carbazoles into the corresponding *N*-vinyl derivatives. Initially they substituted the hydroxyl in 3-chloro-*N*-(β-hydroxyethyl)carbazole by chlorine using phosphorus pentachloride and then dehydrochlorinated the product by the method described above[60].

Certain other procedures are also used to synthesise *N*-vinyl heterocyclic derivatives. Thus it has been stated that *N*-vinyl derivatives are formed when indole and carbazole react with vinyl acetate in solution in aliphatic ketones in the presence of mercury sulphate and sulphuric acid[62,63]. Unfortunately, however, the resulting vinyl compounds are polymerised under the reaction conditions.

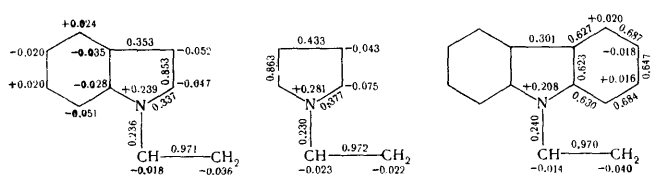
The introduction of a vinyl group into the carbazole molecule by the reaction of the potassium salt of carbazole with vinyl chloride in dimethylcyclohexane under pressure was described as early as the 1930's.[15,64,65]

III. CHEMICAL PROPERTIES OF *N*-VINYLPYRROLES

Although the molecules of *N*-vinyl derivatives of pyrroles and benzopyrroles contain many reaction centres, the chemistry of these compounds has so far been little investigated. For a long time attention was concentrated in the literature solely on the study of the polymerisation of *N*-vinylcarbazole, whereby it is possible to obtain products with valuable properties.

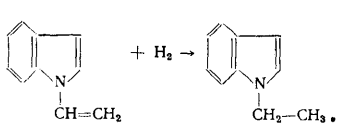
1. Addition Reactions at the Double Bond of *N*-vinylpyrroles

Quantum-mechanical calculations using the semi-empirical self-consistent field MO-LCAO method by Frolov and Kontarev[66,67] showed the following distribution of electron density in the molecules of vinyl derivatives of pyrrole, indole, and carbazole:



The molecular diagrams indicate an increase in the π-electron density at the β-carbon atom of the vinyl group and also at the C_2–C_3 bond of the pyrrole ring. According to modern theoretical concepts, the addition of electrophilic agents to the β-carbon atom of the vinyl group is due to the positive mesomeric and electromeric effects of the imino-nitrogen.

Addition of hydrogen. In the presence of Raney nickel in an alcoholic medium at room temperature and atmospheric pressure *N*-vinylindole readily adds hydrogen to the double bond of the vinyl group, forming *N*-ethylindole[46], the yield of which reaches 80–90%:



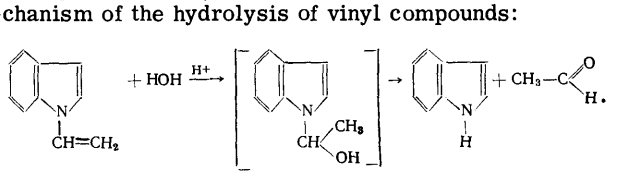
Kawasaki[42] hydrogenated *N*-vinylindole in the presence of the palladium/charcoal catalyst.

N-vinylcarbazole is also readily hydrogenated to *N*-ethylcarbazole[16]. Reppe[15] carried out this process in methanol in the presence of Raney nickel at 80°C and a hydrogen pressure of 15 atm.

Hydrolysis. Like *N*-vinyl-lactams[68], *N*-vinylimides[69,70], and vinylethers[71], *N*-vinylpyrroles are split by mineral acids at the C–N bond with formation of acetaldehyde and pyrroles. Comparison of the literature data[68–71] shows that the hydrolysis of *N*-vinylcarbazole is more difficult than that of *N*-vinyl-lactams and vinyl ethers. The hydrolysis of *N*-vinylcarbazoles requires longer heating and a higher concentration of catalysts. Furthermore, the process is accompanied by side reactions which made it impossible for a long time to isolate the acetaldehyde produced in the reaction, since it immediately interacts with the carbazole to give a crystalline product of unknown structure[60]. When hydrazine hydrate is added to the initial reaction mixture, the hydrolysis goes to completion and acetaldehyde hydrazone is formed almost quantitatively[5]

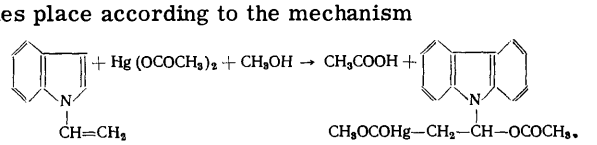
By hydrolysing *N*-vinylcarbazole for four days in a 9 : 1 mixture of methanol and water in the presence of iron(III) nitrate, it proved possible to isolate[72] carbazole and acetaldehyde, identified as the 2,4-dinitrophenylhydrazone. The reaction is accompanied by the formation of 20% of *trans*-1,2-dicarbazolylcyclobutane; the mechanism of this process has been discussed[72].

Shostakovskii et al.[73] investigated the acid hydrolysis of *N*-vinylindole. By varying the concentration of sulphuric acid, temperature, and the duration of reaction, they found that *N*-vinylindole is hydrolysed most completely (to the extent of 97–98%) after 30 h at 60°C in the presence of 4% H_2SO_4. In the presence of a more dilute acid (0.5–3%) the degree of hydrolysis at 30°C did not exceed 15–16%. Shostakovskii et al.[73] suggest that the hydrolysis of *N*-vinylindole proceeds according to the following mechanism, which is analogous to the general mechanism of the hydrolysis of vinyl compounds:



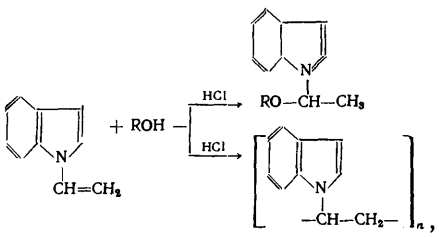
In contrast to *N*-vinylcarbazole, in this case the formation of by-products was not observed; *N*-vinylindole is much more difficult to hydrolyse than alkyl vinyl ethers and *N*-vinyl-lactams[7,74]. However, it is hydrolysed at a lower temperature than aryl vinyl ether. *N*-vinylindole is stable when heated for a long time in dilute alkalis.

Addition of alcohols. Of the reactions involving addition to *N*-vinylcarbazole by a polar mechanism, the interaction of this compound with mercury acetate, which is used for the analytical determination of the monomer, has been described[75]. In absolute methanol the addition takes place according to the mechanism



Skvortsova et al.[76] showed that two competing reactions occur in the interaction of *N*-vinylindole with aliphatic alcohols, phenols, and monocarboxylic acids. The addition of an alcohol to the vinyl group of *N*-vinylindole is accompanied by its homopolymerisation. The alcohols

add in accordance with the Markovnikov rule and the results of quantum-mechanical calculations:

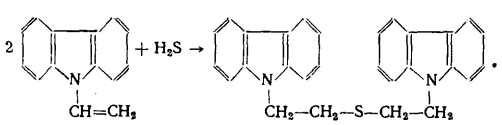


where R = CH_3, C_2H_5, C_3H_7, C_4H_9, or C_6H_5.

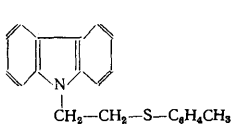
Depending on the reaction temperature, the order of addition of the components, and the nature of the hydroxy-compound, one or other process predominates. It has been established that methanol, ethanol, and propanol react with *N*-vinylindole at temperatures ranging from −7° to +5°C with formation of *N*-α-(methoxy-, ethoxy-, propoxy-)-ethylindoles, their yields reaching 66–74%. C_4 and higher alcohols and also phenols do not add to *N*-vinylindole, since under the reaction conditions (18–20°C) the polymerisation of this compound predominates. It proved impossible to acylate *N*-vinylindole at the double bond of the vinyl group by acids such as formic, acetic, butyric, isobutyric, and valeric. Depending on the strength of the initial acid, *N*-vinylindole polymerises instantly or after several hours.

Addition of thiols. Shostakovskii et al.[77-80] made a detailed study of the thiolation of alkyl vinyl and aryl vinyl ethers and *N*-vinyl-lactams. In her review Prilezhaeva[81] states that the addition of hydrogen sulphide and mercaptans to αβ-unsaturated compounds in the presence of free radical initiators is accompanied by the formation of β-addition products.

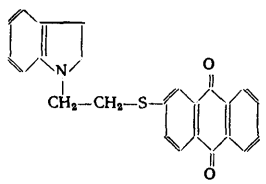
The addition of hydrogen sulphide to *N*-vinylpyrroles is also contrary to the Markovnikov rule[15,16]. Reppe and Nikolai[82,83] obtained di-β-(*N*-carbazolyl)ethyl sulphide by passing hydrogen sulphide into an alcoholic solution of *N*-vinylcarbazole heated to 75°C and containing a small amount of potassium hydroxide:



They synthesised di-β-(1-indolyl)ethyl sulphide by the action of hydrogen sulphide at 80°C on a solution of *N*-vinylindole in butanol in the presence of metallic potassium in an amount of about 0.1%. The reaction of *N*-vinylcarbazole with methane-, ethane-, butane-, dodecane-, and toluene-thiols, thiophenol, thiocresol, chlorothioxylene, thionaphthol, 1- or 2-mercaptoanthraquinone, thioresorcinol, and mercaptobenzothiazole is anomalous[82]. Thus, when thiocresol is refluxed with *N*-vinylcarbazole in a fairly dilute alcoholic solution for 12 h, β-(*N*-carbazolyl)ethylthio-*p*-toluene is formed in the absence of a catalyst:

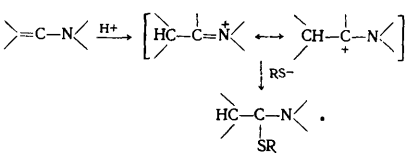


2-Mercaptoanthraquinone reacts with *N*-vinylcarbazole to form 2-anthraquinonylthio-1-(*N*-carbazyl)ethane:

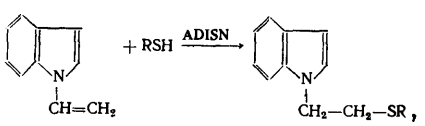


The possibility of an analogous interaction of *N*-vinylpyrrole with hydrogen sulphide and mercaptans to form β-addition products is indicated in patents[82,83], but concrete examples with description of reaction conditions are not given.

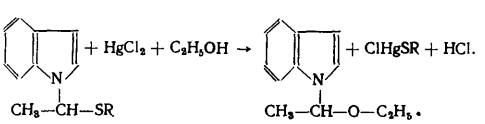
Investigations in recent years showed that certain *N*-vinyl compounds combine with mercaptans in accordance with the Markovnikov rule even under the influence of radical initiators (as in their absence). Leonard and Hay[84] and Lawesson and coworkers[85] found that cyclic enamines interact with mercaptans, forming α-addition products:



Shostakovskii et al.[86] developed a method for the preparation of new sulphur compounds of the indole series consisting in the interaction of *N*-vinylindole with mercaptans. They showed that free-radical addition of thiols to *N*-vinylindole under the influence of azodi(isobutyronitrile) (ADISN) takes place mainly with formation of *N*-(β-alkylthioethyl)indole (yield 75–80% of theoretical):

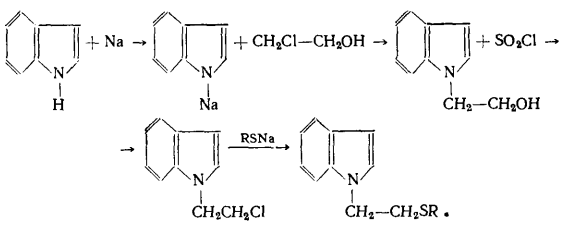


where R = H, C_2H_5, iso-C_3H_7, or t-C_4H_9. Together with this compound, a mixture of α- and β-addition products was isolated. The structure of *N*-(β-ethylthioethyl)indole was demonstrated unambiguously by proton magnetic resonance. Its spectrum consists of four multiplets comprising three triplets (δ = 1.0, 2.57, and 3.96 p.p.m.) and a quartet (δ = 2.14 p.p.m.). The presence of α-addition products is confirmed by the reaction with an alcoholic solution of mercuric chloride[78,87,88]:



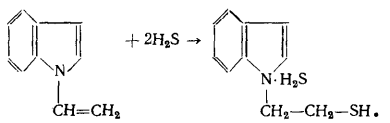
The amount of acid produced from the various alkylthio-derivatives varies from 38 to 95%. The physical constants of *N*-(α-ethoxyethyl)indole isolated from the reaction mixture agree with those of the products of the addition of ethanol to *N*-vinylindole[89,90].

To confirm the structure of the alkylthio-derivatives of *N*-vinylindoles, Domnina [89] attempted an indirect synthesis of the β-addition products by the following process:



Owing to the great tendency of indole derivatives to undergo dimerisation and polymerisation in an acid medium, this synthesis could not be taken to completion [91].

On heating to 80°C in the absence of an initiator, mercaptans do not add to *N*-vinylindole and, when the reaction mixture is distilled, the starting materials are completely recovered. Acidic catalysts, such as sulphur dioxide or *p*-toluenesulphonic acid, also do not facilitate their interaction and at different reaction temperatures only *N*-vinylindole pentamers and hexamers are produced [90]. According to a patent application [82], a sulphide derivative could not be isolated in the reaction of *N*-vinylindole with hydrogen sulphide. It was established that at 80°C *N*-vinylindole interacts with two hydrogen sulphide molecules:

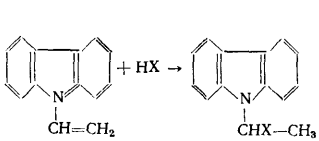


The present authors believe that, by analogy with mercaptans the HS group adds to the β-carbon atom of the vinyl group and the second hydrogen sulphide molecule forms a salt [89].

Halogenation and hydrohalogenation reactions. Studies on the halogenation of *N*-vinyl compounds are limited to only a few examples. The interaction of *N*-vinylcarbazole with bromine is mentioned in Reppe's review [15]. Reppe believes that, in the presence of potassium carbonate at −10°C, *N*-vinylcarbazole reacts with bromine to form methoxybromoethylcarbazole. The structure of the product was not proved. According to a patent [92], *N*-vinylcarbazole polymerises under the action of a small amount of hydrogen chloride.

Pielichowski and coworkers [93,94] recently described the halogenation and hydrohalogenation of *N*-vinylcarbazole. They suggest that bromination with a solution of bromate and bromide involves the vinyl group with formation of a product containing three or six bromine atoms, i.e., together with the addition reaction, hydrogen atoms are also substituted by bromine.

Pielichowski [94] believes that the addition of hydrogen halides to *N*-vinylcarbazole takes place in accordance with the Markovnikov rule, α-halogenoethylcarbazoles being formed:



The reaction is carried out in carbon tetrachloride solution, through which hydrogen chloride, bromide, iodide, or fluoride is passed during 1 h. The addition products have the following melting points respectively: 255°, 165°, 165–166°, and 123–125°C. The structure of the chloro-derivatives is confirmed by the fact that they differ in their properties from those of *N*-(β-chloroethyl)-carbazole synthesised earlier by Clemo and Perkin [60].

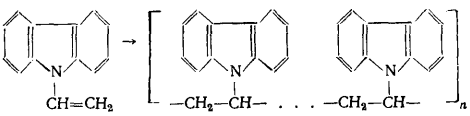
For a long time there was no information in the literature about the halogenation of *N*-vinylindole. Shostakovskii et al. found that chlorine and bromine react vigorously with *N*-vinylindole in the cold in carbon tetrachloride. By analogy with the hydrogenation of vinyl ethers [7] and also *N*-vinylphthalimide [96] and in agreement with data obtained by elemental analysis, the authors initially suggested that bromine adds to *N*-vinylindole at the vinyl group with formation of *N*-(αβ-dibromoethyl)indole or tribromoethylindole. However, subsequent studies of the halogenation of *N*-vinylindole established that, depending on the relative amounts of the starting components and the duration of interaction, polymeric products with various halogen contents are obtained [66] (for a more detailed description, see p. 415).

2. Polymerisation

The structure of the group linked to the nitrogen atom strongly influences the activity of *N*-vinyl compounds in polymerisation. Aliphatic vinylamines are known to be inactive in polymerisation. Plesch [97] explains this inertness of the growing chain by the resonance

In vinylcarbazole this difficulty is overcome as a result of the tendency to retain the aromatic properties of the heterocyclic compound. Because of this, *N*-vinylcarbazole is capable of polymerisation on heating above its melting point (85°C) without catalyst [98,99]. *N*-vinylindole also polymerises readily [46].

Among the vinyl monomers of the pyrrole series, *N*-vinylcarbazole has been most thoroughly investigated [15,100–102]. It can be readily polymerised by the usual methods—in the solid state, in solution, in emulsion, and in suspension in the presence of various initiators [103,104]. The reaction leads to the formation of a linear polymer with the following structure:



N-Vinylcarbazole and *N*-vinylindole undergo both cationic and radical polymerisation and therefore differ from vinyl ethers, which polymerise exclusively under the action of acid reagents [7,105–107].

t-Butylperoxide, azodi(isobutyronitrile), and hydrogen peroxide are used as the radical initiators of the block polymerisation of *N*-vinylcarbazole [108–110]. Benzoyl peroxide does not initiate the polymerisation of *N*-vinyl compounds [111]. Alkaline oxidising agents [5], such as sodium peroxide, perborate, and dichromate are catalysts for the radical polymerisation of *N*-vinylcarbazole in suspension. In the presence of 0.005–0.01% of azodi(isobutyronitrile) *N*-vinylcarbazole is converted into an almost colourless high-molecular polymer [112], while in an aqueous dispersion grains 0.5–1 mm in diameter are produced [113]. Organic bases inhibit its polymerisation [114].

The cationic polymerisation of *N*-vinyl compounds of the pyrrole series takes place readily. Boron trifluoride, various metal chlorides such as zinc chloride, aluminium chloride, etc., acid chlorides (sulphuryl, thionyl, acetyl,

and benzoyl chlorides), and halogeno-hydrocarbons are widely used in this case [92,115-118].

The solid-phase polymerisation of *N*-vinylcarbazole in the presence of Friedel–Crafts catalysts yields polymers with a low molecular weight [119]. In liquid sulphur dioxide at temperatures between −10° and −70°C *N*-vinylcarbazole and *N*-vinylpyrrole form polymers with high molecular weights reaching 90 000. [116,117] The reaction takes place by an ionic mechanism with the initial formation of a complex of *N*-vinylcarbazole with sulphur dioxide [120,121]. These products have valuable technical properties, mainly as impregnating materials [122,124].

N-Vinylcarbazole polymerises even in the presence of morpholine [125]. In the search for the synthesis of pure high-molecular polyvinylcarbazole organic compounds such as *p*-chloroaniline [126], various pyrylium salts [127], and also methyl methacrylate (1–10%) have been investigated as initiators [128]. Recently Japanese workers [129] found that *N*-vinylcarbazole polymerises by a cationic mechanism in the presence of electron acceptors such as gaseous chlorine, sulphur dioxide, and maleic anhydride [130,131]. They suggest that the monomer forms with the acceptor a charge-transfer complex, which is a source of cationic radicals with a localised carbonium ion. Such complexes exhibit paramagnetic properties and initiate the polymerisation of *N*-vinylcarbazole.

When electron acceptors such as dichlorodicyanobenzoquinone, *p*-chloranil, dichlorobenzene, and others were employed [49], the polymerisation activity decreased in the series *N*-vinylcarbazole > *N*-vinylindole > *N*-vinylpyrrole.

The anionic-coordination polymerisation of *N*-vinylcarbazole is carried out in the presence of t-C_4H_9Li–$TiCl_4$ Ziegler–Natta catalysts [132]. The maximum yield of the isotactic polymer reaches 80% for the ratio Li : Ti = 1.5 : 1.7.

Polyvinylcarbazole was obtained in 23–100% yield at temperatures between −78° and +80°C when $C_2H_5AlCl_2$, $(C_2H_5)_2AlCl$, $TiCl_2(OC_3H_7)_2$, $FeCl_2(OCOCH_3)_2$, and $SnCl_2(OCOCH_3)_2$ were used as catalysts [133].

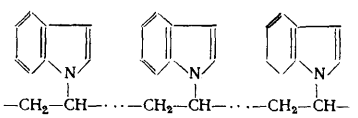
The solid-phase polymerisation of *N*-vinylcarbazole on irradiation with sunlight, ultraviolet light, and γ-rays has been investigated [134-137].

Although the methods for the polymerisation of *N*-vinylcarbazole using all the catalysts enumerated above have been described in many patents, the polymers obtained in this way have not found practical application due to their low molecular weight. The development of the *N*-vinylcarbazole industry in the USA showed that high-molecular weight polymers are mainly manufactured. They are distinguished by their stability to high temperatures and chemical reagents and also by low dielectric constants; such polymers are obtained only by alkaline oxidative polymerisation in emulsion [138]. The process is carried out under a pressure of about 18 atm at 120–180°C. Special initiating agents are potassium or sodium dichromate in an alkaline medium.

Polyvinylcarbazole resins are widely used as surface coatings, for the impregnation of paper, and for the protection of electrical equipment [2].

The information in the literature about the properties and methods of preparation of polyvinylindole is extremely limited. There exist several foreign patents [109,114,116] where the possibility of the polymerisation of *N*-vinylindole is indicated, by analogy with its homologue—*N*-vinylcarbazole. An *N*-vinylindole polymer with a high softening point was obtained by Kawasaki [42] at room temperature in the presence of 4% hydrogen chloride. Schildknecht [100] described the polymerisation of *N*-vinylindole under the influence of 0.01% $BF_3(OC_4H_9)$ below 25°C.

To elucidate the reactivity of the double bond of *N*-vinylindole in polymerisation reactions, Domnina and Skvortsova [139] studied this reaction under the influence of ionic catalysts and free radical initiators. The metal chlorides $SnCl_2.2H_2O$, $SnCl_4$, $AlCl_3$, $TiCl_4$, $TiCl_3$, $FeCl_3$, and also $BF_3O(C_2H_5)_2$ were tested as cationic catalysts. In the presence of 2% $SnCl_4.5H_2O$ *N*-vinylindole polymerises to the extent of 96–98% in 24 h. By analogy with the structural formula of polyvinylcarbazole, it is suggested that the principal unit in polyvinylindole may have the following structure:



The study of the molecular weight distribution in the polymerisation product of *N*-vinylindole by a fractionation procedure showed that polyvinylindole consists mainly of a weakly disperse mixture of polymeric homologues. The maximum on the differential distribution curve is located at low molecular weights, between 700 and 1000, and is fairly broad.

The calculated viscometric constants in the Mark–Houwink equation indicate an extended, rigid, rodlike structure of the polyvinyl molecule and suggest that the latter exhibits electrolytic properties.

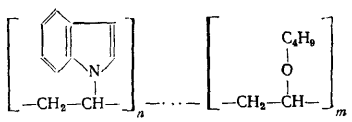
In the presence of benzoyl peroxide *N*-vinylindole does not polymerise, while hydrogen peroxide gives rise to its quantitative conversion into a solid polymeric product. Under the influence of azodi(isobutyronitrile), *N*-vinylindole forms a vitreous substance with a molecular weight in excess of 4000. Thus *N*-vinylindole is an active vinylpolymer capable of polymerising readily both by an ionic and a radical mechanism.

3. Copolymerisation and Activity Constants

Despite the large number of studies dealing with the copolymerisation of unsaturated monomers, so far little work of this kind has been done on the *N*-vinyl compounds of the pyrrole series. There is only one patent [140] which describes a method for the preparation of the copolymer of *N*-vinylpyrrole with tetrachlorodivinylbenzene and acrylonitrile in the presence of organic peroxides. For a long time there were no data whatever about the behaviour of *N*-vinylindole in the copolymerisation reaction.

Shostakovskii et al. [141] studied the free radical copolymerisation of *N*-vinylindole with methyl methacrylate and methacrylic acid. The reaction was carried out with different component ratios in the presence of azodi(isobutyronitrile) at 60°C for 100 h. The resulting copolymers had low molecular weights and a higher relative contents of *N*-vinylindole units than in the mixture of monomers. Potentiometric studies of the copolymers of *N*-vinylindole with methacrylic acid established that they dissociate like acids. The relative activity constants r_1 and r_2 were calculated from the copolymerisation data by a graphical method using the integral equation of Mayo and Lewis. It was found that $r_1 = 1.9 \pm 0.5$ and $r_2 = 0.42 \pm 0.1$ for the monomer pair *N*-vinylindole–methyl methacrylate and $r_1 = 1.43 \pm 0.05$ and $r_2 = 0.096 \pm 0.03$ for the monomer pair *N*-vinylindole–methacrylic acid. These constants confirm that in copolymerisation with methyl methacrylate and methacrylic acid *N*-vinylindole is the more active monomer.

N-Vinylindole retains maximum activity also in the copolymerisation with vinyl ethers. Domnina[89] studied for the first time the copolymerisation of *N*-vinylindole with butyl vinyl ether by ionic and radical mechanisms. Tin, iron, and aluminium chlorides were tested as cationic catalysts. It was shown that, as the amount of *N*-vinylindole in the initial mixture increases, there is an increase in the yield of the copolymer and a decrease in the amount of ether units in the latter. When the *N*-vinylindole : butyl vinyl ether ratio is 20 : 80, both monomers are incorporated in the polymeric chain in approximately equal amounts. Both solid and oily products are then obtained. Spectroscopic and chemical studies suggest the following structure of the principal copolymer units:



where $n > m$. Calculation gives $r_1 = 7.76 \pm 0.58$ for *N*-vinylindole and $r_2 = 0.12 \pm 0.007$ for butyl vinyl ether.

N-Vinylindole is of course the more active in the free radical interaction of these monomers. Thus in copolymerisation initiated by azodi(isobutyronitrile) products with compositions corresponding to component ratios of 90 : 10 and 85 : 15 are formed regardless of the initial component ratio. The low softening points of these copolymers, in the range 350–400°C, and their insolubility in many organic solvents are evidence of their high molecular weight.

Phenyl vinyl ether does not interact with *N*-vinylindole in the presence of cationic catalysts. In this case the polymerisation of each monomer separately takes place. However, phenyl vinyl ether, which does not show a tendency to radical polymerisation, copolymerises with *N*-vinylindole under the action of radical initiators[89].

The behaviour of *N*-vinylcarbazole in copolymerisation reactions has been studied in greater detail and there are more examples. The available literature data on the copolymerisation of *N*-vinylcarbazole with unsaturated hydrocarbons and also with vinyl and acrylic monomers are described below systematically and their practical applications are indicated. Thus polyisobutylene forms with 2% of *N*-vinylcarbazole a rubberlike product[142–149]. It can be vulcanised and, as regards stability to high temperatures, it surpasses polyisobutylene itself. Copolymerisation of *N*-vinylcarbazole with ethylene at 150–300°C under a pressure of 1500 atm in the presence of peroxide catalysts yielded products containing 70–95% of ethylene[146]. Polypropylene is also modified by being mixed with a preformed copolymer of ethylene and *N*-vinylcarbazole[147]. These products are very flexible and highly viscous, have a high tensile strength, and are used as gasket for the protection of glass from cracking. Copolymers of *N*-vinylcarbazole with triphenylethylene have been obtained by solid-state and emulsion polymerisation with peroxide catalysts[148]. *N*-Vinylcarbazole can be copolymerised with vinylphenol by the emulsion method in the presence of 20% H_2O_2 in polyepoxyethane and in the presence of sodium sulphate in sulphonated castor oil[149]. The copolymerisation of *N*-vinylcarbazole with styrenes and a mixture of styrene and acrylonitrile has been investigated in greater detail[33,149–152]. *N*-Vinylcarbazole interacts with styrene in the presence of 0.05–2 parts of alkanethiols and 0.1–10 millimoles of hydroperoxides obtained from di-isopropylbenzene, its halogeno-derivatives, phenylcyclohexane, and an equimolar amount of iron pyrophosphate at 30–40°C.[153] The styrene–*N*-vinylcarbazole copolymers exhibit high thermal stability (127°C) and low dielectric losses (0.00081).[149] Fluorostyrene and 3,4-difluorostyrene form with *N*-vinylcarbazole products which may be used as electrical insulators[154]. In the presence of 0.1% of benzoyl peroxide *N*-vinylcarbazole copolymerises with di(*p*-vinylphenyl)sulphide[155]. The copolymers of *N*-vinylcarbazole and *N*-vinylpyrrolidone[156] are used as stabilisers for hydrazine, fibre-forming compositions, and as adhesives for the improvement of the structure of soils. *N*-Vinylcarbazole forms with acrylonitrile[157,158] polymeric products in the presence of potassium persulphate at 80°C. On irradiation, it reacts with acrylate and methacrylate[159].

The capacity of *N*-vinylcarbazole to copolymerise with other monomers was characterised quantitatively for the first time in 1949 by Alfrey and Kapur[151] in copolymerisation with methyl methacrylate and styrene. Later in 1961 Hart[160] obtained improved values of these characteristics and calculated the specific activity Q and the polarity e.

Table 1. Activity constants for the copolymerisation of *N*-vinylcarbazole (M_1) with certain vinyl monomers (M_2).

M_2	r_1	r_2	Q_1	e_1	Refs.
Methyl methacrylate	0.040	2.0	0.20	−1.20	160
Methyl methacrylate	0.20	2.0	0.25	−0.56	151
Methyl acrylate	0.050	0.50	0.26	−1.32	160
Styrene	0.035	5.7	0.48	−2.07	160
Styrene	0.012	5.5	0.68	−2.45	151
Vinyl chloride	3.7	0.020	3.8	−1.01	160

According to Table 1, the copolymerisation constants show that in reactions with methyl methacrylate and styrene *N*-vinylcarbazole is the less active monomer. The polymeric radical with a terminal *N*-vinylcarbazole unit reacts much more rapidly with methyl methacrylate or styrene than with *N*-vinylcarbazole itself.

Table 2. Copolymerisation constants r_1 and r_2.

M_2	r_1	r_2	$r_1 \cdot r_2$
Vinyl formate	4.220±0.160	0.196±0.004	0.827
Vinyl acetate	3.020±0.240	0.152±0.018	0.465
Vinyl propionate	1.680±0.140	0.076±0.018	0.128
Vinyl butyrate	1.280±0.060	0.059±0.020	0.074

Chernobai et al.[161] made a spectrophotometric study of the copolymers of *N*-vinylcarbazole and methyl methacrylate. Ushakov and Nikolaev[162] studied the copolymerisation of *N*-vinylcarbazole with esters of vinyl alcohol and certain organic acids (formic, acetic, propionic, and butyric) in the presence of 0.5% of benzoyl peroxide. All the systems investigated have been characterised by the copolymerisation constants listed in Table 2.

The calculated copolymerisation constants r_1 and r_2 show that *N*-vinylcarbazole adds to the poly(*N*-vinylcarbazole) radical and to the polymeric chain with a terminal vinyl ester group much more rapidly than the second reaction component.

The experimental data accumulated so far are still insufficient to arrive at reliable conclusions concerning the reactivity of *N*-vinyl compounds of the pyrrole series in copolymerisation as a function of the characteristics of their structure. The number of studies dealing with quantitative calculations of the reactivity is extremely limited even for *N*-vinylcarbazole, the polymers of which are widely used in industry.

IV. CHARGE-TRANSFER COMPLEXES BASED ON PYRROLE, INDOLE, CARBAZOLE, AND THEIR VINYL HALOGEN-CONTAINING DERIVATIVES

The electron-donor properties of the nitrogen atom in the molecules of the heterocyclic compounds are responsible for their capacity to form complexes with various electron acceptors, including iodine, bromine, and chlorine. The study of the problem of intermolecular interaction has developed only recently. Intensive investigation of this problem has been additionally stimulated by the presence of semiconduction in a number of complexes and also by the fact that they can form as intermediates in many complex chemical reactions and biochemical processes [163-167]. The products of intermolecular donor–acceptor interaction are called charge-transfer complexes.

Blyumenfel'd et al. [168] state that such complexes are formed as a result of the redistribution of electron density in the system, leading to a negative charge at the acceptor and a positive charge at the donor. If the degree of transfer of an electron from one molecule to another is slight, the complex is unstable and easily decomposes into the initial molecules. If the interaction is very strong, then redistribution of electron density can lead to complete electron transfer with formation of either an ion pair or of two isolated species.

The theory of intermolecular donor–acceptor interaction was devised as late as the 1960's by Mulliken [169-173], who developed the quantum-mechanical concept of "complex mesomerism" put forward previously by Izmail'skii [174,175]. According to Mulliken's theory, the ground state of the complex is intermediate (mesomeric) between non-ionic and ionic structures, with the former predominating:

$$A + B \rightleftarrows [|\underline{A \ldots B}|] \longleftrightarrow [A^+ \ldots B^-|]$$

Transition to a higher state is accompanied by the appearance of a new intense long-wavelength absorption band, which is frequently the best characteristic of such complexes [176-178].

Aromatic amines and heterocycles with a nitrogen atom, which can be regarded both as π-electron and n-electron donors, constitute an interesting group of donors [179-181]. The study of charge-transfer complexes based on pyrrole compounds has assumed particular importance because they are often constituents of medicinal preparations. Among these compounds, indole derivatives merit most attention. A number of studies carried out by different investigators confirm the electron-donor properties of such compounds. The preparation of complexes of tryptophan or the corresponding indole derivatives with various biochemical electron acceptors containing isoalloxazine or pyridine rings has been described [182-185]. The capacity of indole to form complexes with many electron acceptors such as trinitrobenzene, *p*-benzoquinone, and chloranil is known [186]. A very stable charge-transfer complex of indole and iodine has been described recently [187].

Pullman and Pullman [1], who reviewed studies in quantum biochemistry, state that, judging from the energy coefficient of higher filled molecular orbitals, the electron-donor properties increase on going from pyrrole to indole and remain almost unchanged on going from indole to carbazole. Stable complexes with iodine are formed only by pyrrole and indole. Voronkov et al. [188] investigated by refractometric physicochemical analysis binary systems comprising monosubstituted benzenes of the type C_6H_5X (X = fluorine, chlorine, bromine, or iodine) with simple heterocycles, including pyrrole. They established that they are capable of forming 2 : 1 charge-transfer complexes. The authors concluded that such complexes are formed on the basis of the deviation from additivity of the isotherm and the colour change in the system. Electron transfer reactions with the tropylium cation, carbazole, and *N*-methylcarbazole have been investigated [189].

The studies of charge-transfer complex based on high-molecular-compounds, assumed great importance in the 1960's. [190] Hoegl et al. [190] obtained polymeric complexes based on polyvinyl aromatic, polyvinyl heterocyclic, and other compounds. The methods of their preparation have been described in several German and Belgian patents [191-194]. Hoegl devotes most attention [195,196] to the preparation of complexes based on polyvinylcarbazole. It was established that the latter reacts with nitro-compounds, acids (hydrogen chloride, malonic acid, phthalic acid), esters (dimethyl terephthalate), halogeno-compounds (tetrabromo-*p*-xylene, triphenylchloromethane, 9,10-dichloroanthracene), and quinones (chloranil and bromanil, phenanthrenequinone) [190].

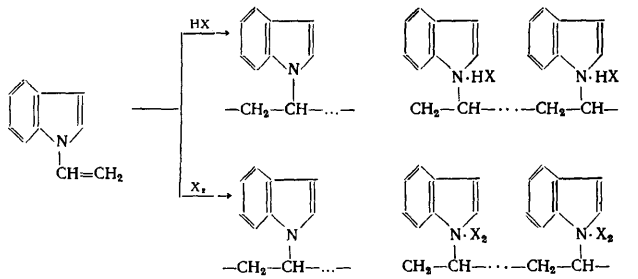
In 1965 Japanese investigators showed that polyvinylcarbazole forms at room temperature in chloroform solution complexes with tetracyanoquinodimethane [197], antimony pentachloride, and iodine [198]. All these products are deeply coloured and absorb in the visible part of the spectrum. Their resistivity is in the range 10^{-12}–10^{-16} Ω^{-1} cm^{-1}.

The solid-phase polymerisation of *N*-vinylcarbazole initiated by charge-transfer complexes of the monomer with acceptors such as Cl_2, Br_2, I_2, $SnCl_4$, and SO_2 is being investigated. Takakura, Okamura, and coworkers [199] made spectroscopic studies of these complexes.

In a more thorough investigation of the halogenation and hydrohalogenation of *N*-vinylindole, Shostakovskii and coworkers [200,201] showed that, instead of the expected products of the addition of the halogen to the double bond of the vinyl group, tetra- and hexamers of the halogeno-derivatives of *N*-vinylindole are mainly formed. It was established that chlorine, bromine, iodine, and the corresponding hydrogen halides readily add to *N*-vinylindole with formation of brightly coloured red, cherry-red, and brown powders which remain stable on storage and are also stable to acid and alkaline hydrolysis. The intense colour, the relatively high molecular weight, the variable composition of the compounds formed, and also the results of quantum-mechanical calculations indicating a relatively low ionisation potential of the *N*-vinylindole molecule led to the hypothesis that polymeric charge-transfer complexes are formed in this case. This is also confirmed by the appearance in the electronic spectra of the halogeno-derivatives of *N*-vinylindole of a broad band with a maximum in the regions 490–500 nm and 350–400 nm.

The fact that all the products of the halogenation and hydrohalogenation of *N*-vinylindole give rise to an ESR signal, which is absent from polyvinylindole, is important evidence for the formation of charge-transfer complexes. The sum of the data obtained suggests that, when halogens

and hydrogen halides react with *N*-vinylindole, the latter undergoes vinyl polymerisation with simultaneous formation of a charge-transfer complex by the following mechanism:



where X = Cl, Br, or I is a σ-electron acceptor component.

According to Mulliken's classification, these complexes may be regarded as the $n\pi\sigma$ type, but in their structure they should also be closer to the $\pi\sigma$ type than to the $n\sigma$ type.

Catalytic amounts of bromine, iodine, chlorine, and the corresponding hydrogen halides initiate the low-molecular polymerisation of *N*-vinylindole and also *N*-vinylcarbazole [121,129,201].

It has been shown that polyvinylindole also readily forms polymeric complexes of the type N...HX and N...X_2 which have a deep colour and give rise to ESR signals [201]. Their resistivity is in the range 10^{-14}–10^{-10} Ω^{-1} cm^{-1}.

Investigations have shown that the halogenation and hydrohalogenation of *N*-vinylindole is a fairly complex process. There are several competing reactions due to the presence in the *N*-vinylindole molecule of several active centres, including the double bond of the vinyl group and the unshared electron pair of the nitrogen atom.

Our earlier hypothesis that bromine adds to the vinyl group [95] appears to be improbable. Probably the same may be said of the work of Pielichowski [93,94], who is also more likely to have dealt with polymeric charge-transfer complexes than with products of the αβ-addition of fluorine, chlorine, bromine, and iodine to *N*-vinylcarbazole.

It follows from the literature data examined that *N*-vinyl compounds of the pyrrole series have been little investigated and are an interesting object for the study of the chemical properties of molecules with several reactive groups.

The Mechanism of the Initiation of the Radical Polymerisation of Polar Monomers in Systems Comprising Organometallic Compounds

E.B.Milovskaya, L.V.Zamoiskaya, and E.L.Kopp

In the present review an attempt is made to examine from the same standpoint the reactions responsible for the development of radical polymerisation in systems comprising organometallic† compounds in combination with oxygen-containing derivatives (oxygen, hydroperoxides, acyl peroxide) or derivatives of variable-valence metals. Attention has been concentrated on systems effective at a low temperature. The causes responsible for the inhibition or total suppression of ionic-coordination polymerisation of polar monomers and favouring the development of the radical process in systems of the Ziegler-Natta type have been discussed. The bibliography includes 135 references.

I. INTRODUCTION

An attempt has been made to use Ziegler–Natta catalysts, which have been successfully employed for the polymerisation of α-olefins, to polymerise other monomers, in particular polar monomers of the vinyl series. At first these attempts were unsuccessful: monomers such as vinyl acetate, methyl methacrylate, acrylonitrile, etc. could not be polymerised. Attempts were made to account for the absence of polymerisation by the breakdown of the catalyst in its interaction with the monomer. The development of studies on the interaction of these catalytic systems with vinyl monomers led to the creation of new initiating systems based on organometallic compounds and oxygen or peroxides capable of inducing radical polymerisation at reduced temperatures. On the other hand, the subsequent employment of the so called modified Ziegler catalysts also made possible the polymerisation of polar monomers.

II. SYSTEMS WITH AN ORGANOMETALLIC COMPOUND (OMC) AND AN OXYGEN-CONTAINING DERIVATIVE

1. Systems with an Organometallic Compound and Oxygen or a Hydroperoxide

It has been shown in a number of studies[1-12] that organic derivatives of Group II and III elements (zinc, cadmium, boron, and aluminium) alone give rise to hardly any polymerisation of polar monomers of the vinyl series; an effective process developed only in the presence of oxygen or peroxy-compounds.

The data presented in Tables 1 and 2 show that the most active of the systems investigated are those containing organoboron compounds in combination with oxygen or a hydroperoxide. The organoboron compounds can be arranged in the following sequence in terms of their activity[13]:

$$(n\text{-}C_4H_9)_2BOB(n\text{-}C_4H_9)_2 > B(n\text{-}C_4H_9)_3 > (n\text{-}C_4H_9)_2B(n\text{-}C_4H_9O) > > (n\text{-}C_4H_9)_2BBr > (n\text{-}C_4H_9)_2BCl$$

The overall activation energy found for a number of systems proved to be very low and comparable to the activation energy for the chain propagation reaction, which made it possible to carry out the process at reduced temperatures[8,12,14-16].

The copolymerisation constants obtained for a number of monomers suggested that radical polymerisation takes place in these systems[2,6,13,16,18,19].

Table 1. Polymerisation of polar monomers under the influence of the systems organometallic compound–oxygen.

Monomer	Process conditions: initiator type	initiator concn., M	10^2 × molar ratio O_2:OMC	time, h	t, °C	Yield of polymer, %	References

**In a sealed tube in air.

***Experiment carried out in a stream of dry and purified air flowing at a constant rate (50 ml min^{-1}).

Welch[2] believes that radicals cannot form as a result of the thermal decomposition of organometallic compounds of this type, since the polymerisation temperature is much below the range corresponding to the thermal decomposition of zinc and cadmium alkyls and boron and aluminium

† The Russian authors use the work "organoelemental" but since the term is not familiar in English and most of the compounds discussed are in fact metal derivatives, it has been replaced by "organometallic", especially since this is the term actually used in the title in the Russian version also (Ed. of Translation).

alkyls altogether fail to yield free radicals on thermal decomposition. The fact that the process can be carried out only in the presence of oxygen or peroxides[20] suggests that the stage preceding the generation of free radicals is the formation of peroxy-derivatives of the organometallic compounds.

The synthesis and reactions of the organometallic compounds have been examined in detail by Sosnowsky and Braun[21], and therefore we shall note only some of their most important (as regards the present topic) reactions. The monoperoxides of cadmium, zinc, boron, and aluminium are extremely unstable at normal temperatures and readily undergo a number of heterolytic and homolytic reactions:

$$-MOOR- \xrightarrow{-MR} 2-MOR \quad (1)$$

$$-MOOR- \longrightarrow -M(OR)_2 \quad (2)$$

$$-MOOR- \longrightarrow -MO^{\cdot} + {}^{\cdot}OR \text{ (or } -MOO^{\cdot} + R^{\cdot}) \quad (3)$$

Alkoxy-derivatives are formed as a result of intermolecular exchange with the initial organometallic compound [reaction (1)][22-25] or by intramolecular exchange [reaction (2)][26,27].

Compounds which might form as a result of further reaction of the free radicals [reaction (3)] have also been identified[23]. The mixture of products formed in the presence of the peroxides of trivalent elements is still more complicated, since diperoxides can also participtae in reactions (1)–(3). For example in the oxidation of organoboron compounds homolytic decomposition takes place to the greatest extent precisely at this stage[23]. A general parallel may be drawn[28] between the ease of the auto-oxidation of organoboron compounds and the capacity of any group to transfer electrons to the unfilled boron orbital, making it less sensitive to attack by oxygen. The activity series of organoboron compounds,

$$BR_3 > R_2BOR > RB(OR)_2 \text{ and } BR_3 > R_2BCl > RBCl_2$$

in oxidation reactions are determined by the overlapping of the boron orbitals by those of chlorine or oxygen. The reactivity of organoboron compounds in oxidation corresponds to their activity in polymerisation processes[13]. The oxidation of organoaluminium compounds and further reactions of peroxides take place even more vigorously than with organoboron compounds[23,27,29]. The only stable peroxides proved to be $Al(OR)_2OOR$, which were isolated and characterised[30]. The fact that the reactions of the peroxy-derivatives of organoaluminium compounds involve a stage with formation of free radicals was demonstrated under model conditions[4] and confirmed by showing that polymerisation in the presence of these peroxides is possible[30]. The peroxy-compounds obtained beforehand at a low temperature are then capable of initiating polymerisation when the monomer is introduced[31]. However, the activity of these pre-formed peroxides is much lower than that of systems which initiate polymerisation by peroxides *in statu nascendi*. In the first case the process develops at temperatures normal for radical initiation‡ and in the second it actually takes place at very low temperatures down to −65°C (for example, with boron compounds).

This phenomenon was explained by the existence of "active" peroxide, since it was established that ethereal solutions of the peroxide rapidly lose their catalytic activty although the peroxide concentration determined iodometrically did not change[31]. It was suggested that the low-temperature polymerisation is initiated by the free radicals formed as a result of a kind of redox reaction between the initial organometallic compound and its peroxide[9,14,33-35].

Bawn et al.[33] showed that in the polymerisation of methyl methacrylate in the presence of $(C_4H_9)_3B-O_2$ neither the peroxide (obtained from part of the boron alkyl) nor the organoboron compound by itself are capable of initiating the low-temperature polymerisation. In a kinetic study they established the following dependence of the reaction rate on the concentrations of the monomer, peroxide, and the initial boron alkyl:

$$V = k_{obs}[M][ROOBR_2]^{1/2}[Br_3]^{1/2}.$$

A mechanism for the formation of free radicals was proposed on the basis of the hypothesis that the reaction is a free radical process. Initially a monomer–boron alkyl complex is produced:

$$BR_3 + M \rightleftarrows BR_3\dot{M}. \quad (4)$$

Equilibrium is established rapidly and is displaced to the right so that the concentration of the complex is almost equal to the initial concentration of tributylboron. Then, in bimolecular redox reaction (5), the initiating radicals are produced:

$$BR_3\dot{M} + R_2BOOR \rightarrow R_3BMRO^{\cdot} + R_2BO^{\cdot}. \quad (5)$$

The authors assume that chain propagation and termination take place as in an ordinary free radical process. The dependence of the rate of initiation on the concentrations of the initiator components obtained from Eqns. (4) and (5) and the variation of the overall rate of the process with the same concentrations found on this basis agree with the experimental findings. These hypotheses might be confirmed by data on the polymerisation kinetics of monomers of low polarity, in particular vinyl chloride. Then the equation for the rate of the process should differ from the corresponding expression for highly polar monomers. Unfortunately Bawn et al.[33] do not present data of this kind.

Talamini and Vidotto[8] believe that the monomer does not participate in the initiation step, since the activation

‡ The period of 50% decomposition of a 1% solution of boron peroxide in octane is 4.3 and 1.5 h at 50° and 100°C respectively; at 25°C the content of the peroxide does not change over a period of 50 h.[32]

energy for initiation under the influence of $(C_4H_9)_3B-O_2$ is the same in the polymerisation of vinyl chloride (a monomer of low polarity) and the highly polar methyl methacrylate§.

Welch[14] believes that the redox reaction between the oxidised and unoxidised forms of the organoboron compound does not require the initial formation of the complex of R_3B with the monomer. The experimental findings for polymerisation agree with the proposed mechanism for the generation of free radicals: the overall rate of the process and the conversion are higher when the concentrations of the boron alkyl and oxygen do not differ very much:

$$BR_3 + O_2 \rightarrow R_2BOOR, \quad (6)$$

$$BR_3 + R_2BOOR \rightarrow BR_3 + R_2BO^{\cdot} + RO^{\cdot}. \quad (7)$$

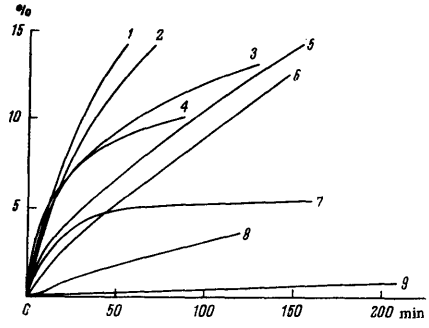

Figure 1. Polymerisation of methyl methacrylate at 30°C in the presence of a constant concentration $[(C_2H_5)_3B]_0 = 7.18 \times 10^{-3}$ M and a variable concentration $[O_2]_0$ (10^{-3} M): 1) 3.36; 2) 1.97; 3) 4.47; 4) 1.14; 5) 5.4; 6) 6.65; 7) 0.51; 8) 7.89; 9) 0.0.

When $[O_2] \gg [R_3B]$, the entire boron alkyl is oxidised to the peroxide and reaction (7) is impossible. When the concentration ratio is reversed, the peroxy-compound is rapidly exhausted, which leads to the decay of the process at a low conversion. From a study of the polymerisation kinetics of methyl methacrylate with $(C_2H_5)_3B-O_2$, Hansen[34] showed that the process can be described by simple relations only at the very beginning. This is because in systems of this type a number of competing reactions take place and lead to the formation of free radicals. The rates of these reactions are different and are determined by the relative amounts of the starting reactants. Figs. 1 and 2 present the kinetic curves obtained for various concentrations of one of the initiating components. The maximum rate occurs when $[R_3B] > 2[O_2]$, but it then falls rapidly as a result of the complete reduction of the peroxide. Under the condition $[O_2] < [R_3B] < 2[O_2]$ the system contains, together with the initial boron alkyl, its hydroxy-form, which is a weaker reducing agent and gives rise to slow and prolonged generation of free radicals at a constant rate:

$$\rangle BOOR + \rangle BR \xrightarrow{fast} R^{\cdot} + (BO^{\cdot}) \quad (8)$$

$$\rangle BOOR + \rangle BOR \xrightarrow{slow} R^{\cdot} + (BO^{\cdot}). \quad (9)$$

The homolytic dissociation of the peroxide bond as a result of the redox reaction was studied under model conditions by Hansen and Hamann[37]. When iodine was used as a free radical acceptor, they established that the interaction of the peroxide with the unoxidised boron alkyl is a reduction process with a stoichiometric ratio close to unity. The formation of ethyl radicals (the only ones reliably demonstrated) does not take place in each step of the interaction in consequency of reduction in the "cage":

$$\begin{array}{l} B-C_2H_5 \\ \uparrow \\ C_2H_5O-O-B\rangle \end{array} \rightarrow \rangle B-OC_2H_5 + C_2H_5^{\cdot} + \rangle BO^{\cdot}. \quad (10)$$

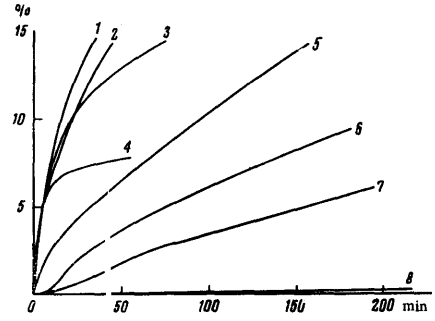

Figure 2. Polymerisation of methyl methacrylate at 30°C in the presence of a constant concentration $[O_2]_0 = 5.4 \times 10^{-3}$ M and a variable concentration $[(C_2H_5)_3B]_0$ (10^{-3} M): 1) 21.5; 2) 71.8; 3) 14.3; 4) 35.5; 5) 7.18; 6) 5.38; 7) 3.6; 8) 1.43; 9) 0.0.

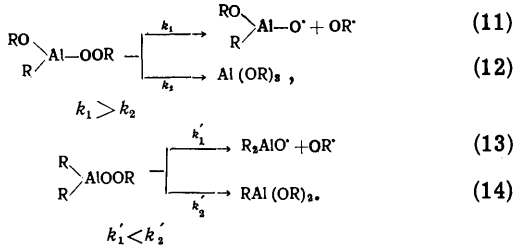
The emergence of the radicals from the "cage" initiates the free-radical processes; the reaction in the "cage" results in the formation of alkoxy-compounds. In agreement with the data obtained under model conditions, a very small boron content was found in the polymer[34].

Furukawa and coworkers[31] showed that systems based on alkoxy-derivatives of zinc in combination with peroxides are more active than those based on zinc alkyls. The latter are weak Lewis acids[38]; this is even more true of the alkoxy-derivatives of zinc, which makes it unlikely that its complex with an electron-donor monomer is formed as a result of reaction (4).

The findings for systems with organoaluminium compounds suggest that in this case too the active polymerisation initiators at low temperature are systems based on monoalkoxydialkylaluminium and oxygen or a hydroperoxide This is confirmed[9,35] by the absence of the polymerisation of vinyl chloride when the system $(C_2H_5)_3Al-O_2$ contains little oxygen and the impossibility of the polymerisation of vinyl acetate under the influence of the system $(C_2H_5)_3Al$–isopropylphenyl hydroperoxide[4]. These findings show that, of the two possible modes of the process: decomposition with formation of free radicals or rearrangement into

§ In the determination of the activation energy for the initiation reaction the value $E_{prop} - \frac{1}{2}E_{term} = 1.5$ kcal mole^{-1} was employed[8]. However, the value of $E_{prop} - \frac{1}{2}E_{term}$ found for vinyl chloride in a number of studies varied from 1.5 to 5 kcal mole^{-1}, [36] and therefore the identity of the activation energies for the initiation reaction found by Bawn[33] and Talamini[8] is purely fortuitous.

an alkoxy-compound, the first takes place with organic derivatives of alkoxyperoxyaluminium [reaction (11)] and the second takes place with the alkylperoxy-derivatives [reaction (14)]:



(11)

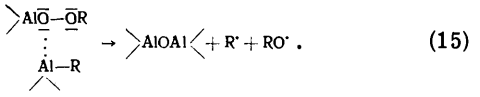
(12)

(13)

(14)

This kind of inversion of rate constants can be explained by the fact that the RO group reduces the electron deficit of the aluminium atom and thus electrons are shifted to the peroxide bond, facilitating its dissociation. On the other hand, in the alkyl peroxide the withdrawal of electrons from the peroxide bond hinders its dissociation and, together with the electron-acceptor properties of the aluminium atom, leads to rearrangement with formation of an alkoxy-derivative. These hypotheses can explain the experimental observations regardless of whether the decomposition of the peroxide is a mono- or bi-molecular process.

Razuvaev and coworkers [35] attributed the formation of free radicals to a redox reaction of the type



(15)

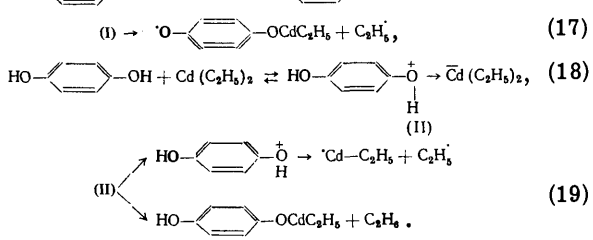
The formation of the R$^{\cdot}$ radical (R = ethyl) was confirmed by the analysis of the gaseous compounds evolved; the RO$^{\cdot}$ radicals were detected in the form of the terminal groups in the polymer.

The results show that the conclusion that polymerisation with organometallic compound–oxygen or hydroperoxide systems has a radical mechanism is fairly well founded. However, the chemistry of the initiation process, in particular the nature of the initiating radicals and the participation of the monomer in this reaction, involves many contradictions. We may note that in the absence of oxygen, boron alkyls are capable of initiating very slow polymerisation of styrene, acrylonitrile, and 1,1-dichloro-2-fluoroethylene, but not vinyl acetate [3].

Hydroquinone does not inhibit this process, which, according to Hansen [34], is evidence of the occurrence of ionic polymerisation. The polymerisation of methyl methacrylate under the influence of (iso-$C_4H_9)_3Al$ and (iso-$C_4H_9)_2Al$.(iso-C_4H_9O) takes place in the absence of oxygen at 60°C and an initiator concentration of 10 mole % relative to the monomer [39]. It was shown that the polymerisation of methyl methacrylate also takes place with $(C_2H_5)_3Al$. [40] The poly(methyl methacrylate) formed has a structure characteristic of polymers produced under the influence of $(C_2H_5)_4CaZn$ and (n-C_4H_9)Li. [41] We may note that extremely large amounts of the catalyst (up to 30% relative to the monomer) are employed in these investigations [39,40]. This leads to the binding of a considerable proportion of the monomer in a complex with the organoaluminium compound (via the carbonyl oxygen), which results in a decrease of electron density at the double bond. Under these conditions, there is a possibility of anionic polymerisation even under the influence of an initiating agent as weak as R_3Al.

2. Systems with Metal Alkyls and Oxygen-Containing Compounds (Quinones, Phenols, and Acyl Peroxides).

Unusual redox systems based on combinations of organometallic compounds and quinones or phenols have been studied by Furukawa et al. [17] The most notable effect was observed in the polymerisation of methyl methacrylate under the influence of $(C_2H_5)_2Cd$–quinone (or phenol) systems. The activity of such systems decreases as a function of the nature of the metal alkyl in the series $R_2Cd > > R_2Zn > R_3Al$. The formation of free radicals is attributed to reaction (16) and (17) in the case of a quinone and (18) and (19) in the case of a phenyl:



(16)

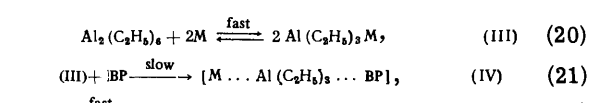
(17)

(18)

(19)

As a result of electron transfer from oxygen to cadmium, unstable addition products (I) or (II) are formed, their decomposition being accompanied by the formation of free radicals.

Milovskaya and coworkers [42–45] obtained systems comprising aluminium alkyls and acyl peroxides capable of initiating the polymerisation of polar monomers (vinyl acetate, methyl methacrylate, acrylonitrile). The process obeys the laws of free-radical polymerisation and occurs much below the temperature of the thermal decomposition of the corresponding peroxides. The step involving the formation of free radicals is unusual in this case and different from the processes occurring in organometallic compound–hydroperoxide systems. The interaction between $(C_2H_5)_3Al$ and benzoyl peroxide (BP) takes place very vigorously in the absence of the monomer by a donor–acceptor mechanism with a stoichiometric ratio of 2:1. Under the experimental conditions, this reaction does not stop at the stage involving the formation of the complex and results in the formation of the following final products: diethylaluminium benzoate and gaseous compounds derived from various reactions of the ethyl radical [46]. An obligatory condition for the occurrence of polymerisation is the participation of the polar monomer in the formation of an intermediate complex [42]. The sum total of the information obtained under model conditions and in polymerisation suggests that free radicals are formed in the following reactions [47]:



(III) (20)

(IV) (21)

(22)

The relation between the rate of initiation and the concentration of the components of the initiating systems obtained from Eqns.(20)–(22) leads to an expression for the variation of the overall rate of the process with the concentration of the aluminium alkyl and the peroxide, which has been confirmed experimentally:

The capacity for complex formation of monomers which are weak electron donors, such as styrene or vinyl chloride, has proved insufficient for the occurrence of polymerisation under the influence of the system $(C_2H_5)_3Al$–acyl peroxide. In this case, for polymerisation to occur, it is necessary to introduce complex-forming agents such as an ether or ester or acetonitrile[47,48]. The results of studies on the kinetics of the polymerisation of vinyl chloride with the system $(C_2H_5)_3Al$–benzoyl peroxide (BP)–ethyl acetate (EA) show that the step involving the formation of free radicals is different in this case from the corresponding reactions in the polymerisation of polar monomers. The expression for the total rate of polymerisation is

$$V = k[M]^n\left[\frac{Al(C_2H_5)_3}{\ni A}\right]^{1/4}[BP]^{1/4},$$

from which it follows that the non-complex form of the organoaluminium compound participates in the stage involving the formation of free radicals; the stoichiometric ratio of the components of the catalytic system is the same as in the model system (without monomer):

$$Al_2(C_2H_5)_6 + 2\,EA \rightleftarrows 2\,Al(C_2H_5)_3\cdot EA, \qquad (23)$$

$$2\,Al(C_2H_5)_3 + BP \xrightarrow{k_1} 2\,C_6H_5COOAl(C_2H_5)_2 + 2\,C_2H_5^{\cdot}. \qquad (24)$$

The observed difference in the behaviour of the complex-forming agents and polar monomers is evidence that the function of the latter (in the free radical formation stage) is not restricted solely to the role of complex-forming agents. Probably the displacement of the monomer by benzoyl peroxide from the complex $(C_2H_5)_3Al.M$ [reactions (21) and (22)] is accompanied by the interaction of the benzoate radical with the double bond (a reaction in the "cage"). This is reflected in a change of the stoichiometric relation between the components of the catalytic system established under model conditions[46] and in the polymerisation of polar monomers[43-45].

The fundamental difference between the mechanisms of the formation of free radicals in systems with participation of hydroperoxides and acyl peroxides is well illustrated by the dependence of the efficiency of the system on the nature of the organoaluminium compounds and monomers employed. In the formation of initiating systems based on acyl peroxides one can use only aluminium alkyls but not alkoxy-derivatives, which are weak Lewis acids and show no tendency to react with electron-donor compounds[42,44,47,49]. On the other hand, in combination with a hydroperoxide, active systems have been obtained only with mono- and dialkoxy-derivatives of aluminium and the electron–donor capacity of the monomer is not an essential condition for the process to occur[4,9,35].

The phenomenological conditions necessary for the development of the polymerisation process with participation of the system R_3Al–acyl peroxide corresponds most closely to the conditions which obtain in the polymerisation of polar monomers with modified Ziegler catalysts. Consequently systems of the first type can be regarded to some extent as models for more complex multi-component systems[50]. Razuvaev and coworkers[51] established that systems based on di-isopropylmercury and benzoyl peroxide are active initiators of the polymerisation of methyl methacrylate and vinyl chloride. The process kinetics indicate free radical polymerisation; the authors believe[52] that the formation of free radicals can probably be attributed to reactions analogous to those proposed in the study of the interaction of the above components under model conditions. The system with the organomercury compound is much less active than that obtained on the basis of aluminium alkyls.

III. SYSTEMS WITH A METAL ALKYL AND A VARIABLE-VALENCE METAL DERIVATIVE

The polymerisation of polar monomers of the vinyl series can be achieved successfully with the so called modified Ziegler catalysts. At the present time there is no single view concerning the mechanism of the process, i.e. whether they are of the radical or ionic-coordination type. Nevertheless the literature data show that there is better evidence for a radical mechanism.

In many cases the catalyst is modified by the introduction into the reaction system of a polar solvent[53-55]. Furukawa and coworkers[54,55] showed that polar monomers such as vinyl acetate or methyl methacrylate themselves behave as polar solvents. Although a rational approach to the choice of the catalytic pair does not exist, nevertheless a necessary condition for the process to occur is the separation of the catalyst components by a complex-forming agent (the monomer or solvent)[54].

Table 3. Activity of the catalytic systems metal alkyl–metal halide in the polymerisation of polar monomers* [54].

Catalyst	Monomer	t, °C	Time, h	Conversion, %
$(C_2H_5)_2Zn$–$VOCl_3$	MMA**	20	24	82
$(C_2H_5)_2Zn$–$FeCl_3$	MMA*	20	24	90
$(C_2H_5)_2Zn$–VCl_4	VA	20	24	56
$(C_2H_5)_2Cd$–VCl_4	VA***	20	27	39
$(C_4H_9)_2Hg$–$BiCl_3$	MMA	15	50	86
$(C_2H_5)_3Al$–VCl_4	VA	20	40	36

*5 ml of solvent; 2 mole % of metal alkyl; 1 mole % of metal halide; 5 ml of monomer.

**The solvent was hexane and in the remaining cases dioxan.

***3 ml of monomer and 1.5 ml of solvent.

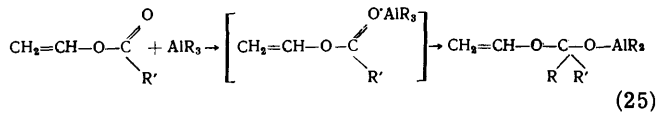
Table 3 presents certain data for the polymerisation of a number of polar monomers under the influence of systems metal alkyl–metal halides. In all cases the components are introduced in a specified order: the metal halide (MX) first, then the monomer, and finally the metal alkyl (RM).

When the order was altered, MX followed by RM and then by the monomer, polymerisation did not occur; this feature differs sharply from the behaviour of the catalytic system in the polarisation of non-polar monomers[54].

Table 4 presents data for the effect of the solvent on the activity of the catalytic system $(C_2H_5)_3Al$–VCl_4.[55]

At present it is not clear why the nature of the monomer affects the relative positions of complex-forming compounds in the activity series (Table 4). The data for the variation of the rate of the process when the order of mixing of the reacting compounds is altered in any way show that in the catalytic system $(C_2H_5)_3Al$–$VOCl_3$ both components are involved in complex formation, but the complex-forming capacities of vinyl and ethyl acetates are by no means equivalent[55]. A similar conclusion is valid also for the system $(C_2H_5)_3Al$–VCl_4 (see Table 4). It may be

supposed that this difference is associated with the irreversible consumption of part of the organoaluminium component by its interaction with the monomer:



(25)

Table 4. Effect of solvent on the activity of the system alkylaluminium–vanadium halide[55].

Monomer	Solvent	Conversion, %	Monomer	Solvent	Conversion, %
VA	n-hexane	4	MMA	n-hexane	2
	toluene	4		toluene	2
	ether	14		ether	7
	tetrahydrofuran	39		tetrahydrofuran	67
	dioxan	29		dioxan	61
	ethyl acetate	61		ethyl acetate	28
	ethanol	traces			
	acetone	traces			

Note. Experimental conditions: 5 ml of monomer, 1 mole % $(C_2H_5)_3Al$, 0.25 mole % $[VCl_4]$, 1 ml of n-hexane as solvent for the catalyst, 4 ml of solvent, room temperature, duration 24 h; order of mixing: (1) metal halide, (2) solvent, (3) monomer, (4) $(C_2H_5)_3Al$.

The occurrence of such reactions has been established for organocadmium compounds[56]. In order to elucidate the mechanism of the effect of such systems, a study was made of the copolymerisation of methyl methacrylate with styrene and of vinyl acetate with styrene using catalysts of the type RM–MX (where M in RM is cadmium, zinc, or aluminium and MX is $VOCl_3$, VCl_4, or $TiCl_4$). It was found that the composition of the copolymer is the same as in a radical process[54,57]. To confirm the radical mechanism of the polymerisation, the ESR method was also employed[54]. In the spectrum of the system ethylene dimethacrylate–$(C_2H_5)_2Zn$–$HgCl_2$ or ethylene dimethacrylate–$(C_2H_5)_2Cd$–$HgCl_2$ the same signals were observed as in the polymerisation of the same monomer under the influence of azobis(isobutyronitrile). On the basis of the data obtained, hypotheses were put forward concerning the free radical mechanism of the polymerisation of polar monomers on Ziegler catalysts[54,55,57].

One may add that in a number of studies[58,59] the possibility of the polymerisation of acrylonitrile and methyl methacrylate under conditions in which the components of the Ziegler catalyst were mixed before the addition of the monomer has been demonstrated.

The catalytic systems $(C_2H_5)_3Al$–$TiCl_4$ and $(C_2H_5)_3Al$–$Ti(OR)_4$, maintained at 0° and 30°C respectively, were used to polymerise methyl methacrylate[58,59]. In view of the enhanced content of the polymer with the syndiotactic structure (92% against 84% in the radical process), the authors concluded that non-radical polymerisation occurs in this case.

Acrylonitrile has been polymerised using the system $(C_2H_5)_3Al$–$VOCl_3$ maintained at 25°C for 20 min[60]. According to infrared spectroscopic data, the resulting polymer (M = 2325) had a structure different from that expected for a radical process.

Much attention has been devoted to the elucidation of the possible use of catalytic systems of the Ziegler–Natta type in the polymerisation of vinyl chloride. The choice of catalytic systems in this case is complicated by the fact that metal alkyls, and in particular aluminium alkyls, are capable of reacting irreversibly with the chlorine-containing monomer and the polymer[61–63]. Organoaluminium compounds are known[64–66] to take part in the reaction

$$AlR_3 + R'X \rightarrow R_2AlX + R'{-}R \qquad (26)$$

more or less readily depending on the structure of the initial compound and that of the halogeno-derivative. In many cases the process goes to completion and results in the formation of aluminium trichloride—a typical cationic catalyst. In the presence of a variable-valence metal halide, aluminium halide formed by the reaction

$$MX_n + AlR_3 \rightarrow RMX_{n-1} + R_2AlX \qquad (27)$$

reacts subsequently even more readily with the chlorine-containing component[62].

Modified catalytic systems suitable for the polymerisation of vinyl chloride differ from the classical Ziegler–Natta catalysts by the fact that they include either an organometallic compound with reduced reactivity or complex-forming agents capable of altering to some extent the nature of the catalyst components.

Razuvaev and coworkers[67–70] must be regarded as pioneers in the field of vinyl chloride polymerisation on complex catalysts. They employed as components of the catalytic system organic derivatives of alkoxyaluminium or an alkoxyalkylaluminium halide combined with Ti^{4+} and Ti^{3+}. The data in Table 5 show that very active catalytic systems can be obtained by a suitable choice of components.

It is interesting to note that there exists an optimum ratio of the complex-forming agent (CFA) and the organoaluminium compound, namely CFA : Al < 1, for which the yields and the molecular weights of the polymer are maximum.

It is believed[68,69] that a necessary condition for the activity of the catalytic system is the presence of an organoaluminium compound in a free state. It has been shown that in the polymerisation of vinyl chloride on modified catalysts the same rules hold as for non-polar monomers (for example, the polymeriastion of propene is influenced by electron-donor additives[71,72]). It is thought[67–70] that this is evidence of the occurrence of an ionic-coordination

process. The improved crystallinity of poly(vinyl chloride) obtained on the heterogeneous catalyst $(C_2H_5)_3Al-TiCl_3-CFA$ compared with the polymer synthesised using radical initiators is quoted by the authors as confirmation of their view. However, it has been established that all poly(vinyl chloride) specimens of low molecular weight show high crystallinity regardless of the method of their preparation[73,74]. Thus the fact of improved crystallinity alone cannot be unambiguously interpreted, since the polymers obtained had $[\eta] = 0.1-0.2$.

Ashikari[75-77] investigated as catalysts for the polymerisation of vinyl chloride a number of catalytic systems of the type $(C_2H_5)_3Al-MX-MC$, where MX is the halide of a variable-valence metal (titanium, iron, vanadium, etc.) and MC is the modifying component (butanol, tetrahydrofuran, dibutyl sulphide, ethyl acetate, acetone). Fig. 3 shows the relation between the rate of polymerisation and the MC : Al ratio for the system $(C_2H_5)_3Al-VCl_3$. Depending on their effect on the rate of the process, the modifying components can be clearly divided into two groups. The first includes butanol, tetrahydrofuran, and dibutyl sulphide which give rise to a distinct maximum in terms of the variables investigated. With butanol, the maximum effect at MC : Al = 3 was attributed[75-77] to the formation of trialkoxyaluminium which is more active in the formation of the catalyst than the initial alkyl. Thus we may note that, for systems with titanium tetrachloride, dialkoxyaluminium derivatives are no longer active as co-components[68]. The maximum rate at MC : Al $\geq$ 1 in the presence of tetrahydrofuran or dibutyl sulphide has been explained[75-77] by the participation in the process of the complex form of the organoaluminium compound. The monotonic increase of the rate in the presence of ethyl acetate is probably associated with the formation of an alkoxy-compound:

$$R-\underset{\underset{OR}{|}}{\overset{\overset{O}{\|}}{C}} + Al(C_2H_5)_3 \rightarrow R-\underset{\underset{C_2H_5}{|}}{\overset{\overset{OAl(C_2H_5)_2}{|}}{C}}-OR \quad . \qquad (28)$$

The occurrence of this type of reaction is extremely likely, since the process was carried out at 40°C. A similar reaction can also take place in the presence of acetone which reacts in the enol form with organoaluminium compounds[78]. In this case too a monotonic increase of the rate was observed with increasing concentration of the modifying agent MC. The lack of an effect on the structure of the polymers produced and also the similarity of the copolymerisation constants of vinyl chloride and acrylonitrile to the usual constants for radical processes lead to the hypothesis of the occurrence of radical polymerisation and the influence of systems of the type $(C_2H_5)_3Al-MX-MC$.[77]

One may add to this that, on the basis of the copolymerisation constants of vinyl chloride and vinyl acetate, Baker[79] regards copolymerisation under the influence of the system $(iso-C_4H_9)_3Al-VOCl_3$ as a radical process.

Systems consisting of alkoxyaluminium compounds and various derivatives of variable-valence metals have been investigated by Giannini and Ceska[80]. The system $(C_2H_5)\cdot AlCl(OC_2H_5)$–vanadium oxide acetylacetonate proved to be the most active; vinyl chloride was polymerised down to temperatures as low as −78°C. The kinetic method was employed to elucidate the mechanism of the action of this catalyst. It was established that the variation of the reciprocal of the degree of polymerisation with the solvent : monomer ratio resembles the corresponding relation in a radical process.

On the basis of these results and the copolymerisation of constants of vinyl chloride and vinyl acetate, it was concluded that the process is of a free radical type. The authors see confirmation of this view[80] also in the fact that the structure and properties of the polymer obtained in the presence of the above catalytic systems and in radical polymerisation (at the same temperatures) are identical. When the reaction was performed under model conditions (in the absence of the monomer), the formation of gaseous compounds (ethane and butane) was observed and was attributed to the occurrence of free radical stages. The participation of ethyl radicals in the initiation step was also established by the finding that a polymer with labelled terminal groups is formed when a labelled organoaluminium component is employed (it was shown that chain transfer to aluminium does not take place). Effective catalytic systems for the polymerisation of polar monomers were obtained by Yamazaki and coworkers[81,82] using titanium tetrabutoxide in combination with organoaluminium compounds. The latter can be arranged in the following series in terms of their activity as co-components of the catalyst: $(C_2H_5)AlCl_2 \gg (C_2H_5)_2AlCl > (C_2H_5)_3Al > AlCl_3 > (C_2H_5)_2\cdot Al(OC_2H_5)$.

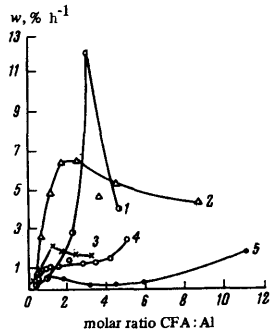

Figure 3. The effect of the nature and concentration of the complex-forming agent (CFA) on the rate of polymerisation of vinyl chloride at 40°C in the presence of the system $(C_2H_5)_3Al-VCl_3$; molar ratio Al : V = 1.37: 1) butanol; 2) tetrahydrofuran; 3) dibutyl sulphide; 4) ethyl acetate; 5) acetone.

Attention was concentrated on the polymerisation of vinyl chloride with the most active system $(C_2H_5)AlCl_2-Ti(OC_4H_9)_4$. In view of the absence of both the inhibiting effect of diphenylpicrylhydrazyl and of the effect of carbon tetrachloride as a chain-transfer agent (carbon tetrachloride did however accelerate the process) and the difference between the copolymerisation constants of styrene and vinyl chloride on the other hand and the values characteristic of radical processes on the other, it was concluded that the reaction occurring under the influence of this system (and other similar systems) is most likely to have an ionic-coordination mechanism[81,82]. For our part, we may note that many facts are fairly consistent with the hypothesis of the radical nature of the process or at least they do not contradict it. The absence of the effect of diphenylpicrylhydrazyl can be probably attributed to the higher rate of the donor–acceptor interaction ($\rangle N \rightarrow Al\langle$) than that of the reaction with participation of an unpaired electron. Furthermore, it was established that carbon tetrachloride is not a chain-transfer agent in the radical polymerisation

of vinyl chloride[83]. The interaction of organoaluminium compounds with carbon tetrachloride takes place via a free radical formation stage[84]¶, which may in fact be responsible for the acceleration of polymerisation[81,82] in the presence of carbon tetrachloride.

Budanova and Mazurek[88] made a detailed study of the kinetics of the polymerisation of vinyl chloride with $Ti(OC_4H_9)_4$–$(iso\text{-}C_4H_9)_2AlCl$, which is very similar to those discussed above[81,82]. They established that the dependence of the rate of polymerisation on the concentration of the components of the initiating system and the rate of formation of Ti^{3+} under model conditions are consistent with a typical radical reaction with bimolecular chain termination. The variation of the reciprocal of the degree of polymerisation with the rate of the process is characteristic of free-radical initiation. The ratio k_{term}/k^2_{prop} obtained proved to be equal to the value quoted for radical initiation[89].

One of the proofs for the ionic-coordination polymerisation of vinyl chloride on modified Ziegler catalysts is the possibility of copolymerising it with propene[82,90]. However, Imoto and coworkers[91] established that vinyl chloride copolymerises with propene also under the influence of radical initiators [azobis(isobutyronitrile)]; as a result, the very fact of the formation of the copolymer in the system metal alkyl–metal halide cannot be interpreted unambiguously. One could postulate that in the case of modified Ziegler catalysts two processes take place: one, with an ionic-coordination mechanism, leads to the formation of polypropylene and the other has a radical mechanism involving the participation of vinyl chloride. The formation of the copolymer may be regarded as a result of the generation of a radical centre in the main chain of the polypropylene, which then initiates the grafting of vinyl chloride or recombines with the growing poly(vinyl chloride) radical.

The results of studies of the polymerisation of polar monomers with many modified catalysts show that the concept of the development of a radical process is in this case fairly well founded[54,55,57,77,79,80,88].

We shall now examine the problem of what reactions between the components of the Ziegler catalyst lead to the formation of free radicals. Unfortunately there are almost no literature data on the interaction between the components of the initiating systems effective in the polymerisation of polar monomers; systems which are relatively inactive in such processes have been mainly examined. Therefore the information given below is to some extent arbitrary.

The reactions between organoaluminium compounds and titanium derivatives have been studied in a number of investigations[92–104]. The rate of reaction and the degree of reduction of titanium depend on the nature of the reacting compound: for example, the interaction of triethylaluminium with titanium tetrachloride at a moderate temperature takes place rapidly even in dilute solution[97]. When the concentrations of R_3Al and $TiCl_4$ are approximately equal, then, on the basis of the final products, the reaction between them can be described as follows:

$$AlR_3 + TiCl_4 \rightarrow AlR_2Cl + RTiCl_3 \quad (29)$$
$$\downarrow$$
$$\frac{1}{2}RH + \frac{1}{2}R_{-H} + TiCl_3.$$

The formation of gaseous compounds (methane, ethane, and butane when R = methyl or ethyl) has been attributed to the breakdown of the organotitanium derivative into free radicals with subsequent reactions of the latter[92–96]. A series of alkyl derivatives of titanium have been obtained and investigated†. They are thermally unstable, the most stable being the methyl derivative. Ethyltitanium trichloride decomposes in 24 h at 20 °C.[106]

The interaction of CH_3TiCl_3 with carbon tetrachloride in the presence of metallic mercury takes place via intermediate stages in which free radicals take part[107]. The possibility of the radical polymerisation of vinyl chloride under the influence of organotitanium compounds in combination with carbon tetrachloride has been established[108].

North[109] showed that the polymerisation of styrene under the influence of $RTi(OC_3H_7)_3$ obeys the laws governing free radical reactions. A number of investigators, however, believe that the breakdown of organotitanium compounds takes place without the formation of free radicals and is subject to relations characteristic of bimolecular reactions[98–104]. On the basis of a study of the products of the reaction of $TiCl_4$ with $(C_2H_5)_2AlCl$, de Vries[99] concluded that in this case free radicals are not formed. This conclusion has been confirmed by experimental facts: when the reaction is carried in cumene, dicumenyl (the product of the recombination of the radicals formed when hydrogen is removed from cumene) was not observed; in the reaction in a deuteriated solvent, deuterium was not detected in the gaseous product. On the other hand, the interaction with a deuteriated aluminium alkyl leads to gaseous products which contain an amount of deuterium consistent with the initial content. The formation of such gaseous compounds has been explained[99] from the standpoint of the "self-consistent" bimolecular interaction in which a β-hydrogen atom is transferred from one molecule of the organotitanium compound to another:

$$2\,TiCl_3\text{—}CH_2\text{—}CH_3 \rightarrow 2\,TiCl_3 + C_2H_6 + C_2H_4. \quad (30)$$

De Vries[99] noted that such concepts are particularly useful for the understanding of the stability of methyl derivatives. Shilov and coworkers[102] established that the interaction of $Ti(OR)_4$ with $(C_2H_5)_3Al$ is a two-stage process: initially there is a rapid reaction with evolution of ethane, whose amount corresponds approximately to half of the initial $Ti(OR)_4$ [reaction (31)] and then ethane is formed slowly as a result of reaction (32), which takes place subsequently. When the above reactants interact in deuteriotoluene, deuteriated ethane is not detected in either the first or the second portions of the gas. According to the authors[102], these findings indicate the absence of free radical stages and the formation of gaseous products is a consequence of intramolecular disproportionation. The process can be described as follows:

$$Al(C_2H_5)_3 + Ti(OC_4H_9)_4 \rightarrow {}^1/_2\,C_2H_6 + {}^1/_2C_2H_4^{\ddagger} + \text{(V)} \quad (31)$$

(V) = $(C_2H_5)_2Al(OC_4H_9)_2Ti(OC_4H_9)_2$, with C_4H_9 on the bridging O atoms.

$$V + Al(C_2H_5)_3 \rightarrow \text{(VI)} \rightarrow \text{slow decomposition}. \quad (32)$$

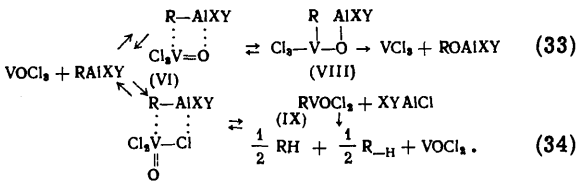
(VI) = $(C_2H_5)_2Al(OC_4H_9)_2Ti(OC_4H_9)_2Al(C_2H_5)_2$, with C_4H_9 on the bridging O atoms and C_2H_5 on Ti.

¶ Systems of the type aluminium alkyl–carbon tetrachloride have been used to initiate the polymerisation of vinyl chloride[85–87].

† See the review of Razuvaev and Latyaeva[105].

‡ The absence of ethylene from the gas evolved is explained by its possible polymerisation.

In the study of the kinetics of the decomposition of CH_3TiCl_3 in carbon tetrachloride Beerman and Bestian[110] established that in this case there is a bimolecular reaction; less than 1% of methyl chloride was detected in the reaction products, which is evidence of only insignificant participation of free radicals in the process. The interaction of organoaluminium compounds with vanadium derivatives, in particular with $VOCl_3$ has been little studied. Petrov showed[111] that the rate of reaction of $VOCl_3$ with $(C_2H_5)_3Al$ is very high; at room temperature the reduction process terminates after less than 2–3 min. Since two possible pathways exist, the process is much more complex than with titanium tetrachloride:



(33)

(34)

The rate of reaction by a particular pathway depends on the relative likelihood of the formation of intermediate complexes (VI) and (VII) and on the stability of compounds (VIII) and (IX).[111] In recent years reliable proof of the formation of organovanadium compounds has been published§. In the study of the mechanism of the breakdown of phenylvanadium oxide dichloride[112] it was established that the decomposition kinetics indicate the occurrence of the following monomolecular reaction:

$$C_6H_5VOCl_2 \rightarrow [C_6H_5^{\cdot} + VOCl_2] \rightarrow C_6H_5{-}C_6H_5. \qquad (35)$$

However, the hypothesis of a radical mechanism for this process is inconsistent with the absence of other reactions characteristic of a highly active phenyl radical (for example the products of the reaction with the cyanodimethylmethyl radical have not been detected, there is no interaction with carbon monoxide, etc.).

Another mechanism has been suggested for the formation of biphenyl[112], which is also consistent with monomolecular decomposition kinetics:

$$2\,C_6H_5VOCl_2 \rightleftarrows (C_6H_5)_2VOCl + VOCl_2, \qquad (36)$$

$$(C_6H_5)_2VOCl \xrightarrow{k} C_6H_5{-}C_6H_5 + VOCl. \qquad (37)$$

The rate of formation of biphenyl is

$$V = k[(C_6H_5)_2VOCl].$$

The equilibrium constant corresponding to reaction (36) is

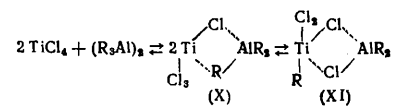
$$K = \frac{[(C_6H_5)_2VOCl]^2}{[(C_6H_5)_2VOCl_2]^2}$$

whence

$$V = k \cdot K^{1/2}[C_6H_5VOCl_2]$$

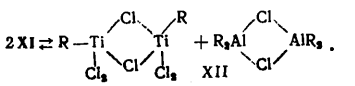
The data quoted demonstrate that the usual procedures in many cases failed to detect the formation of free radicals in the reaction between the components of a Ziegler system in non-polar media. Comparison of the kinetic data for the polymerisation of vinyl chloride under the influence of $(iso\text{-}C_4H_9)_2AlCl{-}Ti(OC_4H_9)_4$ and for the interaction of these components under model conditions established that the fraction of free radical reactions amounts to about 1%.[88] The explanation of the impossibility of isolating the reaction products of free radicals, in particular in experiments with deuteriated solvents, should be based on this finding in the first place. Thus the most sensitive indication of the reactions between the components of the catalyst is the polymerisation itself.

We shall now attempt to represent more fully the reactions which may occur in the catalytic system and the role of the complex-forming agents in the process in those cases where they do not lead to the irreversible consumption of the organometallic compound (the function of the polar monomer should also be determined mainly by its capacity for complex formation). Organoaluminium compounds, which are electron deficient, are known to be capable of forming dimeric species and to participate readily in radical exchange reactions[113–115]. It may be supposed that the first stage of the reaction with a variable-valence metal is the formation of the following association complexes[97]:



(38)

The bimolecular decomposition of compound (XI) leads to the gaseous compounds R–R and $RH(R_{-H})$. Another reaction pathway for the association complex (XI) may be a bimolecular rearrangement of the type¶



(39)

The formation of free radicals may be attributed to the monomolecular decomposition of the organotitanium complex (XII). However, in view of the similarity of the radicals formed, this process takes place mainly by a cryptoradical mechanism with a very small amout of free radicals liberated in the reaction space. The preferential course of the reaction towards the formation of the complexes (XI) or (XII) is associated with the structure of the initial compounds. The specificity of the components of the Ziegler system capable of effecting radical polymerisation consists in the fact that the interaction between them leads to the formation of species tending to undergo homolytic breakdown. In this connection we may note that the stability of organotitanium compounds depends on the nature of R and X (in compounds of the type R_nTiX_{4-n}) and lies in the order indenyl > α-naphthyl > phenyl > *p*-anisyl > > ethynyl > methyl > butyl. On the other hand, the stability increases when the group X has the optimum electronegativity, which is not as high as in the case of fluorine and not as low as in the case of an alkoxy-group[116,117].

The role of complex-forming agents reduces in the first place to the retardation of the subsequent interaction of the metal alkyl and the variable-valence metal having made good their electron deficit; as a result there is a possibility of radical generation in the course of time from rapidly reacting components. The question of the further interaction between the catalyst components in the presence of the complex-forming agent, i.e. the question of the driving forces for this process, remains insufficiently clear. Two pathways may be postulated: in one of them the reaction takes place via non-complex species through the following equilibria:

$$MR_n + K \rightleftarrows MR_n \cdot K,$$
$$MX + K \rightleftarrows MX \cdot K. \qquad (40)$$

§ See the review of Razuvaev and Latyaeva[105].

¶ The absence of an ESR signal in the study of precipitates containing trivalent titanium suggested the existence of dimeric species in titanium halides[100].

i.e. the function of the complex-forming compound is to decrease the concentration of the reacting compounds. This course of the process has been established in the study of the kinetics of the reaction of $(iso\text{-}C_4H_9)_2AlCl-Ti(OC_4H_9)_4$ in the presence of ethyl acetate[118]. Another possibility is the reaction of the complex with displacement of one electron-donor compound by another[119], for example:

$$K\cdot AlR_3 + MX \rightarrow [K \ldots AlR_3 \ldots MX] \rightarrow K + AlR_3\cdot MX\,. \qquad (41)$$

The existence of pentacoordinate aluminium has been unambiguously established recently on the basis of isolated and characterised complexes having the composition

$(C_2H_5)_2AlI\cdot 2\,C_5H_5N$[120] and $(C_2H_5)_3Al\cdot 2,2'$-dipyridyl.[121]

These reactions do not exhaust the role of complex-forming compounds. Association complexes formed by reactions (38) and (39) are also acted upon by the polar reagent, particularly the complexes containing titanium alone [compound (XII)]. There are grounds for the belief that in this case cryptoradical reactions are transformed into true radical reactions. Beerman and Bestian[110] showed that, when CH_3TiCl_3 is decomposed in ether, the process kinetics and the nature of the products formed change. The rate of decomposition increases enormously and the variation with time is consistent with a monomolecular and not a bimolecular reaction. The authors attribute the observed phenomenon to the loosening of the TiR bond under these conditions, which ultimately leads to its homolytic dissociation; the yield of ethane is 28%, while in the absence of ether its amount is negligible.

The decomposition of $C_5H_5VOCl_2$ in the presence of tetrahydrofuran, acetonitrile, and butyl ether is treated by Shilov and coworkers[122] as a free radical process occurring as a result of the increase in the degree of specific solvation of $VOCl_2$ formed relative to the initial compound. A detailed study of the kinetics of the reaction of $(iso\text{-}C_4H_9)_2AlCl$ with $Ti(OC_4H_9)_4$ in the presence of ethyl acetate was made by Budanova and Mazurek[118], who showed that the role of the complex-forming agent at concentrations higher than that of the organoaluminium compound is not restricted solely to the interaction with the initial metal alkyl. In this case there is a change in the order of the reaction with respect to the components of the initiating system, corresponding to a transition from bimolecular to monomolecular breakdown of the intermediate complex of the alkyl derivative of titanium(IV) with generation of free radicals.

The above hypotheses concerning the chemistry of the formation of free radicals and the role of complex-forming compounds are to a large extent tentative. Nevertheless they make it possible to understand the causes of the difference between ionic-coordination polymerisation and the polymerisation of polar monomers. The latter gives rise not to the final reaction product MR_n-MX_m but to unstable intermediate compounds formed in the course of this reaction.

At the present time the hypothesis that in ionic-coordination polymerisation the propagation steps are preceded by the coordination of the double bond of the monomer to the unfilled orbitals of the variable valence metal has been widely adopted. As shown for titanium tetrachloride, in the case of polar monomers where the heteroatom is in the β-position with respect to the double bond the preferred coordination site is located at the polar groups[123]. To what extent such concepts are valid also for trivalent titanium (or other metals in a lower valence state) remains obscure at present. Therefore we should note that the literature data quoted, indicating the occurrence of radical polymerisation of polar monomers using Ziegler catalysts, nevertheless do not exclude the possibility that in special cases ionic-coordination polymerisation of this class of monomers can also take place.

---o0o---

During the preparation of the manuscript for the press new literature data were published which can usefully supplement the corresponding sections of the review.

1. The problem of whether the conversion of organic peroxoboron derivatives into alkoxyboron derivatives takes place by an intramolecular or intermolecular mechanism[22-27] was examined in detail by Mirviss[124].

2. It is interesting to compare the postulates put forward by Hansen[34] with the results of Bednarec et al.[125], who investigated the polymerisation of vinyl chloride under the influence of $(C_4H_9)_3B-O_2$ and showed that the overall activation energy for the polymerisation reaction varies from 11 to 6.5 kcal mole^{-1} between 0° and −30°C and between −40° and −70°C respectively. According to Bednarec et al.[125], the observed effect is evidence for the coexistence under such conditions of several types of initiating systems, which leads to the variation of the activation energy for the initiating reaction and correspondingly the overall energy of the process.

3. It has been established[126] that the interaction of $AlPh_3$ with benzophenone under model conditions is accompanied by the formation of free radicals. This is associated with the ease of homolysis of the adduct $(Ph_3COAlPh_2)_2$ and not with one-electron transfer, postulated[17] for organocadmium compounds.

4. We believe it to be appropriate also to quote data for a very interesting system obtained by combining an aluminium alkyl with azobis(isobutyronitrile)[127]† and to compare the results with other data[42-48]. It has been shown[127] that the systems investigated [R_3Al–azobis(isobutyronitrile) or R_2AlCl–azobis(isobutyronitrile)] are capable of initiating the radical polymerisation of vinyl chloride and styrene (but not methyl methacrylate) at a lower temperature than is the case in the breakdown of the azobis(isobutyronitrile) itself. The nature of the radicals identified by electron spin resonance (ethyl and cyanodimethylmethyl) indicates the participation of both components of the system in the generation of free radicals. The authors[127] attribute their findings to the formation of the complex R_3Al–azobis(isobutyronitrile) (via the nitrile group of the latter) in which radical breakdown is facilitated.

5. The data quoted in Refs. 58 and 59 and 128 are supplemented by the findings that the polymerisation of methyl methacrylate by the catalytic system $(C_2H_5)_3Al-Ti(OC_4H_9)_4$ is also regarded as a catalytic process.

6. In the course of further development of their studies[81,82], Yamazaki and coworkers[129] investigated the polymerisation of deuteriated vinyl chloride by the system $(C_2H_5)AlCl_2-Ti(OR)_4$ and established the presence of terminal alkyl groups. This suggested that the initiation process may have a radical mechanism. However, the authors believe that the nature of the propagation stage is still obscure.

7. The work of Ulbricht et al.[130], who concluded that the polymerisation of vinyl chloride under the action of the

† This is the first piece of evidence indicating the possibility of influencing catalytically the rate of decomposition of azobis(isobutyronitrile).

system $TiCl_4$–Et_2AlOEt–dioxan (on the basis of their kinetics and the measured copolymerisation constants for vinyl chloride–styrene), is related to the investigation in Refs. 80 and 88.

8. The concepts put forward in Refs. 82, 90, and 91 may ber supplemented by the results of Yamazaki and Aridomi[131], who showed that, depending on the composition of the catalyst $TiCl_x(OC_4H_9)_{4-x}$–$AlCl_y(C_2H_5)_{3-y}$ (where x = 0–4 and y = 0–2), the vinyl chloride–propene copolymerisation constants may correspond to either a radical or an ionic-coordination process. Yamazaki and Aridomi[131] suggest that this finding should be attributed to the possibility of the polymerisation of vinyl chloride itself by one or other mechanism.

9. In agreement with the results of Beerman and Bestian[110], it has been shown[132] that the breakdown of CH_3TiCl_3 in tetrahydrofuran is homolytic. The formation of the CH_3 radical has been confirmed by the presence in the reaction mixture of CH_3D when the reaction is carried out in deuteriotoluene.

10. It is interesting to compare the effect of complex-forming additives on the type of decomposition of variable-valence organometallic compounds, established under model conditions[110,122,132], with the findings for the polymerisation process. Thus it has been shown[133] that in the copolymerisation of ethylene with vinyl chloride by the catalytic system Et_2AlCl–$Ti(OR)_4$ the addition of electron donors (tetrahydrofuran, pyridine, ethyl ether, diethylamine) leads to the formation of copolymers, the structure of which fully corresponds to that obtained under the conditions of a radical process[134].

11. A fundamentally new procedure for the ionic-coordination polymerisation of polar monomers by Ziegler catalysts was proposed by Giannini et al.[135] Its essential feature is that one uses in the reaction either monomers with sterically hindered (with respect to the reactions with the catalyst) functional groups or monomers with reduced electron-donor capacity (this is achieved by preliminary complex formation with an organometallic compound or by using monomers containing O–Si bonds).

β-Ketovinylation

M.I.Rybinskaya, A.N.Nesmeyanov, and N.K.Kochetkov

The review deals with the methods of introduction into the molecule of the group RCOCR′=CR″, which has come to be called the β-ketovinylation reaction. It has been shown that the principal starting materials for these reactions are certain β-substituted vinyl ketones, which have surpassed all other activated ethylene compounds in their importance for synthetic organic chemistry. A systematic description of literature data has been given in accordance with methods for *C*-, *N*-, *O*-, *S*-, *P*-, *Hal*-, *Fe*-, and *Co*-ketovinylation. This made it possible to make generalisations and recommendations concerning the choice of the ketovinylating agent in particular cases. The possible mechanism of β-ketovinylation is discussed, particular attention being devoted to kinetic and stereochemical data. The bibliography comprises 300 references.

I. INTRODUCTION

Cyanoethylation, the Michael condensation, and other reactions based on the capacity of the activated double bond to combine with nucleophilic reagents have played a considerable role in the development of synthetic organic chemistry. Among these reaction types, one of the most important is the β-ketovinylation reactions, despite the fact that the method hardly began to be developed until the 1950's. It is noteworthy that the main advances in this field have been achieved by Soviet chemists.

Ketovinylation reactions involve the introduction of a preformed RCOCR′=CR″ group into the molecule[1]. These reactions have led to a new synthesis of αβ-unsaturated ketones, and a very wide variety of β-substituted vinyl ketones, in which the RCOCR′=CR″ group is linked with the atoms of various elements, have become available. Among the compounds obtained particular mention should be made of the σ complexes of the RCOCR′=CR″ group with the atoms of transition metals such as iron and cobalt. The availability of these derivatives extends the possibilities of the synthesis of organometallic compounds, since the RCOCR′=CR″ fragment is bifunctional. The high activity of the carbonyl group in β-substituted vinyl ketones had led in turn to the development of methods for the preparation of many heterocycles. The extensive studies of the properties of β-substituted vinyl ketones have shown that these compounds are not only of interest in connection with synthesis but can serve as convenient models for the elucidation of certain theoretical questions associated with the mechanisms of nucleophilic substitution and addition to an activated double bond.

The RCOCR′=CR″ group may be introduced into the molecule in two ways. 1. By nucleophilic substitution of X in compounds of the type RCOCR′=CR″X:

$$RCOCR'=CR''X + Y^- \rightarrow RCOCR'=CR''Y + X^-,$$

where X = Hal, OR, OH, NR_2, $\overset{+}{N}R_3$, etc. 2. By the addition of nucleophilic agents to the triple bond of ethynyl ketones

$$RCOC{\equiv}CR' + Y^- \xrightarrow{H^+} RCOCH{=}CR'Y.$$

The first method is used more often, and its development has been particularly intense after general methods for the synthesis of β-chlorovinyl ketones have become available[2-4].

Despite the large number of studies on the chemistry of β-substituted vinyl ketones, a systematic account of β-ketovinylation methods has not been published so far. There are several reviews in the literature dealing with syntheses on the basis of β-chlorovinyl ketones[1,5-8] or their derivatives—β-ketoacetals[9]. In 1961 Kochetkov and coworkers published a review on the *C*-ketovinylation of β-dicarbonyl compounds[10]. In the present review the authors attempted to give a systematic account for the first time of other methods of β-ketovinylation, including *C*-, *N*-, *O*-, *S*-, *P*-, *Hal*-, *Fe*, and *Co*-ketovinylation. Examination of the literature data in this context permits certain generalisations and recommendations for the choice of the method of synthesis of αβ-unsaturated ketones in particular cases. The review includes literature data up to 1st January 1968.

II. METHODS OF β-KETOVINYLATION

1. *C*-Ketovinylation

Among other β-ketovinylation reactions, the methods for the formation of a carbon–ketovinyl bond (*C*-ketovinylation) occupy one of the most important places. The development of these methods not only led to the ready availability of all possible αβ-unsaturated aliphatic, aromatic, and heterocyclic ketones, but has also permitted the synthesis of certain cyclic compounds and also stable organic anions and polymers with a conjugated system of double bonds.

It would appear that carbanions should undergo ketovinylation most readily. However, with powerful nucleophilic reagents such as the carbanions of the organometallic compounds of Group I elements and magnesium, complications arise due to the additional possibility of reaction at the carbonyl group. It is noteworthy that numerous investigations of the reactions of αβ-unsaturated ketones with these nucleophilic reagents have not so far provided a definite answer to the question why 1,2- and 1,4-addition takes place. However, with β-substituted vinyl ketones it is possible to follow the effect of the nature of the β-substituent on the mode of attack on the carbanions. It has been found that β-chlorovinyl ketones cannot be used for the ketovinylation of aliphatic and aromatic carbanions. In this case the carbonyl group is mainly attacked and the reaction yields carbinols. It is noteworthy that the rearrangement of such carbinols in an acid medium is used for the preparation of αβ-unsaturated aldehydes of type (I)[11-16]:

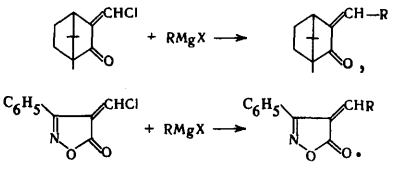
$$RCOCH{=}CHCl + R'M \rightarrow \overline{O}{-}CRR'{-}CH{=}CHCl \xrightarrow{H_3O^+} \underset{(I)}{RR'C{-}CH{=}CH{-}O}.$$

β-Chloroacrolein[17] and its polyhalogeno-derivatives[18-20] react similarly and this was used by Skoldinov et al.[17] in the synthesis of the *cis*- and *trans*-isomers of β-chlorovinyl methyl ketone (see p. 450).

However, in reactions with organometallic compounds having a less polarised metal–carbon bond, such as cadmium derivatives, the successful use of β-chlorovinyl ketones is also possible[21,22]:

$$RCOCH{=}CHCl + \overset{-\delta}{R'}{-}\overset{+\delta}{Cd}{-}R' \rightarrow R{-}\underset{\underset{O}{|}}{C}{-}CH{=}CHR'.$$

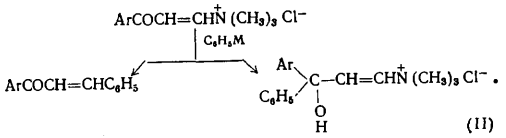
Furthermore, normal ketovinylation of RLi and RMgX by β-chlorovinyl ketones is possible in those cases where the approach to the carbonyl group is sterically hindered (for example, when the carbonyl group is in a ring)[22-25]:



The replacement of the chlorine atom in substituted β-chlorovinyl ketones by a phenoxy-group favours the formation of ketovinylation products and their derivatives, but the yields are only 20–40%:[26]

$$CH_3COCH{=}CHOC_6H_5 \xrightarrow{CH_3MgBr} [CH_3COCH{=}CHCH_3] \xrightarrow{CH_3MgBr} \rightarrow CH_3{-}\underset{\underset{OH}{|}}{\overset{\overset{CH_3}{|}}{C}}{-}CH{=}CH{-}CH_3 \rightarrow CH_2{=}\underset{\underset{CH_3}{|}}{C}{-}CH{=}CH{-}CH_3.$$

Vinyl ketones containing a powerful electron-acceptor group such as the quaternary ammonium group in the β-position relative to the carbonyl group react with C_6H_5Li to form a mixture of *C*-ketovinylation and 1,2-addition [compounds (II)] products in almost equal amounts†. When C_6H_5MgBr is used, the yield of *C*-ketovinylation products is much higher:[27]



(II)

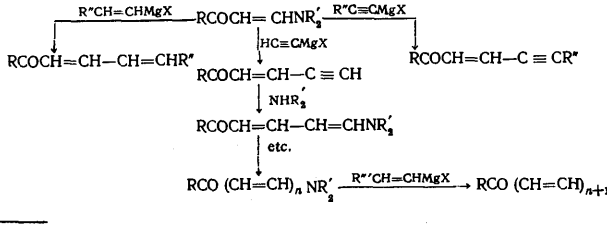
Thus, despite the pronounced electron-acceptor properties of the quaternary ammonium group, which should apparently intensify the electrophilicity of the carbonyl carbon atom, *C*-ketovinylation products are formed in appreciable amounts. This is probably because the $\overset{+}{N}(CH_3)_3$ group attracts electrons by an inductive effect, so that the positive charge appears also at the carbon atoms of the double bonds. In this connection it is interesting to note that the sulphonyl group, which exhibits a powerful I-effect, is also substituted on interaction of organomagnesium compounds with phenyl β-phenylsulphonylvinyl ketone[29]:

$$C_6H_5COCH{=}CHSO_2C_6H_5 + C_6H_5MgX \rightarrow C_6H_5COCH{=}CHC_6H_5.$$

On the other hand, in most cases β-dialkylaminovinyl ketones[30,31], which are less reactive than β-chlorovinyl ketones, are convenient reagents for the ketovinylation of RLi, RNa, and RMgX:

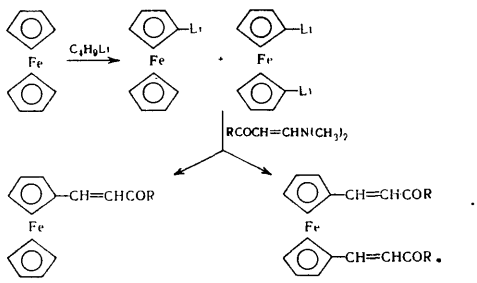
$$RCOCH{=}CHN(CH_3)_2 + R'Li \rightarrow RCOCH{=}CHR'.$$

This was shown experimentally by Benary for the first time[30] and later Normant and coworkers[31] developed an elegant method for the synthesis of conjugated keto-polyenes and keto-enynes:

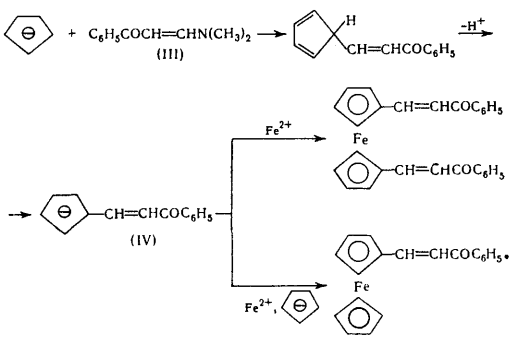


† It has been found[28] that the salts (II) may be used to synthesise the hitherto unknown quaternary ammonium salts containing the indenyl group.

Nesmeyanov and coworkers[32] used this method for the preparation of mono- and di-ketovinylated ferrocenes by the following procedure:



The same compounds were obtained[33] by the ketovinylation of the cyclopentadienide ion with β-dimethylaminovinyl phenyl ketone (III) followed by treatment of the reaction mixture with anhydrous iron(II) chloride:

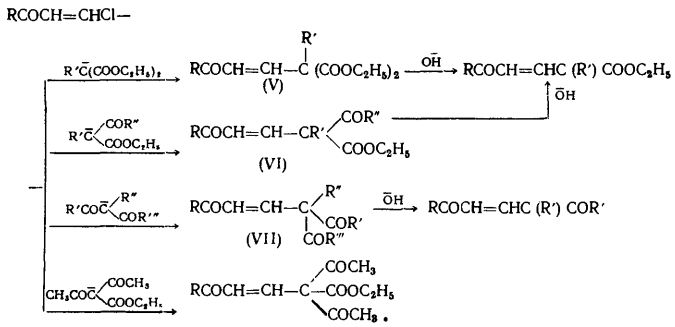


The yield of the ion(IV), which amounted to about 40 mole %, may be estimated from the amounts of mono- and di-ketovinylated ferrocenes produced. Thus the ketovinylation method developed may be used for the synthesis of αβ-unsaturated ketones of the ferrocene series.

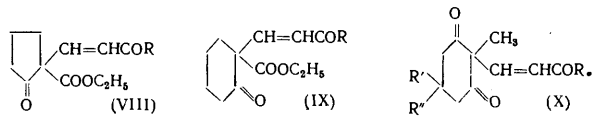
Ketovinylation reactions have assumed particular importance in the synthesis of heteroannular dicarbonylvinyl derivatives of ferrocenes. The very possibility of synthesising such derivatives was discovered solely owing to the development of these methods.

It is interesting to note that β-chlorovinyl ketones can also be used in the reaction with the cyclopentadienide ion‡, but in this case the process does not stop at the first stage and polyketovinylation products are formed[34].

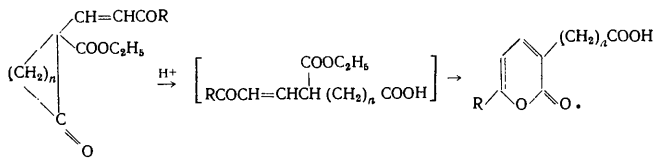
The ketovinylation of carbon-containing ambident anions takes place very readily. Such ions include in the first place the anions of β-dicarbonyl compounds, ketones, nitro-compounds, etc. The reactions with β-dicarbonyl compounds (β-diketones, β-keto-esters, malonic ester, and their derivatives) have been investigated in detail by Kochetkov and coworkers[10]. β-Chlorovinyl ketones were used as ketovinylating agents. It was found that β-dicarbonyl compounds are normally ketovinylated only when they contain one labile hydrogen atom[35-39]:



Methods for the synthesis of unsaturated keto-acids and diketones have been developed on the basis of these reactions. For example, under the action of bases, compounds of type (V) eliminate the ethoxycarbonyl group and are converted into δ-keto-βγ-unsaturated acids[40] and compounds of type (VI) readily undergo the ketonic decomposition[41]. The same reactions were observed with the triketones (VII).[37] Cyclic β-keto-acids[42] and β-diketones[37,43] are of course ketovinylated without complications, compounds of types (VIII)-(X) being formed:



It is noteworthy that the rearrangement of compounds (VIII) and (IX) and analogous compounds under the action of acids has been proposed as a method for the synthesis of α-pyrones[44,45]:

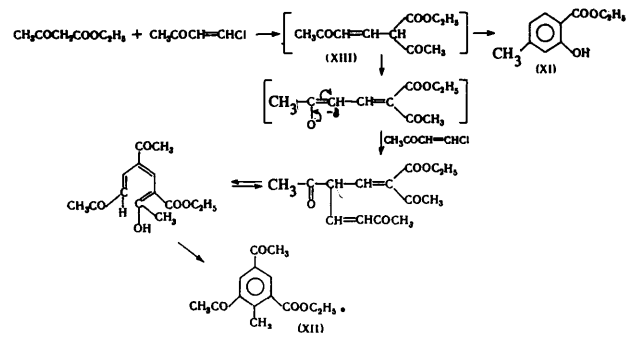


It has been found that the yields of ketovinylation products vary appreciably depending on the nature of the β-dicarbonylcompound: esters of alkylmalonic and α-substituted acetoacetic acids reacts with higher yields than β-diketones, while the diacetylacetic ester does not react at all[10]. Probably the decrease of the yields of ketovinylation products in this series may be attributed to the increase of the stability and hence the decrease of the nucleophilicity of the attacking mesomeric anions formed from the corresponding carbonyl compounds.

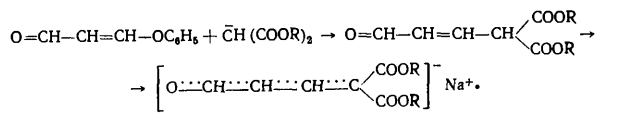
In contrast to the single-proton β-dicarbonyl compounds, the two-proton (with two labile hydrogen atoms) malonic and acetoacetic esters react with β-chlorovinyl ketones under analogous conditions to form a complex mixture of products. For example, when β-chlorovinyl methyl ketone reacts with acetoacetic ester in the presence of potassium carbonate, two compounds are formed: ethyl 4-methylsalicylate (XI) and the ester of 3,5-diacetyl-2-methylbenzoic acid (XII).[46,47] The amounts of the two products, (XI) and (XII), in the mixture depend on the ratio of the starting

‡ In contrast to aliphatic and aromatic ions, the cyclopentadienide ion is not a very powerful base, becoming readily polarised, and therefore it reacts with β-chlorovinyl ketones via the β-carbon atom of the ethylene bond (see page 446).

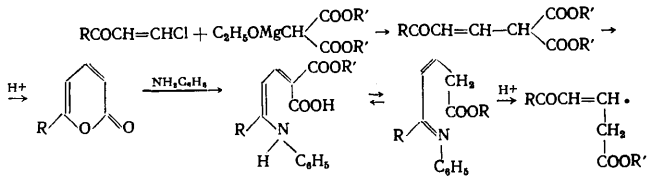
materials. The formation of compounds (XI) and (XII) may be accounted for by the following mechanism:



Under the reaction conditions the mono-ketovinylation product (XIII) undergoes further cyclisation to compound (XI). However, since the intermediate (XIII) is a stronger acid than the initial acetoacetic ester, it readily produces an anion which is capable of being ketovinylated. In turn compound (XII) is formed as a result of the cyclisation of the ketovinylation product. It is interesting to note[48] that, when hydroxymethylene ketones, the double bond of which is less electrophilic than in β-chlorovinyl ketones, are employed in this reaction, the process stops at the mono-ketovinylation stage[48] and only 4-methylsalicylic acid (XI) was isolated. Of course, the capacity for subsequent ketovinylation depends not only on the electrophilicity of the β-carbon atom of the ketovinylating agent but also on the stability of the anion formed as the result of mono-ketovinylation. Thus, in the interaction of sodiomalonic ester with β-phenoxyacrolein[49], the product is the stable anion of an acid with a strength approximately equal to that of acetic acid ($K_a = 1.4 \times 10^{-5}$). The nucleophilicity of this anion proved to be too low for it to react again with β-phenoxyacrolein and the reaction stops in the first stage:

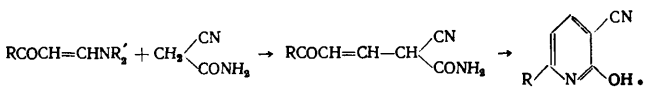


In order to avoid complications associated with successive ketovinylation, Kochetkov and Kudryashov[50] employed the ethoxymagnesium derivative of malonic ester in benzene in the reaction with β-chlorovinyl ketones. In this case the reaction takes place fairly smoothly and α-ethoxycarbonyl-δ-keto-βγ-unsaturated acids are formed in high yields. It proved possible to convert these acids into α-pyrones and further into the vinylogues of acylacetic esters[51]:



It is noteworthy that under these conditions the reaction with acetoacetic ester did not yield satisfactory results[50].

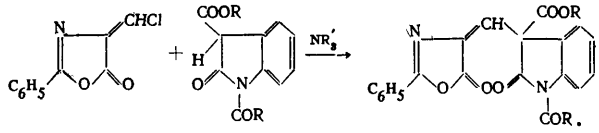
The reaction of β-dialkylaminovinyl ketones with cyanoacetamide can also be regarded as monoketovinylation with subsequent cyclisation—the nitriles of 6-alkyl-2-hydroxynicotinic acids were obtained[52]:



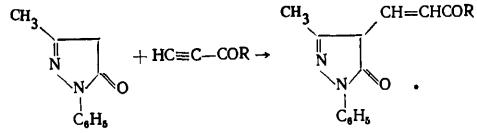
The reaction of ethyl β-diethylaminovinyl ketone with cyclic ketones was achieved by Abe[53].

Ketovinylation with β-hydroxyvinyl ketones[54], β-methoxyvinyl ketones[55] or their derivatives, and also acetals of β-keto-aldehydes[56] requires the use of catalysts, for example piperidinium acetate.

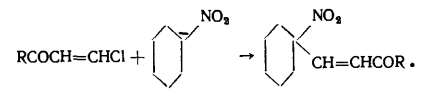
Behringer and coworkers[22,25] used tertiary amines as condensing agents in the reaction of heterocyclic analogues of β-chlorovinyl ketones with various compounds containing a methylene group with labile hydrogen atoms:



Probably quaternary carbonylvinyl ammonium salts, which are very powerful ketovinylating agents, are formed in this case as intermediates. However, the explicit use of the open-chain quaternary salts $RCOCH{=}CH\overset{+}{N}(CH_3)_3Cl^-$ in the ketovinylation of the anions of the malonic and acetoacetic esters did not yield satisfactory results[50]. Ethynyl ketones have also been used for the ketovinylation of heterocyclic compounds[57]:

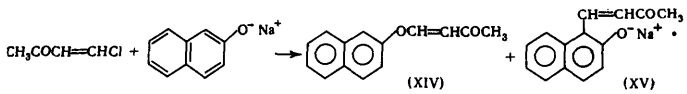


The possibility in principle of the ketovinylation of nitro-compounds with one labile hydrogen atom in the α-position has been demonstrated for 2-nitropropane[58] and nitrocyclohexane[59,60]. The choice of these nitro-compounds was again dictated by the possibility of further ketovinylation in the presence of two labile α-hydrogen atoms:



Unfortunately the yields of ketovinylation products in these cases are low.

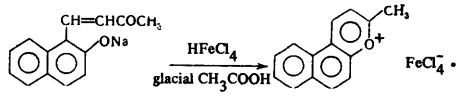
Yet another example of the ketovinylation of an ambident ion is the reaction of sodium β-naphthoxide with β-chlorovinyl ketones. The authors of the present review showed[61] that their reaction yields both series of derivatives§, the ratio of the products of *C*- and *O*-ketovinylation depending markedly on the solvent. In an aqueous alkaline medium the main product is methyl β-(2-naphthoxy)vinyl ketone (XIV) (63%) and only 10% of sodium 1-(β-acetylvinyl)-2-naphthoxide (XV) is formed, while in dioxan the main product is compound (XV) (50.5%) and the yield of compound (XIV) is only 19%:



Probably the effect of the solvent on the mode of ketovinylation is due to the fact that in an aqueous alkaline medium the oxygen of the β-naphthoxide is mainly attacked, while in the reaction in dioxan the oxygen atom is blocked by the cation, since here only the closely linked ion pairs $\beta\text{-}C_{10}H_7O^-Na^+$ exist. For this reason, the *C*-ketovinylation product is formed preferentially in dioxan. The structure

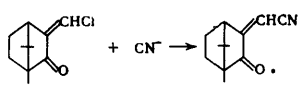
§ We may note that only the *O*-derivative is formed in the ketovinylation of the phenoxide anion[61,62].

of compound (XV) was demonstrated by its ready ring closure to form a salt of 2-methylnaphthopyrylium:



It is noteworthy that the same salt was obtained[61] by the direct reaction of β-chlorovinyl methyl ketone with β-naphthol (see p. 438).

The importance of the correct choice fo the ketovinylating agent is well illustrated by the cyanide ion as an example. The ketovinylation of the cyanide ion with chloromethylenecamphor was achieved for the first time by Bishop et al.[63] as early as the end of the previous century:



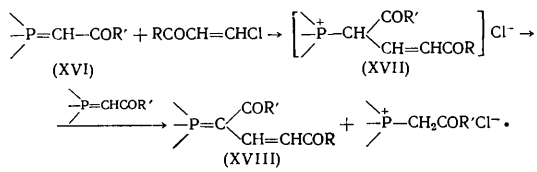
However, the reaction of open-chain β-chlorovinyl ketones with cyanide ions proved to be quite impossible. In his study of this reaction using β-chlorovinyl phenyl ketone in non-polar media, Pannizzi[64] isolated the starting material. The attempts to ketovinylate alkali metal cyanides in polar solvents (water and alcohol) also proved to be unsuccessful. In this case the reaction takes place extremely vigorously and the initial β-chlorovinyl ketones vanish completely, but dark coloured resins are formed instead of the expected products. The ketovinylation of copper cyanide also failed. It is noteworthy that the attempt to replace the chlorine atoms in β,β-dichlorovinyl ketones by CN groups was also unsuccessful[65].

The ketovinylation of the cyanide ion was achieved only when quaternary carbonylvinylammonium salts were employed[66]:

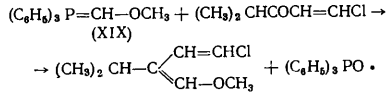
$$RCOCH{=}CH\overset{+}{N}(CH_3)_3 + CN^- \rightarrow RCOCH{=}CHCN + N(CH_3)_3.$$

The ready solubility in water of the initial salts and the sparing solubility of the resulting β-cyanovinyl ketones play a significant role in this synthesis. The successful ketovinylation of the cyanide ion lead to the development of a new synthesis of β-aroylacrylic acids and their amides[67].

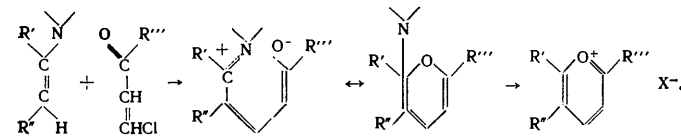
Phosphorylides, which may be regarded as dipolar ions, react in different ways with β-chlorovinyl ketones, depending on the structure of the phosphorylide. Stabilised phosphorylides of type (XVI) probably form intermediate phosphonium salts (XVII), which react further with the second molecule of the phosphorylide and are converted into a ketovinylated phosphorylide (XVIII):



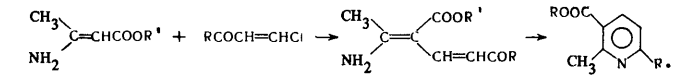
On the other hand, methoxymethylenetriphenylphosphorane (XIX) undergoes the normal Wittig reaction[68]:



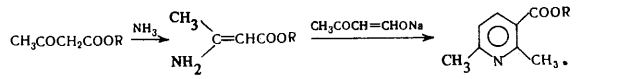
Ketovinylation can be achieved also with neutral unsaturated molecules having a multiple bond with enhanced electron density. Thus it has been found[69] that enamines react very readily with β-chlorovinyl ketones, dipolar ions, from which pyrylium salts were subsequently obtained, being formed as intermediates:



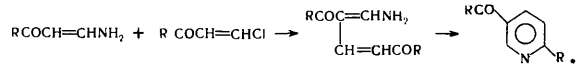
Probably the reaction of β-chlorovinyl ketones with methyl β-aminocrotonate is also accompanied by initial *C*-ketovinylation[70]. A method for the synthesis of 2,6-dialkyl-3-ethoxycarbonylpyridines was developed on the basis of this reaction:



β-Dicarbonyl compounds[70,71] in an excess of ammonia may be used in the reaction instead of the actual enamines. For example, Rabe[71] obtained 3-ethoxycarbonyl-2,6-dimethylpyridine by the reaction

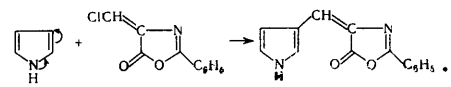


β-Aminovinyl ketones are also capable of undergoing *C*-ketovinylation. A method for the synthesis of 2,6-dialkyl-3-acylpyridines was developed on the basis of this reaction[72,73]:

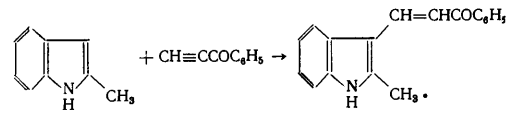


The method is convenient for the synthesis of fusaric acid[74,75].

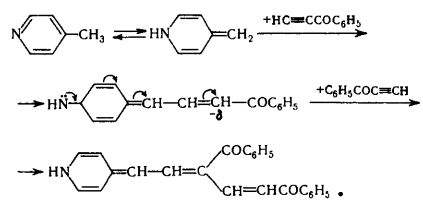
The reaction of β-chlorovinyl ketones and related compounds with pyrroles and indoles may be regarded as a special case of ketovinylation of enamines[22,76]:



Ethynyl ketones have also been used for this purpose[77]:

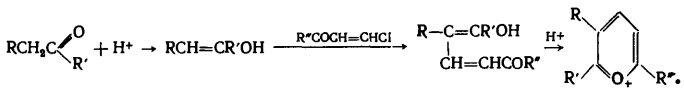


γ-Picolines react with ethynyl ketones like enamines with a longer conjugation chain; the reaction does not stop at the first stage and coloured diketovinylated products are formed[77] (see the section dealing with the ketovinylation of β-dicarbonyl compounds having two labile methylene hydrogen atoms):



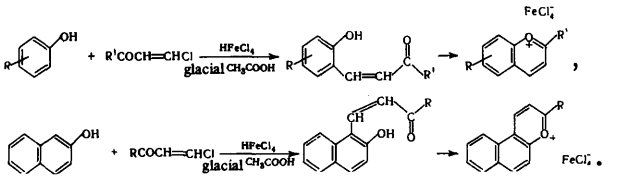
The ketovinylation of the system $\rangle C{=}C{-}OH$ was studied in many instances. The reaction of ketones with hydroxymethylene ketones in an acid medium was discovered[78] as

early as 1924 but was ignored for many years and its systematic study began only recently. It was found that under these conditions not only hydroxymethylene ketones [79-82] but also β-chlorovinyl ketones [83] can enter into the reaction. As a result, a general method has been developed for the synthesis of pyrylium salts:

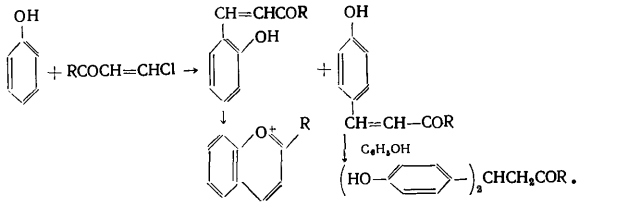


It is interesting to note that, according to the data of Zakharkin and Sorokina [84-87], in the case of ββ-dichloroacrolein the carbonyl group is attacked.

β-Chlorovinylketones react very readily with phenols and β-naphthol in the presence of a condensing agent—a mixture of iron(III) chloride and hydrochloric acid. On the basis of this reaction, Nesmeyanov, Kochetkov, and Rybinskaya developed a preparative method for the synthesis of benzopyrylium [88,89], flavylium [89], and naphthopyrylium salts [88,90]:



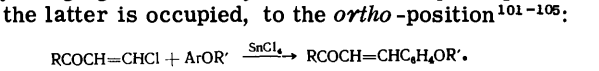
In the case of phenols with a free *para*-position, other products are formed from the phenols ketovinylated in the *para*-position together with the benzopyrylium salts. The former combine with a further phenol molecule at the double bond under the reaction conditions [91]:



A strongly activated system, such as phloroglucinol reacts with β-chlorovinyl ketones even in the absence of catalysts. This led to the development of a very simple synthesis of the methyl ester of a natural anthocyanidine—hesperidin chloride [89]. The reaction with pyrogallol requires heat [22].

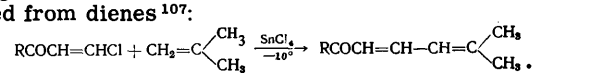
The methods for the synthesis of salts with a pyrylium ring using β-hydroxyvinyl ketones (β-diketones capable of enolisation) were investigated in greater detail [92-100].

Phenolic ethers can also be made to undergo the ketovinylation reaction and best results are achieved when tin(IV) chloride is used as the catalyst. The attack of the ketovinylating agent is mainly directed to the *para*-position and, if the latter is occupied, to the *ortho*-position [101-105]:



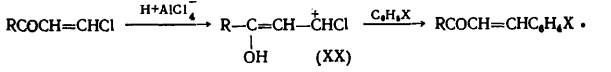
It is noteworthy that thiophen reacts under these conditions like phenolic ethers [106].

Tin(IV) proved to be an extremely active catalyst also in the condensation of β-chlorovinyl ketones with olefins having alkyl substituents at the double bond. This reaction takes place so easily with isobutene that fairly pronounced cooling (−10°C) is required. The reaction yields ketones derived from dienes [107]:

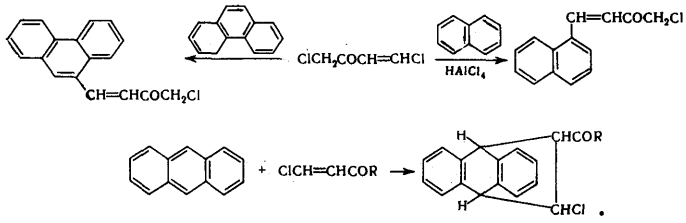


In this connection it is noteworthy that, in the presence of tin(IV) chloride, it even proved possible to achieve the reaction of acetylene with β-chlorovinyl ketones [107]. This reaction is interesting because it permits the preparation of the vinylogues of β-chlorovinyl ketones:

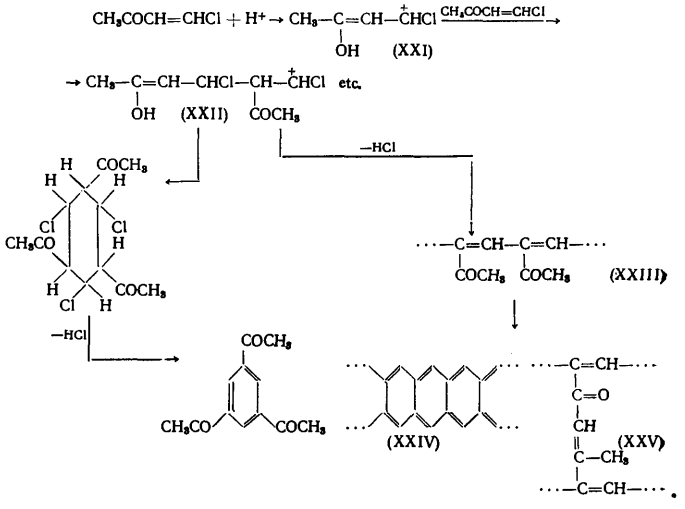
However, with very weak nucleophilic agents such as benzene and its homologues ketovinylation does not occur even in the presence of Friedel–Crafts catalysts. Probably this is because the double bond in β-chlorovinyl ketones, even when it is additionally polarised by the action of the catalyst, is still insufficiently electrophilic. In order to increase the positive charge at the β-carbon atom of the double bond, a stream of moist hydrogen chloride was passed into the reaction mixture containing aluminium chloride. In this case the reaction took place extremely readily and even chlorobenzene could be made to react [108]. It is suggested that the active species in this reaction is the intermediate carbonium ion (XX):



Naphthalene and phenanthrene [34] reacted readily under the same conditions and only in the case of anthracene [109] were diene condensation products obtained instead of the ketovinylated derivatives:



The unusual polyketovinylation or, more correctly, polycondensation of β-chlorovinyl methyl ketone, which is accelerated in the presence of acid reagents, should also be classified as a *C*-ketovinylation reaction. Depending on the reaction conditions, a cyclic trimer (triacetylbenzene) or a polymer with a conjugated system of bonds can then form [34,110]. The active species in this process is probably the carbonium ion (XXI). This ion attacks the next molecule with formation of a new carbonium ion (XXII), etc.:



Condensation in solution yields a cyclisation product, while in the absence of solvent a polymer is formed, which, as a result of spontaneous dehydrochlorination, yields the polyene (XXIII). The polymer (XXIII) changes slowly on heating in a vacuum with evolution of water, which is probably due to the crotonic condensation of the acetyl group in the chain or between the chains. As a result, the polymer may contain units consisting of condensed aromatic rings (XXIV) and units of type (XXV). According to infrared spectroscopic data, fragments of type (XXIV) probably predominate in the polymer. The study of electrical and magnetic properties showed[111,112] that the polymers may be regarded as "organic" semiconductors. Their ability to catalyse certain reactions, in particular the oxidation of toluene to benzaldehyde and benzoic acid[111], proved to be specially interesting.

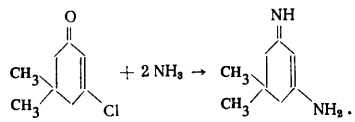
In conclusion it should be noted that the formation of triacetylbenzene was observed also in the polycondensation of other compounds of the type $CH_3COCH=CHX$, for example with X = OH, OCH_3, OCOR, etc. It was found that here too polycondensation is facilitated by acids[113-115].

2. *N*-Ketovinylation

Ammonia and primary, secondary, and tertiary amines readily undergo ketovinylation. The principal ketovinylating agents in these processes are β-chlorovinyl ketones[116-119]:

$$RCOCH=CHCl + NH_3 \rightarrow RCOCH=CHNH_2.$$

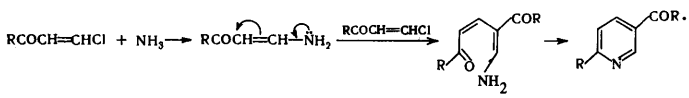
Information about this reaction appeared for the first time in the patent literature[120-121], where it was suggested that β-aminovinyl ketones be used as antidetonators and as intermediates for the synthesis of dyes and insecticides. In some cases two molecules of ammonia enter into the reaction simultaneously (at 100°C), which results in the formation of imines derived from β-aminovinyl ketones[122]:



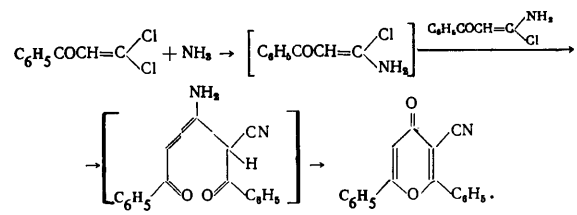
Since ammonia and amines are fairly powerful nucleophilic reagents, hydroxymethylene ketones and their enolates and ethers may take part in *N*-ketovinylation[123]. β-Aminoacrolein was also obtained by the treatment of β-methoxyacrolein with ammonia[124]. Ethynyl ketones were used successfully in this reaction[125]:

$$RCOC\equiv CH + NH_3 \rightarrow RCOCH=CHNH_2.$$

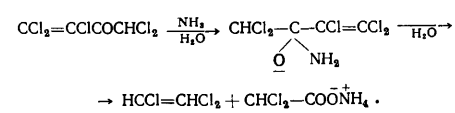
When aqueous ammonia reacts with an excess of β-chlorovinyl ketones[126-128] and ethynyl ketones[129], 2-alkyl-5-acylpyridines are formed. Possibly the intermediates in this reaction are β-aminovinyl ketones, which cyclise with the excess of the initial reagent to form the corresponding pyridine derivative[72,126,129]:



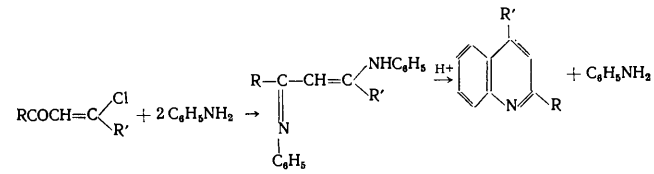
A similar mechanism may be proposed for the reaction of ammonia with ββ-dichlorovinyl phenyl ketone[8], which led to the formation of the nitrile of 2,6-diphenyl-γ-pyrone-3-carboxylic acid:



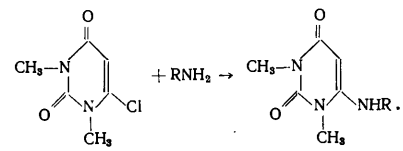
However, the situation changes fundamentally when polychloro-substituted αβ-unsaturated ketones are employed. Roedig and Maier[130] found that this results in the fission of the initial compound into trichloroethylene and a carboxylic acid salt. Probably in this case nucleophilic attack is directed to the carbonyl group:



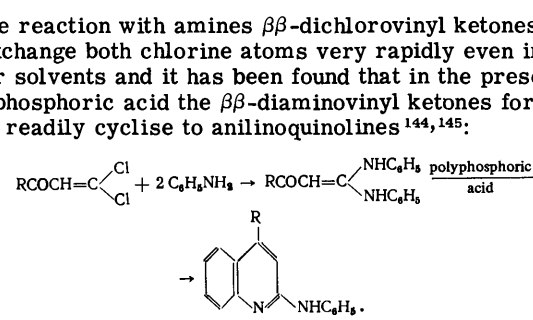
Under conditions analogous to those of reactions with ammonia, primary amines are ketovinylated with β-chlorovinyl ketones[64,120,131-137] and hydroxymethylene ketones[123,138]; ethynyl ketones can also be used[5,125]. In the presence of an excess of aromatic amines, the Schiff bases of β-arylaminovinyl ketones are formed as a rule[122,134,139-142]; they have been used for the synthesis of quinolines[139,140]:



Cyclic β-chlorovinyl ketones with a fixed *S-trans*-conformation react very readily with primary amines[122,143]:



In the reaction with amines ββ-dichlorovinyl ketones rapidly exchange both chlorine atoms very rapidly even in nonpolar solvents and it has been found that in the presence of polyphosphoric acid the ββ-diaminovinyl ketones formed very readily cyclise to anilinoquinolines[144,145]:



Similar results were obtained also with di- and tri-chloroacrolein[146]. In a number of cases the transamination of β-aminovinyl ketones was achieved[147,148]:

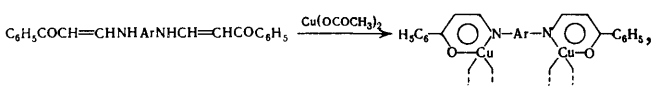
$$C_6H_5COCH=CHNHC_6H_5 + C_{10}H_7NH_2 \rightarrow C_6H_5COCH=CHNHC_{10}H_7 + C_6H_5NH_2.$$

The products of the ketovinylation of aromatic amines with aryl β-chlorovinyl ketones are difficult to purify by recrystallisation from the initial ketones. Therefore in

the synthesis of β-aminovinyl ketones of this kind water-soluble quaternary β-aroylvinyltrimethylammonium salts may be used as the ketovinylating agents [149,150]:

$$ArCOCH{=}CH\overset{+}{N}(CH_3)_3 + NH_2C_6H_5 \rightarrow ArCOCH{=}CHNHC_6H_5.$$

Carbonylvinylammonium salts have played a particularly important role in the synthesis of *NN'*-bisketovinylated aromatic diamines [149]. A synthesis of chelate polymers has been developed on the basis of such diamines:

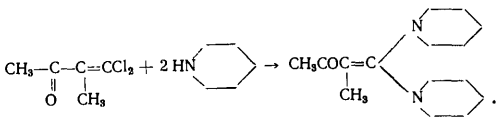


where Ar = $-C_6H_4-$ or $-(C_6H_4)_2-$. Using ammonium salts of the type $RCOCH{=}CH\overset{+}{N}(CH_3)_3Cl^-$, it proved possible to develop a method for the synthesis of hitherto unknown *N*-(β-acylvinyl)-substituted glycines and their ethyl esters [151]. The interaction of quaternary salts with the sodium salt and ester of glycine takes place very vigorously in aqueous solution.

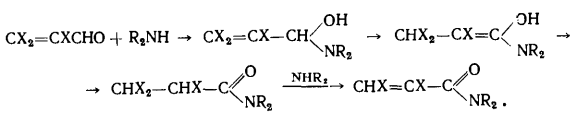
It is noteworthy that tautomerism of an interesting type, ketimine–enol ⇌ enamine–ketone, has been investigated in β-aminovinyl ketones obtained by the ketovinylation of ammonia and primary amines. Tautomerism of this type was investigated in detail by Nesmeyanov and coworkers [117,118,152,153], Potapov et al. [135], and Kazitsyna et al. [154]

Among secondary amines, aliphatic amines and saturated heterocycles are very readily ketovinylated. When they react with β-chlorovinyl ketones [64,120,155–157], ethynyl ketones [125,158], and hydroxymethylene ketones [123,159–162], β-dialkylaminovinyl ketones are formed.

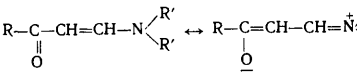
In the reaction with secondary amines both chlorine atoms of ββ-dichlorovinyl ketones [144,163] and dichloroacrolein [164] are substituted, but their α-alkyl derivatives react very slowly due to the breakdown of the coplanarity of the carbonyl group and the double bond [144,163]:



It is interesting to note that with polychlorinated acroleins the secondary amine attacks the carbonyl group. The subsequent allyl rearrangement and elimination of HX leads to the acid amide [165]:



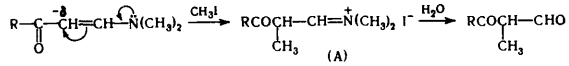
β-Dialkylaminovinyl ketones have high dipole moments [166]. For example, the dipole moment of methyl β-dimethylaminovinyl ketone is 5.67 D.



The capacity of these compounds to react with nucleophilic reagents is very weak (they react only with powerful nucleophilic reagents¶) and conversely their reaction with electrophilic reagents takes place readily. The electrophilic agent attacks the α-carbon atom of the double bond.

¶ For further details see pp. 434 and 447.

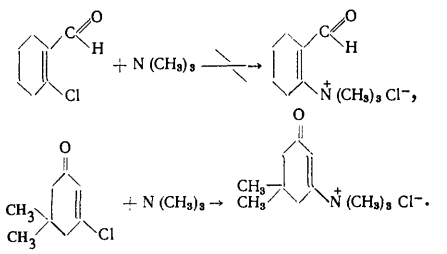
Thus, instead of the expected quaternary β-acylvinyltrimethylammonium salts, the methylation of β-dimethylaminovinyl ketones led to the isolation after hydrolysis of the decomposition products of salts of type (A) [156,167]. The synthesis of α-substituted β-keto-aldehydes is based on this reaction:



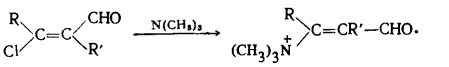
In an acid medium β-dialkylaminoacroleins [160] and β-dimethylaminovinyl ketones [168] exchange the α-hydrogen atom at the double bond for deuterium. Their capacity to enter into the ketovinylation reaction has already been mentioned (see p. 434).

The ketovinylation reaction of tertiary amines occupies a special place, primarily because extremely powerful ketovinylating agents—β-acylvinylammonium salts—were obtained on its basis. A quaternary salt of this type was obtained for the first time by Yakubovich and Merkulova [169] by the action of pyridine on β-chlorovinyl methyl ketone:

Subsequently Kochetkov, Skoldinov, and coworkers [170,171] found a general method for the ketovinylation of tertiary amines with β-chlorovinyl ketones†. Nesmeyanov and Rybinskaya [66] suggested that the same trimethyl- and triethyl- ammonium salts be used without preliminary purification for the ketovinylation of the cyanide ion. It is interesting to note that cyclic β-chlorovinyl carbonyl compounds known to have the *cis*-configuration hardly react with tertiary amines [172,173], while ketones with a fixed *trans*-configuration are converted into quaternary salts with almost quantitative yields [172]:



αβ-Dialkyl-β-chlorovinylaldehydes react with trimethylamine very slowly and the quaternary ammonium salts are then obtained with very low yields [173–175]:



The possibility, in principle, of synthesising quaternary salts by the reaction of ethynyl ketones with tertiary amine hydrochlorides has been demonstrated for ethynyl phenyl ketone as the sole example [127]:

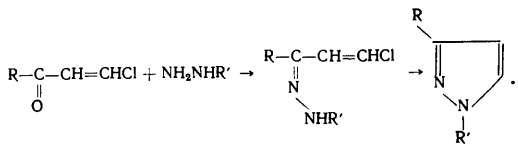
$$C_6H_5COC{\equiv}CH + N(CH_3)_3 \cdot HCl \rightarrow C_6H_5COCH{=}CH\overset{+}{N}(CH_3)_3\,Cl^-.$$

Hydrazines, semicarbazide, and hydroxylamine are much more powerful bases and nucleophilic agents than amines because of the additional electron transfer to the

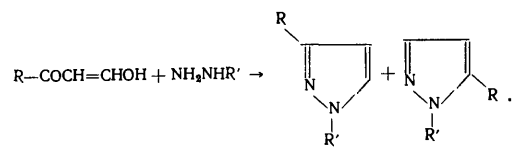
† Because of a number of disadvantages of experiments with β-chlorovinyl ketones, largely due to the high toxicity of these compounds, the above workers suggested that the ketones be converted into quaternary ammonium salts without being isolated from the reaction mixture [171].

nitrogen atom by the adjacent NH_2 and OH groups. It has been found that, in contrast to amines, these reagents are capable of attacking a second electrophilic centre in the β-chlorovinyl ketone molecule, i.e. the carbonyl group (cf. the reactions with RLi and RMgX, p. 434). The capacity to attack the carbonyl group is more pronounced in hydrazines and semicarbazides than in hydroxylamine. The latter is a weaker base and nucleophilic agent and reacts simultaneously with both electrophilic centres. It is noteworthy that the ketovinylation of these compounds leads in most cases to heterocyclic pyrazole and isoxazole systems, the position of the substituents in which shows the direction of the primary attack by the nucleophilic agent.

Nesmeyanov et al.[2] have shown that alkyl β-chlorovinyl ketones react with hydrazine and alkyl hydrazines with formation of 3-alkyl- and 3-alkyl-1-aryl-pyrazoles:

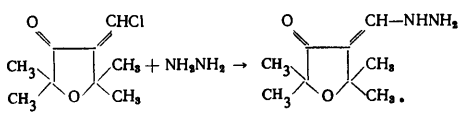


This result is evidence in the first place that the reaction begins with attack on the carbonyl group. This was subsequently confirmed by the isolation of the intermediate hydrazones[16,176,177], which subsequently cyclised to the pyrazole ring. Furthermore, the use of the β-chlorovinyl ketones in this reaction is of practical value, since it provides a preparative method for the synthesis of 1,3-disubstituted pyrazoles. The hydroxymethylene ketones employed previously yield a mixture of 1,3- and 1,5-disubstituted pyrazoles.[178]



Subsequently the reaction was extended also to other aromatic, aliphatic,[90,176] and barene[179] β-chlorovinyl ketones and αβ-disubstituted β-chlorovinyl aldehydes[180,181]. The unsubstituted pyrazole was obtained with the aid of β-halogenoacroleins[182-184]. The reactions with polyhalogenoacroleins and poly(chlorovinyl ketones) also yield hydrazones, which are converted into the corresponding pyrazoles on boiling[185-187], the yield of pyrazole increasing with the degree of chlorination of the ketovinylating agent[187]. In this connection it is interesting to note that cyclic *cis*-β-chlorovinyl ketones (for example, 1-acyl-2-chlorocyclopent-1-ene) readily form hydrazones, which, however, do not cyclise to pyrazoles[188]. This is because of the lower lability of the halogen in the *cis*-configuration.

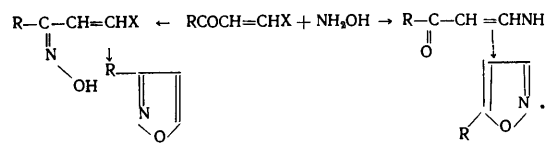
The only known case of *N*-ketovinylation of hydrazine is the reaction with a β-chlorovinyl ketone, the approach to the carbonyl group of which is sterically hindered[189]:



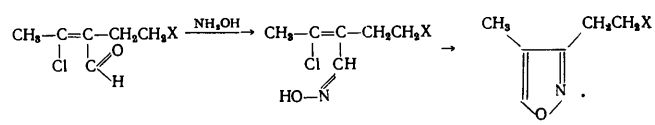
In this connection we may recall that a powerful nucleophilic agent such as RMgX also does not usually react with the carbonyl group of β-chlorovinyl ketones if the approach to the latter is hindered, and attacks the β-carbon atom of the double bond[22-25]. Finally, it should be noted that ethynyl ketones have also been used for the synthesis of pyrazoles[190].

Semicarbazide also reacts with β-chlorovinyl ketones at the carbonyl group with formation of semicarbazones[16,169,191-193]. Like hydrazones, semicarbazones can probably cyclise to the corresponding 1-carbamoylpyrazoles, since it was found that they undergo a change on recrystallisation[169].

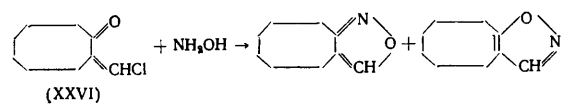
Hydroxylamine is less basic and less nucleophilic and therefore in the reaction with β-chlorovinyl[179,194-196], β-phenoxyvinyl[196], β-phenylthiovinyl[196], and β-hydroxyvinyl[197] ketones it attacks both electrophilic centres simultaneously. Subsequent cyclisation leads to the formation of a mixture of 3- and 5-substituted isoxazoles. Similar results were obtained also with barenylmethyl β-chlorovinyl ketones[179]:



β-Halogenoacroleins have been suggested for the synthesis of unsubstituted isoxazoles[182-184,194]. It is interesting to note that in the reaction of β-alkyl substituted β-chloroacroleins under mild conditions it is possible to isolate oximes[172], while on heating isoxazoles are formed immediately[180,181]:

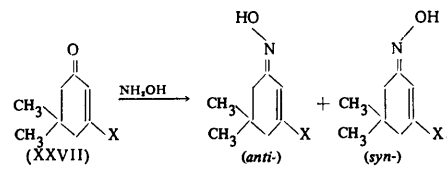


The cyclic β-chlorovinyl ketone (XXVI), with a fixed cisoid conformation, reacts with hydroxylamine to form a mixture of isoxazoles similar to that obtained in the reaction with the corresponding hydroxymethylene ketone[198,199].



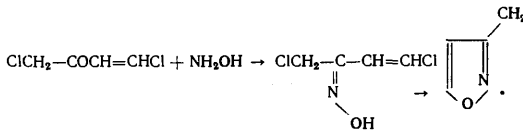
(XXVI)

However, in the reaction of hydroxylamine with the β-chlorovinyl ketone (XXVII), which has a fixed transoid conformation, only oximes (*syn*- and *anti*-isomers) are formed. In this case attack on the electrophilic centre of the double bond is hindered, since the double bond is located in the ring. Furthermore, the fixed transoid conformation prevents cyclisation[172]:

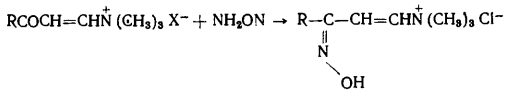


By varying the ketovinylating agents, it is possible to alter the mode of reaction with hydroxylamine. An increase in the electrophilicity of the carbonyl group in alkyl β-chlorovinyl ketones by the introduction of electron-acceptor substituents in the α-position of the alkyl group

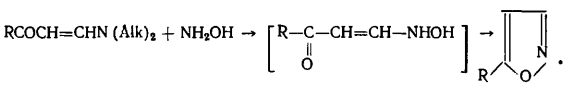
leads to the preferential formation of 3-substituted isoxazoles [195,200]‡. This shows that an oxime is formed as an intermediate in the main reaction:



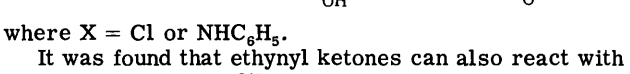
A similar effect can probably be achieved by replacing the chlorine atom in β-chlorovinyl ketones by a quaternary ammonium group. In this case the corresponding oximes could be obtained under very mild conditions [172]:



On the other hand, by introducing into the α-position a powerful electron-donor group $N(Alk)_2$ (instead of chlorine), which suppresses the electrophilic activity of the carbonyl group, the entire process may be reduced to the formation of 5-substituted isoxazoles only, i.e. products of the *N*-ketovinylation of hydroxylamine will form in the first stage of the reaction [52,196]:

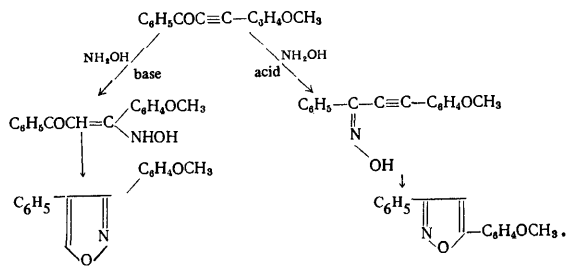


When *N*-phenyl-substituted hydroxylamine is used, only *N*-ketovinylation products are formed [147]:

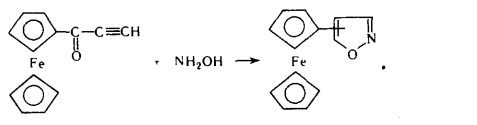


where X = Cl or NHC_6H_5.

It was found that ethynyl ketones can also react with formation of isoxazoles [202]. As in the case of β-chlorovinyl ketones, this reaction takes place in two ways, but, by varying the conditions, the process can be driven one way or another. In an acid medium attack on the carbonyl group is facilitated and in an alkaline medium the 1,4-addition (*N*-ketovinylation) product is formed as an intermediate:



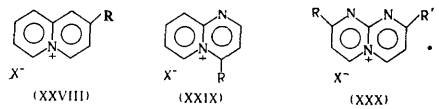
Ferrocenyl-substituted isoxazole was obtained in the same way [190]:



‡ We may recall that Kochetkov and Khomutova [201] developed a method of synthesis based on the reaction of hydroxylamine with β-keto-acetals (ω-acylmethyldioxolanes). An oxime is formed as an intermediate in the reaction, which permits the selective synthesis of trisubstituted isoxazoles.

We may also recall the synthesis of certain nitrogenous six-membered heterocycles using guanidine, alkylamidines, urea, thiourea, α-aminopyridine, 2-aminopyridine, etc. Thus, on heating, β-chlorovinyl ketones [203,204] and β-halogenoacroleins [182,184,205] react with guanidines in a strongly acid medium with formation of 2-aminopyrimidine derivatives. However, in this case the site of the primary attack by the nucleophilic agent cannot be deduced, since the intermediate products were not isolated. The use of thiourea in this reaction leads to the formation of 2-mercaptopyrimidine [184].

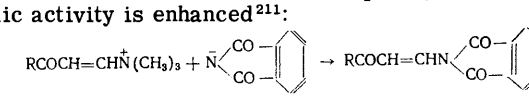
A method of synthesis of heterocyclic cations containing an ammonium nitrogen atom in the bridge—dehydroquinolizinium salts and their 1-aza- and 1,9-diaza-analogues [compounds (XXVIII), (XXIX), and (XXX) respectively]—has been developed on the basis of β-chlorovinyl ketones and their derivatives—β-keto-acetals [206-209]:



(XXVIII) (XXIX) (XXX)

The ketovinylation of carboxylic acid amides is difficult and requires heating to 180–200°C, the yields of products being low (8–22%): [210]

However, the anions of acid amides, for example, the phthalimide ion, are successfully ketovinylated when quaternary β-acylvinyltrimethylammonium salts are used. This reaction takes place at room temperature, and with β-aroylvinyltrimethylammonium salts aqueous solutions may be employed. On the other hand, with quaternary aliphatic ammonium salts [$AlkCOCH{=}CH\overset{+}{N}(CH_3)_3X^-$] the phthalimide ion is much too weak a nucleophilic agent in water and therefore the reaction must be carried out in a dipolar aprotic solvent—dimethylformamide (DMFA). [151] The anions are known to be much less solvated in solvents of this kind than in water and consequently their nucleophilic activity is enhanced [211]:



where R = Ar (solvent—water) or R = alkyl (solvent—dimethylformamide). The structure of the compounds obtained was demonstrated by hydrolysis to the corresponding β-aminovinyl ketones [151].

Carbonylvinylammonium salts proved to be completely irreplaceable in the synthesis of β-nitrovinyl ketones [66]. It is noteworthy that, despite all attempts, β-chlorovinyl ketones could not be made to react with the nitrite ion. The reaction of the quaternary salts with the nitrite ion was carried out in aqueous solution, potassium dihydrogen phosphate being added as a buffer. The buffer solution is necessary because the aryl β-nitrovinyl ketones formed are very sensitive to the action of hydroxide ions, the concentration of which increases as trimethylamine is eliminated. It was found that the yield of aryl β-nitrovinyl ketones falls as the electron-acceptor properties of the substituent in the phenyl ring become more pronounced:

Probably this is associated with the enhanced tendency of the resulting aryl β-nitrovinyl ketones to react further with the nucleophilic agents present in the reaction mixture. Thus the yield of β-nitrovinyl *p*-tolyl ketone is 45%, [212] while *p*-nitrophenyl β-nitrovinyl ketone was obtained in a yield of only 3%. [150]

The *N*-ketovinylation of the axide ion occupies a special position, since it led to possibilities of interest not only for syntheses but also for theory. Since these data were obtained in connection with the study of the stereochemistry of ketovinylation and the effect of groups eliminated on substitution, they will be discussed in detail in a later section (see section IV).

3. *S*-Ketovinylation

Methods for the *S*-ketovinylation have been developed comparatively little. Among these the ketovinylation of RS ions (R = alkyl or aryl), which are very powerful nucleophilic agents, has been investigated in greatest detail. It has been found that the reaction of thiophenoxides with β-halogenovinyl ketones yields β-phenylthiovinyl ketones[213]. Montanari and coworkers[214,215], who investigated the stereochemistry of this reaction, noted that the geometrical configuration of the initial ketone is retained on substitution. The reaction of course takes place more readily than with phenols. In some cases it was found that the halogen is very readily exchanged for an alkanethiolate ion even in benzene solution[216]:

$$RCOCH{=}CHCl + R'S^- \xrightarrow{H^+} RCOCH{=}CHSR' \xrightarrow{R'SH} RCOCH_2CH(SR')_2.$$

When an excess of mercaptans is used in the reaction, the latter does not stop at the β-alkylthiovinyl ketone stage, since a second mercaptan molecule adds to the double bond. This results in the formation of β-keto-mercaptals[217] (cf. the *O*-ketovinylation of OR^- in the presence of ROH):

$$RCOCH{=}CHCl + \bar{S}Alk \rightarrow RCO\bar{C}H{-}CH\!\!\begin{matrix}Cl\\ SAlk\end{matrix} \rightarrow$$

$$\rightarrow RCOCH{=}CHSAlk \xrightarrow{\bar{S}Alk} RCO\bar{C}H{-}CH\!\!\begin{matrix}SAlk\\ SAlk\end{matrix} \xrightarrow{H^+} RCOCH_2CH(SAlk)_2.$$

It was found that under these conditions the reaction with ethane-1,2-dithiol yields cyclic β-keto-mercaptals[217]. The corresponding β-ethylthiovinyl and β-phenylthiovinyl ketones were obtained also with ethynyl ketones as the ketovinylating agents in the presence of basic catalysts[125].

A brief communication has been published on the synthesis of mercaptals when mercaptans react with β-hydroxyvinyl ketones in an acid medium[218].

Phenylthio-derivatives are oxidised with hydrogen peroxide to the corresponding sulphoxides and sulphones[219]:

$$RCOCH{=}CHSC_6H_5 \xrightarrow{H_2O_2} RCOCH{=}CHSOC_6H_5 \xrightarrow{H_2O_2} RCOCH{=}CHSO_2C_6H_5.$$

The latter can also be obtained directly by the ketovinylation of the benzene sulphinate ion[219]:

$$C_6H_5COCH{=}CHCl + \bar{S}O_2C_6H_5 \rightarrow C_6H_5COCH{=}CHSO_2C_6H_5.$$

ββ-Dichlorovinyl methyl ketone reacts with sodium benzenesulphinate in a very unusual manner. Diphenylsulphonylmethane was obtained as the main product[65] together with a small amount of 1-chloro-1-phenylsulphonylbuten-3-one:

$$CH_3COCH{=}CCl_2 + C_6H_5\bar{S}O_2 \rightarrow CH_3COCH{=}C\!\!\begin{matrix}SO_2C_6H_5\\ Cl\end{matrix} + CH_2\!\!\begin{matrix}SO_2C_6H_5\\ SO_2C_6H_5\end{matrix}.$$

The formation of diphenylsulphonylmethane can be explained by the rapid hydrolysis of the intermediate 1,1-diphenylsulphonylbuten-3-one:

$$CH_3COCH{=}C\!\!\begin{matrix}SO_2C_6H_5\\ SO_2C_6H_5\end{matrix} + \bar{O}H \rightarrow CH_3COCH(\bar{O})C\!\!\begin{matrix}SO_2C_6H_5\\ SO_2C_6H_5\end{matrix} \rightleftarrows$$

$$\rightleftarrows CH_3{-}COCH(\underline{O}){-}CH\!\!\begin{matrix}SO_2C_6H_5\\ SO_2C_6H_5\end{matrix} \rightarrow \bar{C}H\!\!\begin{matrix}SO_2C_6H_5\\ SO_2C_6H_5\end{matrix} + (?)\ CH_3COCOH$$

$$\downarrow H^+$$

$$CH_2(SO_2C_6H_5)_2.$$

Another method of ketovinylation, using ethynyl ketones, may be successfully employed for the synthesis of β-keto-sulphones[125,200]. However, the most convenient ketovinylating agents for this purpose proved to be the quaternary ammonium salts $RCOCH{=}CH\overset{+}{N}(CH_3)_3Cl^-$. The reaction, carried out in an aqueous medium, results in a very rapid (literally on mixing the solutions!) formation of the sulphone with a high yield[221]. Ketovinylation with the aid of quaternary carbonylvinylammonium salts has the advantage that the product is obtained immediately in a pure form and does not contain the starting material as an impurity, as happens when aryl β-chlorovinyl ketones are employed. Since both the initial quaternary salts and the resulting sulphones have the *trans*-configuration, it was concluded that the configuration is retained on substitution of the $\overset{+}{N}(CH_3)_3$ group. However, the reaction was not investigated with *cis*-derivatives, since quaternary *cis*-β-acylvinyltrimethylammonium salts are so far unknown.

The ketovinylation of the sulphide ion has been demonstrated with the β-butyrylvinylammonium salt as an example[66]. The doubly charged sulphide ion is then ketovinylated twice and bis-(β-butyrylvinyl) sulphide was isolated in 88% yield:

$$2C_3H_7COCH{=}CH\overset{+}{N}(CH_3)_3 + S^{2-} \rightarrow (C_3H_7COCH{=}CH)_2S.$$

Despite the attempts made, this reaction could not be stopped at the mono-ketovinylation stage. This could not be done even when sodium hydrogen sulphide was employed[222]. Mono-ketovinylation could be achieved only by the reaction of β-chlorovinyl ketones with thioacetate salts. β-Acylethylenethiol is obtained after the hydrolysis of the reaction product[222]:

$$C_4H_9COCH{=}CHCl + CH_3COSNa \rightarrow C_4H_9COCH{=}CHSCOCH_3 \xrightarrow{NaSH} C_4H_9COCH{=}CHSH.$$

It is interesting to note that, according to the data of Nesmeyanov et al.[65], the analogous reaction with ββ-dichlorovinyl ketone yields a thioketen dimer after hydrolysis and elimination of hydrogen chloride:

$$CH_3COCH{=}CCl_2 + CH_3COSNa \rightarrow \left[CH_3COCH{=}C\!\!\begin{matrix}Cl\\ SCOCH_3\end{matrix} \xrightarrow{H_2O} CH_3COCH{=}C\!\!\begin{matrix}Cl\\ SH\end{matrix}\right] \xrightarrow{-HCl}$$

$$\rightarrow [CH_3COCH{=}C{=}S]_2.$$

In the synthesis of β-acylethylenesulphonates it was found that quaternary carbonylvinylammonium salts are the only possible ketovinylating agents, since in their reaction with the SO_3^{2-} ion in an aqueous medium they are sparingly soluble mixed salts of type (XXXI), which makes it possible to stop the reaction at the first stage. The mixed salts (XXXI) can be converted into alkali metal salts be subsequent treatment with KBF_4, KCN, or $NaNO_3$:[221]

$$RCOCH{=}CH\overset{+}{N}(CH_3)_3 + SO_3^{2-} \rightarrow RCOCH{=}CHSO_3^-\overset{+}{N}(CH_3)_3CH{=}CHCOR \xrightarrow{KBF_4}$$

$$\rightarrow RCOCH{=}CHSO_3K\ (soln.) + RCOCH{=}CH\overset{+}{N}(CH_3)_3\bar{B}F_4\ (ppt.).$$

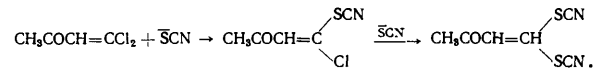
On the other hand, in the synthesis of hitherto unknown salts of phenylacylmethionic acids the fact that with β-chlorovinyl ketones the reaction proceeds further was employed[221,223]:

$$RCOCH{=}CHCl + Na_2SO_3 + NaHSO_3 \rightarrow RCOCH_2CH(SO_3Na)_2.$$

The interaction of β-chlorovinyl ketones with thiocyanate ions may be included among the *S*-ketovinylation reactions. This reaction was achieved for the first time by Panizzi[64] in only one case. It was developed further by Kochetkov[224], who employed a number of alkyl β-chlorovinyl ketones, and by the author of a patent[225], who described the use of ring-substituted aryl β-chlorovinyl ketones:

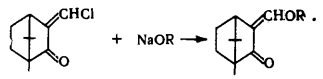
$$RCOCH{=}CHCl + \bar{S}CN \rightarrow RCOCH{=}CHSCN.$$

Nesmeyanov et al.[65] showed that ββ-dichlorovinyl ketones react with the thiocyanate ion, both chlorine atoms being substituted. Also it was possible to isolate the intermediate monosubstituted product:



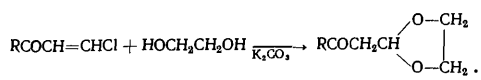
4. *O*-Ketovinylation

The first information about the ketovinylation of OR^- ions appeared in the patent literature in 1937[226-228]. The interaction of β-chlorovinyl ketones with alcohols in the presence of alkaline reagents was investigated in greater detail by Nesmeyanov et al.[229] and simultaneously by Price and Pappalardo[177]. These workers showed that the reaction with alkoxide ions in the corresponding alcohols does not as a rule stop at the substitution stage, the alcohol adding subsequently to the double bond of the intermediate β-alkoxyvinyl ketones. This results in the formation of β-keto-acetals in yields of 50–90%. Furthermore, it was found that β-keto-acetals are formed in low yields also when hydrogen chloride is employed as the catalyst[229]. The intermediate β-alkoxyvinyl ketone was isolated only in the case of the less reactive chloromethylenecamphor[230]:

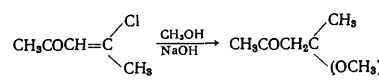


Therefore β-alkoxyvinyl ketones must be obtained by the elimination of the alcohol from the β-keto-acetals using various basic and acid catalysts[231-235].

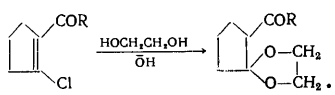
In recent years the synthesis of β-keto-acetals has been extended to higher aliphatic[230,236-239] and heterocyclic[239] homologues. The use of glycols in these reactions lead to the development of a method for the synthesis of stable dioxolane derivatives[233,240]:



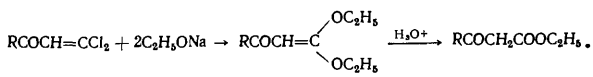
It is noteworthy that β-alkyl-substituted β-chlorovinyl ketones also react with alkoxides, albeit with difficulty, forming monoketals of β-diketones[139]:



Even the relatively unreactive cyclic β-chlorovinyl ketones with a fixed *cis*-configuration react with ethylene glycol in the presence of alkaline agents forming monoketals[188]:



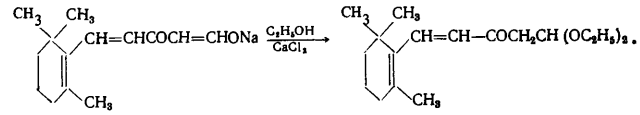
In ββ-dichlorovinyl ketones both chlorine atoms are exchanged for alkoxy-groups. In an anhydrous medium this results in the formation of β-dialkoxyvinyl ketones[65,139,163], which are readily hydrolysed to acylacetate esters[65]:



When alcoholic solutions of alkalis were allowed to react with ethynyl ketones, β-keto-acetals were also obtained[128].

Hydroxymethylene ketones too can be used for the synthesis of β-keto-acetals, but in this case it is necessary to employ acid catalysts[241-247]. Royals and Brannok[248] made a detailed study of the reaction of the sodium salts of hydroxymethylene ketones with alcohols in the presence of hydrochloric acid and found that, depending on the structure of the initial ketones, acetals or β-alkoxyvinyl ketones are formed.

β-Keto-acetals with a fairly complex structure were obtained similarly[249]:



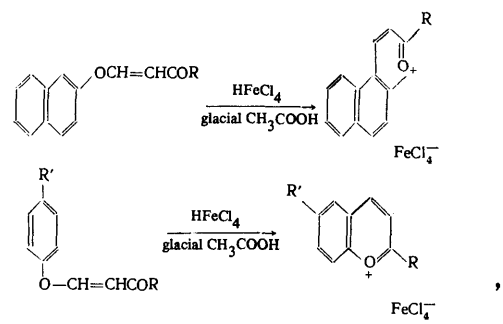
β-Keto-acetals have been used as intermediates for the synthesis of a wide variety of compounds. In particular, they have been employed for the preparation of certain heterocycles[9,250,251]: they are used very often for the synthesis of various derivatives formed by the reaction of the carbonyl group[252,253]. Higher members of the $RCOCH_2CH(OR')_2$ series, where $R = C_9-C_{12}$, have the scent of oranges and therefore it is suggested that they be employed in cosmetics and in the manufacture of perfumed soap[254].

In contrast to alcohols, the reaction of β-chlorovinyl ketones with phenols may be stopped at the first stage, which leads to the formation of β-aryloxyvinyl ketones[62]. It has been shown for alkyl β-chlorovinyl ketones that this reaction is general and is catalysed by alkaline agents in various solvents (water, dioxan, excess of phenol):

During prolonged interaction and when an excess of phenol is used, the reaction proceeds further to some extent, yielding the acetals of β-keto-aldehydes[229] as in the case of alcohols.

The reaction of β-chlorovinyl ketones with sodium β-naphthoxide differs significantly from that described above. Both in aqueous alkali and in dioxan the products of *C*-ketovinylation at the α-carbon atom of the naphthalene ring were isolated[61] together with the *O*-ketovinylation products (see p. 436).

Nesmeyanov et al.[91] showed that the most interesting property of β-aryloxyvinyl ketones is their capacity to undergo a rearrangement analogous to the Fries rearrangement. It was found that, on treating solutions of β-phenoxyvinyl ketones in glacial acetic acid with a solution of iron(III) chloride in concentrated hydrochloric acid, the chloroferrates(III) of 2-substituted benzo- and naphthopyrylium cations are formed. The isomeric 4-substituted pyrylium salts are not produced. Thus it was shown that the products of the *O*-ketovinylation of phenols rearrange in an acid medium to *C*-ketovinylation products:

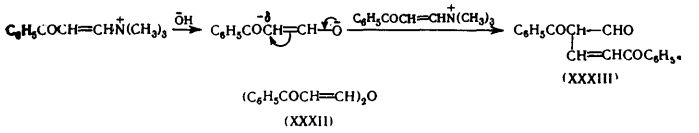


the rearrangement occurring not only in the *ortho*-position but also in the *para*-positions of the phenol ring, if the

latter is free. We may recall that the same pyrylium salts were obtained also by the direct condensation of β-chlorovinyl ketones with phenols and naphthol[88,89].

Finally, it should be noted that nucleophilic addition to ethynyl ketones has also been employed for the *O*-ketovinylation of phenols. Thus Bowden et al.[125] observed the nucleophilic addition of phenols to ethynyl ketones in the presence of bases.

The ketovinylation of the OH^- ion by any of the ketovinylating agents takes place in a complex manner and as a rule results in the formation of ketones (hydrolytic decomposition)[26]. β-Aroylvinyltrimethylammonium salts are an exception. They readily react with aqueous solutions of weak bases and even with water, which sometimes results in complications if the ketovinylation is carried out in an aqueous medium. This leads to products in which there are two carbonylvinyl residues per oxygen atom derived from water. This was noted for the first time by Kochetkov et al.[170] They found that β-benzoylvinyltrimethylammonium chloride undergoes "hydrolysis" in aqueous solution under the action of sodium bicarbonate with formation of a compound for which two alternative structures were proposed on the basis of elemental analysis and molecular weight measurements: either the structure of the β-benzoylvinyl ether (XXXII) or benzoyl(β-benzoylvinyl)acetaldehyde (XXXIII). According to infrared spectroscopic data, the latter is the most likely structure[151], but is complicated by the occurrence of ring–chain tautomerism. It is suggested that the decomposition of the quaternary salt with water is accompanied by successive *O*- and *C*-ketovinylation according to the mechanism

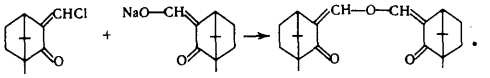


(XXXIII)

$(C_6H_5COCH{=}CH)_2O$

(XXXII)

It is interesting to note that, in contrast to β-aroylacetaldehyde, the enolates of hydroxymethylenecamphor are ketovinylated at the oxygen atom[63]:



The "hydrolysis" is particularly facilitated by the presence of electron-acceptor groups in the aryl ring. Thus β-aroylvinyltrimethylammonium chlorides containing halogen atoms in the *ortho*- or *para*-positions are "hydrolysed" even as a result of atmospheric moisture during storage and consequently these compounds cannot be stored in aqueous solutions. The mechanism of the "hydrolysis" changes sharply when one methyl group in the quaternary salts is replaced by the benzyl group[151]:

$$C_6H_5COCH{=}\overset{+}{N}H(CH_3)_2CH_2C_6H_5 \xrightarrow{H_2O} C_6H_5COCH{=}NH(CH_3)_2 + C_6H_5CH_2OH.$$

The weakly nucleophilic acetate ion could not be made to undergo the ketovinylation reaction for a long time. This became possible only when powerful ketovinylating agents such as β-acylvinyltrimethylammonium salts were employed. In order to avoid "hydrolytic" side processes, it is necessary to employ dry dipolar solvents such as dimethylformamide. In glacial acetic acid the process does not stop at the ketovinylation stage and acylals of β-ketoaldehydes are formed[151]:

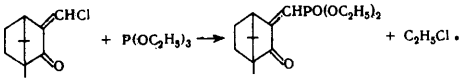
$$RCOCH{=}\overset{+}{N}H(CH_3)_2 + \overline{O}COCH_3 \rightarrow RCOCH{=}CHOCOCH_3 \xrightarrow{CH_3COOH} \rightarrow RCOCH_2CH(OCOCH_3)_2.$$

5. *P*-Ketovinylation

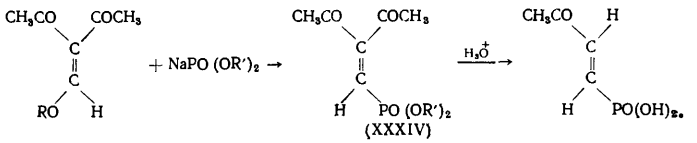
Ketovinylation of a phosphorus–carbonylvinyl group bond has been investigated extremely little and its possibility in principle has been demonstrated in only a few instances. In 1959 Kreutzkamp and Schindler[255] found that β-chlorovinyl methyl ketone undergoes the Michaelis–Arbuzov reaction with tributyl phosphite, forming dibutyl β-acetylvinylphosphonate:

$$CH_3COCH{=}CHCl + P(OC_4H_9)_3 \rightarrow CH_3COCH{=}CH{-}PO(OC_4H_9)_2 + C_4H_9Cl.$$

They showed further that chloromethylenecamphor[256] reacts likewise:



A similar phosphonic acid derivative (XXXIV) was obtained also with β-alkoxyvinyl diketone, subsequent treatment with the acid (XXXIV) leading to the formation of β-acetylvinylphosphonic acid[255,257]:



(XXXIV)

Nifant'ev et al.[258] suggested the reaction with triphenylphosphine for the identification of β-chlorovinyl methyl ketone. The structure of a phosphonium salt was attributed to the product of this reaction.

6. Ketovinylation at a Halogen Atom

The synthesis of β-chlorovinyl ketones from hydroxymethylene ketones under the action of thionyl chloride may be regarded formally as ketovinylation at a halogen atom. The chlorine atoms in β-chlorovinyl ketones are replaced by other halogens on reaction with iodide and fluoride ions. Since these ions are insufficiently nucleophilic in proton-containing media (particularly the fluoride ion!), the exchange of chlorine is carried out in aprotic dipolar solvents. Kochetkov showed[224] that the exchange with sodium iodide takes place fairly smoothly in acetone with formation of alkyl β-iodovinyl ketones. Subsequently it was shown by infrared and proton spin resonance spectroscopy that in this case the initial *trans*-configuration is retained[173]: *trans*-AlkCOCH=CHCl+I^- → AlkCOCH=CHI-*trans*. The exchange of chlorine for fluorine atoms has been recently achieved in α-methyl-substituted β-chlorovinyl phenyl ketone. Dimethylformamide was used as the solvent:

$$C_6H_5COC(CH_3){=}CHCl + F^- \xrightarrow{DMFA} C_6H_5CO(CH_3)C{=}CHF.$$

β-Bromovinyl ketones were not obtained by the exchange reaction, but their synthesis was achieved by another ketovinylation procedure—using ethynyl ketones[125,158,214]. Bowden et al.[125,158] obtained these compounds by the addition of hydrogen bromide to the triple bond of ethynyl ketones. β-Chlorovinyl ketones can be obtained similarly[215].

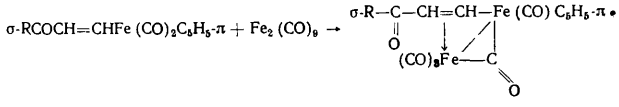
7. *Fe*-Ketovinylation

The ketovinylation of anions containing metals is of considerable interest. Complex anions of transition metals may be sufficiently nucleophilic among these.

In order to synthesise organoiron compounds containing the carbonylvinyl group linked by a σ bond to the iron atom, a study was made of the ketovinylation of the anion $[Fe(CO)_2C_5H_5\text{-}\pi]^-$.[259] Since according to Dessy's data[260] the nucleophilicity of this anion is close to that of the thiophenate ion, β-chlorovinyl ketones, which are known to react smoothly with thiophenate ions[213,214] were chosen as the ketovinylating agents:

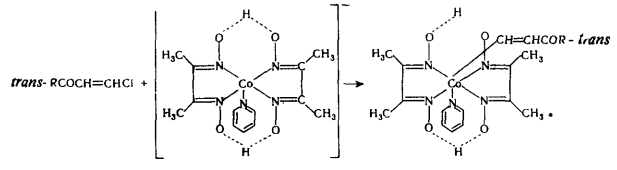
$$RCOCH{=}CHCl + Na^+[Fe(CO)_2C_5H_5]^- \rightarrow \sigma\text{-}RCOCH{=}CH{-}Fe(CO)_2C_5H_5\text{-}\pi .$$

The resulting complexes σ-RCOCH=CHFe=$(CO)_2C_5H_5$-π proved to be interesting objects for the investigation of the synthesis of mixed σ–π complexes with Fe–Fe bonds. The latter are formed when σ-RCOCH=CHFe$(CO)_2C_5H_5$-π reacts with iron nonacarbonyl[261]:



8. *Co*-Ketovinylation

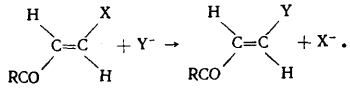
A complex anion of a fundamentally different type—pyridinatocobaloxime—was used to synthesise σ complexes with carbonylvinyl–cobalt bonds. Since the stability of this ion in water is evidence of its relatively low basicity, β-chlorovinyl ketones were chosen as ketovinylating agents[262]:



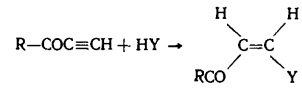
As for the ion $[Fe(CO)_2C_5H_5\text{-}\pi]^-$, it was found that the configuration is retained on substitution in the *trans*-series. It is interesting to note that the Co–CH=CHCOR bond in these complexes readily dissociates under the action of halogens. When the complexes are treated with iodine, *trans*-β-iodovinyl phenyl ketone and the corresponding complex with a Co–I bond are formed. Since the initial σ-(β-benzoylvinyl)pyridinatocobaloxime also had the *trans*-configuration, it was suggested that in this type of dissociation of the carbonylvinyl–cobalt bond the configuration is preserved.

III. CHOICE OF β-KETOVINYLATING AGENT

It follows from the studies reviewed that the correct choice of reagents is important for successful β-ketovinylation. The choice of the ketovinylating agent is determined mainly by the chemical and steric structure of the αβ-unsaturated ketone obtained, the nature of the attacking nucleophilic agent, and the possibility of a particular reaction mechanism. For example, in the synthesis of β-substituted vinyl ketones of the *trans*-series, the first β-ketovinylation method is used, i.e. the nucleophilic substitution reaction with the compounds *trans*-RCOCH=CHX, since it has been demonstrated in numerous instances[32,33,66,150,221,259] that the geometrical configuration is preserved on substitution:



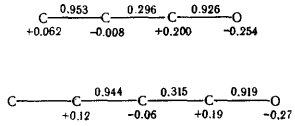
On the other hand in the synthesis of *cis*-isomers one uses as a rule nucleophilic addition to ethynyl ketones (second ketovinylation method), which leads to a *trans*-adduct[125,214,215]:



It is noteworthy that the first method is in principle suitable also for the synthesis of *cis*-isomers[211,215], but ketovinylating agents such as *cis*-β-chlorovinyl ketones are difficult to obtain and are usually synthesised by the addition of hydrogen halides to ethynyl ketones. Various β-substituted vinyl ketones, such as β-chloro- and β-amino-vinyl ketones and β-acylvinyltrialkylammonium salts, are most often used as ketovinylating agents, since nucleophilic addition to the triple bonds of ethynyl ketones does not allow the synthesis of, for example, compounds of the type RCOCR′=CHR″ or RCOCR′=CR″R‴. Furthermore, it is important to note that ethynyl ketones are themselves difficult to obtain.

In choosing the ketovinylating agent it is essential to take into account the selectivity of nucleophilic agents in relation to the particular electrophilic centre. In αβ-unsaturated carbonyl-containing compounds there are at least two electrophilic centres§: the carbonyl carbon atom and the β-carbon atom of the double bond, the electron density of the former being much lower than at the latter. Calculation of molecular diagrams of αβ-unsaturated ketones[265] by the LCAO MO method shows that the partial charge on the carbonyl carbon atom greatly exceeds the positive charge on the carbon atom of the double bond.

Molecular diagrams of the αβ-unsaturated oxo-compounds[265]

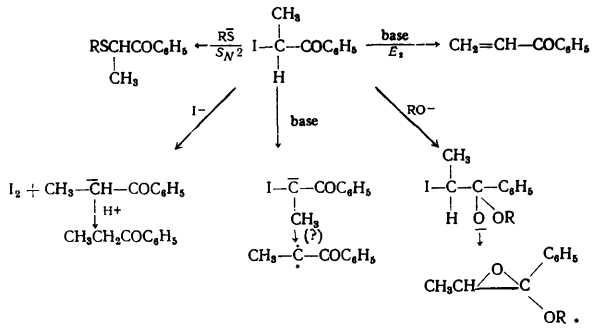


The numerals over the bonds indicate the bond orders and those over the atoms the charges. This calculation is evidently consistent with the empirical rule of vinylogy.

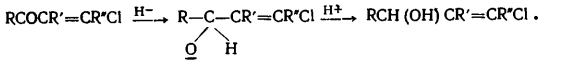
The study of nucleophilic reactivity has shown that nucleophilic agents are selective in relation to an electrophilic centre of a particular type and in the presence of several electrophilic centres in the same molecule various sites of nucleophilic attack are possible depending on the nature of the nucleophilic agent[266,267]. As an illustration,

§ It is also necessary to bear in mind a third possibility: the attack by the nucleophilic agent on the α-carbon atom. However, this probably occurs with much greater difficulty in the case of αβ-unsaturated ketones. For example, Kursanov and Parnes[263] showed that αβ-unsaturated ketones $ArCO\underset{\alpha}{C}H{=}\underset{\beta}{C}H{-}\underset{\gamma}{C}<$ without hydrogen atoms at the C_γ atom do not undergo hydrogen exchange under the action of bases. Miller and Lee[264] arrived at a similar conclusion concerning the derivatives of αβ-unsaturated carboxylic acids.

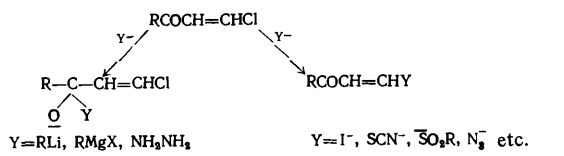
we may examine the interaction of α-halogeno-ketones with various nucleophilic agents[266]:



On the basis of numerous experimental facts, investigators concluded that nucleophilic agents which are at the same time strong bases tend to interact with electrophilic centres having a reduced electron density (for example the carbon atom of C=O group). On the other hand, large readily polarisable anions, which are as a rule weak bases, react preferentially with electrophilic centres having a higher electron density. Jencks and Carriuollo[268] found that, in relation to reactions with a carbonyl carbon atom, the reactivity series of nucleophilic agents is the same as their basicity series. On the other hand, for aliphatic and aromatic electrophilic centres, the reactivity series depends both on the polarisability and on the basicity of the nucleophilic agent and to a greater extent on the polarisability[269]¶. Consequently the presence of two electrophilic centres in the molecules of αβ-unsaturated ketones gives rise to problems of the choice of the ketovinylating agent as a function of the nature of the nucleophilic agent employed. Indeed, the review of all the experimental data concerning the ketovinylation reaction showed that, for example, in the case of β-chlorovinyl ketones there is a distinct tendency for all nucleophilic agents to be classified into two groups. Nucleophilic agents which are very strong bases (RLi, RMgX, NH_2NH_2) react mainly at the carbonyl group (1,2-addition). It is interesting to note that the hydride hydrogen from $LiAlH_4$, $NaBH_4$, and $Al(iso\text{-}OC_3H_7)_3$, which is a very powerful nucleophilic agent, also reacts at the carbonyl group with formation of the corresponding carbinols[163,185,270-272]:



Therefore, with rare exceptions, β-chlorovinyl ketones cannot be used for the ketovinylation of the hydride ion. On the other hand, nucleophilic agents such as the readily polarisable ions RS^-, I^-, SCN^-, N_3^-, $\bar{S}O_2R$, etc., which are weak bases, attack β-chlorovinyl ketones at the β-carbon atom of the double bond. This leads to substitution products (ketovinylation reaction). Hydroxylamine occupies an intermediate position between these two groups, since it reacts in both ways simultaneously:

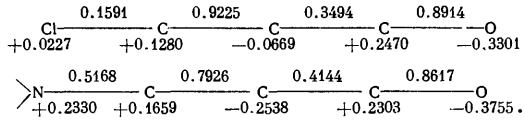


¶ The polarisability and basicity are known not to vary in parallel[269].

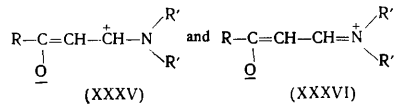
Instead of the sparingly water-soluble β-chlorovinyl ketones, it is very convenient to employ quaternary ammonium salts obtained from them for the ketovinylation of nucleophilic agents of the second type (SO_3^{2-}, CN^-, SO_2R, NO_2^-, CH_3COO^-, etc.). The high electrophilicity of the double bond and solubility in water make these ketovinylating agents very suitable for reactions with anions[34]. In addition, it is important to note that, when quaternary ammonium salts are used, it is possible to achieve the ketovinylation of CN^-,[66] NO_2^-,[150,212] SO_3^{2-},[22] and CH_3COO^- [151] ions, whereas β-chlorovinyl ketones proved to be altogether unsuitable in these cases.

The development of ketovinylation methods made possible the successful application of nucleophilic agents of the first type (RLi, RMgX, NH_2NH_2). It was found that β-dialkylaminovinyl ketones can be usefully employed in reactions with these nucleophilic agents. As a result of the replacement of the chlorine atom by the dimethylamino-group, only powerful nucleophilic agents react with β-dimethylaminovinyl ketones and only at the β-carbon atom of the double bond. In order to account for this sharp change in the properties of the molecule, the following arguments may be put forward. The unshared electron pair of the nitrogen atom very markedly suppresses the electrophilicity of the carbonyl carbon atom. The molecular diagram† of β-aminovinyl ketone shows that the positive charge on the nitrogen atom is larger than the charge on the carbonyl carbon atom.

Molecular diagrams of β-chloro- and β-amino-vinyl ketones

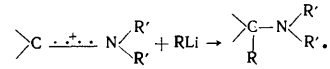


Furthermore, the carbon atom adjacent to the nitrogen also has a large positive charge. Thus structures (XXXV) and (XXXVI) make a considerable contribution to the resonance hybrid of β-aminovinyl ketone, i.e. the groups



characteristic of immonium salts,

are present. In immonium salts the carbon atom adjacent to the nitrogen is attacked by the carbanions derived from RLi and RMgX:[275]



† The molecular diagrams of β-chloro- and β-aminovinyl ketones were calculated by N. P. Gambaryan and A. V. Tutkevich by the LCAO-MO method. The following parameters were used in the calculation: $\alpha_O = \alpha + 1.2\beta$, $\alpha_N = \alpha + \beta$, $\beta_{C=O} = 2\beta$, and $\beta_{CN} = 0.9\beta$;[273] $\alpha_{Cl} = \alpha + 2\beta$ and $\beta_{C-Cl} = 0.4\beta$.[274]

On the other hand, comparison of the molecular diagrams of β-amino- and β-chloro-vinyl ketones shows that the bond order in the C=O group in β-aminovinyl ketones is lower than in the carbonyl group of β-chlorovinyl ketones. Consequently the capacity of the C=O group to undergo addition reactions is much lower in the case of β-aminovinyl ketones. These considerations explain the mode of attack by nucleophilic agents.

It is also clear why β-aminovinyl ketones are passive in relation to weak nucleophilic agents. Indeed, the attack by the nucleophilic agent (Y^-) on the double bond of β-amino- and β-chloro-vinyl ketones leads to the formation of the carbanions RCOĊHCHXY [where X = Cl or $N(CH_3)_2$], in which the electron pairs of the hetero atom X are not conjugated. According to calculation, the gain in conjugation energy in the amino-derivative is higher by 0.42β than in β-chlorovinyl ketones.

Finally, in choosing the ketovinylating agent one should also take into account the possible reaction mechanism. In Section IV, the question of the possible ketovinylation mechanisms will be discussed separately.

IV. STEREOCHEMISTRY AND MECHANISM OF REACTION

The first systematic studies on and the interest in ketovinylation reactions arose in connection with the attempt by Nesmeyanov and coworkers to elucidate nucleophilic substitution at the olefin carbon atom after Nesmeyanov and Borisov[276-278] formulated the rule concerning the retention of configuration in electrophilic and homolytic substitution at an unsaturated reaction centre.

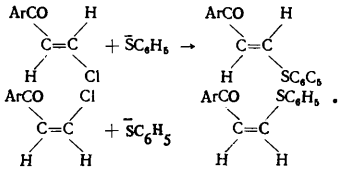
However, the difficulties encountered in the attempt to isolate pure *cis*- and *trans*-isomers of β-substituted vinyl ketones and at the same time the lack of reliable methods for the determination of their configuration directed these studies into the synthetic field.

The mechanism of ketovinylation reactions has so far been little investigated. It has been established in a number of instances that these reactions are bimolecular. Kudryavtseva et al.[279,280] found that the reactions of *trans*-β-chlorovinyl ketones with sodium ethoxide in alcohol are of the second order. However, the stereochemistry of ketovinylation could not be investigated in this model reaction, since the process does not stop at the first stage, a further alcohol molecule adding to the double bond. The kinetics of the reaction of nitrovinyl phenyl ketone with methanol have been studied: one of the pathways in this reaction constitutes ketovinylation[28].

Marchetti and Passalacque[282] found that the reaction of *trans*-β-arylaminovinyl phenyl ketones with pyrrolidine is also a second-order process. It was noted that the configuration is retained during ketovinylation, but this study is likewise restricted to the *trans*-series only.

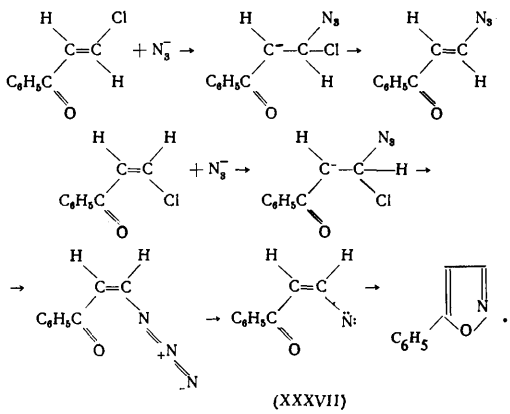
The conclusion that the configuration is retained on substitution in the *trans*-series was based on numerous examples of ketovinylation of nucleophilic agents such as, for example, ferrocenyl-lithium, sodium cyclopentadienide, alkali metal cyanides, potassium phthalimide, sodium nitrite, sulphite, sulphide, and benzenesulphinate, salts containing the complex anions $[Fe(CO)_2C_5H_5\text{-}\pi]^-$ or pyridinatocobaloxime, etc.

However, the stereochemical result of the reaction in the case of both *cis*- and *trans*-isomers has in fact been studied only in two instances—the ketovinylation of thiophenoxide and azide ions. Landini and Montanary showed in a brief communication[215] that aryl *cis*- and *trans*-β-chlorovinyl ketones react with the thiophenoxide ion, the geometrical configuration being mainly retained:



The stereochemistry of the ketovinylation of the azide ion was studied in greater detail. Nesmeyanov and Rybinskaya found that the stereochemical result of the reaction with the azide ion depends on the nature of the substituent X in the compound $C_6H_5COCH{=}CHX$. Thus *trans*-β-chlorovinyl phenyl ketone reacts with sodium azide in aqueous alcohol with formation of *trans*-β-azidovinyl phenyl ketones[283,284]. Other aryl *trans*-β-chlorovinyl ketones and *trans*-β-acylvinyltrimethylammonium quaternary salts react similarly[283]. In the reaction of *cis*-β-chlorovinyl phenyl ketone with sodium azide, 5-phenylisoxazole was isolated as the main product instead of the expected β-azidovinyl phenyl ketone. The formation of this product is regarded as the result of the spontaneous decomposition of the intermediate *cis*-β-azidovinyl phenyl ketone, which, probably as the result of the nearness of the carbonyl and azide groups, is probably converted with evolution of nitrogen into the nitrene species (XXXVII) having the *cis*-configuration. This species is most likely to be stabilised by the reaction of the nucleophilic oxygen atom of the carbonyl group with the electrophilic centre—the nitrene nitrogen:

Scheme 1



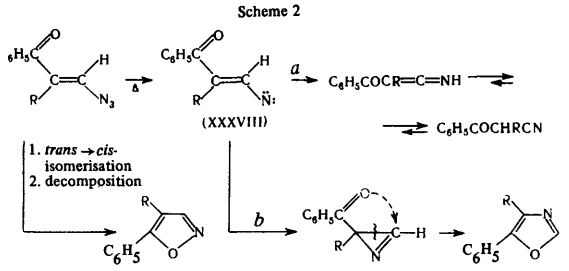
(XXXVII)

In this connection it is interesting to note that benzoisoxazole was obtained from 2-azidobenzophenone, which is known to be a "*cis*-compound"[285].

The configuration of *trans*-β-azidovinyl phenyl ketone was confirmed by spectroscopic and chemical correlation methods[284]. It was found that, when this compound is decomposed by heating in DPA solution, the product is mainly benzoylacetonitrile, 5-phenyloxazole also being isolated in a low yield. Its isomer, 5-phenylisoxazole, was detected only in trace amounts[286]. It may be supposed that the decomposition of *trans*-β-azidovinyl phenyl ketone involves

the formation of the nitrene species (XXXVIII), which has the *trans*-configuration, in contrast to (XXXVII):

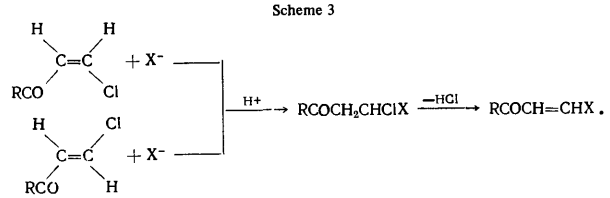
Scheme 2



This species may be stabilised either by rearrangement to the imine of benzoylketen, which is a tautomeric form of benzoylacetonitrile (branch *a* of Scheme 2) or by the formation of the azirine ring, which is known to form readily in the thermolysis of certain vinyl azides[287,288]. The subsequent dissociation of the bond (previously the double bond) with ring closure, as shown in Scheme 2 (branch *b*), leads to the corresponding oxazole. The traces of 5-phenylisoxazole are probably formed as the result of a possible *trans*-*cis*-isomerisation (branch *c*). Consequently the products of the decomposition and subsequent rearrangement differ significantly for *cis*- and *trans*-β-azidovinyl phenyl ketones, which makes it possible to establish the configuration of the products of the ketovinylation of the azide ion. Investigation showed that the ketovinylation of the azide ion with *cis*- and *trans*-β-chlorovinyl phenyl ketones takes place mainly with the retention of the initial geometrical configuration, although it should be noted that in the case of the *cis*-isomer an admixture of *trans*-β-azidovinyl phenyl ketone was isolated as an impurity together with the main product—5-phenylisoxazole.

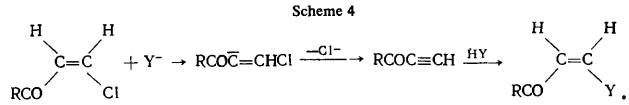
The observed stereochemical results are most consistent with the direct nucleophilic substitution mechanism shown in Scheme 1. The alternative addition—elimination mechanism (Scheme 3), in which the stereochemical result of the reaction should be independent of the configuration of the initial ethylenes, must be rejected on the basis of these results.

Scheme 3

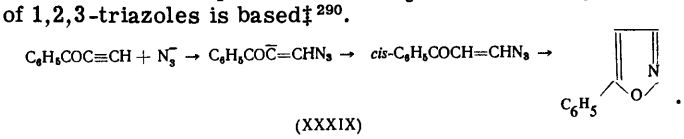


However, it is known that the preferential retention of the initial geometrical configuration in the reaction of the *cis*-isomer is not by itself evidence of the direct nucleophilic substitution mechanism being the only one possible, since the same stereochemical results may be obtained also in the elimination–addition mechanism (Scheme 4).

Scheme 4

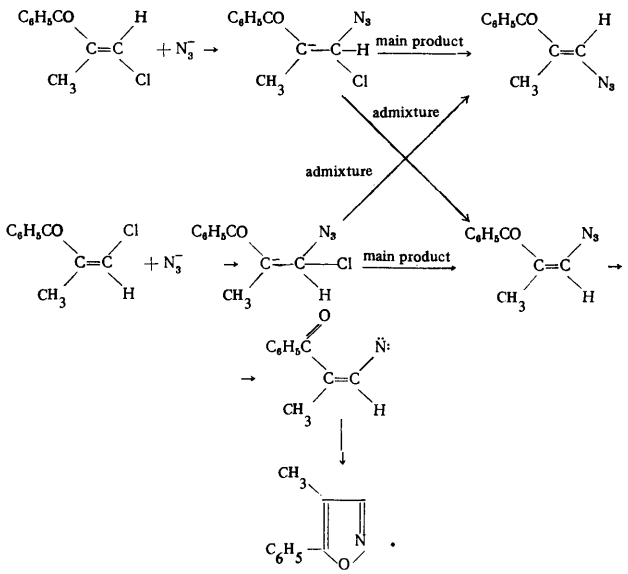


Indeed, on addition of HN_3 to ethynyl ketones at low pH in aqueous solution, 5-phenylisoxazole was obtained[289]. In this connection it is interesting to note that the behaviour of ethynyl ketones in relation to HN_3 differs from the usual reactions of the triple bond with HN_3 on which the synthesis of 1,2,3-triazoles is based‡[290].

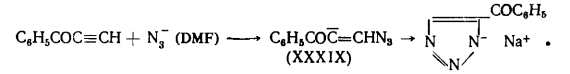


(XXXIX)

In order to exclude the possibility of the elimination–addition mechanism, the stereochemistry of the ketovinylation of the azide ions with both *cis*- and *trans*-α-methyl-substituted β-chlorovinyl phenyl ketones was studied. Since such compounds are much less reactive than the β-chlorovinyl ketones unsubstituted at the carbon atoms of the double bond, dimethylformamide, the nucleophilicity of anions in which is greatly enhanced, was employed as the solvent. Then *trans*-β-chloro-α-methylvinyl phenyl ketone reacted with the N_3^- ion very readily and *trans*-β-azido-α-methylvinyl phenyl ketone was isolated from the nitrogen-containing products. 4-Methyl-5-phenylisoxazole was isolated as an impurity. At the same time, the *cis*-isomer reacted more slowly under the same conditions and 4-methyl-5-phenylisoxazole was isolated from the reaction mixture as the main product; *trans*-β-azido-α-methylvinyl phenyl ketone was isolated as an impurity. Thus, although the elimination–addition mechanism is impossible in such cases (α-hydrogen atoms are absent from the starting materials), substitution products were obtained from both isomers and mainly with retention of the geometrical configuration.



‡ The synthesis of 4-acyl-1,2,3-triazoles on the basis of ethynyl ketones and sodium azide was developed by Nesmeyanov and Rybinskaya using as the medium the aprotic dipolar solvent dimethylformamide[291]:



The sharp difference in the behaviour of ethynyl ketones in relation to azide ions in a proton-containing medium and in dimethylformamide was attributed to different conditions of the stabilisation of the intermediate carbanion (XXXIX), which is very rapidly protonated in the first case with formation of *cis*-β-azidovinyl phenyl ketone (subsequently converted into 5-phenylisoxazole). In dimethylformamide this carbanion can be stabilised only by dipolar cyclisation, which leads to the formation of the stable anion of 4-acyl-1,2,3-triazole.

This shows that in the case considered the direct nucleophilic substitution mechanism probably operates. Recent kinetic data[300] also confirmed this mechanism.

It is interesting to note that, in contrast to unsubstituted *trans*-β-azidovinyl phenyl ketone, the *trans*-β-azido-α-methylvinyl phenyl ketone obtained decomposes on heating with formation of 4-methyl-5-phenyloxazole as the main product and the corresponding benzoylacetonitrile is obtained as an impurity (Scheme 2, branch *b*)[286]. Probably the stabilisation of the nitrene species is influenced not only by stereochemical factors but also by electronic factors. The appearance of the electron-donor CH_3 group adjacent to the double bond facilitates the interaction of the electrophilic nitrene nitrogen atom with the carbon atom of the ethylene bond, which results in the formation of the azirine ring. The conversion of acylazirines into oxazole rings has already been discussed (see p. 449).

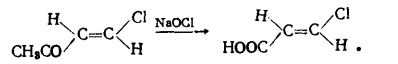
It was found that the stereochemical result of the nucleophilic substitution at the double bond depends on the nature of the group eliminated[292]. In relation to the ketovinylation of the azide ion in proton containing media, the compounds $C_6H_5COCH{=}CHX$ can be divided into several groups.

Compounds of group I, where X = Cl§, Br, $\overset{+}{N}(CH_3)_2$, or NO_2, react with formation of a substitution product, the initial geometrical configuration being largely retained. Compounds where X = $SO_2C_6H_5$ (intermediate group) react with azide ions also forming a substitution product, but in this case the same mixture of substitution products, containing mainly the thermodynamically more stable *trans*-isomer, was obtained regardless of the initial configuration of the substrate. Finally, the reaction of compounds having X = CN or SO_3^- (group II) with the N_3^- ion yielded 4-benzoyl-1,2,3-triazole instead of the substitution product regardless of the initial configuration. As the compounds of both groups contain both powerful [NH_2 and $(CH_3)_3N^+$ in group I and CN in group II] and weak (Cl and Br in group I and SO_3^- in group II) electron acceptors, these observations could not be explained by any electronic effects in the initial molecules. The reasons for the differences in the behaviour of the compounds $C_6H_5COCH{=}CHX$ may be due to the different rates of heterolysis of the C–X bond in the intermediate carbanion $C_6H_5\bar{C}OCH{-}CHXN_3$. If the heterolysis of the C–X bond in this carbanion is fast (group I), or is almost simultaneous with the formation of a new C–N_3 bond, a substitution product with retention on the initial configuration is formed. If the heterolysis of the C–X bond is slower (the intermediate case with X = $SO_2C_6H_5$), the lifetime of such a carbanion is longer and consequently there appears the possibility of free rotation about the single bond in the carbanion. Then of course the thermodynamically more stable substitution product, i.e. *trans*-β-azidovinyl phenyl ketone, is formed with both the *cis*- and *trans*-isomers. Finally, if the heterolysis of the C–X bond is altogether slow, the lifetime of the intermediate carbanion is fairly long and, as a result, there is sufficient time for dipolar cyclisation to occur, i.e. substitution is complicated by cyclisation. This leads to the formation of the triazoline anion, which is converted into the stable heterocyclic 1,2,3-triazole system with elimination of the X^- anion. This classification of eliminated groups in terms of the rate of heterolysis of the C–X bond in the intermediate carbanion into readily and slowly eliminated is supported by the following experimental data. In fact, the chloro- and nitro-groups in β-chloro- or β-nitro-vinyl ketones are substituted by the methoxide anion¶ so fast that it is possible to isolate only the substitution product, while in the case of β-cyanovinyl phenyl ketone the isolation of the addition product $C_6H_5COCH_2CHCN(OCH_3)$ presents no difficulty[294].

V. SYNTHESIS OF GEOMETRICAL ISOMERS OF β-CHLOROVINYL KETONES AND DETERMINATION OF THEIR CONFIGURATION AND CONFORMATION

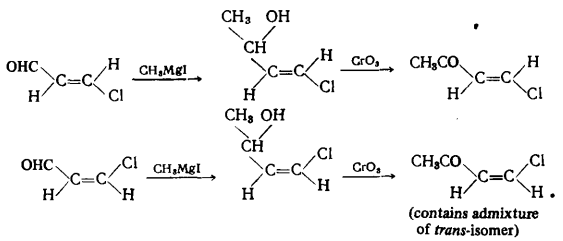
The principal information about the mechanism of nucleophilic substitution at the double bond comes from stereochemical studies. Such data can of course be reliable only if the geometrical configuration of the starting materials and reaction products has been correctly established.

Depending on the method of synthesis, β-chlorovinyl ketones with a definite configuration are obtained as a rule. These methods have been discussed in detail in reviews[1,5-8] and here we shall consider only some of them. The problem of the configuration of β-chlorovinyl ketones obtained by the addition of acid chlorides to acetylene in the presence of aluminium chloride was considered for the first time by Kochetkov et al.[295] It was found that the compounds thus obtained belong to the *trans*-series, since the oxidation of β-chlorovinyl methyl ketone with sodium hypochlorite yielded *trans*-β-chloroacrylic acid:



A detailed study of the infrared[10,173], ultraviolet[173], and nuclear magnetic resonance[173] spectra showed that all β-chlorovinyl ketones obtained in this way belong to the *trans*-series.

Skoldinov et al.[17] developed another version of the synthesis of β-chlorovinyl ketones, whereby both *trans*- and *cis*-isomers can be prepared:



The configuration of the reaction products was established very convincingly by infrared and nuclear magnetic resonance spectroscopy[17,296] and by chemical correlations. However, it was impossible to obtain pure *cis*-β-chlorovinyl methyl ketone by this procedure. According to NMR spectra, the reaction product in this case contained about 30% of the *trans*-isomer[296].

The determination of the configuration of alkyl β-chlorovinyl ketones usually does not present special difficulties. The most important information in these cases was obtained with the aid of infrared and NMR spectra and by chemical correlations. However, Nesmeyanov et al.[259] showed that NMR spectra of aryl β-chlorovinyl ketones of the *trans*-series, susceptible to interpretation, could be

§ Reactions of both *cis*- and *trans*-isomers were investigated with X = Cl.

¶ Both carbon atoms of the ethylene bond in β-nitrovinyl ketones react with $\bar{O}CH_3$. Here we are considering only the attack by $\bar{O}CH_3$ on the β-carbon atom. The problem of the mode of addition of nucleophilic agents to the system XCH=CHY was examined by Nesmeyanov et al.[293]

obtained only with a 100 MHz instrument, since the characteristic AB quartet of the protons at the double bond is partially overlapped by signals due to the protons of the aromatic ring. Aryl *cis*-β-chlorovinyl ketones were obtained by the addition of hydrogen chlorides to aryl ethynyl ketones in the presence of copper(I) chloride[215]:

Their configuration was established by the absence of absorption in their spectra at 930–940 cm^{-1} and on the basis of NMR spectra[284]. In this case the interpretation of the NMR spectrum was extremely simple.

The study of the properties of the *cis*- and *trans*-isomers of aryl β-chlorovinyl ketones[215,284] showed that the *trans*-form is thermodynamically more stable, while the *cis*-isomers are extremely labile and are readily converted into *trans*-isomers under the action of hydrogen chloride even at room temperature. Therefore in their synthesis from ethynyl ketones and hydrogen chloride it is necessary to employ an exactly calculated amount of hydrogen chloride and the reaction temperature should not exceed −40°C. It is noteworthy that *cis*-β-chlorovinyl methyl ketone also proved to be less stable than the *trans*-isomer[17]. The lower stability of the *cis*-isomers can probably be accounted for by the steric interaction between the RCO and Cl groups located close together, in which dipole–dipole repulsion may play a major role[17]. *trans*-β-Chloro-α-methylvinyl phenyl ketone was synthesised using the Claisen method by the formulation of propiophenone with subsequent treatment of the intermediate β-hydroxy-α-methylvinyl phenyl ketone with thionyl chloride in benzene[284].

According to thin-layer chromatographic and NMR spectroscopic data, the product of this reaction contained an insignificant amount (about 5%) of the *cis*-isomer. The content of the *cis*-isomer may be increased by keeping an ethereal solution of *trans*-β-chloro-α-methylvinyl phenyl ketone in diffuse sunlight. The pure *cis*-isomer was isolated from the mixture by means of preparative thin-layer chromatography. However, the most convenient method for the separation of the isomer proved to be a chemical procedure based on the fact that the *trans*-isomer reacts with sodium sulphite in dimethylformamide much faster than the *cis*-isomer[34]. The configuration of α-methyl-substituted β-chlorovinyl phenyl ketones was established on the basis of NMR spectroscopic data and chemical correlations[284], since neither infrared nor ultraviolet spectra provided adequate information.

Conformational analysis of β-chlorovinyl ketones has been carried in a very limited number of cases. For a simpler model, for example acrolein, it has been shown that the transoid conformation is more stable by approximately 2 kcal $mole^{-1}$ than the cisoid conformation[297]. However, in other αβ-unsaturated carbonyl compounds the relative stabilities of S-*cis*- and S-*trans*-forms are strongly influenced by the dimensions and nature of the substituents. The solvent probably also plays a significant role. One may suppose *a priori* that resonance stabilisation with participation of canonical structures of the type $\overset{+}{Cl}=C-C=C-\bar{O}$ plays an appreciable role in β-chlorovinyl ketones[298]. Benson and Pohland[173], who investigated the infrared and ultraviolet spectra of alkyl *trans*-β-chlorovinyl ketones, attributed the transoid conformation to these compounds. In the study of the infrared and quadrupole resonance spectra of *trans*-β-chlorovinyl methyl ketone and its deuterated derivatives on instruments with a high resolving power, Dabrowski and Terpiński[299] concluded that *trans*-β-chlorovinyl methyl ketone exists in both conformations, S-*cis* and S-*trans*, and that the equilibrium S-*cis* ⇌ S-*trans* is displaced to the right in more polar solvents (CH_3CN, CH_3OH) and conversely to the left in non-polar solvents (carbon tetrachloride, hydrocarbons). This problem has also been discussed by Shapet'ko et al.[296] In the conformational analysis of the *cis*- and *trans*-isomers of β-chloroacrolein and β-chlorovinyl methyl ketone they used the nuclear magnetic resonance spectra of carbon tetrachloride solutions. For comparison, a study was made of the spectra of malonic and methylmalonic dialdehydes, which form cyclic enolic forms and consequently have the cisoid conformation. Analysis of the changes in the chemical shifts of the individual protons in the isomeric transition from the *cis*- to the *trans*-configuration is evidence, according to the authors[296], in favour of the cisoid conformation of both isomers of β-chlorovinyl methyl ketone. Unfortunately, in this case the effect of solvents on conformation was not studied specially, so that the data obtained cannot be fully compared with those of Dybrowski and Terpiński[299], but it should be noted that both groups of investigators concluded that the conformation of *trans*-β-chlorovinyl methyl ketone in carbon tetrachloride solution is predominantly cisoid. This is probably because in a non-polar solvent there is a possibility of direct interaction in the molecule (via the field) of oxygen and chlorine atoms which have opposite charges.

In conclusion, we may mention the investigation of the conformation of ββ-dichlorovinyl ketones carried out recently by American workers[298].

Advances in the Asymmetric Synthesis of α-Amino-acids

K.K.Babievskii and V.K.Latov

The review deals with the advances in the asymmetric synthesis of α-amino-acids. Depending on the nature of the asymmetric reactions, the subject matter has been divided into two parts: asymmetric synthesis of α-amino-acids by catalytic hydrogenation and condensation methods of asymmetric synthesis. The principal characteristics of the asyymetric syntheses have been assessed as a function of various factors: the type of catalyst, the structure of the substrates, and the solvent. Much attention has been devoted to theoretical concepts which make it possible to understand the reasons for the occurrence of a new dissymmetric centre and the dependence of its configuration on that of the asymmetrising agent. The bibliography includes 85 references.

I. INTRODUCTION

The requirement for α-amino-acids is at present very great: their use in biochemistry, food, medicine, etc. is being extended. A number of effective synthetic and microbiological methods have been developed for the preparation of α-amino-acids both on laboratory and industrial scales [1,2]. A disadvantage of the synthetic methods is the formation of optically inactive racemic products. Therefore, despite the existence of many methods for the separation of racemic α-amino-acids into optical isomers [1], synthesis has acquired increasing importance, particularly in recent times [3-5].

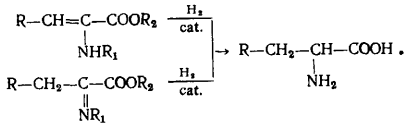
The essential feature of the asymmetric synthesis consists in the generation in the molecule during the reaction under the influence of asymmetrising agents of a new dissymmetric centre with a definite steric configuration. If the asymmetrising agent is an optically active compound, usually eliminated after the formation of the new dissymmetric centre, we are dealing with partial asymmetric synthesis. When a physical asymmetrising factor is employed, for example circularly polarised light, we are dealing with absolute asymmetric synthesis.

While the first successful asymmetric syntheses were achieved as early as the beginning of the present century, the asymmetric synthesis of α-amino-acids began to be investigated systematically only in the last decade. Klabunovskii's monograph [3] published in 1960 described the asymmetric synthesis of α-amino-acids only in general terms, since the bulk of the work on this question was published after 1960. Isolated examples of the asymmetric synthesis of α-amino-acids can be found in books [4,5] dealing with problems of the stereochemistry of organic compounds. These data are supplemented to some extent by the reviews of Mitsui dealing with asymmetric synthesis [6] and asymmetric hydrogenation [7].

In the present paper studies on the asymmetric synthesis of α-amino-acids published up to 1968 are reviewed. In the assessment of the results of asymmetric synthesis the authors endeavoured as far as possible to describe its principal characteristic: the yield of the main product and its optical purity or degree of asymmetric synthesis. Much attention has been devoted to theoretical concepts which explain the relation between the configurations of the new dissymmetric centre and the asymmetrising agent.

II. ASYMMETRIC HYDROGENATION OF DOUBLE BONDS

One of the main methods for the asymmetric synthesis of α-amino-acids is the asymmetric hydrogenation of their unsaturated precursors. This group of compounds includes αβ-unsaturated α-amino-acids and the imino-derivatives of α-keto-acids:



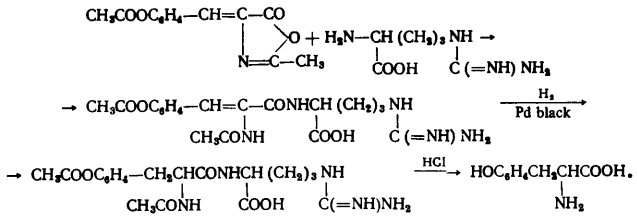
The asymmetric hydrogenation of double bonds results in the formation of an asymmetric α-carbon atom. After the elimination of the groups R_1 and R_2, optically active α-amino-acids are obtained.

The asymmetrising agent in catalytic hydrogenation may be the optically active group R_1 or R_2 forming part of the initial molecule and eliminated after asymmetric hydrogenation or a dissymmetric catalyst may be used. In the latter case the initial molecule does not contain optically active groups.

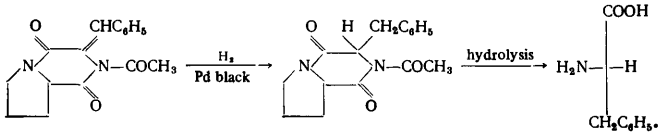
1. Asymmetric Hydrogenation of αβ-Unsaturated α-Amino-acids

The first asymmetric synthesis of an α-amino-acid by catalytic asymmetric hydrogenation was that of D-tyrosine

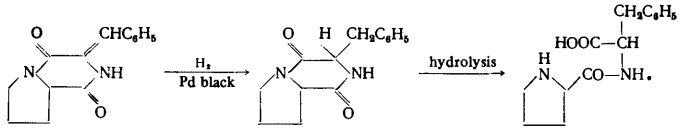
achieved by Bergmann et al.[8] L-Arginine was used as the asymmetrising agent. The hydrogenation over palladium black of the unsaturated peptide of α-acetamido-*p*-acetoxycinnamic acid and L-arginine resulted in the preferential formation of diacetyl-D-tyrosyl-L-arginine. The hydrolysis of the dipeptide in 20% hydrochloric acid yielded D-tyrosine with $[\alpha]_D^{21} = +9.5°$ (4% HCl); for optically pure D-tyrosine, $[\alpha]_D^{20} = +11.8°$:



Somewhat later Bergmann and Tietzmann[9] obtained the dioxopiperazine derivative of *N*-acetyl-L-phenylalanyl-L-proline with $[\alpha]_D^{22} = +202.6°$ in about 50% yield by the reduction of the optically active dioxopiperazine derivative of *N*-acetyldehydrophenylalanyl-L-proline over palladium black. After the hydrolytic elimination of the asymmetrising agent (L-proline), L-phenylalanine with $[\alpha]_D^{27} = -33.9°$ was obtained:

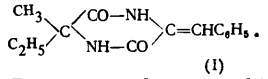


After the hydrogenation of the dioxopiperazine derivative of dehydrophenylalanyl-L-proline over palladium black, the dioxopiperazine derivative of L-phenylalanyl-L-proline was isolated, its hydrolysis in hydrochloric acid giving a 25% yield of pure L-prolyl-L-phenylalanine with $[\alpha]_D^{25} = -40.8°$ (5% in 20% HCl):



Although the initial asymmetrising agent (L-proline) was contained in the resulting dipeptide, nevertheless it can be supposed that L-phenylalanine is formed preferentially during the hydrogenation, since the rotation of the peptide agreed satisfactorily with that of synthetic L-prolyl-L-phenylalanine ($[\alpha]_D^{20} = -40.9$).[10]

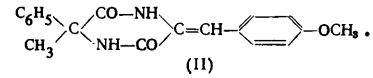
Subsequently, using optically active α-amino-acids as the asymmetrising agents, Akabori and coworkers[11,12] achieved the asymmetric synthesis of phenylalanine. They obtained from the methyl ester of *N*-chloroacetyl-L-isovaline acted upon by ammonia in methanol the dioxopiperazine derived from glycyl-L-isovaline, which in the presence of acetic anhydride at 160°C forms with benzaldehyde the dioxopiperazine derived from dehydrophenylalanyl-L-isovaline (I). Hydrogenation of compound (I) over platinum oxide yields the dioxopiperazine derived from L-phenylalanyl-L-isovaline, from which L-phenylalanine with $[\alpha]_D^{12} = -29°$ was obtained after the hydrolytic elimination of the asymmetrising agent—L-isovaline:



(I)

The corresponding D-compounds were obtained similarly from *N*-chloroacetyl-D-isovaline.

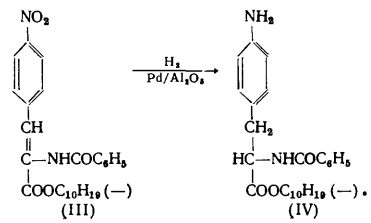
Using the same sequence of reactions, Maeda[13] synthesised optically active L-tyrosine with $[\alpha]_D^{20} = -2.14°$ (20% HCl) by the catalytic hydrogenation over palladium oxide of compound (II) with subsequent hydrolysis of the resulting dioxopiperazine:



(II)

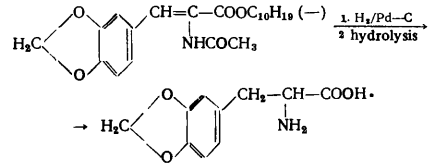
In this case the starting compound and the asymmetrising agent was *N*-chloroacetyl-(+)-α-amino-α-phenylpropionic acid.

Together with optically active amino-acids, optically active menthol has found wide application as an asymmetrising agent. In the hydrogenation of (−)-menthyl esters of α-benzamido-*p*-nitrocinnamic acid (III) over palladium deposited on alumina, Pedrazzoli[14,15] obtained at 60°C a mixture of two diastereoisomeric (−)-menthyl esters of *p*-amino-α-benzamidohydrocinnamic acid containing 30% of the ester (IVa) with $[\alpha]_D = -9°$ (0.5; alcohol) and 60% of the ester (IVb) with $[\alpha]_D = -47.5°$ (0.5; alcohol). After fractional crystallisation, the esters (IVa) and (IVb) were hydrolysed and virtually optically pure D-*p*-aminophenylalanine [from compound (IVa)] with $[\alpha]_D = +45°$ (1.5; water) and L-*p*-aminophenylalanine [from compound (IVb)] with $[\alpha]_D = -42°$ (1.5; water) were obtained:



In order to estimate the degree of asymmetric synthesis achieved in the stage involving the hydrogenation of the ester (III), it is necessary to take into account the relative amounts of the diastereoisomers (IVa) and (IVa). Since the amount of compound (IVb) formed was twice as great as that of compound (IVa), the degree of asymmetric synthesis or the optical yield of the reaction amounts to about 33%. The hydrogenation under the same conditions of the bornyl ester of α-benzamido-*p*-nitrocinnamic acid yielded after one recrystallisation from benzene and subsequent acid hydrolysis virtually inactive *p*-aminophenylalanine with $[\alpha]_D^{25} = +2°$ (1.5; water).

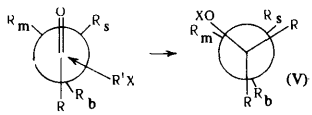
In some cases the isolation of the racemic final product does not alone constitute evidence of the absence of asymmetric synthesis. The isolation of certain α-amino-acids from their derivatives may be accompanied by racemisation. However, if unequal amounts of the diastereoisomers are formed in the hydrogenation stage, asymmetric synthesis still takes place. Thus Yamada et al.[16], who reduced the (−)-menthyl ester of α-acetamido-β-[3,4-methylenedioxyphenyl]acrylic acid in the presence of 10% palladium on charcoal in ethanol and benzene, obtained an excess of the laevorotatory hydrogenation product—an L-alanine derivative, the excess being greater in ethanol than in benzene:



However, both acid and alkaline hydrolysis of the ester was accompanied by almost total racemisation, as a result of which optically inactive 3,4-methylenedioxyphenylalanine was isolated.

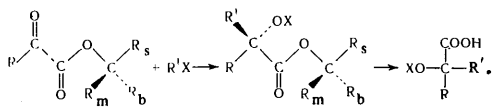
Recently the study of asymmetric syntheses has been based on theoretical concepts whereby it is possible to predict the configuration of the optical isomer formed preferentially. The studies of Cram [17] and Prelog and coworkers [18-21] are important in the development of such concepts, based on the examination of the conformation of molecules.

The investigation of the addition of various reagents, for example hydride hydrogen or organometallic compounds, to the carbonyl group adjacent to the dissymmetric centre, enabled Cram and Abd Elhafez [17] to establish a relation whereby it is possible to predict the configuration of the diastereoisomer formed. The starting material reacts with the reagent R'X in the conformation where the carbonyl oxygen is located between the two smallest substituents and the dissymmetric centre (R_S, R_m, and R_b are small, medium, and big substituents respectively).



The reagent R'X approaches the carbonyl oxygen from the sterically less hindered side, i.e. from the side of the group R_S, which leads to the preferential formation of the compound with the configuration (V). In this case it is possible to observe the maximum influence of the asymmetrising agent, since the centre inducing the asymmetry is directly linked to the dissymmetric centre produced.

Prelog and coworkers [18-21] showed that similar concepts may be used also for systems in which the asymmetrising centre is not located in the immediate vicinity of the dissymmetric centre produced. Thus Prelog examined the stereochemical specificity of the reaction of the α-keto-esters of asymmetric alcohols with Grignard reagents:

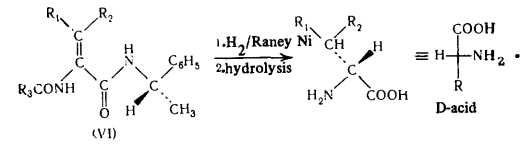


In Prelog's mechanism the α-keto-ester molecule is arbitrarily oriented in such a way that both carbonyl groups are antiparallel and the smallest group R_S of the optically active residue of the alcohol is in the plane of the ester group. Then the reagent R' approaches the ketonic carbonyl group from the side of the medium-size substituent R_m which in fact determines the preferential configuration of the reaction product formed. The reagent can also of course approach the reaction centre from the other, more sterically hindered side, which lowers the optical purity of the product.

Since the reaction products are diastereoisomeric, it may be assumed that the transition states leading to them are also diastereoisomeric and consequently differ in free energy. However, since the initial state in both cases is the same, the activation energies for these reactions are different and the two products are formed at different rates.

Similar ideas can be used also in the study of catalytic asymmetric reactions [20,21]. However, in contrast to homogeneous catalytic syntheses, in asymmetric syntheses in the presence of heterogeneous catalysts such simple relations may be complicated by the orienting effect of the catalyst surface [22].

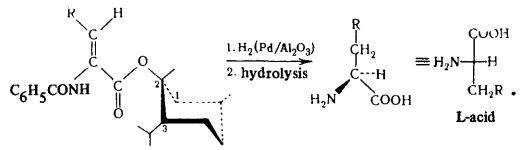
Using the concepts of Cram and Prelog, Sheehan and Chandler [23] were able to predict the configuration of the valine and phenylalanine isomers formed in excess in the hydrogenation of the corresponding optically active methylbenzylamides of α-acetamido-αβ-unsaturated acids over Raney nickel. L-(−)-α-Methylbenzylamine, the L-configuration of which had been established by Leite [24] on the basis of its relation to that of L-alanine, was used as the asymmetrising agent. It was assumed that hydrogen is adsorbed on the surface of the catalyst and that the substrate reaches the catalytic surface from the least hindered side. When L-(−)-α-methylbenzylamine is used, the least hindered side for the substrate (V) will be the region over the plane of the image and consequently the α-amino-acid formed will have the D-configuration.



(VI)

Indeed, in the hydrogenation of L-α-methylbenzylamide of α-acetamido-ββ-dimethylacrylic acid ($R_1 = R_2 = R_3 = CH_3$) followed by the acid hydrolysis of the hydrogenation product, D-valine of 39% optical purity was obtained in 90% yield. The hydrogenation of the corresponding benzoyl derivative ($R_3 = C_6H_5$) also resulted in the formation of D-valine of 18% optical purity in 90% yield. On the other hand, when the D-α-methylbenzylamide of α-benzamido-ββ-dimethylacrylic acid ($R_1 = R_2 = CH_3$; $R_3 = C_6H_5$; asymmetrising agent—D-α-methylbenzylamine) was hydrogenated, the final product was L-valine of 18% optical purity. D-Phenylalanine with an optical yield of 6% (reaction yield 91%) was obtained similarly from L-α-methylbenzylamide of α-benzamidocinnamic acid ($R_1 = R_3 = C_6H_5$; $R_2 = H$).

The preferential formation of L-*p*-aminophenylalanine observed by Pedrazzolli [14,15] can be explained similarly:



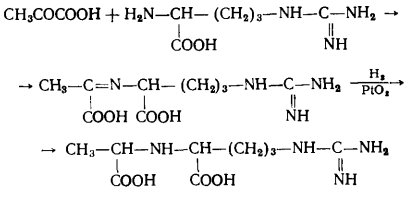
According to Prelog, the (−)-menthyl residue is oriented in such a way that the smallest substituent at the C_2–H atom is screened by the double bond. Of the other two substituents at the C_2 atom, the methylene group of the ring (at C_1) may be regarded as of medium size and the methylidyne group with an isopropyl substituent (C_3) may be regarded as having the maximum size. Consequently hydrogen will attack the double bond preferentially from the least hindered side of the methylene group of the ring (C_1), i.e. from the side opposite to that of the plane of the image. Hence it is clear that an α-amino-acid with the L-configuration should form preferentially.

However, one should bear in mind the possible distortion of the relative amounts of the stereoisomers in the isolation of the reaction product. Therefore in the estimation of the optical yield one should not consider the yield of the optically active substance after isolation but its formation as a result of the reaction. Since in a number of studies [8,9,11-13] the yield of the main reaction product did not exceed 50%, theoretical discussion of these results cannot lead to a reliable interpretation.

2. Asymmetric Hydrogenation of Imino-derivatives of α-Keto-acids

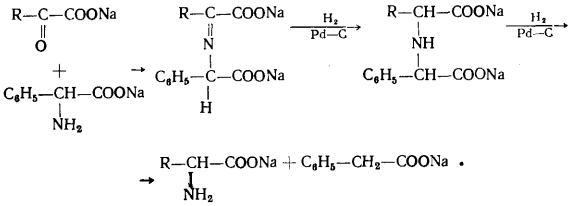
The asymmetric synthesis of α-amino-acids by the catalytic hydrogenation of the imino-derivatives of keto-acids has been most thoroughly investigated. The interest in this reaction is due in the first place to the fact that it constitutes a model of the biochemical transamination of amino-acids in the living organism, which consists in the reversible transfer of the amino-group from the amino-acid to an α-keto-acid without the intermediate formation of ammonia.

In 1939 Knoop and Martius [25] achieved the synthesis of octopine by the reaction of L-arginine with pyruvic acid with simultaneous hydrogenation of the C=N bond over platinum oxide in aqueous solution. The maximum yield of crude octopine reached 85%:



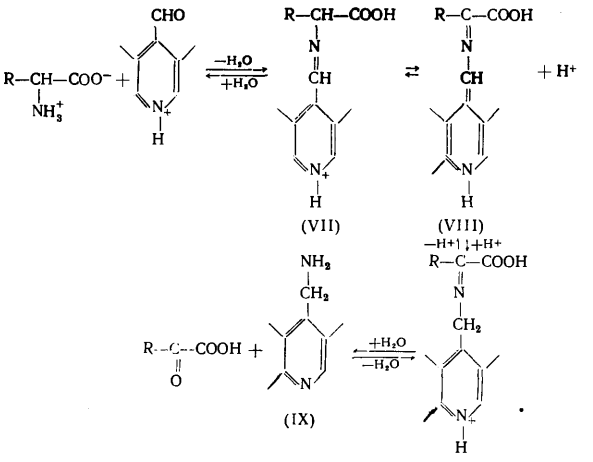
Later Herbst and Swart [26] showed that the product formed in this reaction is iso-octopine—a diastereoisomer of natural octopine containing an alanine residue with the L-configuration. Thus in this case L-arginine induces the formation of a new dissymmetric centre with predominantly the L-configuration.

Recently Harada [27,28] noted that sodium phenylglycinate readily splits into ammonia and phenylacetic acid on hydrogenation in aqueous solution in the presence of palladium or palladium hydroxide on charcoal. Using these data, he achieved a number of asymmetric syntheses, hydrogenating a mixture of sodium D- or L-phenylglycinate with α-keto-acids over the above catalysts in aqueous solution. The reaction probably takes place by the mechanism



In this way he obtained D- and L-alanine with an optical purity of 31–53% in a yield of 28–41%, D- and L-α-amino butyric acids with an optical purity of 24–39% in a yield of 38–41%, and D-glutamic acid with an optical purity of 45–58% in a yield of 25%. It is interesting to note that L-phenylglycine induces the formation of L-amino-acids and D-phenylglycine the formation of D-amino-acids. Harada essentially achieved the reductive asymmetric transamination reaction.

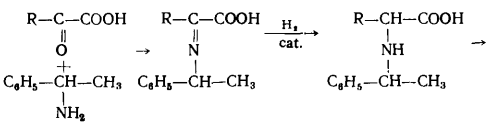
The mechanism of biochemical transamination has been to a considerable degree elucidated and consists in the reductive amination of α-keto-acids by the amino-acid, the process being catalysed by enzymes—amino-transferases. The non-protein component of amino-transferases is pyridoxal phosphate, which plays the role of the agent transferring amino-groups from amino-acids to α-keto-acids [29,30]:



Pyridoxal phosphate forms with the α-amino-acid a Schiff base (VII), from the α-carbon atom of which a proton is readily removed. If the proton adds to the –CH= group of the intermediate (VIII) and then the >C=N– bond is hydrolysed, the final reaction products are an α-keto-acid and pyridoxamine phosphate (IX). The reverse reaction of compound (IX) with the α-keto-acid is a transamination process, the stereochemistry of which is of interest. Enzymes evidently create an asymmetric environment for the strictly stereospecific addition of H to compound (VIII) with formation of compound (VII) and finally of the amino-acid.

However, together with the enzymes, the optically active amino-acid involved in the transamination probably also has an asymmetrising effect. To elucidate this question, Longenecker and Snell [31] carried out the non-enzymic transamination between D- and L-alanine or D- and L-phenylalanine and α-oxoglutaric acid in the presence of a copper(II) complex of pyridoxal. It was found that, regardless of temperature (37–100°C), an excess of glutamic acid with the same configuration as that of the α-amino acid used was always formed, although it did not exceed 10%. Thus 55% of L-glutamic acid and 44.9% of D-glutamic acid was formed when L-phenylalanine was used, while in the presence of D-phenylalanine the yields were 52.7% of D-glutamic acid and 47.3% of L-glutamic acid. When racemic initial amino-acids were employed, racemic glutamic acid was produced. Similar results were obtained also when alanine was the starting material. The data of Longenecker and Snell [31] suggest that in biochemical transamination the main asymmetrising effect is due to enzymes.

Subsequent studies on non-enzymic hydrogenation of optically active imino-derivatives of α-keto-acids demonstrated the possibility of a fairly considerable asymmetrising effect of the optically active component on the stereochemistry of the addition of hydrogen. Hiskey and Northrop [32] used D-(+)- and L-(–)-α-methylbenzylamine as the asymmetrising agent and carried out the hydrogenation according to the following scheme:

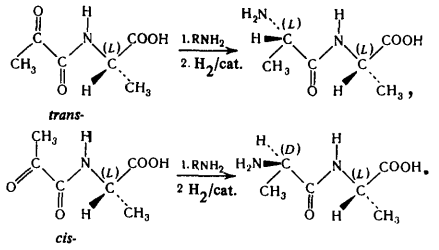


The hydrogenation was performed in the presence of palladium or its hydroxide on charcoal. Optically active alanine, phenylalanine, α-aminobutyric acid, and valine with a high degree of optical purity (56–91%) were obtained in this way. The configuration of the α-amino-acid formed was that of the α-methylbenzylamine employed. The optical purity of the α-amino-acid depended on both the type of catalyst and on the size of the group R in the α-keto acid. In the hydrogenation of the derivative of D-(+)-α-methylbenzylamine and pyruvic acid over the Pd/C catalyst the excess of the D-isomer in the alanine isolated was 85.2% (yield 47.9%), over $Pd(OH)_2/C$ the excess was 91.1% (yield 78%), and over PtO_2 the excess was 56.3% (yield 59.2%). With increase in the bulk of the group R of the α-keto-acid, the hydrogenation becomes less stereospecific: the optical yield of α-amino-acids decreases from 82% for alanine (R = CH_3) to 63% for α-aminobutyric acid (R = CH_2CH_3) and 28% for valine [R = $CH(CH_3)_2$].

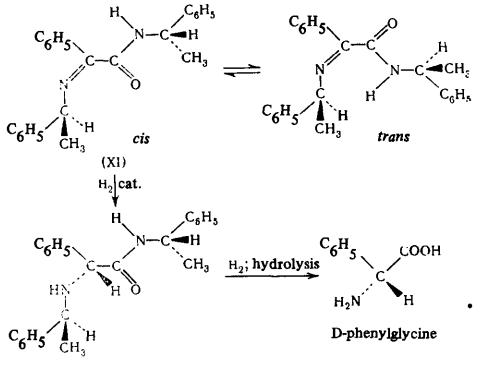
In 1965 Hiskey and Northrop published the results of an interesting investigation [33] in which the asymmetrising role of the amine residue in the azomethine group was assessed. This assessment was achieved by investigating the competing effect of dissymmetric groups at the imino- and carboxy-groups attached to the pyruvic acid residue. For this purpose, the imino-derivatives of *N*-pyruvyl-L-alanine or *N*-pyruvylglycine were hydrogenated together with optically active α-methylbenzylamines. As was to be expected, according to Hiskey and Northrop [32], with *N*-pyruvylglycine, L-(−)- and D-(+)-α-methylbenzylamines lead to the formation of L-alanylglycine (optical yield 53.5%) and D-alanylglycine (optical yield 58%) respectively. The lower optical yield of alanylglycine compared with alanine (82%)[32] or phenylalanine (74%) is attributed by the authors either to an increase in the bulk of the substrate, which leads to a decrease of the stereospecificity of the hydrogenation or to an unfavourable interaction of the catalyst and the substrate due to the presence in the latter of an additional polar group. The second explanation seems more probable, since L-glutamic acid with a relatively low optical yield (35%) was isolated in the hydrogenation of α-oxoglutaric acid (R = CH_2CH_2COOH) in the presence of three equivalents of L-(−)-α-methylbenzylamine. Reductive amination of *N*-pyruvyl-L-alanine in the presence of D-(+)-α-methylbenzylamine led to an excess of D-alanyl-L-alanine (diastereoisomer ratio DL : LL = 74 : 26) and in the presence of L-(−)-α-methylbenzylamine to an excess of L-alanyl-L-alanine (LL : DL = 64 : 36).

This result indicates a more significant asymmetrising effect of the optically active α-methylbenzylimino-group compared with the amino-acid residue at the carboxy-group. To estimate the asymmetrising effect of the L-alanine residue, reductive amination of *N*-pyruvyl-L-alanine was carried out in the presence of benzylamine. An excess of D-alanyl-L-alanine was then obtained (DL : LL = 67 : 33). The authors regard this result as unexpected since, according to Prelog's rule, the L-alanine residue should induce the formation of a new alanine residue with the D-configuration (on the assumption that the carboxy-group is larger than the methyl group).

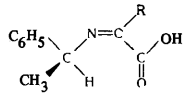
Kanai and Mitsui [34] suggest, however, that in the reductive amination of *N*-pyruvyl-L-alanine the significant factor is the predominant conformation of the substrate. Probably the cisoid conformation predominates, which in fact leads to the formation of D-alanyl-L-alanine:



Kanai and Mitsui arrived at this hypothesis on the basis of the results of the asymmetric hydrogenation of an L-(−)-α-methylbenzylammonium salt (X) and L-(−)-α-methylbenzylamide of L-(−)-α-methylbenzyliminophenylglyoxylic acid (XI) in the presence of the following catalysts: Raney nickel, PtO_2, 5% Pd/C, and 10% $Pd(OH)_2/C$. In the hydrogenation of the salt (X) over $Pd(OH)_2/C$ L-phenylglycine was obtained with an optical yield of 73%, which is similar to the results of Hiskey and Northrop [32]. However, in the hydrogenation of the amide (XI) D-phenylglycine is formed regardless of the type of catalyst. On this basis, Kanai and Mitsui concluded that the predominant conformation of the substrate (XI) is cisoid. It is noteworthy that the optical purity of the D-phenylglycine is low (1–7%).



Harada and Matsumoto [35], who investigated the stereochemistry of the reductive amination of α-keto-acids, believed that the mechanism of Kanai and Mitsui [34] cannot explain the effect of the bulk of the substituents in α-keto-acids on the optical purity of the α-amino-acids formed. Indeed if the substrate molecule were in the cisoid conformation, the substituents R of the α-keto-acids should have scarcely any effect on the mode of addition of hydrogen atoms.

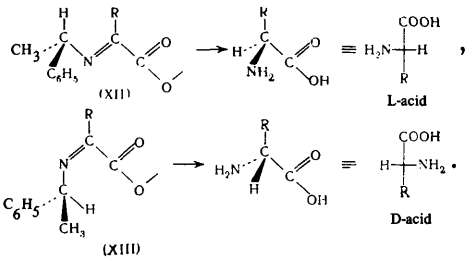


Like Hiskey and Northrop [32], Harada and Matsumoto [35] showed that the optical purity of the α-amino-acid formed decreases with increase in the size of the substituent R:

$$CH_3 > C_2H_5 > C_6H_5 > C_6H_5CH_2 .$$

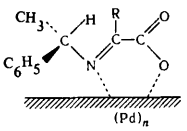
They believe that the most probable conformation of the substrate molecule is the transoid conformation (XII) or

(XIII), the structure (XII) being more probable because of smaller steric hindrance:



The mechanism shows that, when L-α-methylbenzylamine is used, the conformation (XII) leads to the formation of the L-amino-acid, while with the conformation (XIII) the D-amino-acid is formed. As the size of the group R increases, its interaction with the hydrogen atom at the asymmetric carbon atom becomes more pronounced, which may lead to an increase in the fraction of the structure (XIII) and this in turn results in a decrease of the optical purity of the product.

No less important is the examination of the above structures from the standpoint of their capacity to interact with the catalyst. Chang and Hartung [36] believed that such interaction may result in the formation of a rigid cyclic substrate species on the surface of the catalyst. From this point of view, the structure (XII) is to be preferred, since, in contrast to the structure (XIII), it can readily form a five-membered cyclic structure with the catalyst:

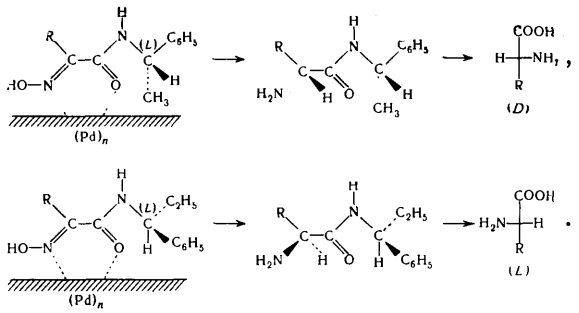


It is readily seen that complex-formation does not lead to a change in the configuration of the α-amino-acid formed.

The replacement of a methyl group by an ethyl group in the optically active alkylbenzylamine [35] leads to a decrease of the optical purity of the hydrogenation products. Prelog established [18,19] that this is caused by a decrease of the difference in the bulk of the substituents at the asymmetric carbon atom of the asymmetrising agent and hence a decrease of the relative steric hindrance to the approach of hydrogen from the two sides of the group >C=N–. This leads to a decrease of the stereospecificity of the hydrogenation and of the optical purity of the α-amino-acids produced.

On the basis of experimental data for the hydrogenation of the oximes of D- and L-α-methylbenzylamide and D- and L-α-ethylbenzylamide of phenylglyoxylic acid and also the Schiff bases formed by benzylamine with the isobutyl esters of *N*-pyruvyl-L-alanine, *N*-pyruvyl-L-valine, and *N*-pyruvyl-D-valine, Harada and Matsumoto [35] gave the most likely explanation of the anomalous synthesis of D-alanyl-L-alanine achieved by Hiskey and Northrop [33].

The hydrogenation of the oximes of L- and D-α-methylbenzylamide of phenylglyoxylic acid led, contrary to Prelog's rule, to the formation of D- and L-phenylglycine respectively. On the other hand, when L- and D-α-ethylbenzylamine were used as the asymmetrising agent, L- and D-phenylglycine were obtained respectively, in agreement with Prelog's rule. Harada and Matsumoto [35] suggest that the substrate molecule is in the cisoid conformation, capable of forming a complex with palladium:

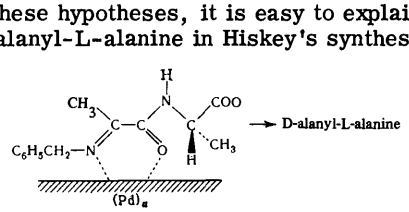


They attribute particular importance to the effect of the catalysts on the conformation of the optically active part of the substrate molecule. The L-α-ethylbenzyl group cannot have the same conformation as the L-α-methylbenzyl group because of the greater bulk of the ethyl group compared with the methyl. Therefore the L-α-ethylbenzyl group rotates with the hydrogen atom, which is least bulky, directed towards the catalyst surface and then the *cis*-addition of hydrogen, occurring on the least hindered side opposite to the plane of the image, leads to the formation of the L-amino-acid.

The hydrogenation of the Schiff bases formed by benzylamine with isobutyl esters of pyruvyl-L-alanine, pyruvyl-L-valine, and pyruvyl-D-valine, which is a closer model of Hiskey's synthesis of D-alanyl-L-alanine, also confirmed these conclusions. When these substrates form complexes with palladium, the methyl group of the alanine derivative and the isopropyl group of the valine derivative lead to different conformations of the asymmetrising agent (in consequence of the different steric hindrance to the interaction with the catalyst surface), exactly as in the preceding case. The Schiff base of the isobutyl ester of pyruvyl-L-alanine gave D-alanyl-L-alanine, while the Schiff bases of the isobutyl esters of pyruvyl-L-valine and pyruvyl-D-valine led to the formation of L-alanyl-L-valine and D-alanyl-D-valine respectively (yield 11–15%, optical purity 32–64%).

The different conformations induced by the groups of the optically active part of the substrate having different sizes (methyl or ethyl, methyl or isopropyl) may be due to the steric hindrance to the interaction between substrate molecules and the catalyst.

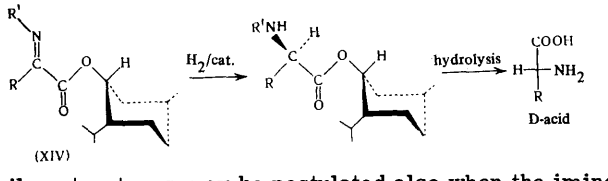
Using these hypotheses, it is easy to explain the formation of D-alanyl-L-alanine in Hiskey's synthesis:



The asymmetric catalytic hydrogenation of (–)-menthyl esters of the imino-derivatives of α-keto-acids was achieved by Matsumoto and Harada [37]. The hydrogenation was carried out over palladium and $Pd(OH)_2$ on charcoal and the amino-acids were isolated by hydrolysing the hydrogenation products in an alkaline medium. D-amino-acids were always obtained from the (–)-menthyl esters of the hydroxyimino- and benzimino-derivatives of pyruvic, α-oxobutyric, and phenylglyoxylic acids, regardless of the type of catalyst employed. The products were D-alanine with an optical purity of 11.0–13.6% and a yield of 67–79%,

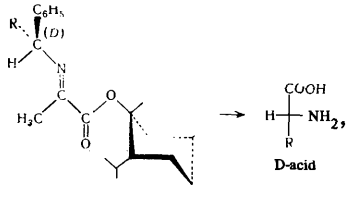
D-aminobutyric acid with an optical purity of 9.44–10.3% and a yield of 62–74%, and D-phenylglycine with an optical purity of 22.7–24.9% (44.2–49.1%)† and a yield of 84–88%. The hydrogenation of the hydroxyimino-derivative led to the formation of the α-amino-acid with a higher optical purity than was obtained with benzimino-derivatives. The type of catalyst employed had virtually no effect on the yield and optical purity of the α-amino-acid, but the benzimino-derivatives of (–)-menthyl esters of pyruvic and α-oxobutyric acids could not be hydrogenated over the Pd/C catalyst. Phenylglycine was synthesised only from the hydroxyimino-derivative of phenylglyoxylic acid, since the benzimino-derivative could not be prepared.

The most interesting results were obtained in the hydrogenation of L-(–)- and D-(+)-α-methylbenzylimino-derivatives of (–)-menthyl pyruvate. The L-(–)-α-methylbenzylimino-derivative gave L-alanine with an optical purity of 16–18% (19–24%) and a yield of 57–62% and the D-(+)-α-methylbenzylimino-derivative gave D-alanine with an optical purity of 56–64% (59–66%) and a yield of 61–67%. If it is remembered that, according to this investigation the (–)-menthyl residue induces the formation of the D-amino acid and according to Hiskey and Northrop [32] the D-(+)-α-methylbenzylimino-residue also induces the formation of the D-acid, then the high optical purity of the D-alanine obtained in the hydrogenation of the D-(+)-α-methylbenzylimino-derivative of (–)-menthyl pyruvate is evidence that the two asymmetrising agents act in accord. On the other hand, the formation of L-alanine in the hydrogenation of the L-(–)-α-methylbenzylimino-derivative of (–)-menthyl pyruvate is evidence of the greater asymmetrising effect of the α-methylbenzylimino-group compared with the (–)-menthyl ester residue, which is consistent with the result of the investigation [33]. The authors explain [37] the steric specificity of the reaction on the basis of the concepts of Cram and Prelog. It is suggested that the most probable structure of the imino-derivative of the (–)-menthyl esters of the α-keto-acid is (XIV). The molecules are adsorbed on the surface of the catalyst from the less hindered side, as a result of which hydrogen atoms will attack the C–N bond from the side opposite to that of the plane of the representation of the mechanism. The products are α-amino-acids with the D-configuration:

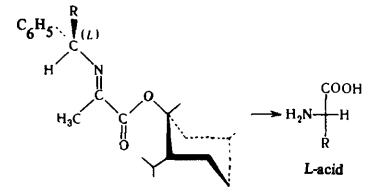


(XIV)

Similar structures may be postulated also when the imino-derivatives of optically active alkylbenzylamines and (–)-menthyl esters of α-keto-acids are employed [35]:



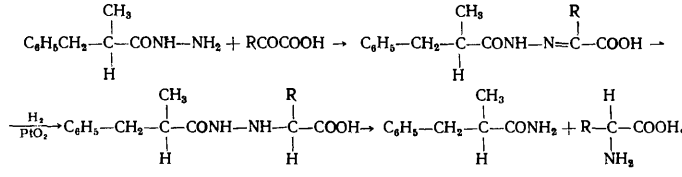
†The figures in brackets indicate, here and subsequently, the optical purity of the amino-acids isolated as the 2,4-dinitrophenyl derivatives.



This mechanism also explains why α-ethylbenzylamine leads to a lower optical purity of the final product than does α-methylbenzylamine.

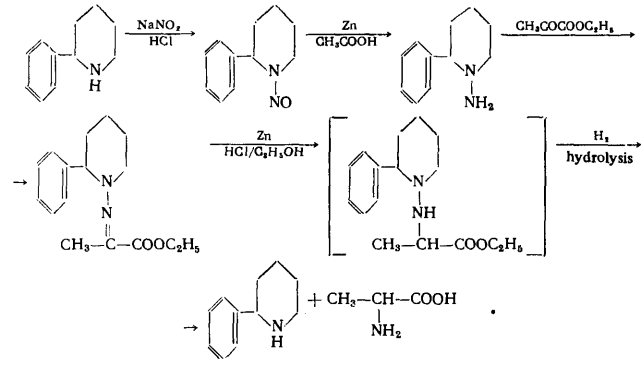
Apart from the asymmetrising agents examined above, such as optically active amino-acids, α-alkylbenzylamines, and (–)-menthol, other optically active substances have also been employed.

Akabori and Sakurai [38] used the optically active hydrazide of D-methylbenzylacetic acid as the asymmetrising agent. The imino-derivatives obtained from the hydrazide and α-keto-acids were hydrogenated over PtO_2 and the optically active α-amino-acids were isolated after the elimination of the asymmetrising agent:



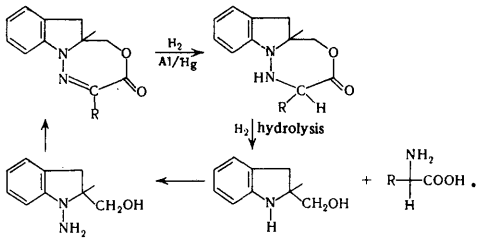
However, the optical yield of the α-amino-acids was low. L-Alanine (R = CH_3) with $[\alpha]_D^{19} = +1.21°$ (8% of asymmetric synthesis) and L-phenylalanine (R = $C_6H_5CH_2$) with $[\alpha]_D^{16} = -1.55°$ (4% of asymmetric synthesis) were obtained in this way.

Kost and coworkers [39,40] used anabasine (the alkaloid of *Anabasis Aphylla*) as the asymmetrising agent. Anabasine was converted into the *N*-amino-compound by nitrosation with subsequent reduction of the nitroso-group. The interaction of *N*-aminoanabasine with ethylpyruvate gave an optically active hydrazone, which was reduced with zinc in alcoholic hydrochloric acid:



This led to the formation in the molecule of a second dissymetric centre. Simultaneously (or subsequently) in the second stage the N–N bond is hydrogenolysed and optically active D-alanine is formed with an optical purity of 40% in a yield of 10%. Despite the low yield of D-alanine (which precludes the conclusion that asymmetric synthesis really takes place), it is noteworthy that the reaction regenerates the asymmetrising agent (anabasine) with virtually the initial (90%) optical activity.

A high optical yield in the synthesis of α-amino-acids was achieved by McCaully [41]. He carried out the asymmetric hydrogenation of an optically active hydrazonolactone with aluminium amalgam with preferential formation of one diastereoisomeric hydrazinolactone. Hydrogenolysis of the hydrazinolactone in an acid medium gives the optically active α-amino-acid and optically active 2-hydroxymethylindoline, which is converted into 1-amino-2-hydroxymethylindoline by nitrosation and subsequent reduction.



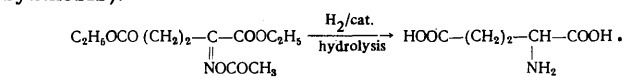
When the last compound is condensed with an α-keto-ester, the hydrazonolactone is formed anew. Optically active alanine (R = CH_3) with an optical yield of 82% and α-aminobutyric acid (R = C_2H_5) with an optical yield of 98% were obtained in this way, the reaction being virtually stereospecific in the second case.

3. Hydrogenation in the Presence of Dissymmetric Catalysts

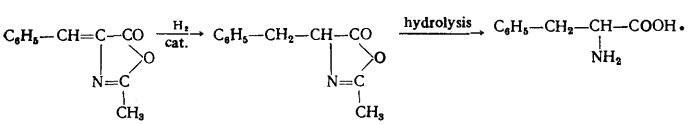
The hydrogenation of unsaturated precursors of α-amino-acids with an optically active asymmetrising group in the initial molecule was described above. This section deals with the formation of optically active α-amino-acids in the hydrogenation of unsaturated optically inactive precursors under the influence of dissymmetric catalysts. Such catalysts are of particular interest, since asymmetric syntheses, analogous to those occurring in the nature under the influence of enzymes, takes place in their presence.

In 1956 Akabori and coworkers [42-44] described the preparation of a dissymmetric heterogeneous catalyst based on the fact that many enzymes (oxidoreductases) are metalproteins. The catalyst, which consisted of a dissymmetric carrier (silk fibroin or acetylfibroin [45]) on which palladium was absorbed, was obtained by reducing the fibroin–$PdCl_2$ complex. The properties of the catalyst were described in detail by Izumi [46-48].

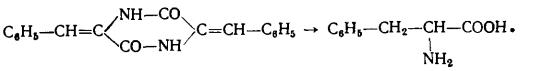
When diethyl α-acetoxyiminoglutarate was reduced over this catalyst at 50°C and 80 atm, optically active L-glutamic acid was formed ($[\alpha]_D^{15}$ = +2.25°, 39% of asymmetric synthesis):



Ethyl α-acetoxyiminophenylpropionate was reduced to D-phenylalanine (yield 25%, optical purity 26.3%) in a similar manner at 70°C and 90 atm. The highest optical purity of D-phenylalanine (35%) was achieved in the hydrogenation under the same conditions of 4-benzylidene-2-methyloxazol-5-one, although the yield of D-phenylalanine was only 6.5%:



D-phenylalanine with the specific rotation $[\alpha]_D^{15}$ = +8.0° was obtained in the hydrogenation of dibenzylidenedioxopiperazine:



The maximum yield (80%) of phenylalanine was achieved in the hydrogenation of α-acetamidocinnamic acid, although the product was inactive.

The study of the infrared spectra of the dissymmetric catalyst [48] showed that, when $PdCl_2$ is adsorbed on silk fibroin, chelate bonds are formed between $PdCl_2$ and fibroin groups such as NH, OH, COOH, and CONH. When the chelate is reduced with hydrogen, the chelate bonds break down and the fibroin resumes its initial structure. The study of X-ray diffraction by the catalyst suggests that part of the palladium in the latter is in the cryptocrystalline state and the remainder assumes the dissymmetric structure of the fibre and this is in fact responsible for the asymmetric synthesis. However, the latest studies suggest that the mechanism of the asymmetrising effect of the dissymmetric catalyst probably consists in the initial asymmetric adsorption of the reactant on the surface of the dissymmetric carrier with subsequent non-stereospecific catalysis [3].

One of the methods developed recently for imparting stereospecificity to optically inactive hydrogenation catalysts consists in their modification with optically active substances—for example α-hydroxy-acids or α-amino-acids. Thus Isoda et al. [49] described a new dissymmetric hydrogenation catalyst based on an amino-acid—palladium and an amino-acid—Raney nickel complex. Best results were achieved when optically active tyrosine was employed. L-Glutamic acid was obtained in this way in the reduction of diethyl α-acetoxyiminoglutarate and D-phenylalanine was synthesised by the reduction of 4-benzylidene-2-methyloxazol-5-one. However, the efficiency of this catalyst was lower than that of palladium on silk fibroin prepared by Akabori and the experimental results were poorly reproducible.

L-Phenylalanine was synthesised similarly by the hydrogenation of α-acetamidocinnamic acid over palladium deposited on charcoal and modified with L-methionine [50].

Studies on catalysts of this type are being vigorously continued at the present time. Best results are obtained with Raney nickel treated with aqueous solutions of optically active substances [51,52]. In the most successful experiments a mixture of methyl α-hydroxybutyrates, consisting of 75% of the L-form and 25% of the D-form was obtained by the hydrogenation of methyl acetoacetate, used as a model compound, over Raney nickel modified with D-tartaric acid.

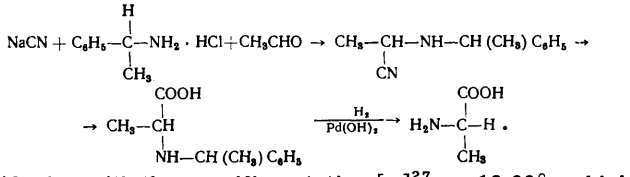
Asymmetric catalytic hydrogenation was achieved in many cases in the presence of optically active substances. Thus Isoda et al. [53] obtained optically active glutamic acid in the hydrogenation of α-hydroxyiminoglutaric acid in the presence of (+)-camphor and (+)-borneol over Raney nickel. Nakazaki [54] achieved the asymmetric hydrogenation of α-acylaminocinnamic acid over Raney nickel in the presence of glucose. After the hydrolysis of the hydrogenation products, optically active D-phenylalanine was isolated with the rotation $[\alpha]_D^{15}$ ranging from +2.22° to 3.58°, depending on the reaction conditions.

In the experiments described above the active substances constitute an optically active medium rather than dissymmetric organic catalysts, since they show no independent catalytic effect.

III. ASYMMETRIC SYNTHESIS OF α-AMINO-ACIDS BY CONDENSATION METHODS

1. The Strecker Synthesis

In 1963 Harada [55] achieved the asymmetric synthesis of alanine by the Strecker reaction. The asymmetrising agent was (−)-α-methylbenzylamine. The synthesis consisted in the interaction of acetaldehyde with HCN or NaCN and (−)-α-methylbenzylamine in methanol at 20°C, the hydrolysis of the resulting aminonitrile to *N*-(α-methylbenzyl)amino-acid, and the elimination of the methylbenzyl group by catalytic hydrogenolysis over $Pd(OH)_2$ by Hiskey's procedure [32]:

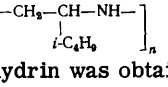


L-Alanine with the specific rotation $[\alpha]_D^{27} = +13.99°$, which corresponds to 95% of asymmetric synthesis, was obtained in this way. Subsequently Harada and Fox [56] carried out this synthesis starting with the previously prepared acetaldehyde cyanohydrin. Depending on the duration of the reaction, L-alanine was obtained with optical purities in the range 86–99% (after one recrystallisation).

The reaction mechanism is still obscure. However, the authors [56] suggest that the most likely cause of the asymmetric synthesis is different rates of the reactions of the D- and L-cyanohydrins with the (−)-amine.

It is believed [57] that this synthesis constitutes a good model of the formation of active α-amino-acids in the prebiological period of the development of the earth.

Interesting results were obtained by Tsuboyama [58] in the cyanohydrin synthesis from benzaldehyde and hydrocyanic acid in benzene in the presence of optically active poly-L-isobutylethyleneimine as the catalyst:

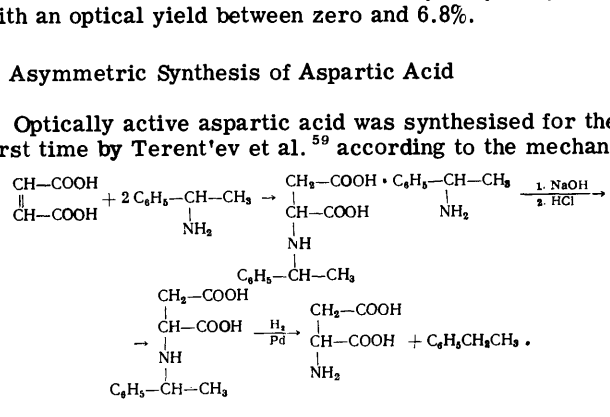


Benzaldehyde cyanohydrin was obtained with an optical yield up to 20%. The asymmetrising effect of the catalyst was attributed by the author to the stereoregularity of the polymer, the presence of dissymmetric centres in the main chain, and the spiral structure of the polymer, which enhances the asymmetrising effect.

The application of styrene–divinylbenzene copolymers containing methyl-α-glucosamine, diethylaminoethylcellulose, and L-leucinol as catalysts of cyanohydrin synthesis led to the formation of benzaldehyde cyanohydrin with an optical yield between zero and 6.8%.

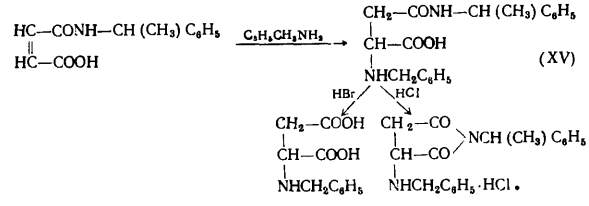
2. Asymmetric Synthesis of Aspartic Acid

Optically active aspartic acid was synthesised for the first time by Terent'ev et al. [59] according to the mechanism



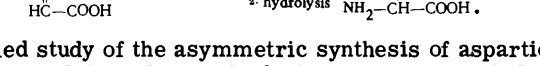
The reaction of maleic acid with (−)-α-methylbenzylamine yields a salt the decomposition of which gives an *N*-substituted aspartic acid. The acid consists of two types of crystals with different solubilities—large, well formed crystals in an amount greater than small crystals combined into spherical pellets. When the large crystals were debenzylated over palladium black, D-aspartic acid with an 88% optical purity was obtained. The small crystals yielded racemic aspartic acid. When (+)-α-methylbenzylamine was employed, two types of crystals were also obtained, in approximately equal amounts. After debenzylation the large crystals gave L-aspartic acid ($[\alpha]_D^{20} = +4.83°$) and the small crystals the racemic acid. The authors [59] suggest that in this case there is either partial asymmetric synthesis or the diastereoisomers are recrystallised.

Livshits and Singerman [60], who repeated Terent'ev's experiment, reject the occurrence of asymmetric synthesis in this process and believe that true asymmetric synthesis of aspartic acid takes place when benzylamine adds to the double bond of poly-(+)-α-methylbenzylamide of maleic acid:



Thin-layer chromatography of the amide (XV) showed the presence of only one substance. Its hydrolysis in a sealed tube at 100°C with 20% hydrochloric acid led to the formation of the imide. On the other hand, when the imide (XV) was refluxed with 48% hydrobromic acid, the product was *N*-benzyl-L-aspartic acid of 60% optical purity, which the authors [61] believe may be debenzylated with complete retention of the configuration.

Subsequently Vlasova [62], who carried out the reaction of mono-(−)-α-methylbenzylamide of maleic acid with ammonia, really achieved the asymmetric synthesis of D-aspartic acid with an optical purity of 80% and a yield of 90%:



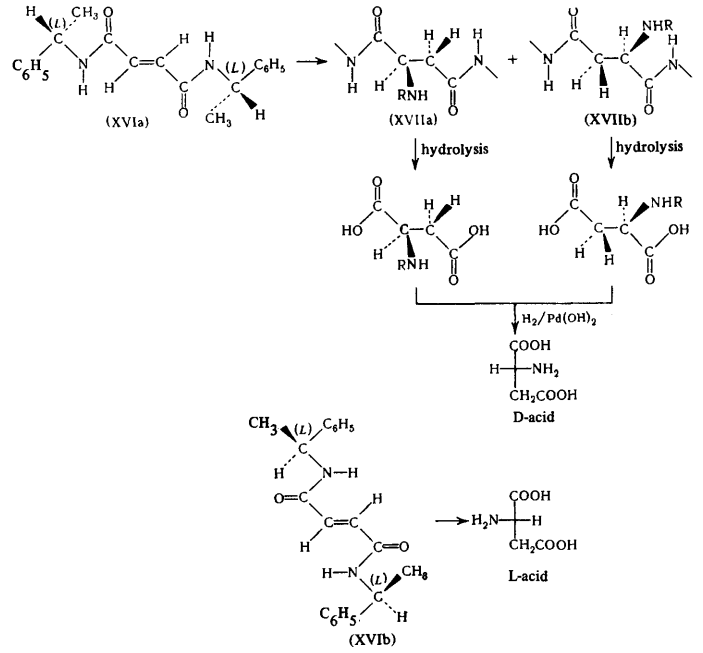
A detailed study of the asymmetric synthesis of aspartic acid from maleic and fumaric derivatives was carried out by Harada and Matsumoto [63]. The following reactions were investigated: (1) the reaction of L-(−)- and D-(+)-α-methylbenzylamine with *NN'*-di-L- and *NN'*-di-D-α-methylbenzylfumaramide (L- and D-fumaramide); (2) the reaction of L-(−)- and D-(+)-α-methylbenzylamine with diethyl maleate and diethyl fumarate. Debenzylation was carried out in the presence of $Pd(OH)_2$ by Hiskey's procedure [32].

The reaction of L-fumaramide with L-(−)-α-methylbenzylamine gave D-aspartic acid with an optical purity of 10.2% (15.3% in the form of the dinitrophenyl derivative) and a yield of 64%. D-Fumaramide and L-(−)-α-methylbenzylamine reacted to form L-aspartic acid with an optical purity of 11.0% (13.7%). The reaction of diethyl maleate with D-(+)-α-methylbenzylamine yielded D-aspartic acid with an optical purity of 12.2% (15.4%) and the reaction with L-(−)-α-methylbenzylamine gave L-aspartic acid. Similarly the interaction of diethyl fumarate with L-(−)-α-methylbenzylamine led to the formation of L-aspartic acid with an optical purity of 7.5% (4.6%) and the interaction with

D-(+)-α-methylbenzylamine gave D-aspartic acid with an optical purity of 6.3%(4.5%).

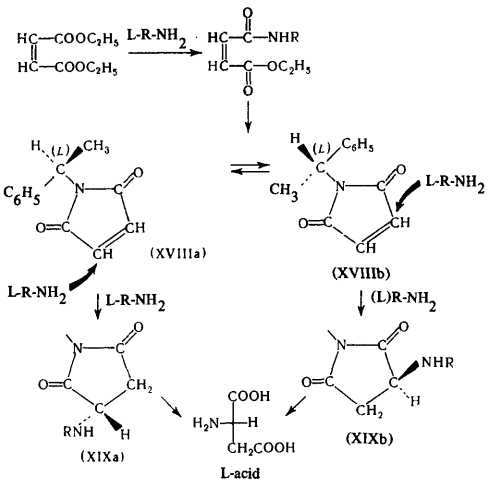
The principal asymmetrising effect in the reaction of L- and D-fumaramide with optically active amines is shown by optically active amide groups. Amides with the L-configuration induce the formation of D-aspartic acid and conversely. The configuration of the amine entering into the reaction apparently does not have a decisive influence on the configuration of the acid formed. Indeed, when optically active amines are replaced by benzylamine, the situation does not change: D- and L-fumaramide yield L- and D-aspartic acid respectively. However, the optical purity of the acids obtained is then lower.

Harada and Matsumoto explained the configuration of the final product on the basis of the hypotheses of Cram and Prelog:

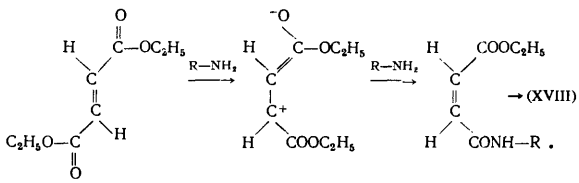


The possible conformations of L-fumaramide are cisoid (XVIa) and transoid (XVIb). The addition of L- or D-α-methylbenzylamine to the double bond of fumaramide in the cisoid conformation takes place preferentially from the least hindered front side of the plane of the image, since both methyl groups are on the reverse side. In this case both addition products, (XVIIa) and (XVIIb), are identical and yield aspartic acid with the D-configuration. The addition of the amine to fumaramide in the transoid conformation (XVIb) leads ultimately to the formation of L-aspartic acid. However the transoid conformation of L-fumaramide (XVIb) is energetically less favourable, since, by virtue of steric hindrance, it cannot be planar. It was shown with the aid of Dreiding stereomodels that in the transoid conformation the distance between the hydrogen of the amide group and the hydrogen at the β-carbon atom is 1.65 Å. Since the van der Waals radius of the hydrogen atom is 1.15 Å, these two hydrogen atoms overlap and prevent the formation of a planar molecule. On the other hand, in the cisoid conformation there is no such steric hindrance and therefore the molecule can form a planar structure.

In the reaction of diethyl maleate and diethyl fumarate with L- or D-α-methylbenzylamine the first stage is the formation of the amides of these acids, which then cyclise to the imide (XVIIIa) or (XVIIIb) as shown below:

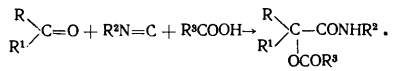


Regardless of the conformation of the *N*-alkylmaleimide (XVIIIa) or (XVIIIb), it is attacked by L-α-methylbenzylamine from the least hindered side (indicated by arrows) forming a derivative of L-aspartic acid. The intermediate addition product—succinimide (XIX)—was isolated as the main reaction product, which confirms this mechanism. Since (XIX) is formed also from diethyl fumarate, Harada and Matsumoto [63] suggested the possibility of the conversion of fumarate into maleate in the reaction



3. Asymmetric Synthesis of α-Amino Acids by the Ugi Reaction‡

As early as 1921 Passerini [67] observed that isonitriles readily condense with carbonyl compounds in the presence of carboxylic acids, forming the amides of α-acyloxy-acids:

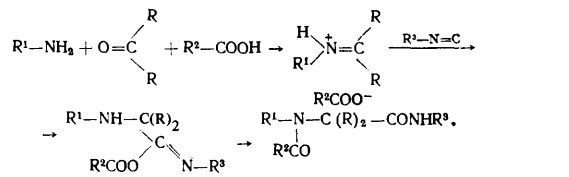


The reaction takes place under very mild conditions (between −20° and +20° C) with almost quantitative yields of the final products [68]. It is noteworthy that the use in the Passerini reaction of an optically active acid leads to the preferential formation of one of the two possible diastereoisomers [69].

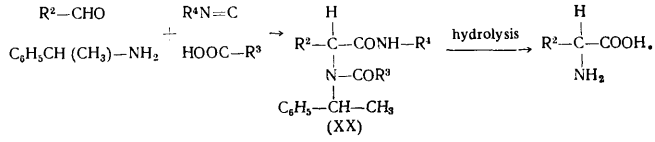
In 1960 Ugi [70] carried out this condensation in the presence of a fourth component (an amine), which led to the discovery of the reaction involving the aminoalkylation of isonitriles by immonium salts, formed from the carbonyl

‡For further details of the reaction, see the reviews of Ugi [64,65] and Gambaryan [66].

compound, the amine, and the acid. The reaction gives under mild conditions almost quantitative yield of the α-amino-acid derivative:



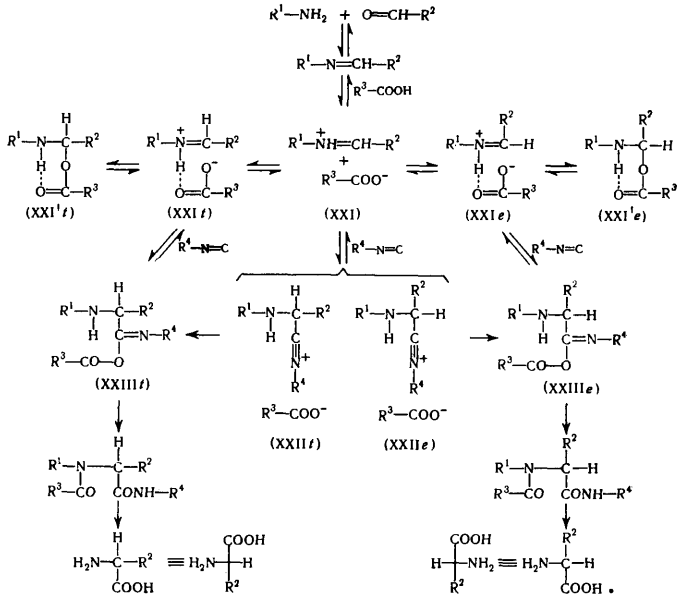
When an optically active amine, for example α-methylbenzylamine, is used, one of the diastereoisomers is formed preferentially and its hydrolysis gives the optically active α-amino-acid [71-73]:



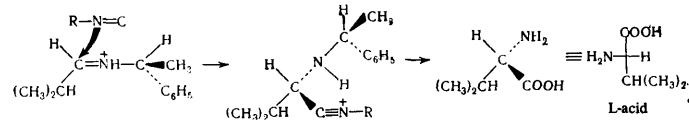
The configuration of the asymmetric carbon atom produced in compound (XX) depends both on the configuration of the asymmetrising agent (the amine) and on the reaction conditions (polarity of the solvent, concentrations of the reactants, and temperature). Thus the interaction of isobutyraldehyde [$R^2 = CH(CH_3)_2$], D-(+)-α-methylbenzylamine, benzoic acid ($R^3 = C_6H_5$), and t-butyl isocyanide [$R^4 = C(CH_3)_3$] at $-70°C$ and about 1 molar reactant concentrations in methanol (conditions *A*) led to the preferential formation of L-valine, while at 0° C and reactant concentrations about 0.1 molar (conditions *B*) D-valine was formed. Similar relations were observed also when other aldehydes, including optically active ones, were employed in the reaction. For example, under conditions *A* the reaction of L-(−)-α-methylbenzylamine, benzoic acid, t-butyl isocyanide, and butyraldehyde ($R^2 = n\text{-}C_3H_7$) or L-(+)-ethylmethylacetaldehyde [$R^2 = L\text{-}CH(CH_3)C_2H_5$] gives D-norvaline or D-alloisoleucine, while under conditions *B* the products are L-norvaline or L-isoleucine respectively. Similarly, when D-(+)-α-methylbenzylamine is employed, the products under conditions *A* are L-norvaline or L-isoleucine and under conditions *B* D-norvaline and D-alloisoleucine respectively. Compounds of type (XX) are usually formed with an optical purity in the range 70–75% and yields of 70–95%; their hydrolysis in hydrochloric acid results in a quantitative yield of the α-amino-acids with the retention of the configuration and optical purity [73].

Thus, when the temperature is reduced and the concentration of the reactant is increased, the configuration opposite to that of the initial amine is induced at the newly formed asymmetric carbon atom, and, conversely, on raising the temperature and lowering the reactant concentration, a compound with the same configuration is formed. The reversal of the configurational relation between the induced and inducing dissymmetric centres as a function of reaction conditions is explained by the fact that the Ugi reaction takes place under different conditions by two stereochemically different mechanisms [72,74-77].

All the reactions of isonitriles, including the Ugi reaction, reduce essentially to electrophilic α-addition of the cationic and anionic centres to the isonitrile carbon atoms. Initially the azomethine derivative is formed from the carbonyl compound and the amine. In a strongly polar medium it is present as a solvated non-oriented ion pair (XXI) with the carboxylic acid. In less polar solvents the azomethine derivatives and the carboxylic acids form hydrogen-bonded diastereoisomeric ion pairs (XXI*t*) and (XXI*e*), which may be in equilibrium with the adducts (XXI′*t*) and (XXI′*e*), where *t* denotes the *threo*-form, i.e. the diastereoisomer in which on direct combination both dissymmetric centres would have the identical configuration, and *e* denotes the *erythro*-form with different configurations of the dissymmetric centres. It is readily seen that the mechanism and stereochemistry of the α-addition of the immonium cation and the carboxylate anion to the isonitrile depend to a high degree on the polarity of the medium. This is either a two-stage process (conditions *B*): (XXI) → (XXII*t*, *e*) → (XXIII*t*, *e*), or a one-stage process (conditions *A*): (XXI*t*, *e*) → (XXIII*t*, *e*):



In strongly polar solvents, for example in ethylene glycol or methanol, at low reactant concentrations and high temperatures the ratio of the products [(XXII*t*): (XXII*e*)] of the addition of the solvated ion pair (XXI) to the isonitrile is determined by steric factors. The *threo*-isomer then forms preferentially, as can be seen in the case of the azomethine derivative obtained from L-(−)-α-methylbenzylamine and isobutyraldehyde:



The two-stage reaction *B* is a kinetically controlled process and the ratio of the reaction products (XXII*t*): : (XXII*e*) is determined by the steric strain of the conformation of the transition state, i.e. depends on the difference between the free energies of the transition states, which, as found for the reaction of L-(−)-α-methylbenzylamine, isobutyraldehyde, benzoic acid, and t-butyl isocyanide, is $\Delta F^{\neq}_{(XXI)\rightarrow(XXII e)} - F^{\neq}_{(XXI)\rightarrow(XXII t)} = 0.71$ kcal mole^{-1}. [74]

In a less polar medium, for example in ethanol and in methanol, at high reactant concentrations or at a low temperature the diastereoisomeric hydrogen-bonded ion pairs

(XXI*t*) and (XXI*e*) formed are in equilibrium, the position of which plays a decisive role in determining the steric course of the process (thermodynamically controlled reaction). Because of the smaller conformational strain, the *erythro*-isomer (XXI*e*) is energetically more favourable and therefore under the given conditions there is preferential formation of α-amino-acids having the configuration opposite to that of the initial amine. If the equilibrium (XXI*t*) ⇌ (XXI*e*) is established rapidly, the ratio of the products of the single-stage reaction A [(XXIII*t*) : (XXIII*e*)] may be determined by the Curtin–Hammett principle. Indeed, for the same reaction of L-(−)-α-methylbenzylamine, isobutyraldehyde, benzoic acid, and t-butyl isocyanide under conditions *A*, we have $\Delta F = F^{\neq}_{(XXI t)\rightarrow(XXIII t)} - F^{\neq}_{(XXI e)\rightarrow(XXIII e)} = 1.02$ kcal mole^{-1}. Evidently the experimental values of $\Delta F^{\neq}$ both for reaction *A* and *B* essentially confirmed the above hypotheses concerning the stereochemistry of these reactions. This concerns of course only the preferential occurrence of the reaction by mechanisms *A* and *B*. However, the high sensitivity of the Ugi reaction to changes in conditions, within the limits of which there is a possibility of controlled synthesis of both L- and D-amino-acid with a high optical purity and yield, makes it one of the most promising synthetic procedures for optically active α-amino-acids.

4. Application of Complexes in the Asymmetric Synthesis of α-Amino-acids

The stereospecificity of coordination compounds in certain reactions is well known[78]. However, only a few papers have been published[79,81,83] on studies where the asymmetrising effect of optically active complexes was employed for the asymmetric synthesis of α-amino-acids. The asymmetric transamination of α-amino-acids in the presence of the copper(II) complex of pyridoxal[31] was mentioned above. It was suggested[31] that a dissymmetric chelate compound is formed and then undergoes stereospecific protonation.

Using the Akabori method[82], Murakami and Takahashi[79–81] achieved the asymmetric synthesis of threonine by the Knoevenagel, reaction involving the condensation of acetaldehyde with the active methylene group of optically active L-[Coen$_2$gly]I$_2$. After the breakdown of the complex reaction products, either optically active threonine with $[\alpha]_D^{13} = +3.84°$ ($c = 2.345$; water) or its 2,4-dinitrophenyl derivative with $[\alpha]_D^{11} = -8.22°$ ($c = 2.34$; 4% aqueous solution of $NaHCO_3$) was isolated. The asymmetric yield of threonine was 8%. Paper chromatography showed that the crude products contained threonine, allothreonine, and glycine in the proportions 7 : 2 : 1.

The condensation of acetaldehyde with glycinatobis-[(−)-propylenediamine]cobalt(III) chloride gave a mixture of threonine, allothreonine, and glycine in the proportions 6.5 : 3 : 0.5. However, the crude threonine in the form of the 2,4-dinitrophenyl derivative (yield 75%) exhibited only weak laevorotation $[\alpha]_D^{11} = -1.2°$ ($c = 5.822$; 4% aqueous solution of $NaHCO_3$). The asymmetric yield of threonine was in this case only about 1%.

Asperger[83] achieved the synthesis of optically active alanine by the coordination of methylaminomalonic acid via both carboxy-groups to the ion (+)-*cis*-α-[Co(LL-αα′-dimethyltriethylenetetramine)Cl$_2$]$^+$ with subsequent decarboxylation of the complex. This gave an alanine complex containing L-alanine with 75% optical purity. However, on liberation from the complex ion and isolation, the L-alanine racemised. Asperger believes that the asymmetrising effect of the complex ion consists in a template action in the coordination of methylaminomalonic acid; the decarboxylation of the optically active complex is stereospecific, leading to the formation of a new dissymmetric centre.

---o0o---

The studies on the asymmetric synthesis of α-amino-acid examined above demonstrate a rapid increase of interest in this problem. Both asymmetric hydrogenation and condensation methods make it possible to achieve in some cases a high degree of non-enzymic asymmetric synthesis of α-amino-acids. However, systematic studies on this problem are essentially only just beginning and further investigations in this field will be of interest.

So far asymmetric synthesis has been carried out for a restricted number of the simplest α-amino-acids. Therefore it will be very important to develop methods for the asymmetric synthesis of essential α-amino-acids such as tryptophan, lysine, methionine, threonine, etc. The study of the effect of the substrate–catalyst interaction on the optical purity and the configuration of the final product has assumed considerable importance in catalytic asymmetric hydrogenation. The study of the effect of hydrogenation conditions (temperature, pressure, medium) on the degree of asymmetric synthesis is noteworthy, since such conditions can affect not only the magnitude but also the sign of the optical rotation of the hydrogenation products. Interesting results may be obtained in investigations of new types of heterogeneous dissymmetric catalysts. In this connection considerable interest attaches to further investigation of the modification of hydrogenation catalysts by low-molecular optically active substances and also of new complexes of optically active polymers with hydrogenation catalysts, which may serve as models of metal enzymes.

The study of optically active polymers as asymmetrising agents with which the substrate can be linked by bonds of different types—covalent, coordination, salt type, hydrogen bonds, van der Waals forces, electrostatic attraction, etc.—has hardly begun. The progress in synthetic polymer chemistry already permits the preparation of polymeric systems which may serve as simple models of natural enzymes. Probably condensation methods of asymmetric synthesis should yield best results in such systems and much attention must be devoted to the development of such methods. In the study of new procedures for asymmetric synthesis attention must be concentrated on those where the asymmetrising agent is regenerated. Then one may hope that further investigation of the asymmetric synthesis of α-amino-acids and other optically active substances will yield, together with useful practical results, also invaluable information about the nature of enzyme action.

During the preparation of the manuscript for the press several papers on the asymmetric synthesis of α-amino-acids were published. Klabunovskii's monograph[84] contains a number of data on the asymmetric synthesis of α-amino-acids by asymmetric catalytic hydrogenation. The asymmetric synthesis of the monomethyl ester of D-aspartic acid with 98% optical purity is almost stereospecific. It was achieved by Vigneron et al.[85] in the hydrogenation over Raney nickel of the cyclic product of the reaction of (+)-*erythro*-1,2-diphenylethanolamine with dimethyl acetylenedicarboxylate followed by the hydrogenolysis of the reduction product over Pd(OH)$_2$.

The Chemistry of Quinuclidine

L.N.Yakhontov

The review deals with the chemical properties and the biological activity of the derivatives of 1-azabicyclo[2,2,2] octane widely known as quinuclidine. The work of the Soviet School of Chemists, founded by M.V.Rubtsov, in the field of quinuclidine derivatives is reviewed in detail.
In the review an attempt is made in the first place to examine as a whole the chemistry and the biological action of quinuclidine derivatives from the standpoint of the characteristics of the structure of the quinuclidine molecule. The description of the methods of synthesis of various quinuclidine derivatives features prominently in the review. These data are presented with separate discussion of the methods of synthesising the bicyclic quinuclidine system and the methods for the introduction of various substituents into the preformed quinuclidine ring. This system made it possible to give a general account of the abundant factual data which have accumulated so far on the synthesis of quinuclidine derivatives and to emphasise the characteristics of the synthetic studies on this class of substances.
A special section deals with the comparatively new reactions involving the expansion of the quinuclidine ring. The bibliography comprises 227 references.

I. INTRODUCTION

The heterocyclic quinuclidine 1-azabicyclo[2,2,2]octane system is a structural fragment in a number of natural physiologically active substances and synthetic medicinal preparations†.

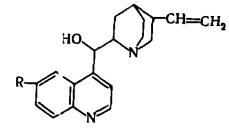
Among natural alkaloids, derivatives of quinoline and indole, containing the quinuclidine ring in the molecule, mention should be made of the cinchonine–cinchonamine (alkaloids of the bark of the cinchona tree)[8–12], sarpagine–ajmaline (Rauwolfia alkaloids)[8,13,14], and macusaine (strychnine alkaloids)[15,16] groups.

In connection with the high chemotherapeutic activity of the cinchona alkaloids, among which quinine occupies a particularly important place as an antimalarial drug, the study of the methods of synthesis of quinine and its analogues has occupied the attention of investigators in many countries for a long time. The ability of natural quinuclidine compounds (quinidine, ajmaline) to reduce the capacity of heart muscle to be stimulated, the comparatively recently discovered high pharmacological activity of certain synthetic quinuclidine derivatives and its wide variety, and the possibility of employing quinuclidine compounds as catalysts for the synthesis of polymers[17] have all stimulated further interest in studies on the quinuclidine series.

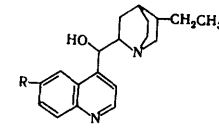
Among important advances in the investigation of natural quinuclidine compounds, mention should be made of the total synthesis of quinine achieved by Woodward and Doering[18] in 1944 and also the synthesis of cinchonamine carried out in 1958 by Ch'ên Ch'ang-Pai et al.[19] The total synthesis of racemic homomeroquinene, an intermediate in the synthesis of quinine, was achieved by Rubtsov from trichlorocollidine[20].

† Previously a number of reviews were published giving a fairly complete description of the development of the chemistry of quinuclidine derivatives[1–7].

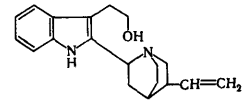
Alkaloids of the cinchonine–cinchonamine group



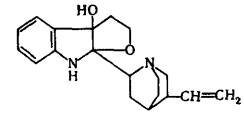
R = H cinchonine, cinchonidine
R = OH cupreine
R = OCH_3 quinine, quinidine, epiquinine, epiquinidine



R = H hydrocinchonine, hydrocinchonidine
R = OCH_3 hydroquinidine, hydroquinine

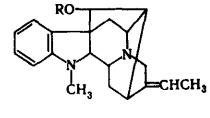


cinchonamine

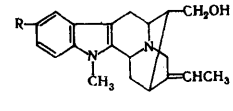


quinamine, conquinamine

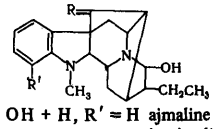
Alkaloids of the sarpagine, ajmaline, and macusaine group



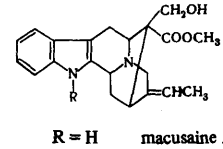
R = H tetraphyllicine
R = $(CH_3O)_3C_6H_2CO$ rauvomitine



R = OH sarpagine
R = OCH_3 lochnerine



R = OH + H, R′ = H ajmaline, isoajmaline, sandwicine
R = O, R′ = H ajmalidine
R = O, R′ = OCH_3 vamalidine



R = H macusaine A
R = CH_3 voachalotine

A number of reviews have been devoted[8-12,21], to problems connected with the chemistry of natural quinuclidine compounds and in particular the history of their discovery and practical applications, the examination of the natural sources, the methods of analysis and isolation, the determination of the structure and reactions of these compounds, and also problems of their stereochemistry. Therefore these data need not be described again and attention may be concentrated in the present review on the general chemical characteristics of quinuclidine derivatives, the methods of synthesising the quinuclidine ring and introducing substituents into the quinuclidine molecule, and also the biological properties of synthetic quinuclidine derivatives.

II. SOME CHARACTERISTICS OF QUINUCLIDINE DERIVATIVES

Quinuclidine (I) is the saturated bicyclic system with a nodal nitrogen atom

(I)

In contrast to aliphatic tertiary amines and *N*-substituted piperidines, quinuclidine has a rigidly fixed structure. The atoms comprising the quinuclidine ring are incapable of altering their relative positions by rotating about their bonds, which are included in a bicyclic system where each ring has the "boat" form. Compared with other 1-azabicycloalkanes, quinuclidine is characterised by high symmetry and only slight strain of the cyclic system. A distinctive feature of the quinuclidine molecule is also almost complete absence of screening of the sp^3-hybridised unshared electron pair at the nitrogen atom. These characteristics of the structure explain many physical and chemical properties of both quinuclidine itself and its various derivatives. For example, quinuclidine is a volatile crystalline substance with a high melting point (158°C). It readily sublimes even on standing in air. Breakdown of the symmetry of the quinuclidine molecule (by its conversion into condensed systems or by introduction of alkyl substituents) leads to a lowering of the melting point[22-26].

Interesting results were obtained in a comparative study of the infrared spectra of quinuclidine and piperidine and piperazine derivatives substituted at the nitrogen atom[27]. The spectra of the monocyclic compounds show in the range 2700–2800 cm^{-1} characteristic absorption bands due to the interaction of the free electron pair of the nitrogen atom with the adjacent axial C–H bonds. Quinuclidine does not absorb in this region, probably because of the absence of such interaction. Characteristic absorption bands at 2430, 2915, and 3405 cm^{-1} have been noted for quinuclidine[28].

The basicity of quinuclidine, which depends on the electron density at the nitrogen atom, is fairly high and close to that of the lower aliphatic amines and *N*-alkylpiperidines. The basicity of the condensed systems of benzo- and dibenzo-quinuclidine is reduced because of the inductive effect of the phenyl groups[26,29]. Comparison of the pK_a of the benzo- and dibenzo-quinuclidines with those of diethylaniline and diphenylamine, which have similar structures, demonstrates clearly the effect of the rigidity of the structure of quinuclidine derivatives (Table)[30].

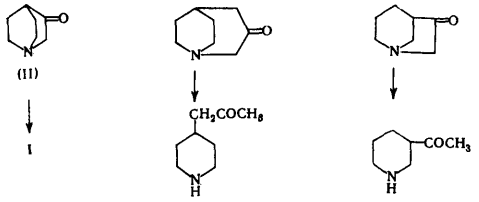
Like other aliphatic tertiary amines, quinuclidine readily forms salts with mineral and organic acids and also quaternary derivatives with alkyl halides. However, kinetic studies have shown[32] that the rate of reaction of alkyl iodides with quinuclidine is much higher than in similar reactions with aliphatic tertiary amines. For example, quinuclidine reacts with methyl iodide 50 times faster and with isopropyl iodide 700 times faster than does triethylamine. The trimethylborane adduct of quinuclidine proved to be more stable than the corresponding adducts of the trialkylamine series. These results can be explained by the virtual absence of steric hindrance at the electron pair of the nitrogen of the bicyclic system.

pK_a values for quinuclidine and related compounds

Compound	pK_a	References
Dimethylamine	10.77	31
Diethylamine	10.93	31
Triethylamine	10.87	31
N-Methylpiperidine	10.08	31
Quinuclidine	10.58	26
Benzoquinuclidine	7.79	26
Diethylaniline	6.56	31
Dibenzoquinuclidine	4.46	26
Diphenylamine	0.79	31.

The considerable chemical stability of the quinuclidine molecule is associated with the characteristics of its structure. Quinuclidine does not change on heating with concentrated mineral acids and on oxidation with potassium permanganate[22].

Leonard et al.[33] showed that, when 3-quinuclidone (II) is subjected to the Clemmensen reduction, the quinuclidine ring is retained, while ring fission occurs in other 1-azabicyclic ketones:

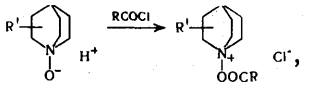


Quinuclidine is not dehydrogenated by mercury acetate, probably because in this case the reaction would have to proceed via a salt of Δ^1-dehydroquinuclidine and the formation of the latter is impossible according to the Bredt rule[2,34]. Quinuclidine can be dehydrogenated only under severe conditions (300°C) using palladium on charcoal or selenium[35]. The C–N bond then breaks and 4-ethylpyridine is formed.

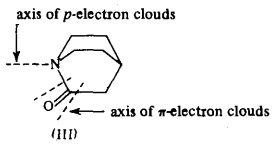
The pyrolysis and hydrogenolysis of quaternary quinuclidine salts leads to high yields of quinuclidine[2,36-38]. The formation of tertiary amines, in this case due to the elimination of aliphatic alcohols, is also a fundamental process accompanying the Hofmann degradation of quaternary quinuclidinium bases[39-41]. For example, in the Hofmann degradation of 1-methylquinuclidinium hydroxide unsubstituted quinuclidine was isolated in 35% yield together with products obtained as a result of the opening of the quinuclidine ring—1-methyl-4-vinylpiperidine and 1-methyl-4-(β-hydroxyethyl)piperidine[39]. All these findings constitute additional confirmation of the thermal and chemical stability of the quinuclidine ring.

The *N*-oxides of quinuclidine derivatives are capable of forming *O*-acylium salts which are stable to hydrolysis in neutral or acid media. On the other hand, their sensitivity

to alkalis is so high that they can be titrated as dibasic acids[42]:

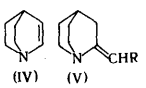


where R = CH_3 or C_6H_5. Interesting chemical properties have been found in bicyclic amides of the type of 2-quinuclidone (III).[43-46] The axes of the free *p*-electron clouds of nitrogen in such compounds prove to be almost perpendicular to the axes of the π-electron clouds of the carbonyl group:



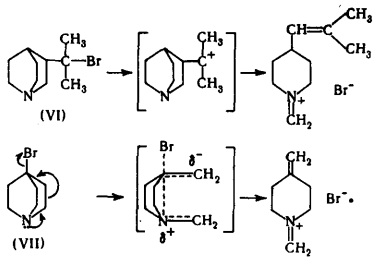
(III)

As a result, conjugation of the type  , which is characteristic of amides, is impossible in 2-quinuclidones. A number of properties of 2-quinuclidones, which makes them similar to amino-ketones, are connected with this fact. The nitrogen atom in 2-quinuclidones is readily protonated (ordinary amides and lactams are protonated at the oxygen) and methylated; 2-quinuclidones are highly basic (pK_a = 5.33–5.6)[44] compared with other amides (for example, *N*-acetylpiperidine has pK_a = 0.4). In the infrared spectra of these substances the frequency of the C=O stretching vibrations is on the average higher by 80 cm^{-1} than in ordinary lactams and the integral intensity of the carbonyl band is smaller by a factor of almost 2. The absorption maxima of 2-quinuclidones in the ultraviolet spectra occupy a position intermediate between the maxima of amides and ketones. The absence of amide mesomerism in 2-quinuclidones results in an increase of their reactivity, which is reflected in a higher rate of hydrolysis and alcoholysis of their hydrochlorides. The kinetics of the above reactions can be investigated by polarography, while normal amides and lactams cannot be reduced polarographically. The high reactivity of the C=O group in 2-quinuclidones is reflected also in the acidity of the adjacent CH_2 groups, which shows a tendency to undergo deuterium exchange. Finally, the C=O group in 2-quinuclidone is capable of nucleophilic substitution reactions which are characteristics of ketonic carbonyls—for example the formation of oximes with hydroxylamines[43]. Certain unusual chemical features are shown also by unsaturated quinuclidine derivatives—Δ^2-dehydroquinuclidine (IV),[47,48] its 2-substituted derivatives[49], and quinuclidines (V) with an exocyclic double bond in the 2-position[49]. As was to be expected on the grounds of structural considerations, these compounds differ in their properties from normal tertiary α-vinylamines. For example, dehydroquinuclidines do not exhibit the absorption at 230 nm characteristic of enamines and are not hydrolysed under mild conditions by dilute acids.



(IV) (V)

In contrast to the analogous aliphatic and nitrogen-free bicyclic compounds, the fragmentation of quinuclidine derivatives[50-57] takes place unambiguously. 2-(Quinuclidin-3′-yl)-2-bromopropane (VI) undergoes solvolysis by a stepwise mechanism[50,51] and 4-bromoquinuclidine (VII) is solvolysed by a synchronous mechanism[50,53]:



(VI)

(VII)

Because of the ease of protonation of the nitrogen atom in the quinuclidine ring, the competing reactions involving the isomerisation of the carbonium ion and also substitution and elimination processes do not play a significant role in these cases.

III. METHODS OF SYNTHESIS OF QUINUCLIDINE AND ITS DERIVATIVES

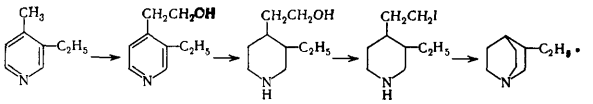
In the course of investigations over a period of many years a large number of a wide variety of quinuclidine derivatives have been synthesised. In order to give a systematic account of the literature data and the methods of preparation of quinuclidine and its substituted derivatives, in this review a distinction is drawn between methods of synthesis associated with the formation of the quinuclidine ring and methods for the introduction of various substituents into the preformed quinuclidine ring. Reactions accompanied by the expansion of the quinuclidine ring with formation of derivatives of other 1-azabicycloalkanes are described in a special section.

1. METHODS FOR QUINUCLIDINE RING CLOSURE

The starting compounds for the formation of the quinuclidine ring may be both piperidine derivatives and aliphatic substances: trihalogenoalkanes and dihalogenoalkylamines. The piperidine derivatives are obtained mainly from pyridine bases. Dihalogenoalkylamines and trihalogenoalkanes are usually synthesised from tetrahydropyran derivatives, dialkoxymalonic esters, or alkanetricarboxylic acid esters.

The quinuclidine ring closure is as a rule achieved by two mechanisms when piperidine derivatives are used: (1) by intramolecular alkylation or acylation or (2) by Dieckmann's intramolecular cyclisation.

Intramolecular alkylation was proposed in 1904 by Koenigs[58,59] for the preparation of the first synthetic representative of the quinuclidine series—3-ethylquinuclidine (VIII):



(IX) (X) (XI) (VIII)

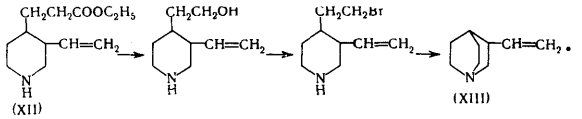
The starting material in Koenigs scheme was 3-ethyl-4-methylpyridine (IX). The product of the condensation of compound (IX) with formaldehyde was reduced with sodium in alcohol. The hydroxy-group in the piperidine derivative (X) obtained was replaced by iodine and 3-ethyl-4-(β-iodoethyl)piperidine (XI) was cyclised under the influence

of sodium carbonate with formation of 3-ethylquinuclidine (VIII).

A similar scheme using 4-methylpyridine as the starting material was employed in 1909 by Löffler and Stitzel[60] to prepare unsubstituted quinuclidine. However, these workers were unable to isolate pure quinuclidine and it was not until 1920 that Meisenheimer[22] obtained it. Meisenheimer[22] also described the conversion of 4-methylquinoline into benzoquinuclidine by Koenigs' method.

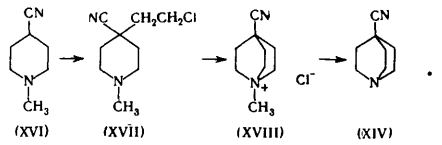
Later intramolecular alkylation of 4-(β-halogenoalkyl)-piperidines in the presence of alkaline reagents (sodium hydroxide, sodium bicarbonate, potassium carbonate, pyridine, etc.) was used frequently to synthesise quinuclidine[61] and its various derivatives. 2-Methylquinuclidine[23,62,63], 4-methylquinuclidine[25], dibenzoquinuclidine[26], 3-hydroxymethyl-3-methylquinuclidine[36,37,64], the lactone of 3-carboxymethyl-3-hydroxymethylquinuclidine[65], etc. were obtained by this procedure.

Lukeš and Galik[66] converted by a similar procedure the ethyl ester of meroquinene (XII), isolated from natural cinchonine, into optically active 3-vinylquinuclidine (XIII):



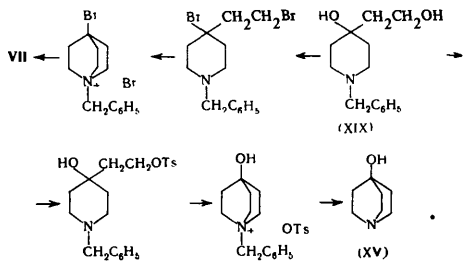
(XII) (XIII)

Grob et al.[67,68] used Koenigs' method to prepare 4-monosubstituted quinuclidines, including 4-cyano- (XIV), 4-bromo- (VII), and 4-hydroxy-quinuclidines (XV). The cyclisation in these syntheses was not based on secondary amines of the piperidine series but was carried out using tertiary *N*-substituted (*N*-methyl- and *N*-benzyl-)piperidines:



(XVI) (XVII) (XVIII) (XIV)

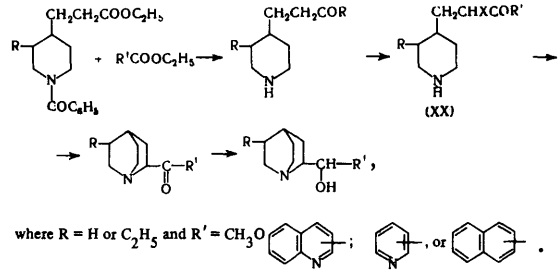
For example, 4-(β-chloroethyl)-4-cyano-1-methylpiperidine (XVII), obtained by the condensation of 4-cyano-1-methylpiperidine (XIV) with dichloroethane, was cyclised to the methochloride of 4-cyanoquinuclidine (XVIII), from which methyl chloride was eliminated on heating in a vacuum to 260–270°C.[67] The analogous conversion of 1-benzyl-4-hydroxy-4-(β-hydroxyethyl)piperidine (XIX) into 4-bromoquinuclidine (VII) and 4-hydroxyquinuclidine (XV)[68] can be represented as follows:



(XIX) (XV)

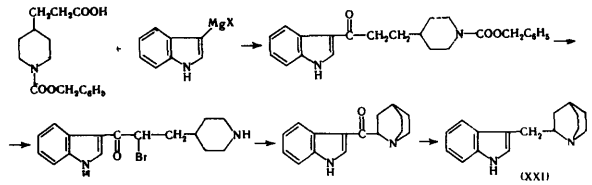
Rabe[69,70] and later other investigators[71–75] employed the above method of formation of the quinuclidine ring in their syntheses of analogues and isomers of cinchona alkaloids.

In this case the starting materials were not 4-halogenoalkyl piperidines or the analogous tosyl esters but halogeno-oxo-derivatives of the piperidine series—4-(β-halogeno-γ-oxoalkyl)piperidines (XX), the syntheses and reactions of which are shown below:



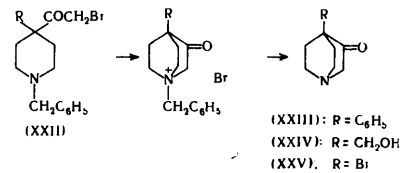
(XX)

A similar scheme was employed also in the synthesis of 2-scatylquinuclidine (XXI):[76]



(XXI)

Starting with the halogeno-oxo-derivatives of piperidine of another type, compounds of the 4-(β-bromo-α-oxoethyl)-piperidine (XXII) series, 3,4-disubstituted quinuclidines were prepared: 3-oxo-4-phenylquinuclidine (XXIII),[38] 4-hydroxymethyl-3-oxoquinuclidine (XXIV),[77] and 4-bromo-3-oxoquinuclidine (XXV):[78]

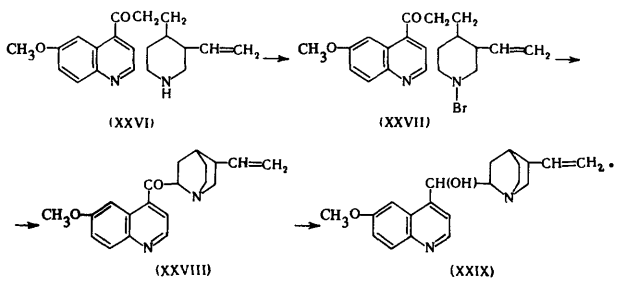


(XXII)

(XXIII): R = C_6H_5
(XXIV): R = CH_2OH
(XXV): R = Br

It was then shown[78] that quinuclidine ring closure is possible only with the axial disposition of both the 4-bromoacetyl residue and of the electron pair at the nitrogen atom. The formation of this conformation in the transition state is facilitated by the introduction of bulky substituents in the 1- and 4-positions of the piperidine ring. The attempts to cyclise compounds without such substituents (for example, 4-bromoacetylpiperidine) were unsuccessful[78].

Rabe[79,80] developed a somewhat different method of quinuclidine ring closure for the synthesis of cinchona alkaloids containing the vinyl group in the molecule. In this case it is difficult to introduce a halogen into the oxoalkyl residue of 4-oxoalkyl-3-vinylpiperidines (XXVI) without affecting the double bond. Therefore *N*-bromo-substituted and not *C*-substituted piperidines were employed for quinuclidine ring closure:

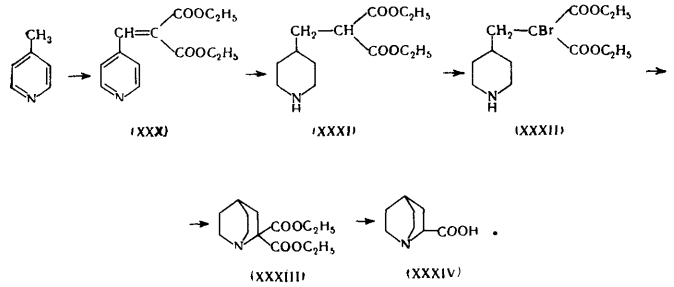


(XXVI) (XXVII) (XXVIII) (XXIX)

Quinotoxine (XXVI) was converted by treatment with sodium hypobromite into *N*-bromoquinotoxine (XXVII), which was cyclised under the influence of alkoxides to the corresponding quinuclidine derivative—quininone (XXVIII). The scheme developed by Rabe was used in the total synthesis of quinine (XXIX)[18] and also for the preparation of a number of analogues of this alkaloid[81,82].

In contrast to the unambiguous cyclisation of *N*-halogeno-4-oxoalkylpiperidines, considerable difficulties were encountered when 4-alkyl-*N*-halogenopiperidines were used for quinuclidine ring closure. Wawžonek and coworkers[83,84,87] and Lukeš and coworkers[85,86,88] established that the application of the Hofmann–Löffler reaction to 4-alkyl-*N*-chloropiperidines leads to the formation of a mixture of products in which quinuclidine derivatives are present together with the isomeric alkyl-1-azabicyclo[2,2,1]heptanes. The treatment of *N*-(β-chloroethyl)piperidine or its derivatives with a methanol solution of potassium hydroxide[27,89] leads to the formation of Hofmann degradation products, arising in the synthesis of 1,4-bispentamethylenepiperazinium dichloride. The main product is 1,2-bis(*N*-piperidino)ethane[27].

The Koenigs reaction was developed further in the work of Rubtsov, Dorokhova, and Mikhlina[90,91] and also Grob and coworkers[92,93], who employed α-halogeno-acids of the piperidine series and their esters for intramolecular alkylation. Rubtsov and Dorokhova[90] developed in 1953 a simple method for the synthesis of quinuclidine-2-carboxylic acid in five stages:

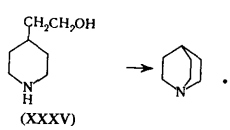


(XXX) (XXXI) (XXXII) (XXXIII) (XXXIV)

The condensation of γ-picoline with mesoxalic ester gave 4-(ββ-diethoxycarbonylvinyl)pyridine (XXX). The unsaturated ester (XXX) was hydrogenated using platinum to compound (XXXI), which was then treated with bromine. The resulting 4-(β-bromo-ββ-diethoxycarbonylethyl)piperidine (XXXII) was cyclised in the presence of pyridine to 2,2-diethoxycarbonylquinuclidine (XXXIII). The latter was hydrolysed and partially decarboxylated with formation of quinuclidine-2-carboxylic acid (XXXIV).

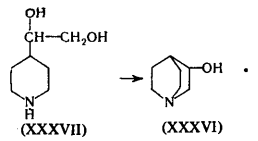
The above principle involving the cyclisation of α-halogeno-esters of the piperidine series was widely employed subsequently for the synthesis of various 2,3- and 2,5-disubstituted quinuclidines: 3-carboxymethylquinuclidine-2-carboxylic acid[94], 3-methylquinuclidine-2-carboxylic acid[95], and 5-[β-hydroxy(methoxy)ethyl]quinuclidine-2-carboxylic acid[96,97].

A variant of the intramolecular alkylation method is the gas-phase cyclodehydration of 4-(β-hydroxyethyl)piperidine (XXXV) proposed by Leonard et al.[98]:



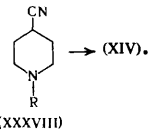
(XXXV)

The same method was used to synthesise 3-hydroxyquinuclidine (XXXVI) from piperid-4'-ylethane-1,2-diol (XXXVII):[99]



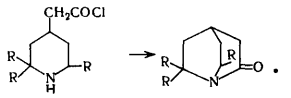
(XXXVII) (XXXVI)

Another variant of the intramolecular alkylation method is the synthesis of 4-cyanoquinuclidine (XIV) by the condensation of 1-alkyl-4-cyanopiperidines (XXXVIII) with ethylene glycol esters in the presence of alkali metals[100]:

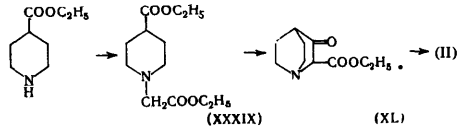


(XXXVIII)

The intramolecular acylation of piperidine derivatives has been used together with intramolecular alkylation for the formation of the quinuclidine ring. Yakhontov and Rubtsov and subsequently Pracejus and coworkers synthesised in this way 2-quinuclidone (III)[43] and its 6,6-dimethyl-[44] and 6,6,6-trimethyl-[45,101] derivatives from the corresponding acid chlorides under the influence of anhydrous potassium carbonate or tertiary amines:



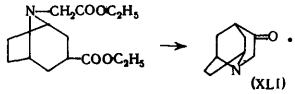
Another method for the closure of the quinuclidine ring is based on Dieckmann's *intramolecular cyclisation*. This procedure was proposed for the first time by Clemo and Metcalfe[102] for the synthesis of 3-quinuclidone (II):[102]



(XXXIX) (XL)

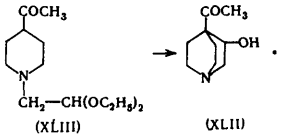
Ethyl isonipecotate was converted by alkylation with chloroacetic ester into ethyl 1-ethoxycarbonylmethylisonipecotate (XXXIX). The latter was cyclised in the presence of metallic potassium in toluene and the resulting β-keto-ester (XL) was hydrolysed and decarboxylated without isolation. Later this method was improved and the yield of the ketone (II) in the cyclisation stage was increased to 84%.[103-107]

The isolation of the intermediate in the synthesis—ethyl 3-oxoquinuclidine-2-carboxylate (XL)[108]—made it possible to develop methods based on it for the preparation of various 2,3-disubstituted quinuclidines[49,108,109]. Subsequently the Clemo reaction was used to synthesise ring-substituted quinuclidines: 5-oxoquinuclidine-2-carboxylic acid[110], 6-methyl-3-quinuclidone[111], 6,7-dimethyl-3-quinuclidone[112], and also compounds of the tropaquinuclidine series (XLI):[113]



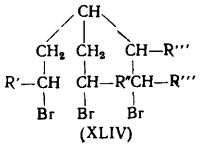
(XLI)

The recently described quinuclidine ring closure by intramolecular aldol condensation in the synthesis of 4-acetylquinuclidin-3-ol (XLII) from 4-acetyl-1-(2′,2′-diethoxyethyl)piperidine (XLIII) [77] is unusual:



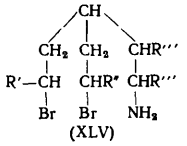
(XLIII) (XLII)

A fundamentally different approach to the synthesis of quinuclidine and its derivatives was developed by Prelog and coworkers [114,115]. The methods which they proposed are based on the action of ammonia under pressure at 100–120°C on tribromoalkanes (XLIV):



(XLIV)

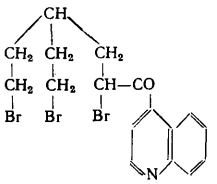
or on double intramolecular alkylation consisting in the treatment with alkali of dibromoalkylamines (XLI):



(XLV)

Quinuclidine [39,114-117], its 2-alkyl- [23,24], 3-alkyl- [24], and 4-alkyl-derivatives [25], and also quinuclidine-2-carboxylic acid [118] were obtained in this way.

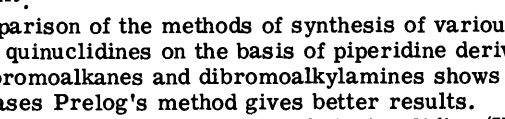
Prelog's attempts to achieve the cyclisation of the tribromoalkyl derivative (XLVI),



(XLVI)

in order to obtain a quinine analogue proved to be unsuccessful [119].

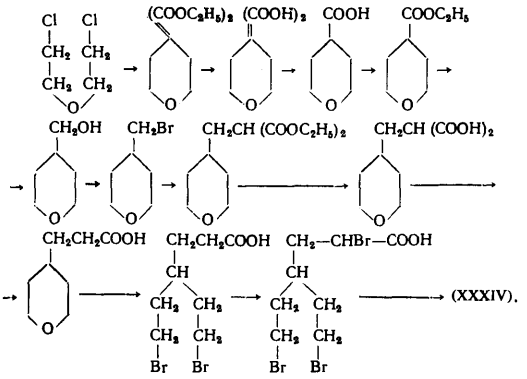
Comparison of the methods of synthesis of various substituted quinuclidines on the basis of piperidine derivatives and tribromoalkanes and dibromoalkylamines shows that in some cases Prelog's method gives better results. For example, in the synthesis of 2-methylquinuclidine (XLVII) by this procedure Lukeš achieved a yield of 37%: [23]



(XLVII) (XLVIII)

The sole example of 3,5-disubstituted quinuclidines described, 3,5-dimethylquinuclidine (XLVIII), [120] was synthesised by Prelog's method.

At the same time the synthesis of quinuclidine derivatives from tribromoalkanes and dibromoalkylamines involves in many cases starting materials which are difficult to obtain and are formed in multistage syntheses with low yields. Prelog's method is also less suitable for the synthesis of quinuclidine derivatives containing functional groups. As an example, one may quote the methods of preparation of quinuclidine-2-carboxylic acid (XXXIV): [118]



In this case the synthesis of compound (XXXIV) is achieved by a multistage procedure (12 stages) and the overall yield is about 4%. In the five-stage synthesis of compound (XXXIV) starting with γ-picoline described above the yield of quinuclidine-2-carboxylic acid is 30%. [90]

2. METHODS FOR THE INTRODUCTION OF SUBSTITUENTS INTO THE QUINUCLIDINE RING

As already mentioned above, the quinuclidine molecule is a saturated bicyclic system. The introduction into this molecule of functional groups by direct substitution presents considerable difficulties and experiments of this kind have not been carried out at all so far. Therefore reactive groups are usually introduced during the closure of the quinuclidine ring and are then used to convert the product into various classes of quinuclidine derivatives. The most readily available compounds containing such functional groups are the carboxy- and carbonyl derivatives: quinuclidine-2-carboxylic acid, 3-quinuclidone, and others. Almost all substituted quinuclidine derivatives of a wide variety of types were obtained from the carboxy- and carbonyl derivatives using the usual methods of organic synthesis.

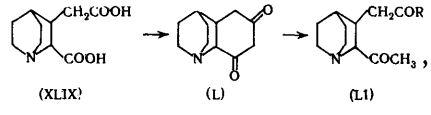
(1) Syntheses of Substituted Quinuclidines from Quinuclidinecarboxylic Acids

At the present time all three monocarboxylic acids of quinuclidine are known: quinuclidine-2-carboxylic [90,118], quinuclidine-3-carboxylic [121,122], and quinuclidine-4-carboxylic [67,100], and also quinuclidine-2-carboxylic acids with various substituents in the 3-position [95,108] and the 5-position [96,110] and quinuclidine-3-carboxylic acids with substituents in the 2-position [123] and the 6-position [111]. Only one compound containing 2-carboxy-groups in the quinuclidine ring has been described: quinuclidine-2,3-dicarboxylic acid [109]. A large number of homologues of quinuclidinecarboxylic acids have been obtained, among which quinuclidine-3-acetic [124-127] and 3-carboxymethylquinuclidine-2-carboxylic acid [94] are of definite interest for further reactions. The syntheses of quinuclidine derivatives from quinuclidinecarboxylic acids may be divided into three large groups: (a) reactions without change in the length of the carbon chain; (b) reactions accompanied by the dissociation of the C–C bond and a decrease in chain length;

(c) reactions associated with an increase in the length of the carbon chain.

a. Reactions without change in the length of the carbon chain. Quinuclidinecarboxylic acids readily form acid chlorides which can be converted without isolation into the corresponding esters [67,96,125,128-130] or amides [125,130,131]. It is noteworthy that other methods have also been used to prepare the esters of quinuclidinecarboxylic acids; esterification in the presence of sulphuric acid and hydrogen chloride and also transesterification with alkali metal alkoxides [96,109,110]. The amides of Δ^2-dehydroquinuclidine-2- and -3-carboxylic acids were obtained from the corresponding esters by the action of alcoholic ammonia [47,49]. Esters of quinuclidinecarboxylic acids have also been used to synthesise many hydrazides and their hydrazones [95,132] and the amides were used to synthesise nitriles [47,49,90].

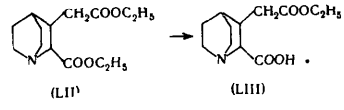
The attempt to obtain the anhydride from 3-carboxymethylquinuclidine-2-carboxylic acid (XLIX) in the presence of acetic anhydride and sodium acetate unexpectedly led to the formation of the tricyclic β-diketone (L). [133] On interaction with substances with a mobile hydrogen atom (water, alcohols, amines), the latter readily underwent ring opening with formation of derivatives of 2-acetylquinuclidine-3-acetic acid (LI): [133]



(XLIX) (L) (LI)

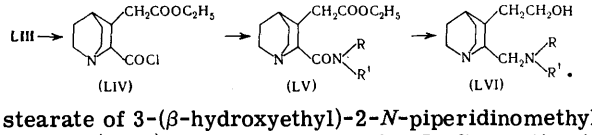
where R = OH, OC_2H_5, or NR'_2.

Esters of acids of the quinuclidine series are readily hydrolysed, the reaction being particularly easy for alkoxycarbonyl groups in the α-position of the quinuclidine ring [134]. On prolonged storage of aqueous solutions of diethyl 3-carboxymethylquinuclidine-2-carboxylate (LII) at room temperature, the acid ester (LIII) is formed [134], and this has been used to synthesise compounds containing various functional groups in the 2- and 3-positions of the quinuclidine ring:



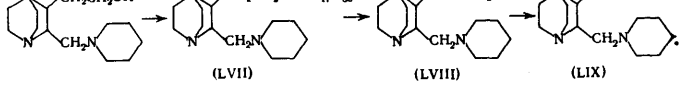
(LII) (LIII)

For example, when compound (LIII) reacts with thionyl chloride, the monochloride (LIV) forms readily and in the presence of primary and secondary amines is converted into the amides of 3-ethoxycarbonylmethylquinuclidine-2-carboxylic acid (LV). [130,134] The reduction of these amidoesters with lithium aluminium hydride leads to 2-alkyl(dialkyl)-3-(β-hydroxyethyl)aminomethylquinuclidines (LVI):



(LIV) (LV) (LVI)

The stearate of 3-(β-hydroxyethyl)-2-*N*-piperidinomethylquinuclidine (LVII) was converted by the Kraft reaction into the unsaturated compound (LVIII) from which 2-*N*-piperidinomethylquinuclidine-3-carboxylic acid (LIX) was obtained by oxidation with potassium permanganate [123]:

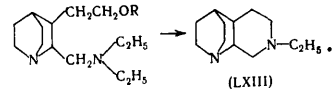


(LVII) (LVIII) (LIX)

The formation as a result of the above reactions of a derivative of quinuclidine-3-carboxylic acid (LIX) is convincing proof that the ethoxycarbonyl group in the 2-position is the first to be hydrolysed in the diethyl ester (LII).

A similar phenomenon obtains also in the diethyl ester of quinuclidine-2,3-dicarboxylic acid [109], which is consistent with the known greater ease of hydrolysis of α-amino-acid esters compared with β-amino-acid esters.

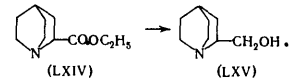
The unusual reaction of 2-diethylaminomethyl-3-(β-hydroxyethyl)quinuclidine is noteworthy [123]. It has been found that, on distillation under atmospheric pressure, compounds (LX) and (LXI) cyclise with elimination of an ester molecule and the formation of a new tricyclic system—*N*-ethylpiperidino[3,4-*b*]quinuclidine (LXIII). The corresponding amino-alcohol (LXII) behaves analogously on heating with phthalic anhydride in the presence of benzenesulphonic acid [123]:



(LXIII)

(LX): R = COC_6H_5
(LXI): R = $COC_{17}H_{35}$
(LXII): R = H

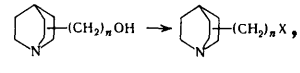
The reduction of ethyl quinuclidine-2-carboxylate (LXIV) by the Bouveault–Blanc method or with lithium aluminium hydride yields quinuclidin-2-yl-methanol (LXV): [24]



(LXIV) (LXV)

The second reduction procedure is easier to handle and gives better yields and therefore lithium aluminium hydride is mainly used in most studies for the preparation of various alcohols [67,95,121,125,134] and glycols [94,109] of the quinuclidine series.

Halogenoalkylquinuclidines have been synthesised by the reaction of the corresponding alcohols with thionyl chloride or hydrogen halides [24,49,121,135,136]:



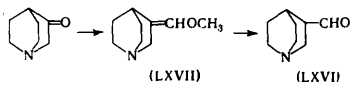
where $n = 1$ or 2.

Examination of the chemical properties of halogenoalkyl-substituted quinuclidines shows that the halogen atoms in the 2-halogenomethyl group are not very labile: for example, 2-chloromethylquinuclidine does not react with ammonia and amines [137] and the corresponding reactions of 2-bromomethylquinuclidine take place with low yields [137].

Although the halogen atoms in 3-halogenoalkylquinuclidines are more reactive, the use of compounds of this type as starting materials in various syntheses is made difficult by the ease of their conversion into quaternary polymeric derivatives [136]. These features of halogeno-derivatives of quinuclidine limit their application only to those cases where powerful nucleophilic agents are employed. Therefore the principal method for the synthesis of aminoalkylquinuclidines is not the interaction of halogeno-derivatives of quinuclidines with amines but the reduction with lithium aluminium hydride of the corresponding quinuclidinecarboxylic acid amides [122,130,131,138].

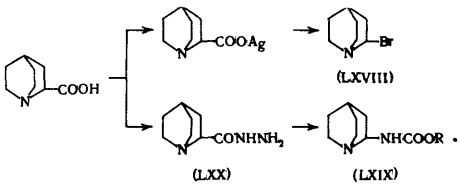
Aldehydes of the quinuclidine series are of considerable interest for the synthesis of various quinuclidine derivatives. At the present time all three monoformylquinuclidines are known. 2-Formylquinuclidine and 3-formylquinuclidine [139,140] have been obtained by the reduction of the

N-methylanilides of the corresponding quinuclidinecarboxylic acid with a calculated amount of lithium aluminium hydride or by the reduction of the ethyl esters of these acids with sodium aluminium hydride; 4-formylquinuclidine[67] has been obtained by the oxidation of quinuclidin-4-ylmethanol with potassium dichromate. 3-Formylquinuclidine (LXVI) has also been synthesised from 3-quinuclidone by its reaction with methoxymethylenetriphenylphosphorane and subsequent hydrolysis of 3-methoxymethylenequinuclidine (LXVII) with hydrochloric acid[141]:



(LXVII) (LXVI)

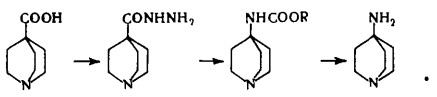
b. Reactions accompanied by the dissociation of a C—C bond and a decrease in the length of the carbon chain. Substances with less carbon atoms have been synthesised from quinuclidine-2-carboxylic acid: 2-bromoquinuclidine (LXVIII)[90] and urethanes of 2-aminoquinuclidine (LXIX).[142] These compounds are of considerable interest, since they contain at the same carbon atom a bromine atom and an amino-group (in 2-bromoquinuclidine) or two amino-residues (in 2-aminoquinuclidine derivatives). Such combination of functional groups leads to the appearance of new chemical properties in these compounds. For example, compound (LXVIII) does not form Grignard reagents and compound (LXIX) is so stable that in the hydrolysis of its urethanes under mild conditions ammonia is eliminated and polymers of dehydroquinuclidine are formed. The synthesis of compound (LXVIII) was achieved using the Borodin reaction[90]; the urethanes of compound (LXIX) were obtained starting with the hydrazide of quinuclidine-2-carboxylic acid (LXX) by the Curtius reaction[142]:



(LXVIII)

(LXX) (LXIX)

Analogous reactions in the quinuclidine-4-carboxylic acid series made it possible to obtain 4-aminoquinuclidine (LXXI):[143]

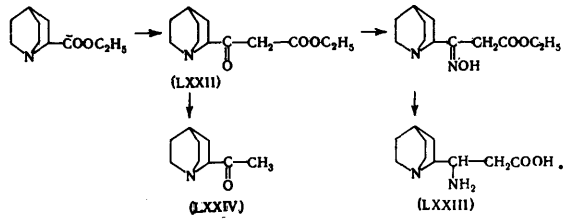


(LXXI)

The same compound was synthesised directly from quinuclidine-4-carboxylic acid by the Schmidt reaction. However, despite the greater number of stages, the first method proved to be more rational.

c. Processes associated with the growth of the carbon chain. Claisen, Grignard, etc. reactions have been used to synthesise quinuclidine derivatives with increase in the length of the carbon chain.

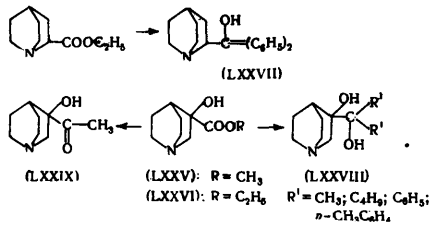
The Claisen condensation of ethyl quinuclidine-2-carboxylate with ethyl acetate led to the formation of ethyl β-oxo-β-(quinuclidin-2-yl)propionate (LXXII), which was then further converted into β-amino-β-(quinuclidin-2-yl)-propionic acid (LXXIII)[108] and 2-acetylquinuclidine (LXXIV):[43]



(LXXII)

(LXXIV) (LXXIII)

The carbinols (LXXVII)[24] and pinacones (LXXVIII)[144] were obtained by the Grignard reaction from the esters of quinuclidine-2-carboxylic and 3-hydroxyquinuclidine-3-carboxylic acids [compounds (LXXV) and (LXXVI)] respectively:

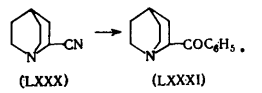


(LXXVII)

(LXXIX) (LXXV): R = CH_3 (LXXVIII)

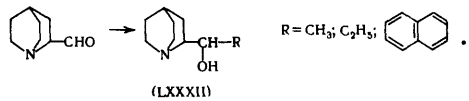
(LXXVI): R = C_2H_5 R' = CH_3; C_4H_9; C_6H_5; *n*-$CH_3C_6H_4$.

It is noteworthy that in the interaction of the hydroxy-ester (LXXV) with methylmagnesium iodide the process terminates at the stage involving the formation of the ketone (LXXIX). A Grignard reaction has also been described for 2-cyanoquinuclidine (LXXX), which was converted into 2-benzoylquinuclidine (LXXXI):[49]



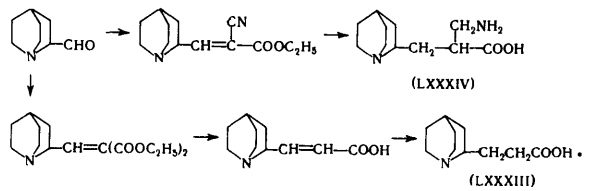
(LXXX) (LXXXI)

The introduction of 2-formylquinuclidine into reactions with organomagnesium compounds led to the development of a new method of synthesis of quinuclidin-2-ylmethanols (LXXXII) which are analogues of cinchona alkaloids[145]:



(LXXXII)

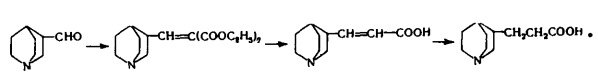
The condensation of 2-formylquinuclidine by the Knoevenagel reaction with cyanoacetic[108] and malonic[129] esters was used to synthesise quinuclidine-2-β-propionic acid (LXXXIII) and its α-aminomethyl derivative (LXXXIV):



(LXXXIV)

(LXXXIII)

Quinuclidine-3-β-acrylic and quinuclidine-3-β-propionic acids were synthesised similarly from 3-formylquinuclidine[140]:

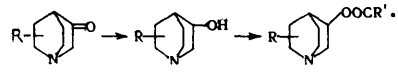


The malonic ester synthesis was used to prepare quinuclidine-2-β-propionic acid from 2-bromomethylquinuclidine[128] and quinuclidine-3-γ-butyric acid from 3-(β-chloroethyl)quinuclidine[125].

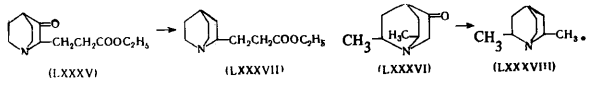
(2) Syntheses of Substituted Quinuclidines from 3-Quinuclidone

Among oxo-derivatives of quinuclidine the most readily available is 3-quinuclidone. The derivatives of 2-quinuclidone have been little investigated and at the present time are hardly used as starting materials in synthetic studies. There is an extremely wide variety of syntheses on the basis of 3-quinuclidone and they can be divided into two groups: (a) reactions with retention of the carbon chain length and (b) reactions involving an increase in the carbon chain length.

a. Reactions with retention of the carbon chain length. The hydrogenation of 3-quinuclidone and its substituted derivatives to the corresponding alcohols with subsequent esterification made it possible to synthesise a large number of esters and urethanes of 3-quinuclidinol, which are of considerable interest from the standpoint of the investigation of their biological activity [33,102,103,111,112,146-151]:

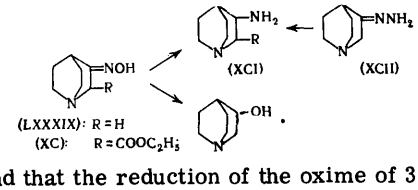


The Clemmensen[33] and Wolff–Kishner[152] reduction of 3-quinuclidone yields quinuclidine. The application of the Wolff–Kishner reaction to 2-substituted derivatives of 3-quinuclidone made it possible to obtain 2-substituted quinuclidine derivatives. Ethyl quinuclidine-2-β-propionate (LXXXVII)[104] and 2,6-dimethylquinuclidine (LXXXVIII)[11] were obtained in this way from the corresponding 3-oxo-derivatives (LXXXV) and (LXXXVI):



(LXXXV) (LXXXVII) (LXXXVI) (LXXXVIII)

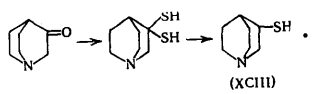
The oximes of 3-quinuclidone (LXXXIX)[103,122] and of ethyl 3-oxoquinuclidine-2-carboxylate (XC)[108] were reduced to the amines (XCI):



(LXXXIX): R = H
(XC): R = $COOC_2H_5$

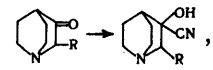
It was found that the reduction of the oxime of 3-quinuclidone (LXXXIX) in acid and neutral media is accompanied by hydrogenolysis and the reaction leads to the formation of 3-quinuclidinol together with 3-aminoquinuclidine (XCI, R = H). The reduction of the hydrazone of 3-quinuclidone (XCII) to 3-aminoquinuclidine takes place more unambiguously[122].

When 3-quinuclidone is treated with hydrogen sulphide and this is then followed by reduction with sodium tetrahydroborate, a sulphur-containing compound is produced—3-mercaptoquinuclidine (XCIII)[153]:

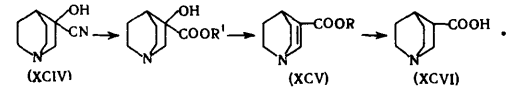


(XCIII)

b. Reactions involving an increase in the length of the carbon chain. The interaction of 3-oxo-derivatives of quinuclidine with potassium cyanide[109,121,154] or acetone cyanohydrin[122] was used to prepare cyanohydrins of the quinuclidine series:

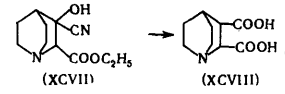


where R = H or $COOC_2H_5$. The hydrolysis of the cyanohydrin of 3-quinuclidone (XCIV) and subsequent dehydration led to the synthesis of 3-alkoxycarbonyl-Δ^2-dehydroquinuclidines (XCV), which were then reduced and hydrolysed to give quinuclidine-3-carboxylic acid (XCVI)[121,122]:



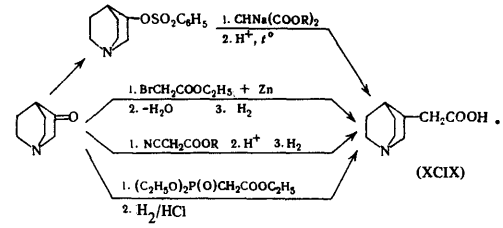
(XCIV) (XCV) (XCVI)

Quinuclidine-2,3-dicarboxylic acid (XCVIII) was obtained similarly from the cyanohydrin of 2-ethoxycarbonyl-3-quinuclidone (XCVII):[109]



(XCVII) (XCVIII)

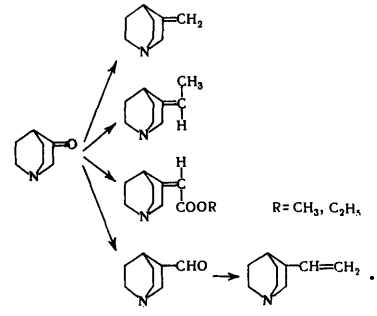
Various methods for incrementing the carbon chain were used to synthesise quinuclidine-3-acetic acid (XCIX):



(XCIX)

Comparison of different syntheses shows that the smallest yield of the acid (XCIX) is observed in sodiomalonic synthesis (13.4%),[125] much better results being obtained in the Reformatsky (40%)[125] and Knoevenagel condensations (65–70%):[126] a nearly quantitative yield can be achieved in the Wittig–Horner reaction[155].

The application of the Wittig–Horner reactions to 3-quinuclidone and other β-oxo-derivatives of quinuclidine[127,140,155-157] made possible the preparation of a wide variety of 3-substituted quinuclidines[128,140,157]:

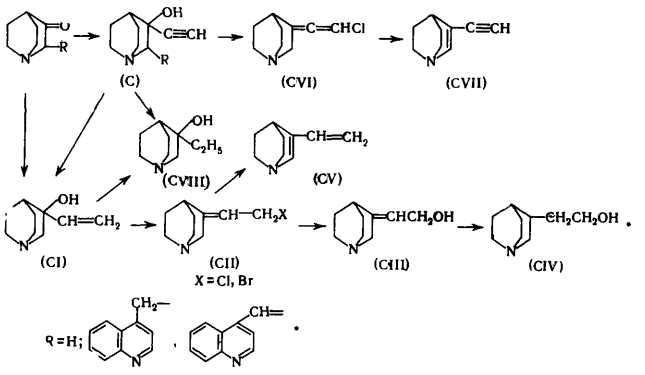


R = CH_3, C_2H_5

For example 3-methylene-, 3-ethylidene-[157], 3-alkoxycarbonylmethylene-[128], and 3-formyl-quinuclidines[140] have been synthesised by means of the above reactions. The reactions were found to be stereospecific[157]. In the synthesis of 3-ethylidenequinuclidine the ylide was found to attack predominantly from the sterically more favourable direction, when the methyl group in the transition complex is furthest removed from the 2 α-protons of the

quinuclidine ring. In the synthesis of 3-alkoxycarbonylmethylenequinuclidines the stereochemistry of the process was determined by the interaction of the nitrogen of the quinuclidine ring with the alkoxycarbonyl groups which led to the formation of only that geometrical isomer in which the above groups are close to one another.

Double application of the Wittig reaction initially with methoxymethylenetriphenylphosphorane and then with methylenetriphenylphosphorane led to the conversion of 3-quinuclidone into 3-vinylquinuclidine in two stages with an overall yield of 50%.[156] The above method for the introduction of the vinyl group into the β-position of the quinuclidine ring is of considerable interest, since various other synthetic procedures[36,37,158,159] either did not result in the formation of unsaturated quinuclidine compounds or involved the migration of the double bond to an exocyclic position. The introduction of an ethyne group into 3-quinuclidone[136,160] and its 2-substituted derivatives leads to 3-ethynyl-3-hydroxyquinuclidines, which are readily hydrogenated to 3-ethyl-3-hydroxyquinuclidines:

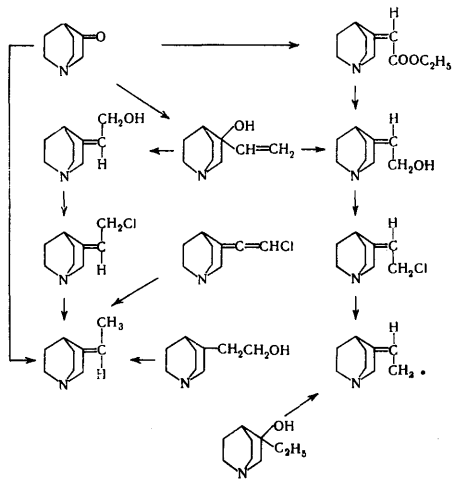


The selective reduction of 3-ethynyl-3-hydroxyquinuclidine, (C, R = H) led to the preparation of 3-hydroxy-3-vinylquinuclidine (CI)[136]. The latter was also synthesised directly from 3-quinuclidone and vinylmagnesium bromide[161].

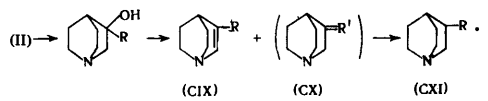
The substitution of the hydroxy-group in compound (CI) by a halogen with thionyl chloride or hydrobromic acid is accompanied by allyl rearrangement with formation of 3-(β-halogenoethylidene)quinuclidines (CII). 3-(β-Bromoethylidene)quinuclidine was converted via the 3-(β-hydroxyethylidene) derivative (CIII) into 3-(β-hydroxyethyl)-quinuclidine (CIV)[136] and then 3-vinyl-Δ²-dehydroquinuclidine (CV) was obtained by the dehydrohalogenation of 3-(β-chloroethylidene)quinuclidine[161].

Similar processes, associated this time with the acetylene–allene rearrangement were observed also when the hydroxy-group in 3-ethynyl-3-hydroxyquinuclidine (C, R = H) was replaced by a halogen. In this case the product was 3-(β-chloroallene)quinuclidine (CVI)[157] which readily eliminates hydrogen halide with formation of 3-ethynyl-Δ²-dehydroquinuclidine (CVII). The study of the allyl and acetylene–allene rearrangements in the series of 3-substituted quinuclidines[161] led to the determination of the effect of these processes on the positions of the multiple bonds in unsaturated quinuclidine compounds. In the course of these investigations it was shown that in the oxidation and ozonolysis of substances containing functional groups in the allyl position relative to the double bond not only the multiple but also the single C–C bonds adjacent to them are dissociated. For example, in the oxidation with potassium permanganate under mild conditions and in the ozonolysis of 3-hydroxy-3-vinylquinuclidine (CI), 3-quinuclidone is formed[161]. Therefore the position of multiple bonds in such allyl systems may be established unambiguously not with the aid of oxidative procedures but by analysing the NMR spectra[161].

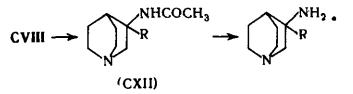
Two series of geometrical isomers of 3-substituted quinuclidines with a semicyclic double bond were synthesised by various reactions of 3-quinuclidone: 3-ethylidene[136,157,162], 3-(β-hydroxyethylidene)-[136,157], and 3-(β-chloroethylidene)-quinuclidines[157]; within each series interconversions were carried out[157] and the steric structure of the compounds was established with the aid of NMR spectra[16,157,163]:



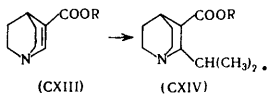
The interaction of 3-quinuclidones with organolithium or organomagnesium compounds is a general method for the synthesis of a large number of tertiary alcohols (CVIII)[47,162,164–168]. Their subsequent dehydration led to the formation together with Δ²-dehydroquinuclidines (CIX) of substances with an exocyclic double bond (CX)[165–168]. The reduction of the unsaturated products made it possible to obtain various 3-substituted quinuclidines (CXI):



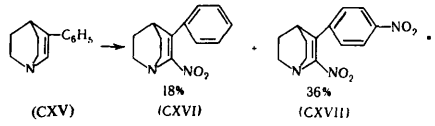
When 3-alkyl(aryl)-3-hydroxyquinuclidines (CVIII) were allowed to react with acetonitrile under the conditions of the Ritter reaction, acetylated 3-alkyl(aryl)-3-aminoquinuclidines (CXII) were obtained:



An interesting method for the introduction of substituents into the 2-position of the quinuclidine ring on the basis of 3-substituted Δ²-dehydroquinuclidines (CIX) has been described[47]. When methyl Δ²-dehydroquinuclidine-3-carboxylate (CXIII) reacts with isopropylmagnesium bromide, 1,4-addition takes place with subsequent formation, in the course of further treatment, of 2-isopropyl-3-methoxycarbonylquinuclidine (CXIV):

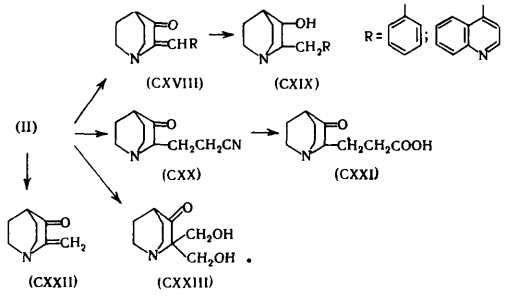


Unusual 2-substituted quinuclidines were obtained also on nitrating 3-phenyl-Δ^2-dehydroquinuclidine (CXV). The reaction products in this case proved to be 2-nitro-3-phenyl-Δ^2-dehydroquinuclidine (CXVI) and 2-nitro-3-(*p*-nitrophenyl)-Δ^2-dehydroquinuclidine (CXVII)[47]:



(CXV) (CXVI) (CXVII)

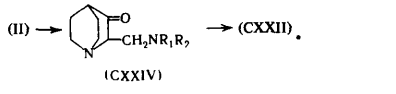
A number of 2-substituted quinuclidines were obtained by the condensation of 3-quinuclidone with aldehydes[77,103,109] and acrylonitrile[104]:



(CXVIII) (CXIX) (II) (CXX) (CXXI) (CXXII) (CXXIII)

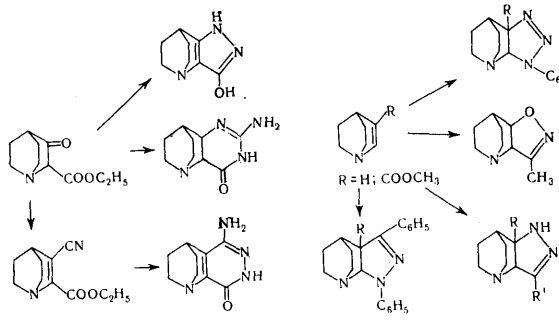
These reactions made it possible to convert 3-substituted quinuclidines into 2,3-disubstituted derivatives. For example 3-quinuclidone was converted via 2-[phenyl(quinolin-4′-yl)methylene]-3-quinuclidone (CXVIII) into 2-[phenyl-(quinolin-4′-yl)methyl]quinuclidin-3-ol (CXIX) and also into 2-(β-cyanoethyl)-3-oxoquinuclidine (CXX) and further into 3-oxoquinuclidine-2-β-propionic acid (CXXI). The formylation of 3-quinuclidone leads to the formation of 2-methylene-3-quinuclidone (CXXII) and, when a large excess of formaldehyde is employed, the product is a β-ketol—2,2-bishydroxymethyl-3-quinuclidone (CXXIII)[77].

2-Methylene-3-quinuclidone (CXXII) was also obtained by the Mannich reaction[170]. The 2-dialkylaminomethyl-3-quinuclidones (CXXIV) formed as intermediates in this case are converted into compound (CXXII) on distillation:



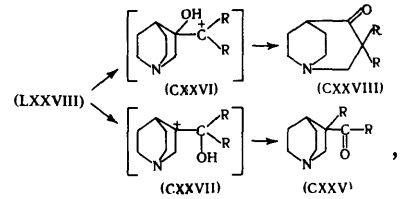
(II) (CXXIV) (CXXII)

Condensed heterocyclic systems containing the quinuclidine ring (pyrazolo-, oxazolo-, triazolo-, pyrimidino-, and pyridazino-quinuclidines[171]) were synthesised from ethyl 3-oxoquinuclidine-2-carboxylate (CXXXV) and also from Δ^2-dehydroquinuclidine and methyl Δ^2-dehydroquinuclidine-3-carboxylate obtained from 3-quinuclidone:



3. REACTIONS INVOLVING THE EXPANSION OF THE QUINUCLIDINE RING

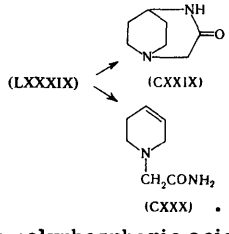
The study of the pinacol rearrangement of ditertiary quinuclidine alcohols of the type of compound (LXXVIII)[144,172] showed that, depending on the nature of the substituents R and the reactants employed, the process takes place either with ring expansion or with the formation of ketones of the quinuclidine series [compounds (CXXV)]:



(LXXVIII) (CXXVI) (CXXVIII) (CXXVII) (CXXV)

where R = CH_3, C_4H_9, C_6H_5, or *p*-$CH_3C_6H_4$. This is associated with the possible reaction via two types of carbonium ions [(CXXVI) and (CXXVII)] with electrophilic centres at the C_3 atom of the quinuclidine ring or at the carbon atom of the side chain respectively. The subsequent migration of the aryl or alkyl group leads in the first case to ketones of the quinuclidine series (CXXV) and the migration of the methylene group in the second case leads to the formation of 4-oxo-derivatives of 1-azabicyclo[3,2,2]nonane (CXXVIII). For aryl substituents, stabilisation is achieved as a result of the conjugation of carbonium ions of type (CXXVI). Therefore, on treatment with sulphuric acid, 3-($\alpha\alpha$-diaryl-α-hydroxymethyl)-3-hydroxyquinuclidines (LXXVIII, R = Ar) are more readily converted into compounds (CXXVIII) than the analogous 3-($\alpha\alpha$-dialkyl-α-hydroxymethyl)-3-hydroxyquinuclidines (LXXIII, R = Alk). The use of an aprotic reagent, zinc chloride in acetic anhydride, yields carbonium ions (CXXVII) as a result of the elimination of an acetate ion from the initially formed monoacetyl derivatives of the glycols (LXXVIII). Therefore in aprotic media expansion of the quinuclidine ring does not take place and the reaction leads to ketones of the quinuclidine series (CXXV) or dehydration and acylation products of the initial glycols.

The Beckmann rearrangement of the oxime of 3-quinuclidone (LXXXIX) in the presence of polyphosphoric acid or oleum takes place with expansion of the quinuclidine ring and the formation of 3-oxo-1,4-diazabicyclo[3,3,2]nonane (CXXIX)[173,174]:



(LXXXIX) (CXXIX) (CXXX)

In the reaction with polyphosphoric acid the intermediate cation is stabilised after the dissociation of the C_3–C_4 bond not only by the formation of a new C–N bond but also by the elimination of the proton from C_5. In the latter case a product resulting from the opening of the quinuclidine ring is formed: the amide of Δ^3-dehydropiperidine-*N*-acetic acid (CXXX).

The same products of quinuclidine ring expansion or opening arise also on treatment of 3-quinuclidone with hydrazoic acid under the conditions of the Schmidt reaction[175]. However, in the latter case the process is largely displaced towards the monocyclic amide (CXXX).

When the oxime of 3-quinuclidone reacts with arenesulphonyl chlorides in an alkaline medium, *N*-substituted 4-cyanopiperidines are formed[176,177].

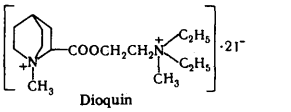
IV. BIOLOGICAL PROPERTIES OF QUINUCLIDINE DERIVATIVES

There have been mainly two aspects to the study of the biological properties of quinuclidine derivatives: on the one hand natural alkaloids, their synthetic analogues, and reaction products were investigated and on the other the characteristics of the pharmacological activity of compounds associated with the presence of the quinuclidine ring were elucidated. In the present review it is probably useful to consider only the investigations of the second type, since, as mentioned above, a number of reviews are available on the biological activity of the quinuclidine alkaloids.

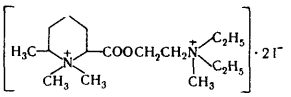
The first study on the pharmacological activity of unsubstituted quinuclidine was carried out by Stern in 1941.[178] In experiments on animals, it was shown that the hydrochloride of unsubstituted quinuclidine exhibits appreciable hypotensive activity and relaxes the smooth musculature, while the corresponding quaternary ammonium salts show a curare-like activity. In the course of subsequent systematic studies of quinuclidine and other 1-azabicycloalkane derivatives in the USSR under the direction of M. V. Rubtsov, synthetic methods were developed and a large number of compounds of this series were obtained and subjected to biological tests. The study of the pharmacological properties of quinuclidine and other 1-azabicycloalkane derivatives carried out under the direction of M. D. Mashkovskii revealed the high activity of compounds of this kind and led to the discovery of effective medicinal preparations, which have found application in medical practice[130,179-182].

The experimental investigation of aminoalkyl esters of quinuclidinecarboxylic acids and their halogenoalkylate derivatives and also tertiary amines of the 2- and 3-monosubstituted and 2,3-disubstituted quinuclidine series led to the discovery of preparations which interfere with the transmission of nervous excitation in ganglia[130,183]. Thus ethyl quinuclidine-3-carboxylate shows a nicotine-like activity and 2-diethylaminoethylaminomethylquinuclidine and other similar tertiary amines suppress the excitation in ganglia. The most active ganglion-blocking agents proved to be the quaternary derivatives of dialkylaminoethyl esters of quinuclidine-2- and quinuclidine-3-carboxylic acids. The di-iodomethylate of the diethylaminoethyl ester of quinuclidine-2-carboxylic acid (CXXXI), which was called Dioquin, is one of the most powerful modern ganglion-blocking agents[184-188]. Substances with similar activity, namely the di-iodomethylate of the dimethylaminoethyl ester of quinuclidine-3-carboxylic acid and the di-iodomethylate of the dimethylaminoethyl ester of quinuclidine-2-carboxylic acid, i.e. the dimethyl analogue of Dioquin, are three times more active than Dioquin itself. In subsequent studies of the relation between chemical structure and biological activity it was established that the ganglion-blocking activity persists on going over from the bicyclic quinuclidine system to the monocyclic piperidine system: the di-iodomethylates of the dimethylaminoethyl (CXXXII) and diethylaminoethyl (CXXXIII) esters of 1,6-dimethylpipecolic acid, called Dimecoline and Dicoline[189-196], have been introduced into the medical practice in the USSR as active ganglion-blocking agents for the treatment of hypertonia, stomach ulcers, bronchial asthma, and many other diseases. The introduction into the molecule of the active compound of various branched dialkylaminoalkyl chains instead of the dialkylaminoethyl substituents lowers the ganglion-blocking activity of these substances[197].

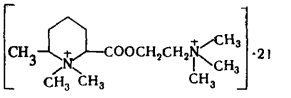
It is interesting to note that the ganglion-blocking activity of secondary-tertiary amines of the type of 2-benzylaminomethyl-3-(β-benzylaminoethyl)quinuclidine (CXXXIV) is closely associated with the presence of the bicyclic quinuclidine system in the molecule in contrast to the analogous activity of the quaternary salts of aminoalkyl esters of quinuclidinecarboxylic acid. In this case, on going over to compounds without the quinuclidine ring, the effect on the ganglia of the vegetative nervous system disappears.



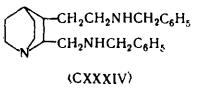
Dioquin
(CXXXI)



Dicoline
(CXXXIII)

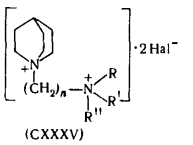


Dimecoline
(CXXXII)

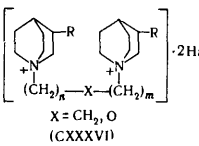


(CXXXIV)

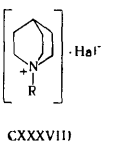
In the search for ganglion-blocking and curare-like preparations diquaternary salts in which one [as in compound (CXXXV)][198,199] or both [as in compound (CXXXVI)][200-202] quaternary nitrogen atoms linked by the alkylidene chain are constituents of the quinuclidine ring were synthesised and tested together with 1-alkylquinuclidinium halides[203] (CXXXVII, R = Alk) and *N*-aminoquinuclidinium salts (CXXXVII, R = NH_2)[204]:



(CXXXV)

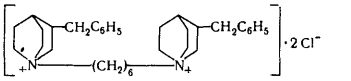


X = CH_2, O
(CXXXVI)



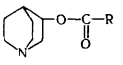
CXXXVII)

The most pronounced curare-like properties were found in the dichloride of 1,6-di-(3′-benzylquinuclidin-1′-yl)hexane (CXXXVIII), which has been introduced in the USSR medical practice under the name of Qualidyl[200,202] as a curare-like preparation with a competitive activity:

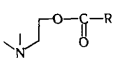


Qualidyl
(CXXXVIII)

The esters of 3-hydroxyquinuclidine (CXXXIX), which are bicyclic analogues of the esters of 2-dialkylaminoethanol (CXL), were found to have interesting pharmacological properties:



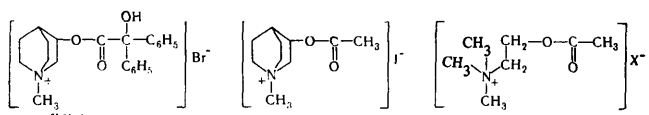
(CXXXIX)



(CXL)

Many esters formed by 2-dialkylaminoethanols with various carboxylic acids are known to have neurotropic properties. The first studies by Sternbach, Kaiser, and coworkers[103,146-148,164] already showed that the esters of 3-hydroxyquinuclidine and aromatic acids (benzilic, tropic, etc.) caused the relaxation of the smooth musculature.

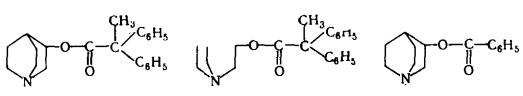
Almost at the same time Duschinsky[149] showed that carbamic esters of 3-hydroxyquinuclidine have a similar effect. The bromomethylate of the benzilate of 3-hydroxyquinuclidine (CXLI), called Clidinium bromide (Quartzan bromide or Marplan) has found application in the medical practice of the USA and of many other countries as a cholinolytic agent[205-211]:



clidinium bromide

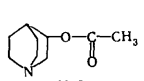
(CXLI) (CXLII) (CXLIII)

A systematic study of the pharmacological properties of the esters of 3-hydroxyquinuclidine and related compounds was carried out by Mashkovskii and coworkers[179,180]. In the first place the iodomethylate of 3-acetoxyquinuclidine (CXLII), which is a bicyclic analogue of acetylcholine (CXLIII), was investigated. The compound exhibited a cholinomimetic activity but its action was weaker than that of acetylcholine. The corresponding tertiary amine, 3-acetoxyquinuclidine, which, in contrast to acetylcholine, shows a more selective effect on muscarine receptors and readily penetrates through the haematoencephalic barrier, is an effective cholinomimetic agent. The salicylate of 3-acetoxyquinuclidine (CXLIV), called Aceclidine[181,212,213] is used in the USSR and a number of other countries in ophthalmology for the treatment of glaucoma and also in surgical and obstetric and gynaecological practice as a means of combating postoperative atonia of the organs in the abdominal cavity, including the postnatal atonia of the mother. Further studies showed that the cholinomimetic activity of Aceclidine is to a considerable degree associated with the presence in the molecule of the quinuclidine ring[151,214,215] and the replacement of 3-hydroxyquinuclidine and other similar bicyclic or monocyclic amino-alcohols results in a reduction or complete loss of activity:



aprolidine (CXLV) aprophene (CXLVI) oxilidine (CXLVII)

The cholinomimetic activity also falls when an alkyl group is introduced in the 6- and 8-positions of the quinuclidine ring. The replacement of the acetyl group in Aceclidine by the residues of homologous aliphatic acids leads initially to a decrease of the cholinomimetic activity (propionic ester) and then to the appearance of cholinolytic properties (butyric and isovaleric esters). The esters of 3-hydroxyquinuclidine and aliphatic–aromatic acids are also powerful cholinolytic agents. For example, the diphenylpropionate of 3-hydroxyquinuclidine (CXLV) (Aprolidin)[216-218] greatly surpasses[219] in its effect on the central and peripheral choline-reactive systems the analogous ester of 2-diethylaminoethanol (CXLVI) [known in the USSR as Aprophen]:



$C_7H_6O_3$

Aceclidine

(CXLIV)

The esters of 3-hydroxyquinuclidine with aromatic acids have a calming effect on the central nervous system. For example, the hydrochloride of 3-benzoyloxyquinuclidine (CXLVII), employed in the USSR under the name of Oxylidine[182,220-226] has a very pronounced sedative activity. Oxylidine is particularly effective in nervous breakdowns associated with the failure of blood circulation in the brain. At the same time Oxylidine also exhibits a hypotensive activity and has found application in the therapy of hypertonia. It is noteworthy that, as in the case of Aceclidine, the high biological activity of other 3-hydroxyquinuclidine esters is also associated with the presence in their molecules of the azabicyclic quinuclidine system. This is confirmed by the weakening of the pharmacological activity in the corresponding esters of 3-hydroxypiperidines and the esters of the completely open-chain type related to 3-hydroxyquinuclidine (*N*-alkyl-*N*-cycloalkylaminoethanols) and also by the lowering of pharmacological activity on going over to analogous esters of other 1-azabicycloalkanols. Possibly the higher activity of 3-hydroxyquinuclidine derivatives, compared with that of the analogous derivatives of other mono- and bi-cyclic amino-alcohols is associated with the characteristics of the quinuclidine molecule, noted above, in which the unshared electron pair of the nitrogen atom is not hindered.

The more ready interaction of the free electron pair of the nitrogen atom in the quinuclidine ring with electrophilic centres of the corresponding receptors in the organism is responsible, according to some workers[227], for the higher psychotropic activity of the benzilic esters of 3-hydroxyquinuclidine compared with the esters of other *N*-substituted amino-alcohols. The low probability of intramolecular bonds and interactions in 3-hydroxyquinuclidine esters, where the acyl component of the molecule and the free electron pair of the nitrogen atom are oriented in different directions, has also been noted. Probably further studies will lead to a more complete elucidation of the effect of the characteristics of the chemical behaviour of the quinuclidine molecule, its conformation, the nature of the free electron pair of the nitrogen atom, etc. on the physiological activity of various quinuclidine derivatives and will lead to the discovery of new active compounds.

Ketens *in situ* and Cycloaddition to Them

F.I.Luknitskii and B.A.Vovsi

The review deals with the methods of generation of ketens *in situ*, particularly their reaction behaviour, mainly in cycloaddition to compounds containing multiple bonds. The ways in which ketens are polymerised *in situ*, associated both with the structure of the ketens themselves and the methods of their preparation, are also discussed. The bibliography incorporates 102 references.

4. Cyclic di- and tri-merisation 492

1. INTRODUCTION

More than 60 years have elapsed since the first mention of ketens in papers by Wilsmore[1] and Staudinger and co-workers[2], and yet at present only a few stable representatives of this class of compound have been isolated in a pure state: keten itself, dimethyl-, diphenyl-, and perfluoro-dimethyl-ketens, and certain others. Monosubstituted ketens are particularly difficult to prepare.

At the same time the number of ketens which have not been characterised in a free state but are used as intermediates (*in situ*) is much greater. Because of their high reactivity, ketens are of considerable interest for organic synthesis both in the laboratory and in industry. For this reason, several reviews have been devoted to the chemistry of ketens (mainly to the simplest of them)—the reviews of Lacey[3], Kagan[4], and somewhat earlier Hanford and Sauer[5] and Quadbeck[6]. A recent review by Dashkevich and Beilin was devoted to the chemistry of carbon suboxide.

However, none of the authors enumerated above dealt with the problem of the reactivity (and also a systematic account of the data concerning the methods of generation) of ketens *in situ*, which sometimes differs from the reactivity of ketens isolated in a pure state even in the same reactions.

The aim of the present review is to give a general account of the literature information (up to 1967 inclusive) on the methods of generation of ketens *in situ* and their participation in cycloaddition reactions†. The review is restricted to only this type of reaction because it is precisely in these reactions that the specific reactivity of keten *in situ* is shown most markedly. In this connection di- and tri-merisation are also discussed, but the reactivity of the dimers themselves, which has been described fairly completely in the available reviews on the chemistry of diketen, is consistently disregarded.

An exception to this principle is made in the present review only under discussion of the mechanism of addition to ketens (including ketens *in situ*) where it is possible for a better understanding of the problem to give a more general account also of certain other addition reactions of ketens apart from cycloaddition.

† The term "cycloaddition" is employed by the present authors in view of its wide use in the chemical literature, instead of the term "cycloformation" which they believe to be more correct.

We also believe it to be desirable to restrict the discussion of ketens formed as intermediates as a result of the Wolff rearrangement[8] in the photolysis and thermolysis of diazo-carbonyl compounds exclusively to reactions involving cycloaddition to these ketens *in situ*, particularly since, when the Wolff rearrangement is carried out in an aprotic medium, certain ketens can be isolated and characterised in a pure form[9,10].

The review also does not deal with the structural analogues of ketens, for example sulphenes *in situ*, the chemistry of which was dealt with in a recent review by Opitz[11].

2. METHODS OF GENERATION OF KETENS IN SITU

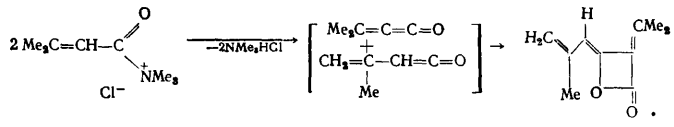
One of the early and most widespread methods for the generation of ketens *in situ* is the elimination of hydrogen halides from acid halides with a hydrogen atom in the α-position under the action of strongly basic tertiary amines[12,13]:

$$\text{>CH—C(=O)Cl} + \text{Alk}_3\text{N} \rightarrow [\text{>C=C=O}] + \text{Alk}_3\text{NHCl}.$$

However, this method has not been used for a long time, since initially only diphenylketen could be isolated in monomeric form and used further for preparative purposes. Other ketens formed by this method underwent di- and tri-merisation before isolation. Only in recent years have attempts been resumed to find preparative applications of ketens *in situ* using various "intercepting" components. By dehalogenating the halides of mono- and di-substituted acetic acid, it proved possible to generate and introduce into further reactions many ketens which have not been described in a pure state. For example, after unsuccessful attempts by Staudinger[14] to isolate dichloroketen by the thermolysis of dichloromalonic anhydride, there was no further information in the literature about the participation of this keten in any reactions until in 1965 Stevens et al.[15] obtained dichloroketen as an intermediate from dichloroacetyl chloride and a trialkylamine in the presence of cyclopentadiene as an "interceptor" of keten *in situ*. Hull obtained difluoroketen by a similar procedure[16]. Since this method of generation of ketens *in situ* has been extended to reactions of tertiary amines with acid dichlorides of the type $ClCO-(CH_2)_n-COCl$, the intermediate bisketens also became available[17-21].

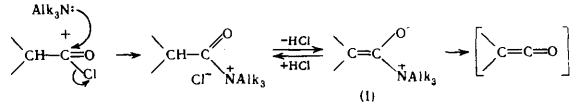
The intermediate formation of ketens in the interaction of tertiary amines with the chlorides of $\alpha\beta$-unsaturated

acids is unlikely, since in this case the α-hydrogen atom is by no means as labile as in substituted acetylchloride. Nevertheless the formation of a β-lactone in the solvolysis of a quaternary salt obtained from the chloride of dimethylacrylic acid and trimethylamine is evidence, according to Payne[22], of the intermediate formation of ketens, which are then further dimerised:



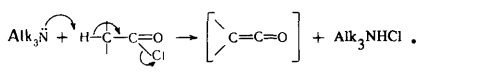
The mechanism of the interaction of acid chlorides with tertiary amines has not been the subject of a special investigation. However, since it proved possible to isolate the adducts of acid halides with weakly basic tertiary amines (pyridine, *NN*-dialkylanilines, etc.), it was suggested[13], by analogy, that the reaction of acid halides with strongly basic amines also involves the formation of a quaternary salt of the type $Alk_3\overset{+}{N}COR\,Cl^-$.

According to Pracejus[23], keten is formed from this quaternary salt via an intermediate dipolar compound (I) of keten with trialkylamine:



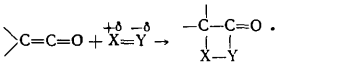
(I)

This mechanism of the formation of intermediate ketens from quaternary ammonium salts, analogous to the Hofmann degradation, is one of several which are possible. On the other hand, intermediate ketens can be obtained also without the preliminary formation of quaternary salts from acid chlorides and amines—by an E_2 bimolecular elimination mechanism:

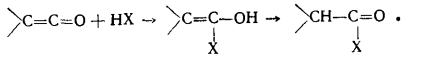


The problem of which of these two mechanisms actually occurs in the interaction is important for the elucidation of the mode of the secondary process—the addition of the "interceptor" reagent to the C=O or C=C bond of the intermediate keten, provided a stabilised keten is not formed in the reaction.

Nevertheless this aspect too remained fairly obscure for a long time, i.e. as regards the mode of reactions involving additions to stable ketens. Most investigators regarded the addition to the C=C bond of ketens and the addition to the C=O bond with subsequent isomerisation to the product of addition to the C=C bond as equally probable[24-26]. Mueller[27], who summarised the various views, suggested that reagents containing multiple bonds (C=C, C=O, C=N, N=N,) etc., add to ketens at their C=C bond with formation of cycloadducts:

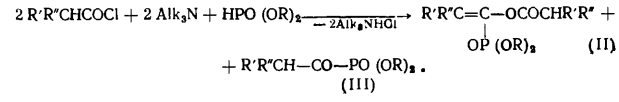


Reagents without multiple bonds, mainly substances with a mobile hydrogen atom (water, amines, alcohols, acids) add to ketens at their carbonyl group with possible (but not obligatory) subsequent isomerisation of the vinyl alcohol to a carbonyl derivative:



In some cases it is possible to acylate the intermediate vinyl alcohol by a second keten molecule, whereupon of course isomerisation does not occur. Hydrocyanic acid[28], Gringard reagents[29], lithium tetrahydroaluminate[30], and dialkyl phosphites[31,32] add to the carbonyl group of keten in this way.

The intermediate ketens from acid chlorides and tertiary amines probably also enter into addition reactions both at the C=C and C=O bonds. For example, addition to the C=O bond is observed in the interaction of dialkyl phosphites with mono- and di-substituted acetyl chlorides in the presence of triethylamine[33]:



(II)

(III)

When R′ = R″ = H and R = CH_3, the yields of compounds (II) and (III) are 70 and 16% respectively. The formation in this case of α-oxophosphonic esters (III) together with the acyloxyvinyl adduct (II) can be explained both by addition to the C=C bond of the intermediate keten *in situ* and by the isomerisation of the vinyl alcohol derivative, which may occur at the same time as the acylation of the hydroxy-group of a second keten molecule *in situ*; finally, the formation of compounds (II) and (III) may be caused by the difference in the rates of addition of the vinyl alcohol derivative and dialkyl phosphite to the C=C bond of a keten *in situ*.

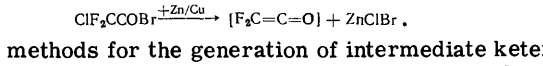
Although the method of generation of ketens *in situ* discussed has found wide application, it is not universal. Unsuccessful attempts to intercept many potential ketens without their preliminary isolation from the reaction mixture can probably be explained by the short lifetime of the intermediate ketens in monomeric form or by the low rate of interception of ketens *in situ*, as a result of which the principal reaction products are often resinous oligomers or at best keten dimers and trimers.

The fluoride of hexafluoroisobutyric acid reacts with triethylamine in quite a different way[34]. Neither the hydrofluoride of triethylamine, nor perfluorodimethylketen (known in a pure state), nor the product of its oligomerisation are formed, fluorophosgene and a complex adduct with the amine being isolated. In the presence of an alkyl halide RX, the corresponding triethylammonium halide is obtained, but not the fluoride, the formation of which might confirm indirectly the intermediate generation of the keten:

Among other methods for the generation of ketens *in situ*, the dehalogenation of α-halogeno-acid halides, for example with the aid of zinc activated with copper[35-37], is of practical interest. The bromides of trihalogenoacetic acids in a solvent inert with respect to ketens (ether, ethyl acetate) enter into this reaction most readily:

where X = Cl[35], or Br[36].

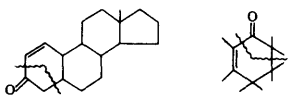
Difluoroketen, which is intercepted with ammonia *in situ* to avoid oligomerisation[37], was obtained similarly:



Other methods for the generation of intermediate ketens with interception *in situ* are also known. For example, Ziegler and Sterk[38] confirmed the intermediate formation of ketens in the thermolysis of β-diketones with the aid of infrared spectroscopy and also subsequent solvolysis:

Ziegler et al.[30] also suggested the intermediate formation of ketens in the dehydration of benzylmalonic acid with acetic anhydride.

The formation of ketens following the electron bombardment of conjugated cyclohexenones has been observed mass-spectrometrically[40] (the wavy line indicates the keten fragment formed):



According to Schneibaum[41], the oxidation of certain acetylenes with nitrobenzene is accompanied by the intermediate formation of ketens, which are intercepted *in situ* by solvolysis:

$$C_6H_5NO_2 + -C\equiv C- \rightarrow C_6H_5NO + \left[\rangle C{=}C{=}O\right] \rightarrow \text{solvolysis products.}$$

A "keten" mechanism has also suggested[42] for the reaction of substituted acetylenes with per-acids; according to this view, the hypothetical acetylene α-oxide rearranges to a keten, which undergoes solvolysis *in situ*:

$$RCO{-}OOH + -C\equiv CR' \rightarrow \underset{\diagdown O \diagup}{-C=\!=C-R'} \xrightarrow{H^+} \left[R'{-}\underset{|}{C}{=}C{=}O\right].$$

We believe that the intermediate formation of ketens in this reaction can be explained also in a different way—by the oxidation of acetylene to alkyn-1-ol with subsequent El'tekov rearrangement:

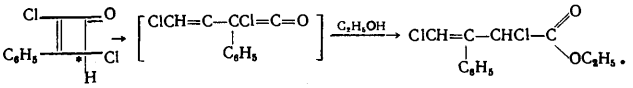
$$RCO{-}OOH + -C\equiv C{-}R' \rightarrow HO{-}C\equiv C{-}R' \rightarrow [O{=}C{=}CH{-}R'].\quad ‡$$

Such a mechanism can explain satisfactorily the intermediate formation of monosubstituted ketens only, while the mechanism proposed by Stille and Whitehurst[42] is suitable also for disubstituted ketens *in situ*.

Richard[43] suggested the intermediate generation of a keten to account for the conversion of α-halogeno-ketones into acids in the course of the Favorskii rearrangement:

$$ArCHClCOR \rightarrow [ArRC{=}C{=}O] \xrightarrow{H_2O} ArRCHCOOH.$$

In the alcoholysis of optically active dichlorophenylcyclobutenone, Jenny and Roberts[44] isolated a racemic ester:

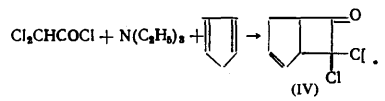


They explained the racemisation by the intermediate formation of a keten in which the asymmetric carbon atom of the initial keten ceases to be asymmetric by virtue of its transition to an sp^2-hybridised state.

3. CYCLOADDITION OF KETENS *IN SITU*

a. Cycloaddition to the C=C Bond

Activated olefins, for example, cyclic dienes are used as a rule to intercept ketens *in situ*. Products of 1,2-cycloaddition are then formed in high yield. Thus the intermediate formation of dichloroketen from dichloroacetyl chloride and triethylamine was confirmed for the first time, and the use of cyclopentadiene[15] as an "interceptor" permitted the synthesis of 7,7-dichlorobicyclo[3,2,0]hept-2-en-6-one(IV)



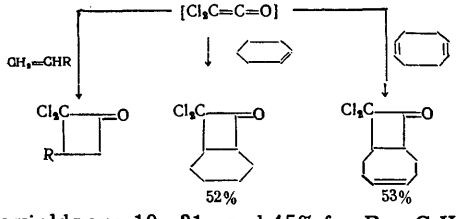
Further reactions of compound (IV) led to a new synthesis of tropolone.

The corresponding bicyclic dibromo-analogue was synthesised[36] similarly, both dehalogenation of tribromoacetyl bromide with zinc and the reaction of dibromoacetyl chloride with triethylamine being used for the generation of the intermediate dibromoketen.

Monosubstituted intermediate ketens add *in situ* to cyclic dienes by the same mechanism[45].

Non-activated olefins also react with ketens *in situ* forming cyclic products, electrophilic substituents in the keten molecules favouring its interception by the olefin.

For example, dichloroketen reacts more vigorously *in situ* than does dimethylketen under the same conditions. Cyclopentene[46], cyclohexene[47], cyclo-octadiene[47], styrene[47], and ethyl vinyl ether[47] are used as "intercepting" agents. In all cases cyclobutanones are formed. The yields of the corresponding reactions involving the interception of dichloroketen *in situ* are given below:

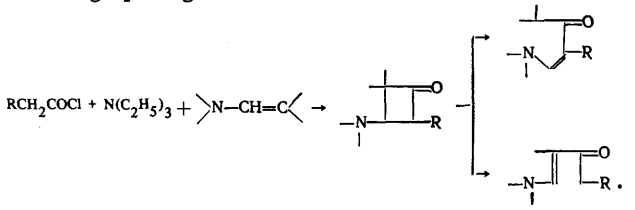


where the yields are 19, 31, and 45% for R = C_6H_5, C_3H_7, and OC_2H_5 respectively.

The choice of the method of generation of intermediate ketens in the presence of olefins is determined both by the nature of the olefin and the activity of the keten and the duration of its existence as a monomer. In the case of olefins which are not polymerised in the presence of zinc halides, the method of generation of ketens *in situ* by the dehalogenation of α-halogeno-acid halides is suitable. Otherwise, for example, when vinyl ethers are used as interceptors for ketens *in situ*, the method of generation based on the reaction of substituted acetyl chlorides with trialkylamines is more convenient, provided of course that the ketens themselves are not polymerised *in situ* in the presence of the amine and (or) its hydrochloride at a rate comparable to the rate of interception[5,47].

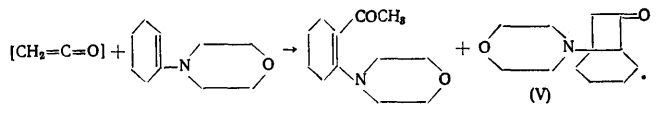
It has been mentioned[48] that the addition of dichloroketen *in situ* to indene (in a yield of 12%) leads to the formation of the corresponding 4,5-benzotropolone as a result of further reaction of the adduct.

Enamines add to aldoketens *in situ* with formation of β-aminocyclobutan-2-one derivatives which can be converted, under the reaction conditions, into acyclic amide vinylogues with ring opening:



‡ $RCO{-}OOH + -C\equiv C{-}R' \rightarrow H{-}O{-}\overset{H^+}{C}\equiv C{-}R' \rightarrow [O{=}C{=}CH{-}R']$ (Ed. of Translation).

In the reactions of ketens *in situ* with 1-morpholinocyclohexene (as the interceptor), the presence in the reaction mixture of a bicyclic addition product (V) has been confirmed[49] by infrared spectroscopy, but 2-acetyl-1-morpholinocyclohexene was isolated as the main product:

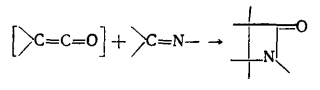


(V)

b. Cycloaddition to Multiple Carbon–Nitrogen Bonds

The addition of stable ketens to reagents containing a double or triple carbon–nitrogen bond can be achieved successfully only under very severe conditions and only a highly polarised C=N bond takes part in the reaction.

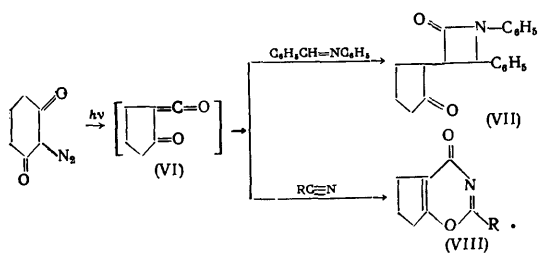
In contrast, ketens *in situ* add to both C=C and C=N bonds under mild conditions with formation of cyclic products. The addition of intermediate ketens to azomethines leads to the formation of β-lactans[50]:



The synthesis of β-lactams by cycloaddition to ketens *in situ* has been widely investigated[51-54] in connection with its employment for the synthesis of penicillins, the molecules of which contain condensed β-lactam rings. The chlorides of phthaloyl and succinyl glycine, which are introduced into the reaction with triethylamine in the presence of the corresponding azomethines, are used as a source of ketens in this case.

The photolysis of β-diazocarbonyl compounds[55] is also used for the synthesis of α-lactams via ketens *in situ*[55]. It has been noted that ketens with electronegative substituents (for example, *p*-chloro- and *p*-nitro-phenylketens) enter into the cycloaddition reaction at the C=N bond of the intercepting agent either with difficulty or do not react at all (in contrast to the effect of substituents of the same type on the cycloaddition of ketens *in situ* to olefins).

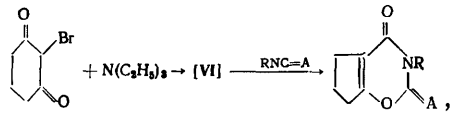
Intermediate α-oxoketens have a marked tendency to undergo 1,4-cycloaddition of reagents with multiple bonds[56], but in the reaction with anils 1,2-cycloadducts are nevertheless formed, albeit in a low yield. For example, β-oxoketen (VI) reacts *in situ* with benzylidene-aniline, forming a β-lactam(VII):



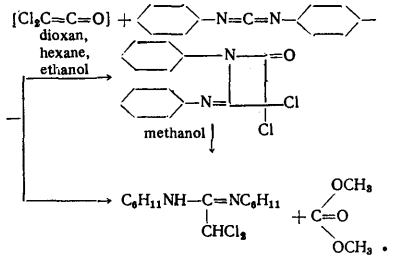
(VI) (VII) (VIII)

On the other hand, in the reaction of the keten (VI) *in situ* with nitriles a 1,4-cycloaddition product is formed—a condensed oxo-1,3-oxazine (VIII).

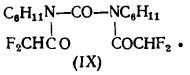
The reactions of the intermediate keten (VI) with isocyanates and isothiocyanates has been investigated by Selvarajan et al.[57], ketens being generated *in situ* by the reaction of triethylamine with 2-bromocyclohexa-1,3-dione;



where A = O or S, and



Difluoroketen reacts *in situ* with carbodi-imide forming acylated dicyclohexylureas (IX)[16]:



(IX)

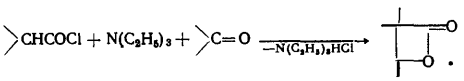
In this case the 1,4-cycloaddition product is obtained in a yield of the order of 25%.

Hull[16] noted that carbodi-imides add to ketens *in situ* with the cleavage of only one C=N bond; if the process is carried out in boiling dioxan, hexane, or ethanol the 1,1-adduct is a β-lactam, but if the solvent is methanol the final reaction product is a substituted dichloroacetamidine produced, according to the author, as a result of the solvolysis of the β-lactam formed initially.

c. Cycloaddition to the Carbonyl Group

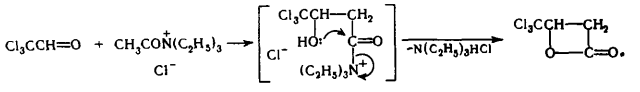
Stable ketens add to the carbonyl group of aldehydes and ketones with formation of β-lactones. These reactions take place only in the presence of various catalysts, which polarise the carbonyl group of the aldehyde or ketone. As a rule such catalysts are Lewis acids[3,58-61]. Evidently catalysts of this type are unsuitable for the reactions *in situ* of aldehydes or ketones with ketens generated by the action of trialkylamines on acid chlorides, since the Lewis acids would be immediately neutralised by the amines. Therefore, in the synthesis of β-lactones via ketens *in situ*, generated in this way, only highly polarised carbonyl components which do not require additional activation by a catalyst are employed as interceptors.

Thus β-trichloromethyl-β-propiolactone was synthesised[62] in 92% yield from acetyl chloride, triethylamine, and chloral. The replacement of acetyl chlorides by methanesulphonyl chloride made it possible to synthesise the corresponding β-sultone derivative[63]. Borrmann and Wegler[64] showed that this synthesis of β-lactones is general. The authors used the chlorides of acetic, dichloroacetic, and ring-substituted phenoxyacetic acids for the generation of the intermediate ketens and polyhalogeno-substituted aldehydes and ketones as intercepting agents:



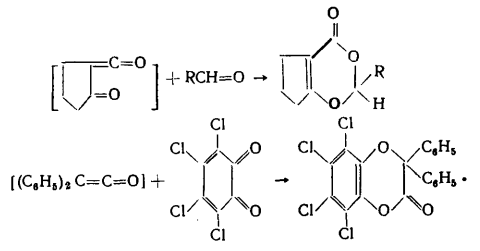
When optically active highly basic tertiary amines (for example brucine) are used for the generation of ketens *in situ*, it is possible to obtain[65] optically active β-lactones with one or two asymmetric carbon atoms.

Although at first sight the "keten" mechanism of the synthesis of β-lactones from substituted acetyl chlorides and tertiary amines in the presence of carbonyl intercepting agents appears to be the most likely, we believe that this process can also be explained in a different way[66], omitting the intermediate generation of the keten. Thus it may be supposed that the quaternary salt formed by reaction of the amine with the acid chloride, which has a hydrogen atom with enhanced lability in the α-position relative to the carbonyl, adds initially to the highly polarised carbonyl group of the intercepting agent; subsequently the alcoholic hydroxyl is acylated intramolecularly with the elimination of triethylamine hydrochloride and the closure of the β-lactone ring (shown below in the synthesis of β-trichloromethyl-β-propiolactone as an example:



This mechanism is supported, for example, by the fact that the yield of diketen in this reaction is negligible, becoming zero at sufficiently high dilution. Nevertheless, as will be shown below, the dimerisation of ketens *in situ* is strongly catalysed by tertiary amines and their salts. This should undoubtedly result in a decrease of the yield of β-lactone if an intermediate keten forms in the reaction. On the other hand, the absence from the reaction medium of diketen as a side product can be accounted for by the lower rate of its formation from the keten *in situ* compared with the rate of interception of the latter by the carbonyl compound. This view is confirmed by the finding that the yields of other β-lactones (except β-trichloromethyl-β-propiolactone) are not so high[64] although the formation of keten dimers as side products is not reported.

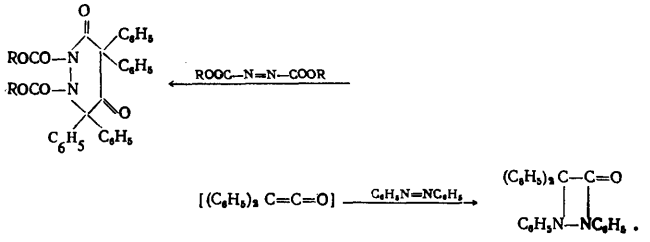
So far there is no convincing evidence in favour of any one of the mechanisms of the synthesis of β-lactones from acid halides, trialkylamines, and carbonyl compounds discussed above. On the other hand, when other methods are used for the generation of intermediate ketens in the presence of carbonyl compounds, β-lactones are not formed. Thus, when ketens are generated *in situ* by the thermolysis or photolysis of α-diazo-carbonyl compounds in the presence of aldehydes[56] or quinones[67,68], only 1,4-cycloaddition products having the structure of oxodioxans are isolated:



It is noteworthy that such a comparison of the reactivity of ketens generated *in situ* by two different methods in the presence of aldehydes is not entirely valid, since in the examples quoted the ketens, whose formation was suggested, have different structures; furthermore carbonyl compounds with insufficiently polarised carbonyl groups were employed as intercepting agents in these investigations[56,67,68]. This probably in fact accounts for the preferential 1,4-cycloaddition rather than 1,2-cycloaddition.

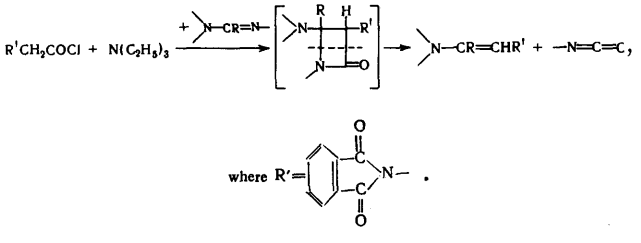
d. Cycloaddition to the N=N Bond

The cycloaddition of stable ketens, for example diphenylketen, to azo-compounds is achieved only on ultraviolet irradiation with formation of 1 : 1 adducts having the structure of 1,2-diazacyclobutan-3-one[69,70]. In contrast, the reaction of azo-compounds with the intermediate diphenylketen generated *in situ* by the photolysis of α-diazocarbonyl compounds leads to both 1 : 1 [71] and 2 : 1 [68] adducts:

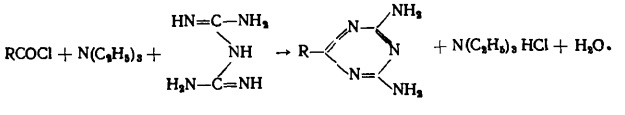


e. Cycloaddition to Amidines, Guanidines, and Urea Derivatives

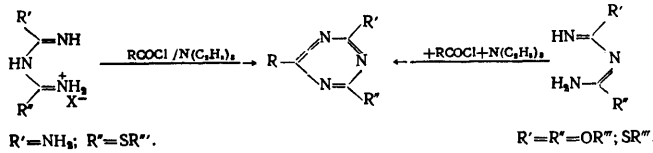
The addition *in situ* of intermediate ketens to amidines fully substituted at the nitrogen atom probably takes place at the C=N bond with formation of β-lactams[72]; the authors believe that further degradation of the lactams in fact results in the formation of the final products—an enamine and an isocyanate; in this case the reaction of the chloride of phthaloylglycine with triethylamine was employed to generate the keten; in the presence of azomethines, the reaction[51-54] (see preceding page) led to the formation of β-lactams in high yields:



When acid chlorides react with diguanidine in the presence of triethylamine, derivatives of 1,3,5-triazine are formed[73,74]:



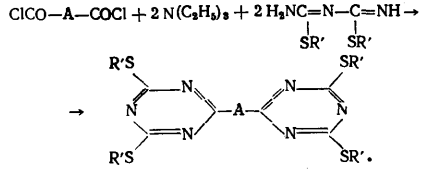
The corresponding 1,3,5-triazines are produced also when derivatives of biuret and dithiobiuret and *S*-alkylguanylisothiuronium salts are used as the intercepting agents[75]:



However, it should be noted that not only the chlorides of mono- and di-substituted acetic acids, in which a hydrogen atom is retained in the α-position, but also the halides

of acids lacking the capacity to serve as a source of intermediate ketens, for example trichloroacetyl chloride, substituted benzoyl chlorides, and the chlorides of $\alpha\beta$-unsaturated acids, were used in these reactions. These findings suggest that the synthesis of trazines under conditions of this kind may not in fact be accompanied by the formation of ketens as intermediate structures.

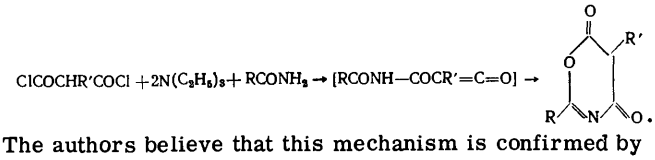
The interaction of dicarboxylic acid chlorides with triethylamine in the presence of dithiobiuret derivatives leads to the formation of the corresponding bistriazines [75]:



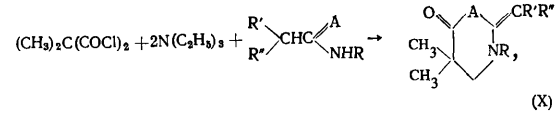
When A = $(CH_2)_n$, this process may be accompanied by the intermediate formation of a keten or a bisketen, while with

intermediate ketens are not formed.

Ziegler and coworkers [76,77] proposed a "keten" mechanism for the synthesis of dioxo-1,3-oxazines by the interaction of unsubstituted or monosubstituted malonic acid chlorides with amides in the presence of triethylamines:

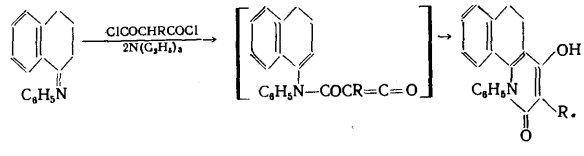


The authors believe that this mechanism is confirmed by the fact that they were unable to achieve analogous reactions with disubstituted malonyl dichlorides. However, some time later Martin et al. [78] synthesised successfully a number of derivatives of 1,3-oxazine, 1,3-thiazine, and pyrimidine (X) by the interaction of disubstituted malonyl dichlorides with amides, thioamides, and amidines in the presence of triethylamine:

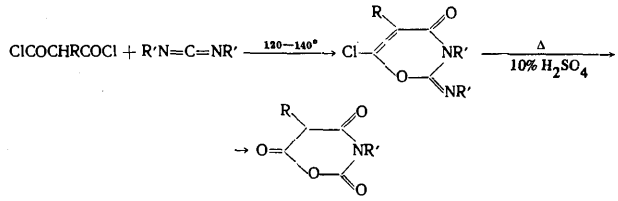


(X)

where A = O, S, or NR'''. Of course in this case the intermediate formation of a keten cannot occur. Furthermore in the reaction of butyramide with dimethylmalonyl dichloride the derivative of dioxo-1,3-oxazine (X, A = O, R' = R'' = CH_3, are obtained both in the presence [in this case R = $COCH(CH_3)_2$] and in the absence (R = H) of triethylamine. However, the formation of ketens in the reaction of monosubstituted malonyl dichlorides with tertiary amines is confirmed not only by the formation of 2-pyridones when ketimines and azomethines are employed as "interceptors" but also by infrared spectroscopic data [79-81]:



It is suggested [82] that the synthesis of barbituric acids by the cycloaddition of monosubstituted malonyl dichlorides to carbodi-imides also takes place by a "keten" mechanism:



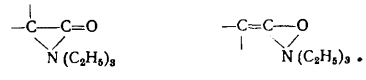
where R = H or alkyl and R' = H or C_6H_5.

4. CYCLIC DI- AND TRI-MERISATION

Reactions involving cycloaddition to ketens *in situ* are complicated by their polymerisation, which is usually limited to di- and tri-merisation. These side processes are most significant in the generation of ketones from acid chlorides under the action of trialkylamines.

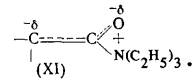
Even in the early studies by Staudinger [83,84] it was noted that stable ketens polymerise in the presence of tertiary amines. It would appear that this must be an indication of the interaction of ketens with trialkylamines, but there is still not single view concerning the nature of this interaction.

Wedekind [85,86] isolated in low yields weakly basic compounds which, according to their composition, appeared to be the products of the addition of triethylamine to keten in proportion of 1 : 1 ("ketenium" compounds) or 2 : 1 ("ketenates"). The following mesomeric structures with pentavalent nitrogen were attributed to the "ketenium" compounds:



Wedekind's results were not examined further for almost 30 years until Miller and Johnson [87] disproved the existence of the "Wedekind ketenium bases", having shown that the "ketenium" compounds are in fact the diethylamides of the corresponding acids, formed as a result of the presence of an admixture of diethylamine in the initial triethylamine. This accounts for both the low yield of Wedekind's "ketenium" compounds and their "anomalous" (according to Wedekind) reactivity.

Pracejus and Oehme [88] were unable to detect by infrared spectroscopy the interaction of trialkylamines with ketens and the possible structure of the adduct (XI) presented below was rejected on the basis of spectroscopic data:



(XI)

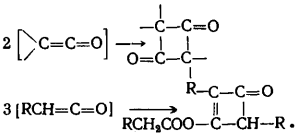
However, subsequent kinetic investigation and the measurement of the isotope effect in the alcoholysis of ketens in the presence of tertiary amines enabled Tille and Pracejus [89] to attribute the structure (XI) to the postulated keten–amine complex.

Di- and tri-merisation of ketens *in situ* is observed in all the methods of their formation without exception [2,3,5,90-92]. The catalysis of these processes by tertiary amines and their salts was investigated in greatest detail [93]. The study of the polymerisation of ketens *in situ* and the dependence of the structure of the keten dimers and trimers on the method of their formation permits controlled synthesis of products with a specified degree of polymerisation [94].

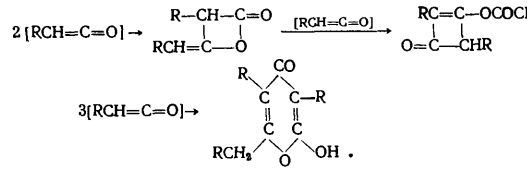
The dimer of the simplest keten (diketen) is obtained in high yield from keten *in situ* in the interaction between acetyl chloride and trialkylamines[93]. It is noteworthy that the rate of dimerisation of keten *in situ* is higher than the rate of dimerisation of the stable keten.

With the aid of modern methods for the investigation of structures (nuclear magnetic resonance[95], isotope methods[96]), it was possible to resolve the long-standing controversy concerning the structure of diketen and to demonstrate that it is a β-lactone:

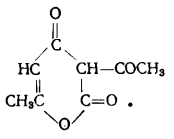
Later it was established[94] that, with the exception of keten itself, which is readily converted into the β-lactone even in the absence of catalysts, other ketens dimerise spontaneously *in situ* to cyclobutane-1,3-diones[95] or trimerise with formation of 3-hydroxycyclobutenone derivatives[97]:



Tertiary amines and their salts catalyse both the dimerisation *in situ* of the intermediate aldoketens, formed in the reaction between acid chlorides and tertiary amines, to β-lactones[98] and their trimerisation to 3-acylhydroxybutenones[99] (with R = alkyl) or pyranones (with R = aryl)[100]:



In addition in the case of an unsubstituted keten formed *in situ* in the interaction between acetyl chloride and triethylamine there is a possibility of further dimerisation of the diketen with formation of a tetramer—dehydroacetic acid (XII)[101]:

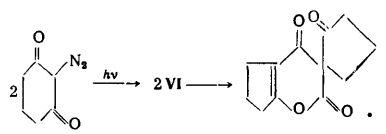


(XII)

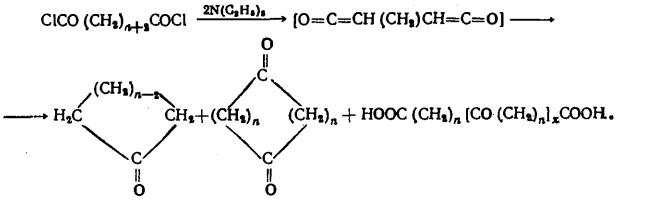
Ketens formed in the dehalogenation of α-halogeno-acid halides with zinc dimerise *in situ* in a different way. Here, the zinc halide formed in the reaction favours the dimerisation of the ketens to β-lactones with both R = alkyl and R = aryl[95].

Ketens derived from α-diazo-carbonyl compounds dimerise *in situ* in the presence of silver and copper catalysts for the Wolff rearrangement with formation of cyclobutane-1,3-diones[68].

Stetter and Kiehs[102] showed that the dimer of the intermediate keten derived from 2-diazodihydroresorcinol is a spiropyranone:



Acid dichlorides of the type $ClCO-(CH_2)_nCOCl$ react with tertiary amines in an unusual way. The intermediate bisketens formed in this case are converted into a mixture of cyclic ketone and diketone; furthermore, the formation of a polymer was observed[17-21] but its structure was not established:



Certain biologically active natural compounds previously difficult to obtain were synthesised by this method (muscone, civetone, and others). The concentration of the reactants plays a decisive role in this synthesis: for example, with sebacyl dichloride cycloketones can be isolated only when the reaction is carried out in highly dilute ethereal solutions.

Phosphorus Hydrides

I.M.Osadchenko and A.P.Tomilov

The chemistry of phosphorus hydrides has assumed considerable importance—phosphine is the starting material for the synthesis of numerous organophosphorus compounds and fire resistant polymers; in recent years phosphorus hydrides have begun to be used in the semiconductor industry for the preparation of metal phosphides with a high degree of purity. The range of applications of phosphorus hydrides has increased in connection with the synthesis of a new class of complex compounds.

The review deals with the physical and chemical properties of the phosphorus hydrides investigated. The methods of synthesis of phosphorus hydrides, particularly phosphine, are examined. The applications of phosphine in industry are discussed. The bibliography comprises 141 references.

CONTENTS

1. Hydrogen phosphide (phosphine) 495
2. Diphosphine 497
3. Solid phosphorus hydrides 498
4. Applications of phosphorus hydrides 498
5. Methods of preparation of phosphine 499

Phosphorus forms the following compounds with hydrogen: PH_3—gaseous hydrogen phosphide (phosphine)[1]; P_2H_4—liquid hydrogen phosphide (diphosphine, biphosphine[1], hydrogen hemiphosphide), and solid hydrogen phosphides [1-5] which include compounds with the empirical formulae $P_{12}H_6$, P_7H_2, P_9H_2, and $(PH)_x$. There is no doubt about the structural formulae of the first two compounds, but no single view exists concerning the structure of the solid hydrides.

1. HYDROGEN PHOSPHIDE (PHOSPHINE)

a. Physical Properties

Phosphine is a colourless gas with an unpleasant smell, sparingly soluble in water (26 volumes of the gas in 100 volumes of water) and readily soluble in carbon disulphide, benzene, cyclohexanol, ether, and other solvents [1-3]. Some of the physical properties of phosphine [2,3] are listed in Table 1. Phosphine has been investigated by infrared, microwave, NMR, and Raman spectroscopy and mass spectrometry [2].

The structure of the phosphine molecule has been established on the basis of infrared and microwave spectra[2]. The molecule has the form of a trigonal pyramid with the phosphorus atom at the apex and has low polarity (dipole moment 0.55 D). All three hydrogen atoms in the molecule are equivalent, with the P–H distance 1.419 Å the height of the pyramid 0.70 Å, and the H–P–H angle 93.7°. [2,3]

The density and compressibility of phosphine have been thoroughly investigated to determine the atomic weight of phosphorus. These data have established that the molecular weight of phosphine is 34.000. Accurate determinations of the density and the compressibility made it possible to establish the deviation of phosphine from ideal gas laws and to derive an equation of state for phosphine vapour [2]. The physical constants of liquid phosphine show [2] that there is some molecular association in the liquid state but that the degree of association is much less than in water.

Comparison with the hydrides of the adjacent elements in the Periodic Table shows that phosphine forms few hydrogen bonds or none at all.

The surface tension of phosphine at −100°C is [2] 22 dyn cm^{-1}. In the solid state phosphine exists in four modifications with transition temperatures of −185.06°, −223.75°, and −242.87°C. Over a short temperature range near the absolute zero the supercooled form has an anomalously high heat capacity. The solution of phosphine in liquid ammonia conducts electricity. When the solution is electrolysed, elemental phosphorus is deposited at the anode[4,5]. Evidently ammonia forms a salt-like compound with phosphine having the probable formula $NH_4^+(PH_2)^-$.

Table 1. Physical properties of phosphine (PH_3).

B.p., °C	Q_{vap}, kcal mole^{-1}	Trouton's constant	ρ, g cm^{-3}	M.p., °C	Q_f, kcal mole^{-1}	$t_{crit.}$, °C	$P_{crit.}$, atm	Q_{form}, kcal mole^{-1}
−87.8	3.49	18.8	1.529	−133.8	0.27	+51	64	+2.29

Phosphine is extremely poisonous and must be handled with care—it is a poison which acts predominantly on the nervous system and interferes with metabolism. The maximum permissible concentration of phosphine in industrial buildings amounts to [6] 0.1 mg m^{-3}.

b. Chemical Properties

When phosphine is heated in the absence of air, it dissociates:

$$4\,PH_{3(gas)} \rightleftarrows P_{4(gas)} + 6H_{2(gas)}.$$

The thermal dissociation of phosphine was investigated in detail by Ipat'ev [7-9] and Frost [10]. At a high temperature the equilibrium is displaced to the right but at low temperatures the gas is quite stable.

The reaction of phosphine with oxygen is a branched-chain process resembling the oxidation of white phosphorus [2,11,12]. Studies on the mechanism of the combustion of phosphine were begun by van de Stadt [12] and the problem was elucidated in detail by Semenov [11].

In air phosphine burns with formation of phosphorus pentoxide:

$$2PH_3 + 4O_2 \rightarrow P_2O_5 + 3H_2O.$$

On considerable rarefaction and particularly in the presence of water vapour, slow oxidation without inflammation, accompanied by the formation of phosphorus acids, may take place [13]:

$$2PH_3 + 3O_2 \rightarrow 2H_3PO_3,$$
$$PH_3 + O_2 \rightarrow HPO_2 + H_2.$$

It has been suggested [14] that the first stage of the slow oxidation is the formation of phosphine oxide PH_3O. However, the latter could not be obtained by direct oxidation of phosphine with nitrobenzene or trimethylamine oxide [10]. The attempt to synthesise phosphine oxide by reducing phosphorus oxychloride and oxybromide with metal hydrides (LiH, $LiBH_4$) in ether at low temperatures was unsuccessful; phosphine oxide was not isolated probably because of its high reactivity, the tendency to polymerise with the elimination of water, and thermal instability at temperatures in excess of $-115°C$.

Since it is a branched chain reaction, the oxidation of phosphine has upper and lower critical pressure limits. Inert gases decrease the lower limit, preventing diffusion to the walls of the vessel, if the pressure of the inert gas is less than that of phosphine or oxygen. Irradiation with ultraviolet light reduces the limiting oxygen pressure [2] through phosphines' forming a substance (possibly atomic hydrogen) which affects the chain reaction. The upper limiting pressure of oxygen in the oxidation of phosphine is independent of the dimensions of the reaction vessel, decreasing somewhat in the presence of an inert gas.

The solution of phosphine in water has virtually no acid or basic properties; however, phosphine hydrate probably does exist. Phosphine dissolved in water gradually decomposes into hydrogen, phosphorus, and a solid phosphorus hydride.

With acids, phosphine forms phosphonium salts. Phosphonium halides can be obtained by the reaction of phosphine with hydrogen halides and the sulphate and perchlorate by the reaction with sulphuric and perchloric acid. The reaction with hydriodic acid can be represented by the equation

$$PH_3 + HI \rightarrow PH_4I.$$

In water these compounds hydrolyse almost completely with formation of phosphine, the hydrogen ion, and the halide ion.

Phosphine is a more powerful reducing agent than ammonia; it reacts spontaneously with chlorine at room temperature, forming phosphorus chlorides and hydrogen chloride, and with fused sulphur it forms hydrogen sulphide. Hydrogen sulphide and phosphine also interact (much more slowly than phosphine and sulphur), hydrogen and phosphorus sulphides being formed [2]. Reaction between phosphine and phosphorus trihalides leads to the formation (together with other products) of elemental phosphorus and the hydrogen halide:

$$PCl_3 + PH_3 \rightarrow 2P + 3HCl.$$

The reaction with pentahalides yields the trihalide and the hydrogen halide:

$$3PCl_5 + PH_3 \rightarrow 4PCl_3 + 3HCl.$$

As a reducing agent, phosphine reacts with many oxidising agents [2]: for example, it reduces metal ions to the free metal:

$$PH_3 + 6AgNO_3 + 3H_2O \rightarrow 6Ag + 6HNO_3 + H_3PO_3,$$

oxides to the phosphides [15]:

$$In_2O_3 + 2PH_3 \rightarrow 2InP + 3H_2O,$$

and iodine to iodides [2]:

$$PH_3 + 3I_2 + 3H_2O \rightarrow H_3PO_3 + 6HI.$$

The reactions of phosphine with silver nitrate, iodine, potassium permanganate, etc. are used for its quantitative determination. The phosphine molecule has a free electron pair at the phosphorus atom and exhibits electron-donor properties, so that phosphine, like ammonia, shows at least some tendency to form complexes with electron-acceptor molecules. For example, phosphine forms complexes of the type $P_2Hg_3.3HgCl_2$ with mercuric chloride [2], $PH_3.BF_3$ and $PH_3.2BF_3$ with boron trifluoride, $2PH_3.B_2H_6$ with diborane, and $[V(CO)_4PH_2]_2$ with vanadium hexacarbonyl [16].

Phosphine reacts with many organic compounds and this leads to the possibility of synthesising compounds with a phosphorus–carbon bond which cannot be prepared in other ways.

The interaction of phosphine with organic compounds takes place stepwise with formation of mono-, di-, and trisubstituted phosphines and sometimes quaternary phosphonium compounds in the presence of strong inorganic acids. The reaction of phosphine with aldehydes and ketones has been thoroughly investigated [17–18]. In the presence of a strong acid this reaction takes place according to the following general equation:

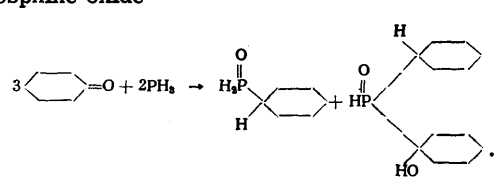
$$PH_3 \xrightarrow{>C=O} >C(OH)-PH_2 \xrightarrow{>C=O} (>C-OH)_2PH \xrightarrow{>C=O}$$

$$(>C-OH)_3P \xrightarrow{>C=O,HX} (>C-OH)_4PX.$$

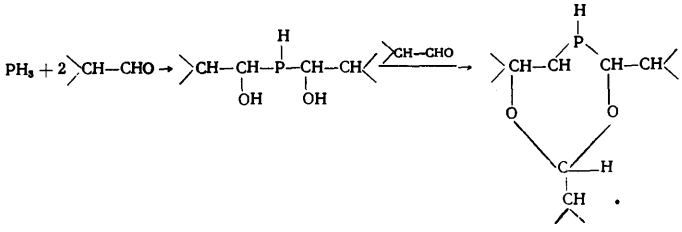
With aliphatic aldehydes, a mixture of mono-, di-, and tri-substituted phosphines and quaternary phosphonium salts is obtained, while aliphatic ketones and aromatic aldehydes yield mono-, and di-substituted phosphines [19,20], which isomerise to phosphine oxides. A classical example of the reaction of phosphine with aldehydes is the reaction of phosphine with formaldehyde in aqueous solution in the presence of hydrochloric acid discovered by Hofmann [23]. The reaction yields tetra(hydroxymethyl)phosphonium chloride—the starting material for the synthesis of many compounds, including fire-resistant polymers [24,25]. Soborovskii and coworkers [26,27] later showed that the reaction of phosphine with formaldehyde can take place also in the absence of a catalyst under a pressure of 150–300 mmHg. Under pressure paraformaldehyde reacts with phosphine [26,27] forming tri(hydroxymethyl)phosphine. With acetone, isopropoxyisopropylphosphine is obtained:

$$2CH_3COCH_3 + PH_3 \rightarrow (CH_3)_2CH-\overset{O}{\overset{\|}{P}}-C(OH)(CH_3)_2$$

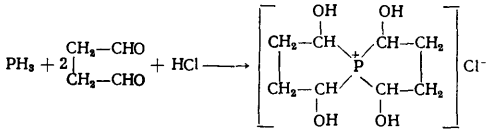
while the reaction with cyclohexane gives a mixture of cyclohexylphosphine oxide and cyclohexyl-1-hydroxycyclohexylphosphine oxide [19,20]



The condensation of phosphine with α-substituted aldehydes stops at the stage involving the formation of a disubstituted product[21], which is converted in the presence of an excess of the aldehyde into a heterocyclic compound:



Phosphine reacts with dialdehydes, forming a spiro-ring compound[19,20]:



but the rings are only five- and six-membered; glyoxal gives rise to a product with a linear structure; the reaction with epoxy-compounds gives low yields of a mixture of mono-, di-, and tri-substituted phosphines; for example, the reaction with epoxyethane takes place as follows[21,24,28]:

$$PH_3 + 6CH_2{-}CH_2 \rightarrow HOCH_2CH_2PH_2 + (HOCH_2CH_2)_2PH + (HOCH_2CH_2)_3P .$$

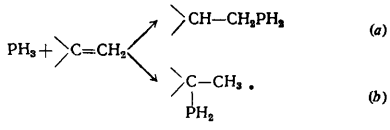
With organomagnesium compounds phosphine forms monosubstituted analogues of the Grignard reagent[21] with high reactivity:

$$PH_3 + RMgX \rightarrow H_2PMgX + RH .$$

Phosphine adds to olefinic compounds in the presence of strong acids[29,31] with formation of mono-, di-, and trisubstituted phosphines and phosphonium salts and also to 1-olefins[32] in the presence of catalysts at 100°C:

$$PH_3 + CH_2{=}CH{-}CH_2Cl \rightarrow H_2PCH_2CH_2CH_2Cl .$$

In a radical mechanism the phosphorus atom adds to the terminal carbon atom (*a*) and in an ionic mechanism to the middle carbon atom (*b*):



With tetrafluoroethylene, a mixture of products is formed[31]:

$$4CF_2{=}CF_2 + 4PH_3 \rightarrow F_2CH{-}CF_2PH_2 + H_2P{-}CF_2{-}CF_2{-}PH_2 + (F_2CH{-}CF_2)_2PH .$$

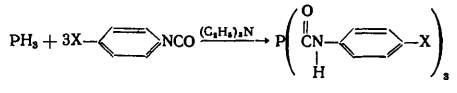
Phosphine reacts with organic acid chlorides to form a mixture of mono-, di-, and tri-substituted products[31]:

$$CCl_3COCl + PH_3 \rightarrow CCl_3COPH_2 + HCl .$$

The reaction with alkyl halides takes place similarly[21]:

$$PH_3 + RX \rightarrow RPH_2 + HX ,$$

while the reaction with isocyanates is



where X = H, Cl, or NO_2.

2. DIPHOSPHINE

Diphosphine is a colourless highly refractive liquid, which ignites spontaneously in air at room temperature (the principal physical properties are listed in Table 2) and is insoluble in water; alcohol and turpentine appear to dissolve diphosphine (P_2H_4), but the solution is very unstable and rapidly decomposes in the presence of the catalysts: hydrogen chloride, charcoal, pumice[2]. Diphosphine is sparingly soluble in liquid ammonia, and the solutions are unstable and readily decompose. Evers and Street[33,34] stated that diphosphine decomposes on storage into phosphine and solid phosphorus hydrides of composition P_9H_2 and P_5H_2, which decompose further to elemental phosphorus. When diphosphine is stored above 0°C or in the presence of hydrochloric acid, it gradually turns yellow owing to the precipitation of solid phosphorus hydrides†. The structure of the diphosphine molecule was established by NMR:[35]

Table 2. Physical properties of diphosphine (P_2H_4).

56	6.89	21	(1.02—1.007)	—99

Diphosphine is a powerful reducing agent, largely resembling hydrazine in its chemical properties. Its reactions have been scarcely investigated. Gattermann and Hausknecht[36] unsuccessfully attempted to obtain compounds of diphosphine with aldehydes and ketones. Diphosphine was obtained in a mixture with phosphine for the first time in 1945 by Thenard[37,38], who allowed calcium phosphide to react with water:

$$Ca_3P_2 + 6H_2O \rightarrow 3\,Ca(OH)_2 + P_2H_4 + H_2 .$$

The possibility of synthesising diphosphine by this method was suggested long ago by Leverriers[39,40]. Subsequently this reaction was the sole preparative method for synthesising diphosphine[36,41]. According to the recommendations of Gattermann and Hausknecht[36], diphosphine is synthesised as follows.. The apparatus consists of a round-bottomed flask connected to a receiver via a cooling coil. The receiver is immersed in a cooling mixture. Water is poured into the flask and the apparatus is thoroughly flushed with hydrogen. The water is heated to 60°C and calcium phosphide is added in pea-sized lumps at 150–200 g h^{-1}. Diphosphine begins to collect in the cooled receiver after approximately 15 minutes.

Recently, reports have been published[42-44] on the preparation of liquid triphosphine (P_3H_5) by the decomposition of phosphine in a reactor consisting of two concentric tubes, the temperature of the inner tube being 65°, and that of the outer 63°C, and on its preparation by the hydrolysis of calcium and magnesium phosphides in the presence of arsenides and germanides with heating under a high pressure[42,43].

P_3H_5 was identified by mass-spectroscopy and gas-chromatography (on kieselguhr with silicone oil).

†Recently a new phosphorus hydride P_2H_2 was prepared by the pyrolysis of diphosphine[140].

3. SOLID PHOSPHORUS HYDRIDES

The most familiar solid phosphorus hydride, $P_{12}H_6$, is a pale yellow powder stable in air, insoluble in water and organic solvents, and soluble in diphosphine and fused yellow phosphorus. Its density, determined for a suspension in a mixture of chloroform and bromoform, is 1.83 g cm^{-3} at 19°C.[2] The product decomposes rapidly in the light, ignites spontaneously at 200°C, and vaporises without change only in a high vacuum.

The solid hydride $P_{12}H_6$ was obtained for the first time in 1827 by Rose[45,46]. When diphosphine was passed through an aqueous solution of hydrochloric acid, Rose observed the precipitation of a solid yellow compound. Later this method was employed by Thenard[37,38] and Schenk[47]. Schenk prepared $P_{12}H_6$ by the reaction of calcium phosphide with water followed by treatment of the gas evolved with hydrochloric acid. The yield of the solid hydride was very low—about 3 g per kilogramme of calcium phosphide. Gattermann[36] improved somewhat the experimental technique but even in his synthesis the yield of $P_{12}H_6$ does not exceed 8 g per kilogramme of calcium phosphide. Up to the present time, this is the only method suitable for preparative purposes.

Other methods of synthesising the solid phosphorus hydride have been reported. Jolibois[48] stated that the solid hydride $P_{12}H_6$ may be obtained by the decomposition of zinc phosphide with hydrochloric acid. Later it was suggested that the hydride be obtained by the decomposition of aluminium phosphide with dry hydrogen chloride[2] or by the reaction of white phosphorus with potassium hydroxide in glycerol[49,50]. Rüdorf[51] suggested a synthesis of $P_{12}H_6$ from phosphorus iodide and water, in which the product is obtained in a low yield, and Besson[52] and Stock[53] proposed syntheses in which phosphine is passed through phosphorus trichloride or tribromide, but the method failed in practice.

Stock et al.[54] reported that the yellow phosphorus hydride $P_{12}H_6$ eliminates PH_3 on heating and is converted into the orange-red solid hydride P_9H_2. The same substance is obtained when liquid ammonia is allowed to react with $P_{12}H_6$,[33,54] the reaction being accompanied by the evolution of phosphine.

Hackspiel[55] showed that the solid hydride to which Thenard assigned the formula $P_{12}H_6$ in fact has the formula P_5H_2. This compound has acid properties and can form metal phosphides. In a vacuum P_5H_2 evolves pure phosphine.

Recently Weiberg and Müller-Schiedmayer[56] reported the preparation of a new phosphorus hydride with the formula $(PH)_x$ by the reduction of phosphorus halides and oxyhalides with lithium and aluminium hydrides in ethereal solution at low temperatures. The yield of this hydride can reach 90% in the reduction of phosphorus dibromide with lithium hydride at 30°C. It is a brown solid stable at room temperature. On heating to 400°C in a vacuum, it decomposes:

$$3(PH)_x \rightarrow 2xP + xPH_3.$$

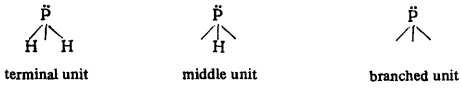
It exhibits weak basic properties, similar to those of trimethylamine, and is a powerful reducing agent—for example, on heating it reduces sulphuric acid to hydrogen sulphide. It is oxidised to phosphoric acid by strong oxidising agents such as hydrogen peroxide or sodium hypochlorite.

When yellow phosphorus is reduced electrochemically at a lead cathode[57], vigorous absorption of hydrogen without evolution of gaseous phosphorus-containing products is observed during the initial period. It is suggested[57] that the first stage of the reduction is the formation of the hypothetical hydride P_4H_4 by the reaction

$$P_4 \xrightarrow{4H^+,4e^-} P_4H_4.$$

This conclusion is based on the study of the variation of the concentration of yellow phosphorus during the electrolysis, but the hydride of the above composition was not isolated.

There exist various views concerning the structures of solid phosphorus hydrides. Royen[42,43] suggested that solid phosphorus hydrides are products of the sorption of PH_3 by one of the forms of yellow phosphorus. According to another view, solid phosphorus hydrides are macromolecular substances resembling in many respects organic plastics and phosphate glasses, which have the general formula P_nH_{n+2} and consist of three of the structural units shown below.



Diphosphine consists of two terminal units linked together. Triphosphone P_3H_5 consists of one middle and two terminal units. The hydride $(PH)_x$ consists only of middle units. There is probably a state of equilibrium between the groups, for example:

$$2\,\rangle PH \rightleftarrows -PH_2 + \rangle P.$$

The hydrides in which the molar H/P ratio is less than unity must contain branched elements in their structure; these compounds are probably analogous to three-dimensional polymers and this is why they cannot be dissolved in any solvent without breakdown of the molecule.

4. APPLICATIONS OF PHOSPHORUS HYDRIDES

Of the known phosphorus hydrides, only phosphine has practical importance. So far no applications have been found for the other hydrides. The possibility of the spontaneous ignition of phosphine constitutes a great risk in experiments with this material. For this reason, much attention has been devoted to the problem of the spontaneous ignition and stabilisation of phosphine. The spontaneous ignition temperature of pure phosphine in the presence of air is 140°C,[1] but when the gas contains a very small admixture of diphosphine (1 : 500), it ignites spontaneously in air even at −40°C.[1,2] The problem of the spontaneous ignition of phosphine has attracted attention for a long time. Ter-Gazaryan[58] believed that the most effective method for the purification of the gas from traces of other phosphorus hydrides and hydrogen is repeated liquefaction and fractional distillation of the liquid. However, later studies showed that the capacity of phosphine for spontaneous ignition can be suppressed by simpler means. Trautz[59] showed that the gas mixed with hydrogen and alcohol vapour does not ignite spontaneously. Graham[60,61], who studied the conversion from the inflammable to the non-inflammable form of the gas, established that, to achieve this conversion, it is sufficient to keep the gas under water containing air. The conversion can be achieved with the aid of a cork stopper or a lump of gypsum containing air in its pores. If the walls of the vessel are wetted with concentrated phosphoric, sulphuric, and arsenic acids, the conversion takes 2–3 min. Mercurous oxide acts most rapidly, while potassium hydroxide requires several hours for this purpose. Metallic potassium and its amalgam (one part of potassium in 350 000

parts of mercury) suppress the inflammability in several minutes. Johnson[62] recommends that alumina dehydrated at a low temperature be used as the drying agent for the preparation of non-inflammable phosphine. Thenard[37,38] and Amato[63] showed that phosphine loses the capacity for spontaneous ignition in air if it is treated with concentrated hydrochloric acid or stored in a glass vessel in sunlight. Under these conditions the diphosphine in the gas decomposes. Dilution of phosphine with an inert gas can also be used[64].

Until recently phosphine had only limited applications. Thus it was used to combat plant pests[65] and rodents[66], for the preparation of a layer of phosphides of metals resistant to mechanical, thermal, and chemical action, for the preparation of rare-metal phosphides used in semiconductor engineering, and for the preparation of phosphide bronzes used in machine engineering[66]. At present phosphine is attracting much attention in connection with possible new applications. For example, it has been found that phosphorus obtained by the thermal decomposition of its hydrides[67] has high purity and may be used as a semiconductor. The possibility of its military applications has also been noted[67a].

There exist wide possibilities for the application of phosphine in the synthesis of organophosphorus compounds, in particular the preparation of tetra(hydroxymethyl)phosphonium chloride—an intermediate in the manufacture of fire-resistant polymers[22,24,25], the preparation of extracting agents for rare metals, plasticisers for plastics[19,20], etc.

5. METHODS OF PREPARATION OF PHOSPHINE

Since there is a much greater variety of data on phosphine compared with the other hydrides, the methods of its preparation are discussed separately.

a. Synthesis from Metal Phosphides

Phosphine can be obtained by the action of water or dilute acid on alkali and alkaline earth metal phosphides. For example, Hugot[68] obtained phosphine by the action of water or dilute acids on sodium trihydrophosphide:

$$Na_3H_3P_2 + 3H_2O \rightarrow 2PH_3 + 3NaOH,$$

or

$$Na_3H_3P_2 + 3HCl \rightarrow 2PH_3 + 3NaCl,$$

or by heating this substance to 100°C at a reduced pressure. As the temperature is increased, more hydrogen and less phosphine is obtained.

A number of workers recommend that phosphine be obtained by the action of water or a dilute acid on calcium phosphide[35-38,69]. Moissan[70] was the first to obtain phosphine from calcium phosphide and water:

$$Ca_3P_2 + 6H_2O \rightarrow 2PH_3 + 3Ca(OH)_2.$$

As already mentioned, diphosphine is obtained as a side product in this process.

The gas produced by the action of water on technical calcium phosphide contains considerable amounts (up to 30%) of diphosphine and hydrogen. Phosphine can be synthesised by the action of water and hydrochloric acid on a specially prepared mixture of calcium and aluminium phosphides and on the phosphides of iron, magnesium, and aluminium[71].

The reaction of aluminium phosphide[49,50] with water takes place with evolution of much heat and is difficult to control. Kuznetsov and coworkers[72,73] showed that phosphine can be synthesised by the decomposition of water on aluminium phosphide suspended in an inert liquid; it is stated that the decomposition of aluminium phosphide suspended in organic solvents (methanol, ethanol, acetone, etc.) takes place comparatively smoothly and is easier to control. The decomposition of zinc phosphide with dilute acids (hydrochloric and sulphuric acids) has been thoroughly studied:

$$Zn_3P_2 + 6HCl \rightarrow 2PH_3 + 3ZnCl_2.$$

This reaction is most often used for the synthesis of phosphine[3]. The methods of preparation of phosphine discussed above have certain disadvantages[74-78]: contamination of the gas, expense, and the formation of waste—spent solutions and sludge.

b. Synthesis from Other Phosphorus Compounds

Hofmann[41] attempted to prepare pure phosphine by the decomposition of phosphonium iodide with water or potassium hydroxide solution, but it was found that the resulting gas contains also diphosphine and may ignite spontaneously in air:

$$PH_4I + KOH \rightarrow PH_3 + KI + H_2O.$$

Berzelius and Lüpke[79-81] obtained gaseous phosphine by the reduction of phosphites or a mixture of phosphite and hypophosphite with iron or zinc. An American patent[82] states that, when phosphites and hypophosphites are heated to 300–400°C, phosphine is obtained in yields of 18 and 46% respectively. Thorpe and Tutton[83] obtained phosphine by the action of dilute hydrochloric acid on the amide of phosphorous acid.

Phosphine can be synthesised by heating lower oxygen-containing phosphorus acids, for example hypophosphorous and phosphorous acids[45,46]:

$$2H_3PO_2 \rightarrow PH_3 + H_3PO_4,$$
$$4H_3PO_3 \rightarrow PH_3 + 3H_3PO_4,$$

but in this reaction only 50 and 25% of phosphorus respectively is usefully employed. It has been reported that phosphine is obtained when atomic hydrogen is allowed to react with lower phosphorus acids[84], the reactions including cathodic reduction[85], thermal decomposition of lower phosphorus hydrides[86], particularly at a reduced pressure, for example:

$$15P_2H_4 \rightarrow 18PH_3 + P_{12}H_6,$$
$$P_{12}H_6 \rightarrow 2PH_3 + 10P,$$

and also in acid and alkaline hydrolysis of phosphorus sulphides (yield 3–5%).[2]

Gutmann[87] reported that, when phosphorus halides are reduced with hydrogen in the gas phase in a gas-discharge tube, phosphine is formed together with red phosphorus.

Paddock, Wiberg, and Müller-Schiedmanyer[14,56,88,89] investigated the hydrogenation of phosphorus halides and oxyhalides with metal hydrides in ethyl ether. They showed that, together with phosphine, the reaction products may contain the solid hydride to which the formula $(PH)_x$ was attributed:

$$PX_3 \xrightarrow[-3X^-]{+3H^+} \begin{cases} PH_3 & \text{(a)} \\ (PH)_x + H_2 & \text{(b)} \end{cases}.$$

By choosing appropriate conditions, the reaction can be driven along pathway (a) or (b). In the synthesis of phosphine it is best to employ as low a temperature as possible. The maximum yield of phosphine (85%) was achieved in the reduction of phosphorus trichloride at −115°C with aluminium hydride and in the reduction of $POCl_3$ at −115°C with lithium tetrahydroaluminate.

The reduction of phosphorus pentahalides [88] with metal hydrides at temperatures between −80° and −100°C led to the formation of a equimolar mixture of phosphine and hydrogen. It has been noted [90] that phosphine (and other hydrides of Group V elements of the Periodic System) can be obtained by the reduction with lithium hydride of phosphorus halides at temperatures in the range 150–250°C. Lithium hydride is mixed with an inert powder (quartz, sodium chloride, etc.) in an inert gas, the halide vapour in an evaporator being supplied to the fluidised bed from below.

c. Synthesis from Elemental Phosphorus

Chemical methods. Phosphine may be obtained by the reaction of phosphorus with hydrogen, but only in a small yield. Rötgers [91] was the first to report the formation of phosphine by the reaction of incandescent red phosphorus with hydrogen. Dolique [92] did not confirm these data. He observed the formation of only traces of phosphine at 400°C. The use of decomposition and hydrogenation catalysts (activated charcoal, kieselguhr, pumice, nickel, copper, and iron) had no effect on the results.

Ipat'ev, Nikolaev, and Frost [7–10] observed the formation of phosphine on heating yellow phosphorus with hydrogen in a sealed tube at 360°C; the yield did not exceed 2%. Langmuir [93,94] obtained phosphine by the reaction of phosphorus with atomic hydrogen, formed from molecular hydrogen by heating the latter in the presence of platinum, palladium, or tungsten to 1100°C at a pressure of 0.001–0.2 mmHg. The synthesis of phosphine by the action on phosphorus of hydrogen activated in an electric discharge or by high-energy radiation has been patented [95].

A number of methods of the synthesis of phosphine are based on the reduction of yellow phosphorus with hydrogen at the instant of precipitation. The experiments of Vournasos [96] constituted one of the first studies based on this principle. By heating a mixture of sodium formate and red phosphorus, he obtained a spontaneously inflammable gas. Probably in this gas the hydrogen formed in the decomposition of formate reacted with the phosphorus:

$$6\,HCOONa \rightarrow 6\,H + 3Na_2C_2O_4,$$
$$2\,P + 6H \rightarrow 2PH_3.$$

Yellow phosphorus is reduced by the hydrogen evolved when zinc reacts with a concentrated solution of alkali. The reaction begins about 60°C. Brössler [97] obtained phosphine by adding yellow phosphorus to dilute sulphuric acid. Vitali [98] established that the presence of mercuric chloride in the acid retards the formation of phosphine.

Dusart [84] and Davy [99] believe that only traces of phosphine can be obtained by this procedure, while Dumas [100] altogether rejects the possibility of the formation of phosphine in this reaction. Oppenheim [101] obtained phosphine by heating red phosphorus with concentrated hydrochloric acid in a sealed tube to 600°C; when hydriodic acid is used, the same effect is achieved on heating to 160°C. Oppenheim heated phosphorus with glacial phosphoric acid in a sealed tube at 200°C, which led to the formation of hypophosphorous acid and this was subsequently converted into phosphine and phosphoric acid. Weyl [102] obtained phosphine by the action of hydrogen peroxide on red phosphorus. It has been stated [103] that phosphine is formed when ammonia and sodamide and also a mixture of sulphuric and phosphoric acids are allowed to react with yellow phosphorus.

Palmer [104–107] suggested that phosphine be obtained by the action of zinc and cadmium amalgams in acid solutions on yellow phosphorus. The yield of phosphine reaches 90%, but the apparatus and technology of the synthesis are very complex; furthermore, apparatus for the preparation of the amalgams is necessary.

In much later patents [108–110], it was stated that phosphine can be synthesised by heating white phosphorus with water vapour in the presence of phosphorus pentoxide:

$$8P + 12H_2O \rightarrow 3H_3PO_4 + 5PH_3.$$

The content of phosphine in the gas reaches 94–99 vol.% (yield 62.5%). Condensed phosphates are produced in addition to phosphine. For a successful reaction, it is recommended that finely ground red phosphorus containing up to 4% of white phosphorus be used. Because of the highly corrosive nature of the medium, the process is carried out in a graphite or quartz reactor. In the absence of phosphorus pentoxide the reaction of phosphorus with water is possible only under a pressure of 50 atm and in the presence of catalysts [111,112].

Phosphine is known to form [113] in small amounts in the industrial preparation of yellow phosphorus by the thermal reduction of phosphorites in electric furnaces as a result of the partial reduction of the elemental phosphorus. The phosphine content in the furnace gases amount to 1 vol.%.

Phosphine was obtained for the first time by Gengembre [114] in 1773 and independently by Kirwan [115] in 1789 by boiling a concentrated solution of potassium hydroxide with yellow phosphorus. Rose [45,46], who made a detailed study of this reaction, found that the gas is evolved at a temperature as low as 15°C. The phosphine obtained by this method contains a considerable amount of diphosphine. The main reaction may be represented by the equation

$$4P + 3KOH + 3H_2O \rightarrow 3KH_2PO_2 + PH_3,$$

and the side reaction by

$$6P + 4KOH + 4H_2O \rightarrow 4KH_2PO_2 + P_2H_4.$$

The diphosphine produced decomposes partially with formation of a solid phosphorus hydride:

$$15\,P_2H_4 \rightarrow P_{12}H_6 + 18PH_3.$$

A considerable amount of hydrogen is produced together with phosphine. According to the data of Dumas [99] [Davy ? or Dumas [100] ? (Ed. of Translation)] and Hofmann [41], it is difficult to obtain phosphine containing less than 55–60% of hydrogen. Hydrogen is formed by the reaction

$$4P + 5KOH + 3H_2O \rightarrow PH_3 + 2H_2 + KH_2PO_2 + 2K_2HPO_3.$$

When calcium hydroxide is used, the hydrogen content of the gas is 89–90%. It is stated in patents [116–118] that, when an alcoholic solution of alkali (more than 70% of alcohol) is used, 95% of the theoretical yield of phosphine is obtained.

Phosphorus is hydrogenated by the organism phihothion [119].

All the methods of preparation of phosphine from elemental phosphorus enumerated above give relatively low yields of the product with considerable amounts of impurities. The possibility of synthesising phosphine by the electrochemical reduction of yellow phosphorus must be regarded as more promising.

Electrochemical Synthesis

The preparation of phosphine with the aid of an electric current was first reported by Grove [120] in 1863. He passed an electric current through moist phosphorus in order to fuse it and observed the formation of phosphine.

Blumenberg [65] asserted that phosphine can be obtained like arsine by the cathodic reduction of phosphorus salts and oxides. However, this has still not been confirmed. Subsequently it was stated in a French patent [105] that, in the preparation of hypophosphorous acid by the anodic oxidation of yellow phosphorus (or phosphorus alloys—for example ferrphosphorus), phosphine is formed at the cathode, probably as a result of the reduction of hypophosphorous acid. This was also reported by Baudler [85], but the process conditions were not given. Somewhat later, West German, British, and United States patents appeared [74,121,122], in which it is suggested that phosphine be obtained by the cathodic reduction of yellow phosphorus in aqueous solutions of salts and acids on metals with a high hydrogen overvoltage, for example, lead, zinc, mercury, etc. Aqueous solutions of hydrochloric, sulphuric, phosphoric, and acetic acids and their salts were used as the catholyte. To prevent the oxidation of phosphorus and its reduction products, the cathodic compartment was separated from the anodic compartment by a diaphragm. Since the solubility of phosphorus in aqueous solutions is very low, the solution was stirred mechanically (or magnetically) to emulsify the phosphorus. Price and Gordon [74,121,122] assert that, under these conditions, fused phosphorus rises vertically along the cathode like liquid in a wick ("wick effect"), wetting its entire surface. Platinum, lead, lead dioxide, lead–arsenic alloy, graphite, and stainless steel have been used as anode materials. The maximum yield of phosphine was observed in a solution of orthophosphoric acid (4 M) at mercury and zinc cathodes and amounted to 87%.

It is stated in patents [121,122] that the yield of phosphine falls with time and, in order to improve the yield, it is recommended that salts of certain metals (lead, barium, calcium, zinc, etc.) be added to the catholyte. The temperature is kept above the melting point of phosphorus (44°C) and below the boiling point of the solution (below 110°C) and the current density is maintained in the range 150–400 A m^{-2}. The authors do not describe the optimum conditions.

Recently a large number of patents have been published [75-78,123-132], describing various versions of the electrochemical method for the preparation of phosphine and its further development. The process conditions and the yields of phosphine are given in Table 3, which shows that comparatively concentrated aqueous solutions, mainly of phosphoric acid, are most often employed as the electrolyte. Only in one case was the employment of an aqueous sodium chloride solution described [74] and it was noted that sodium hypophosphite was formed together with phosphine.

In all cases the electrolysis is carried out at elevated temperatures (between 50° and 120°C). Usually comparatively low current densities are stated (in the range 50–300 A m^{-2}). Ceramics, tantalum, titanium, rubber, and polyethylene are employed as constructional materials for the electrolysers. Judging from later patents [129-132], the electrochemical preparation of phosphine has encountered considerable difficulties in attempts to achieve a continuous process. It appears that the most serious are the following: rapid loss of reducing activity by the cathode; the adhesion of phosphorus to the surface of the cathode leading to an increase of voltage in the electrolyser; contamination of the electrolyte; blocking of diaphragm pores. The aim of the improvements to the process described in the patents is to eliminate the phenomena listed above.

In order to stabilise the activity of the electrode, it is suggested that bismuth, cadmium, and mercury salts be added to the electrolyte, whereby the yield of phosphine can be raised to 92–92%. In one patent [75] it is recommended that the electrolysis be carried out in the presence of lead ions which are generated by a periodic replacement of the

platinum anode by a lead anode. This modification increases the stable yield of phosphine to about 85%.

In all the examples quoted it is noted that, after prolonged operation, loose spongy deposits are formed on the cathode, which increase the electrical resistance of the electrolyser and, since part of them crumble away, they contaminate the phosphorus present in the solution. A special design of the electrolyser has been described[78], in which the cathode is located above the anode. According to the authors of the patent[78], in this case deposits are formed on the upper side of the electrode and do not hinder the passage of current. A special device has been described with the aid of which it is possible to remove continuously part of the catholyte and phosphorus to free them from contamination. Finally, an unusual form of cathode is recommended. The cathode should have ribs, projections, and channels. It is not clear from the patent data how a cathode of this shape prevents the formation of loose deposits.

To achieve the best contact between the electrode and phosphorus, the cathode should either touch the layer of fused phosphorus at the bottom of the electrolyser, or the phosphorus should be introduced in amounts such that its thickness on the cathode does not exceed 0.7 mm.

To prevent the blocking of the pores of the diaphragm, it is recommended that the latter be covered by a layer of polyethylene or another material which is not wetted by phosphorus[129,130]—fibreglass, plastics, graphite, etc. In one patent[77] it is suggested that the level of the anolyte be maintained above that of the catholyte, whereupon hydrostatic pressure will prevent the adhesion of phosphorus to the diaphragm.

One of the methods for reducing the adhesion of phosphorus consists in the introduction into the electrolyte of hydrocarbons, hydrogen, or cathode gas containing hydrogen[131]. On dissolving in phosphorus, these substances reduce its viscosity and hence the possibility of its adhesion to the diaphragm and to the walls of the electrolyte. A noteworthy application of a catholyte mixed with organic solvents in different proportions has been described[123]. It is asserted that in this case the cathode gas does not contain phosphorus hydrides other than PH_3.

Various improvements in the electrolyser design (for example, use of a carbon cathode, when there is no need for a diaphragm) are proposed in patents[125-128]. However, despite these improvements, optimum conditions for the electrochemical synthesis of phosphine have probably still not been found.

Recently studies were made[57-133] to determine favourable conditions for the electrochemical preparation of phosphine in aqueous solutions. It was established that the optimum conditions are as follows: current density of the order of 1800–2000 A m^{-2}, temperature 75–85°C, and a zinc cathode in solutions of 40% phosphoric acid. Under these conditions the current yield of phosphine (and the yield with respect to the phosphorus employed) reaches 65%. In contrast to the data of other patents[74-78,121-132], it is then unnecessary to use special devices for the circulation and purification of the catholyte and phosphorus, for coating the diaphragm, etc.

The mechanism of the electrochemical reduction of phosphorus has been investigated in fair detail for the mercury cathode[134,135]. It was established that phosphorus in aqueous ethanol solutions is reduced by mechanism with addition of twelve electrons per molecule:

$$P_4 + 12H^+ + 12\,e^- \rightarrow 4PH_3\,.$$

In aprotic media the process takes place by the addition of two electrons with formation of an anion and subsequent protonation of the latter[136]. The study of the reduction at a pendant mercury drop showed[135] the intermediate formation of a chemisorbed P_4Hg_X complex and in this respect the electrochemical reduction of phosphorus is analogous to the reduction of sulphur. Electrochemical reduction of phosphorus at a lead cathode is complicated by the formation of an intermediate phosphorus hydride[57].

A method for the preparation of phosphine and other volatile hydrides (silicon, boron, etc. hydrides) has been described recently[67,137-139]. The essential feature of the process is the electrolysis of fused lithium chloride, the lithium formed at the cathode reacting with the hydrogen supplied to the cathodic compartment forming lithium hydride; the latter passes to a separate chamber, where it reacts with phosphorus trichloride:

$$3\,LiH + PCl_3 \rightarrow PH_3 + 3\,LiCl\,.$$

The process is carried out at a temperature such that the phosphine formed is thermally stable. The chlorine evolved at the anode is used to prepare fresh portions of phosphorus trichloride. The design of the electrolyser provides for the elimination of contact between the phosphorus trichloride and the alkali metal to avoid the formation of free phosphorus.

A cell design has been developed for periodic and continuous operation. The anodic and cathodic compartments are separated either mechanically or a zone of "frozen melt" is set up in the middle. The anode and cathode are both made of graphite. This may be regarded as a method for the indirect chemical preparation of phosphine.

---o0o---

It follows from the foregoing that phosphine has already found practical applications and that their range is being continuously extended. In this connection the development of rational methods for the preparation of phosphine on an industrial scale is assuming increasing importance. Comparison of the various methods for the synthesis of phosphine shows that the only procedure which has found practical application hitherto, despite its disadvantages, is the decomposition of metal phosphides. Although it is being tested under experimental industrial conditions[141], the synthesis of phosphine by the reaction of phosphorus with steam is scarcely likely to prove economical in view of the considerable consumption of phosphorus in the formation of phosphorus acids.

The most promising is the electrochemical method but its application has encountered certain difficulties, which, judging from the literature data, have not been resolved.

The chemistry of other phosphorus hydrides has been hardly investigated and probably the time is now ripe for systematic research in this field.

Present-day State of the Theory of Bimolecular Reactions

E.E.Nikitin

Various simple models of bimolecular reactions are discussed which provide a qualitative interpretation of the principal aspects of the elementary act in the redistribution of atoms. The limitations imposed by the law of the conservation of total angular momentum have been elucidated for processes involving the intermediate formation of long-lived complexes. The limiting cases of the mechanisms of dislodgment and stripping have been examined for direct processes. The latter mechanism is interpreted in terms of an optical model. A list of 38 references is included.

1. INTRODUCTION

The Review discusses the most recent development of the theory of bimolecular reactions, i.e. processes of the type

$$X + Y \rightarrow Z + U \qquad (1.1)$$

occurring in the gas phase. Since elucidation of the mechanism of this process is based in general on solving a many-body (in the simplest case the three-body) problem, the modern theory of bimolecular reactions is largely governed by progress in computational technique. Analysis of the trajectories of the representative point has yielded important results on the energy dependence of reaction cross-sections, on the energy distribution function of the reaction products, and on the angular distribution of elastically and inelastically scattered particles. Another line of research is based in large measure on models of the mechanism of the redistribution of particles and on certain hypotheses concerning the interaction of reactant molecules. This approach enables the final results to be obtained without complicated intermediate calculations, and thus permits several redistribution processes to be interpreted (if this is possible) in terms of relatively simple models. The most widely used are discussed below.

These models are most conveniently classified according to the extent to which the energy of the unstable molecular system formed on collision is able to undergo redistribution among the various degrees of freedom before the reaction can be regarded as complete. On the basis of these considerations the following classification is useful.

1. Reactions involving an intermediate complex. In these processes the mechanism of the redistribution of energy approaches a statistical process.
2. Direct reactions. According to the way in which the particles are redistributed, these are subdivided into three subgroups—(*a*) rebound mechanism, (*b*) mechanism of direct dislodgement, and (*c*) stripping or pick-up mechanism.

Several processes occurring by the above mechanisms will be examined in the present Review. We shall not in general be concerned with the rebound mechanism, since the chief advances in this field have been achieved by taking into account the simultaneous interaction of several atoms, this requiring the use of computers. Reactions having a rebound mechanism are usually considered in terms of the transition stage theory, and several problems for thermal reactions have been clarified in a previous review[1].

2. STATISTICAL THEORY OF REACTIONS. EXCHANGE OF ATOMS WITH FORMATION OF AN INTERMEDIATE COMPLEX

Discussion of General Formulation

The chief assumption in the statistical theory of bimolecular reactions is that the elementary act (1.1) takes place in two independent stages. The first stage involves formation of a complex or composite system XY*. In the second stage the complex XY* breaks down along all possible channels, the probability P of breakdown being calculated from the statistical theory of unimolecular reactions. It is clear that, for the assumed independence of the two stages to be valid, the lifetime τ of the composite system XY* should exceed substantially the characteristic times of the intramolecular motions. An estimate of τ can be obtained from the statistical theory of unimolecular reactions, which has now been quite well developed[2-4] and enables the mean lifetime of an active molecule before spontaneous breakdown to be calculated with satisfactory accuracy.

Let us suppose that the initial states of the molecules X and Y are characterised by a set of quantum numbers i. On formation of the complex the numbers i are supposed to lose their significance, the activated molecule being characterised by a new set of quantum numbers ϵ. Further, let the final products Z and U be characterised by the quantum numbers f. The cross-section of the elementary act is then written

$$\sigma_{if}(v_i) = \sum_{\varepsilon} \delta\sigma_{i\varepsilon}(v_i) P_{\varepsilon f}, \qquad (2.1)$$

where $\delta\sigma_{i\epsilon}$ is the cross-section of formation of the composite system XY* (or, as we shall call it, the capture cross-section of X and Y) in the state ϵ, and $P_{\epsilon f}$ is the probability of its breakdown along the channel f. The summation in Eqn. (2.1) is made over all states ϵ which can be formed from the initial state i. The symbol v_i denotes the initial relative velocity of the molecules X and Y.

The probability of breakdown $P_{\epsilon f}$ is given by the normalised partial rate of breakdown along the specified channel:

$$P_{\varepsilon f} = k_f(\varepsilon)/[k_1(\varepsilon) + k_{-1}(\varepsilon)] \qquad (2.2)$$

where

$$k_1 = \sum_f k_f(\varepsilon), \quad k_{-1} = \sum_i k_i(\varepsilon)\ . \qquad (2.3)$$

Here the summations with respect f and i are made over all channels in forward and reverse directions. The decomposition rate constants $k_n(\epsilon)$ of the active molecule $(XY^*)_\epsilon$ are in turn calculated from the theory of unimolecular reactions.

In classical mechanics the differential capture cross-section $\delta\sigma_{i\epsilon}(v_i)$ is given by the relation

$$\delta\sigma_{i\varepsilon}(v_i) = 2\pi b_i db_i \qquad (2.4)$$

where b_i is the impact parameter, which satisfies the condition $b_i < b_i^c$, while b_i^c is the maximum impact parameter at which capture takes place. In this formulation it is assumed, of course, that formation of the composite system does not involve surmounting a potential barrier, i.e. that the first stage in the reaction takes place with zero activation energy. The relation (2.4) is conveniently expressed in terms of the relative momentum l_i of the molecules X and Y:

$$\delta\sigma_{i\varepsilon}(v_i) = \frac{2\pi}{p_i^2} l_i dl_i, \quad p_i = \mu v_i\ . \qquad (2.5)$$

Although the condition of capture is most simply formulated by the requirement $l_i < l_i^c$, it is useful to introduce into (2.5), instead of l_i, the total momentum J of the system of colliding molecules, since it alone is a complete integral of the motion. Henceforward for simplicity we shall discuss the collision of an atom A with a molecule BC, so that the total angular momentum J is given by the vector sum

$$l_i + j_i = J \qquad (2.6)$$

in which j_i denotes the intrinsic momentum of BC.

Transformation from the variable l_i to the variable J (with j_i fixed) is most simply accomplished by means of the rules of vector addition[5,6]. As a result of this transformation the differential capture cross-section $\delta\sigma_{i\epsilon}$ is written

$$\delta\sigma_{i\varepsilon}(v_i) = \frac{2\pi}{p_i^2} \varphi(J; j_i, l_i^c) J dJ \qquad (2.7)$$

where the explicit form of the function φ has been given in a previous paper[6]. Here we note merely that φ vanishes when $J > j_i + l_i^c$. In order to determine l_i^c, we must formulate the conditions of capture. If the capture of A and BC takes place at sufficiently great distances, the main contribution will be made by the isotropic polarisation interaction $W(R) = q(R_0/R)^s$, and l_i^c then depends on the relative kinetic energy of the fragments[5-7]:

$$l_i^c(v_i) = (2\mu E_i R_0^s)^{1/s} \left(\frac{sq}{2E_i}\right)^{1/s} \left(\frac{s}{s-2}\right)^{1/s - 1/s} \qquad (2.8)$$

$$E_i = \mu v_i^2/2\ .$$

The energy E_i is subject, of course, to the limitations indicated below, which result from neglect of the contribution made by short-range forces[8].

We now specify the set of quantum numbers ϵ, on the assumption that the only integrals of motion of the composite system are the total energy E and the total angular momentum J[5-11]. Certain assertions must also be made concerning the electronic states between which a statistical redistribution of energy is possible. The probabilities of non-adiabatic transitions between these states are supposed to be sufficiently high for them not to limit the transfer of the representative point from one potential surface to another.

This last hypothesis cannot be regarded as valid for all reactions in which an intermediate complex is formed. Several ion–molecule reactions are now known whose very small cross-section is ascribed to the low probability of non-adiabatic transitions between the electronic states linking the initial and final terms of the partners[12].

The total cross-section σ_1 of reaction (1.1) can now be rewritten

$$\sigma_1(v_i) = \frac{\pi}{p_i^2} \int 2 J dJ \varphi(J; j_i, l_i^c) \frac{k_1(E, J)}{k_1(E, J) + k_{-1}(E, J)} \qquad (2.9)$$

where k_1 and k_{-1} are the rates of the spontaneous breakdown of ABC* in forward and reverse directions. In calculating the cross-section of reaction (1.1) into a specified channel (e.g. in a state having specified vibrational or rotational quantum numbers), we must replace $k_1(E,J)$ in the numerator of (2.9) by the corresponding partial rate constant. In most cases Eqn. (2.9) can be considerably simplified, since the relative momentum l_i usually exceeds appreciably the intrinsic angular momentum of the reactant molecules. In this case we can put $J \simeq l_i = p_i b_i$, and Eqn. (2.9) becomes

$$\sigma_1 = \frac{2\pi}{p_i^2}\int_0^{l_i^c} 2\, l_i dl_i \frac{k_1(E,J)}{k_1(E,J)+k_{-1}(E,J)} = 2\pi\int_0^{b_i^c} \frac{k_1(E,J)\, b_i db_i}{k_1(E,J)+k_1(E,J)} \quad (2.10)$$

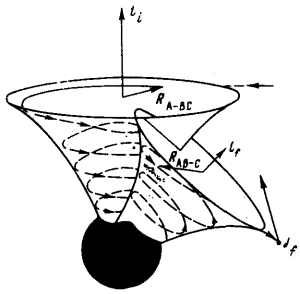

Figure 1. Energy surface for reaction involving an intermediate complex.

A reaction of this type can be represented diagrammatically by the movement of a representative point along potential-energy surfaces (Fig. 1). The relative motion of A and BC in the initial stage of capture takes place in a plane perpendicular to the relative angular momentum $\boldsymbol{l}_i$. If the energy axis lies in the direction of the vector $\boldsymbol{l}_i$, capture is represented by the trajectory described by the vector R_A–BC, as it descends spirally into the "funnel" corresponding to the potential W_{A-BC}. The representative point then reaches a region of strong interaction, where the redistribution of energy is described by statistical laws (shaded region). Finally, the representative point begins to rise along a second "funnel", which corresponds to the potential W_{AB-C} and whose axis lies in the direction of the vector of the relative motion of the products $\boldsymbol{l}_f$. The direction of the vector $\boldsymbol{l}_f$ is related to that of the intrinsic angular momentum j_f of the fragment AB and to the vector $\boldsymbol{J}$ by the conservation law $\boldsymbol{J} = \boldsymbol{l}_f + \boldsymbol{j}_f$.

If the dependence of the rates of decomposition k_1, k_{-1} on the total momentum $\boldsymbol{J}$ is neglected in the calculation of σ_1, formula (2.9) simplifies further to

$$\sigma_1 = \left[2\pi\int_0^{b_i^c} bdb\right]\frac{k_1(E)}{k_1(E)+k_{-1}(E)} = \sigma_1^{c_0}(v_i)\frac{k_1(E)}{k_1(E)+k_{-1}(E)} \quad (2.11)$$

where the first factor in the right-hand formulae gives the total capture cross-section, while second factor is the probability of breakdown in the forward direction.

Since the values of k_n are proportional to the number n of states in a channel, it is clear that the larger of the two constants k_1 and k_{-1} will be that which corresponds to the exothermic direction of the reaction. Let us assume for definiteness that reaction (1.1) is exothermic in the forward direction. Let us suppose further that the total energy E_1 of the initial state satisfies the condition $E_1 \ll Q$, where Q is the heat of reaction. Then the inequality $k_1 \gg k_{-1}$ will probably hold, and Eqn. (2.11) will give

$$\sigma_1 = 2\pi\int_0^{b_i^c} bdb = \sigma_1^c(v_i)\,. \quad (2.12)$$

Nevertheless, the cross-section σ_{-1} for the reverse reaction will contain the ratio $k_{-1}(E,J)/k_1(E,J) \ll 1$ following the integral sign. This ratio is proportional to the ratio of the number of open decomposition channels in reverse and forward directions. Provided that $E_1 < \hbar\omega$, i.e. when vibrations of BC cannot be excited on breakdown of the complex ABC*, the energetic dependence of σ_{-1} on the total energy of the partners AB and C near the threshold Q is described by the formula [8]

$$\sigma_{-1} = \text{const}\,(E-Q)^{s/2}\,. \quad (2.13)$$

This threshold dependence of the rate is related fundamentally to the law of the conservation of angular momentum. This can be seen from the argument that the first stage of the reaction involves formation of the composite system ABC*, the angular momentum of which is distributed within a certain range $0 < J < l_f^c$. On decomposition in the direction A + BC the maximum anular momentum j_i of the molecule BC is small, being determined by the excess of energy $E-Q$ over the threshold. On the other hand, l_i is also small for low values of E_i. This means that the vector sum of j_i and l_i is small, certainly much smaller than l_f^c. Thus only complexes having a small angular momentum $0 < J < l_i^c$ are actually able to break down in the direction A + BC. For complexes having $l_i^c < J < l_f^c$ only one type of decomposition is available—breakdown in the reverse direction: ABC* → AB + C.

Model Reaction $A_2^+ + A_2 \rightarrow A_3^+ + A$

As illustration of the statistical theory of bimolecular reactions we shall discuss an ion–molecule reaction of the above type. An actual example of such a reaction is the process

$$H_3^+(E_{i,n}) + H_2 \rightarrow H_3^+ + H + Q,\ Q = 1{,}1\ \text{eV} \quad (2.14)$$

in which the H_3^+ ions possess a specified vibrational excitation (quantum number n) and a relative kinetic energy E_1. The problem consists in calculating the cross-section σ of this reaction as a function of n and E_i.

Let us first consider the calculation of the total reaction cross-section for the ground state $n = 0$. An estimate based on a simplified form of the statistical theory [13] (disregarding the conservation of total momentum) shows that, with energy $E_i < 0.1$ eV, the rate of breakdown of the complex $[H_4^+]^*$ in the forward direction substantially exceeds the rate in the reverse direction. The cross-section of the reaction should then coincide with the capture cross-section σ^C, which in turn is given by the general formula (2.12) with the polarisation potential $W(R) = -\alpha e^2/2R^4$ (in which α is the polarisability of the neutral particle):

$$\sigma^c(v_i) = 2\pi e\sqrt{\frac{\alpha}{2E_i}},\ E_i = \mu v^2/2 \quad (2.15)$$

where μ is the reduced mass of the partners. An experimental investigation of the formation of H_3^+ ions (and of D_3^+

ions in the analogous reaction with deuterium) confirms the diminution in cross-section with increase in energy, the experimental absolute cross-sections being close to the theoretical values over the energy range investigated[15,16].

Let us now examine the dependence of σ on the vibrational quantum number n of the H_2^+ ion. In calculations based on the general formulae (2.9) it must be borne in mind that the initial angular momentum of this ion is quite small if it is produced by ionisation of low-energy H_2 molecules. Therefore the simplified formula (2.10) can be used to calculate σ_1, and for $n \neq 0$ the contribution of E_i to the total energy of the composite system $[H_4^+]^*$ can in general be neglected if $E_i < n\hbar\omega^+$ (where ω^+ is the vibration frequency of H_2^+). The cross-section σ_1 is conveniently written $\sigma_1 = \sigma^C P(E_{i,n})$, where $P(E_{i,n})$ is to be interpreted as the mean probability of reaction along the given channel. Different calculations of this factor[17,18] are difficult to compare directly, since the second was based on a simplified form of the theory[13], and took no account of identical channels of decomposition.

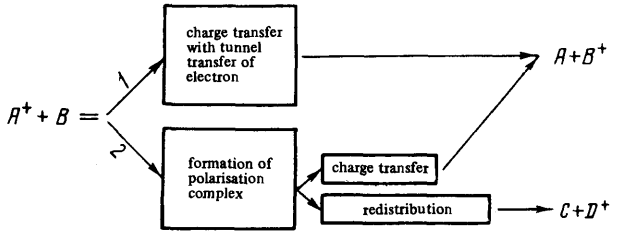

Figure 2. Competition between charge transfer with tunnel transfer of an electron, charge transfer with complex formation, and redistribution with complex formation.

Examination of the different cases of addition of the angular momenta of molecules resulting from breakdown of the composite system $[H_4^+]^*$ leads to the following estimate for the relative efficiency of decomposition in the forward direction with energy $E_i = 0.04$ eV[17]:

$$P(n=0):P(n=1):P(n=2):P(n=3):P(n=4) = 1:0.9:0.75:0.62:0.52. \quad (2.16)$$

This agrees qualitatively with the initial terms in the analogous series representing the experimental data[19]

$$1:0.5:0.4:0.5:0.0\ . \quad (2.17)$$

The discrepancy between theory and experiment, and in particular the inability of the statistical theory to explain the very marked decrease in probability of reaction for $n \geq 4$, are perhaps due to the breakdown of the main assumption of the theory, that a long-lived complex is formed at sufficiently high energies, and to the disregard of the effect of anisotropic interaction in determining the boundary between open and closed channels†. It must also be remembered that the experiment giving the series (2.17) was interpreted on the assumption that the Franck–Condon principle applied to the ionisation of H_2. It is possible, however, that this principle is not satisfied in the vicinity of the threshold[21].

In calculating the cross-sections of reactions between an ion and a molecule we must take into account the competition between the redistribution of particles and the transfer of charge[16,22]. An important aspect is that, as the kinetic energy increases, the charge-transfer cross-section diminishes more slowly than does the redistribution cross-section. Fig. 2 illustrates such competition in the case of resonance charge transfer. Along path *1* either the transfer of an electron by the tunnel effect or the formation of a polarisation complex is possible. The relative efficiency of these processes is proportional to the corresponding cross-sections, which in turn are determined by the critical values of the impact parameters.

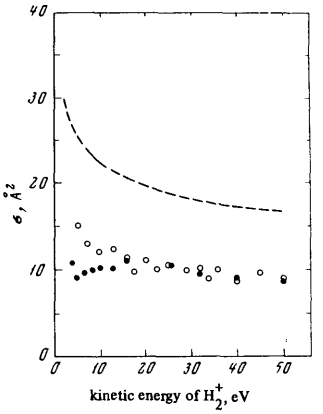

Figure 3. Charge transfer as one of the paths of the competing reactions (2.14) and (2.19). The broken curve shows the calculated charge-transfer cross-section, and the points represent experimental results.

Along branch *2* the relative efficiency of the two paths is now determined by the distribution of energy in the complex, depending mainly on the sign and magnitude of the energy evolved during the redistribution. In particular Markin and Tal'roze[23] investigated the reaction

$$H_2^+ + O_2 \rightarrow [H_2O_2^+]^* \begin{cases} HO_2^+ + H & (a) \\ O_2^+ + H_2 & (b) \end{cases} \quad (2.18)$$

which satisfies this condition. The ratio σ_a/σ_b of the cross-sections was found to diminish with increase in energy, and the cross-section of reaction (*a*) became very small at a relative energy of the ions of about 10 eV. This immediately shows that the lifetime of the composite system decreases with increase in energy, and ultimately the very concept of an intermediate complex becomes devoid of meaning.

Another example, from the work of Levental et al.[24], is illustrated in Fig. 3. The broken curve represents the calculated cross-section σ_{calc} of resonance charge transfer

$$H_2^+ + H_2 \rightarrow H_2 + H_2^+ \quad (2.19)$$

† Such anisotropy is most clearly apparent in reactions between an ion and a molecule having a dipole[20]. In this case the field of the ion retards the rotation of the molecule, and in the limiting case completely orients it in the direction of the line of collision, so that the classification of channels into closed and open should allow for interaction of the momenta l_i and j_i.

while the points give the experimental values of the cross-sections σ_{exp} for this process. The divergence between the two curves is due to reaction (2.14), which "cuts out" from the cross-section σ_{calc} the internal region σ_1 in such a way that $\sigma_{exp} = \sigma_{calc} - \sigma_1$.

3. THEORY OF DIRECT REACTIONS. MECHANISM OF DIRECT DISLODGMENT

Experimental investigation of reactions occurring in molecular beams shows that many exchange reactions, particularly those of alkali-metal atoms with halogen and hydrogen halide molecules, do not involve the formation of a long-lived intermediate complex: i.e. they take place by a direct mechanism. Henceforward we shall take "direct mechanism" to mean a mechanism of interaction of the partners in which the residence time in a volume of molecular dimensions is of the order of a few nuclear vibration periods or less. Fig. 4 shows the various possibilities for the redistribution of atoms in the simplest reaction A + BC → AB + C which has a direct mechanism. In the rebound mechanism A approaches BC, a chemical bond AB is formed, and then the atom C is repelled from the resulting molecule AB. As already mentioned, this situation is usually discussed in terms of the transition state theory.

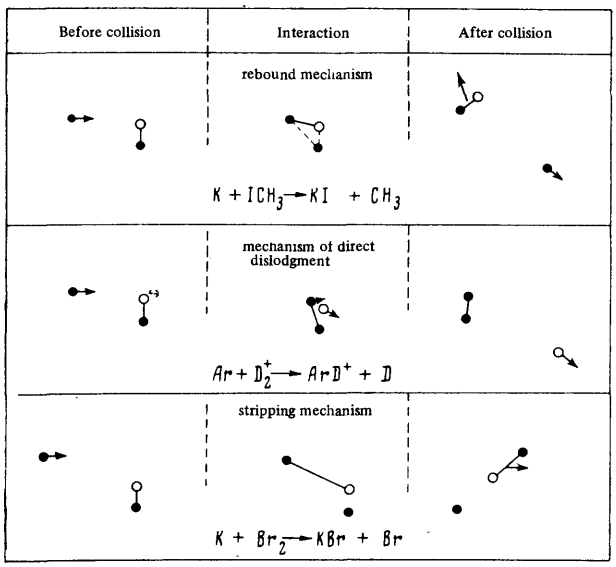

Figure 4. Diagrammatic illustration of rebound mechanism, mechanism of direct dislodgment, and stripping mechanism.

If a mechanism of direct dislodgment operates, the atom A dislodges the atom C from the molecule BC, is slowed down, and remains combined with the atom B.

With a stripping mechanism the atom A interacts mainly with atom B, and the interaction of A with C can often be neglected. The resulting diatomic molecule is scattered mainly in the direction of motion of the atom A.

Fig. 4 includes examples of reactions of the above types.

It is an extremely complicated theoretical task to calculate the cross-sections of such processes. However, the theory assumes a simple form when the time of interaction τ_{st} between the incident atom A and one of the atoms in the molecule BC can be regarded as small in comparison with the period of vibration of the initial molecule BC or the final molecule AB (the so called impulse approximation) [25-27]:

$$\tau_{st}\omega_{AB},\ \tau_{st}\omega_{BC} \ll 1 . \qquad (3.1)$$

An analytical expression can be obtained for the reaction cross-section if two additional conditions are introduced besides (3.1): it must be postulated that the amplitude of the pair scattering A_{XY} is far smaller than the interatomic distances in the molecules:

$$A_{XY} \ll R_{XY},\ X, Y = A, B, C \qquad (3.2)$$

and that the interaction potential U of three particles is additive in character:

$$U = U_{AB} + U_{BC} + U_{AC} . \qquad (3.3)$$

The pair potentials are completely arbitrary: the only limitation imposed on them is due to condition (3.1). It must be noted that the additive potential approximation (3.3) permits no description of a potential barrier or a region of breakdown, nor a region of transition from one surface to another. Therefore the approximation (3.3) can be applied only to reactions in which neither activation energy nor non-adiabatic effects play a significant part.

Condition (3.1) imposes a lower limit of 5–10 eV on the relative energy of the partners on collision. With such energies the exchange

$$A + BC \rightarrow AB + C \qquad (3.4)$$

begins to be subject to competition by the dissociation

$$A + BC \rightarrow A + B + C . \qquad (3.5)$$

The existing theory enables the reaction cross-sections for exchange σ_{exch} and dissociation σ_{diss} to be calculated with the quantum character of the motion of the nuclei in the intermediate and resulting molecules taken into account. Here we shall give merely a brief account of the classical form of the theory describing the broad features of the energy dependence of the cross-section in the range above the above lower limit [25].

Assuming for simplicity that the target molecule is at rest before collision, we shall consider that a stable molecule AB is formed if the relative energy E_{AB} of the atoms A and B after the dislodgment of C is less than the bond energy D_{AB}.

The starting point for deducing an expression for σ_{exch} is the formula for the differential cross-section of the loss of energy ΔE by the atom A incident with energy E on the stationary atom C. For a model of rigid spheres we have

$$d\sigma = \pi R_0^2 \frac{d\Delta E}{\Delta E_{max}},\quad \Delta E_{max} = E\frac{4\mu_{AC}}{m_A + m_C} . \qquad (3.6)$$

The energy E_{AB} of atom A after dispersions on C, expressed in the system of the centre of mass A–B, is

$$E_{AB} = (E - \Delta E)\frac{\mu_{AB}}{m_A} . \qquad (3.7)$$

Expressing $d\Delta E$ in Eqns. (3.6) in terms of dE_{AB}, and equating the differential retardation cross-section $d\sigma$ to the differential capture cross-section, we find that

$$d\sigma_{exch} = d\sigma(E_{AB}) = \pi R_0^2 \frac{m_A}{\mu_{AB}}\frac{dE_{AB}}{\mu_{AB}} . \qquad (3.8)$$

The total exchange cross-section is obtained from this by integrating with respect to dE_{AB}:

$$\sigma_{exch} = \pi R_0^2 \frac{m_A}{\mu_{AB}\Delta E_{max}} \left[\min \begin{Bmatrix} \frac{\mu_{AB}}{m_A} E \\ D_{AB} \end{Bmatrix} - \frac{\mu_{AB}}{m_A} (E - \Delta E_{max}) \right]. \quad (3.9)$$

Hence it follows that, when $E \leq D_{AB} m_A/\mu_{AB}$, the exchange cross-section is πR_0^2. This is clearly the case: right from the start the relative energy of A–C is such that every dislodgment of C enables a stable molecule to be formed. When $E > D_{AB} m_A/\mu_{AB}$, the exchange cross-section diminishes because the dissociation channel is opened:

$$\sigma_{exch} = \frac{\pi R_0^2}{4} \left[\frac{(m_A + m_C)^2 (m_A + m_B)}{m_A m_B m_C} \cdot \frac{D_{AB}}{E} - \frac{(m_A - m_C)^2}{m_A m_C} \right]. \quad (3.10)$$

When the energy has the value E^* at which the expression in square brackets vanishes, the exchange channel is completely closed, and every collision A + BC leads to the dissociation of BC.

The concepts of a mechanism of direct dislodgment cannot usually be applied, either to thermal reactions or to processes in molecular beams, if the kinetic energy of the partners does not exceed several tens of electron-volts. Nevertheless, this mechanism represents an important particular case in which a many-body problem reduces to a problem of pair interactions. The more exact quantum theory of reactions of direct dislodgment enables us to take into account the effects of repeated scattering, a sudden change in potential, preliminary rotational and vibrational excitation of the target molecule, and the dependence of the effective dissociation energy of the resulting molecule AB on its rotational state[26,27]. In particular, the quantum distribution of momenta of atoms in the vibrational ground state of the hydrogen molecule has been suggested to be responsible for the rapid fall in the cross-section of the reaction

$$Ar^+ + H_2 \rightarrow ArH^+ + H \quad (3.11)$$

in the energy range $E > E^*$, where according to classical views the cross-section of the process should have been precisely zero. A mechanism of direct dislodgment provides an explanation for the slower fall (with increase in energy) in the cross-section of the reaction

$$Ar + D_2^+ \rightarrow ArD^+ + D \quad (3.12)$$

than in that of the reaction

$$Ar^+ + D_2 \rightarrow ArD^+ + D \quad (3.13)$$

as a consequence of initial vibrational excitation[27]. Furthermore, a simple interpretation is given of the fact that the cross-section of formation of the ion ArH^+ in the reaction Ar + HD^+ exceeds that for formation of the ion ArD^+.[27]

However, the interpretation of the above reactions of direct dislodgment is not unambiguous. In many cases reactions of this type can be successfully described in terms of a stripping model[12,28,29]. Nevertheless, a mechanism of direct dislodgment should always be considered as a possible mechanism at high collision energies, especially as it permits of relatively simple theoretical treatment.

4. THEORY OF DIRECT REACTIONS. MECHANISM OF STRIPPING

Let us now discuss another type of reaction, taking place by the so called stripping mechanism. This term applies to reactions in which an incident atom A interacts mainly with the atom in the molecule BC which is directly involved in the exchange‡. The interaction of A with C in reaction (3.4) can be neglected, for example, in rapid collisions where the time of interaction of A with B is less than the time required for substantial transfer of momentum from B to C. It is possible that processes of this kind, together with those of direct dislodgment, play a part at energies exceeding 5–10 eV. With ordinary thermal reactions (below 10 000°K) the relation between the collision time and the time of intramolecular vibrations is such that there can be no question of impulse interaction of A with B. Nevertheless, there exist certain types of reaction, even at low energies, whose formal characteristics satisfy the conditions of stripping. The cross-section of these reactions is usually very large ($\sigma \geq 100$ Å), and the resulting diatomic molecule is scattered mainly ahead relative to the direction of motion of the atom A. Since large cross-sections indicate that detachment occurs at large impact parameters ($b > 6$–7 Å), a model having a short-range potential (e.g. a rigid-sphere model) cannot be used to interpret these reactions.

Examples of processes of this type are provided by the reactions

$$M + X_2 \rightarrow MX + X \quad (4.1)$$

where M is an alkali-metal atom and X a halogen atom. A "spectator–stripping" model describes approximately the kinetics of such reactions, the M atom stripping an X atom from the X_2 molecule, while the momentum of the other X atom remains almost unchanged. A suggested interpretation of the dynamics of these reaction[30–32] starts from a mechanism of "harpooning", in which the first stage of the process involves dissociative charge transfer, and the second stage the formation of a bound ion-pair:

$$M + X_2 \rightarrow M^+ + X_2^- \rightarrow M^+ + X^- + X \rightarrow M^+X^- + X \rightarrow MX + X \quad . \quad (4.2)$$

The first stage—charge transfer—is the only inelastic process occurring at large distances, so that elastic processes make the chief contribution to scattering without redistribution of particles. The fact that all non-elastic channel without particle redistribution can be excluded from consideration enables the reaction and the elastic scattering to be described relatively simply in terms of a so called optical model. This model consists essentially in replacing the actual potential $W(R_{X_2-M})$, which leads to elastic scattering, by a complex potential[33] (R_{X_2-M}), the imaginary part of which (in a quantum treatment of the process of scattering) is responsible for partial absorption of the scattered particles. This absorption, which is shown in a weakening of the beam of incident particles, must be attributed, of course, to the reaction. If the elastic scattering of particles can be interpreted in terms of an optical model, therefore, it will give direct information on the probability of reaction as a function of the impact parameter. While describing reaction as absorption of the initial particles, an optical model, of course, will give no indication of the way in which energy is distributed among the degrees of freedom of the reaction

‡ The distinction between a model of direct dislodgment and a stripping model is most simply explained by comparing the limiting energies E^* of the incident atom A at which the exchange channel is closed. For the former case

$$E^* = \left(\frac{m_A + m_C}{m_A - m_C}\right)\left(\frac{m_A + m_B}{m_B}\right) D_{AB}$$

and for the latter

$$E^* = \left(\frac{m_A + m_B}{m_B}\right) D_{AB}.$$

products. In this sense it will give less information on the reaction than will detailed dynamic models. However, it possesses the advantage that it permits a simple interpretation of elastic scattering in terms of an interaction potential and an interaction responsible for charge transfer.

An energy diagram illustrating dissociative charge transfer is shown in Fig. 5. On the right are depicted the terms of the molecule X_2 and the ion X_2^- (internuclear distance r) when the intermolecular distance R is infinite. The left-hand side of the diagram shows the terms as a function of R. Term *1* corresponds to effective interaction of X_2 and M in the initial state with a fixed angle γ between the vector R and the molecular axis r of the molecule X_2. At great distances, which are of interest in the present problem, this interaction $W_C(R)$ is characterised by weak attraction. When the centrigual energy is taken into account, however, the effective potential $W_{C,\mathrm{eff}}(R) = W_C(R) + l^2/2\mu R^2$ represents repulsion. The set of effective ionic terms $W_i(R)$ corresponds to Coulombic attraction. For every energy ϵ reckoned from the level of the separated system $X_2(n = 0) + M$ there is a corresponding term $W_i(\epsilon,R)$, and $W_{\mathrm{eff}}(\epsilon,R) = W_i(\epsilon,R) + l^2/2\mu R^2$. Among them Fig. 5 shows the boundary of the continuous spectrum *2* ($\epsilon = \epsilon_0$), term *3* corresponding to a vertical transition ($\epsilon = \epsilon^*$), the boundary of the Franck–Condon region *5* ($\epsilon = \epsilon^* - \Delta\epsilon$), and *6* ($\epsilon = \epsilon^* + \Delta\epsilon$), one of the terms of the continuous spectrum *4* (arbitrary ϵ).

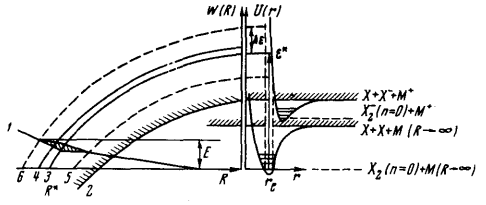

Figure 5. Electronic and vibrational terms involved in the dissociative charge transfer $M + X_2 \rightarrow M^+ + X^- + X$.

Interaction between covalent and ionic states can be described in different ways. Firstly, we can speak of non-adiabatic transitions between the covalent term and a continuous system of ionic terms. Secondly, we can speak of a broadening of a covalent term immersed in a continuum of ionic terms, and of conversion of a stationary into a quasi-stationary state. The second interpretation is illustrated in Fig. 5, where the covalent term *1* is shown broadened within the Franck–Condon region.

Let us suppose that the breakdown of each vibrational state of the molecule X_2 in the region $R \simeq R^*$ can be considered independently, and that the relative motion of X_2 and M can be described by means of classical mechanics. The first of these postulates permits a substantial simplification of the general problem, by reducing it actually to a two-body problem. The possibility of the independent description of dissociations arises only if, during passage through the Franck–Condon region, the interaction X_2–M does not induce vibrational transitions between the levels of X_2 (condition that the collisions shall be adiabatic) and if the interaction is sufficiently weak in absolute magnitude for no overlapping of the broadened vibrational levels of the X_2 molecule to occur in the region $R \simeq R^*$. These conditions can be written

$$\omega(X_2)\,\tau_{st} \gg 1 \qquad (4.3a)$$

$$\bar{\Gamma}_n/\hbar\omega(X_2) \ll 1 \qquad (4.3b)$$

where τ_{st} denotes the characteristic time of traversal of the Franck–Condon region, while $\bar{\Gamma}_n$ is the mean width of the vibrational level at $R \simeq R^*$. When conditions (4.3) are satisfied, the probability of dissociation of every level can be calculated by means of the formulae of the quasi-stationary adiabatic approximation

$$P_n = \exp\left[-\frac{1}{\hbar}\int_R \Gamma_n(R)\,dt\right] \qquad (4.4)$$

This approximation forms the basis of the so called optical model in stripping reactions [33–38]. Formula (4.4) gives the attenuation of a beam of elastically scattered particles moving along the trajectory $\mathbf{R} = \mathbf{R}(t)$. A rough estimate of the exponential (4.4) yields

$$\frac{1}{\hbar}\int \Gamma_n(R)\,dt = \frac{\bar{\Gamma}_n\tau_{st}}{\hbar} = \left(\frac{\bar{\Gamma}_n}{\hbar\omega}\right)(\omega\tau_{st}) \qquad (4.5)$$

We can see that conditions (4.3) do not restrict the value of this integral (4.5): the first factor on the right-hand side is small, while the second is large. This means that, to the approximation of independent vibrational states, a case of considerable absorption is possible, i.e. a relatively high probability of reaction. It is clear that, with sufficiently large impact parameters, the relations (4.3) will always be satisfied. However, the total contribution of those collisions for which the condition of relatively strong absorption $\bar{\Gamma}_n\tau_{st}/\hbar > 1$ is satisfied as well as conditions (4.3) will depend on the features of the interaction responsible for charge transfer.

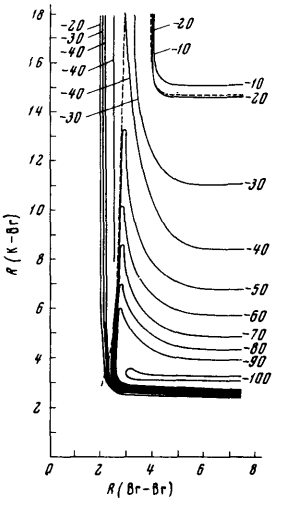

Figure 6. Energy surface for the reaction $K + Br_2 \rightarrow KBr + Br$ constructed by adiabatic mixing of covalent and ionic terms [32].

Infringement only of the first of the two conditions (4.3) implies that the channel of vibrational excitation can compete with the dissociation channel. If only the second condition is infringed, the probability of vibrational excitation is low, but the mutual influence of different vibrational states of the covalent electronic term must be taken into

account in calculating the probability of transition. However, these conditions are not fundamental, in the sense that an approximate solution of the problem can still be obtained from a consideration of two interacting particles. If neither of the conditions (4.3) is satisfied, the problem of calculating the cross-section, both of elastic scattering and of scattering accompanied by reaction, reduces to the general three-body problem, where we need consider only the one electronic term arising from the adiabatic mixing of both covalent and ionic states. The principal characteristics of the potential energy of a system for which a covalent state and an ionic state are fundamental are illustrated in Fig. 6. Here we note the main features of the motion of the representative point along a surface of this type. The presence of a sharp break on the surface, corresponding to transition from a covalent state to an ionic state of the partners, is very vividly illustrated by the concept of an "electronic harpoon"[30-32]. The atom M approaches the molecule X_2, and at quite a large distance, when the relative motion of the neutral pair M and X_2 can still be regarded as free, an electron passes from the atom M to the molecule X_2. After the electronic "harpoon" has linked the pair M^+ and X_2^- by Coulombic attraction, rearrangement of the system is possible, resulting in formation of the pair M^+X^- and X. The actual process of rearrangement can take place in various ways. In particular, the electronic term of the system X_2^- may correspond to an unstable state. If the time required for dissociation of the ion were short compared with that during which the distance between M^+ and X_2^- changed significantly, the angular distribution of the particles and the energy distribution could be calculated formally from the conservation laws for momentum and for energy. In contrast to a true stripping reaction, however, these relations should have also taken into account the change in energy and relative momentum of the pair X_2^- occurring on non-adiabatic transition of the X_2 molecule from a neutral to an ionic state. These ideas have been used to interpret experiments on the reactions of potassium, rubidium, and caesium atoms with bromine and iodine molecules[32]. If dissociation of the ion cannot be regarded as instantaneous, the general problem cannot be divided into a set of two-particle processes, and its solution requires explicit consideration of the interaction of three particles. In this way we arrive at the general problem mentioned in the Introduction.

Some Aspects of the Kinetics of Molecular Reactions

F.B.Moin

Experimental data on the kinetics of elementary gas-phase reactions undergone by molecules are reviewed. The classification of reactions is discussed on the basis of the structure of activated complexes. Reaction mechanisms of various types are analysed in detail. The activation energy is shown to be determined additively mainly by activated bonds: the presence of substituents, which play no direct part in the reaction, has little effect on the activation energy. An analysis is made of the effect of conjugated and cumulative π-bonds in the activated complex on the activation energy. Conjugation and cumulation substantially lower the potential barrier to reaction. A list of 206 references is included.

I. INTRODUCTION

In the present paper the term "molecular reactions" will imply those elementary reactions where the initial systems and products contain only *molecules*—not atoms, radicals, or biradicals.

Investigations of molecular reactions occupy an important place among the numerous papers on the kinetics of elementary reactions which have been published to date. Nevertheless, these results have not been summarised and systematised to the same extent as has been done for the reactions of atoms and radicals. The reasons for this are the considerably greater qualitative diversity of elementary molecular reactions and the far less complete theoretical study that has been made of them because of their greater complexity.

Actually, in the commonest and most thoroughly studied radical substitutions of the type $R + R'X \rightarrow RX + R'$ only one chemical bond is broken, and the transition state has an extremely simple structure. In thermal decompositions of molecules into two atoms or radicals, of the type $R-R' \rightarrow R + R'$, too, only one chemical bond is broken, while the potential barrier to reaction is given by the energy of rupture of the bond R–R'. Radical reactions of this type have been the subject of quite full theoretical study.

A characteristic feature of molecular reactions is that they involve the cleavage of more than one chemical bond, while the activated complex has a more complicated structure. Nevertheless, kinetic investigations of molecular reactions are usually made on a particular restricted class of reactions, and very little attempt has been made to establish an interrelationship between and general laws for the kinetics of molecular reactions belonging to different classes.

The present Review represents an attempt to summarise, analyse, and systematise published information on the kinetics of molecular reactions, the starting point being the additive method for calculating the activation energies of chemical reactions which I have developed[1].

II. CLASSIFICATION OF REACTIONS

A rational classification of elementary reactions is of paramount importance for the analysis and generalisation of kinetic data. It is advisable to base such a classification on the structure of the activated complexes, which reflects most profoundly all the fundamental kinetic features of the reactions.

Szabó[2] worked out a possible classification based on the structure of the activated complexes. It contains a total of 23 different types of reactions and the same number of empirical coefficients for calculating the activation energy. A fundamental defect of this classification is that in many cases forward and reverse reactions are of different types, in spite of the obvious identity of the corresponding activated complexes. As a consequence, the difference between the activation energies of forward and reverse reactions, calculated by Szabó's method, is not in general equal to the heat of reaction, as it should be in reality.

The classification of chemical reactions which I have proposed is also based on the most fundamental features of the structure of the corresponding activated complexes. As before[1] an activated complex is regarded as a molecule whose atoms are combined with one another not by chemical but by weaker, "activated" bonds. Since each activated bond corresponds to a definite chemical bond in the initial system or in the reaction products, the number of activated bonds is given by the sum of the numbers of chemical bonds cleaved N_{cl} and formed N_f:

$$N^{\neq} = N_{cl} + N_f.$$

Table 1 lists the main types of activated complexes. An activated complex of any type is the same for forward and reverse reactions. The only difference between the latter is that formed and cleaved bonds interchange roles. Other activated complexes are also possible, e.g. seven-membered, eight-membered, etc. complexes. However, these are encountered considerably more rarely in the reactions under investigation. This classification covers not only molecular but also radical and biradical reactions.

Analysis of numerous experimental data on the mechanisms of reactions whose molecular character has been established shows that they nearly all involve the formation of either four-membered or six-membered activated complexes†.

† Except for *cis–trans* isomerisations involving an activated complex having $N^{\neq} = 1$. For the mechanism of these reactions see Section IV, 1.

In cases in which the reaction mechanism cannot be represented by the above complexes, there are usually sound reasons for supposing that the reaction is not elementary, but passes through several stages (not excluding the intermediate formation of radicals, for example).

Table 1. Classification of activated complexes.

$N^{\neq}$	N_{cl}	N_f	Structure of activated complex
1	1 0	0 1	A...B
2	1	1	A...B...C
3	2	1	A···B...C...D
	1	2	A...B ·C·
4	2	2	A...B D...C
5	3	2	A...B E·C·D·
	2	3	
6	3	3	A...B F C E...D

Table 2. Mean energies of bonds in molecules (Q) and in activated complexes ($Q^{\neq}$) at 0°K (kcal)*.

Bond	Q, kcal	$Q^{\neq}$, kcal
H—H	103	48
C—H	99	45
σ-C—C (in alkanes)	79	28
π-C—C (in alkenes)	61	17
π-C—C (in acetylene)	56	9
σ-C—O	80	27
π-C—O (in aldehydes and ketones)	88	18
π-C—O (in acids)	124	45
O—H	105	55
σ-C—N	66	11
N—H	92	25
C_{prim}—Cl	76	18
C_{sec}—Cl	76	25
C_{tert}—Cl	76	32
C_{prim}—Br	63	16
C_{sec}—Br	63	21
C_{tert}—Br	63	26
C_{prim}—I	47	8
C_{sec}—I	47	16
C_{tert}—I	47	24
H—Cl	102	40
H—Br	87	33
H—I	70	23

* Here and subsequently we shall for brevity write "kcal" instead of "kcal mole^{-1}".

Note. Correction for conjugation $\Delta Q^{\neq}_{conj} = 12$ kcal; correction for cumulation $\Delta Q^{\neq}_{cum} = 8$ kcal.

An important characteristic of activated bonds is that their mean energy is about the same in different activated complexes. Table 2 gives values of mean bond energies in molecules and activated complexes, from which it is easy to calculate the activation energy of a chemical reaction by means of the additive principle

$$E = \Sigma Q - \Sigma Q^{\neq} \qquad (1)$$

where Q and $Q^{\neq}$ are the mean energies of a bond in a molecule and in an activated complex respectively.

A more detailed account of the method of calculation will be found in the previous review[1]. Table 2 has been somewhat expanded and refined in comparison with the corresponding previous table[1]; in particular, the bond energies for nitrogen have been added, and also a correction $\Delta Q^{\neq}_{cum}$ for the effect of the cumulation of three or more π-bonds in a chain.

If a reaction involves cleavage of cyclic bonds, one energy of rupture of a carbon–carbon bond in the ring (50, 60, and 72 kcal respectively for cyclopropane, cyclobutane, and cyclopentane) is substituted in Eqn. (1) and also the corresponding energy of an activated bond (4, 12, and 22 kcal for the same rings).[1]

Before surveying published information, we must comment on experimental methods for studying the kinetics of molecular reactions.

III. METHODS OF STUDYING THE KINETICS OF MOLECULAR REACTIONS

In principle the determination of the rate constants of molecular reactions is considerably simpler than of radical or ionic reactions, since the concentrations of all the species involved can easily be measured. Nevertheless, methods for the study of molecular reactions have several peculiarities, associated not so much with determining the rate constants as with proving that the measured constants do relate to the given elementary processes. The reaction under investigation is sometimes complicated by several side-reactions, and this makes an unambiguous interpretation of the results considerably more difficult. The complications met most frequently are due to the occurrence of heterogeneous and radical–chain processes.

Heterogeneous Reactions

Many molecular decompositions and isomerisations are extraordinarily sensitive to the condition of the walls of the reaction vessel. The effect of the walls on reaction velocity may have several causes. The first possibility to be borne in mind is heterogeneous catalysis of the reaction by the walls. Such reactions as hydrogenation and dehydrogenation, for example, can easily be catalysed by various surfaces, especially metallic surfaces. Apparently the wall also catalyses the decomposition of certain alkyl halides (e.g. ethyl chloride[3,5]). In several cases the rates of the homogeneous reaction and of the catalytic reaction on the wall are comparable. In other cases the reaction takes place almost solely on the wall (e.g. the decomposition of ammonia[4]).

The relative rates of homogeneous and heterogeneous (catalytic) reactions is determined by several factors, including the nature and the state of the surface, the ratio of the surface area of the vessel to its volume S/V, and the experimental conditions (temperature and pressure). Heterogeneous catalytic decompositions usually have lower activation energies than the homogeneous reactions, so that the relative contribution of the heterogeneous reaction diminishes with rise in temperature.

In the kinetic study of molecular reactions the occurrence of heterogeneous reactions is usually detected by making experiments at different S/V ratios, and also by special treatment of the surface of the reaction vessel.

The latter effect is often achieved by "aging", i.e. by making a large number of experiments in the same vessel. This quite often improves the reproducibility of the results. "Aging" is explained by the appearance on the walls of a thin film of carbon deposits, which are inert towards the given reaction.

Heterogeneous reactions can be entirely eliminated by a special technique[5] for studying the kinetics of first-order reactions in a stream of an inert gas, which completely prevents reactant molecules from striking the walls of the reaction vessel. In this technique the reaction is conducted under streamline flow conditions in the initial (diffusion) portion of the zone in which a current of the reactant mixes with an accompanying coaxial flow of the inert gas. By this means kinetic measurements are made only on the homogeneous reaction.

Heterogeneous reactions can be eliminated also by means of a shock tube, which has recently become widely used. In this method a detonation wave effects rapid heating of the initial gaseous mixture, while the walls of the vessel remain cold.

Radical-Chain Processes

Molecular reactions are often complicated also by radical-chain processes, and therefore methods for the detection and suppression of radical reactions are of primary value. The most convincing evidence for the participation of free atoms and radicals in a reaction is their direct detection and measurement of their concentrations. Various physical and chemical methods (electron spin resonance, mass spectrometry, the mirror technique, etc.) are used for this purpose. In the study of molecular reactions, however, it is not so important to detect radicals as to prove their absence. This is a more complicated task, since a failure to detect radicals still does not mean that there are absolutely none in the system. Nevertheless, the inhibition method, consisting in adding substances which can react readily with radicals and thereby remove them from the system, has become widely used for assessing the possible part played by radical processes. The most frequently used inhibitors are nitric oxide, propene, toluene, and cyclohexene. If the rate of a reaction is not affected by the addition of inhibitors, this is regarded as an argument in support of its molecular character. Even when an inhibiting effect is present, it is sometimes considered that the "residual" inhibited reaction is molecular, since secondary radical processes are then completely suppressed.

To ascertain the possible effect of heterogeneous and radical processes on the kinetics and the mechanism of molecular reactions it is now standard practice to conduct experiments at various S/V ratios and also with additions of inhibitors, and if no appreciable change in reaction velocity is detected, it can be more or less confidently stated that the reaction is molecular.

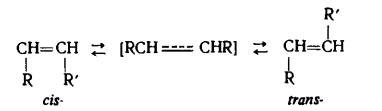
Careful analysis of the reaction products and the use of isotopes are extremely useful in the detection of radical processes. When radicals are present, many secondary products are usually formed. If, however, the reaction is conducted in a mixture, say of an undeuteriated and a completely deuteriated reactant, radical reactions will yield partly deuteriated products. In the absence of free radicals the products of the reaction should be either undeuteriated or completely deuteriated compounds. This method is applicable, of course, only to decompositions and isomerisations, and only if no deuterium exchange takes place either between molecules of the initial reactant or between molecules of the reaction products.

However, it must be borne in mind that short-lived biradicals can sometimes take part in a reaction, these being able to isomerise into molecules in a time less than that between collisions. In this case attempts to detect such biradicals by means of inhibitors will be unsuccessful, but this does not prove their absence. Additional difficulties are thereby created for the experimental investigation of the reaction mechanism. Determining the stereochemical structure of the reaction products may prove of some assistance here, since molecular reactions, unlike radical reactions, are usually stereospecific.

IV. ANALYSIS OF EXPERIMENTAL DATA

1. *cis–trans*-Isomerisation of Ethylenic Compounds

The *cis–trans* isomerisation of ethylenic compounds is the only example of a molecular reaction whose activated complex contains a single activated bond:



cis- *trans-*

The activation energy of reactions of this type, calculated additively, is

$$E = Q_{\pi\text{-C=C}} - Q^{\neq}_{\pi\text{-C=C}} = 61-17=44 \text{ kcal} .$$

Certain existing experimental values would appear to agree fairly well with this calculation, as can be seen from Table 3.

Table 3. Experimental values of the activation energy and of the logarithms of the pre-exponential factor for the *cis–trans* isomerisation of alkenes.

Alkene	Reaction	lg$A$*	E, kcal	Ref.
CHD=CHD	*cis* → *trans*	13.00	65.0	11
CHCl=CHCl	*trans* → *cis*	12.70	42.0	6
CHCl=CHCl	*trans* → *cis*	12.68	55.3	9
CHCl=CHCl	*cis* → *trans*	12.76	56.0	9
$CH_3CH=CHCH_3$	*cis* → *trans*	13.78	62.8	15
$CH_3CH=CHCH_3$	*cis* → *trans*	11.00	52.0	14
$CH_3CH=CHCH_3$	*cis* → *trans*	14.54	65.0	18
$CH_3CH=CHCH_3$	*cis* → *trans*	14.00	64.2	16
$CF_3CF=CFCF_3$	*cis* → *trans*	13.53	56.4	20
p-$CH_3OC_6H_4CH=CHC_6H_5$	*cis* → *trans*	10.23	35.5	22
p-NO_2—$C_6H_4CH=CHC_6H_5$	*cis* → *trans*	10.23	34.0	22
$C_6H_5CH=CHCOOCH_3$	*cis* → *trans*	10.54	41.6	21
$C_6H_5CH=CHCN$	*cis* → *trans*	11.60	46.0	23
$C_6H_5CH=CHCN$	*trans* → *cis*	11.80	46.0	23
$C_6H_5CH=CHC_6H_5$	*cis* → *trans*	12.78	42.8	24
$CH_3CH=CHCOOCH_3$	*cis* → *trans*	13.20	57.8	70
$CH_3CH=CHCN$	*cis* → *trans*	11.00	51.3	71

* Here and subsequently the units of A are s^{-1} and cm^3 $mole^{-1}$ s^{-1} for first-order and second-order reactions respectively.

However, careful analysis shows that the matter is complicated by several secondary factors, which throw doubt on the reliability of the results. It has recently become obvious that many *cis–trans* isomerisations, which have previously been regarded as unimolecular homogeneous reactions, are actually initiated by free radicals or are heterogeneous.

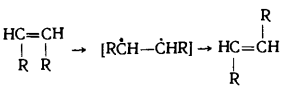
An example of such a reaction is the isomerisation of 1,2-dichloroethylene. In this case it was discovered[6] that, in order to obtain reproducible results, the reaction vessel had to be "aged", but even in an "old" vessel the reproducibility of the rate constant rarely became better than 50%.[7] A considerable departure from the first order was found[8] during the first 5 min of an experiment. The reaction velocity depends also on the surface–volume ratio S/V of the reaction vessel[9]. Finally, Steel[10] showed that the isomerisation of 1,2-dichloroethylene is strongly inhibited by toluene and propene, so that it is a radical-chain reaction. The isomerisation rate constant has been measured[9] in excess of toluene. This constant, when extrapolated to $S/V = 0$, is ascribed to a true unimolecular reaction, the activation energy then being 56 kcal.

The above complications explain the contradictions in published experimental results, and prevent an unambiguous conclusion from being drawn on the reaction mechanism.

A similar situation is found in the isomerisation of dideuterioethylene. The rate of this reaction depends[11] on the surface area of the reaction vessel, and increases on the addition of oxygen, ethanethiol, azomethane, and nitric oxide. The first-order rate constant increases with pressure over a wide range (9–312 mmHg). The activation energy at $p = \infty$ is 65 kcal. The isomerisation of dideuterioethylene in the presence of nitric oxide is of the first order with respect to the latter, and the activation energy is 27.5 kcal[12].

Many investigators have studied the *cis–trans* isomerisation of but-2-ene. In 1936 Kistiakowsky and Smith found[13] that the activation energy of this reaction had the unexpectedly low value of $E = 18$ kcal, which was difficult to explain. Later measurements by Anderson et al.[14], who used an improved method, gave a value of 52 kcal. In these experiments (over the pressure range 200–400 mmHg) some increase in pressure was observed during the reaction, probably caused by secondary reactions. Rabinovitch and Michel[15] found that, at pressures exceeding 10 mmHg, the reaction was complicated in character (autocatalytic) and sensitive to additions of oxygen, azomethane, and propene. Below this pressure, however, isomerisation was regarded[15] as unimolecular with an activation energy of 62.8 kcal. Other authors[16,17] have reached similar conclusions. The kinetics of the isomerisation of but-2-ene has been studied also at considerably higher temperatures in a shock tube[18]. On extrapolating the early results[16,17] to the conditions of their own experiments, these workers found[18] the activation energy to be 65 kcal.

Thus at present the mechanism of *cis–trans* isomerisations cannot be regarded as finally established. Complications due to the occurrence of heterogeneous reactions and the possible influence of free radicals, observed by several workers, compel a very cautious approach to the expressions obtained for the isomerisation rate constants. If recent results are correct, the activation energies of *cis–trans* isomerisations will be larger than those assumed earlier. These quantities are close to the mean energy of the π-C=C bond in alkenes, and it may therefore be supposed that isomerisation is accompanied by the formation of an unstable biradical intermediate:



This possibility had been pointed out earlier by Kondrat'ev[19]. The intermediate biradical is in a singlet state, so that the reaction takes place without change in the multiplicity, as is indicated by the "normal" values of the pre-exponential factors.

With this reaction mechanism *cis–trans* isomerisation by definition is not a molecular reaction, and its consideration is in general outside the scope of the present review. Nevertheless, certain other reactions are discussed, where the mechanism is also a matter of controversy.

2. Decomposition and Isomerisation of Cyclobutanes

Two types of chemical changes—(1) decomposition into two alkene molecules and (2) *cis–trans* isomerisation—are possible in the case of cyclobutane derivatives.

If the decomposition of cyclobutane is a single-stage unimolecular reaction, the structure of the corresponding activated complex can be represented

This involves the cleavage of two σ-C=C bonds in the four-membered ring, with the formation of two π-C=C bonds. The additive activation energy of this reaction is $E = 60 + 79 - (12 + 28 + 2 \times 17) = 65$ kcal, which agrees with most of the experimental results in Table 4.

However, we have tacitly assumed that activated π-bonds are not conjugated, and we have not introduced appropriate corrections. This can be justified by the fact that the decrease in energy of the system resulting from conjugation is to a considerable extent balanced by the increase due to the high deformation energy for the four-membered ring. Indeed, the deformation energy in cyclobutadiene, for example, is so large that this compound is probably absolutely unstable, and all attempts at its synthesis have failed.

A single-stage mechanism is supported by the fact that the rate of this reaction depends neither on the surface–volume ratio S/V nor on additions of inhibitors of radical reactions. Nevertheless, several workers assume that the decomposition of cyclobutanes takes place in two stages, with the intermediate formation of an unstable biradical:

If the first stage is rate-determining, the activation energy should be equal to the energy of rupture of a carbon–carbon bond in cyclobutane, i.e. 60 kcal. This value is also close to experimental values of the activation energy.

It is therefore difficult to draw a final conclusion on the mechanism of the reaction. However, interesting work[25,26] on the decomposition and isomerisation of *cis-* and *trans-*1,2-dimethylcyclobutanes shows that, if an intermediate biradical is formed, its decomposition is more rapid than rotation about the carbon–carbon bond. Indeed, this work has revealed firstly that the rate of *cis–trans* isomerisation of cyclobutane is far lower than its rate of decomposition, although the activation energy of isomerisation is also rather smaller; and secondly that, in the decomposition of 1,2-dimethylcyclobutanes with the formation of but-2-ene and ethylene, non-equilibrium proportions of the *cis-* and *trans-*isomers are formed, the butene which corresponds in configuration to the original cyclobutane always being produced preferentially. These facts undoubtedly suggest that the lifetime of the hypothetical biradical is extremely short, probably shorter than the time of rotation about the carbon–carbon bond. Experimental data on the kinetics of the *cis–trans* isomerisation of cyclobutanes are listed in Table 5.

It is interesting also to note the appreciable differences in decomposition kinetics between cyclobutane and its derivatives containing a double bond in the β-position relative to the ring: the activation energy of decomposition of the latter is about 12 kcal smaller than that of cyclobutane.

With a biradical mechanism this decrease in the activation energy of decomposition is attributed to the resonance (stabilisation) energy of an allylic radical $\cdot CH_2CH_2CH_2\dot{C}HCH:CH_2$.[27,28] However, this energy is considerably smaller than for allyl itself $CH_2:CH.CH_2\cdot$, where it is 22 kcal‡.

3. Isomerisation of Cyclobutenes

The isomerisation of cyclobutene and its derivatives into dienes has been studied in detail by Frey and Walters[56–65]. These are first-order reactions, and their rate is affected neither by change in the surface–volume ratio nor by additions of inhibitors. The view that these are true unimolecular reactions is entirely justified. Isomerisation involves the cleavage of one C–C bond in the four-membered ring and one π-bond, while three (activated) cumulative π-bonds and one σ-bond are formed:

The additive activation energy of this reaction is $E = 60 + 61 - (12 + 3 \times 17 + 3 \times 8) = 34$ kcal.

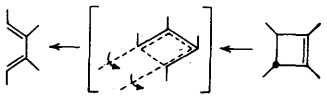
				14.00	39.5	69

This value shows excellent agreement with available experimental data (Table 6), except for the reactions of dicyclic compounds and perfluorocyclobutene, the activation energies of which are 10–13 kcal higher. In the case perfluorocyclobutene the presence of fluorine atoms probably greatly affects the energies of the bonds in the molecule. Such deviation from a simple additive scheme is a

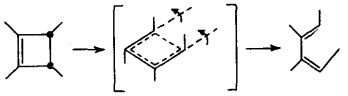
‡ The stabilisation energy of a radical can be estimated as the difference between the mean energy and the energy of rupture of a carbon–hydrogen bond in the molecule[29]. For propene this will give[30] $E_{stab} = 99 - 77 = 22$ kcal.

general phenomenon in the reactions of perfluorinated compounds, which requires the introduction of appropriate corrections into the scheme.

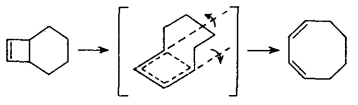
Special interest attaches to the isomerisation of dicyclic compounds, where the departure from additivity is due to the peculiar stereochemistry of the process. In fact the isomerisation of substituted cyclobutenes involves rotation of the terminal groups formed, where "unidirectional" rotation (the *conrotatory* process) is energetically more favourable. Thus, *trans*-1,2,3,4-tetramethylcyclobutene yields 3,4-dimethylhexa-*trans*-2,*trans*-4-diene:



whereas, *cis*-1,2,3,4-tetramethylcyclobutene gives 3,4-dimethylhexa-*cis*-2,*trans*-4-diene[64]:



In dicyclic molecules, however, such unidirectional rotation is impossible, and isomerisation is accompanied by rotation in the opposite direction (*disrotatory* process)[64]:



Since "opposite" rotation is energetically less favourable, the activation energy is appreciably higher in these cases.

There is a qualitative quantum-mechanical explanation of these peculiarities in terms of the symmetry of the molecular orbitals of the electrons taking part in the reaction[68]. In a conrotatory process two σ-electrons and two π-electrons of the initial molecule pass into the two lowest orbitals ψ_1 and ψ_2 of the resulting butadiene:

$$\sigma^2\pi^2 \rightarrow \psi_1^2\psi_2^2.$$

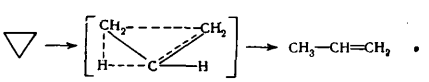
With a disrotatory process two of these electrons should pass into a higher level ψ_3 in order to maintain the symmetry of the orbitals:

$$\sigma^2\pi^2 \rightarrow \psi_1^2\psi_3^2 \ .$$

Thus the departure from additivity in the isomerisation of dicyclic molecules finds a simple explanation in the method of molecular orbitals.

4. Isomerisation of Cyclopropanes

Two types of isomerisation—structural isomerisation with the formation of alkenes and geometrical *cis–trans* isomerisation—occur in cyclopropane and its derivatives, as also in cyclobutane. A theoretical treatment of and kinetic data on the structural isomerisation of cyclopropanes into alkenes will be found in several papers[72-92,202]. Two mechanisms have been suggested for this reaction. Smith[72] suggested that isomerisation involves formation of a transition state containing five atoms in the same plane:



An alternative mechanism, with intermediate formation of the short-lived biradical trimethylene, was put forward by Rabinovitch et al.[73]:

Additive calculation of the activation energy of isomerisation and also several other arguments[74,81] tip the balance in favour of the biradical mechanism of isomerisation. In fact the calculated activation energy for the first mechanism $E = 50 + 99 - (4 + 2 \times 45 + 17) = 38$ kcal differs markedly from the experimental value of 65 kcal. This implies that the reaction does not take place by the first mechanism.

The scheme proposed by Rabinovitch for the alternative biradical mechanism must be supplemented by reaction *2*, the reverse reaction to formation of the trimethylene radical[75]:

The isomerisation rate constant for this extended mechanism is $k = k_1k_3/(k_2 + k_3)$, where k_1, k_2, and k_3 are the rate constants of the corresponding reactions. When $k_3 \ll k_2$, we have $k \simeq k_3k_1/k_2 = k_3K_{eq}$, where K_{eq} is the equilibrium constant for the formation of trimethylene from cyclopropane. According to Benson[75]

$$k_1 = 10^{16.0}\exp(-64200/RT)$$
$$k_2 = 10^{13.0}\exp(-8200/RT)$$
$$k_3 = 10^{13.2}\exp(-9500/RT) \ .$$

The expression for k_1 was obtained on the assumption that the rate of reaction *1* was equal to the rate of geometrical isomerisation of cyclopropane.

Rabinovitch and his coworkers found[73] that the rate of geometrical isomerisation of dideuteriocyclopropane exceeded its rate of structural isomerisation about sixteenfold. This is perfectly understandable when it is remembered that the intermediate trimethylene biradical is common to the two reactions:

Comparison of data on the kinetics of the geometrical isomerisation of cyclopropanes (Table 8) with those on the structural isomerisation of the same compounds (Table 7) shows that the activation energy of *cis–trans* isomerisation is the lower. This is due to the lower potential barrier to internal rotation in the biradical than to its isomerisation into propene. Hence in this case $k_3' \gg k_2$ and $k_{geom} = k_1k_3'/(k_2 + k_3') \simeq k_1$, in agreement with Benson's conclusions[75].

It is interesting that 1,1-dichlorocyclopropane isomerises into 2,3-dichloropropene with migration of a chlorine atom, not of a hydrogen atom[76]:

From the experimental results the authors[76] conclude that this reaction has a single-stage mechanism with an activation energy of 57.8 kcal, which agrees with the additive value of 55 kcal.

5. Isomerisation of Vinylcyclopropanes

A peculiar type of isomerisation with expansion of the ring is observed with compounds containing a C=C double bond in the β-position to the ring. The simplest compound

of this type is vinylcyclopropane, which isomerises into cyclopentene:

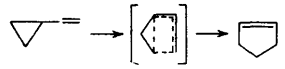


Table 7. Kinetic data on the structural isomerisation of cyclopropanes (VI).

			14.09	50.2	90
			14.58	46.6	91

This reaction involves the cleavage of one π-bond and one σ-C–C bond in the three-membered ring. The additive activation energy of this reaction is $E = 50 + 61 - (4 + 17 + 17 + 22) = 51$ kcal.

Two mechanisms have been suggested for reactions of this type—via a four-membered activated complex, as indicated above[95], and a biradical mechanism involving the formation and isomerisation of a biradical[96]

The first mechanism is supported by two arguments: firstly the pre-exponential factor in these reactions is smaller by $10^{1.5-2}$ than in the isomerisation of cyclopropanes into alkenes, which involves the intermediate formation of biradicals (see subsection 4); secondly, the activation energy of the isomerisation of vinylcyclopropane into pentadienes, which has a biradical mechanism, exceeds that for the present reaction by 6–7 kcal (see Table 7).

Table 8. Kinetic data on the geometric isomerisation of cyclopropanes (VI). *cis*-VI → *trans*-VI

VI A	VI B	lg A	E, kcal	Ref.
CHD	CHD	16.00	64.2	73

CHC_2H_5	$CHCH_3$	15.08	58.9	93
1,2,3-trimethylcyclopropane		15.78	60.9	94

Available experimental data (Table 9) show excellent agreement with the additive activation energy, which suggests that the reaction takes place by the first mechanism.

It is interesting that the activation energy of the isomerisation of perfluorovinylcyclopropane is considerably smaller because of the greater deformation energy of this compound compared with cyclopropane. It has been estimated[103] as $\Delta Q_{def} = 43–50$ kcal, compared with ~ 28 kcal in the case of cyclopropane[155].

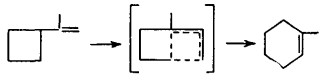
Substituted cyclobutanes undergo analogous isomerisation with an activation energy of 51 kcal[28]:



6. Decomposition of Esters

Esters containing a carbon atom in the β-position relative to the carboxyl decompose into an acid and an alkene:

$$RCOOR' \rightarrow RCOOH + \text{Alkene}\ .$$

The activated complex of this reaction is either four-membered or six-membered:

8. Decomposition of Alkyl Halides

A large number of investigations have been made on the mechanism and the kinetics of the thermal decomposition of alkyl halides to form an alkene and a hydrogen halide. The study of reactions of this type is complicated by the fact that, depending on their structure, alkyl halides may decompose either by a molecular or by a chain mechanism. Summarising a large amount of experimental information, Semenov[29] concluded that a molecular mechanism of decomposition was undergone only by those alkyl halides which, having lost a hydrogen atom, were incapable, because of the peculiar structure of the molecule, of forming an alkene by elimination of the halogen atom. Furthermore, the decomposition of alkyl halides is extraordinarily sensitive to the condition of the surface of the reaction vessel[29].

Experimental determination of the rate constants of unimolecular decomposition in particular is therefore difficult. Szwarc[116] used a toluene method to determine the unimolecular decomposition constants of an alkyl bromide, on the assumption that the presence of toluene suppresses radical side-reactions. To eliminate the effect of heterogeneous reactions on the kinetics of the unimolecular decomposition of ethyl chloride, we have studied[5] the reaction kinetics in a stream of an inert gas. Comparison of the rate of decomposition under these conditions with the rate on the packing in a column also enabled the rate constant of the heterogeneous reaction to be determined.

In spite of the above difficulties, a large number of rate constants have now been determined for the elementary reactions in the decomposition of alkyl halides. In all reactions of this type a four-membered activated complex is formed:

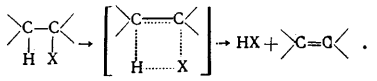

Table 13. Activation energy for the decomposition of alkyl halides (calculated). RX → HX + Alkene

Alkyl	X		
	Cl	Br	I
Primary	55	51	53
Secondary	48	46	45
Tertiary	41	41	37

Analysis of existing experimental results shows that the activation energy of these reactions is appreciably dependent on whether the halogen atom X is attached to a primary, secondary, or tertiary carbon atom. The activation energy for the decomposition of primary alkyl halides is rather higher (5–8 kcal) than for the secondary compounds, and the values for the latter are higher than for tertiary alkyl halides.

In the additive calculation of activation energy this is allowed for by the different mean energies of the activated bonds $C_{prim}...X$, $C_{sec}...X$, and $C_{tert}...X$. The influence of the immediate environment of the carbon atom on the energy of the activated bond C...X is exhibited here quite clearly. This effect is observed only with halogen atoms, and is probably caused by their great electronegativity, as a consequence of which the activated bond is strongly polar in character, approaching an ionic bond in polarity.

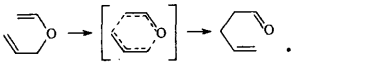
The additive activation energy for the decomposition of alkyl halides can be represented by the formula

$$E = 99 + Q_{C-X} - (45 + 17 + Q^{*}_{H-X} + Q^{*}_{C-X}) = 37 + Q_{C-X} - Q^{*}_{H-X} - Q^{*}_{C-X}.$$

Calculated activation energies for the decomposition of primary, secondary, and tertiary alkyl halides are listed in Table 13. Comparison with the numerous experimental values available (Table 14) shows good agreement with the calculated additive values.

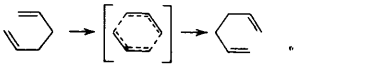
9. Claisen and Cope Rearrangements

Intramolecular rearrangements accompanied by inversion of an allyl group are widely known in organic chemistry. In the case of ethers such reactions are termed Claisen rearrangements. The reaction can be represented by the scheme



(1)

The Cope rearrangement can be represented by a similar scheme. The only difference is that here we have a carbon atom instead of the oxygen atom:



(1′)

The additive activation energies are—for the Claisen rearrangement

$$E = 2 \cdot 61 + 80 - (3 \cdot 17 + 18 + 27 + 28 + 4 \cdot 12) = 30 \text{ kcal}$$

and for the Cope rearrangement

$$E = 2 \cdot 61 + 79 - (4 \cdot 17 + 2 \cdot 28 + 4 \cdot 12) = 29 \text{ kcal}.$$

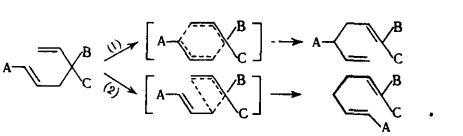
These values agree excellently with available experimental data (Table 15).

In the case of these rearrangements the experimental evidence for the structure of the activated complex, i.e. for the reaction mechanism, is quite complicated, and indeed a six-membered structure for the cyclic transition state has been confirmed only in isolated cases. Sometimes, however, the possibility is admitted[74] that a four-membered activated complex can be formed:

(2)

for the Cope rearrangement. A completely analogous scheme applies to the Claisen rearrangement.

To choose between these two mechanisms it is necessary to use a compound containing substituents attached both to the extreme carbon atom in the molecule (at position 6) and at position 3. Only in this case do reactions (1) and (2) yield products differing in structure:



The additive calculation of activation energy provides new opportunities for establishing the mechanism of a reaction. In the present case the activation energies calculated for six-membered and four-membered activated complexes differ markedly. For reaction (2), for example, the activation energy is $E = 79 + 61 - (2 \times 17 + 2 \times 28) = 50$ kcal.

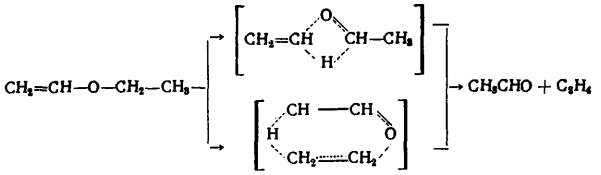
The analogous calculation for the Claisen rearrangement via a four-membered complex gives 51 kcal. These values differ by more than 20 kcal from the experimental values of the activation energy. The agreement with experiment of activation energies calculated for the six-membered complex, and the sharp divergence between the corresponding values for the four-membered complex, show quite obviously that the reaction takes place by the first mechanism.

10. Decomposition of Unsaturated Ethers

Several unsaturated ethers decompose with the formation of alkenes and aldehydes. For example, ethyl vinyl ether when heated breaks down into acetaldehyde and ethylene. Two possible mechanisms—



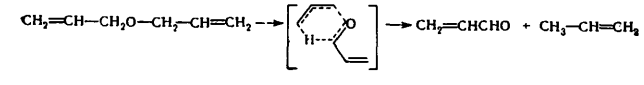
have been suggested and discussed[161,162] for this reaction. Additive calculation of the activation energy for the first mechanism, involving formation of a four-membered activated complex, gives $E = 80 + 99 - (18 + 27 + 2 \times 45) = 44$ kcal. For the second route, with formation of a six-membered activated complex, $E = 90 + 80 + 61 - (2 \times 45 + 18 + 27 + 2 \times 17 + 2 \times 12) = 47$ kcal.

Table 15. Kinetic data on allylic rearrangements.

Reaction	lgA	E, kcal	Ref.
$CH_2=CHCH_2CH_2CH=CHCH_3 \rightarrow CH_2=CHCH_2CHCH=CH_2$ (CH₃)	9.09	32.5	144
$CH_2=CHCH_2CHCH=CH_2 \rightarrow CH_2=CHCH_2CH_2CH=CHCH_3$ (CH₃)	9.84	32.5	144
$CH_2=CHCH_2C(CN)_2C=CHCH_3 \rightarrow CH_2=CHCH_2CHC=C(CN)_2$ (C₂H₅; CH₃, C₂H₅)	10.94	25.78	157
$CH_2=CHCH_2C(CO_2C_2H_5)C=CH-CH(CH_3)_2 \rightarrow CH_2=CHCH_2CHC(CH_3)=CCO_2C_2H_5$ (CN; CH₃; CH(CH₃)₂; CN)	10.36	28.62	157
	10.80	26.16	157
$CH_2=CHCH_2CH_2CH=C=CH_2 \rightarrow CH_2=CHCH_2C(=CH_2)-CH=CH_2$	9.93	28.47	158
$CH_2=CHCH_2OCH=CH_2 \rightarrow CH_3=CHCH_2CH_2CHO$	11.70	30.6	159
$CH_2=CHCH_2OC=CH_2 \rightarrow CH_2=CHCH_2CH_2COCH_3$ (CH₂)	11.37	29.3	160

Activation energies calculated for both mechanisms agree with the experimental values $E_{exp} = 42.3$–48.5 kcal (Table 16). However, analysis of the entropies of activation shows that the reaction involves formation of a six-membered complex[161]. There is also a direct experimental confirmation of this conclusion: the decomposition of isopropyl vinyl ether yields acetaldehyde and propene[163], whereas reaction involving a four-membered complex should have given ethylene and acetone.

A peculiar mechanism is observed in the decomposition of diallyl ether to form propene and acrylaldehyde[165]:



The activated complex in this case differs from the preceding one only in the relative position of the activated

bonds: therefore the calculated activation energy is also 47 kcal, which agrees satisfactorily[165] with the experimental value of 42.3 kcal.

11. Diels–Alder Reactions

Reactions of this type, which are termed also diene syntheses, are extremely important in organic chemistry and are widely used in the synthesis of various organic compounds. According to present-day ideas Diels–Alder reactions take place in a single act involving a six-membered activated complex:

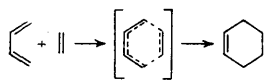


Table 16. Kinetic data on the decomposition of unsaturated ethers.

Reaction	lg A	E, kcal	Ref.
$CH_2=CHOC_2H_5 \rightarrow CH_3CHO + C_2H_4$	11.43 11.60	43.8 44.4	161 162

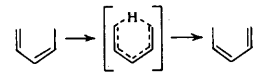
* Reaction in the liquid phase.
** Data on the kinetics of the reaction in various solvents.

All six π-electrons of the initial system are involved in the reaction. The activated complex contains four activated π-C=C bonds and two σ-C–C bonds. Three of the activated π-bonds form a cumulative chain, while one π-bond is conjugated.

Additive calculation gives a value for the activation energy of $E = 3 \times 61 - (4 \times 17 + 2 \times 28 + 3 \times 8 + 12) =$ 23 kcal, which agrees well with experimental data (Table 17). Rather larger deviations are observed with reactions in which dicyclic compounds are formed. In this case the additivity of the mean bond energies in the molecules probably breaks down.

12. Diene Rearrangements

Dienes undergo an interesting type of reaction, accompanied by migration of a hydrogen atom:



The additive activation energy of this process is $E = 2 \times 61 + 99 - (2 \times 45 + 4 \times 17 + 4 \times 8) = 31$ kcal. Here the activated complex contains two activated C–H bonds and a chain of four cumulative π-bonds. Thus the cumulation of four π-bonds must be taken into account in this case. The calculated activation energy agrees excellently with existing experimental data (Table 18).

Table 18. Kinetic data on diene rearrangements.

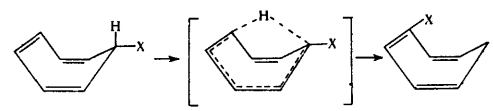
	12.5	30.6	181

* Reaction in the liquid phase.

A particular type of diene rearrangement, which, however, has been most thoroughly studied, is the isomerisation of substituted cycloheptatrienes:



Although the structure of cycloheptatrienes differs from that of normal alkadienes, the activation energies of isomerisation are similar in the two cases. This fact yet again supports the concept underlying the additivity principle, that the energy of the transition state is determined solely by the activated bonds, while the presence of other chemical bonds, not altering in the activated complex and not involved in the reaction, has no effect on the activation energy within the limits of accuracy of the additive calculation.

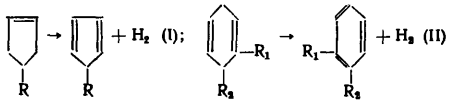
13. Dehydrogenation

In most cases the dehydrogenation of molecules takes place by a chain mechanism. A classic example is the decomposition of ethane into ethylene and hydrogen. The mechanism of the dehydrogenation of ethylene with the formation of acetylene is a matter of controversy: some papers[184] assume a molecular mechanism, and others[185] a chain mechanism. The spread of experimental values for the activation energy of this reaction—from 20[186] to 86[187] kcal—is extremely wide. For the molecular mechanism

the additive activation energy is $E = 2 \times 99 - (2 \times 45 + 48 + 9) = 51$ kcal. According to the additive principle the dehydrogenation of alkanes to alkenes

should be characterised by a lower activation energy $E = 2 \times 99 - (2 \times 45 + 48 + 17) = 43$ kcal, which agrees e.g. with data on the dehydrogenation of cyclopentane ($E_{exp} = 44$ kcal[188]).

Table 19. Kinetic data on the dehydrogenations (I) and (II).



Reaction	lgA	E, kcal	Ref.
I, R=H	13.34 13.01	59.9 58.8	189 190
I, R=O	12.72	48.5	191
II, $R_1=R_2=H$	12.36 12.02	43.8 42.7	192 90
II, $R_1=CH_3$; $R_2=H$	12.69	44.7	193
II, $R_1=H$; $R_2=CH_3$	12.47	42.95	194

Several studies have been made of the dehydrogenation of cycloalkenes, where hydrogen atoms are detached not from neighbouring carbon atoms but from those in the β-position with respect to the double bond:

Reactions of this type are probably molecular.

Additive calculation gives for the activation energy $E = 2 \times 99 + 61 - (2 \times 45 + 48 + 3 \times 17 + 3 \times 8) = 46$ kcal, which agrees well with existing experimental results (Table 19). The data on the dehydrogenation of cyclopentene constitute an exception, and it is possible that in this case the reaction occurs partly by a chain mechanism.

14. Decomposition of Unsaturated Alcohols

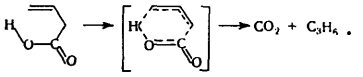
In concluding this survey of experimental data let us consider the decomposition of an unsaturated alcohol into an alkene and an aldehyde or a ketone. Such decomposition has been most thoroughly studied with alcohols whose hydroxyl is in the γ-position relative to the double bond. The reaction is assumed to involve the formation of a six-membered activated complex:

The activation energy calculated for this mechanism $E = 105 + 79 + 61 - (55 + 45 + 2 \times 17 + 28 + 18 + 2 \times 12) = 41$ kcal agrees excellently with existing experimental data (Table 20).

Table 20. Kinetic data on the decomposition of unsaturated alcohols.

Reaction	lgA	E, kcal	Ref.
$CH_2=CH(CH_2)_2OH \rightarrow H_2CO + C_2H_6$	11.65	41.0	195
$CH_2=CHCH_2CH(CH_2)OH \rightarrow CH_2CHO + C_2H_6$	11.93	40.8	195
$CH_2=CHCH_2C(CH_3)_2OH \rightarrow CH_2COCH_3 + C_2H_6$	12.14	40.7	195
$CH_2=C(C_6H_5)(CH_2)_2OH \rightarrow CH_2C(C_6H_5)=CH_2 + H_2CO$	11.80	38.9	195
$C_6H_5CH=CH(CH_2)_2OH \rightarrow C_6H_5CH_2CH=CH_2 + H_2CO$	11.58	42.8	195
$C_6H_5CH=CHCH_2C(C_2H_5)_2OH \rightarrow C_6H_5CH_2CH=CH_2 + (C_2H_5)_2CO$	12.04 12.14	41.75 41.8	196 195

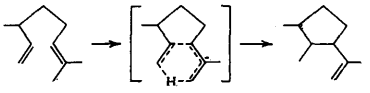
It is interesting that but-3-enoic acid decomposes by an analogous mechanism to form propene and carbon dioxide:



In this case, too, the experimental activation energy $E_{exp} = 39.3$ kcal[197] is close to the calculated value.

V. EFFECT OF CONJUGATED AND CUMULATIVE BONDS ON THE KINETICS OF MOLECULAR REACTIONS

Even a cursory analysis of the experimental information on the kinetics of molecular reactions shows that π-bonds are involved in the reaction in the vast majority of cases. It is therefore natural to expect that energy effects due to the peculiarities of behaviour of π-electrons would be revealed in the height of the potential barrier to the reaction. This is in fact so, and here we shall examine the effect of conjugation and cumulative π-bonding on the kinetics of molecular reactions. The influence of conjugation is shown most distinctly by comparing the experimental activation energy with the additive value calculated without correcting for conjugation. For the isomerisation of 3,7-dimethylocta-1,6-diene into 1-isopropenyl-2,3-dimethylcyclopentane, the activated complex of which contains two conjugated π-bonds,



for example, the experimental activation energy is $E_{exp} = 35.2$ kcal[198], whereas the additive value calculated without regard to conjugation is 58 kcal.

Reactivity of Radicals and Molecules in Radical Reactions

Yu.L.Spirin

A survey is made of the effect of polar interactions, due to substituents and the medium, on the reactivity of radicals and molecules in radical additions (polymerisation of monomers), and the metathesis and decomposition of molecules. Analysis of experimental information by the perturbation method leads to the conclusion that the reactivity of radicals increases, while that of molecules falls, with increase in their electronegative properties produced by the introduction of substituents, interaction with the solvent, etc. The non-additivity of the polar effect of substituents, which is known from the copolymerisation of vinyl monomers, is apparent also in several other reactions. A list of 94 references is included.

I. INTRODUCTION

If only physical constants are used, the description of a reacting system by the equations of quantum physics cannot give solutions which are suitable for practical application to complicated systems. This led to the need to introduce parameters of the hypothetical constants for a given configuration of atoms and electrons, such as the Coulombic and exchange integrals. As the result of the work of London[1] and of Eyring[2] this way of stating the problem for radical reactions enabled the valence bond method to be used to decipher the nature of the activation barrier in chemical reactions and to estimate the rate constant of the exchange between a hydrogen atom and a hydrogen molecule. A significant consequence of this work for an understanding of any radical reaction was the possibility of regarding activation energy as the superposition of bonding and antibonding terms. Analysis of radical reactions from this point of view permitted the extremely important Polanyi–Semenov rule to be formulated[3], which enabled the activation energy of a radical reaction to be estimated from the properties of the reactants. Comparison of this rule with experimental results showed that it had several significant exceptions[3]. Several of them can be described by regarding the rule as a consequence of the London relation and introducing the polarisability as an additional parameter[4]. The need to consider polarisability indicates that the higher unoccupied orbitals of the reactants have a considerable effect on the activation energy. However, no soundly based analysis of the dependence of activation energy on the properties of the reactants has been undertaken by the valence bond method, apparently owing to the difficulties of allowing for the large number of structures necessary for calculating the energy of a complicated polyatomic system of variable configuration.

The molecular orbital (MO) method provides considerably greater opportunities for ascertaining the dependence of reactivity on the structure of the reactants. With atomic orbitals as basis, however, the molecular orbital method does not enable the concept of activation barrier to be formulated, because incorrect allowance is made for the antibonding terms. In the analysis of radical reactions by the molecular orbital method[5-7], therefore, it is postulated that the activation energy E is related to some parameter Z of the system, which can be calculated by the molecular orbital method, using the relation

$$E = C + \alpha Z \qquad (1)$$

where C is constant for a given series of reactions of the same type, and α is a coefficient of proportionality.

The energies of localisation, stabilisation, hyperconjugation, etc. have been used as Z. A feature of the Z parameters is that by means of them the effect of a substituent as a whole is described, without separating it into components, e.g. into polar and resonance interactions. A satisfactory description of experimental results can usually be obtained, this being achieved in several cases by a "happy choice" either of the characteristics of the atoms or of the parameter Z.

The relation (1) can be satisfied if bonding and antibonding terms are connected by a linear dependence, which cannot be correct in general, since during the reaction these terms depend on different variables. Such proportionality is apparently observed in some reactions of a given type. Thus the relation (1) is observed in the polymerisation of vinyl hydrocarbons and in the abstraction of a hydrogen atom from hydrocarbons, whereas departures from this relation are found in the polymerisation of vinyl compounds containing heteroatoms[5,6,8].

Bazilevskii[8] has recently been able to overcome certain difficulties and show that the effect of the antibonding terms can be allowed for in the molecular orbital method. An activation barrier arises, in molecular orbital calculations on a reaction, if we pass by some method from a non-orthogonal set of atomic orbitals to an orthogonal set, i.e. if we make more correct allowance for repulsion between the reactants. In this case an expression is obtained for the energy of a system having non-zero activation energy in Pople's approximation. By using generally accepted assumptions this author[8] has calculated the activation energy for the reaction of the methyl radical with ethylene and has also described the effect of substituents on the activation energies of the polymerisation of several vinyl compounds.

In spite of the attractiveness of semi-empirical methods for calculating the activation energies and the rate constants of chemical reactions, their application to actual systems is at present essentially illustrative in character, since the large number of approximations in the values of atomic and bond parameters, both in the initial and especially in the transition states, leads in several cases to indeterminate results and divergence from experiment. As a consequence the advantages of the method, consisting in the possibility of calculating the effect of differential changes in the structure and the composition of the reactants on the rate of the reactions, have not yet been effectively realised. A considerable amount of work is evidently still necessary on evaluating atomic and bond parameters and elucidating the form of dependence of reactivity on these parameters before it will become possible to investigate reactions by a method of calculation.

An empirical method of investigating reactions, which has been termed the principle of the linear dependence of free energy of activation on structural parameters[9,10], has acquired great practical value. It is based on the hypothesis that the influence of fragments of molecules and radicals (ions) which remain unchanged during the reactions, i.e. substituents at the reaction centre, can be divided into three independent types of interaction—steric, polar (inductive), and resonance—and that the effectiveness of a substituent in the corresponding interaction can be determined by one parameter. Because of the impossibility of an unambiguous separation of the forms of interaction, these parameters have no physically based units of measurement, and are determined as relative values from reactions chosen as a standard. Only polar interactions could in practice be described with satisfactory accuracy, and scales of polar (inductive) constants compared for the substituents. The existing Hammett, Taft, etc. constants[9] differ mainly in the way in which allowance is made for the effect of conjugation. It is possible also to set up scales for the effectiveness of substituents for conjugation (resonance) with the reaction centre. Thus the Q scale is known for describing the ability of vinyl monomers to undergo copolymerisation[11]. Steric interactions cannot be described by a single scale.

Mathematically this principle is equivalent to expanding the free energy of activation $\Delta F^{\neq}$ in a series involving the parameters X_i describing the properties of the structure:

$$\Delta F^{\neq} = \Delta F_0^{\neq} + \frac{\partial \Delta F^{\neq}}{\partial X_i} dX_i + \frac{\partial^2 \Delta F^{\neq}}{\partial X_i^2} dX_i^2 + \ldots \qquad (2)$$

and to the assumption that the first approximation, i.e. retention of terms in the first derivatives, is sufficient to describe the experimental results. Since the free energy of activation depends both on the entropy and on the energy of activation, which in general are not interrelated, and all types of interaction are involved in the reaction, the successful description of a series of reactions using only one variable as its first derivative, must be regarded as the exception rather than the rule. Actually, a so called "compensation effect" is evident in many cases, represented by a linear dependence of the variation in energy and entropy of activation, conjugation and polarity, etc. There are reactions for which taking only the first approximation (additive action of substituents) into account is insufficient. The well studied radical copolymerisation of vinyl monomers is described only by allowing for the non-additive polar interaction of the substituents (the Alfrey–Price relation[5,11]), which corresponds formally to the second approximation (2). In view of the fact that non-additivity of the substituent effects may appear in other reactions, and of the arbitrary character of the separation of the overall effect of substituents into polar and resonance components, it is more correct to regard the influence of substituents as a small perturbation of the reaction centre, which enables non-linear terms in the expansion to be used for the analysis. A new possibility then appears for describing the influence of the structure of the reactants on their reactivity, by calculating the characteristics of the substituents and the constants for series of reactions by semi-empirical methods.

The laws of radical reactions have been more fully studied than those of other reactions, because they vary little with the external conditions. The effect of conjugation on the reactivity of radicals and molecules has been well investigated, and quite satisfactory criteria have been obtained in both the semi-empirical method (stabilisation, localisation, etc. energies) and in the empirical method (heat of reaction)[5-7]. Steric interactions have no common quantitative criteria, which makes their analysis difficult. The σ_S-parameters, introduced by Taft[9], are suitable only for a relatively narrow range of reactions. Information on the effect of steric interactions in homolytic reactions is in most cases qualitative in character and does not allow of generalisation[12]. It may be regarded as fortunate that the steric effect always promotes a decrease in interaction between the reactants, i.e. a decrease in the rate of bimolecular reactions and an increase in unimolecular reactions, so that its role can always be determined qualitatively.

Hardly any general analysis has been made of the effect of polar interactions, in spite of a large number of investigations and also particular relations concerned mainly with the effect of substituents on the activity of molecules. The display of polar interactions in radical reactions and elucidation of the common features thereof constitute the subject of the present Review. Consideration is given to the polar effect of substituents and of the medium on bimolecular substitutions and additions (polymerisation) and the formation of radicals.

II. POLAR EFFECTS OF SUBSTITUENTS IN ADDITION AND SUBSTITUTION

Data on reaction series of radical substitutions and additions are assembled in Table 1. In most of the systems investigated aromatic compounds have been chosen[9] as reactant molecule, the choice of scale (σ) leading to no great differences in the ρ-values for these compounds, as can be judged, for example, from the reaction series 21–25, for which σ and σ^+ scales have been used. This permits a comparative analysis in qualitative form, without the necessity for laborious recalculation. For the additions 13, 14, 46, and 47 the properties of the substituents are characterised by the Taft σ^*-constants. It may be supposed that, since in this case the substituents are separated from the reaction centre by a C=O group, the transfer coefficient of the polar effect through which apparently differs little from the transfer coefficient through a CH_2 group ($\frac{1}{3}$), the range of ρ-values for these reactions is closed to the remaining reactions.

Most reaction series are satisfactorily described by using only one parameter (σ). Only in certain reaction series, e.g. 12, 17, 48, are deviations found, which were explained by conjugation of the substituents with the reaction centre, not taken into account by σ.

It may be noted from Table 1 that the "sensitivity" ρ of the reaction centre is in most reactions negative: i.e. electron-donor substituents in a molecule increase the reaction velocity, whereas electron-acceptor substituents slow down the reaction. The relation of a radical to a molecule in these reactions resembles that of an acid to a base, the role of acid being played by the radical, and that of the base by the molecule. Only for a relatively small number of reactions is $\rho \geqslant 0$: for the addition of benzyl, phenyl, and poly(methyl acrylate) radicals to a double bond (series 12–14, 46–48, 54–56) and for the abstraction of a hydrogen atom by methyl (11) and benzyl (17) radicals. The negative sign of ρ is explained by most authors[5,13,22] by the electron-acceptor properties of the radicals. Indeed, Table 1 shows a tendency for ρ to decrease with increase in the acceptor properties of the radicals. Thus on passing from the benzyl (17, 48) to the methyl (11) and then to the trichloromethyl radical the value of ρ diminishes from +0.8 to −1.75 (26, 45). An analogous tendency is observed with phenylated radicals (52–56). The value of ρ is also

less than zero for electronegative radicals (Br•, Cl•, RO•, RO_2•, R_2N•). The minimum value of ρ is observed with the diphenylpicrylhydrazyl radical, which is apparently explained by the electron-acceptor properties of nitro-groups.

The effect of the structure of the molecule on the value of ρ is less clearly developed. On examining the reaction series 1 and 2, 8 and 9, 13 and 14 we can see that replacing hydrogen by a methyl group in the molecule leads to a decrease in the modulus ρ. For phenols and aromatic amines (18–23, 24, 33–38) the value of ρ is in most cases negative, and for vinyl compounds it is indeterminate (12–16, 46, 47). The magnitude of ρ apparently increases as the electron-donor power of the molecule becomes stronger, but this tendency is very weak.

To analyse the dependence of reactivity on the structure of the reactants, let us expand the reaction rate constant in a series:

$$\lg k_{ij} = \lg k_0 + \left(\frac{\partial \lg k}{\partial \sigma}\right)_R \sigma_i + \left(\frac{\partial \lg k}{\partial \sigma}\right)_M \sigma_j + \left[\left(\frac{\partial}{\partial \sigma}\right)_R \sigma_i + \left(\frac{\partial}{\partial \sigma}\right)_M \sigma_j\right]^2 \lg k + \ldots \quad (3)$$

where k_0 is the reaction rate constant disregarding polar interactions, and σ a measure of the polar properties of the substituents in the radical R and the molecule M, e.g. the Hammett, Taft, Alfrey–Price, etc. constants. Since the Alfrey–Price relation, including terms in $\sigma_i\sigma_j$, is observed in radical copolymerisations, whereas a linear dependence on σ is found with most reactions, it is apparent that in general it is sufficient to confine ourselves to the approximation

$$\lg k_{ij} = \lg k_0 + \rho_R\sigma_i + \rho_M\sigma_j + \rho_{RM}\sigma_i\sigma_j \quad (4)$$

for the rate constant, in which terms in σ_i^2 and σ_j^2 are neglected in comparison with Eqn. (3), in view of their smallness or indistinguishability from terms in σ, while the constants ρ denote the corresponding derivatives with respect to σ.

Experimentally reaction series are usually investigated, in which the relative rate of addition of a molecule containing different substituents to some radical is determined: i.e. the σ_i are constant for a series, and presumably also k_0, this converts formula (4) into

$$\lg \frac{k_{ij}}{k_0} = (\rho_M + \rho_{RM}\sigma_i)\sigma_j \equiv \rho_{exp}\sigma_j \qquad (5)$$

which is formally analogous to the Hammett, Taft, etc. relations. Equation (5) shows that the experimental quantity ρ_{exp} gives no information on the "sensitivity" of the radical to the polar effect of its substituents, since the term in ρ_R is constant in a given series of reactions, and is included in $k_0' = k_0 + \rho_R\sigma_i$. The sign and magnitude of ρ_{exp} give information only on the energy of polar interaction of substituents in the molecule with the radical or its substituents and on the "sensitivity" of the molecule. As already remarked, the magnitude of ρ_{exp} diminishes with increase in the electronegativity of the radical, which can be related to the quantity σ_i. Hence $\rho_{RM} < 0$. If we examine reaction series for different hydrocarbon radicals towards a single series of molecules for which ρ_M is constant, the whole difference in ρ_{exp} is determined by the electronegativity of the substituents in the radical, not by the properties of the radical as such. This is an important confirmation of the correctness of the Alfrey–Price relation in reactions involving detachment of a hydrogen atom. The negative sign of ρ_{RM} is explained by the effect of polar structures on the energy of the transition state in radical reactions, from which it follows that differently charged substituents in radical and monomer lower the energy of the transition state[5].

Existing data do not enable the sign of ρ_M to be assessed. Since for most reactions $\rho_{exp} < 0$ and $\rho_{RM} < 0$, it can be assumed that ρ_M is small and apparently slightly exceeds zero.

To determine ρ_R data are required on the absolute or relative rate constants in the reactions of different radicals with some one molecule. The experimental difficulties in the way of carrying out such a programme are great, which explains the extraordinary sparsity of such data. Bagdasar'yan's monograph[5] gives data on the absolute constants for addition of the radicals $CH_3^\bullet$, $CCl_3^\bullet$, and $CF_3^\bullet$ to hept-1-ene at 60°C, which are respectively 0.0005, 0.00062, and 1.7 $M^{-1}\,s^{-1}$, and which indicate an increase in reactivity of the radicals with increase in the electronegativity of the substituents, this occurring in spite of an increase in the energy of conjugation in the radical on the introduction of substituents. Some conformation of the increase in activity of the radicals with increase in electronegativity is the decrease in activation energy in the detachment of hydrogen from alkanes on passing from the radical $CH_3^\bullet$ to $CF_3^\bullet$.[4] The literature contains hardly any systematic data on the absolute rate constants for reactions involving the detachment of hydrogen. In this connection great significance is acquired by results obtained for the polymerisation and copolymerisation of vinyl monomers, from which reliable values of the relative reactivity of monomers have now been obtained. There are considerably fewer data on the relative reactivity of radicals and on the absolute rate constants, and they are less reliable. Existing data on the absolute rate constants of chain growth can, on certain assumptions concerning the energy of conjugation in the monomers, be described by means of Eqn. (4). With $\rho_{RM} = -1$† it was found[31,32] that $\rho_R = 1.6$ and $\rho_M = -0.35$: i.e. in polymerisation reactions the radical is more "sensitive" than the monomer to the polar effect of substituents, and further the effects of substituents in the radical and in the monomer are opposite in sign. From the fact that $\rho_R > 0$ it follows that electron-acceptor substituents increase the reactivity of radicals, whereas electron-donor substituents diminish it. Indirect data indicate that such a relation cannot be a particular case, but it is characteristic of all radical reactions involving molecules containing substituents at the site of formation of the radical. This generalisation is not valid for the addition of radicals to $\alpha\beta$-substituted vinyl compounds, owing to the change in nature of the interaction of the substituents: i.e. formula (4) is not applicable to such reactions. Thus in the copolymerisation of β-fluorinated styrenes (2), in which the fluorine has relatively little influence on the steric interactions, with styrene itself (1) it is found[35] that $r_1 = K_{11}/K_{12} > 1$, while $r_2 = K_{22}/K_{21} \to 0$, i.e. $K_{22} \to 0$. Formal treatment of these results on the basis of the Q–e (or Q'–e) scheme[31,32] for β-fluorostyrenes yields $e_2 > e_1$ and $Q_2 \to 0$. The latter is, of course, incorrect, since the energy of conjugation in β-fluorostyrenes is close to that in styrene itself, and $Q_2 \simeq 1$. A correct description of such systems needs to take into account terms in the expansion of the expression for the rate constants describing the effect of β-substituents.

Summarising, we can conclude that the introduction of electron-acceptor substituents into a radical, or increasing the electronegativity of the radical, increases its "sensitivity" to polar changes in the molecule, and increases the reactivity of the radical. Electron-acceptor substituents in the molecule (at the site of formation of the radical) change reactivity mainly by polar interaction with the radical or with substituents therein.

III. EFFECT OF THE POLAR PROPERTIES OF SUBSTITUENTS ON THE DECOMPOSITION OF PEROXIDES AND AZO-COMPOUNDS

The influence of the polarity of substituents on the rate constants for decomposition of organic compounds involving the formation of two radicals has been investigated mainly with peroxides and azo-compounds as examples.

The decomposition of substituted benzoyl peroxides was described by Swain and his coworkers[36], who discovered the additive effect of substituents, present in the rings of different aromatic peroxides, on the reaction rate constant:

$$\lg \frac{k}{k_0} = -0.38(\sigma_1 + \sigma_2).$$

These workers also concluded that the term in $\sigma_1\sigma_2$, describing the interaction of the substituents, was small or even absent.

Later investigations[37] have led to the conclusion that the effect of substituents on the decomposition of substituted benzoyl peroxides is described by a more complicated relation, and that conjugation of the reaction centre with a substituent exerts a considerable influence on the decomposition rate constant. Table 2 lists data obtained by different workers[36–38] on the decomposition of peroxides. It shows that electron-donor substituents accelerate decomposition, whereas electron-acceptor substituents slow de-

† The calibration $\rho_{RM} = -1$ corresponds to the Alfrey–Price scale for the polar constants of substituents, which are proportional to the Hammett constants[33,34].

composition down. An analogous effect can be observed in the decomposition of saturated per-esters: when chlorine in the α-position to a carbonyl group is replaced by an isopropyl group, the decomposition rate constant increases fourfold[39]. It can also be concluded from these observations that increase in the acceptor properties of radicals should increase their activity in recombination reactions.

Table 2. Decomposition of substituted benzoyl peroxides.

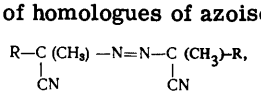
p-CN	0.97	0.68	0.81
p-NO_2	0.87	—	1.45

An accelerating action of electron-donor substituents has been observed[40] in the decomposition of substituted dithenoyl peroxides of general formula

The observed relations are consistent with the tendency of the energy of the O–O bond, which is equal to the activation energy for decomposition of the peroxide, to decrease on passing from hydrogen peroxide to alkyl peroxides[41].

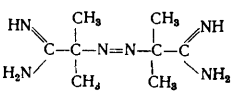
Several investigations[42–44] have been made on the effect of substituents on the decomposition of azo-compounds. Overberger et al.[43] found that the effect of substituents on the decomposition of homologues of azoisobutyronitrile



where R = CH_3, C_2H_5, n-C_3H_7, iso-C_4H_9, can be explained by steric causes. In another investigation Overberger and his coworkers[42] found that the substituent in compounds of the type

where X = Cl, H, NO_2, has a weak polar effect.

The substituent has been found to have a considerable effect in the thermal decomposition (at 60–85 °C of azoisobutyramidine



and its nitrates[44]. The addition of one molecule of nitric acid produces a very considerable increase in the rate of decomposition of this compound. Addition of a second molecule of the acid also leads to an increase in the rate of decomposition, but the effect is less marked. Decomposition of the azo-compound and its salts apparently takes place entirely by a radical mechanism, since, when the reaction is conducted in the presence of methyl methacrylate, the latter polymerises at a rate which parallels the rate of decomposition. Since the addition of acid to an amidino-group is equivalent to increasing the electron-acceptor properties of the substituent, the effect of the polarity of the substituent on the decomposition of this compound is formally opposite to the effect of substituents on the decomposition of peroxides, which appears improbable. A possible explanation of the accelerated decomposition of azoisobutyramidine on interaction with an acid is an increase in energy of conjugation in the substituent, which tends to stabilise the radicals and hence diminish the energy of the C–N bond.

IV. EFFECT OF THE MEDIUM ON RADICAL ADDITIONS AND SUBSTITUTIONS

The interaction of radicals with the medium, by which will be understood any set of molecules which do not react directly, including one complexing molecule, can take place in two ways—(1) by interaction of the atom carrying the unsatisfied valency with the medium, and (2) by interaction of substituents on the radical with the medium. A recent review[45] has discussed several radical reactions in which the effect of the medium is evident. In the present Review the effect of the medium is examined as a function of the structure of the radicals and the molecules.

There are few investigations in which the direct effect of the medium on an atom carrying the unpaired electron has been observed experimentally. Most of the systems described relate to reactions in which the radical is a free or substituted heteroatom, e.g. Cl or RO, having a lone pair of electrons directly on the atom containing the unpaired electron. Interaction of such radicals with the medium takes place mainly either by a mechanism of hydrogen bonding or by complex formation with the π-bonds of the solvent. The complicated electronic structure of radicals does not allow the nature of the interaction to be determined unambiguously[45]. Russell[46], who observed that the aromatic character of the solvent influenced the reactivity of the chlorine atom, suggested that a linear relation should exist between the ionisation potential of the radical and the energy of its interaction with the solvent. Investigations of the reactivity of the chlorine atom and of the t-butoxy-radical showed that in aromatic solvents the activity of the radicals diminished with increase in the basic character of the medium. It is significant that the effect of the solvent is considerably more strongly developed on the chlorine atom than on the alkoxy-radical[46,47]. Other investigations[48,49] on the effect of solvents on the activity of the t-butoxy-radical showed a considerably stronger solvent effect. However, while investigating the reaction of the t-butoxy-radical with substituted toluenes in different solvents, Sakurai and Hosomi concluded[49] that the solvent, although strongly influencing the ratio of the rate constant for reaction of the radical with toluenes to the rate constant for decomposition of the t-butoxy-radical into acetone and a methyl radical‡, has little effect on the value of ρ in a series of reactions. Thus values of −0.35, −0.32, and −0.39 were obtained for ρ for Freon-113, chlorobenzene, and acetone at 45°C, whereas the above ratio of the constants for this series of solvents is respectively 2.19, 1.31, and 0.52. From these observations it was concluded[49] that the solvent has a greater effect on the decomposition of the t-butoxy-radical than on its ability to abstract a hydrogen atom. In the opinion of these workers, the effect of the solvent on the reactivity of the radical is described by the variation in ρ with the solvent, and is therefore

‡ The reactivity of the t-butoxy-radicals was determined[47,48] by the method of competing reactions, on the assumption that the decomposition constant of the t-butoxy-radical is independent of the solvent.

small. Investigation of the effect of solvents on the decomposition of oxygen-containing radicals[45] showed that the rate of decomposition of such radicals depended on the presence of hydrogen bonds between the radical and the solvent.

In comparison with heptane, pyridine has been found[50] to have an activating effect, and ethylbenzene a deactivating action, on the reactivity of certain nitric-oxide radicals, in particular on that of the bismethoxyphenylnitrogen oxide radical toward 2,6-di-t-butylphenol. It is assumed[50] that the solvents form π-complexes with the radical. According to spectrophotometric data the heat of complex formation with benzene is 6.2 and 7.5 kcal mole^{-1} in ground and excited states[51].

To ascertain the nature of the effect of the medium it is extremely interesting to examine the action of solvents on the polymerisation and copolymerisation of vinyl monomers, since in this case the atom carrying the radical contains no lone pairs of electrons, which simplifies the pattern of interaction of the radical with the medium. As early as the end of the 1940s the influence of the medium on radical copolymerisation constants was investigated[11] in connection with the parameter e in the $Q-e$ scheme. It was established that copolymerisation constants, measuring the relative activity of the monomers, were independent of the solvent. In particular, such independence was found for the styrene–methyl methacrylate system, copolymerisation of which was conducted in benzene, acetone, and methanol[52]. It follows from these data that the reactivity of hydrocarbon radicals is independent of the properties of the medium. This postulate has become widely accepted, and on its basis vinyl monomers have been classified according to the $Q-e$ parameters[5,11], which represent the reactivity of the monomers. It should be noted that experimental errors in determining the composition of copolymers are fairly substantial, and it is highly probable that the solvent effect will be hidden by these errors. Several investigations have recently been made on the effect of the nature of the solvent on the kinetics of the polymerisation of styrene and methyl methacrylate. In a study of the polymerisation of methyl methacrylate in aromatic solvents, initiated by azoisobutyronitrile, the rate of breakdown of which is practically independent of the solvent[53], Burnett and his coworkers[54] found that the rate of polymerisation increases in the series of solvents—benzene, chlorobenzene, bromobenzene, iodobenzene—by more than 50%. They consider that the solvent, while not affecting the decomposition of the initiator, nevertheless influences the efficiency of initiation by the fact that radicals formed by decomposition of the initiator react with the solvent. In a later paper Burnett et al.[55] have examined the effect of tri- and tetra-halogenated benzenes. It was found that disubstituted benzenes have a greater effect on the rate of polymerisation than have monosubstituted compounds, whereas tri- and tetrasubstituted benzenes have hardly any effect on the rate of polymerisation. In no case was incorporation of the solvent into the polymer observed, which might have indicated an effect of the medium on the reaction by a mechanism of chain transfer. It is curious that the above solvents do not affect the rate of polymerisation when the reaction is initiated by benzoyl peroxide[54]. This supports the view that the solvent influences the efficiency of initiation.

A criticism has recently appeared[56] of the views of Burnett et al. on the mechanism by which the medium affects the polymerisation of methyl methacrylate. The experimental results are confirmed, but it is concluded that the influence of the medium on this process, as on the polymerisation of styrene investigated previously[57], can be explained by the hypothetical formation of a charge-transfer complex between the growing radical and the monomer or the solvent. According to these authors[57] the rate of chain growth V_{gr} is proportional to the concentration of the radical–monomer complex:

$$V_{gr} = K_{gr}[R][M] = K'_{gr}[RM]$$
$$[R] = [RM] + [RS]$$

where R is the free radical, M the monomer, S the solvent, and RM and RS are the complexes formed by the radical with the monomer and with the solvent respectively.

Introducing the mean lifetimes of the complexes τ_M and τ_S and taking into account the stationary state conditions $[RM]/[RS] = \tau_M[M]/\tau_S[S]$, the authors derive an expression for the rate of chain growth:

$$V_{gr} = K_{gr}[R][M] \cdot \varphi^{+}_{gr}, \text{ where } \varphi^{+}_{gr} = \frac{[M]_{S=0}}{[S] \cdot \tau_S/\tau_M + [M]},$$

while $[M]_S = 0$ is the initial concentration of the monomer during bulk polymerisation.

The quantity φ^{+}_{gr} can provide information on the interaction of the radical with the medium. It is determined experimentally from the expression for the rate of polymerisation $V_{pol} = (V_{in}/K_0)^{\frac{1}{2}}[M]\varphi^{+}_{gr}$ or from the corresponding expression for the degree of polymerisation. Using the value obtained for φ^{+}_{gr}, we determine τ_S/τ_M from the relation

$$\frac{[M]_{S=0}}{\varphi^{+}_{gr} \cdot [M]} = 1 + \frac{\tau_S [S]}{\tau_M [M]} .$$

Table 3 gives these authors' results for several solvents.

Table 3. Effect of solvents on the polymerisation of styrene (1.82 M at 50°C with azoisobutyronitrile as initiator)[57].

Solvent	φ^{+}_{gr}	τ_S/τ_M	Solvent	φ^{+}_{gr}	τ_S/τ_M
Bromobenzene	1.01	0.93	Dimethylformamide	0.77	0.91

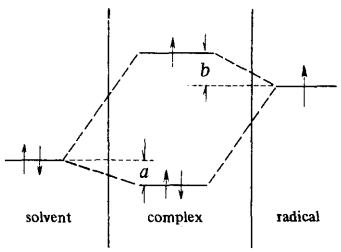
Mesitylene	0.79	1.62			

The idea[57] that the solvent effect is due to complex formation with the radical is supported also by the work of Bamford and Brumby[58], who have investigated the polymerisation of methyl methacrylate in aromatic solvents at 25°C. They find that complex formation influences both the rate constants for chain growth and for chain termination, although the effect is small. Thus the growth rate constant increases from 260 to 330 M^{-1} s^{-1} on passing from benzene to benzonitrile. The diminution in the reaction velocity by solvents parallels their capacity for π-complex formation, and varies in the sequence—benzene > fluorobenzene > chlorobenzene > bromobenzene > benzonitrile.

The tendency of radicals to undergo reactions mainly with aromatic solvents indicates $\pi\pi$-interaction rather than

polar (acceptor or donor) interaction. According to Russell[46] the activity of the chlorine radical falls with decrease in the electronegativity of the substituents in the aromatic solvents. A similar tendency can be observed also in polymerisations. This indicates that the radical acts as an acceptor of electrons in the π-complex. It may be supposed that a π-complex is formed mainly by the superposition of a non-bonding orbital of the radical, in which is located the unpaired electron, with a higher occupied orbital of the solvent, which, as is evident from the diagram, leads to a gain in energy ($E = 2a + b > 0$), and hence a diminution in the activity of the radical. The energy of interaction in the complex is 6 kcal mole^{-1}.[59] However, experimental data indicate the almost complete absence of delocalisation over the solvent of the unpaired electron in complexes of stable radicals with solvents[45], which is inconsistent with participation of the non-bonding orbital of the radical in formation of the complex.



Formation of complex between radical and solvent.

A very curious effect of organoboron compounds on the polymerisation of vinyl monomers has been reported[60,61]: Arimoto[60] discovered that, in the presence of aliphatic organoboron compounds, polymerisation of the monomers—styrene, methyl methacrylate, acrylonitrile, and vinyl acetate—is not inhibited by typical inhibitors of radical processes, e.g. quinol, *N*-phenyl-2-naphthylamine, etc., even when present in excess relative to the organoboron compound. He suggests that the radical forms a complex with the organoboron compound. This complex is reactive towards the monomer and inactive towards inhibitors. Triarylborons do not produce such effects.

The effect of hydrogen bonds on the reactivity of radicals localised on heteroatoms has been examined in a review[45], where it is stated that "... in all cases, when a radical forms hydrogen bonds with those molecules with which it does not react, the result is a decrease in its reactivity in the main reaction". The decreased activity of the radicals must evidently be attributed to steric causes, since, owing to the predominance of electrostatic forces in a hydrogen bond, the energy of the ground state of the radical is lowered, and consequently its reactivity is increased. A solvating molecule impedes the access of reactant molecules to the radical, thereby diminishing the reaction velocity.

Hydrogen bonds have been found to influence the kinetics of radical reactions in the polymerisation of several vinyl monomers containing heteroatoms. On complex formation between the monomer and a hydroxylated solvent through a heteroatom, the change in electronegativity of the heteroatom in the monomer produces a change in the charge distribution, which leads to a change in the polar properties of the double bond and in some cases a change in the conjugation energy. When the monomer becomes a radical as a result of the reaction, the energy of the hydrogen bond is somewhat modified, which complicates interpretation of available results. However, this effect is apparently small, and the characteristics of atoms involved in the hydrogen bond can be assumed to remain unchanged during the reaction. This permits the application to these systems of various correlation formulae.

As remarked above, the composition of copolymers of styrene with methyl methacrylate is unaffected by changing the medium from benzene and acetonitrile to methanol, which indicates that hydrogen bonds have no effect on the reactivity of methyl methacrylate[52]. The rate of polymerisation of *N*-vinylpyrrolidone is increased by conducting the process in aqueous solution, which produces an increase in molecular weight[62], this indicating either a change in the rate constant of chain growth or a decrease in the rate constant of chain termination. Direct experimental evidence of a change in the reactivity of monomers and the corresponding radicals on formation of hydrogen bonds with the solvent was obtained by Ryabov and his coworkers[63]. They found that the composition of styrene–2-vinylpyridine, styrene–methacrylic acid, and methyl methacrylate–methacrylic acid copolymers depends on the nature of the solvent. Subsequent investigations by other workers[64,65] have confirmed these observations. The published data are listed in Table 4. They show that the monomers—vinylpyridines and vinylpyrrolidone—which are electron donors with respect to hydroxylated solvents, are characterised by an increase in the acceptor properties of the substituent (increase in e) with increase in the acidity of the solvent. Acrylic and methacrylic acids, on the other hand, exhibit a diminution in electron-acceptor properties with increase in the basic strength of the solvent. Variation in the properties of the solvent probably affects also the value of Q, which in most cases increases with increase in e. However, this tendency is not clearly defined, and for several systems (Table 4) Q remains unchanged with variation in e. The change in Q produced by varying the solvent indicates that variation in the polarity of the substituent leads to a change in the energy of conjugation in the monomer: i.e. Q and e are not independent quantities, as is assumed in the Q–e scheme. However, these observations require confirmation.

In several cases the rate of polymerisation of monomers has been found to vary with the properties of the medium. Thus the rate of homopolymerisation of methacrylic acid diminishes on the addition of dimethylformamide[63]. Increase in the pH of the medium has been found[68] to decrease the rate constant of chain growth K_{gr} in the polymerisation of acrylamide. The rate of polymerisation of this monomer depends also on the nature of the solvent[59]: the value of $K_{gr}/K_0^{\frac{1}{2}}$ decreases in the sequence—water, dimethyl sulphoxide, tetrahydrofuran. The reason for the change in the rate of polymerisation of *N*-vinylpyrrolidone when dichloroethane is replaced by methanol is the change in K_{gr} due to the diminished electron-donor properties of the pyrrolidone ring. The observed doubling of K_{gr} shows good qualitative correlation with Eqn. (4).

Several interesting results have recently been obtained on the effect of metal salts on the activity of monomers in radical polymerisation. As early as 1957 Bamford et al.[69] reported that a lithium salt accelerates the polymerisation

of acrylonitrile. Several papers have since been published on the influence of salts of zinc [70-75], cadmium [74], mercury [73], and aluminium [76-78].

*Values in parentheses have been calculated by me from the values given for r_1 and r_2.

Imoto and his coworkers [70,71] have found that during polymerisation methyl methacrylate forms an active complex MMA.$ZnCl_2$ in the presence of zinc chloride. Copolymerisation constants have been determined for this complex with vinylidene chloride, whose activity is unaffected by zinc chloride, and the parameters Q and e have been calculated (Table 5). These workers have investigated also the effect of zinc chloride on the polymerisation of acrylonitrile.

Okamura and his coworkers [73-75] have made a series of studies of the effect of complex formation with metal salts on the reactivity of vinylpyridines. They find that complexes are formed containing two molecules of the monomer and one molecule of the salt. The rate of polymerisation of the complex is higher than that of the pure monomer. The increase in rate is assumed to be due to an increase in K_{gr}. For 4-vinylpyridine the accelerating effect increases in the sequence [74]

$$Cd(CH_3COO)_2 > ZnCl_2 > Zn(CH_3COO)_2 > ZnBr_2 > ZnI_2$$

which is almost the same as the sequence for 2-methyl-5-vinylpyridine [73]. Values of Q and e for vinylpyridines included in Table 5, have been determined for copolymerisation with styrene, which does not form complexes with metal salts.

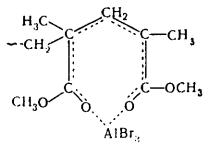
*MMA = methyl methacrylate.
**VP = vinylpyridine.

Direct confirmation of the increase in K_{gr} on complex formation between methyl methacrylate and zinc chloride has been obtained by Bamford et al. [79], who find that at 25°C the value of K_{gr} increases from 250 M^{-1} s^{-1} for the pure monomer to 610 M^{-1} s^{-1} for its complex.

A characteristic feature of the monomer–metal salt complexes investigated is the simultaneous increase in the parameters Q and e relative to the pure monomer (Table 5). This indicates the complicated nature of the interaction between metal salts and monomers, caused by the formation of a single system of molecular orbitals in the complex compound. Examination of the electronic absorption spectra showed that the complexes exhibit a red shift in the $\pi-\pi$ transition as compared with the pure monomer [75]. The magnitude of the displacement correlates with the value of Q. An attempt has been made to examine the structure of the complexes by the method of molecular orbitals [94].

The effect of Lewis acids on the reactivity of monomers has been investigated in the copolymerisation of acrylonitrile and methyl methacrylate [76,77]. Addition of aluminium chloride led to a decrease in the acrylonitrile content of the copolymer. The complex of acrylonitrile with aluminium chloride proved to be incapable of homopolymerisation, which must apparently be attributed to electrostatic repulsion between the radical and the monomer. The photoinitiated polymerisation of methyl methacrylate in the presence of aluminium chloride and aluminium bromide revealed [78] a considerable increase in the rate of the process compared with polymerisation of the pure monomer, which was ascribed to increase in K_{gr} due to the coordinating action of the aluminium salt. Use of electron spin resonance in the same investigation established that the unpaired electron is

partly transferred to the aluminium atom. The following scheme is suggested [78] for the transition state in chain growth



according to which growth is accelerated by coordination of the monomer and the radical.

The interaction of acrylonitrile with ethylaluminium dichloride [80] leads to the formation of a 1 : 1 complex. It is remarkable that the complex is incapable of homopolymerisation, but copolymerises well, e.g. with propene to form an alternating 1 : 1 copolymer. The alternation may be caused by the formation of a charge-transfer complex between the monomers. The possibility of the formation of such complexes must in general be taken into account in ascertaining their reactivity, since considerable anomalies may be observed. For example, it has proved possible to copolymerise 1,4-dioxen with maleic anhydride [81], although neither monomer polymerises separately by a radical mechanism; their copolymerisation was made possible by complex formation.

Thus the polar effect of the medium on the reactivity of radicals and molecules, effected through hydrogen bonds, complex formation with metal salts, etc., can be identified with the change in the properties of the substituents, and described by Eqn. (4). The nature of the change in the energy of radicals on π-complex formation with solvents and on interaction with electron pair acceptors, such as organoboron compounds, is obscure. It may be supposed that π-complex formation is accompanied by a decrease in the energy of the radical caused the solvent utilising a non-bonding orbital of the radical.

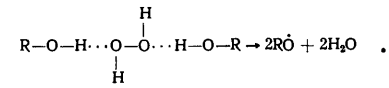
V. EFFECT OF SOLVENTS ON THE THERMAL DECOMPOSITION OF AZO-COMPOUNDS AND PEROXIDES

The influence of solvents on the unimolecular decomposition of molecules has been investigated on the decomposition of peroxides and azo-compounds, which are initiators of various radical processes.

Arnett [82] investigated the thermal decomposition of azoisobutyronitrile in various solvents, and found the rate constant to vary little with the solvent. In a thorough investigation Morou [53] also detected only a slight variation in the rate constant for the decomposition of azoisobutyronitrile with the nature of the solvent. Thus in the series of solvents—methyl methacrylate, xylene, cyclohexanol, dioxan, *o*-dichlorobenzene, and dimethylformamide—the decomposition rate constants at 60°C were respectively (8.40, 10.40, 12.5, 8.70, 11.0, and 10.94) $\times 10^{-6}$. Because of the unsystematic collection of solvents, these results are insufficient to determine the effect of solvents. An attempt to interpret the effect of solvents on the decomposition of phenylazotriphenylmethane was unsuccessful [83].

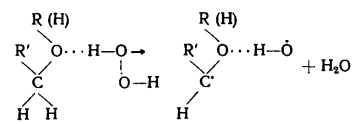
The effect of solvents on the decomposition of benzoyl peroxide is discussed in Bagdasar'yan's monograph [5]. Analysis of the experimental data shows that this compound tends to undergo chain decomposition. At low concentrations of the peroxide or in the presence of inhibitors the decomposition rate constant is almost independent of the solvent. An appreciable solvent effect is observed in the decomposition of t-butyl 2,3-dipropylcycloprop-2-eneper-carboxylate [84]. The rate of decomposition increases in the sequence—ethylbenzene, chlorobenzene, benzonitrile, acetonitrile, benzyl alcohol.

Complicated phenomena are observed in the decomposition of hydroperoxides, including hydrogen peroxide, in various solvents. The energy of the O–O bond is 48 kcal mole^{-1} in hydrogen peroxide [85], and rather lower (42 kcal mole^{-1}) in aliphatic hydroperoxides [41]. In an investigation of the thermal decomposition of butyl and cumene hydroperoxides Stannett and Mesrobian [86] observed an accelerating effect with alcohols, ethers, acids, and vinyl monomers in comparison with benzene, cyclohexane, carbon tetrachloride, chloroform, chlorobenzene, and even pyridine. The authors did not suggest any mechanism to explain the effect of the solvents. Later investigation of the decomposition of hydroperoxides [87–93] have yielded additional data enabling the reaction mechanism to be assessed to a certain extent. It was ascertained that in active solvents the activation energy of the decomposition of hydroperoxides is lowered to around 20 kcal mole^{-1}, [88–92] which is 15–20 kcal mole^{-1} lower than the value in the gas phase and apparently in inert solvents [41,85]. To explain such a large energy discrepancy it has been suggested [88,89] that in alcohol it is not a hydroperoxide molecule but its complex with the solvent which decomposes:



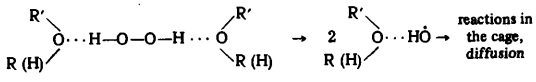
According to this scheme simultaneous cleavage of three bonds and the formation of two new bonds take place in the activated complex. The scheme provides an explanation of the decrease in activation energy of decomposition, but is inconsistent with the formation of terminal hydroxy-groups in the oligodienes obtained by initiating the polymerisation of dienes with hydrogen peroxide in methanol [91].

It was also found [91] that replacing the alcohol by tetrahydrofuran has little effect on the rate or the efficiency of initiation, but substantially affects the concentration of hydroxyls in the polymer. In the opinion of the authors the following scheme for the transition state



which takes into account solvation of the peroxide by the solvent, enables the observed phenomena to be understood. According to this scheme the low efficiency of initiation is explained by the abstraction of α-hydrogen atoms from the solvent and subsequent recombination of the resulting radicals in the cage. The diminished concentration of hydroxyls in the polymer is also explained by instantaneous transfer of the radical to the solvent on formation. Since the transfer reaction is exothermic, and can occur at the same time as cleavage of an O–O bond, the decrease in activation energy for decomposition of the peroxide can also be explained. According to later, unpublished results obtained by the same workers [91], however, polymerisation of dienes initiated by hydrogen peroxide is observed also in solution in t-butyl alcohol which has no α-hydrogen atom, and occurs at the same rate as in methyl alcohol, leading to the formation of oligomers containing two terminal hydroxy-groups. This indicates that abstraction of an α-hydrogen atom is independent of cleavage of the O–O bond.

With all the above facts taken into account, the suggestion is made that hydrogen peroxide (and hydroperoxides) decompose according to the scheme



the realisation of which requires that the energy of interaction of the hydroxyl radical with the heteroatom of the solvent should be increased by 10–15 kcal mole^{-1} as compared with the energy of a hydrogen bond. This increase in interaction energy is possible as a consequence of the formation of complexes analogous to charge-transfer complexes or π-complexes (see diagram).

Acceleration of the decomposition of hydroperoxides is observed also in hydrocarbon solvents containing double bonds[89-93]. The acceleration apparently results mainly as a consequence of the reaction

$$ROOH + H_2C{=}CHR_1 \rightarrow HOCH_2{-}\dot{C}HR_1 + \dot{O}R$$

suggested by Denisov[92], in which the vinyl compound acts as an electron donor. Walling and Heaton[93] found styrene oxide, t-butyl alcohol, and water among the products of the reaction of t-butyl hydroperoxide with styrene, and assumed that decomposition of a hydroperoxide partly involves cleavage of the O–H bond:

$$ROOH + CH_2{=}CHR' \rightarrow R\dot{O}O + CH_2\dot{C}HR' .$$

When the polymerisation of isoprene is initiated with cumene hydroperoxide in heptane solution, the polymeric products are found to contain on the average one hydroxy-group per macromolecule[91], which confirms Denisov's scheme.

From the above results on the effect of solvents on the decomposition of hydroperoxides and hydrogen peroxide it can be seen that all solvents which accelerate the decomposition contain either heteroatoms having lone pairs of electrons or π-bonds: i.e. they are donors of electrons relative to hydroxy-groups. Some analogy is evident in the effect of solvents on the reactivity of radicals in reactions involving hydrogen atom abstraction, which have become known from the work of Russell[46], and in the decomposition of hydroperoxides. This analogy has a single cause—the diminution in the reactivity of radicals on complex formation with the solvent.

---o0o---

The analysis which has been made of various radical reactions shows that the reactivity of radicals and molecules is considerably influenced by polar interactions of the reaction centre with substituents and with the medium. With few exceptions the reactivity of radicals is increased by the introduction of electron-acceptor substituents and by increase in the acidity of the medium or decrease in the electron-donor properties of the solvent. The opposite relations are observed for molecules.

Condensation of Oxazoles with Dienophiles—a New Method for the Synthesis of Pyridine Bases

M.Ya.Karpeiskii and V.L.Florent'ev

The condensation of oxazoles with dienophiles is of the diene synthesis type, the final reaction products being substituted pyridine bases. The review deals with the literature data concerning the preparative applications of the condensation and the elucidation of the theoretical features of this process. In conclusion of the review, the application of heterodiene synthesis with participation of oxazoles in the preparation of vitamin B_6 and its analogues is discussed. The bibliography comprises 38 references.

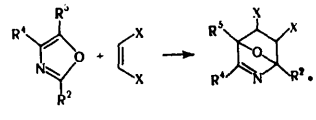
III. Aromatisation of the adducts from diene synthesis 541
IV. Application of heterodiene synthesis with participation of oxazoles in the preparation of vitamin B_6 and its analogues 544

I. INTRODUCTION

Towards the end of the 1950's, Kondrat'eva [1,2] showed that the azadiene system of oxazoles readily reacts with an activated double bond by the diene synthesis mechanism [Diels–Alder mechanism (Ed. of Translation)]. The final products of this reaction are substituted pyridine bases. The reaction constitutes a very promising method for synthesising substituted pyridines including biologically important compounds—derivatives of nicotinic and isonicotinic acids, i.e. B_6 vitamins and their analogues.

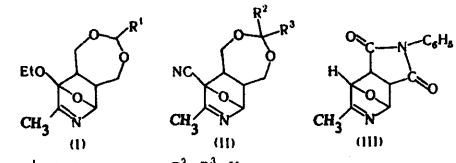
A series of papers have now been published on studies of the interaction between oxazoles and dienophiles both as regards the development of preparative methods for the synthesis of pyridine derivatives and the elucidation of the theoretical features of this interesting process. The synthesis of pyridine bases by the condensation of oxazoles with dienophiles consists of two stages. The first stage, the diene synthesis proper, results in the intermediate formation of bicyclic adducts:



Depending on the structure of the initial compound, the second stage can take place in several ways (see Scheme 1 and p. 37). Each of these stages has specific features and is of independent interest.

II. DIENE SYNTHESIS WITH PARTICIPATION OF OXAZOLES

The bicyclic adducts formed in the interaction between oxazoles and dienophiles are extremely unstable and usually cannot be isolated from the reaction mixture. Only three cases where the intermediate formation of the adducts has been rigorously established have been described. Thus in the reaction of 5-ethoxy-4-methyloxazole [3] and 5-cyano-4-methyloxazole [4,5] with substituted 4,7-dihydro-1,3-dioxepines. The racemates of the *endo*- and *exo*-isomers of compounds (I) and (II) were isolated:



(I) R^1 = H; iso-C_3H_7

(II) $R^2 = R^3 = H$; $R^2 = R^3 = CH_3$; R^2 = H; R^3 = iso-C_3H_7; R^2 = H; $R^3 = C_6H_5$

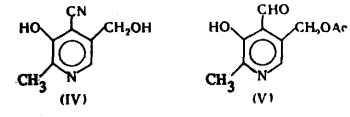
(III)

Similarly the condensation of 4-methyloxazole with *N*-phenylmaleimide yielded the adduct (III). [6] The stereochemistry of this compound was not studied.

As a result of the lability of the adducts produced in heterodiene synthesis, the characteristics of the individual reaction stages cannot be taken into account separately. Of the effects which should obtain mainly in the first stage of the heterodiene synthesis, it is necessary to consider in the first place the orientation of asymmetric dienophiles in the interaction with oxazoles.

In most cases the usual Diels–Alder reaction yields both possible isomers. In contrast, in heterodiene synthesis with participation of oxazoles only one of the products is formed as a rule. In her study of the interaction of alkyloxazoles with acrylic acid, Kondrat'eva [7] showed that this involves the formation exclusively of substituted isonicotinic acid and only in a few cases was it possible to detect traces of the second isomer–substituted nicotinic acid.

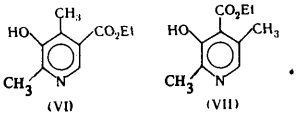
A similar observation was also made in the condensation of 5-ethoxy-4-methyloxazole with the nitrile of 4-hydroxycrotonic acid [8] and 4-acetoxycrotonic aldehyde [9]. Compounds (IV) and (V) respectively were isolated:



(IV) (V)

Thus, as a rule, the heterodiene synthesis takes place in such a way that the fifth position in the adduct is occupied by the most electronegative group of the dienophile.

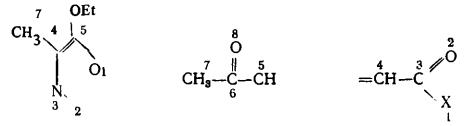
Exceptions to this rule were noted only with 4-methyloxazole. Thus in the reaction of this diene with ethyl crotonate the ester of 3-hydroxy-2,4-dimethylpyridine-5-carboxylic acid (VI) was obtained in 12% yield instead of the expected product (VII):[10]



(VI) (VII)

The sole attempt at a theoretical explanation of the first stage of the heterodiene synthesis was undertaken[11] in the study of the interaction between 5-ethoxy-4-methyloxazole and asymmetric dienophiles—β-acetylacrylic acid (VIIIa) and its ethyl ester (VIIIb). The authors[11] start with the hypothesis that the extreme polarisation of the azadiene oxazole system should favour reaction by a two-stage mechanism with separation of charges in the transition state. Then the orientation should be determined by the distribution of π-electron densities at the atoms participating in the transition state. To test this hypothesis, the parameters of the 5-ethoxy-4-methyloxazole molecule and its cation and also the anion and the ethyl ester of β-acetylacrylic acid were calculated. The calculations were performed by the LCAO-MO method in the Hückel approximation taking into account the effect of the hyperconjugation of the methyl group.

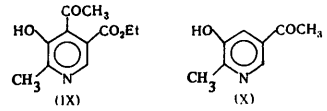
Distribution of π-electron densities



(VIIIa): X=O⁻
(VIIIb): X=OEt

Compound	q^{π} at different atoms							
	1	2	3	4	5	6	7	8
5-Ethoxy-4-methyloxazole	1.733	1.020	1.196	1.042	1.095	1.921	1.070	—
Cation of 5-ethoxy-4-methyloxazole	1.663	1.781	1.609	0.994	1.055	1.915	1.069	—
Ethyl β-acetylacrylate (VIIIb)	1.922	1.321	0.815	0.950	0.937	0.763	1.075	1.318
β-Acetylacrylate anion (VIIIa)	1.825	1.396	0.823	0.932	0.962	0.764	1.075	1.323

The Table shows that, in the product of the interaction of 5-ethoxy-4-methyloxazole with compound (VIIIb), the acetyl group must occupy the fourth position in the pyridine ring, while the opposite orientation should obtain in the reaction with the free acid (VIIIa), and the formation of substituted 5-acetylpyridine as the main product is to be expected. Indeed, after the condensation of 5-ethoxy-4-ethyloxazole with compound (VIIIb) only 4-acetyl-5-ethoxycarbonyl-3-hydroxy-2-methylpyridine (IX) was isolated, while in the condensation with compound (VIIIa) the only product obtained was 5-acetyl-3-hydroxy-2-methylpyridine (X).

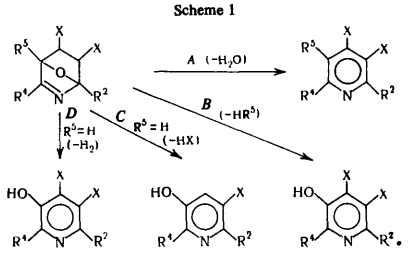


(IX) (X)

III. AROMATISATION OF THE ADDUCTS FROM DIENE SYNTHESIS

As already mentioned, the bicyclic adducts readily undergo aromatisation, particularly in acid media, and, depending on the structure of the starting compounds, the reaction can take place in four principal ways (Scheme 1).

Scheme 1

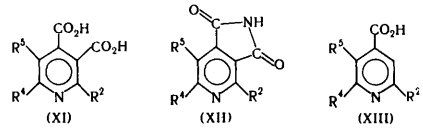


Usually all or several pathways operate simultaneously and heterodiene synthesis yields a more or less heterogeneous mixture of products. Analysis of literature data shows that the mode of aromatisation is determined by the nature of two substituents in the adduct—the substituent R^5 in the 4-position and the substituent X in the 5-position.

1. Aromatisation with Elimination of a Water Molecule (Kondrat'eva's Reaction)

The aromatisation of adducts via pathway *A* has been called Kondrat'eva's reaction. It resembles the aromatisation in acid media of the adducts obtained in the condensation of furan derivatives with dienophiles and usually takes place if the substituents R^5 and X in the adduct do not show a tendency to be eliminated in the form of anions.

Alkyloxazoles react in this way with maleic anhydride and maleic acid[2,12], forming alkyl-substituted cinchomeronic acids (XI); the reaction with maleimide[12-14] yields under these conditions the imides of cinchomeronic acids (XII) while the reaction with acrylic acid[7] gives analogues of isonicotinic acid (XIII):



(XI) (XII) (XIII)

where $R^2 = R^5$ = alkyl and R^4 = alkyl or aryl.

With other dienophiles, alkyloxazoles having an unsubstituted 5-position react via pathways *C* and *D* (see Section III, Subsection 3). Kondrat'eva[14] studied the behaviour in diene synthesis of oxazoles substituted in the 2- and 5-positions by electronegative groups. Dienes of this type do not react with maleic anhydride, but do react with maleimide via pathway *A*, forming normal products with yields lower by approximately 50% than for the corresponding alkyl-substituted oxazoles. Thus 2,4-dimethyloxazole gives the product (XII) in 93% yield, while with

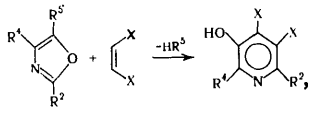
5-acetyl-4-methyl- and 5-ethoxycarbonyl-4-methyl-oxazoles, the yields of compound (XII) are 45 and 37% respectively.

The introduction of a phenyl group in the 4-position of oxazole has almost no effect on the interaction with dienophiles but 2- and 5-phenyloxazoles do not take part in heterodiene synthesis. On the basis of these data, the substituents of the oxazole ring can be arranged in the following sequence in terms of their effect on the reaction: alkyl ≃ 4-phenyl > $COCH_3$ > $COOC_2H_5$ ≫ 2- and 5-phenyl, the activity of oxazoles in the diene synthesis decreasing from left to right.

The occurrence of the reaction by pathway *A* is favoured when the diene synthesis is carried out in aprotic solvents. Japanese workers [12] have shown that the replacement of acetic acid by benzene in the reaction of 4-methyloxazoles with maleic anhydride leads to an increase of the yield of 2-methylcinchomeronic acid from 40 to 65%.

2. Aromatisation with Elimination of a Molecule of Alcohol or Hydrocyanic Acid

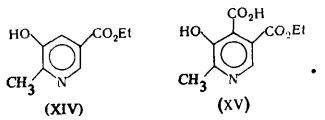
If a substituent which is readily eliminated in the form of an anion is present in the 4-position of the adduct, aromatisation takes place via pathway *B*, the final products being substituted 3-hydroxypyridines:



where R^5 = Oalkyl, $OCOOC_2H_5$, or CN. This reaction is characteristic of 5-hydroxyoxazoles with a protected hydroxy-group or of 5-cyanooxazoles.

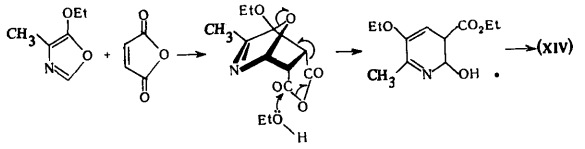
It is noteworthy that 5-alkoxyoxazoles, which are the most active dienes among oxazole derivatives, are comparable in their reactivity with carbocyclic dienes, the yields of the final products being usually high.

Firestone et al. [15], who studied the reaction of 5-ethoxy-4-methyloxazole with maleic acid anhydride in ether at 0°C, isolated 5-ethoxycarbonyl-3-hydroxy-2-methylpyridine (XIV) and the monoethyl ester of 3-hydroxy-2-methylpyridine-4,5-dicarboxylic acid (the main reaction product) after the aromatisation of the adduct with a solution of dry hydrogen chloride in absolute ethanol. The relative positions of the carboxy- and ethoxycarbonyl groups in the second product were not established rigorously, but the authors suggest the structure (XV) for this compound:



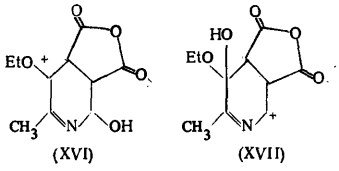
(XIV) (XV)

According to the authors, compound (XIV) is formed by the mechanism



Naito and Yoshikawa [6] did a lot of work on the determination of the composition of the reaction mixtures formed in the interaction between 5-ethoxy-4-methyloxazole and a number of dienophiles and showed that the main product is always accompanied by a certain amount (frequently traces) of a side product—3-hydroxypyridine with a free 4-position [a derivative of type (XIV)].

Firestone proposed two alternative mechanisms of the formation of the main product (XV) of heterodiene synthesis, differing in the position of the hydroxy-group and the localisation of the positive charge in the key intermediate (XVI) or (XVII). Both cations may arise in the heterolysis of the bonds of the oxygen bridge in the adduct by each of the possible pathways:

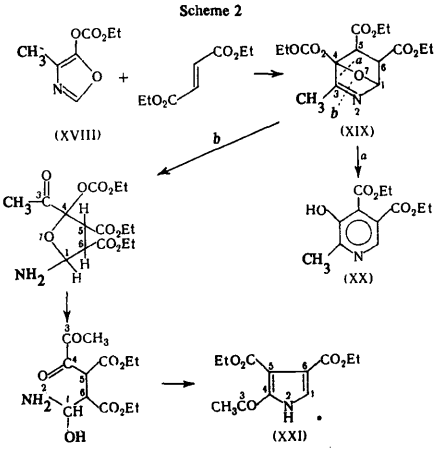


(XVI) (XVII)

Interesting results were obtained by Murakami et al. [16] in the study of the interaction of 5-ethoxycarbonyl-4-methyloxazole (XVIII) with diethyl fumarate (Scheme 2, below). The authors believe that, depending on the aromatisation conditions, the process may begin either with the dissociation of the C–O bond of the adduct (XIX), which leads to the diester of 3-hydroxycinchomeronic acid (XX), or with the dissociation of the C=N bond. In the latter case 2-acetyl-3,4-diethoxycarbonylpyrrole (XXI), the structure of which was demonstrated rigorously by proton magnetic resonance spectroscopy and by preparative synthesis, is obtained via a number of intermediates.

The particular pathway of the aromatisation of the adduct probably depends on the presence of water in the reaction mixture. Thus, by treating the adduct with a solution of dry hydrogen chloride in absolute ethanol, Murakami et al. [16] obtained 50% of the "normal" product (XX) and only 5% of the "anomalous" product (XXI), while treatment with concentrated hydrochloric acid gave the reverse proportions—5 and 54% respectively.

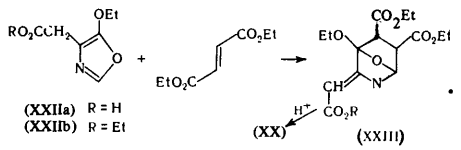
Scheme 2



(XVIII) (XIX) (XX) (XXI)

The above finding requires serious attention and further investigation in other instances of heterodiene synthesis via pathway *B*.

Miku and Matsuo [17] studied the interaction with dienophiles of 5-ethoxyoxazole-4-acetic acid (XXIIa) and its ethyl ester (XXIIb):



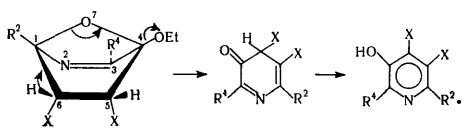
(XXIIa) R = H
(XXIIb) R = Et

The condensation of the ester (XXIIb) with diethyl fumarate leads, according to Miku and Matsuo [17], to the adduct (XXIII) with an exocyclic double bond. The structure of the latter was demonstrated by proton magnetic resonance and mass spectroscopy. The aromatisation of the adduct under the influence of acids is accompanied by the hydrolysis of the α'-ester group and the decarboxylation of the intermediate substituted pyridine-1-acetic acid, which is a β-imino-acid.

In the interaction of the free acid (XXIIa) with various dienophiles the aromatisation and decarboxylation take place directly during the reaction. Miku and Matsuo [17] do not associate this interesting phenomenon with the heterodiene synthesis but, referring to Doering and Pasternak [18], attribute it to the extremely ready decarboxylation of pyridine-1-acetic acids in an acid medium.

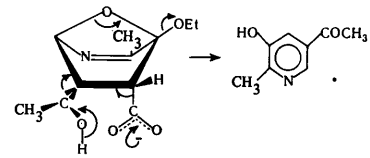
The following fact may be mentioned in connection with further consideration of the mechanism of the aromatisation of the adducts via pathway *B*: none of the investigators succeeded in isolating or demonstrating the presence in the reaction mixture of products corresponding to Kondrat'eva's reaction—substituted 3-alkoxypyridines.

The following mechanism was proposed for the adduct aromatisation stage [11]:



According to the authors the isomerisation of the adducts begins with the dissociation of the C^1–O bond. This conclusion is based on the following main postulates: (1) the C^1–O bond is in fact the one weakened to the greatest extent due to σ–π conjugation with the C^3=N bond. Under the isomerisation conditions (usually a solution of dry hydrogen chloride in alcohol), the heterolysis is favoured by the protonation of the adduct both at the nitrogen and at the oxygen atom; (2) the dissociation of the C^4–O bond with subsequent hydrolysis is unlikely if only because the diene synthesis and the isomerisation are most often carried out in complete absence of water. The validity of this hypothesis is confirmed by the examination of the diene synthesis with participation of 5-ethoxy-4-methylthiazole (see p. 544), the products of which are always 3-alkoxypyridines despite the fact that the aromatisation conditions (heating with concentrated hydrochloric acid) favour hydrolysis. (3) Finally, if the dissociation of the C^4–O bond is assumed, it is difficult to explain the exclusive formation of 3-hydroxypyridines in the interaction of dienophiles with 5-cyano-oxazoles.

In support of this mechanism, the authors quote the fact that the condensation of 5-ethoxy-4-methyloxazole with β-acetylacrylic acid is always accompanied by decarboxylation regardless of the reaction conditions, which results in the formation of 5-acetyl-3-hydroxy-2-methylpyridine:



Although the mechanism of heterodiene synthesis described above [11] is to a considerable degree speculative, it nevertheless accounts for the characteristics of this interesting reaction known at the present time.

As far as one can judge from the literature data, solvents do not have much effect on diene synthesis by the above mechanism. There is an indication [15] that small amounts of acids (for example, trifluoroacetic acid) catalyse heterodiene synthesis.

The reaction constitutes a very convenient method for the preparation of substituted 3-hydroxypyridines. The high reactivity of azadienes permits condensation with a wide range of dienophiles. Among the latter, the following compounds have been used: maleic anhydride [15,19], maleimide [19], esters of maleic and fumaric acids and fumaronitrile [9,15–17,20], 1,4-diacetoxy- and 1,4-dimethoxy-but-2-ene and 2,5-dihydrofuran [9,15,20–22], 2-substituted 4,7-dihydro-1,3-dioxepins [3,5], and a number of other compounds.

It is noteworthy that the limitations consisting in the low availability of the initial oxazoles which initially arrested the development of this method have now been to a large degree overcome as a result of a number of successful investigations of the synthesis of oxazoles [9,23–27].

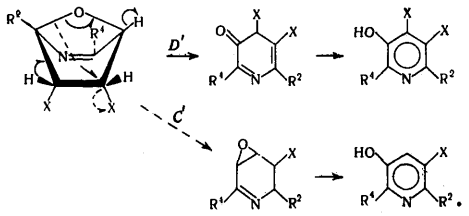
3. Other Pathways of the Aromatisation of Adducts

The aromatisation of adducts via pathways *C* and *D* is characteristic of the interaction of 5-unsubstituted oxazoles with dienophiles the substituents of which tend to be eliminated as anions. This type of aromatisation was investigated in the interaction of 4-methyl-, 4-phenyl-, and 2,4-dimethyl-oxazoles, with acrylonitrile [28], fumaronitrile and the diesters of maleic and fumaric acids [6,12], and a number of other dienophiles (see Scheme 1). As for pathway *B*, the final reaction product is 3-hydroxypyridine. In most cases both pathways operate simultaneously and, depending on the reaction conditions and the structure of the initial compounds, both products are obtained in various proportions.

We believe that the aromatisation of the adduct includes a stage in which the anion is displaced from the 3- or 4-position. This hypothesis is confirmed by the following findings. (1) According to the hypothesis, the reaction via pathway *C* should include the displacement from the 4-position of the substituent in the form of an anion, i.e. the substituent which previously belonged to the dienophile. Indeed, it has been shown [12] that, in the reaction of 4-methyloxazole with a series of dienophiles (fumaronitrile, acrylonitrile, diethyl fumarate, diethyl maleate, and ethyl acrylate), the yields of products via pathway *C* decrease from left to right in parallel with the capacity of the substituent of the dienophile to be eliminated as an anion. (2) The reaction via pathway *D* should include a stage in which an anion, i.e. a hydride ion, is displaced from the 3-position. Since this type of process is energetically unfavourable, the product of the reaction via pathway *D* is usually obtained in insignificant amounts, as an admixture to the product formed via pathway *C*. However, when the

reaction is carried out in the presence of hydride ion acceptors (hydrogen peroxide [12,29] or nitrobenzene at elevated temperatures [30]), pathway *D* becomes the main one and the yields of products reach 50–60%.

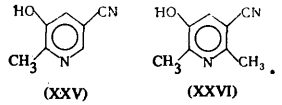
We believe that all these findings can be explained if it is postulated that the isomerisation of the adduct begins with the dissociation of the C^1–O bond of the oxygen bridge:



The liberated electron pair may attack either C^4 or C^5 atoms, displacing by a mechanism of the nucleophilic type either an X anion or a hydride ion.

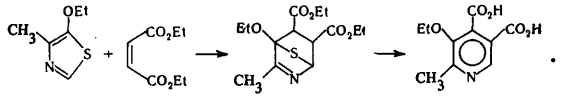
When the reaction is carried out in acid media, the yields of the products of heterodiene syntheses via pathway *C* are improved [1]. Thus, in the reaction of 4-methyloxazole with acrylonitrile [28] in benzene, 3-hydroxy-2-methylpyridine is obtained in 12% yield, while in acetic acid the yield is 28%.

The above pathway of heterodiene synthesis is not of particular value for synthetic purposes because of the low yields (usually 5–25%). An exception is the reaction of fumaronitrile with 4-methyloxazole [12,31] and 2,4-dimethyloxazole [6], which leads to substituted 5-cyano-3-hydroxypyridines (XXV) and (XXVI) in yields of 71 and 55% respectively:



(XXV) (XXVI)

In conclusion of the discussion of the diene synthesis of oxazoles, we shall describe the only study so far of the interaction with dienophiles of a derivative of thiazole—an oxazole heteroanalogue [32]. On heating for 8 h at 200°C with diethyl maleate, 5-ethoxy-4-methylthiazole (XXVII) forms the adduct (XXVIII), which undergoes aromatisation on heating with concentrated hydrochloric acid, hydrogen sulphide being eliminated:



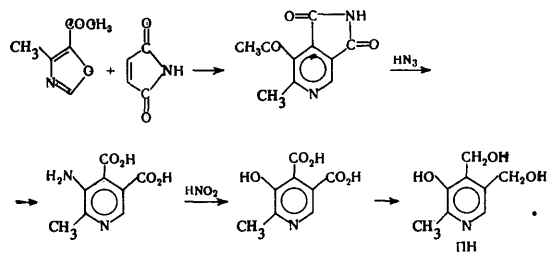
(XXVII) (XXVIII) (XXIX)

It is interesting to note that, in contrast to 5-alkoxyoxazoles, the isomerisation takes place in this case by a process of the type of Kondrat'eva's reaction and the final product is 3-ethoxy-2-methylpyridine-4,5-dicarboxylic acid (XXIX). The same product was obtained [32] by the reaction of compound (XXVII) with diethyl fumarate and maleic anhydride.

IV. APPLICATION OF HETERODIENE SYNTHESIS WITH PARTICIPATION OF OXAZOLES IN THE PREPARATION OF VITAMIN B_6 AND ITS ANALOGUES

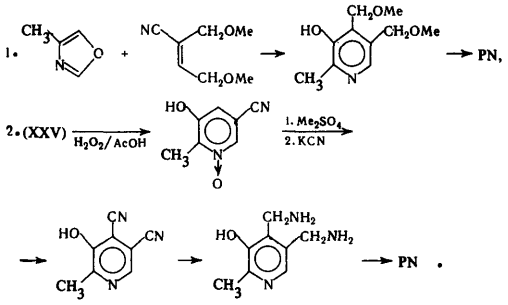
The interaction of oxazoles with dienophiles has been successfully used for the preparation of vitamin B_6 (pyridoxine) and its analogues. Methods for the synthesis of pyridoxine—3-hydroxy-4,5-bis(hydroxymethyl)-2-methylpyridine (PN) using heterodiene synthesis via pathways *A*, *B*, and *C* (Scheme 1) have been proposed. Kondrat'eva's reaction is not of great interest for the synthesis of pyridoxine, since the introduction of a hydroxy-group in the 3-position of the pyridine ring involves considerable difficulties. The sole attempt on these lines [33]—the synthesis of pyridoxine via Scheme 3—cannot be regarded as successful because of the complexity of the method and the low yields in the first two stages:

Scheme 3



In the series of pyridoxine analogues, this scheme can be used only to obtain products modified in the 3-position of the pyridine ring.

Two schemes based on heterodiene synthesis via pathway *C* have now been proposed for the synthesis of pyridoxine [10,34]:



The first synthesis is of exclusively theoretical interest, since the yield of 3-hydroxy-4,5-bis(methoxymethyl)-2-methylpyridine is very low. The second synthesis, despite the large number of stages, may find application in the synthesis of pyridoxine labelled at a carbon atom.

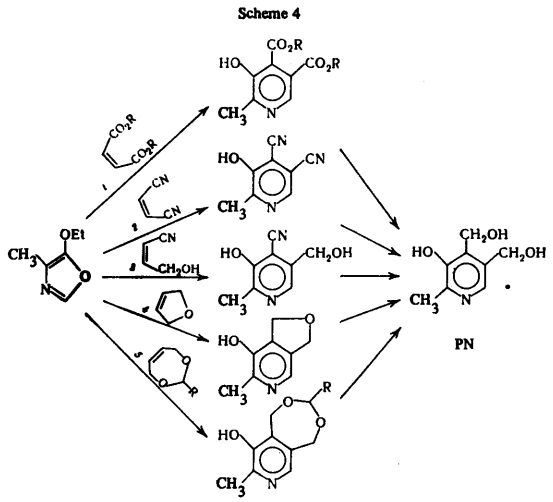
The most successful synthesis of pyridoxine and its analogues is heterodiene synthesis via pathway *B*. Its advantages include the following: high reactivity of 5-alkoxyoxazoles as dienes, high yields of final products, and simplicity. It is therefore not surprising that the efforts of investigators have been concentrated on the development of precisely this reaction (Scheme 4).

In syntheses *1–3* oxazole undergoes condensation with active dienophiles, which makes it possible to carry out the reaction under mild conditions (usually at 60–110°C). The yields of the final products amount to 75–86%. Further conversion of the compounds into pyridoxine does not present difficulties.

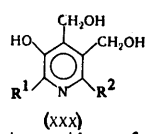
Since direct interaction of oxazole with but-2-ene-1,4-diol gives a low yield of pyridoxine, various butenediol derivatives have been used as dienophiles. Best results were obtained with 2,5-dihydrofuran [9,15,20–22] and 4,7-dihydro-1,3-dioxepine [3–5] (Scheme 4, pathways *4* and *5*). In this case the diene synthesis is carried out under more severe conditions than for pathways *1–3* (usually in an autoclave at 170–200°C) and the yields of the primary reaction products are somewhat lower (50–60%). However, the simplification of the process and the very high yields

of the final products give approximately the same yield of pyridoxine as in syntheses *1–3* of Scheme 4.

Scheme 4



The type of heterodiene synthesis considered above is very promising for the preparation of pyridoxine analogues. It makes it possible to modify virtually any position of the pyridine ring, with the exception of the third. A number of alkyl analogues of pyridoxine [compounds (XXXa)–(XXXf)] have been obtained by the interaction of 2- and 4-alkyl substituted 5-ethoxyoxazoles with diethyl maleate followed by the reduction of the esters of cinchomeronic acids with lithium aluminium hydride [35–38]:



(XXX)

a: $R^1=R^2=H$;
b: $R^1=H$; $R^2=CH_3$;
c: $R^1=R^2=CH_3$;
d: $R^1=C_2H_5$; $R^2=H$;
e: $R^1=$ iso-C_3H_7; $R^2=H$;
f: $R^1=$ n-C_4H_9; $R^2=H$.

Thus, the interaction of oxazoles with dienophiles constitutes a promising method for the synthesis of pyridine bases, in particular substituted 3-hydroxypyridines.

---o0o---

During the preparation of the review for the press, a communication dealing with the condensation of 5-ethoxy-4-methyloxazole with *cis*- and *trans*-2,5-dimethoxy-2,5-dihydrofuran was published [39]. The authors isolated diene synthesis adducts and showed that the ratio of the *endo*- and *exo*-adducts is 2 : 1 in both cases. Aromatisation with an alcoholic solution of alkali gave 3-hydroxy-2-methylpyridine-4,5-dialdehyde.

Ion Exchange and the Swelling of Ion-exchange Resins

G.V.Samsonov and V.A.Pasechnik

The review deals with the modern hypotheses concerning the physicochemical properties of ion-exchange resins and their effects in the interaction between resins and solvents and solutes, mainly electrolytes. The problems associated with the permeability of resins, the steric accessibility of the functional centres, and their screening are discussed. Particular attention has been devoted to the interaction between resins and solvents. The thermodynamic conditions of such interaction (the changes in the integral and differential thermodynamic functions of swelling) have been elucidated. The isotherms for the absorption of water vapour have been discussed as a function of the content of the cross-linking agent, the ionic form of the resin, and the hydrophilicity of the matrix. In the section dealing with the comparison of the isotherms for the absorption of water vapour by resins with different degrees of cross-linking, attempts to describe them on the basis of osmotic concepts are discussed. The methods of the osmotic theory have been examined in detail: the characteristics of the hydration of ion-exchange resins which follow from the analysis of the differential and integral free energies of swelling and also from data derived by other methods, such as infrared and nuclear spin resonance spectroscopy. Certain model approaches to the study of the selectivity of ion exchange with participation of the solvent have been described. The thermodynamic methods for the analysis of the relation between the selectivity and swelling of resins are quoted.
The bibliography includes 126 references.

I. POROSITY, PERMEABILITY, AND SWELLING OF ION-EXCHANGE RESINS

Ion-exchange sorption and chromatography which originated on the basis of mineral and certain natural organic ion exchangers have assumed considerable importance following systematic studies on the synthesis of ion-exchange resins. The formation of a wide variety of cross-linked polymers containing acid or basic functional groups gave rise to insoluble acids, bases, and amphoteric compounds and salts capable of the absorption and exchange of various types of ions or the absorption of electrolytes from solutions. The possibility of modifying the structure of the matrix of a three-dimensional polymer and the properties and positions of acid–base groups and other active groups led to the creation of highly specific ion-exchange resins absorbing preferentially particular types of ions from solution. Ion exchange on resins takes place in heterogeneous systems incorporating a gel-like phase consisting of the grains of the swollen resin and the external solution. The capacity of the ions present in solution to reach all the functional groups in the resin and to exchange with the ions reversibly bound to the functional groups (counterions) is determined by the permeability of the gel phase of the resin grains to the ions undergoing sorption and desorption. Precisely in this sense one speaks of the porosity of the resin within the three-dimensional network or the microporosity, these terms being understood as the permeability to mobile ions. In the exchange of inorganic and organic ions of low molecular weight there is interaction with all the centres regardless of their positions in the bulk of the grains.

However, other cases are known where only part of the exchange centres are accessible to the ions absorbed. We encounter such phenomena in the absorption by resins of ions having large molecular weights, in particular organic ions[1,2]†. In the sorption of the triply charged streptomycin ions (M = 580 conventional units) on carboxylic acid resins, the exchange capacity of the sorbents is found to increase with the swelling coefficient, but the total ion exchange capacity of the resins with respect to metal ions cannot be attained. This phenomenon is attributed to the fact that the sorption of the streptomycin ion is accompanied by the screening of part of the exchange centres of the cation exchanger[4] because the dimensions of the organic ions exceed the average distance between adjacent functional groups. The same tendency is observed with the sextuply charged neomycin ions (mycerin, M = 720 conventional units): the sorption capacity increases with the swellability of the resins, but the total exchange capacity cannot be attained. When the sorbent grains are considerably comminuted, which usually leads to a sharp increase in capacity when the functional centres are sterically inaccessible, only a slight increase in the exchange capacity of the resin with respect to neomycin is noted. On the other hand, ion-exchange resins (even resins with relatively low swellability) with reduced exchange capacity absorb large organic ions at all the functional groups. Thus carboxy-phenolic resins with reduced exchange capacity sorb streptomycin and neomycin at all the functional centres regardless of the swelling coefficient[5].

A similar phenomenon was observed in the sorption of nucleotides on ion-exchange resins. The sorption capacity of Dowex-1 with respect to ATP, AMP, and UMP depends little on the content of the cross-linking agent in the resin and hardly changes over a certain range (1–8% of divinylbenzene).[6] It is much lower than the total exchange capacity of the resins with respect to small ions, i.e. a

†The phenomenon of the inaccessibility of part of the sorption centres to inorganic ions has been observed on zeolites[3].

large part of the active centres do not participate in the exchange processes. Partial deamination of the resin and the associated decrease of the total exchange capacity lead to a sharp increase of the relative exchange capacity with respect to the nucleotides. In the cases considered part of the exchange centres are screened, which makes them inaccessible to interaction with the ions in solution.

Another example of the dependence of the equilibrium properties of ion-exchange resins on their structure is the problem of the correspondence between ionic dimensions and the dimensions of the effective channels in which ions can migrate. This phenomenon is widespread and is sometimes called the phenomenon of ionic sieving (by analogy with molecular sieving in the separation of materials); it is revealed both in the dependence of the sorption capacity with respect to the given ion on the swellability of the resin and in the dependence of the sorption capacity of the given resin with respect to ions of different dimensions. Thus the sorption capacity with respect to singly charged cations of tetracycline antibiotics increases with the swellability of sulphonated resins and almost reaches the total exchange capacity with respect to metal ions (Fig. 1). Similar phenomena occur also in anion exchange.

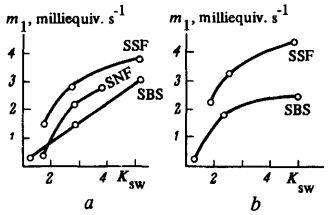

Figure 1. Dependence of the absorption capacity of sulphonated resins with respect to aureomycin (a) and terramycin (b) on resin swellability; K_{SW}—the swelling coefficient in the initial ionic form.

On increase in the swelling coefficients of anion exchangers, there is an increase in the sorption capacity with respect to the singly charged penicilin ion (M = 244 conventional units).[7] The dependence of the sorption capacity with respect to the singly charged novobiocin anion (M = 612 conventional units) on the swelling coefficient of the FAF resin is also described by an S-shaped curve. Screening of part of the sorption centres in the sorption of large organic ions and the inaccessibility of the sorption centres cannot be always unambiguously distinguished. The problem of the correspondence of the physicochemical properties of ion-exchange resins and the characteristics of the chemical and steric structures covers a wide range of phenomena and is one of the central problems in the theory of ion exchange. The solution of this problem involves the determination of quantitative relations between the properties of the initial components of the reaction mixture and those of the copolymers formed under the chosen conditions. At the present time the problem cannot be solved in a general form, although parts of it are susceptible to quantitative studies. The principal feature of the problem is the hypothesis of channels or pores through which the substances sorbed by the resin migrate. There exist ion-exchange materials, for example mineral and synthetic zeolites, which have channels which are homogeneous with respect to size and regular in shape. Zeolites are aluminosilicates and the characteristics of their structure are associated with the tetrahedral coordination of oxygen around aluminium and silicon and also the strength of the bonds between these elements and oxygen. In cross-linked organic polyelectrolytes such homogeneity of the channels cannot be achieved because of the different reactivities of the monomers, their complex dependence on the conversion, and also the possibility of various orientations of the polymer chains as a result of the rotation of methyl and other groups. The channels along which sorption of substances by ion-exchange resins takes place cannot be characterised in detail. Average characteristics such as porosity and permeability have been adopted for their description. The porosity P is the fraction of the volume of the resin grain occupied by pores, i.e.

$$P = \frac{v_1}{v_2},$$

where v_1 and v_2 are the pore volume and the total volume of the resin grain. For some resins, v_1 and v_2 change relatively little on hydration‡. The porosity of such resins has been called the intrinsic porosity.

Swelling resins can also be characterised by the porosity P, but the latter is not a constant. In the dry state $P \simeq 0$ and in the swollen state it can be extremely high and can exceed the value of P for intrinsically porous ion-exchange resins. This porosity has been called the latent porosity. The concept of "permeability" has been introduced in the study of liquid flow through membranes and filters formed from finely disperse materials. In this case the permeability is characterised by the permeability coefficient which enters into D'Arcy's linear filtration law. The permeability of ion-exchange resin grains cannot be defined in this simple form due to the lack of an evident analogy with the phenomenon of liquid flow and the complexity of the conditions in which the diffusion of substances absorbed takes place. Therefore it is now usual to speak of the permeability of disperse ion-exchange materials in the sense that it characterises their capacity to absorb substances. A measure of the permeability of an ion-exchange resin is the amount of substance absorbed under the given conditions. Thus porosity characterises mainly the sorbent, while permeability characterises its interaction with the medium§. The permeability of ion-exchange resins depends on the type of substance absorbed. Therefore the permeability to the solvent, for example, may differ from the permeability to ions. The permeability of ion exchangers depends on the amount of cross-linking agent and its nature. Thus when 20% of divinylbenzene is used in the synthesis of KU-2 sulphonated styrene resin, the product has a swelling coefficient of 1.3–1.4. A similar low swellability of the analogous SBS sulphonated styrene resin is achieved by the introduction of 70% of butadiene (divinyl). Three cross-linking agents

‡Ion-exchange resins may be hydrated both without a significant change in grain volume (resins with a large content of the cross-linking agent, macroporous resin) and with a considerable change in this volume. In the latter case hydration is frequently referred to as swelling. In the literature on ion exchange the term "swelling" is used as a synonym for "hydration".

§In resins with latent porosity the porosity and permeability characterise only the interaction between the resin and the medium.

are most widely used: divinylbenzene (*o*-, *m*-, and *p*-isomers), butadiene, and triazine. A copolymer with the most regular structure is formed when one of the pure isomers of divinylbenzene is used as the cross-linking agent. We believe that ion exchangers with butadiene or triazine as cross-linking agents have a less regular structure [8].

The number and relative positions of the functional centres have a significant influence on the permeability of resins. This phenomenon was discussed above (see p. 1257).in connection with the problem of the inaccessibility and screening of functional centres. Numerous methods developed earlier for mineral sorbents are used to estimate the permeability and porosity of ion-exchange resins. Mineral sorbents are in most cases intrinsically porous and their porosity can be investigated both in the dry state and in the presence of a solvent in the pores. A similar approach is unfortunately inapplicable to all types of ion-exchange resins, since, on swelling of resins with latent porosity, the permeability changes. To investigate the structure of ion-exchange resins, it is best to use methods which permit the estimation of the dimensions of the "expanded" regions between three-dimensional networks in the presence of maximum swelling of the resins, since it is then possible to compare the results with those for their permeability under ordinary conditions. It is noteworthy that none of the methods employed at present to estimate the porosity or permeability of resins is absolute. The choice of a particular method depends both on the characteristics of the given problem and on the individual characteristics of the sorbents. Various methods for the investigation of the structure of ion-exchange resins are listed in Table 1 and have been described in a number of reviews [4,74].

Figure 2 presents graphical models of ion-exchange sorbents with different porosities and permeabilities. Until recently the structural type A, characterised by an alternation of expanded and contracted regions in the polymer network, was most widely used. It should be noted that we are dealing with swelling ion-exchange resins and therefore structure A represents the state of the resin containing a solvent. When the latter is removed, the polymer chains close up and the differences between regions with different cross-linking densities are to a large degree smoothed out. In the dry state the packing density of the polymer chains is such that the resin hardly absorbs neutral gas molecules (see Table 2).

In the swollen state ion exchangers of this type are characterised by considerable intramolecular permeability. Almost all their functional centres are accessible to inorganic ions. However, when the degree of cross-linking of resins increases, the functional groups may become screened and sterically inaccessible. A steric model of the styrene–divinylbenzene cation-exchange resin of this structural type was proposed by Grubhofer [18].

If x is the molar percentage of the cross-linking agent (divinylbenzene), then the number of ethylene groups per

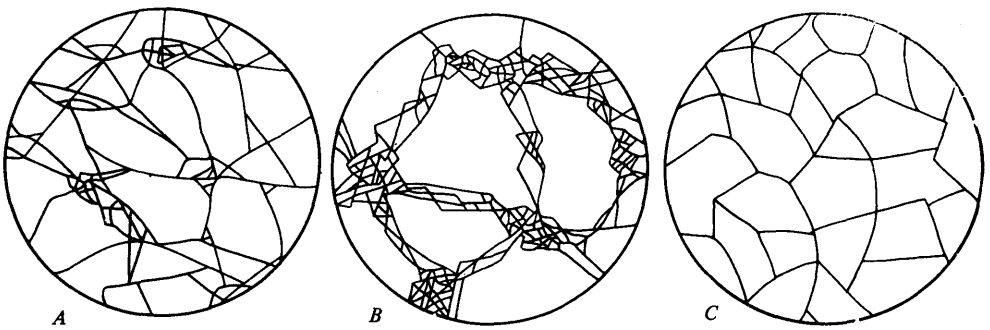

Figure 2. Graphical models of resins of different structural types: A) resin of Dowex-50 type; B) macroporous resin; C) macronetwork resin.

cross-link between the points of attachment of the latter is $y = \frac{1}{2}(100/x + 1)$. The distance between two branching points in the network [taking into account the thickness of the benzene ring (4.5 Å), the length of two carbon–carbon bonds in the phenyl group (2×1.5 Å), and the size of a single monomer unit (2.2 Å)] is

$$a(\text{Å}) = 2.2y + 7.5.$$

Table 2. Internal surfaces of various sorbents.

Sulphonic acid cation exchanger	H, Na		<0.1	10, 5

The angle between the main chain and the cross-link is assumed to be 90°. To obtain the dimensions of the cell accessible to the diffusion of ions, it is necessary to subtract from the resulting cell diameter the thickness of the polystyrene chain, i.e. 15 Å. Grubhofer's results for a high content of cross-linking agents in resins agree well with independent estimates of their cell dimensions, and for low contents of the cross-linking agents they agree with data obtained by the electron microscope study of the same specimens in the dry state. This shows that the model describes correctly the fundamental structural characteristics of resins based on styrene and divinylbenzene, despite the fact that it is undoubtedly a very rough approximation, disregarding a whole series of phenomena which obtain in the formation of copolymer structures (the presence of amorphous regions, non-uniform sulphonation, intertwining of chains, etc.).

An unusual type of porosity arises in the synthesis of resins where an inert component (including polymers) is used in the copolymerisation process [52–55]. Resins of this type are called macroporous. They are distinguished by a considerable heterogeneity of structure and are characterised by the presence of regions with higher and lower matrix densities (Fig. 2*B*). The macroporosity of a resin differs significantly from the permeability within the three-dimensional network. The channels in a macroporous sorbent, which have a large internal area, exist also in the unswollen polymer (Table 2). Such channels are absent from ordinary ion-exchange resins. Comparison of the structures of macroporous and ordinary resins with maximum moisture content shows that in the first case there are pores whose dimensions are several times greater than the "expanded" regions between the networks in ordinary resins. When macroporous resins are hydrated, their degree of swelling changes insignificantly. Owing to regions with high matrix density, macroporous resins are distinguished by considerable mechanical strength. The porosity of resins of this type may be characterised as intrinsic porosity.

Certain physicochemical characteristics of the resins are given in Table 2. KR-2 cation-exchange resin was obtained using additives of lower molecular weight than for KR-1 cation exchanger, as a result of which it has a higher surface area, but the average dimensions of its pores are smaller.

It is interesting that cases intermediate between macroporous and ordinary resins are possible; these resins are characterised by latent porosity. Thus AR-1 anion-exchange resin exhibits all the features of a macroporous resin and yet is capable of swelling. Electron diffraction shows that the structures of macroporous resins consist of agglomerates of quasispherical particles with interconnecting cavities between them. The microspherical particles of macroporous resins consist of a gel similar in properties to the gel of ordinary resins, but containing a much higher amount of the cross-linking agent and consequently having a much higher matrix density. The active centres can be located both on the surface of the microspherical particles and within them. Therefore diffusion coefficients measured in macroporous resins are a result of the superposition of the diffusion of ions in the system of cavities and in the gel of the microspherical particles. Similarly the absorption of a solvent by macroporous resins must be regarded as occurring both in the microspherical particles and in the spaces between them. Kunin [56] showed that the absorption of a solvent by macroporous resins takes place in two stages. Initially the microspheres are hydrated and then the spaces between them are filled, the fraction taken up by the microspheres in the cases which he investigated amounting to 28–30% of the total amount of the solvent absorbed. Experimental proof of the occurrence of this phenomenon is provided by the dependence of the amount of mercury which can be forced into the resin on the content of the solvent $\bar{n}_W$. Up to a certain value of $\bar{n}_W$, the porosity either does not change or increases somewhat, but, after the attainment of a critical value, it falls sharply. Evidently a significant cause of the decrease of the porosity is the end of the hydration and swelling of the microspherical particles and the appearance of the solvent between them. The results of experiments in which mercury is forced into the resin also show that the pore dimensions change in the swelling of macroporous resins: large pores become still larger and smaller pores decrease further in size. This phenomenon may be explained by the competition between the processes involving the swelling of the microspherical particles and their deformation on swelling.

The microspherical particles in macroporous resins may be regarded as having latent porosity. In the exchange of small inorganic ions all the functional centres of macroporous resins are accessible. With organic ions, the permeability falls sharply. This may be attributed to the steric inaccessibility to organic ions of the functional centres within the bulk of the microspherical particles and the accessibility of those on the surface of the particles. The phenomenon of steric inaccessibility to tetraethylammonium, triethylbenzylammonium, Methylene Blue, and Crystal Violet ions has been observed in macroporous ion-exchange resins where the capacity due to the functional centres on the surface of microporous particles amounted to 40–50% of the capacity with respect to inorganic ions. On further increase of ionic size, the permeability of the resin changes relatively little [2]. The presence of heterogeneous regions is reflected also in the kinetic properties of macroporous resins. When the functional centres of the microspherical particles are sterically inaccessible, the diffusion coefficient is determined solely by the dimensions

of the macropores. Thus the diffusion coefficients of the ions of quaternary ammonium bases in the macroporous KU-2 resin depend little on the dimensions of the ions in the series tetramethylammonium–triethylbenzylammonium. On the other hand, for ordinary resins of a similar type the rates of diffusion within the same group of ions decrease significantly with increase in their size.

A number of papers have been published recently on the methods of synthesis and the properties of new types of resins with enhanced permeability. Thus, when a telogen is used as a diluent, there is a possibility of breaks in the main chain [57]. The permeability of resins of this kind is higher due to the formation of "defects" in the main chain and due to the dilution of the monomer mixture. A method has been developed for the synthesis of sulphonic acid and carboxylic acid cation exchangers with larger dimensions of the interchain spaces as a result of the use of cross-linking agents with different chain lengths. *NN'*-Alkylenedimethacrylamides proved to be suitable for this purpose [4,10,58-60]. The elementary unit of KMDM macronetwork resins has the following structure.

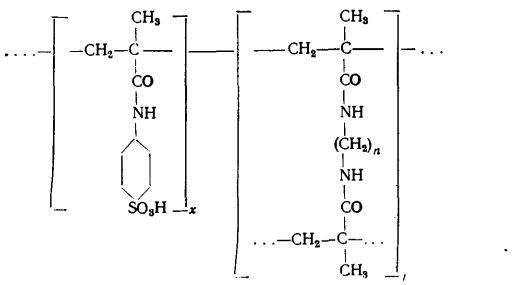

Table 3. Mutual diffusion coefficients of Methylene Blue and streptomycin ions in resins.

Sorption of Methylene Blue on KU-2 sulphonic acid resin (H^+-form, 40°C)		Sorption of streptomycin on KMDM-6* carboxylic acid resin (Na^+-form, 20°C)	
degree of saturation F	diffusion coefficient $10^{10}D$, $cm^2 s^{-1}$	degree of saturation F	diffusion coefficient 10^7D, $cm^2 s^{-1}$
0	1.7	0.23	1.1
0.13	1.6	0.35	1.1
0.40	0.5	0.51	1.3
0.62	0.25	0.86	1.3
0.80	0.35	0.95	1.2

*Cross-linking agent—hexamethylenedimethacrylamide.

The permeability of such resins may be altered both by changing the content of the cross-linking agent and by changing the length of its chain. Macronetwork resins probably have a structure of type *C* (Fig. 2), which is called isoporous. With suitable "pore" dimensions in these resins, there is a possibility in the latter only of the screening of functional centres. The high permeability of such resins to organic ions is reflected, in particular, in their capacity to sorb rapidly ions of large molecular weight. The diffusion coefficient of streptomycin ions in the grains of this resin is not only very high but also it does not decrease during the sorption process (Table 3).

Until recently it was suggested that a cross-linking three-dimensional polyelectrolyte capable of swelling may be regarded as a system with highly elastic properties in which thermal density fluctuations take place [61]. On this basis, the hypothesis was put forward that the incorporation of ions into the grains of the swollen resins may be associated not only with the presence of permanent pores of channels but also with the presence of fluctuating expanded regions in the polymer network. Then the conformational properties of the polymer network can be calculated on the basis of Flory's theory of polymer solutions, one of the results of which is a decrease of the entropy of the network on swelling. However, in a study of the thermodynamics of the exchange of quaternary ammonium ions for Na^+ ions on cross-linked sulphonated polystyrene resins (containing 8% of divinylbenzene), Boyd and Larson [62] observed that, when the resin is converted into the quaternary ammonium-form, its volume increases but the network entropy increases also instead of decreasing. The study of the elastic characteristics of films of sulphonated phenol–formaldehyde resins also showed [63] that the entropy of their extension is positive. These experimental findings and also the value of Young's modulus of ion-exchange resins, which is 10^8–10^9 dyn cm^{-2}, i.e. higher by a factor of ten than the value of Young's modulus of rubbers, led to the conclusion [64] that ion-exchange resins of certain types behave as if they were polymers in the vitreous state. Then one may expect that the mobility of the polymer network is fairly low and network density fluctuations under the influence of thermal motion cannot lead to significant changes in the shape of the "pores".

II. INTERACTION OF ION-EXCHANGE RESINS WITH SOLVENTS

a. Methods for the Investigation of the Interaction of Ion-Exchange Resins with Solvents

The study of the solvation of ion-exchange resins¶ is important both for the investigation of their physicochemical properties (structure, amount of cross-linking agents, hydrophilicity of the fixed groups and counterions, etc.) and for the elucidation of the mechanism of ion exchange. A quantitative characteristic of the interaction of the resin with a solvent is provided by the isotherms for the adsorption of the latter from the vapour phase or from solution (the so called isopiestic lines). Isopiestic lines are usually measured in the vapour pressure range from negligibly low values up to the vapour pressure (p_0) of the pure solvent ($0 \leq p/p_0 = \alpha \leq 1$). The temperature coefficients of isopiestic lines over the entire range of values of α are also important. The composition of the vapour phase is regulated by solutions of salts [65,66] or sulphuric acid [67], the water vapour pressure above which is known over a wide range of temperatures and concentrations. On the basis of the isopiestic lines and their temperature coefficients (or on the basis of the heats of hydration), it is possible to calculate all the thermodynamic functions characterising the interaction of the resin with the solvent. The application of the thermodynamic method to resins [68,69] has developed largely by analogy with the thermodynamics of the hydration of natural macromolecular compounds [70,71].

Suppose that we have a resin with a specified ionic composition containing a certain amount of absorbed solvent

¶We shall consider only the interaction with water.

$\bar{n}_{1w}$ moles per equivalent of ions) in equilibrium with the vapour of the latter whose pressure is p_1. If the pressure changes, for example increases, there is a corresponding change also in the equilibrium content of the solvent in the resin. The increase in moisture content in the process where sorption does not alter the equilibrium vapour pressure may be represented by the following equation:

$$n_i[\bar{n}_{1w}(p_1)] + n_w(p_2) \rightarrow n_i[\bar{n}_{1w} + \bar{n}_w, (p_2)], \quad (1)$$

where n_i is the amount of ion-exchange resin (in grammes) containing E equivalents of exchange centres and $n_w(p_2) = \bar{n}_w(p_2)$.

The increment of the Gibbs free energy of the system during process (1) is

$$\Phi_{sw} = n_i[\mu_i(p_2) - \mu_i(p_1)] + \bar{n}_{1w}[\bar{\mu}_w(p_2) - \bar{\mu}_w(p_1)] = n_i\Delta\mu_i(p_2, p_1) + \bar{n}_{1w}RT\ln\frac{p_2}{p_1}, \quad (2)$$

where Φ_{sw} is the free energy of swelling in process (1) and $\bar{\mu}_w(p_2) = \mu_w(p_2)$. The change in the composition of the vapour phase may be neglected in the derivation of Eqn. (2), because swelling can always be studied under conditions such that the change in the number of moles of water in the vapour phase is very small, with a small resin sample, or under conditions such that this change is compensated by the evaporation of part of the solvent from the electrolyte maintaining the given vapour pressure. The change in the free energy of the vapour is then zero (at T = const. and p = const.) and therefore makes no thermodynamic contribution to the swelling process. On the other hand, the Gibbs–Duhem equation applies to the equilibrium system (at a pressure p_2):

$$n_i d\mu_i + (\bar{n}_{1w} + \bar{n}_w)\, d\bar{\mu}_w = 0, \quad (3)$$

$$d\mu_i = -\frac{(\bar{n}_{1w} + \bar{n}_w)}{n_i}\, d\bar{\mu}_w. \quad (4)$$

According to Eqn. (4), the change in the chemical potential of the ion-exchange resin when the equilibrium vapour pressure changes from p_1 to p_2 is

$$\mu_i(p_2) = \mu_i(p_1) = -\int_{\mu_w(p_1)}^{\mu_w(p_2)} \frac{(\bar{n}_{1w} + \bar{n}_w)}{n_i}\, d\mu_w. \quad (5)$$

Since $\bar{n}_{1w}$ is independent of the pressure p_2, it follows that

$$\mu_i(p_2) - \mu_i(p_1) = -\frac{\bar{n}_{1w}}{n_i}RT\ln\frac{p_2}{p_1} - \int_{\bar{\mu}_w(p_1)}^{\bar{\mu}_w(p_2)} \frac{\bar{n}_w}{n_i}\, d\mu_w.$$

On substituting the change in the chemical potential of the resin determined from Eqn. (6) in Eqn. (2), we obtain

$$\Phi_{sw} = -\int_{\ln\alpha_1}^{\ln\alpha_2} \bar{n}_w RT\, d\ln\alpha, \quad (7)$$

where $\alpha = p/p_0$ and p_0 is the vapour pressure of the pure solvent. To facilitate the comparison of the free energies of swelling of various resins, it is necessary to select standard states for the resin and solvent vapour; usually one chooses the dry resin and the vapour over the pure solvent ($p = p_0$). Then swelling is measured from the state where $p_1 = 0$. The free energy of the transfer of n_w moles of the solvent from the vapour at a pressure p_0 to the vapour at a pressure p_2 is

$$\Phi_{sw_2} = n_w[\mu_w(p_2) - \mu_w(p_0)] = n_w RT\ln\alpha. \quad (8)$$

Thus the change in the free energy of swelling of the resin from the chosen standard states to the specified mixed state is

$$\Phi_{sw} = \Phi_{sw_1} + \Phi_{sw_2} = \bar{n}_w RT\ln\alpha - RT\int_0^{\alpha} \bar{n}_w\, d\ln\alpha = RT\int_0^{n_w} \ln\alpha\, dn_w. \quad (9)$$

We may note that the value of Φ_{SW} calculated by Eqn. (9) corresponds to a hypothetical swelling process where in the equilibration of the dry resin ($p = 0$) with the vapour of the pure solvent ($p = p_0$) the equilibrium vapour pressure decreases to $p_2 > p_0$. Φ_{SW_1} corresponds to the process in a humidifier where p_2 = const. Eqn. (9) thus corresponds to the following free energy difference [68,69]:

$$\Phi_{sw} = \bar{n}_w\bar{\mu}_w(p_2) + n_i\mu_i(p_2) - n_w\mu_w(p_0) - n_i\mu_i(p=0) = \bar{n}_w[\bar{\mu}_w(p_2) - \mu_w(p_0)] + n_i[\mu_i(p_2) - \mu_i(p=0)]. \quad (10)$$

Comparison of Eqns. (9) and (10) shows that the first term in the former characterises the change in the state of the solvent and the second the change in the state of the resin during the sorption process. Similar equations can be written also for the heat of sorption [assuming that $\bar{h}_w(p_2) = h_w(p_2)$]:

$$H_{sw} = \bar{n}_w[\bar{h}_w(p_2) - h_w(p_0)] + n_i[h_i(p_2) - h_i(p=0)], \quad (11)$$

where $\bar{h}_w$ and h_i are the partial heats of sorption of the solvent and of the swelling of the resin. The partial quantities referring to the solvent can be found in the following way:

$$\bar{h}_w(p_2) - h_w(p_0) = \frac{\partial\left(\frac{H_{sw}}{n_i}\right)}{\partial\left(\frac{\bar{n}_w}{n_i}\right)}. \quad (12)$$

On combining Eqns. (11) and (12), we obtain the difference between the partial heats $h_i(p_2) - h_i(p=0)$ characterising the swelling of the resin:

$$h_i(p_2) - h_i(p=0) = \frac{H_{sw}}{n_i} - \frac{\bar{n}_w}{n_i}\cdot\frac{\partial\left(\frac{H_{sw}}{n_i}\right)}{\partial\left(\frac{\bar{n}_w}{n_i}\right)} = -n_e^2\frac{\partial\left(\frac{H_e}{n_e}\right)}{\partial n_e}, \quad (13)$$

where $\bar{n}_e = \bar{n}_w/n_i$ is the equivalent moisture content of the resin and $H_e = H_{SW}/n_i$ the equivalent heat of sorption of the solvent.

Subdivision of the experimental heat of sorption of the solvent into components associated with the change in the thermodynamic state of the resin (the matrix or the ions and counterions fixed on the matrix) and the solvent permits the estimation of their relative contributions and thereby provides quantitative data for the elucidation of the thermodynamic effects of the swelling process. Additional information can also be obtained by comparing the changes in the Gibbs free energies and enthalpies of swelling:

$$\bar{\mu}_w(p_2) - \mu_w(p_0) = \bar{h}_w(p_2) - h_w(p_0) - T[\bar{S}_w(p_2) - S_w(p_0)], \quad (14)$$
$$\mu_i(p_2) - \mu_i(p_0) = h_i(p_2) - h_i(p_0) - T[S_i(p_2) - S_i(p_0)].$$

Eqns. (14) and (15) permit the determination of the partial entropies of sorption of the solvent and of swelling of the resin ($\bar{S}_w$, S_i). The determination of the partial thermodynamic quantities of Eqns. (12)–(15) is possible when the heats of sorption are measured together with the sorption isotherms of the solvent [frequently called "isopiestic" lines, the term reflecting the sorption mechanism defined by Eqn. (1), since the vapour pressure then remains unchanged]. Calorimetric determination of the heat of sorption of the solvent is most advantageous, since

it is then possible to obtain the most accurate values of the enthalpy of swelling as a function of the equilibrium amount of solvent absorbed. From the experimental standpoint, the following procedure for the determination of this function is convenient. Initially it is necessary to measure the integral heat of sorption when the dry resin is mixed with an excess of the solvent. Then the resin is equilibrated with the vapour of the solvent and the heat of mixing with an excess of the solvent is determined for this state. The difference between the two heats represents the heat of conversion of the dry resin into the partially hydrated state corresponding to the chosen vapour pressure. By varying the equilibrium vapour pressure, it is possible to obtain a curve relating H_{SW} to the content of the solvent in the resin. However, this relation can also be calculated provided that the isopiestic lines for the given resin are available at several temperatures. It is known that the heat of a chemical reaction which is independent of temperature (if it does vary with temperature, then the average heat in the given temperature range is employed) may be calculated from the temperature variation of the Gibbs free energy:

$$H_{sw} = -T^2 \frac{\partial \frac{\Phi_{sw}}{T}}{\partial T} \qquad (16)$$

When the temperature changes, the free energy of swelling changes too, since this involves a change in the content of the solvent in the resin. For further discussion, it is convenient to introduce the concept of the isosteric heat change H_{is}, i.e. the heat change occurring when the solvent is redistributed between the resin and the vapour on changing the temperature but the total amount of solvent remains constant:

$$H_{is} = -T^2 \frac{\partial^2}{\partial T\, \partial \bar{n}_w} \left[\frac{\Phi_{sw}}{T}\right] . \qquad (17)$$

It is easy to show that

$$H_{is} = \left.\frac{\partial H_{sw}}{\partial \bar{n}_w}\right|_{T,p} . \qquad (18)$$

The isosteric heat change can be conveniently determined from two isopiestic lines corresponding to different temperatures on the basis of the following equation:

$$H_{is} = \frac{RT_1T_2}{T_2 - T_1} \ln \left.\frac{\alpha_1}{\alpha_2}\right|_{\bar{n}_w} , \qquad (19)$$

where $T_2 > T_1$ and α_2 corresponds to the temperature T_2. If H_{is} is determined for different values of $\bar{n}_w$, then the integral heat of sorption H_{SW} may be determined as follows [see Eqn. (18)]:

$$H_{sw} = \int_0^{\bar{n}_w} H_{is}\, d\bar{n}_w . \qquad (20)$$

The calculation of H_{SW} by Eqns. (16) and (20) should in principle yield the same enthalpies of swelling, but in the second case the results are more accurate, since there is an additional computational operation in Eqn. (16) involving integration.

The change in the solvent content of the resin with temperature in the range of several tens of degrees is small, which of course leads to a low accuracy in the determination of the enthalpy of swelling from the temperature variation of Φ_{SW}. In consequence of the condition $\bar{n}_w$ = const., H_{SW} can be calculated down to the smallest swellability in the given temperature range (as a rule it corresponds to the highest temperature).

Together with the development of thermodynamic techniques for the investigation of ion-exchange resin solvation, physical methods are being increasingly employed at the present time: NMR and infrared spectroscopy, methods based on the study of the dielectric properties of the resins, etc. The principal conclusions arrived at on the basis of these methods are described below.

b. Characteristics of the Interaction of Ion-Exchange Resins with Solvents

The isotherms for the absorption of water by an ion-exchange resin depend on the type (types) of counterions, the content of the cross-linking agent, the hydrophilicity of the matrix and the cross-linking agent, and also on the characteristics of the steric structure of the resin matrix. According to Brunauer's classification [72], they can be assigned to the second type, characterised by multilayer adsorption without capillary condensation, With increase of the relative humidity of the vapour phase, the isotherms are nearly linear in the vicinity of zero [pressure ? (Ed. of Translation)]. For sulphonated polystyrene ion-exchange resins saturated with alkali metal or alkaline earth metal ions, the slopes of these curves are particularly high [68]. They are somewhat lower for sulphonated resins containing Ag^+ ions [68] and also organic ions. A sharp change in the isotherms in this region is characteristic of certain carboxylic acid resins in the H^+-form [4] and also for anion exchangers [76]. In the region of intermediate values of α the slope of the $\bar{n}_w - \alpha$ curve decreases compared with the first section but, as a rule, it is higher the higher is its value in the first section. The overall absorption of solvent along both sections of the isotherms is lower (sometimes much lower) than the maximum absorption of the solvent by the resin at $\alpha = 1$. Therefore the greatest change in swelling occurs in the region of relative humidity close to unity. The slopes of the isotherms in this region are also various. The following two series illustrate the variation of the swellability with the type of ion and α:[68]

$\alpha = 1$; $Mg^{2+} > H^+ > Li^+ > Na^+ > Ca^{2+} > NH_4^+ > K^+ > Ba^{2+} > Ag^+ \approx (CH_3)_4N^+$

$\alpha = 0{,}29$; $Mg^{2+} > H^+ > Ca^{2+} > Li^+ > Ba^{2+} > Na^+ > (CH_3)_4N^+ > NH_4^+ > K^+ > Ag^+$.

A change in the content of the cross-linking agent in the resin has the greatest effect along the third section of the isotherms: with increase in the degree of cross-linking, the swellability falls sharply. At lower values of α two opposed results have been noted: the swellability of resins with a high degree of cross-linking is lower for some resins [72,73] and higher for others [64,74,75] than for less cross-linked analogues (in this case the swelling isotherms at low and high values of α are reversed). Gregor [69] was the first to describe the reversal of the isotherms and explained it qualitatively. According to his hypothesis, in the region of low values of α in resins with a low content of cross-linking agents there is more intense interchain interaction, which reduces the degree of swelling. Because of its rigidity, the cross-linking agent limits this interaction, which leads to the reversal of isotherms. It is interesting to note that the isotherms for the absorption of solvents by non-cross-linked polyelectrolytes are also below the isotherms for the cross-linked analogues at low values of α and above them at high values. The reversal of isotherms is shown particularly clearly for macronetwork ion-exchange resins, which is evidently favoured by the interaction between the amide groups of the cross-linking agent and the monomer. It is noteworthy that,

in the hydration of macronetwork resins, data confirming Gregor's hypothesis were obtained: a change in the chain length of the cross-linking agent while retaining its relative content leads to the reversal of the isotherms[4]. The effect of the structural characteristics of resins on swellability may be followed in the usual sulphonated cation-exchange resins of the polymerisation type (macronetwork[75] and macroporous[76]) as examples. For the same content of cross-linking agent in KU-2 resin and in a macronetwork resin, their isotherms virtually merge in the first two regions of α values but differ significantly in the third, where there is a characteristic, particularly sharp rise for macronetwork resins, as a result of which the maximum swellabilities of the resins at $\alpha = 1$ differ severalfold. This phenomenon is associated with the large dimensions of the unit cell of the macronetwork resins and the smaller number of physical nodes in its structure. The isotherms for macroporous resins resemble those for macronetwork resins. They are also characterised by a sharp increase of swellability at α close to unity, but in this case the rise is not due to the formation of a homogeneous internal solution but is probably caused by capillary condensation in the pores of these resins. At lower values of α the hydration of macroporous resins takes place in the more condensed parts of the matrix†, i.e. as in the usual resins with a high content of cross-linking agent. The presence in the resin matrix of other types of hydrophilic centres influences all three sections of the isotherm for the absorption of solvent. Thus the presence of phenolic groups in KU-1 sulphonated cation exchanger appreciably enhances the equivalent content of the solvent in it compared with Dowex-50 × 2 resin (Na^+-form). On the other hand, the presence of amide groups in sulphonated cation exchangers has an insignificant effect on solvent absorption isotherms. The description of the factors influencing the shape of the isotherms for the absorption of solvent by resins shows that their quantitative representation by the function $\bar{n}_W = \varphi(\alpha)$ over the entire range of variation α is exceptionally difficult. Some authors proposed empirical equations describing the adsorption of water in narrow ranges of α. Recently the applicability of the BET equation to the adsorption of water in the region $0 < \alpha < (0.5\text{–}0.7)$ [77,78] has been extensively investigated. In this connection, it must be noted that the possibility of representing adsorption isotherms over a narrow range of α by the linear relation

$$\frac{\alpha}{v(1-\alpha)} = \varphi(\alpha)$$

is not sufficient proof that the adsorption mechanism is identical with that underlying the BET theory. It is necessary that the constants C and v_m (in the two-parameter equation) should lie within certain ranges consistent with the physical nature of the process. The second condition is that the measured temperature variation of the constant C should agree with the predictions of the theory. These problems were examined in greater detail by Flood[79].

The difference in the isotherms for the absorption of solvent by resins may be attributed to the different degrees of swelling of the resins in the three regions of the isotherms. The analysis of these effects is based mainly on the variation of the free energies of swelling with α (see p. 552).

†In Kunin's microspheres[56].

The difference in the isotherms for resins containing various amounts of the cross-linking agent may be formally based on osmotic theory in which it is assumed that the components in the resin phase are under a higher pressure ($p_0 + \pi$) than in solution (p_0).[64,68] This postulate, which constitutes the basis of the osmotic theory of ion exchange, has not been confirmed experimentally and must be regarded as hypothetical. One of its consequences is that the introduction of the cross-linking agent is equivalent to an increase of the pressure π. The pressure π is calculated from the isotherms for the absorption of water vapour by resins containing different amounts of the cross-linking agent. According to the osmotic theory, the chemical potential of the solvent in the resin may be represented thus:

$$\bar{\mu}_w = \bar{\mu}^0_w(T, p_0 + \pi) + RT \ln \bar{a}_w, \tag{21}$$

where $a_W \neq \varphi(\pi)$. Evidently

$$\frac{\partial \bar{\mu}^0_w(T, p_0+\pi)}{\partial \pi} = \frac{\partial^2 \Phi}{\partial \pi \partial n_s} = \bar{v}^0_w, \tag{22}$$

where $\bar{v}^0_W$ is the partial molar volume of the solvent in the standard state of the resin:

$$\bar{\mu}^0_w(T, p_0+\pi) = \bar{\mu}^0_w(T, p_0) + \int_{\pi=0}^{\pi} \bar{v}^0_w d\pi. \tag{23}$$

On expanding the partial molar volume of the solvent in series in terms of π, we obtain

$$\bar{\mu}^0_w(T, p_0+\pi) = \mu^0_w(T, p_0) + \int_{\pi}^{\pi} \left[\bar{v}^0_w(p_0) + \pi \frac{\partial \bar{v}_w(p_0)}{\partial \pi} + \right.$$
$$\left. + \frac{1}{2!}\pi^2 \frac{\partial^2 \bar{v}_w(p_0)}{\partial \pi^2} + \ldots\right] d\pi \simeq \bar{\mu}^0_w(T, p^0) + v^0_w\left(1 - \varkappa \frac{\pi}{2}\right)\pi = \bar{\mu}^0_w(T, p_0) + \pi \hat{w}^0_s, \tag{24}$$

where κ is the compressibility of water and v^0_W the partial molar volume of water in the standard state at a pressure $\pi/2$. Therefore the expression for the chemical potential of the solvent in the cross-linked resin assumes the following form:

$$\bar{\mu}_w(T, p_0+\pi) = \bar{\mu}^0_w(T, p_0) + \pi \hat{w}^0_w + RT \ln \bar{a}_w. \tag{25}$$

At equilibrium with the vapour of the solvent ($\bar{\mu}_W = \mu_W$)

$$\bar{\mu}^0_w(T, p_0) + \pi \hat{w}^0_w + RT \ln \bar{a}_s = \mu^0_w(T, p_0) + RT \ln \bar{\alpha}. \tag{26}$$

If the standard chemical potentials of the solvent in the resin and in the vapour are chosen the same ($\bar{\mu}^0_W = \mu^0_W$), then

$$\pi \hat{v}^0_w + RT \ln \bar{a}_w = RT \ln \bar{\alpha}. \tag{27}$$

Assuming that in a weakly cross-linked resin $\pi = 0$, we have

$$RT \ln \tilde{a}_w = RT \ln \tilde{\alpha}, \tag{28}$$

$\tilde{\alpha}$ being the relative vapour pressure of the solvent in equilibrium with the weakly cross-linked resin. We may note that an equation of type (22) can be applied not only to the standard chemical potential of the resin but also to the chemical potential of the resin with any solvent content (it is then necessary to satisfy also the condition of a constant moisture content in resins with different values of π):

$$\bar{\mu}_w(T, p_0+\pi) = \bar{\mu}_w(p_0) + \pi \hat{w}^0_w \text{ when } x_w = \text{const} \tag{29}$$

or, taking into account Eqns. (25) and (28) and putting $\bar{\mu}_W(p_0) = \tilde{\mu}_W(p_0)$:

$$\bar{\mu}^0_w(p_0) + \pi \hat{w}^0_w + RT \ln \bar{a}_w = \tilde{\mu}^0_w(p_0) + RT \ln \tilde{\alpha} + \pi \hat{v}^0_w$$
$$\text{when } \bar{x}_w = \tilde{x}_w. \tag{30}$$

For the above choice of standard states, we obtain‡

$$\bar{a}_w = \tilde{a}_w \text{ when } \bar{x}_w = \tilde{x}_w \quad (31)$$

or

$$\bar{f}_w = \tilde{f}_w \text{ when } \bar{x}_w = \tilde{x}_w . \quad (32)$$

Then it follows from Eqns. (27) and (28) that

$$\pi = \frac{RT}{\hat{v}_w^0} \ln \frac{\bar{\alpha}}{\tilde{\alpha}} \text{ when } \bar{x}_w = \tilde{x}_w . \quad (33)$$

Eqn. (33) is the starting point for the determination of the osmotic pressure. Since $\hat{v}_w^0$ corresponds to the partial molar volume of the pure solvent, it can be determined from tabulated data. Sometimes another expression is used for the pressure π:

$$\pi = \frac{RT}{v_w} \ln \frac{\bar{\alpha}}{\tilde{\alpha}} \text{ when } \bar{x}_w = \tilde{x}_w , \quad (34)$$

where v_w is the partial molar volume of the solvent in the swollen (cross-linked) resin.

Eqn. (34) is associated with another form of the expression for the chemical potential of the solvent in the resin, different from Eqn. (21):

$$\bar{\mu}_w(T, p_0 + \pi) = \bar{\mu}_w^0(T, p_0) + RT \ln \bar{x}_w \bar{\gamma}_w(p_0 + \pi) . \quad (35)$$

The possibility of this approach was first pointed out by Holm [81]. The principal difference between Eqns. (21) and (35) is due to the choice of different ideal reference systems§. In the first case it [the reference system? (Ed. of Translation)] is defined at the same pressure $p_0 + \pi$ as that of the components of the cross-linked resin and in the second case at a constant pressure p_0 (x_w is almost independent of π):

$$\frac{\partial \bar{\mu}_w(T, p_0 + \pi)}{\partial \pi} = RT \frac{\partial \ln \bar{\gamma}_w}{\partial \pi} = v_w , \quad (36)$$

where v_w is the partial molar volume of the solvent in the swollen cross-linked resin. It follows from Eqn. (36) that

$$RT \ln \bar{\gamma}_w(p_0 + \pi) = RT \ln \gamma_w(p_0) + \int_{\pi'}^{\pi} v_w d\pi \quad (37)$$

where $\bar{x}_w$ = const. In the region of not unduly low values [pressures (Ed. of Translation)], we have $\alpha \bar{v}_w$ = const. [82] and then

$$\bar{\gamma}_w(p_0 + \pi) = \bar{\gamma}_w(p_0) e^{\frac{\pi v_w}{RT}} \text{ when } \bar{x}_w = \text{const} . \quad (38)$$

At equilibrium between the cross-linked resin and the pure solvent

$$\bar{\mu}_w^0(p_0) + RT \ln \bar{a}_w(p_0 + \pi) = \mu_w^0(p_0) + RT \ln \bar{\alpha} \quad (39)$$

or

$$\bar{a}_w(p_0 + \pi) = \bar{\alpha} \quad (40)$$

when the standard chemical potentials are assumed to be equal in both phases. An analogous expression is obtained for the non-cross-linked resin:

$$\tilde{a}_w(p_0) = \tilde{\alpha} . \quad (41)$$

At equilibrium with vapour of the same composition

$$\frac{\bar{a}_w(p_0 + \pi)}{\tilde{a}_w(p_0)} = \frac{\bar{x}_w}{\tilde{x}_w} \cdot \frac{\bar{\gamma}_w(p_0 + \pi)}{\tilde{\gamma}_w(p_0)} = 1 . \quad (42)$$

‡Condition (31), based on osmotic theory, constitutes essentially the mathematical statement of the postulate indicated above.

§An ideal reference system is a system whose chemical potential satisfies the equation $\mu_i = \mu_i^0 + RT \ln x_i$.

Then using Eqn. (38) we obtain

$$\frac{\bar{x}_w}{\tilde{x}_w} \cdot \frac{\bar{\gamma}_w(p_0 + \pi, \bar{x}_w)}{\tilde{\gamma}_w(p_0, \tilde{x}_w)} = \frac{\bar{x}_w}{\tilde{x}_w} \cdot \frac{\tilde{\gamma}_w(p_0, \bar{x}_w)}{\tilde{\gamma}_w(p_0, \tilde{x}_w)} \cdot e^{-\frac{\pi v_w}{RT}} . \quad (43)$$

The moisture contents to which the activity coefficients correspond are indicated in Eqn. (43). We may note that in the derivation of Eqn. (43), as in Eqn. (30), the fundamental condition of the osmotic theory was employed, i.e.

$$\bar{\gamma}_w(p_0, \bar{x}_w) = \tilde{\gamma}_w(p_0, \bar{x}_w) .$$

Eqn. (43) can also be written as follows [see Eqns. (40) and (41)]:

$$\frac{\bar{a}_w(\bar{x}_w)}{\tilde{a}_w(\bar{x}_w)} = \frac{\bar{\alpha}(\bar{x}_w)}{\tilde{\alpha}(\bar{x}_w)} \cdot e^{-\frac{\pi v_w}{RT}} , \quad (44)$$

which is identical with Eqn. (34).

Comparison of Eqns. (33) and (34) shows that the osmotic pressure depends on the method of calculation, while the chemical potential does not. Compensation is achieved by means of different activity coefficients.

To determine the osmotic pressure in the resin phase, use is also made of the distribution of non-electrolytes between the solvent and the resin (the method of Ginzburg and Cohen). [83] Using Eqn. (25) for a solvent and a non-electrolyte, we obtain

$$\pi(v_w^0 - v_e^0) = RT \ln \frac{\bar{m}_e}{m_e} \frac{\bar{f}_e}{f_e} \cdot \frac{f_w}{\bar{f}_w} = RT \ln \left[K_e \frac{\bar{f}_e f_w}{f_e \bar{f}_w} \right] , \quad (45)$$

where K_e is the partition coefficient¶, $\bar{m}_e$ and m_e are the molalities of the non-electrolyte in the resin and in the external solution, and $\bar{f}_e$, f_e, $\bar{f}_w$, and f_w are the activity coefficients of the non-electrolyte and the solvent in the resin and in the solution respectively. It was found that, for a number of non-electrolytes (sucrose, glucose, arabinose, mannitol, raffinose, glycerol, and ethylene glycol), $\ln K_e$ is directly proportional to $v_w^0 - v_e^0$. The slope of the plot of $RT \ln K_e$ against $v_w^0 - v_e^0$ yields the osmotic pressure when the ratio $\bar{f}_e f_w / f_e \bar{f}_w$ varies insignificantly with $v_w^0 - v_e^0$. The osmotic pressures obtained in this way are fairly consistent with the values given by Eqn. (33), but they do exceed them by a factor of 2–3. This method must be regarded as an independent procedure for the determination of π, since it does not involve the postulates of the osmotic theory.

The qualitative description of the form of the solvent absorption isotherm shows that osmotic pressure increases with the content of the cross-linking agent in the range of relatively high values of α. The reversal of solvent absorption isotherms at low values of α is explained by the supporters of the osmotic theory as an effect of negative osmotic pressure, since it is believed that in this case π is zero in the reference ion-exchange resin (resins containing 0.5–2% of the cross-linking agent are usually chosen as a reference [62,64]).

The linear variation of the osmotic pressure with the equivalent volume of the resin V_e is also of interest [64]. Such relations have been found for Dowex-50 cation-exchange resins saturated with alkali metal ions and also for Dowex-1 anion-exchange resins saturated with halide ions [64]. In the exchange of tetraethylammonium and sodium ions on Dowex-50 × 8 Boyd and Schwarz [117] also observed a linear relation of the type

$$\pi = a \Delta V_e + b \quad (46)$$

¶The partition coefficient was found from the retention volumes of the non-electrolytes in a column experiment.

with the constants $a = 1.05$ cm^3 mole^{-1} atm^{-1} and $b = -239$ cm^3 mole^{-1}. It is nowadays believed[64] that relations of type (46) indicate that the resin may be regarded as a solid elastic body or as an elastomer. Putting Eqn. (46) in the form

$$\pi = k(V_e - V_e^0) = B\frac{\Delta V_e}{V_e^0}, \quad (47)$$

where V_e^0 is the value of V_e at $\alpha = 0$ and B is a constant which has the dimensions of the modulus of elasticity, it is possible to calculate from B an effective Young's modulus for resins. The values of Young's modulus for Dowex-50×8 and Dowex-1 × 6 resins are both 2.2×10^8 dyn cm^{-2}, which is higher by almost a power of ten than the values of Young's modulus for elastic polymers (in particular rubbers). We believe that another explanation of Eqn. (46) is also possible, not involving the characteristics of the elastic deformation of the polyelectrolyte network but associated with the characteristics of resin hydration in the region where $\alpha \to 1$ [at low moisture contents a and b in Eqn. (46) begin to vary with moisture content]. In this region of α values the slope of the solvent absorption isotherms and in particular the derivative $\partial n_w/\partial \ln \alpha$ varies relatively little with moisture content (a) and with the ionic form of the resin (b). Therefore, for each resin, it is possible to find a range of α values ($\alpha^* < \alpha < 1$) in which the following approximation is valid:

$$\Delta \bar{V}_e = \int_0^{\bar{n}_w} \bar{v}_w\, dn_w = \int_{-\infty}^{\ln \bar{\alpha}} \bar{v}_w \frac{\partial \bar{n}_w}{\partial \ln \bar{\alpha}} d\ln\alpha = \Delta v_e + \int_{\ln \bar{\alpha}^*}^{\ln \bar{\alpha}} \bar{v}_w \frac{\partial \bar{n}_w}{\partial \ln \bar{\alpha}} d\ln\alpha \simeq$$

$$\simeq \Delta v_e^0 + \overline{\bar{v}_w \frac{\partial \bar{n}_w}{\partial \ln \bar{\alpha}}} \cdot \ln \frac{\bar{\alpha}}{\bar{\alpha}^*} = \simeq v_e^0 + \beta \frac{v_w \pi}{RT} + \beta \ln \frac{\bar{\alpha}}{\bar{\alpha}^*} \simeq C + \gamma\pi, \quad (48)$$

where $\beta = v_w \frac{\partial \bar{n}_w}{\partial \ln \bar{\alpha}}$, γ, and C are constants, and Δv_e is the value of ΔV_e corresponding to the value of α at which the condition $\beta \simeq$ const. begins to hold.

If in the range of relative moisture contents considered $\partial \bar{n}_w/\partial \ln \bar{\alpha}$ and $\bar{v}_w$ are relatively constant, then Eqn. (48) is equivalent to Eqn. (47). The following comments may be made on these conditions: (a) the steepness of the isotherms for the absorption of solvents by resins saturated by univalent ions is the same for many resins in the vicinity of $\alpha = 1$;[68] the steepness of the solvent absorption isotherms changes on transition to polyvalent ions and also to organic ions[68,122,123]; thus it has been shown[73] that equations of type (46) for the Ba^{2+}- and H^+-forms of KU-2 resin have different constants a and b; (b) since the partial molar volume of the solvent in resins near $\alpha = 1$ changes relatively little with the moisture content of the resins[124], $\bar{v}_w \frac{\partial \bar{n}_w}{\partial \ln \bar{\alpha}}$ may indeed be regarded as constant in this region.

The significance of the concept of osmotic pressure in the resin is very important in the osmotic theory. According to one view this is a real pressure in the resin[64,85]. Subsequently it has been stated that the pressure π is merely a measure of all those changes in the system which are introduced by cross-linking[84]. Attempts have been made to associate π with capillary pressure[76]. In this case the strain in the polymeric skeleton of the sorbent is regarded as a response to capillary pressure, arising in consequence of the curvature of the outer surface of the resin grains.

In all cases the pressure π arises from the use of the relation between the chemical potential and the external pressure. The identity of the measure of the network effect with a real hydrostatic pressure is thereby asserted. So far there has been no experimental proof of the existence of an excess pressure in the resin compared with the solution. The method of Ginzburg and Cohen also does not provide a proof of the existence of the osmotic pressure, since the latter is used in the calculation. The application of the osmotic theory to isotherms for the absorption of solvents by resins with different degrees of cross-linking does not lead to an understanding of the essential feature of the swelling process. This is because a relation between the pressure π and the hydration mechanism has not been established. Somewhat greater advances have been made in the analysis of relations between the differential and integral free energies and α, the type of counterions, and the degree of cross-linking of the resins. When α (or $\bar{n}_w$) increases from zero, the integral free energies of swelling increase sharply but remain negative. The greatest changes occur in the absorption of the first solvent molecules, after which the free energies of swelling vary relatively little. However, it is precisely in this region that the resin absorbs the greatest amount of solvent. (This applies to an equal degree to integral and differential thermodynamic functions of swelling.) At high values of α, H_{sw} and S_{sw} for certain resins have a weak maximum, i.e. the changes in them with increasing α in the vicinity of $\alpha = 1$ are positive. The variation of the thermodynamic functions of swelling H_{sw} and S_{sw} with increase of α or $\bar{n}_w$ is explained at the present time mainly in the same way as the concentration dependence of the heats and entropies of hydration of crystalline salts[86].

The principal energy effects are the hydration of the fixed functional groups in the matrix and the counterions ($H_h < 0$ and $S_h < 0$) and also the dissociation of the fixed group–counterion pair ($H_d > 0$, $S_d > 0$). Since the overall values of H_{sw} and S_{sw} are negative, it is reasonable to suppose that the hydration effect exceeds the dissociation effect. The influence of the second effect prevails when α is close to unity in those cases where

$$\frac{\partial H_{sw}}{\partial \alpha} > 0 \text{ and } \frac{\partial S_{sw}}{\partial \alpha} > 0.$$

It should be borne in mind that in the swelling of resins the thermodynamic functions H_h, S_h, H_d, and S_d refer to interionic interactions only when the thermodynamic characteristics of the hydration and dissociation of the nonionogenic parts of the polymer (Φ_{hm}, H_{hm}, S_{hm}, Φ_{dm}, H_{dm}, S_{dm}) are treated independently. It was shown above that interchain interaction may be considerable even in somewhat swollen resins (the reversal of isopiestic lines). In dry resins this interaction is probably even more pronounced and can lead to an ordered arrangement of the polyelectrolyte chains. This is indicated in particular by electron microscope photographs of dehydrated resins obtained by Kargin et al.[87] and also the data of Laskorin et al.[17]

It is of great interest to establish a relation between the thermodynamic functions of swelling and the degree of order in the arrangement of chains in dry resins.

In the description of the dependence of Φ_{sw}, H_{sw}, and S_{sw} on α, it is usual also to indicate two further factors determined by the high molecular weight of the resin—the increase in the strain of the matrix on swelling and the mixing of the polymer chains with the solvent. The experimental methods for the determination of these effects are lacking; they can be estimated qualitatively with the aid of the theory of the swelling of cross-linked polyelectrolytes of Rice and Harris[88]. When the dehydrated cross-linked polyelectrolytes and the pure solvent are chosen as

the standard states, both contributions are negative. Calculations show that the contributions of these components (of the conformational entropy and enthalpy of swelling H_{SW} and S_{SW}) are indeed low [89]. For example, in the swelling of Dowex-50 cation-exchange resin in the K^+-form (from the dry resin to the resin with the maximum degree of swelling) the conformational free energy is −0.43 and −0.81 kcal equiv.$^{-1}$ for divinylbenzene contents of 3 and 15% respectively, which amounts to 10 and 20% of the integral free energy of swelling. Thus the integral free energy of swelling Φ_{SW} is affected by at least five factors.

$$\Phi_{sw} = \Phi_h + \Phi_d + \Phi_{con} + \Phi_{hm} + \Phi_{dm} \qquad (49)$$

However, at present it is possible to determine experimentally only Φ_{SW}, so that the contributions of each separate effect remain unknown†. This is one of the main obstacles to the development of a theory of swelling of cross-linked polyelectrolytes, since it makes it impossible to obtain quantities necessary to simulate the individual effects and to test them. Further accumulation of experimental data in this field is necessary.

Ion-exchange resins have come to be regarded as electrolytes with a high concentration of ions set up by their fixation on the matrix. It is interesting to note some similarity and also a difference in the thermodynamic functions of the hydration of resins and crystalline salts (using heat as an example): 1. H_{SW} changes sharply on sorption of the first solvent molecules and then the variation is slight. The heat of solution in water of a crystalline salt varies relatively little with dilution in the region close to the saturated solution. On the other hand the heats of solution of salts in organic solvents are much more exothermic and their variation with concentration is also more pronounced. Possibly the effect of the organic resin matrix is identical with the effect of the organic solvent. 2. The relation between the enthalpies and entropies of hydration of salts is close to linearity [90]. Fig. 3 shows that there is also a linear relation between H_{SW} and S_{SW} for resins in water. Points corresponding to a given degree of cross-linking of the resins in different ionic forms and also points corresponding to resins with different contents of the cross-linking agent but in the same ionic form are plotted on this curve. We may note that the thermodynamic functions of the swelling of Dowex-50 resins depends little on the degree of cross-linking while those for macronetwork resins depend on cross-linking to a much greater extent. With increase in the degree of cross-linking of macronetwork resins and Dowex-50 resins, the absolute values of H_{SW} and S_{SW} increase. The thermodynamic functions H_{SW} and S_{SW} for non-cross-linked polymethylstyrenesulphonic acid and its sodium salt exceed the corresponding thermodynamic functions for cross-linked resins (up to 15% of divinylbenzene). Nevertheless these values are consistent with the relations presented in Fig. 3. The existence of relations of a similar form between the enthalpies and entropies of swelling of resins and of the hydration of crystalline salts shows that there is a profound analogy between these processes. As far as we are aware, these relations have not been explained.

†Analogous problems occur in the theory of electrolyte solutions at moderate and high concentrations where the concentration variation of the heats and entropies of hydration is also determined by a number of separate factors [86].

The mechanism of the absorption of water vapour by ion-exchange sorbents has also been investigated by analysing the differential free energies, enthalpies, and entropies of swelling. The differential thermodynamic functions of swelling have been used most successfully for the analysis of the mechanism of the interaction with the solvent, particularly in the region of low values of α.

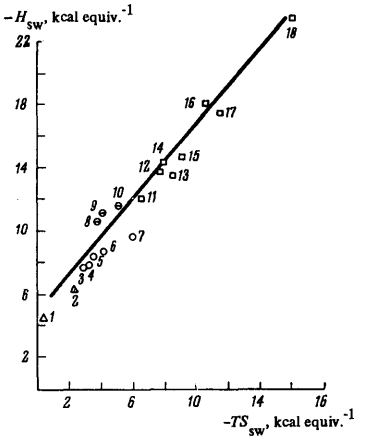

Figure 3. Relation between the enthalpies and entropies of swelling of resins in water: 1) Dowex-50 × 3, K^+; 2) Dowex-50 × 15, K^+; 3) Dowex-50 × 1, Na^+; 4) Dowex-50 × 3, Na^+; 5) Dowex-50 × 8, Na^+; 6) Dowex-50 × 15, Na^+; 7) KU-2, Na^+; 8) Dowex-50 × 0.5, H^+; 9) Dowex-50 × 3, H^+; 10) Dowex-50 × 8, H^+; 12) KU-2, H^+. Macronetwork resins with different amounts of cross-linking agent: 11) decamethylenedimethacrylamide (DMDMA), 16%, H^+; 13) DMDMA, 16%, Na^+; 14) hexamethylenedimethacrylamide (HMDMA), 9%, Na^+; 15) ethylenedimethacrylamide (EDMA), 16%, H^+; 16) HMDMA, 16%, Na^+; 17) EDMA, 16%, Na^+; 18) HMDMA, 41%, Na^+.

The work of Gluekauf and Kitt [91] largely initiated these investigations. The hydration of ion-exchange resins is regarded as a stepwise adsorption process. Analysis of the thermodynamic functions of the sorption of water shows that the first water molecule is sorbed exclusively by an SO_3^- group fixed on the matrix. Such a mechanism of the absorption of water has been attributed to all the salt-forms of sulphonated resins. The scatter of the differential thermodynamic functions of different salt-forms is probably due to different interactions between the non-hydrated cations and the hydrated groups. It has also been shown that the second and subsequent hydration shells are formed as a result of the hydration of the cation.

The enthalpy and entropy components for the sorption of the first, second, and subsequent solvent molecules per functional group of the resin have been calculated from the temperature variation of the water vapour absorption isotherms. Analysis of the heats and entropies of solvent absorption led to the following conclusions. If there is one molecule per active group, then its interaction with the counterion and also the interaction of the counterion with the water molecule is not a linear function of the ionic radius alone, i.e. is not purely Coulombic. For large ions

such as Ag^+ and Cs^+, these interactions may depend in addition on factors such as polarisation. The addition of a second water molecule probably loosens somewhat the structure of the sorption complex and weakens the polarisation interactions occurring over short distances. Beyond this point Coulombic interaction becomes typical for the entire series of alkali metal ions. Later these methods were criticised both from the standpoint of the validity of the thermodynamic description of the hydration of resins and from the standpoint of the reliability of the experimental data[89,92]. The inflections in the plots of the thermodynamic functions obtained from the temperature variation of the isotherms were not confirmed by calorimetric measurements on similar resins[89,92-94]. We may note that for all the ionic forms investigated by Gluekauf and Kitt[91] the error in the determination of the differential thermodynamic functions is approximately the same and yet the curves for different ionic forms differ significantly. The H^+-, Ba^+-, and Ca^{2+}-forms of the resins do not show inflections, while for the Li^+-, Ag^+-, Na^+-, K^+-, NH_4^+-, and Cs^+-forms the inflections in the thermodynamic functions are fairly pronounced. Recently the inflections in the differential thermodynamic functions for certain types of sorbents have been observed also by calorimetric methods[95,97]. Nevertheless, final conclusions concerning the presence or absence of inflections in the differential thermodynamic functions of swelling would be premature, since in all the studies of which we are aware no estimate was made of the reliability of these functions when inflections are present.

The mechanism of the hydration of ion exchangers has been vigorously investigated also by a wide variety of physical methods. The study of the infrared spectra of thin films (up to 5 μm) of sulphonated polystyrene led to the conclusion[29,30] that the hydration of the salt-forms of sulphonated resins begins with the interaction of water with the counterion. On combining with a first water molecule, the cation becomes somewhat removed from the fixed group in the sorbent. The subsequent hydration shells are formed both between the counterion and the fixed group and in the space surrounding both ions. These findings are based mainly on the study of the stretching and deformation vibrations of sorbed water molecules. However, direct investigation of the frequencies of interionic vibrations[96] in films of polyvinylsulphonic [polyethylenesulphonic ? (Ed. of Translation)] acid and its salts shows that, on absorption of the first solvent molecule, the distance between ions changes relatively little. The interionic distance increases but this change is insufficient for the incorporation of water molecules between the ions. It was also shown that the water of hydration does not participate in ionic vibrations, i.e. there is no rigid binding of water molecules. On this basis, it was concluded that ion pairs and not individual ions are hydrated in ion-exchange films. Thus there exist different explanations of the mechanism of primary hydration. The reason for this remains obscure. With decrease in crystallographic ionic radius (from Rb^+ to Li^+ and from Ba^{2+} to Mg^{2+}), the interaction of ions with water molecules intensifies. The splitting of asymmetric stretching vibrations of the SO_3^- group and in particular the independence of this splitting of moisture content for all counterions shows that in all cases the counterion is located asymmetrically in the pyramidal structure of the sulphonato-group, namely in the vicinity of one of the oxygen atoms. The following counterions have been examined[29,30]: H^+, Li^+, Na^+, K^+, Rb^+, Mg^{2+}, Ca^{2+}, Ba^{2+}, NH_4^+, $(CH_3)_4N^+$ and $(C_2H_5)_4N^+$. In the hydration of the hydrogen-forms of sulphonated resin films aggregates of several hydrogen-bonded water molecules having the general formula $H_{4n+3}O_{2n+1}$ (n is independent of the relative moisture content) are formed. For all moisture contents, hydronium ions are also distributed asymmetrically in relation to the sulphonato-group, the proton being capable of migrating readily from one water molecule in the aggregate to another. Judging from the differential thermodynamic functions, the mechanism of the primary hydration of carboxylic acid cation exchangers[98] in the H^+-form is similar to the mechanism of the hydration of the salt-forms of sulphonated resins discussed above[96]. After the formation of the primary hydration shell, polymolecular condensation of water takes place. On the other hand, the mechanism of the hydration of the salt-forms of carboxylic acid cation exchangers is probably similar to the mechanism of the hydration of the salt-forms of sulphonated cation-exchange resins proposed by Gluekauf and Kitt[91].

The NMR method has been used to characterise moisture absorption by hydrogen-forms of Dowex-50 resin with different degrees of cross-linking[33,35-39]. Quantitative information about the state of water in resins has been obtained from chemical shifts and changes in signal width. A decrease in the moisture content of resins leads to an increase of signal width and its maximum is displaced towards lower field strengths. This shift is different for resins with different amounts of the cross-linking agent. The chemical shift depends also on the presence of hydrogen bonds in the sorbed water. Therefore at a low moisture content, when the normal structure of water breaks down due to the vigorous interaction of water molecules with the polar groups of the solvent, the resonance band is displaced towards lower field strengths as in ordinary water on increase of temperature. The chemical shift towards higher magnetic field strengths is proportional to the number of benzene rings and to the increase of the distance between the sulphonato-group and the molecules of water of hydration. The width of the resonance absorption band for sorbed water is much higher than for pure water (20–100 Hz compared with 0.5 Hz) but is less than for ice. This means that water molecules in the resin phase are in a state of rapid albeit restricted motion. The increase in absorption band width has been attributed to the inhomogeneity of the magnetic field of the resin grains. At low moisture contents not all the active groups of the resin can be hydrated to an equal extent and therefore different chemical shifts are possible. Then the observed resonance band will consist of bands corresponding to several different states of the water molecules, which is the reason for its broadening. Together with the absorption band due to sorbed water, an absorption band due to the water between the grains is also observed. The disappearance of this second band on reducing the moisture content of resins and the reversible sharpening and smoothing out of the bands on lowering and raising the temperature respectively show that there is exchange between the protons of the water in the resin and outside. The kinetics of this exchange have been investigated using heavy water and the results have been interpreted by the method of Boyd and Soldano[99]. The diffusion coefficient proved to be of the order of 800×10^{-6} cm^2 s^{-1}. The NMR method enables the heterogeneity of resins to be quantitatively characterised. The presence of a single narrow absorption band due to internal water indicates a high degree of homogeneity of the materials employed. This homogeneity must be regarded as indicating a constant time-average environment of the molecules of sorbed water. Since one cannot exclude the possibility of the presence in resin

grains of density gradients of the cross-linking agent or concentration gradients of the active groups, this result may be evidence of rapid exchange between water molecules in different states. The exchange within grains is considered, since it has been shown by the same method that the exchange of water molecules between grains is much slower.

Thus the narrow resonance absorption line may be due to kinetic causes (migration of water molecules and structural features of the resins such as a constant density of the cross-linking agent and of the concentration of active groups throughout the bulk of the grain. By studying the temperature variation of the half-width of the resonance band, it is possible to distinguish both components in individual cases, since the first of these depends on the change in temperature and the second does not.

III. FREE ENERGY OF ION EXCHANGE

There have been many studies where the ion-exchange equilibria between inorganic and also between organic and inorganic ions were investigated [100–105]. The nature of the ion has a significant effect on the selectivity of its absorption: factors which are dominant in the first case may be secondary in the second. These studies, in particular by Boyd and coworkers [101,102], confirm the qualitative hypotheses concerning the principal effects which determine the thermodynamic selectivity (electrostatic interaction, different structure of the hydration shells of ions in the resin compared with the solution, effect of solvent structure on the interaction between ions, effect of resin matrix, etc.). Among these qualitative concepts, mention should be made of the theories of Daimond [107], Eisenman [108], and Izmailov [109]. Further development of these concepts requires, however, a knowledge of the thermodynamic functions associated with the different states of the solvent in the resin and in solution. In this connection it is necessary to consider the methods of calculation of the thermodynamic functions associated with the changes in the hydration of resins during ion exchange.

Experimental data show that in ion exchange the state of equilibrium depends on the change in the degree of swelling and hence on the factors which determine the interaction between the resin and the solvent. When the selective absorption of ions is determined by the reduction of the enthalpy of the system, i.e. when the electrostatic interaction with the fixed group increases, their interaction with the solvent is weakened. When Li^+ ions are displaced by other alkali metal ions from Dowex-50 resin, the selectivity increases on going from Na^+ to Cs^+ ($\Delta H^0 < 0$) and the swellability of the resin decreases steadily. Since the affinity of the carboxy-group for the proton is particularly high, the swellability of carboxylic acid cation exchangers in the H^+-form is much lower than that of the salt-forms. The selective sorption of quaternary ammonium ions and a number of other organic cations on Dowex-50 resins is also accompanied by a decrease of the swelling of the resin [62]. In those cases where the decrease of the free energy of ion exchange is due to an entropy increase, the swellability of the resin may decrease to a smaller extent, while in some others it can increase [110]. In the early theory of ion exchange (Gregor [80], Gluekauf [111]) it was assumed that the change in the degree of swelling of the resin in ion exchange determines entirely its specificity. The effect of swelling on selectivity in this theory is taken into account quantitatively in two ways: in terms of the osmotic work $\pi\Delta v_i$ (π is the swelling pressure and Δv_i the difference between the partial molar volumes of the resinates) and also to some extent in terms of the activity coefficients of the resinates. In the two methods of choosing a reference system in the osmotic theory (see Section II), there is a possibility of two formally different expressions for the thermodynamic ion-exchange equilibrium constant‡. If the reference states in the solution§ and in the resin are chosen at different pressures (in solution $p = 1$ atm and in the resin $p = \pi$), the following expression is obtained [81] for K_B^A:

$$RT \ln K_B^A = \int_{p_0}^{p_0} [z_B v_A^0 (p, m_A, m_B) - z_A v_B^0 (p, m_A, m_B)]\, dp, \qquad (50)$$

where

$$K_B^A = \frac{\bar{a}^{z_A}_B}{\bar{a}^{z_B}_A} \frac{a^{z_B}_A}{a^{z_A}_B} = \tilde{K}_B^A \frac{\bar{\gamma}^{z_A}_B}{\bar{\gamma}^{z_B}_A} = \tilde{K}_B^A \frac{\bar{\gamma}^{z_A}_B}{\bar{\gamma}^{z_B}_A} \cdot \frac{\gamma^{z_B}_A}{\gamma^{z_A}_B},$$

$$RT \ln \tilde{K}_B^A = RT \ln \frac{\gamma^{z_A}_B}{\gamma^{z_B}_A} - RT \ln \frac{\bar{\gamma}^{z_A}_B}{\bar{\gamma}^{z_B}_A} (\pi, m_A, m_B) + \int_{p_0}^{p_0+\pi} (z_B v_A^0 - z_A v_B^0)\, dp \simeq$$

$$\simeq RT \ln \frac{\gamma^{z_A}_B}{\gamma^{z_B}_A} - RT \ln \frac{\bar{\gamma}^{z_A}_B}{\bar{\gamma}^{z_B}_A} (\pi, m_A, m_B) + \pi [z_B v_A^0 - z_A v_B^0]. \qquad (51)$$

Here v_B^0 and v_A^0 are the partial molar volumes of the resinates in the standard state. In this equation the swellability of the resin influences two terms—the last and the penultimate. The term $RT \ln (\bar{\gamma}^{z_A}_B / \bar{\gamma}^{z_B}_A)$ takes into account also the interaction of the ions with the resin and with one another. On the other hand, when all the reference states are chosen at the same pressure, for example, atmospheric, then the following expression is obtained for K_B^A (the standard states of all the components are the same¶):

$$\ln K_B^A = 0,$$

$$RT \ln \tilde{K}_B^A = RT \ln \frac{\gamma^{z_A}_B}{\gamma^{z_B}_A} - RT \ln \frac{\bar{\gamma}^{z_A}_B}{\bar{\gamma}^{z_B}_A} (p_0, m_A, m_B) + \int_{p_0}^{p_0+\pi} (z_B v_A - z_A v_B)\, dp \simeq$$

$$\simeq RT \ln \frac{\gamma^{z_A}_B}{\gamma^{z_B}_A} - RT \ln \frac{\bar{\gamma}^{z_A}_B}{\bar{\gamma}^{z_B}_A} (p_0, m_A, m_B) + \pi [z_B v_A - z_A v_B]. \qquad (52)$$

In Eqn. (52) the activity coefficients in the resin phase are independent of pressure and consequently of the swelling of the given cross-linked resin. The effect of swellability on selectivity is associated with the last term on the right-hand side. However, this term also takes partially into account the deviation of the system from ideality. Thus in none of the cases is it possible to distinguish the component which depends entirely on the change in swellability during ion exchange†. The quantities v_B^0 and v_A^0 in Eqn. (51) correspond to the partial molar volumes of the hydrated resinates at infinite dilution and can be estimated approximately from the corresponding values for the low-molecular electrolytes which are suitable models for

‡Holm [81] showed that both equations can be obtained from a more general equation with a different choice of reference states.

§The reference state in solution corresponds to infinite dilution.

¶For a more general case, see Holm [81].

†As pointed out correctly by Holm [81], for the same reason the osmotic free energy and the energy of interionic interaction introduced by Boyd [82] are not independent.

resins. In order to find the osmotic work from Eqns. (51) and (52), it is necessary to employ isopiestic measurements (which determine πv_W) and also pyknometric measurements (which determine v_W and Δv_i). When Eqn. (52) is used, it is possible to indicate a simpler method for the determination of osmotic work, involving isopiestic data only. For many resins, there is a relation (in some cases linear) between the swelling pressure π and the equivalent resin volume V_e:[64]

$$\pi = F(V_e) \quad . \tag{53}$$

According to the definition of the equivalent volume,

$$z_A z_B dV_e = (z_B v_A - z_A v_B)\, d\theta_A + z_A z_B v_W dn_W , \tag{54}$$

where v_A, v_B, and v_W are the partial molar volumes of the resinates A and B and the solvent and θ_A is the equivalent fraction of the ions A in the sorbed state. Hence it can be shown [112] that

$$\pi(z_B v_A - z_A v_B) = z_A z_B \int_0^{\bar{n}_W} \frac{\partial w_W}{\partial \theta_A} dn_W \quad . \tag{55}$$

The integral on the right-hand side of the equation can be calculated provided that the absorption isotherms for the vapour of the given and reference resin are known for several ionic compositions.

In the osmotic theory there are several methods for the calculation of the activity coefficients of the resinates (and also their ratios) from the solvent absorption isotherms. A large group of studies (Gluekauf, Gregor, Soldano, and others) deals with the determination of the dependence of the osmotic coefficient of the solvent in the resin on the molality of the counterions, the calculation by the Gibbs–Duhem equation of the activity coefficients of the mono-ionic forms, and their combination of determine the activity coefficients of ions in resins having a mixed composition [100,111,113,115]. Soldano showed [114] that the Harned rule does not apply to the resin phase and an empirical relation with the molality in the resin has been proposed for the interaction coefficients, on the basis of which it proved possible to obtain satisfactory agreement between the calculated and experimental $\tilde{\tilde{K}}_B^A$ in the exchange of a series of univalent and divalent ions. Boyd's method [82] is more rigorous from the thermodynamic standpoint. For subsequent discussion, it is convenient to consider the derivation of Boyd's equation by a method somewhat different from that employed in the original paper [112].

If the resin is regarded as a three-component system (two counterions and the solvent), the McKay relation becomes

$$\left.\frac{\partial \ln \bar{a}_B}{\partial \bar{n}_W}\right|_{\bar{n}_A \bar{n}_B} = \left.\frac{\partial \ln \bar{a}_W}{\partial \bar{n}_B}\right|_{\bar{n}_A \bar{n}_W} , \tag{56}$$

$$\left.\frac{\partial \ln \bar{a}_A}{\partial \bar{n}_W}\right|_{\bar{n}_A \bar{n}_B} = \left.\frac{\partial \ln \bar{a}_W}{\partial \bar{n}_A}\right|_{\bar{n}_B \bar{n}_W} . \tag{57}$$

Eqns. (56) and (57) are now multiplied by z_A and z_B respectively. On subtracting Eqn. (57) from Eqn. (56) and remembering‡ that

$$\frac{\bar{a}_B}{\bar{a}_A} = \frac{\bar{m}_B \bar{\gamma}_B}{\bar{m}_A \bar{\gamma}_A} = \frac{\bar{x}_B \bar{\gamma}_B}{\bar{x}_A \bar{\gamma}_A} , \tag{58}$$

where $\bar{m}_B$ and $\bar{m}_A$ are the molalities of the counterions, $\bar{\gamma}_B$ and $\bar{\gamma}_A$ the molal activity coefficients, and $\bar{x}_B$ and $\bar{x}_A$ the equivalent fractions, we obtain the following equation:

$$\left.\frac{\partial \ln \dfrac{\bar{\gamma}_B^{z_A}}{\bar{\gamma}_A^{z_B}}}{\partial \bar{n}_W}\right|_{\bar{n}_A, \bar{n}_B} = z_A \left(\frac{\partial \ln \bar{a}_W}{\partial n_B}\right)_{\bar{n}_A, \bar{n}_W} - z_B \left(\frac{\partial \ln \bar{a}_W}{\partial \bar{n}_A}\right)_{\bar{n}_B, \bar{n}_W} . \tag{59}$$

We shall now convert the independent variables $\bar{n}_B$, $\bar{n}_A$, $\bar{n}_W$ to the variables $\bar{\theta}_B$, $\bar{\theta}_W$, and n, where

$$\bar{\theta}_B = \frac{\bar{n}_B z_B}{\bar{n}_A z_A + \bar{n}_B z_B} = \frac{\bar{n}_B z_B}{n} = \text{equivalent fraction of the ion B in the resin} \tag{60}$$

and

$$\bar{\theta}_W = \frac{\bar{n}_W}{\bar{n}_A z_A + \bar{n}_B z_B} = \frac{\bar{n}_W}{n} = \text{equivalent content of the solvent} \quad (\bar{n} = \bar{n}_A z_A + \bar{n}_B z_B). \tag{61}$$

It can be shown [125] that

$$z_A \left(\frac{\partial \ln \bar{a}_W}{\partial \bar{n}_B}\right)_{\bar{n}_A, \bar{n}_W} - z_B \left(\frac{\partial \ln \bar{a}_W}{\partial \bar{n}_A}\right)_{\bar{n}_B \bar{n}_W} = \frac{z_A z_B}{n} \left(\frac{\partial \ln \bar{a}_W}{\partial \theta_B}\right)_{\bar{\theta}_W, \bar{n}} . \tag{62}$$

Then we obtain from Eqn. (59), taking into account Eqn. (62),

$$\left.\frac{\partial \ln (\bar{\gamma}_B^{z_A}/\bar{\gamma}_A^{z_B})}{\partial \theta_W}\right|_{\theta_B n} = z_A z_B \left(\frac{\partial \ln \bar{a}_W}{\partial \theta_B}\right)_{\theta_B n} . \tag{63}$$

We shall now consider Eqn. (63) under the condition n = const., i.e. when the exchange capacity is constant [taking into account Eqn. (40)]:

$$\ln \frac{\bar{\gamma}_B^{z_A}}{\bar{\gamma}_A^{z_B}} = \ln \frac{\bar{\gamma}_B^{z_A}}{\bar{\gamma}_A^{z_B}} (\text{отсч}) + z_A z_B \int_{\theta_{W(\text{ref.})}}^{\bar{\theta}_W} \frac{\partial \ln a}{\partial \theta_B} d\theta_W , \tag{64}$$

where $\theta_{W(\text{ref})}$ is the equivalent content of the solvent in the reference state of the resin (for example in the resin swollen to the maximum extent). The integral on the right-hand side of Eqn. (64) is equal to the integral J_R in Boyd's paper [82]§ to within a numerical multiplier:

$$\int_{\theta_{w(\text{ref.})}}^{\bar{\theta}_n} \frac{\partial \ln \bar{a}_W}{\partial \bar{\theta}_B} d\theta_W = \frac{\partial}{\partial \bar{\theta}_B} \left[\int_{\bar{\theta}_{w(\text{ref.})}}^{\bar{\theta}_W} \ln \bar{a}_W d\theta_W\right]_{\bar{\theta}_W, \bar{\theta}_{w(\text{ref.})}} = -\int_0^{\ln \bar{a}_W} \frac{\partial \bar{\theta}_W}{\partial \bar{\theta}_B} d \ln a_W =$$

$$= 55.51 \int_0^{\ln \bar{a}_W} \frac{\partial \frac{1}{m}}{\partial \bar{\theta}_A} d \ln a_W = 55.51\, J_R . \tag{65}$$

The integral J_R [or the integral in Eqn. (64)] is calculated from isopiestic data for several ionic compositions of the resin. In Eqn. (52) the apparent ion-exchange equilibrium constant $\tilde{\tilde{K}}_B^A$ at $\pi = 0$ depends on the ratio of the activity coefficients of the cross-linked resin $[\ln (\bar{\gamma}_B^{z_A}/\bar{\gamma}_A^{z_B})(p_0 m_A m_B)]$. If it is assumed, as in the osmotic theory, that they can be equated to the activity coefficient of the non-cross-linked resin having the same ionic composition, i.e:

$$\ln \frac{\bar{\gamma}_B^{z_A}}{\bar{\gamma}_A^{z_B}}(p_0, m_A, m_B) = \ln \frac{\bar{\gamma}_B^{z_A}}{\bar{\gamma}_A^{z_B}}(p_0, m_A, m_B) , \tag{66}$$

then substitution of Eqns. (64) and (66) in Eqn. (52) yields

‡In Boyd's theory the molal concentration scale is employed.

§In Boyd's paper [82] there is a misprint: the sign on the right-hand side of Eqn. (7e) and of the integrals in the subsequent equations should be reversed. This misprint was eliminated from Boyd's subsequent papers [116,117]. Nevertheless it has found its way into certain monographs on ion exchange (see, for example, Helfferich [100]).

the required relation between $\tilde{\tilde{K}}_B^A$ and a function of the swellability of the cross-linked resin:

$$RT\ln\tilde{\tilde{K}}_B^A = RT\ln\frac{\bar{\gamma}_B^{z_A}}{\bar{\gamma}_A^{z_B}} - RT\ln\frac{\tilde{\gamma}_B^{z_A}}{\tilde{\gamma}_A^{z_B}}\text{ (ref.)} + z_A z_B\int_{\bar{\theta}_{w(ref.)}}^{\bar{\theta}_w}\left(\frac{\partial\ln\tilde{a}_w}{\partial\tilde{\theta}_B}\right)_{\theta_w,\pi}d\theta_w + \pi[z_B v_A - z_A v_B]. \quad (67)$$

The effect of the swellability of the cross-linked resin is shown in the quantities π, $\bar{\theta}_w$, v_A, and v_B. The term $RT\ln(\bar{\gamma}_B^{z_A}/\bar{\gamma}_A^{z_B})$ (ref.) is determined by applying Eqn. (67) to a weakly cross-linked resin, from the absorption isotherm of which the integral $J_R(\bar{\theta}_w = \bar{\theta}_{w(ref)},\ \pi = 0)$ is calculated:

$$RT\ln\tilde{\tilde{K}}_B^A\text{ (ref.)} = RT\ln\frac{\bar{\gamma}_B^{z_A}}{\bar{\gamma}_A^{z_B}} - RT\ln\frac{\tilde{\gamma}_B^{z_A}}{\tilde{\gamma}_A^{z_B}}. \quad (68)$$

The ratio of the activity coefficient in the external solution is the same in Eqns. (67) and (68) if the apparent ion-exchange equilibrium constants $\tilde{\tilde{K}}_B^A$ and $\tilde{\tilde{K}}_B^A$ (ref.) are determined for the case where the cross-linked and the weakly cross-linked reference resins are in contact with the same solutions. Substitution of Eqn. (68) in Eqn. (67) gives

$$RT\ln\tilde{\tilde{K}}_B^A = RT\ln\tilde{\tilde{K}}_B^A\text{ (ref.)}) + \int_{\bar{\theta}_{w(ref.)}}^{\bar{\theta}_w}\left(\frac{\partial\ln\bar{a}_w}{\partial\theta_B}\right)_{\theta_w,\pi}d\theta_w + \pi[z_B v_A - z_A v_B]. \quad (69)$$

Eqn. (69) permits the calculation from a combination of isopiestic and pyknometric data [and for systems obeying Eqn. (53) isopiestic data alone] of the ratio of the apparent ion-exchange equilibrium constants for the cross-linked and reference resins: $\tilde{\tilde{K}}_B^A/\tilde{\tilde{K}}_B^A$ (ref.). To determine $\tilde{\tilde{K}}_B^A$ for the cross-linked resin, it is also necessary to determine experimentally $\tilde{\tilde{K}}_B^A$ (ref.). It is important to note that, when $\tilde{\tilde{K}}_B^A$ (ref.) and the integral J_R are known for any one reference resin, it is possible to calculate $\tilde{\tilde{K}}_B^A$ for any resin which obeys condition (66). When Eqn. (51) is used, it is also possible to arrive at Eqn. (69) with the aid of the following relation between the activity coefficients of the components and pressure:

$$RT\frac{\partial\ln\bar{\gamma}_i(\pi)}{\partial p} = v_i - v_i^0\frac{\partial p_r}{\partial p}, \quad (70)$$

where p_r is the pressure in the system in the reference state. In Eqn. (51) it is assumed that the reference states are chosen at the same pressures as those present in the real system. In ion-exchange resins such a pressure is the osmotic pressure. Combination of the integrals in Eqn. (70) for counterions A and B leads to the following relation:

$$RT\ln\bar{\gamma}_B^{z_A}/\bar{\gamma}_A^{z_B}(\pi, m_A, m_B) = RT\ln\bar{\gamma}_B^{z_A}/\bar{\gamma}_A^{z_B}(p_0, m_A, m_B) + \int_{p_0}^{p_0+\pi}(z_A v_B - z_B v_A)\,dp - \pi(z_A v_B^0 - z_B v_A^0). \quad (71)$$

When Eqn. (71) is substituted in Eqn. (51), Eqn. (69) is obtained. Therefore the methods for the determination of $\pi\Delta v_i$ and $RT\ln[(\bar{\gamma}_B^{z_A}/\bar{\gamma}_A^{z_B})(p_0, m_A, m_B)]$ described above have a direct bearing on the analysis of the selectivity of ion exchange from the standpoint of this version of the osmotic theory. Boyd suggested that condition (66) applies to ion-exchange resins of a single type, for example sulphonated polystyrene resins cross-linked with divinylbenzene¶. Comparison of the values of $\tilde{\tilde{K}}_B^A$ calculated by Eqn. (69) and found experimentally shows that the methods of the osmotic theory give a satisfactory quantitative representation of the variation of the apparent ion-exchange equilibrium constant with the degree of cross-linking of the resin (or its swellability). At present such comparisons have been made both for low values of $\pi\Delta v_i$ together with high contributions of the activity coefficients (exchange of alkali metal ions on Dowex-50 cation exchangers [82], exchange of halide anions on anion exchangers [116]) and for high values of $\pi\Delta v_i$ together with relatively smaller contributions of the activity coefficients (tetramethylammonium–sodium exchange on sulphonated polystyrene resins). It is interesting that in the latter case the theory predicts the reversal of selectivity, which is observed experimentally. In all cases the discrepancy between the theory and experiment increases with the degree of cross-linking of the resin. No attempt has been made to treat this discrepancy quantitatively.

Together with the osmotic theory, other methods have been developed, among which particularly interesting are the formally thermodynamic methods unrelated to any models or assumptions apart from those which follow from the nature of thermodynamic laws. Such are the methods of Bonner and Davidson [118,119] and Gaines and Thomas [120,121]. Despite the fact that the first method does not take the solvent into account while the second does involve an estimate of its contribution, both methods yield virtually identical activity coefficients and ion-exchange equilibrium constants. If can be readily shown that the reason for this lies in the nature of the standard states of the resins (pure monofunctional forms in equilibrium with an infinitely dilute solution or pure solvent). When other standard states are employed, the thermodynamic contribution of the solvent increases. Although the choice of standard chemical potentials is in principal arbitrary, it is nevertheless useful to choose them so that the contribution of each component involved in the method is convenient for experimental estimation. Only then is it possible to compare the changes of the individual effects when the type of ion, the type of resin, etc. are varied, i.e. it is possible to obtain a quantitative relation with models. We believe that the choice of dehydrated monofunctional forms of ion-exchange resins as the standard states satisfies these requirements. We shall examine the calculation of the activity coefficient and ion-exchange equilibrium constant for this choice of standard states. To do this, Eqn. (63) is applied to a cross-linked resin remembering that in this case the activity of the solvent in the resin is assumed equal to its activity in the vapour phase regardless of the content of the cross-linking agent. Integration of Eqn. (63) from the state of the dehydrated resin ($\bar{\theta}_w = 0$) to the state of the resin swollen to the maximum extent in the solvent gives

$$\ln\frac{\bar{\gamma}_B^{z_A}}{\bar{\gamma}_A^{z_B}} = \ln\frac{\bar{\gamma}_B^{0z_A}}{\bar{\gamma}_A^{0z_B}} + z_A z_B\int_0^{\bar{\theta}_w}\frac{\partial\ln\alpha}{\partial\bar{\theta}_B}d\theta_w \quad \bar{\theta}_B = \text{const},\ \bar{n} = \text{const}, \quad (72)$$

where $\bar{\gamma}_B$ and $\bar{\gamma}_A$ are the activities [activity coefficients] of the counterions in the swollen resin with the ionic composition defined by $\bar{\theta}_A$ and $\bar{\theta}_B$ and $\bar{\gamma}_B^0$ and $\bar{\gamma}_A^0$ are the

¶In some cases a resin of a different chemical type may serve as a reference. If such substitution is permissible, the scope of the osmotic theory becomes wider.

activities [activity coefficients] of the counterions in the dehydrated resin of the same ionic composition.

The integral in Eqn. (72) may be transformed using the rule governing the differentiation of a definite integral with respect to a parameter and also Eqn. (9):

$$\ln\frac{\bar{\gamma}_B^{z_A}}{\bar{\gamma}_A^{z_B}} = \ln\frac{\bar{\gamma}_B^{0z_A}}{\bar{\gamma}_A^{0z_B}} + z_A z_B \frac{1}{RT}\frac{\partial\left(\frac{\Phi_{sw(n_w)}}{n}\right)}{\partial\bar{\theta}_B}\bigg|_\alpha - \frac{\partial\bar{\theta}_w}{\partial\bar{\theta}_B}\bigg|_{\bar{a}_w} \cdot \ln\bar{a}_w z_A z_B \,. \quad (73)$$

On substituting Eqn. (73) in the expression

$$-RT\ln\tilde{K}_B^A = -RT\ln K_B^A + RT\ln\frac{\bar{\gamma}_B^{z_A}}{\bar{\gamma}_A^{z_B}} \quad (74)$$

we have the following equation for $\tilde{K}_B^A$:

$$-RT\ln\tilde{K}_B^A = -RT\ln K_B^A + RT\ln\frac{\bar{\gamma}_B^{0z_A}}{\bar{\gamma}_A^{0z_B}} + z_A z_B\Delta\Phi_{sw} - RT z_A z_B\frac{\partial\bar{\theta}_w}{\partial\bar{\theta}_B}\bigg|_\alpha \ln\alpha, \quad (75)$$

where $\Delta\Phi_{SW}$ is the differential free energy of swelling during ion exchange [$\Delta\Phi_{SW} = \partial(\Phi_{SW}/n)/\partial\theta_B|_\alpha$]. The term $(\partial\theta_W/\partial\theta_B)\ln\alpha$ becomes zero when ion-exchange equilibrium in an infinitely dilute solution is considered ($\alpha = 1$). In more concentrated solutions it remains small. This term takes into account the deviation of the state of water in the system from its standard state. $\Delta\Phi_{SW}$ is calculated from isopiestic data for the cross-linked resin at several ionic compositions. It is noteworthy that in Eqn. (75) the term $RT\ln(\bar{\gamma}_B^{0z_A}/\bar{\gamma}_A^{0z_B})$ takes into account the interaction effects in the absence of solvent in the resin, while the term $[\Delta\Phi_{SW} - RT\ln\alpha(\partial\bar{\theta}_W/\partial\bar{\theta}_B)_\alpha] = \Delta\Phi_S$ represents the change in all interactions due to the solvent. In order to find the term $RT\ln(\bar{\gamma}_B^{0z_A}/\bar{\gamma}_A^{0z_B})$, we shall examine the state of the dehydrated resin of mixed ionic composition. This can be regarded as a two-component system, i.e. we have

$$\bar{n}_A\, d\ln\bar{\gamma}_A^0 + \bar{n}_B\, d\ln\bar{\gamma}_B^0 = 0 \,. \quad (76)$$

This equation will be solved simultaneously with the differential of Eqn. (75):

$$d\ln\bar{\gamma}_B^0 = -\frac{\bar{\theta}_A}{z_A}d\ln\tilde{K}_B^A - \frac{z_B\bar{\theta}_A}{RT}d\Delta\Phi_s \,, \quad (77)$$

$$d\ln\bar{\gamma}_A^0 = \frac{\bar{\theta}_B}{z_B}d\ln\tilde{K}_B^A + \frac{z_A\bar{\theta}_B}{RT}d\Delta\Phi_s \,. \quad (78)$$

When the dehydrated monoionic forms of resins are chosen as standard states (here we shall use a symmetrical comparison system [126]), we obtain

$$\lg\bar{\gamma}_B^0 = -\frac{\bar{\theta}_A}{z_A}\ln\tilde{K}_B^A(\theta_A) - \int_1^{\bar{\theta}_B}\frac{\ln\tilde{K}_B^A}{z_A}d\theta_B - \frac{z_B\bar{\theta}_A}{RT}\Delta\Phi_s - \frac{z_B}{RT}\int_1^{\bar{\theta}_B}\Delta\Phi_s\, d\theta_B, \quad (79)$$

$$\lg\bar{\gamma}_A^0 = \frac{\bar{\theta}_B}{z_B}\ln\tilde{K}_B^A(\theta_A) - \int_0^{\bar{\theta}_B}\frac{\ln\tilde{K}_B^A}{z_B}d\theta_B + \frac{z_A\bar{\theta}_B}{RT}\Delta\Phi_s - \frac{z_A}{RT}\int_0^{\bar{\theta}_B}\Delta\Phi_s\, d\theta_B \,. \quad (80)$$

Substitution of Eqns. (79) and (80) in Eqn. (75) yields

$$-\Delta\Phi^0 = RT\ln K_B^A = RT\int_0^1\ln\tilde{K}_B^A\, d\theta_B + z_A z_B\int_0^1\Delta\Phi_s\, d\theta_B \,. \quad (81)$$

At equilibrium in very dilute solutions

$$-\Delta\Phi^{0*} = RT\ln K_B^A = RT\int_0^1\ln\tilde{K}_B^A\, d\theta_B + z_A z_B[\Phi_{sw}(\theta_B=1) - \Phi_{sw}(\theta_B=0)] \,. \quad (82)$$

Thus when dehydrated monoionic forms are chosen as standard states, the contribution of the solvent to selectivity is proportional to the difference between the free energies of swelling of the resins in the pure monoionic forms. Table 4 lists the thermodynamic quantities associated with the exchange of triethylbenzylammonium and sodium ions on KU-1 and Dowex-50 × 2 resins, from which it is evident that, with this method of calculation, the standard free energy of ion exchange becomes more negative. This increase is necessary to compensate the thermodynamically unfavourable effect involving the displacement of the solvent from the resin during ion exchange.

Table 4. Thermodynamic functions of swelling and the exchange of triethylbenzylammonium (TEBA) and Na^+ ions on Dowex-50 and KU-1 resins.

	θ_{TEBA}	Φ_{sw}/n, kcal equiv.$^{-1}$	$\Delta\Phi_{sw}$, kcal equiv.$^{-1}$	$\tilde{\tilde{K}}^{Na}_{TEBA}$	$\ln K^{Na}_{TEBA} = \int_0^1 \ln\tilde{\tilde{K}}^{Na}_{TEBA}\, d\theta_{TEBA}$	$\Delta\Phi^0 = -RT\ln K^{Na}_{TEBA}$, kcal equiv.$^{-1}$	$\Delta\Phi^* = \Delta\Phi^0 + \Phi_{sw}[\theta_{TEBA}=1] - \Phi_{sw}[\theta_{TEBA}=0]$
Dowex-50 × 2	0	4.7	4.0	—			
	0.14	4.2	2.4	7.4			
	0.23	4.1	1.2	5.8	1.7	−1.0	−2.0
	0.48	3.9	0.6	3.6			
	0.95			2.0			
	1.0	3.7	0.3				
KU-1	0	8.7	7.5	—			
	0.15	7.7	6.0	450			
	0.32	6.8	4.5	230	5.6	−3.4	−7.0
	0.40	6.6	2.8	180			
	0.95			20			
	1.0	5.1	2.2	—			

Note. The values of $\tilde{\tilde{K}}^{Na}_{TEBA}$ at $\theta_{TEBA} = 0$ and $\theta_{TEBA} = 1$ were obtained by extrapolation. It was assumed that $\gamma_{TEBA}/\gamma_{Na} = 1$ under the experimental conditions (μ = 0.1 M).

Thus the lowering of the selectivity with respect to ions on reduction of the degree of cross-linking of resins is determined to a large degree by the thermodynamically unfavourable contraction of the resin and the decrease of its solvent content, which are in many cases larger for more readily swelling sorbents. We arrived at similar conclusions in the study of other systems [122,123]. We may note that the use of Eqns. (75), (79), and (80) permits the calculation of $\tilde{\tilde{K}}^A_B$ from isopiestic data for the given resin having several compositions and also from the ion-exchange isotherm for the resin. It is, however, possible to reduce the calculation of $\tilde{\tilde{K}}^A_B$ for a cross-linked resin to a calculation from isopiestic data for another resin of a different type with a different amount of cross-linking agent, since there exists the following expression relating the values of $\Delta\Phi_S$ for resins cross-linked to a different extent [125]:

$$\Delta\Phi_s - \Delta\Phi_s(\text{ref.}) = \int_0^{\theta_w}\frac{\partial(\pi v_w)}{\partial\theta_B}d\theta_w + RT\int_{\theta_w(\text{ref.})}^{\theta_w}\frac{\partial\ln\alpha}{\partial\theta_B}d\theta_w \,. \quad (83)$$

For systems in which $\pi = F(V_e)$ [see Eqn. (53)],

$$\Delta\Phi_s - \Delta\Phi_s(\text{ref.}) \simeq \pi\Delta v_l + RT\int_{\theta_w(\text{ref.})}^{\theta_w}\frac{\partial\ln\alpha}{\partial\theta_B}d\theta_w \,. \quad (84)$$

If it is assumed that the ion-exchange equilibrium constant K^A_B is independent of the degree of cross-linking [Eqn. (52) of the osmotic theory is based on a similar assumption], then, combining different expressions, it is possible to obtain an equation for the determination of $\tilde{\tilde{K}}^A_B$ for the

given resin from $\approx{}^{A}_{B}K$ (ref.) for the reference resin from its isopiestic data at several compositions and the maximum swellability of the given resin at several compositions. Thus, within the framework of the formal thermodynamic method too, it is possible to calculate independently the apparent ion-exchange equilibrium constants.

The structural characteristics of ion-exchange resins are shown in particular in the phenomena of the steric inaccessibility and the screening of sorption centres, while the hydration properties of resins also have a significant influence on their selectivity with respect to different ions. Systematic accumulation of experimental data on the relation between the selectivity and swellability of ion-exchange resins of different structures is necessary for further development of theories in this field.

Methods of Measurement of Small Separation Coefficients

D.A.Knyazev, Ya.D.Zel'venskii, N.F.Myasoedov, and G.G.Filippov

Methods of measurement of small separation coefficients are reviewed. The methods cover the whole range of separation conditions used in practice. Their main characteristics are tabulated, and each method is discussed mathematically in detail. The limitations of their applicability are considered, together with the magnitude of likely sources of error. The preferred regions for the various methods are identified, specific features of the experimental procedure are listed, and the apparatus is described. Most of the examples are taken from papers on the separation of isotopes, because this work demands the highest precision and reliability in the measurement of separation coefficients, and offers the widest choice of published results. 87 references.

I. INTRODUCTION

A new and fast-developing area in chemical engineering and in preparative and analytical chemistry is concerned with the separation of mixtures of closely similar constituents. Systems of this type include many mixtures of biologically important substances, such as mixtures of aminoacids and of polysaccharides, mixtures of members of genetic and of homologous series, of polymers, of isomers, of isotopes, of rare earths, etc., all of which are notoriously difficult to separate.

The thermodynamic properties of these compounds are usually very similar over a wide range of conditions and for the most diverse chemical forms and states of aggregation into which they can be transformed. Hence the difficulty experienced in separating them. The corresponding separation processes (or reactions) are characterised by single-stage separation factors close to unity, and therefore methods which automatically perform a multiplicity of separation acts are used to prepare the pure compounds. The most important of these methods are fractional distillation, extraction, chromatography, fractional crystallisation, and their many variants.

The rational application of these processes demands a knowledge of the separation coefficients of the components in the particular physicochemical systems under study. This is clearly recognised in the area of isotope and rare-earth separation, and one of the main research activities with these materials is a search for systems and conditions giving rise to significant or acceptable separation coefficients. On the other hand, in biochemistry and related areas the approach tends to be empirical, and preliminary studies of the magnitude of the elementary act are usually omitted. There can be no doubt that a more quantitative approach is needed in this area also, involving a sufficiently accurate analytical assessment of the efficiency of the process under study.

The methods most frequently used to determine separation coefficients are listed in Table 1 together with a brief summary of their main characteristics.

Definitions

The term "small separation coefficient" is used to denote values close to unity, but the extent of approach to unity is not defined. It may be convenient to include all value not exceeding two, because their measurement requires the use of high-precision methods such as those discussed in this review. These special methods must be used also when the separation coefficients being measured differ fractionally from unity: hence there is a similarity between very small separation coefficients and those of the order of two.

Separation coefficient. Given two chemical forms, phases, or states A and B between which the components i and l can undergo chemical or phase exchange, the separation coefficient α_{il} which characterises the exchange of the components is defined by

$$\alpha_{il} = \frac{[x_i]_A}{[x_l]_A} \cdot \frac{[x_l]_B}{[x_i]_B}$$

where $[x_i]_A$, $[x_l]_A$, $[x_i]_B$, and $[x_l]_B$ are the mole fractions of the components in forms A and B respectively. Both equilibrium and non-equilibrium process can be characterised by means of α. In the former case the concentrations must meet the usual requirements of dynamic equilibrium. The following terms are often used synonymously with separation coefficient: single-stage separation factor, equilibrium constant, relative fugacity.

The *enrichment coefficient* is defined by the expression

$$\varepsilon_{il} = \alpha_{il} - 1.$$

The value of ϵ for mixtures which cannot be easily separated is often much smaller than unity, and in these cases the separation obtainable in the system is best described in terms of ϵ. This quantity will therefore be used most frequently in what follows, and the precision of the experimental methods will be referred to it.

Table 1.

Method / Characteristics	Single contact	Differential	Multistage extraction	Rayleigh's continuous extraction	Elution chromatography	Rectangular cascade	Craig counter-current extraction
Field of application	Heterogenous phase exchange	Phase exchange	Heterogeneous exchange	Heterogeneous and homogeneous phase exchange	Heterogeneous exchange	Heterogeneous phase exchange	Heterogeneous exchange
Lowest measurable values	0.03	0.005	0.002	0.002	0.0002	0.01	0.01
Amount of mixture (mmole) needed	0.1—10	5—20	10^2—10^4	10^2—10^4	10^{-2}—10^{-1}	10^4	10^{-1}—1
Number of precision analytical determinations per measurement	2	0	2	2	10	2—10	10
Duration of experiment ignoring preparative stages	minutes to hours	minutes to hours	over an hour	hours	hours to days	hours to days	hours to days

Degree of separation. The efficiency of any separation process operated in an apparatus designed to maximise the effect of single-stage separation is characterised by the degree of separation, which is generally referred to the initial and the final state of the product, to some fixed points in the apparatus, and to a specified time:

$$Q_{il} = \frac{[x_i]_1}{[x_l]_1} \cdot \frac{[x_l]_2}{[x_i]_2}.$$

The time parameter needs to be considered only in special cases, and is therefore often omitted in the definition of Q_{il}.

II. SINGLE CONTACT METHOD

The field of application of the single contact method embraces all types of physicochemical equilibrium. The method is used to measure small coefficients when only a preliminary assessment is required, or when the result is sufficiently different from unity to ensure that the desired precision is achieved without resorting to multiple separations. In this case the problem consists in measuring the concentrations of the materials in the phases or forms to be equilibrated. The measurement accuracy can be improved by a number of simple procedures, by the use of special analytical methods, or by taking a large number of measurements and applying a standard statistical analysis.

If a method for measuring the difference in concentration of components i and l in the forms to be equilibrated is available, and the concentration of the components in the initial mixture is accurately known, the coefficient ϵ_{il} for the multicomponent mixture can be determined from the expression

$$\varepsilon_{il} = \frac{x_l^0 \Delta i - x_i^0 \Delta l}{(x_l^0 - \theta \Delta l)\left[x_i^0 - (1-\theta)\Delta l\right]} \qquad (1)$$

where $\Delta i = x_1 - y_1$, $\Delta l = x_1 - y_1$, x_1^0 and x_1^0 are the initial concentrations of the components i and l, and θ is the fraction of the material in form B, for which the concentrations are denoted by the symbol y.

In the case of a binary mixture the expression can be simplified, and only the concentration difference Δ_1 of the first component and the quantity θ need to be measured:

$$\varepsilon = \frac{\Delta_1}{(1 - x_1^0 - \theta\Delta_1)(x_1^0 - \Delta_1 - \theta\Delta_1)}. \qquad (2)$$

It is often possible and desirable to contact small amounts of form B with large amounts of form A. In this case $\theta \to 0$, and the measurement of ϵ involves simply a measurement of the difference Δ_1:

$$\varepsilon = \frac{\Delta_1}{(1 - x_1^0)(x_1^0 - \Delta_1)}. \qquad (3)$$

It is evident from the above expressions that, other conditions being equal, the value of Δ_i and Δ_l increases with x_l and x_i. Since the accuracy of the measurement of ϵ is determined by the accuracy with which Δ can be measured, conditions tending to maximise Δ should obviously be chosen if possible.

The relationship between the accuracy of the measurement of ϵ and that of the analytical method used is illustrated by the highly precise work of Boato and coworkers [1], who studied the separation of nitrogen, oxygen, and noble gas isotopes by liquid–vapour phase exchange. Due to the small error of their mass-spectrometric method of analysis, they were able to measure ϵ to the fourth decimal place.

The experimental requirements of the single contact method are determined primarily by the nature of the separation process under study. In the case of equilibrium separation processes the requirements coincide with the well known conditions for the achievement of true dynamic equilibrium. The most important of these is a correct choice of equilibration time, which implies a fairly precise knowledge of the kinetics of the process. The equilibrium criterion most commonly adopted is agreement between

values of ϵ obtained after long and significantly different contact times, or after approaching equilibrium from different directions.

In the study of non-equilibrium separation processes, on the other hand, we must ensure that the reaction can proceed in one direction only. This is most frequently achieved by working on the initial portion of the relaxation curve or under artificially maintained quasi-stationary conditions. For example, in high-vacuum distillation studies the molecules emitted from the liquid at a given temperature must be condensed at a very much lower temperature to ensure that the backward flow of molecules is negligibly small.

The apparatus required for the single contact method is usually fairly simple. Typically, temperature-control and stirring facilities are needed. The apparatus and techniques used in extraction, crystallisation, and ion exchange studies have been discussed in recent review articles [2-4]. The monograph by Hala and coworkers [5] gives an extensive and detailed review of the experimental assemblies used to study liquid–vapour equilibria. Apparatus based on Bushmakin's design [6] is most commonly used in Soviet laboratories investigating liquid–vapour equilibria. Combs and coworkers have proposed a contact apparatus which ensures complete saturation of the carrier gas by the vapour. More complicated designs are used in studies of non-equilibrium processes or under extreme experimental conditions. For example, the apparatus for studying separation by high-vacuum distillation has some unusual design features [8].

III. DIFFERENTIAL METHOD

The differential method [9,10] applies only to the liquid–vapour phase transition in binary mixtures, since it relies on the difference in equilibrium vapour pressure of two liquids at the same temperature, or alternatively on the difference in boiling point at a fixed pressure. There is a simple relationship between these easily measurable quantities and the separation coefficient, due to the similarity in thermodynamic properties of substances which are difficult to separate, which ensures that liquid and gaseous mixtures of this type are thermodynamically ideal. At a constant temperature, the vapour pressure of an ideal binary liquid mixture is the sum of two partial pressures which are themselves determined (according to Raoult's law) by the composition of the liquid mixture in equilibrium with the vapour:

$$P = P_1^0 x_1 + P_2^0(1 - x_1); \quad y_1 = \frac{P_1^0 x_1}{P}; \quad y_2 = 1 - y_1 = \frac{P_2^0(1 - x_1)}{P}. \quad (4)$$

The separation coefficient of the equilibrium distillation process is

$$\alpha = \frac{y_1}{y_2} \cdot \frac{x_2}{x_1} = \frac{P_1^0}{P_2^0} = 1 + \frac{P_1^0 - P_2^0}{P_2^0}. \quad (5)$$

The measurement of α involves merely a determination of the difference in vapour pressure between the two liquids (Δp) [9,11] and of the absolute vapour pressure of one of the liquids (isothermal variant). The same problem can be solved indirectly by measuring the difference in boiling point between the liquids as a function of pressure, and also the vapour pressure of one of the liquids as a function of temperature (isobaric variant [10]). The method can be used also to test the ideality of mixtures [12] or to study the variation of α with composition of the liquid phase [13]. In this case the vapour pressure of a series of mixtures is measured with respect to that of a standard mixture, or of a pure component. *A priori* evidence of the ideality of the mixture is often available, as in the case of mixtures of isotopic forms, of isomers, or of near homologues. In these systems, a relative measurement of the vapour pressure of two mixtures of known and different composition is sufficient to determine α. The quantities P_1^0 and P_2^0, and therefore also α, are obtained by solving the simple system of simultaneous equations

$$P' = P_1^0 x' + P_2^0(1 - x')$$

$$P'' = P_1^0 x'' + P_2^0(1 - x''). \quad (6)$$

The same information can be obtained by measuring differences in boiling point. The isobaric (ebullioscopic) method involves the determination of Δt as a function of total pressure in order to arrive ultimately at expressions (4)–(6). The mathematical transformation is performed graphically or by means of empirical expressions.

These two methods offer a number of advantages over alternative methods of measuring small values of ϵ. The apparatus and procedure are relatively simple, no special analyses are required, the parameter α can be measured over a very wide range of temperatures and pressures, and as a function of composition, and lastly very small amounts of material are needed for the measurement, and can be recovered. The main drawback of the method is the requirement of extreme purity, since both modifications of the method are very sensitive to the presence of volatile impurities. The isothermal modification has the advantage that measurements of Δp as a function of temperature are not normally required, but there is little to choose between the two variants when measurements of α are required over a fairly wide range of conditions.

The method has become generally used [9-11,13-16] as one of the most reliable procedures for measuring α in isotopic mixtures. It has also been applied to mixtures of isomers [12] and to non-ideal mixtures [13].

The main parts of an isothermal apparatus for the measurement of α by the differential method are a manometer to indicate the pressure of the substances or mixtures to be compared, a differential manometer, a temperature control system, a vacuum system, and a gas-handling system (Fig. 1). In the best designs, the manometers are in the form of holes drilled through metal blocks of high thermal conductivity in order to minimise temperature differences and to increase the thermal inertia of the system [14]. Constructions have been described which allow the temperature to be controlled to 0.0001° at the −195°C level, and to 0.01° at +370°C. [15,15a,16]

Combs and coworkers [7] used an unusual form of the differential isothermal method. A stream of carrier gas is led alternatively through thermostatted saturators containing the liquids to be compared and through desorbers. The design of the saturators and desorbers ensures quantitative saturation and scrubbing: the vapour pressure of the liquids is measured by the increase in weight of the desorbers.

Isobaric assemblies are based on ebulliometers essentially similar in design to the device described by Hala and coworkers [5]. The only difference is that two ebulliometers are used together, in a common manometric system.

The accuracy of the method is controlled by the following factors: the absolute difference in vapour pressure or in boiling point of the substances being compared, the precision of the equipment used to measure Δp or Δt, the

Figure 1. grade of the thermostat or manostat, and the purity of the compounds. Differential manometers are usually read with a cathetometer, which allows Δp to be measured with a precision of 0.01 mmHg. In principle, therefore, it is possible to measure ϵ with an error of a few units in the fifth decimal place. The isobaric method is more complicated and not so widely used. It requires specially calibrated resistance thermometers and a special electrical measuring bridge. The measurement accuracy can be as high as 0.001°, and the error in ϵ can be of the same order as in the isothermal variant.

Purity of the samples to be compared is the overriding condition for a successful and accurate determination of ϵ. To achieve the requisite purity, a complex sequence of purifications is often required, involving the development of special procedures and apparatus.

IV. MULTISTAGE EXTRACTION (CONDENSATION) METHOD

The multistage extraction method consists in the gradual enrichment (with respect to one or several components) of one of the two forms, achieved by simple repetition of a single-stage separation procedure. The experimental pair of chemical forms A and B is brought into dynamic equilibrium, the mixtures in form A and B respectively being taken in comparable amounts. Forms A and B are separated before the establishment of equilibrium: one of these forms becomes enriched with respect to one of the components, and vice versa. The entire operation (equilibration and separation of the forms) is termed a condensation stage. After the first stage, some fraction of form (or phase) A is converted into form (or phase) B by chemical or thermal methods. The sample of form B thus obtained, and the remainder of form A, are then brought into dynamic equilibrium once again, and forms A and B are again separated. As a result of the second stage, form A is enriched still further in the given component, and the subsequent "condensation" stages of form A raise the level of separation of the components to the point when the separation of all the components becomes accurately measurable. The degree of separation is measured with respect to the concentration of the components in form A after the first "condensation" stage. The amounts of forms A and B are controlled at each stage at the moment of separation. It is often desirable to condense both forms A and B: this two-fold condensation procedure yields two final samples A_f and B_f, enriched in different components. By comparing the degrees of separation of these two samples it is possible to double the accuracy of the determination of the separation coefficient.

The efficiency of the condensation process depends on two factors: the number of separation stages and the distribution of the degree of condensation over the stages. The degree of condensation of one stage is defined as the reciprocal of the recovery θ, i.e. the ratio of the amount of the form to be extracted obtained at the stage $(j-1)$ to the amount of the same form obtained at the jth stage: $L_j = G_{j-1}/G_j$. Katal'nikov and Boreskov [17] studied this problem and showed that for a given number of stages n and a given total degree of condensation ($L_\Sigma = \Pi_i L_i$) the maximum separation is obtained for equal degrees of condensation at all stages: $L_j = \sqrt[n]{L_\Sigma}$. They also showed that for a given degree of condensation the separation increases approximately exponentially with the number of stages: hence it is rational to choose a relatively small number of condensation stages (Fig. 2).

The same authors [17] proposed an accurate graphical method of calculation of small values of ϵ from the results of multistage extraction experiments for binary mixtures. This method is similar in many ways to the familiar

procedure for computing the number of theoretical plates. It enables the concentration of one of the components to be very simply computed after any number of extraction stages, whether one form is being extracted or both simultaneously. However, a knowledge of α is needed before the graphical method can be applied. The calculation is therefore made by trial and error, and the correlation between ϵ and Δx_{Σ} is used to give a more accurate value of ϵ.

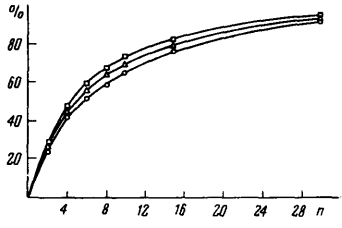

Figure 2. Ratio $\frac{\ln Q_{m.e.}}{\ln Q_{c.e.}}$, expressed as %, against number of condensation steps n. $Q_{m.e.}$ is the separation of the components of a binary mixture by the multistage extraction method, $Q_{c.e.}$ is the separation of the same mixture by Rayleigh's continuous extraction method. Circles for $\alpha = 1.001$; triangles for $\alpha = 1.010$; squares for $\alpha = 1.100$.

Kuznetsova and coworkers [18] proposed an analytical expression for calculating $\epsilon \ll 1$ directly from multistage extraction results (n stages) assuming an equal degree of condensation for each stage:

$$\alpha = \frac{\sqrt[n]{\frac{x_0}{x_n}} - \theta}{1 - \theta}. \qquad (7)$$

This equation is not entirely satisfactory, because it can be applied only at low concentrations of one component. Outside the low concentration region the relative error in ϵ becomes large, since it is directly proportional to x_0.

The equation proposed by Mikhailichenko and Shcheglov [19] is free from the last two drawbacks, but it also applies only for $\epsilon \ll 1$:

$$\varepsilon = \frac{x_n - x_0}{x_0(1 - x_0)\left(n - \sum_{j=1}^{n} Q_j\right) - x_0(x_n - x_0)}. \qquad (8)$$

An analogous expression for an n-component mixture ($\epsilon_{ek} \ll 1$) was obtained by Knyazev and Bantysh [20]:

$$\varepsilon_{ek} = \frac{\ln Q_{ek}}{n - \sum_{j=1}^{n} \Theta_j - \sum_{l=k}^{m} x_l}. \qquad (9)$$

Hence ϵ_{ek} is the enrichment coefficient, referred to some reference component k, Q_{ek} and Q_{jk} are the separations of components j and e with respect to the reference component. When the separation coefficients are significantly different from unity ($\epsilon \leqslant 0.2$) this expression becomes inaccurate. In these cases systems of equations of the following form must be used:

$$\ln Q_{ek} = \varepsilon_{ek} \sum_{j=1}^{m} \frac{1 - q_j}{1 + q_j \sum_{i=1}^{n} \varepsilon_{ik} y_{ij}} - \frac{\varepsilon_{ek}^2}{2} \sum_{j=1}^{m} \frac{(1 - q_j)^2}{\left(1 + q_j \sum_{i=1}^{n} \varepsilon_{ik} y_{ij}\right)^2}. \qquad (10)$$

The system can be solved by successive approximation; the first approximation for ϵ_{ek} can be the values given by Eqn. (9), and $\sum_{i=1}^{n} \epsilon_{ik} y_{ij}$ for each stage can be evaluated with sufficient accuracy by assuming that this sum is linear in the number of stages j. When the assumption that the quantity ϵ_{ek} is linearly related to some known parameter of the component e can be justified, measurement of all the Q_{ek} becomes superfluous, and only the separations of the two "extreme" (most easily separable) components needs to be measured. For example, in multicomponent isotopic mixtures ϵ_{ek} varies linearly with the isotopic mass M_e:

$$\varepsilon_e = \varepsilon_0 (M_e - M_k).$$

By using expressions of this type Eqn. (10) can be rewritten

$$\varepsilon_0 = \frac{\ln Q_{ek}}{(M_e - M_k)\left(m - 1 - \sum_{j=2}^{n} q_j\right) - \ln Q_{ek} \sum y_{i0} (M_e - M_k)}. \qquad (11)$$

The method has been most generally applied to measurements of the separation coefficients of isotopes. Many systems involving heterogeneous isotope exchange have been investigated, including solution–sorbent, solution–crystals, and liquid–liquid systems [21–26]. The main attraction of the method is that it can be applied without special equipment, using only the apparatus needed to measure ϵ by the single contact method.

V. RAYLEIGH'S CONTINUOUS EXTRACTION METHOD

Rayleigh's method [27,28], also known as the continuous extraction or residue concentration method, is most commonly applied in distillation theory. It does not suffer from any of the limitations of the separation methods discussed above, and is undoubtedly applicable to the most diverse systems even though it is mostly used in studies of liquid–vapour equilibria at present.

The main difficulty associated with the Rayleigh method is the need to observe two sets of conditions at the same time: on the one hand, the concentrated (extracted) form must be free from concentration gradients, and on the other hand the concentration of this form and the take-off of the resulting new form must be carried out in infinitesimally small amounts. It is not difficult to comply with these conditions in simple distillation, but the study of other separation processes by this method is often complicated by the properties of the forms under investigation, or may require special experimental techniques.

The advantages of the method include: relatively high separation, allowing the separation coefficients to be measured accurately; non-equilibrium as well as equilibrium processes can be investigated; short experimental time (in the study of fast processes); relatively simple apparatus.

Since the method can be applied to a wide variety of separation processes, we shall describe it in the most general terms. Let the system have n components, and assume that each component can exist in two states (1 and 2). At the beginning of the experiment the whole of the mixture (G_0) is in state 1. We assume that the mixture can be transferred by some method from state 1 to state 2 in infinitesimally small increments dG, and that a method for instantaneously removing the mixture in state 2 is available. We further assume that the transition of an

arbitrary component (i) from state 1 to state 2 occurs with probability $P_i x_i$, where P_i is in general some function of the concentration of all the components in the mixture (x_i) in state 1, and also of the experimental conditions. Lastly, let the concentrations of the substances in the mixture in state 1 be described by their mole fractions x_i, and those in state 2 by their mole fractions y_i. It can easily be shown that the following relationship exists between the quantities x_i, y_i, P_i, dG_i, and dG:

$$\frac{dG_i}{dG} = y_i = P_i x_i = P_i \frac{G_i}{G}. \qquad (12)$$

Dividing Eqn. (12) for component i by the analogous equation for component j, we obtain after some simple transformations

$$d \ln G_i = \frac{P_i}{P_j} d \ln G_j. \qquad (13)$$

The probability functions P_i and P_j depend on a number of factors, including first of all some specific properties of states 1 and 2. For example, we may be considering two processes as closely related as equilibrium distillation and vacuum distillation of liquid mixtures. In the former, the probabilities of $1 \rightarrow 2$ transitions will be determined by temperature and by the difference between the thermodynamic properties of the components in the different states; in the latter, they will be determined by temperature and by the molecular weight of the components. Furthermore, pressure, reactions with extraneous chemical compounds, concentration gradients, etc. may also affect the values of P_i and P_j. Lastly, the dependence of P_i and P_j on the concentration of the components i and j, and of other components undergoing the transition $1 \rightarrow 2$, should in general be considered. For a Rayleigh process in which all conditions except the concentrations of the i and j components are kept constant, integration of Eqn. (13) is possible only if the functions P_i and P_j are available in an explicit form. However, at least as regards thermodynamic separation processes, near-unity separation coefficients can be taken as evidence that the mixtures under study are close to ideality. This implies constancy of P_i and P_j (and even more so of their ratio P_i/P_j). Since the separation coefficient can be accurately measured with relatively small concentration changes, the assumption is fully justified. Thus, if the above assumptions hold true,

$$\frac{P_i}{P_j} = \frac{y_i}{x_i} \cdot \frac{x_j}{y_j} = \alpha_{ij} = \text{const}.$$

After integration we have

$$\ln \frac{G_{i_0}}{G_i} = \alpha_{ij} \ln \frac{G_{j_0}}{G_j}. \qquad (14)$$

Transformation of Eqn. (14) gives the following forms of the Rayleigh equation:

$$\ln Q_{ij} = \ln \frac{x_{i_0}}{x_i} \cdot \frac{x_j}{x_{j_0}} = \ln \frac{y_{i_0}}{y_i} \cdot \frac{y_j}{y_{j_0}} = \varepsilon_{ij} \ln \frac{G_{j_0}}{G_j}. \qquad (14a)$$

$$\ln Q_{ij} = \varepsilon_{ij} \left[\ln \frac{G_0}{G} + \ln \frac{x_{j_0}}{x_j} \right] = \varepsilon_{ij} \left[\ln \frac{G_0}{G} + \ln \frac{y_{j_0}}{y_j} \right]. \qquad (14b)$$

The approximate form

$$\ln Q_{ij} = \varepsilon_{ij} \ln \frac{G_0}{G}, \qquad (14c)$$

can be used if $\epsilon_{ij} \ll 1$.

For the case of two-component systems, Eqn. (14) can be converted into well known, precise expressions in which the ratio of concentrations of component 1 is presented[27] as a function of the degree of condensation[25]:

$$\ln \frac{x_{10}}{x_1} - \alpha \ln \frac{1 - x_{10}}{1 - x_1} = (\alpha - 1) \ln \frac{G_0}{G}.$$

$$Q = \frac{x_{10}}{x_1} \cdot \frac{1 - x_1}{1 - x_{10}} = \left(\frac{G_0}{G} \right)^{\alpha - 1} \left(\frac{1 - x_{10}}{1 - x_1} \right)^{\alpha - 1}. \qquad (15a)$$

For $\epsilon \ll 1$ we have

$$\ln \left(\frac{x_{10}}{1 - x_{10}} \cdot \frac{1 - x_1}{x_1} \right) = \ln Q \cong \varepsilon \ln \frac{G_0}{G}, \qquad (15b)$$

and with the additional condition $x_{10} \ll 1$, leading to $\alpha = y/x$, we obtain

$$\ln Q \ln \frac{x_{10}}{x_1} \approx \ln \frac{y_{10}}{y} \approx \varepsilon \ln \frac{G_0}{G}. \qquad (15c)$$

It is evident from Eqns. (14), (14a), and (15c) that measurement of α_{ij} requires only a knowledge of the initial and the final amount of material in the mixture in state 1 (to be condensed), as well as of the concentrations of the components of interest at those times. In other words, these quantities need to be known, in principle, before the beginning of the process and at any one time during the process. In this sense, Eqn. (14) and Eqns. (14a)–(14c) are equivalent. However, they are far from being equivalent as regards the accuracy with which $(\alpha_{ij} - 1)$ can be calculated. As can readily be shown, the relative errors in the calculation of ϵ_{ij} by Eqn. (14) and by the widely used Eqn. (14c) are given, respectively, by the expressions

$$\frac{\Delta \varepsilon_{ij}}{\varepsilon_{ij}} = \frac{\Delta \ln Q_{ij}}{\ln Q_{ij}} + \frac{\Delta \ln z}{\ln z} \qquad (16a)$$

$$\frac{\Delta \varepsilon_{ij}}{\varepsilon_{ij}} = \frac{\Delta \ln Q_{ij} + 2 \Delta \ln z}{\ln Q_{ij}}. \qquad (16b)$$

Since Q_{ij} is usually close to unity, the second term in the numerator of the right-hand side of Eqn. (16b) contributes very significantly to the overall error, whereas the second term in the right-hand side of Eqn. (16a) is small because of the magnitude of $\ln z$. Because Q_{ij} does not differ much from unity and is therefore difficult to measure accurately, multiple measurements of Q_{ij} and z are desirable. Since samples of the "condensed" state 1 are usually more difficult to remove, and involve a correction for the effective degree of condensation z, it is preferable to analyse the material in the "drawn off" state 2. In the case of simple distillation, for example, vapour samples are usually analysed.

Any method of analysis requires a finite sample of the material to be analysed. It is important to establish the relationship between the size of the sample and the size of the permissible final residue of extracted mixture in state 1. It can be shown that the error arising from the discrepancy between the theoretical concentration (corresponding exactly to G) and the actual mean concentration becomes negligible if the degree of condensation is calculated for a value of G corresponding to the "mean point" of the sample taken off (volume $2\Delta G$). When the degree of condensation is calculated in this way, the relative error in the measurement of concentration becomes

$$\frac{\Delta y}{y} \cong -\frac{(\alpha - 1)}{3} \left(\frac{\Delta G}{G} \right)^3. \qquad (17)$$

Thus, the removal of samples of finite volume does not impose rigid limitations on the size of the minimum permissible final residue. This allows significant degrees of condensation to be achieved without serious error.

Until recently, Rayleigh's method has been applied to the measurement of small separation coefficients when the

process under investigation is not complicated by the presence of extraneous separation processes, and when the experimental arrangements needed to realise the basic conditions of the Rayleigh process are not unduly complex. These requirements are easily met in simple distillation processes, and in particular in the equilibrium distillation of mixtures consisting of members of a series of related compounds or other materials with closely similar properties [29], in the molecular distillation of isotopic mixtures [30], in some isotope exchange processes [31], in electrolytic methods of isotope separation [32,33], and also in separation processes relying on equilibrium crystallisation from aqueous solutions [34].

More recently, Rayleigh's method has been shown to be applicable to the study of homogeneous isotope exchange and exchange in heterogeneous extraction, ion-exchange, and other heterogeneous systems [35-37].

Lastly, the Rayleigh process can be used to study separation phenomena such as the diffusion of gases through porous partitions, diffusion through liquid films, etc.

1. Rayleigh Distillation

Rayleigh's method is used mostly to study separation in liquid–vapour systems, for which the correct experimental conditions have been most accurately identified and suitable apparatus and experimental procedures have been developed. Only the basic features of the method will be discussed in the present review: some of these are general features, others are more specific. Even the latter, however, are almost invariably present (in a modified form) in other separation processes as well.

In the experimental realisation of Rayleigh's method, various specific features of the distillation process itself must be taken into account. Furthermore, the simpler laboratory assemblies invariably present some undesirable aspects which must be minimised. Lastly, some unavoidable phenomena must quantitatively evaluated and allowed for.

1. True liquid–vapour equilibrium occurs when the evaporation and condensation fluxes are equal. Since evaporation of the liquid must proceed at a practically useful rate in the Rayleigh process, this process is a quasi-stationary one, and the separation coefficients obtained can approach the equilibrium values only in the most favourable (or most unfavourable) cases [38,39]. Obviously, the measured coefficients will be closer to the equilibrium values, the smaller the vapour take-off is in relation to the exchange flow of material between liquid and vapour. In practice, the optimum rate of evaporation is found experimentally, by monitoring the dependence of the observed separation coefficient (α) on the evaporation rate. The range of evaporation rates corresponding to a constant value of α is chosen for the experiment. Conversely, in molecular distillation the true value of the separation coefficient can only be obtained in the total absence of vapour condensation. This condition can be met by removing the evaporated material from the vicinity of the liquid as rapidly as possible [30].

2. The application of the integral forms of the Rayleigh equation presupposes constancy of the separation coefficients. As stated above (see p. 571), this in turn implies independence of the separation coefficient upon the composition of the mixture and constancy of temperature. In practice, the process is most frequently applied at constant pressure [29]. As the composition of the liquid phase changes, the boiling point under isobaric conditions also changes. However, near-unity separation coefficients usually imply that the substances to be separated have similar boiling points, so that at moderate degrees of separation isobaric evaporation is a good approximation to isothermal evaporation. This is also true when the components differ significantly in boiling point provided that the measurements are confined to low concentrations of one component. In these cases, the condition of constancy of the separation coefficient is automatically satisfied.

3. It follows from the initial, differential form of the Rayleigh equation (Eqn. (12)) that the composition of the sample must be representative of that of the whole of the condensed phase. From the standpoint of equilibrium and molecular distillation, this implies that the composition of the liquid near the evaporating surface must be identical to the composition at any other point in the liquid phase, i.e. that the liquid phase must be free from concentration gradients. Mechanical stirring is therefore widely used. The stirring conditions depend on the design and type of stirrer, and are chosen empirically. The criterion for satisfactory stirring is independence of the observed value of α upon the intensity of stirring (number of revolutions per minute).

4. The definition of separation coefficient in both equilibrium and molecular distillation implies that the vapour phase must be strictly homogeneous and must not contain any particles of the liquid phase. Since boiling of the bulk liquid usually gives rise to a large amount of spray, the distillation process is usually carried out under conditions approximating to isothermal evaporation from the surface, which imposes severe limitations on the effectiveness of mixing. Stirring helps to avoid overheating of the liquid and to obtain quiet evaporation. However, the intensity of stirring must be kept below the limit at which spray formation sets in.

5. The equilibrium separation coefficient in distillation cannot be measured under conditions leading to multiple separation acts. Hence, vapour condensation and reflux from the vapour to the liquid is permissible only at the main condensation surface. Vapour condensation in the vapour volume and at the walls of the evaporation vessel must be excluded, and hence the vapour and the walls of the evaporator must be kept at a temperature such that condensation is impossible.

6. Evaporation vessels are usually designed (Fig. 3) so that the total volume occupied by the liquid and the vapour phase is constant throughout the experiment. Under these conditions the amount of material in the vapour state at the end of the experiment is comparable with the amount of liquid mixture. Mechanical stirring of the liquid may be supplemented by stirring of the vapour, which is even more effective, since it brings a finite amount of the vapour phase into equilibrium with the liquid rather than an infinitesimally thin layer. Allowing for these conditions [39], the initial differential and the final integral equation for the process should be written in a form which differs substantially from Eqn. (12) and following. Allowing for the volume of the stirred vapour phase leads to the equations:

$$\lg\frac{y_i}{y_f}=\lg\frac{x_i}{x_f}=\frac{\alpha\,(v_v-v_l)}{v_v-\alpha v_l}\cdot\lg\frac{G_i\,(v_v-\alpha v_l)+\varepsilon V}{G_f\,(v_v-\alpha v_l)+\varepsilon V}+\lg\frac{G_f}{G_i} \qquad (18a)$$

$$\lg\frac{x_i}{z_f}=\frac{\alpha\,(v_v-v_l)}{v_v-\alpha v_l}\cdot\lg\frac{G_i\,(v_v-\alpha v_l)+\varepsilon V}{G_f\,(v_v-\alpha v_l)+\varepsilon V}-\lg\frac{G_f\,(v_v-\alpha v_l)+\varepsilon V}{G_f\,(v_v-v_l)}+\lg\frac{G_f}{G_i} \qquad (18b)$$

$$\lg\frac{x_i}{x_f}=\frac{\alpha\,(v_v-v_l)}{v_v-\alpha v_l}\lg\frac{\alpha V+g_{li}\,(v_v-\alpha v_l)}{\alpha V+g_{lf}\,(v_v-\alpha v_l)}+\lg\frac{V+g_{lv}\,(v_v-v_l)}{V+g_{lf}\,(v_v-v_l)}. \qquad (18c)$$

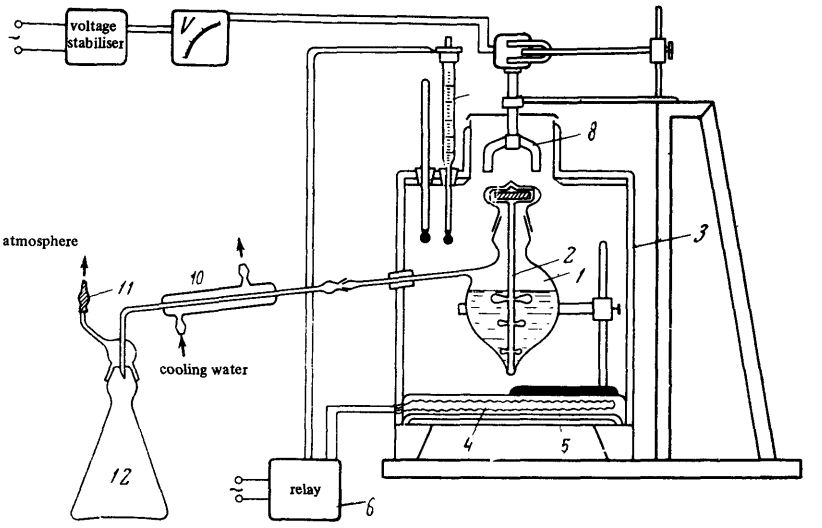

Figure 3. Apparatus for Rayleigh distillation; *1*) still; *2*) magnetic stirrer; *3*) air thermostat; *4*, *5*) electric heaters; *6*) relay; *7*) contact thermometer; *8*) magnet; *9*) voltage stabiliser; *10*) condenser; *11*) calcium chloride tube; *12*) receiver.

Here, V is the volume of the Rayleigh still, v_l is the molar volume of the liquid phase, v_V is the molar volume of the vapour phase, G is the number of moles of the mixture in the still, x and y are the mole fractions of the minority component in the liquid and the vapour phase respectively, z is the mean concentration of the minority component in G moles of mixture in the still; $x, y \ll 1$, $\alpha = y/x$, $\epsilon = \alpha - 1$.

As Fig. 4 shows, using the Rayleigh equation directly in the form (14a)–(14c) and (15a)–(15c) leads to large errors in the measurement of α, particularly at high degrees of condensation. If the separation is determined from an analysis of the vapour phase, and the degree of condensation is measured as the ratio G_0/G_i, the error is minimised, but even in this case degrees of condensation in excess of 10^2–10^3 lead to intolerably high errors in α.

7. Because of the need for visual observation of the progress of distillation and for an approximate estimate of the degree of condensation, evaporation stills are usually made of glass, which is not a good conductor of heat. This, in turn, produces significant temperature gradients at the walls of the still, and hence a temperature difference between the thermostat medium (air, or water) and the evaporation temperature must be specially maintained.

8. In addition to the designs involving mechanical stirring of the two phases, designs similar to the contact apparatus with rotating drums [7] and with inert carrier gas bubbling [31] have been proposed. These offer the advantage of a more precise temperature control of the contents of the still. In complicated systems, containing volatile impurities (see p. 574), this facility is extremely valuable, because the boiling point of these mixtures at constant pressure is a sensitive function of composition. Furthermore, the process takes place much faster, with a consequent reduction in the duration of the experiment. These designs can be additionally provided with facilities for liquid circulation, resulting in a large increase in the initial volume of liquid and hence in an enhanced ultimate degree of condensation and of separation. Lastly, these advanced designs allow the volume of vapour in equilibrium with the liquid to be kept small and constant, which largely removes the limitations discussed above and simplifies the experimental procedure.

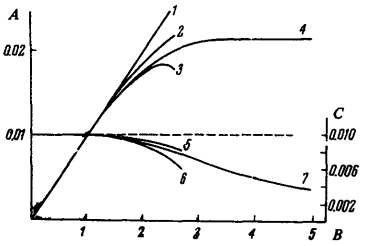

Figure 4. Plots of separation (x_i/x_f, x_i/z_f) against degree of condensation (G_i/G_f, g_i/g_f) assuming complete mixing of the vapour phase. Plots of the effective enrichment coefficient ϵ against degree of condensation assuming complete mixing of the vapour phase. *A*) values of $\lg\frac{x_i}{x_f}$ and $\lg\frac{x_i}{z_f}$; *B*) values of $\lg\frac{g_i}{g_f}$ and $\lg\frac{G_n}{G_f}$; *C*) effective ϵ values. Condensation conditions: initial amount of mixture $G_i = 10$ mole, volume of Rayleigh still $V = 0.6$ litre, molar volumes of liquid (v_l) and vapour (v_V) 0.05 and 22.4 litre mole^{-1} respectively, equilibrium value of the enrichment coefficient $\epsilon = 0.010$. Curves *1*, *2*, *3*, and *4* correspond to Eqns. (14a), (18a), and (18c) respectively. Effective ϵ values calculated from Eqn. (14a), allowing for the actual degrees of separation and condensation by means of Eqns. (18a)–(18b); curves *5*, *6*, and *7* correspond to Eqns. (18a), (18b), and (18c) respectively.

2. Rayleigh's Equation in a Form Suitable for Studying the Dependence of α on the Composition of the Phases

The integral forms of Rayleigh's equation given above were obtained on the assumption of constant separation coefficients α_{ik}. This condition is often inappropriate, and the equations given above then lead to some average value of α_{ik}. There is a simple method by which true values of α_{ik} can be obtained, and related to any concentration of the component k which is encountered during Rayleigh extraction [40,41]. A different mathematical procedure is used, based on a more convenient form [13] of the differential Rayleigh equation:

$$d\ln Q_{ik} = -\varepsilon_{ik}(d\ln G + d\ln x_k), \qquad (19)$$

whence

$$\varepsilon_{ik} = \frac{\dfrac{d\ln Q_{ik}}{d\ln G}}{1+\dfrac{d\ln x_k}{d\ln G}}. \qquad (20)$$

Since Q_{ik} varies as a function of G during the extraction, the wanted differentials are readily found from the analytical results obtained by any convenient method. The most accurate results are obtained by expressing $\ln Q_{ik}$ and $\ln x_k$ (or $\ln x_k$ and $\ln x_i$) in the form of Lagrange polynomials, which can then be differentiated numerically. Graphical differentiation procedures are also possible (from experimental plots of x against $\ln G$).

In the case of two-component mixtures the problem becomes simpler, since $x_2 = 1 - x_1$, and the relationship between $\ln x_1$ and $\ln G$ is sufficient to define α. For $\epsilon \ll 1$ (and particularly for $x_k \ll 1$) the differentials $\dfrac{d\ln x_k}{d\ln G}$ become negligibly small, and the expression takes the form

$$\varepsilon_{ik} = \frac{d\ln Q_{ik}}{d\ln G} = \frac{d\lg Q_{ik}}{d\lg G}. \qquad (21)$$

Examples of the use of these expressions can be found in the literature [29,40]. The experimental technique differs from the Rayleigh distillation procedure (see p. 577) in that the amount and composition of the distillate are monitored periodically. From these measurements it is a simple matter to calculate the amount and composition of the liquid in the still and to establish the dependence of $\lg Q$ upon $\lg G$. For the case of α = const this dependence will take the form, according to Eqn. (21), of a straight line of slope α.

3. Application of the Rayleigh Equation to Measurements of Separation Coefficients in the Presence of Additives, During Extraction, and During Ion Exchange

Additives showing preferential chemical or physical interaction with one or several of the components of a mixture, and therefore having a beneficial effect on the separation coefficient, have been used increasingly in recent years to facilitate the separation of difficult mixtures. Additives in various forms have been used in practically all countercurrent processes, in which separation depends on phase equilibria or chemical equilibria (azeotropic and extractive distillation, extraction and ion exchange at low degrees of complex formation in the aqueous phase).

The effective separation coefficient in the presence of additives is determined by two effects: the phase equilibrium, and the physical or chemical equilibrium between the initial forms of the components and the additive. The interaction can take place in one of the phases under study, or in both phases. In either case the Rayleigh process is complicated by the fact that the concentration of the additive (and therefore also α) varies as the condensed phase is removed. Nevertheless, useful analytical expressions for the separation coefficient relevant to the homogeneous exchange process can be obtained by making some specific assumptions as to the nature of the homogeneous exchange of the components between their initial form and their reaction products with the additive. This approach can be used to evaluate the effectiveness of the additive and to study the homogeneous reactions involving the additive.

Table 2.

Method	Logarithm of enrichment in the liquid phase as a function of degree of condensation. Isothermal regime	Logarithm of enrichment in the vapour phase as a function of degree of condensation. Isothermal regime
With involatile additive	$\ln\frac{z}{z_0} = \frac{1}{\alpha}\ln\frac{G_c+\beta G_a^0}{G_c+\beta G_a} - \ln\frac{G_c+G_a}{G_c+G_a^0}$	$\ln\frac{x}{x_0} = \frac{\alpha-1}{\alpha}\ln\frac{G_c+\beta G_a^0}{G_c+\beta G_a}$
With volatile additive	$\ln\frac{y}{y_0} = \frac{\gamma-\alpha}{\alpha(\gamma-1)}\ln\frac{\beta-c(\beta-1)}{\beta-c_0(\beta-1)} + \frac{(\alpha-1)\gamma}{\alpha(\gamma-1)}\ln\frac{c}{c_0}$	$\ln\frac{x}{x_0} = \frac{(\alpha-1)}{\alpha(\gamma-1)}\ln\frac{[\beta+(\gamma-\beta)\bar{c}]\bar{c}_0}{[\beta+(\gamma-\beta)\bar{c}_0]\bar{c}} + \ln\frac{\beta+(\alpha-\beta)\bar{c}}{\beta+(\alpha-\beta)\bar{c}_0}$
Extraction	$\ln\frac{Z_f}{Z_0} = \ln\frac{x_f}{x_0} = (\alpha-1)\frac{\delta R}{\alpha\delta R+S}\ln\frac{G_0}{G_f}$	
Ion exchange	$\ln\frac{x_f}{x_0} = \ln\frac{y_f}{y_0} = \frac{(\alpha-1)}{\alpha\delta R+S}\left[\delta R\ln\frac{G_S^f}{G_S^0} - \frac{S}{\alpha}\ln\frac{S+\alpha\delta R+(\delta-1)G_S^f}{S+\alpha\delta R+(\delta-1)G_S^0} - \left(\delta R-\frac{S}{\alpha}\right)\ln\frac{S+(\delta-1)G_S^f}{S+(\delta-1)G_S^0}\right]$	

G_S, G_R are the amounts of mixture in the system in the organic and the aqueous layer respectively;

R, S are the volumes of the organic and the aqueous phase in the case of extraction;

R, S are the molar capacities of the organic and the aqueous phase in the case of ion exchange.

The simplest case is found when the additive is present in the phase to be extracted and cannot be transferred to the phase to be removed [35]. Such a process is characterised by the phase separation coefficient α and also by a separation coefficient β which relates to the homogeneous reaction in the phase to be extracted. Then, from the differential form of the Rayleigh equation, we obtain

$$\frac{dz}{z-x} = \frac{dG}{G},$$

where z is the mean concentration of the given component, G is the amount of mixture in the phase to be extracted, and x is the concentration of the same component in the phase to be removed. Starting from the differential form of the Rayleigh equation we can arrive at a number of expressions for isothermal conditions: these are set out in Table 2. They all involve the assumption that the phase and the homogeneous exchange equilibria are maintained at all times. Very low concentrations of the particular component are also assumed (x, $z \ll 1$).

The case of an additive which can distribute itself between the two phases is more complicated [36]. On the

assumption that equilibrium in the phase to be removed is determined by the same coefficient (β) as in the phase to be extracted, and that the distribution of the additive between the two phases can be described in terms of a distribution coefficient γ, the integral forms of Table 2 can be obtained from the differential form. Analogous expressions can be derived for the isobaric regime, but these are complicated by the need to allow for the temperature dependence of α.[35]

In the above discussion of non-distributed and of distributed additives, the volume of phase to be removed (in equilibrium with the phase to be extracted) is assumed to be negligibly small. This condition is easily satisfied in Rayleigh distillation, but not in extraction or in ion exchange processes. In the latter, the condition of constant volume of the two contacting phases is more easily realised. Hence, and using the distribution coefficient δ to characterise the phase equilibrium of the mixture as a whole for extraction systems and δ' for ion exchange systems, appropriate integral forms of the Rayleigh equations can be obtained[37]. These, too, are given in Table 2.

The tabulated relationships are transcendental in α and β (with the exception of the extraction equation). Hence, the required values must be found by selection or by successive approximation methods, which are in general very time-consuming.

VI. SQUARE CASCADE METHODS

The term square cascades is used[42] in the general theory of separation processes to denote columns operating in the countercurrent regime and characterised by a constant flow of material at any cross-section. We shall retain this term in order to include in the following discussion, without distinction of any kind, processes such as rectification, extraction, hypersorption, development chromatography, heterogeneous isotope exchange, and others. Cascade methods enable the separation effects under study to be strongly enhanced, leading to reliable and accurate measurements of α and ϵ. It is usually necessary to resort to these methods when ϵ is small, particularly if the apparatus is simple and no preliminary investigation of the process is required (rectification, development chromatography).

The separation obtainable in square cascades is characterised by the number of theoretical plates (n), which is a function of the hydrodynamic operating regime of the cascade, and of the properties of the mixture to be separated. Thus, the determination of α by a cascade method is always a problem with two unknowns, requiring two independent equations. Bearing in mind that the measurement error associated with various characteristics of the process can seriously degrade the accuracy of the measurement of α and n, it is often the best practice to extract these values from the largest possible number of experiments over the widest possible range of cascade parameters.

1. Equations for Stationary Operating Regimes of the Cascade

States of the cascade for which all parameters and their characteristics remain constant with time are termed stationary states.

We shall deal first with the equations and methods which apply to total reflux conditions. The separation Q_{ie} is related to the separation coefficient α_{ie} of a cascade with n theoretical stages by the Fenske-Underwood equation[43,44]

$$Q_{ie} = \alpha_{ie}^{n}. \qquad (22)$$

In order to calculate α_{ie} from the experimentally observed value of Q_{ie} we must know the number n of theoretical separation stages under the conditions of the particular experiment. In the case of two-component mixtures, we can use the mass conservation equation for one of the components for this purpose, and arrive[45] at the following analytical expression for α:

$$\ln \alpha = \frac{G \int_{h_1}^{h_2} (x - x_0)\, dn}{G \cdot \ln \frac{1 - x_{h_2}}{1 - x_{h_1}}}.$$

In this expression the numerator is the experimentally measurable excess of the component under study in a section of the cascade between points h_1 and h_2 (as compared with the initial state, for which the concentration is everywhere x_0). G is the number of moles of material in the same section of the cascade, x_{h_1} and x_{h_2} are the concentrations of the component at the points h_1 and h_2.

In practice, measurements of α have often been made by inserting into the Fenske–Underwood equation the number of theoretical plates, obtained by independent methods. The precision of the measurement of α by Fenske–Underwood equation is much more sensitive to errors in n than to errors in Q_{ie}:

$$\frac{\Delta \ln \alpha_{ie}}{\ln \alpha_{ie}} = |\Delta \ln \ln Q_{ie}| + |\Delta \ln n|. \qquad (23)$$

For the case of rectification in unpacked, liquid-film columns the number of plates n can be calculated to an accuracy of 10–15% from the parameters of the column and from the flow by using semi-empirical relations[46,47]. This calculation cannot yet be made in the case of the more efficient, packed columns, and an approximate estimate of α for these columns is sometimes made by inserting the value of n obtained for a model mixture (with physicochemical properties as close as possible to those of the unknown mixture) in the same cascade[45]. Bushmakin and coworkers[48–50] suggested the measurement of α at low concentrations of one of the components by using the number of theoretical plates (n) obtained in experiments with the same mixture but at concentrations high enough to allow α to be measured by other methods. This procedure ignores the dependence of the HETP (height of the equivalent theoretical plate) upon composition, and must therefore be treated as approximate.

More accurate values of α are obtained if the separation Q and the number of plates n can be measured in a single experiment. This condition can be realised if the unknown mixture contains more than two components, and the separation coefficient α_{ik} for one pair of components is known. In this case there is a simple relationship which allows the unknown separation coefficients to be evaluated in terms of the known value α_{ik}:[51,52]

$$\ln \alpha_{em} = \ln \alpha_{ik} \frac{\ln Q_{em}}{\ln Q_{ik}}. \qquad (24)$$

The equations for stationary separation regimes of multicomponent mixtures with take-off are complicated, and cannot be applied to the measurement of α. The numerous and simpler relationships which have been proposed for binary mixtures[53–59], on the other hand, can be used. Experimental tests of some of these equations have been carried out[60–62]. The procedure for measuring α in

the presence of take-off involves measuring the separation of the mixture by the cascade either as a function of relative take-off or as a function of the position of the take-off point (multipoint take-off). In both cases a large number of experiments is desirable, followed by statistical treatment of the results, because the separation is very sensitive to the take-off ratio, which cannot be measured with great precision. Since the equations for the take-off regime are transcendental in α, it is convenient to use the so-called graphical least-squares method, which does not require normal equations to be set up[63,64]. Smoker's equation, which applies for any value of α and any concentration of either component, is presented in Table 3.

Table 3. Operating equation of the column in the stationary regime:

$$\left(\frac{\alpha}{\gamma c^2}\right)^n = \frac{x'}{x}\left[\frac{1-\left(\frac{\gamma c(\alpha-1)}{\alpha-\gamma c^2}\right)x}{1-\left(\frac{\gamma c(\alpha-1)}{\alpha-\gamma c^2}\right)x'}\right]. \qquad (25)$$

Variable	Section of cascade	
	Rectifying	Scrubbing
x'	$x_p-\beta$	$x_0-\beta$
x	$x_0-\beta$	$x_p-\beta$
c	$1+(\alpha-1)\beta$	
β root of equation $(0\leq\bar{x}\leq 1)$ $0<\beta<1$	$\gamma(\alpha-1)\bar{x}^2+[\gamma+b(\alpha-1)-\alpha]\bar{x}+b=0$	
b	$x_p\Theta$	$-\frac{x_p\Theta}{1-\Theta}$
γ	$1-\Theta$	$\frac{1}{1-\Theta}$

γ is the ratio of heavy phase and light phase flows; Θ is the relative take—off (product/feed); x is the reduced concentration in the heavy phase; subscripts 0 and p refer to the feed and the outlet section respectively.

Simpler equations, shown in Table 4, are used for the low-concentration region, when the equilibrium equation is linear[45,65-67].

2. Expressions for Non-stationary Regimes

During the establishment of a stationary state at any point in the cascade, the concentrations of the components show a continuous change which is (to a first approximation) exponential. In principle, the separation coefficient of a binary mixture can be calculated from measurements of the concentration of one of the components as a function of time. However, none of the many expressions which have been proposed to describe the achievement of steady state is truly exact[45,65,67-75]. This is because of the lack of accurate methods of solution of non-linear partial differential equations, such as the basic non-stationary state equation. The equations which have been proposed involve various simplifying assumptions on the distribution of concentrations along the column and with time; these assumptions do not usually lend themselves to strict mathematical analysis, and existing experimental data are insufficient for a detailed study of the assumptions.

The adequacy of the equations for non-stationary processes is most satisfactorily established by comparing the numerical values of various parameters given by the equations with the values obtained by numerical solution of the original differential equation on an electronic computer. Jackson and Pigford (quoted in Ref. 72) were able to show in this way that some published equations[68,70,71] were unacceptable. Other equations[72,74] were shown to be inaccurate by comparison with experimental results[45,67].

Table 4. Operating equations of the column in the stationary regime for the case $x \ll 1$.

Section	Component	
	light	heavy
Rectifying	$Q=\frac{x_p}{y_0}=\frac{(\alpha-\gamma)\left(\frac{\alpha}{\gamma}\right)^n}{\gamma(\alpha-1)+\alpha(1-\gamma)\left(\frac{\alpha}{\gamma}\right)^n}$	$Q=\frac{y_0}{x_p}=\frac{\gamma(\alpha-1)(\alpha\gamma)^n-(1-\gamma)}{(\alpha\gamma-1)}$
Scrubbing	$Q=\frac{x_0}{x_p}=\frac{\left(\frac{\alpha}{\gamma}\right)^n(\alpha-1)-(\gamma-1)}{(\alpha-\gamma)}$	$Q=\frac{x_p}{x_0}=\frac{(\alpha\gamma)^n(\alpha\gamma-1)}{(\alpha-1)+\alpha(\gamma-1)(\alpha\gamma)^n}$

γ is the ratio of heavy phase and light phase flows; n is the number of theoretical plates; x is the concentration in the heavy phase; y is the concentration in the light phase; subscripts 0 and p refer to the feed and the outlet ends of the section respectively.

The equation of Babkov and Zhavoronkov[75] was tested most stringently against experiment and against a model of the achievement of steady state (electronic computer), and the discrepancy during the relaxation time was found to be insignificant (0.6%). Rozen's equation[67] also gave satisfactory results. The full forms of these equations are shown in Table 5 together with approximate expressions applicable at low concentrations. All these equations are transcendental in α and Q_∞ (degree of separation at steady state). The usual procedure for calculating α is to insert the rather inaccurate experimental values of Q_∞ into the kinetic equations. An additional source of error could be the inaccuracy of the kinetic equations themselves at times long compared with the relaxation time. The most satisfactory procedure is to calculate α and Q_∞ together by least squares[63].

The mass conservation equation for either of the components to be separated can be used as an additional source of information on the value of α. When high-efficiency cascade processes are used, the kinetic curves show an extensive linear portion, indicating that during an appreciable time the longitudinal transfer of any component is practically constant and is determined by the difference in equilibrium concentrations at the feed plate of the cascade. If the cascade flows (L) are constant, measurement of the amount of component i accumulating in the cascade in time t ($G\int_0^n (x_i - x_{i_0})dn$) enables this difference to be determined.

$$y_i^0 - x_i^0 = \frac{G\int_0^a (x_i - x_i^0)\,dn}{tL} \qquad (26)$$

The equations relating this difference to α_i can then be used to evaluate the latter.

Unlike the kinetic methods described above, the mass balance method offers two important advantages: on the linear portion of the kinetic curve, Eqn. (26) is both accurate and applicable to multicomponent systems. Of course, with multicomponent systems it becomes necessary to measure the integrated transport of all the components, whether or not the experimenter is interested in their separation. The accuracy of measurements of ϵ by this method is well illustrated by the excellent agreement with results obtained by other methods [67,76].

Table 5.

Region of application	Analytical expressions for the time to reach steady state	Literature references
$0<x\leqslant 1$	$t=\frac{1}{L}\left\{\frac{\varepsilon}{1+x_0\varepsilon}+\frac{\alpha}{\varepsilon(1-x_0)(1+x_0\varepsilon)^2}\left[(\alpha^n-1)\frac{1-x_n}{x_n-x_0}+\varepsilon\right]\ln\left(1+\right.\right.$ $\left.\left.+\frac{1+x_0\varepsilon}{x_0(\alpha^n-1)\frac{1-x_n}{x_n-x_0}}\right)\right\}\times\left[(x_n-x_0)\left(v_0-\frac{Hn}{\frac{1-x_n}{1-x_0}\alpha^n-1}\right)+\right.$ $\left.+\frac{H(\alpha^n-1)}{\ln\alpha}\cdot\frac{\frac{1-x_n}{1-x_n\alpha^n-1}}{1-x_0}\cdot\ln\frac{1-x_0}{1-x_n}\right]$	75
$x\ll 1$	$t=\frac{1}{L}\cdot\frac{\alpha}{\alpha-1}\left[\left(H\frac{\alpha}{\alpha-1}+v_0\right)\cdot(\alpha^n-1)-nH\right]\cdot\ln\frac{\alpha^n-1}{\alpha^n-\frac{x_n}{x_0}}$	75
$0<x\leqslant 1$	$M=\left\{v_0\frac{(\alpha^n-1)(1-x_0)}{1+x_0(\alpha^n-1)}+H\left[\frac{\ln[1+x_0(\alpha^n-1)]}{x_0\cdot n\cdot\ln\alpha}-1\right]\right\}x_0;\ t_0=\frac{M}{j_0}$	67
$x\ll 1$	$t_0=\frac{\left[v_0(1-e^{\varepsilon.i})+H\left(1-\frac{1-e^{\varepsilon.i}}{\varepsilon n}\right)\right]}{L\varepsilon}$	67

t is the time to reach steady state, L is the flow of material in the column (mole h^{-1}), x_0 and x_n are the initial and the final concentration, n is the number of theoretical plates, H is the delay for one plate, v_0 is the capacity of the still, t_0 is the total relaxation time of the column, j_0 is the limiting transfer, M is the total equilibrium hold-up in the column.

VII. CHROMATOGRAPHIC METHODS

The field of application of chromatographic methods of measuring separation coefficients is rapidly expanding. It already includes phenomena such as liquid–vapour and liquid–gas equilibria, sorption of vapours and gases on solid sorbents, ion exchange and non-ionic sorption on resins, liquid–liquid equilibria, and homogeneous reactions in solutions. These methods are being applied to the separation of a wide variety of mixtures. Examples of their successful application to the separation of every kind of difficult mixture can be found in numerous textbooks, review articles, and bibliographies. We need only mention some of the most important classes of mixtures: isotopes, isomers, inorganic and organic polymers, rare earths and actinides, numerous homologues and genetically related compounds, aminoacids, polypeptides, sugars, and other biologically active materials.

All three main variants of the chromatographic process (elution, frontal, and displacement methods) can be used to measure small separation coefficients. The development or elution method has attracted most attention, the frontal method has attracted the least. A vast amount of work has been devoted to the separation of the most diverse materials by elution, but often the authors have neglected to calculate the separation coefficients even when sufficient information was available.

We shall consider below the special equations which allow measurement of ϵ from quite small separation effects in small columns. These equations are valuable mainly in measurements of $\epsilon \ll 1$, i.e. in problems as difficult as isotope separation, but they can also be used successfully in the study of many other difficult mixtures.

1. Elution Chromatography

The principle of the method is the following: a sample of the mixture to be separated, containing much less material than the total capacity of the sorbent in the column, is introduced at the top of the chromatographic column. A mobile phase (liquid or gas) containing a displacement agent is then used to elute the sample. The condition for the establishment of the elution regime is that the affinity of the displacement agent for the sorbent must be less than the affinity of any component of the mixture. As a result of elution, the components move downwards along the column, at different rates, and gradually become separated. In addition, each individual band becomes broader as it moves downwards. The effluent at the bottom of the column consists of concentration waves of the various components, overlapping to a greater or lesser extent. The extent of overlap depends on the distribution coefficients of the components between the mobile and the stationary phase, and also on the length and the efficiency of the packing, and on the operating regime of the column. Initially, the form of the concentration peaks depends on the type of the adsorption isotherms of the components, but further down the column it approaches the shape of a Gaussian distribution. If the adsorption isotherms are linear and mutually independent, the relationship between the distribution coefficients λ_i of the components, their separation coefficients α_i, and the volumes v_i and v_j of the mobile phase for which the respective concentrations are at a maximum takes the simple form

$$\alpha_{ij}=\frac{\lambda_i}{\lambda_j}=\frac{\bar{v}_i-v_0}{\bar{v}_j-v_0};\quad \varepsilon_{ij}=\frac{\bar{v}_i-\bar{v}_j}{v_j-v_0}, \tag{27}$$

where v_0 is the free volume of the column.

Thus, the measurement of separation coefficients by elution chromatography involves, firstly, the establishment of conditions consistent with the assumptions made in the derivation of the equations, and secondly a very accurate measurement of the quantities $\bar{v}_i$, $\bar{v}_j$, and v_0.

The condition of linearity and mutual independence of the sorption isotherms is best satisfied at low concentrations of the materials to be separated. However, the initial concentration of the mixture in the mobile phase is usually fairly large, and in relatively short columns the concentration peaks do not achieve the Gaussian form. In long columns, the concentration peaks travel through most of the distance at fairly low concentrations, such that the sorption–desorption process takes place in the linear part of the isotherm. Also, the components in this case are almost completely separated provided that the enrichment coefficient ϵ is not too small, and the problem of possible interaction between the components ceases to be relevant. If the separation achieved is sufficient to allow direct measurement of $\bar{v}_i$ and $\bar{v}_j$, the separation coefficient is measured directly by means of Eqn. (27).

When the isotherms show substantial deviation from linearity, the concentration peaks are often seriously distorted when separation is complete. In these cases formula (27) gives only approximate values of ϵ_{ij}, and a better estimate is obtained by inserting $\bar{v}_i$ values corresponding to the centre of gravity of the various bands [77] instead of the concentration maxima.

When $\epsilon_{ij} \ll 1$, and also when short columns are used, the individual bands overlap so strongly that direct determination of $\bar{v}_i - \bar{v}_j$ is impossible: the detector finds only a combined peak for two or more components, and its shape is indistinguishable from that of the individual components. Special relationships, allowing indirect measurement of $\bar{v}_i$ and $\bar{v}_j$, must then be used.

By applying the general theory of elution chromatography [78] to the separation of substances with closely similar properties, Glueckauf obtained [79] the following relationship between the separation of the components i and j and the elution volume v:

$$\ln Q_{ij} = \varepsilon_{ij} N \frac{\bar{v}_\Sigma - v}{\sqrt{\bar{v}_\Sigma - v}}, \qquad (28)$$

where $\bar{v}_\Sigma$ is the elution volume corresponding to maximum total concentration and N is the number of theoretical plates in the column†. Glueckauf's expression can easily be converted into the form

$$\varepsilon_{ij} = -N \frac{d \ln Q_{ij}}{d \ln v}. \qquad (29)$$

The precision with which ϵ can be measured depends on the precision of the estimate of N as well as on the precision of the measurement of separation as a function of volume. When the shape of the elution waves corresponds accurately to the normal Gaussian distribution the value of N can be calculated [77] by the expression

$$N = 8\left(\frac{\bar{v}_\Sigma}{B}\right)^2, \qquad (28a)$$

where B is the width of the peak at a concentration a factor of e below the maximum. If the peak is distorted, on the other hand, it is better to use Keuleman's expression

$$N = 16\left(\frac{\bar{v}_\Sigma}{W}\right)^2, \qquad (28b)$$

where W is the base of the triangle obtained by drawing two tangents through the points of inflection of the elution peak.

Two unsatisfactory aspects of Eqns. (28) and (29) must be pointed out. Firstly, the calculation of ϵ requires a knowledge of the differential of the degree of separation with respect to volume, involving at least ten measurements of Q_{ij} for different fractions of the total peak. Secondly, these equations assume relatively large column lengths, in which the total capacity of the sorbent is large compared with the amount of material in the initial sample. Some expressions compatible with simpler experimental procedures are described below.

As before, we assume [82] that the individual peaks are in every way similar to the combined peak, i.e. we consider only very weak separations of the peaks. No assumption is made as to the shape of the peaks, and therefore no limitation is imposed on the size of sample in relation to the capacity of the column. According to this method, the concentration peak at the outlet of the column is divided into two parts containing approximately equal amounts of the mixture. These two parts are then analysed for the components. Consider the separation of a binary mixture. The general expression takes the form

$$\Delta x = x_t - x_h = \frac{(m_h + m_t) \cdot \varkappa_0 c_\Sigma \varepsilon (\bar{v}_\Sigma - v_0)}{\{m_t (1+\varkappa_0) + c_\Sigma \varepsilon [N - \varkappa_0 (1-N)] (\bar{v}_\Sigma - v_0)\}} \times \times \frac{1}{\{m_h(1+\varkappa_0) - c_\Sigma \varepsilon [N - \varkappa_0 (1-N)] (\bar{v}_\Sigma - v_0)\}}, \qquad (30)$$

where x_t and x_h are the mole fractions of the component in the tail and the head parts of the combined peak, m_t and m_g are the amounts of mixture in the same parts, c_Σ is the total concentration at the point where the peak is cut, $\kappa_0 = x_0/(1 - x_0)$, $\bar{v}_\Sigma$ is the elution volume corresponding to the centre of gravity of the combined peak, v_0 is the free volume of the column, N is the tail section of the base of the triangle W (see above) defined by the tangents to the peak.

For $m_t \simeq m_h$ the expression simplifies to

$$\varepsilon = \frac{(1+\varkappa_0)^2 \cdot \Delta x (m_t + m_h)}{4 c_\Sigma \cdot \varkappa_0 \cdot (\bar{v}_\Sigma - v_0)}. \qquad (31)$$

Eqn. (30) can be generalised for the case of a multicomponent mixture, involving division of the peak into several parts [83].

2. Development and Frontal Chromatography Method

In the development chromatography method, the mixture to be separated moves along the column in the form of steady-state bands which retain their linear dimensions by virtue of a specially chosen set of conditions (initial form of the sorbent, presence of a desorbent). In a system of coordinates strictly related to the steady-state band, this method has the properties of a rectangular cascade operating in the total reflux regime [76,84]. Hence, all the expressions derived for the evaluation of α and ϵ in rectangular cascades are applicable in principle to the development chromatography method. The total reflux [84] and constant transfer [76] methods have been used in practice.

Separation by the frontal method is also described by rectangular cascade equations. The only difference from the development variant is that the band of varying concentrations (or band of concentration gradients) must now be treated as a rectangular cascade operating in the open mode [67,85].

VIII. CRAIG'S METHOD (COUNTERCURRENT EXTRACTION)

The principle of the method is as follows [86]. We postulate a system containing a sufficiently large number of identical contact cells in series, which can be interconnected at will, and containing equal amounts of phase A. At time zero, we introduce into the first cell a volume of the second phase (B) containing two substances I and II, whose exchange with phase A involves linear distribution isotherms:

$$\frac{c_{IA}}{c_{IB}} = \lambda_1 \text{ and } \frac{c_{IIA}}{c_{IIB}} = \lambda_2.$$

After sufficient time, equilibrium distribution of the two substances between the phases will be established in the first contact cell. The mobile phase B is then completely transferred to cell 2, and the same volume of phase B

†An expression similar to Glueckauf's has been proposed independently [80]. However, the authors (who used the Mayer–Tompkins theory of chromatography [81]) treated elution as a stepwise process, and therefore their expression is inaccurate.

(without the substances to be separated) is introduced into cell 1. Equilibrium is again allowed to develop in both cells, and the equilibrium phase B is transferred from cell 1 to cell 2 and from cell 2 to cell 3, pure phase B being again added to cell 1. All these operations are then repeated the requisite number of times. The overall operation shows some close similarities to elution chromatography, from which it differs only in that the equilibration processes and the relative motion of the phases are separated in time, and the motion of the two phases is stepwise.

However, these differences are reflected only in the quantitative aspects of the problem. The distribution curves of the components after a sufficiently large number of steps look like elution chromatograms, and correspond to the normal Gaussian distribution. In common with elution chromatography, the method allows any number of components to be separated at the same time (Fig. 5). Furthermore, the Craig method is a more complex variant of the multistage condensation method, since the tail fractions of both phases are effectively subjected to multistage stripping, and their compositions must therefore obey the equations which describe this method.

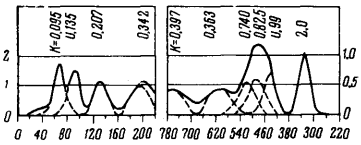

Figure 5. Distribution of aminoacids in a 220-cell Craig apparatus. From left to right, peaks correspond to tryptophan, phenylalanine, leucine, isoleucine, tyrosine, methionine, valine, α-aminobutyric acid, alanine, and glycine.

The theory of elution chromatography with stepwise motion of the mobile phase developed by Mayer and Tompkins [81] is fully applicable to the Craig process. This theory gives the relationship between the coefficients of the isotherms of the components, the ordinal number (p) of the volume of mobile phase, the ordinal number (n) of the contact cell, and the concentrations of the components in either phase.

Three methods of determining small separation coefficients in systems equipped with a sufficient number of contact cells can be distinguished.

1. By analogy with the elution chromatography method, we can use Eqn. (26), allowing however for the fact that $v_0 = 0$. According to Mayer and Tompkins [81], the maximum concentration of any component is achieved, for a given number n of cells, after the passage of a volume $P_i = n\lambda$. The maximum values of c_i and c_j are related by

$$\varepsilon_{ij} = \frac{\overline{P}_i - \overline{P}_j}{\overline{P}_i}.$$

If ϵ_{ij} is large enough, P_i and P_j can be determined directly by any convenient analytical method, and a large number of contact cells is no longer required. But if $\epsilon_{ij} \ll 1$, it becomes possible to measure ϵ indirectly (as in Glueckauf's method). The concentrations of components i and j in the fractions of the mobile phase appearing at the outlet of the Craig system are related by the equation (in which n = const)

$$\ln \frac{c_{ip}}{c_{jp}} = \ln \frac{\lambda_1}{\lambda_2}(p-1) + (p+n)\ln \frac{1+\lambda_2}{1+\lambda_1}. \quad (32)$$

After differentiation and some simplification we arrive at the expression

$$\ln \alpha = \frac{d \ln Q_{ij}\,(1+\lambda)}{dp}, \quad (33)$$

where λ is the distribution coefficient for the combined substances i and j.

2. If the Craig process is carried out with $p \leq n$ (i.e. no mobile phase is withdrawn at the outlet of the system), it is easy to show by means of the Mayer–Tompkins theory that the separation of the components in the two extreme cells (numbers 1 and n) are described by Eqn. (34). In this variant, the equality

$$p + n = p' + 1,$$

applies in any cell, where p' is the total number of steps made in the system. Substituting this equality into Eqn. (32) we arrive at [76]

$$\ln Q_{ij} = (n-1)\ln \alpha; \quad \alpha = \frac{d \ln Q_{ij}}{dn}. \quad (34)$$

3. Lastly, as stated above, the end fractions of both phases undergo double multistage extraction in Craig's process, and therefore any of the expressions given above for the multistage condensation method can be used to calculate the separation of the components in the end fractions. In one sense, the Craig process is more economical (by a factor of two) than the normal double multistage condensation method. Half as many operations are needed to achieve a given separation, since one Craig operation results in the extraction of both end fractions.

The process has so far been applied only to the separation of substances by extraction, because the two phases can be separated rapidly and quantitatively with the apparatus developed by Craig and Past [87]. In principle, however, the method is applicable to any system including a mobile liquid phase, i.e. to the whole range of solution–sorbent systems. The main use of the method has been as a convenient laboratory means of separating substances and analysing mixtures.

D.I.Mendeleev and His Discovery

V.N.Kondrat'ev

The centenary of D. I. Mendeleev's discovery of the Periodic Law of the chemical elements is being celebrated during 1969 by scientists in many parts of the world. The significance of this discovery in relation to the development of chemistry, physics and borderline sciences as well as for the advancement of agriculture and industry cannot be overestimated. It is impossible to visualise modern science and technology without the Periodic Law which has been a guide line both for theoretical and practical advances.

Mendeleev's discovery of the Periodic Law was not an accident. He, like many scientists whose names are associated with some scientific discovery, had predecessors. The discovery of the Periodic Law is a particularly good example of the sequential type of scientific thinking which is characteristic of all sciences and of all periods in time.

In order to understand the position which chemistry had reached by the time the Periodic Law was discovered one must recall the great chemical revolution associated with Lavoisier, the celebrated French scientist. In Lavoisier's time chemistry consisted of a mass of facts which needed to be arranged systematically and comprehended. Lavoisier created a new system in chemistry by drawing on the experience of his predecessors and his contemporaries and on the results of his own experiments; this system completely refuted the then accepted phlogiston theory. In his "Elementary Course of Chemistry" written in 1789, Lavoisier gives a list of "simple substances" which formed the foundation of the chemical nomenclature which he introduced. Among these simple substances Lavoisier distinguished what he termed "elements", defining them as simple substances which could not be broken down by chemical analysis. He included among them oxygen, nitrogen and hydrogen which he had discovered. Lavoisier was clearly aware of the fact that the concept of "a simple substance—an element" which he had introduced was in a sense relative, since, as he said in his text-book of chemistry "a given substance represents the contemporary limit of chemical analysis" since "at the present stage of our knowledge, analysis cannot further fragment it".

In fact all the subsequent advances in analytical chemistry, which had been enriched by new techniques (to mention a few; gas analysis, electrolysis, spectroscopic analysis), have characteristically led to the separation of a number of Lavoisier's simple substances into elements which could not be broken down any further. Many new elements were already discovered in the first quarter of the nineteenth century. Among the alkali metals discovered then were lithium, sodium and potassium, among the halogens—fluorine, chlorine and iodine; a series of metals of the platinum group—palladium, rhodium, osmium, iridium and ruthenium (platinum itself having been discovered in the eighteenth century), a number of alkali and alkaline earth elements, and many other elements were discovered at the beginning of the nineteenth century. Their discovery is associated with the names of such renowned scientists as Berzelius, Gay-Lussac, Davy and many others—chemists and physicists from many countries: Britain, France, Germany, Holland, Sweden, Russia and others.

The large numbers of elements newly discovered now had to be designated. The symbols for the elements which have been retained to the present day were proposed by Berzelius in 1813.

Dalton's atomic theory (1803), published by him in 1808 in a two-volume book "A New System of Chemical Philosophy", played a key role in defining the concept of an element. One of the hypotheses of Dalton's theory states that "every chemical element consists of simple atoms proper to it, which are different from the atoms of every other element". With the help of symbols which he introduced, Dalton could represent the molecules of various compounds (he called molecules complex atoms) by formulae which were sometimes quantitative. Thus, for example, he represented the molecule of carbon dioxide by a formula which consisted of three spheres—two white ones (representing atoms of oxygen) on the outside and a black one (representing an atom of carbon) between them. These were the first quantitative chemical formulae.

The discovery of new elements was parallelled by investigations of the chemical and physical properties of the elements and their compounds. In order to determine the structure of various substances it was essential to know their elemental composition quantitatively. Bergman in Sweden was the first to begin quantitative study of the composition of chemical substances, he started as early as 1770. Lavoisier placed exceptional emphasis on the quantitative analysis of substances and he, together with the French school of chemists and chemists in other countries, were responsible for developing many new techniques for exact quantitative analysis. The quantitative study of chemical substances is based on the law of the constancy of their composition. The French chemist Proust, who was much concerned with the preparation of chemically pure substances and their analysis, formulated this hypothesis as follows: "Nature, even through the agency of man, never produces compounds without scales in her hands—by weight and by measure". The techniques of quantitative analysis naturally continued to improve with time, reaching ever greater degrees of precision.

Much attention was paid to the study of the chemical properties of the elements. Investigations of the composition of chemical substances led to the concept that all substances were formed by the substitution of some atoms or groups of atoms by other ones. This view was first expressed by Dumas and Regnault in 1840 and developed further by Gerhardt and Kekulé. It followed from this concept that the atom of each element has a certain "capacity", i.e. can substitute or add on only a quite definite number of other atoms. This conclusion was reached by the British chemist Frankland in 1848-1852. The quantitative measure of such capacity is given by the valency of the atom—a term introduced by Wichelhaus in 1868.

Long before this, at the end of the eighteenth and beginning of the nineteenth century it was shown that chemical elements combined with one another in definite ratios by weight, which in itself asserted the constant nature of chemical substances. Analysis of oxygen compounds resulted in determining the amounts of various elements which combined with the same amount of oxygen. Wollaston (1814) called these values chemical equivalents. Ber-

zelius and Richter were largely responsible for determining precisely the weight ratios and chemical equivalents of elements. Faraday, working on the quantitative studies of electrolytic phenomena, opened up new possibilities for measuring chemical equivalents. Faraday measured the amounts of various elements by passing the same current through a solution of electrolyte and referring these to the amount of one of the elements, calling them electrochemical equivalents. The latter proved to be identical with the chemical equivalents. When the concept of valency was introduced it became evident that these values represented the ratio of the atomic weight to the valency of an element.

Thanks to the accuracy of determining the weight ratios of the elements Berzelius could determine equally precisely the atomic weights of many of the elements known in his day. The Belgian chemist Stas should be mentioned here; he determined very accurately the atomic weights of oxygen, silver, nitrogen, sulphur, chlorine, bromine, iodine, potassium, sodium, lithium, lead and carbon using his measurements of chemical equivalents. The Avogadro hypothesis played an important part in the exact determination of gaseous substances. Taking this hypothesis as a basis, Cannizzaro proceeded in the eighteen-fifties to establish more precisely the atomic weights of a series of elements, including hydrogen, oxygen, chlorine and others. Dulong and Petit found in 1819 that the product of the heat capacity of a solid element and its atomic weight had a constant value (the Dulong and Petit Law). Using this Law, Regnault first found the correct atomic weights of bismuth, silver, potassium and sodium, and Cannizzaro determined the atomic weight of copper and other elements.

As the result of the Herculean labours of many chemists and physicists from various countries and nations by 1869 there were 64 elements instead of the 35 simple substances of Lavoisier (1789), of which no more than 20 could be accurately described as elements; for most of these 64 elements the atomic weights were known sufficiently accurately, as were their chemical and some physical properties. All this accummulated material now needed to be systematically arranged.

The first attempt in this direction was made by Doebereiner who as early as 1829 noted that some elements which were similar in their chemical properties could be grouped into threes (triads). Such triads included: chlorine, bromine and iodine; lithium, sodium and potassium; and calcium, strontium and barium. At the same time in each such triad there was some consistency in relation to the atomic weights of the elements forming the given triad, viz., the atomic weight of the middle element in the triad was approximately equal to the arithmetic mean of the atomic weights of the two end elements. In 1851 Dumas gave some attention to Doebereiner's triads.

In 1850 Pettenkofer published a table of the equivalent weights of eighteen elements, arranged in five groups consisting of elements with similar chemical properties. Three of these groups included the elements which figured in Doebereiner's triads, but they now consisted of four elements, e.g. oxygen, sulphur, selenium and tellurium formed a group. He also noted that the difference of the equivalent weights in each group was approximately a multiple of a whole number. In the lithium, magnesium and oxygen groups this number equalled 8. Analogous groups of elements also appeared in Dumas (1851). In 1857 Lenssen's table appeared, in which he quite formally grouped all the elements then known into triads, with the result that some triads contained as chemically dissimilar elements as, for example, oxygen, nitrogen and carbon. In 1862 de Chancourtois arranged all the elements in an ascending order of atomic weights along a helix encircling a cylinder whose circumference he divided into 16 equal parts. Some elements with similar properties were found to lie one over the other along a vertical line, but this was not always the case. De Chancourtois worked on the hypothesis that the properties of the elements change periodically, each period consisting of 16 elements.

In his book "Modern Theories of Chemistry and their Significance for Chemical Statics" which was published in 1864, Lothar Meyer using new, more accurate atomic weights, made up three tables in which elements with similar valency (or atomicity as he termed it) were grouped together; in other words the chemical properties of the elements in each group were similar and there was an approximately constant difference in their atomic weights. The first table contained quadrivalent elements from carbon to lead, trivalent ones from nitrogen to bismuth, divalent ones from oxygen to tellurium, monovalent ones from fluorine to iodine, monovalent metals from lithium to caesium (Meyer included in this group also thallium, which he erroneously considered as a monovalent metal) and divalent metals from beryllium to barium. In the second table Meyer put quadrivalent titanium, zirconium and tantalum and hexavalent molybdenum, vanadium and tungsten. The third table contained quadrivalent manganese, iron, ruthenium, platinum, nickel, rhodium, iridium, cobalt, palladium and osmium, divalent zinc, cadmium and mercury, and without indicating their valency, copper, silver and gold. Meyer wrote: "Undoubtedly, there is some regular consistency in the numerical values of the atomic weights ..." without attempting to discover what this consistency might be. In the same year, 1864, Odling presented a table of the elements in his text-book of chemistry also using the new atomic numbers without indicating the principle underlying the arrangement of the elements in the table and only remarking that "the regular arithmetic ratios represented by the atomic weights are too numerous and too clear not to depend on some unknown law". Finally, one must also mention the table made up by Newlands in 1866, in which the elements were arranged in order of ascending atomic weights, eight to a row. Newlands called his table "the Law of Octaves" and noted a periodic recurrence of the elements' properties. At the same time there are obvious inconsistencies in Newland's table, such as for example the appearance of such dissimilar elements as hydrogen, fluorine and cobalt in one group.

It can thus be seen that by 1869 there were already many attempts at systematising all the then known chemical elements. Mendeleev was aware of all these attempts and divided them into artificial, i.e. formal ones, and natural ones. He assigned attempts such as Newland's octaves to the former, and those tables which were based on chemical and other properties of the elements—to the latter. This principle, which was the only correct one, also underlay Mendeleev's own system of the elements, which he rightly termed natural.

Unlike his predecessors, who could not see the general law which some of them only vaguely guessed at beyond the particular relationships noted for individual groups of elements, Mendeleev aimed right from the start at finding a general law which would be characteristic of the system of the elements as a whole. In his article "The Problem of a System of the Elements", Mendeleev wrote: "I took, with a few exceptions, the same groups of similar elements as did my predecessors, but my aim was to study the consistent features in the relationships between the groups. This led me to ..... a general principle which is applicable to

all the elements and embraces many of the previously expressed analogies, but also allows consequences which would have been formerly impossible". Speaking to the Chemical Society in England in 1889, Mendeleev said that his predecessors de Chancourtois and Newlands had "stood foremost in the way towards the discovery of the periodic law, and that they merely wanted the boldness necessary to place the whole question at such a height that its reflection on the facts could be clearly seen". It is not, of course, a question of their having lacked decisiveness and his having had the necessary daring and persistence. The discovery of the Periodic Law was the culmination of the whole of Mendeleev's earlier scientific endeavour. As his colleague, Ozarovskaya, relates, when she asked Mendeleev how his periodic system occurred to him, he said: "I have been pondering on it for perhaps twenty years".

Referring to one of his first scientific papers "Isomorphism in Connection with Other Relationships of the Crystalline Form to Composition", which he presented as a dissertation on graduating from the Principal Pedagogical Institute in St. Petersburg in 1855, Mendeleev wrote: "The writing of this dissertation involved me predominantly in the study of chemical relationships. It determined much of what was to come".

Mendeleev's particular scientific outlook and the breadth of his views and interests played an exceptional role in the fact that he was the first to see that the laws of the periodic system of the elements were of outstanding significance for the development of science. L. A. Chugaev, in characterising Mendeleev as a scientist of exceptionally wide horizons, wrote in his biographical article: "Mendeleev .... had the ability to bring a philosophical outlook to chemistry, physics and other natural sciences with which he came into contact, and a scientific experimental approach to problems in philosophy, economics and sociology". Further on Chugaev wrote: "in his endeavours to take into account the physical conditions and factors of chemical processes, Mendeleev was imperceptibly led into probing questions poised on the borders between chemistry and physics; he became interested in solutions and isomorphism, capillary phenomena, changes in state for substances and, in particular, the change in the volume of gases as a function of pressure and temperature. Work with rarefied gases opened up for him wide vistas of possible applications to meteorology; he developed a desire to probe the conditions prevailing in the upper strata of the atmosphere; he carried out remarkable work on the flow resistance of liquids, closely related to the problems of aeronautics, etc.". And further on: "With such a broad sweep of thought and many-sidedness of activity, all Mendeleev's work was both deeply pondered and carefully carried out. This became possible only thanks to his extraordinary capacity for work, which enabled him to work throughout whole nights, with hardly a few hours' rest".

While studying capillary phenomena Mendeleev discovered critical temperature which he termed "the temperature of absolute boiling". Mendeleev's studies of the compressibility of liquids, of solutions, of ammonia-metal compounds and thionic acids, as much of his other research, invariably represented new advances in science. The range of Mendeleev's scientific views and interests can be judged from his works on fuels, petroleum technology, explosives, metallurgical problems, metrology, agriculture and many other topics.

D. I. Mendeleev was born in 1834, the son of the Director of the Tobolsk Gymnasium. He entered the Gymnasium in 1841, finishing school in 1849, and in 1850 he was accepted at the Principal Pedagogical Institute in St. Petersburg. He graduated from the Institute in 1855 with a Gold Medal and was appointed to teach science in Simferopol, from which he moved to Odessa when the school in Simferopol was closed because of the Crimean War. Towards the end of 1856 Mendeleev returned to St. Petersburg. He gained his Master's degree there and defended a dissertation for the title of Privatdozent; in 1857–1858 he began teaching organic chemistry at the University of St. Petersburg. In January 1859 Mendeleev was sent abroad, to Heidelberg, for two years, returning in 1861. Whilst abroad, Mendeleev took part in the famous International Chemical Congress in Karlsruhe in 1860. When Mendeleev returned to Russia he resumed lecturing at the University. In 1861 he published his book "Organic Chemistry" which was the first Russian text-book of organic chemistry. In 1864 Mendeleev was elected Professor at the Department of Chemistry of the Petersburg Technological Institute. In 1865 he presented his doctoral thesis "The Combination of Alcohol with Water" and at the end of that year his appointment as Professor of St. Petersburg University in the Department of Technological Chemistry was ratified. In 1867 he was appointed to the Chair of General Chemistry.

In 1876 Mendeleev was elected Corresponding Member of the Petersburg Academy of Sciences. He was an honorary member of five Russian Universities. Mendeleev was also awarded honorary degrees by Cambridge, Oxford and several more of the oldest Universities of Europe. He was elected Fellow of the Royal Society of London; member of the Rome, Paris, Berlin and other Academies of Science and honorary member of many scientific Societies. In 1896 Mendeleev became head of the Principal Bureau of Weights and Measures in St. Petersburg. Mendeleev died in 1907, in St. Petersburg.

Mendeleev was convinced of the existence of a periodic law by the periodicity of the chemical properties of the elements which he had clearly demonstrated in his Natural System of the Elements in 1870, by the formulae of the higher oxides and hydrides of the elements, the regularities in the realtionships of the atomic weights of the elements in each group of chemical analogues, the periodicity in the change of specific gravities and atomic volumes, in the properties of the various compounds of the elements and in a number of their other special features.

Mendeleev was deeply convinced that the Periodic Law was objectively correct and of the utmost scientific and practical importance and he spared no effort in making it widely available to science as soon as possible. He wrote: "Each law of Nature becomes of scientific significance only if it allows, as it were, some practical consequences, i.e. logical deductions of the sort that would explain the hitherto unexplained and indicate phenomena unknown until then, and especially if the law leads to predictions which can be verified experimentally".

Mendeleev used the Periodic Law to predict the existence and properties of many of the then unknown elements. The first one was gallium, discovered by Lecocq de Boisbaudran in France in 1875, scandium, discovered by Nielsen in Sweden in 1880 and germanium, discovered by Winckler in Germany in 1886. The discovery of these elements was a triumph for the Periodic Law, and many of those who at first doubted that Mendeleev's Law was in fact general and correct, became his supporters.

The same conviction of the rightness of the Periodic Law enabled Mendeleev to alter the atomic weights of a number of elements. Thus, for example, he indicated that according to his Periodic System uranium should be hexavalent and not trivalent as had been accepted up to then, and hence the atomic weight of uranium should be 240 and not 120.

CHEMICAL SOCIETY REFERENCE LIBRARY BURLINGTON HOUSE, W.1

The atomic weight of indium was similarly corrected from the previously accepted 75 to 113. The atomic weights of uranium and indium are now known to be 238.07 and 114.82 respectively.

With time the atomic weights of elements were corrected and determined more precisely, new elements were gradually discovered as predicted by Mendeleev and marked with dashes in the empty positions of his Table. Some of these elements were not discovered until many years after Mendeleev's death in 1907. Thus, rhenium (Mendeleev's bimanganese) was discovered by V. and E. Noddack, Tacke and Berg in 1925, and francium (ekacaesium) by Perey in 1939.

Mendeleev, naturally, could not have predicted the group of inert gases because of their characteristic chemical inertness. Rayleigh and Ramsay discovered argon in 1894 in England, and in 1895 Ramsay discovered helium which had been discovered as early as 1868 in the sun's atmosphere by its spectrum (Jansen and Lockyer). Ramsay was convinced that helium and argon were chemical analogues, unlike any of the known elements in their chemical properties, and therefore must constitute a separate group in Mendeleev's Table; in 1897 he therefore predicted, on the basis of the quantitative relationships of the atomic weights of the elements in each group that other elements must exist in the helium group with the atomic weights of 4(helium) + 16 = 20, 40(argon) + 44 = 84 and 84 + 44 = 128, which he and his assistant Travers subsequently discovered in the atmosphere. The new rare gases, as Ramsay named them, had the following atomic weights: 20.18 (neon), 83.7 (krypton) and 130.2 (xenon). The group of rare elements was included by Mendeleev in his Table as the zero group.

Nevertheless, neither the creation of new groups, nor the more accurate determination of the atomic weights could remove those exceptions, although not numerous, which were observed in the distribution of the elements in Mendeleev's Table. Namely, in arranging the elements in an ascending order of atomic weights, Mendeleev had to make the following exceptions: potassium, with an atomic weight of 39.10 was placed before argon with an atomic weight of 39.94, nickel (58.69) after cobalt (58.93) and iodine (126.93) after tellurium (127.61). Apart from these exceptions Mendeleev encountered difficulties in placing the rare earth elements (lanthanides). He wrote in the eighth edition of "The Fundamentals of Chemistry": "For some rare metals with the R_2O_3 type of oxides there is no place in Group III of the Periodic Table .... I have not yet found any personal interpretation of this, and it appears to me as one of the most difficult problems presented by the Periodic Law".

These and similar difficulties (especially the difficulties in arranging the actinides) were not, and could not be, solved during Mendeleev's lifetime, since the atomic weight was the only reliable characteristic of an element then available.

Several years after Mendeleev's death his Periodic Law found an ally in the theory of atomic structure which began to develop vigorously from 1911, when Rutherford discovered the atomic nucleus. The next important step along the path of discovery of atomic structure and establishment of a connection between the structure of the atom and the Periodic Law was made by Moseley in 1913. Moseley studied the X-ray spectra of various elements and as a result of these established a simple connection between the wave length of certain lines of the characteristic X-ray spectra of the elements and their atomic number, which Moseley correctly identified with the nuclear charge, expressed in units of elementary charge. The truth of this conclusion was substantiated a little later in the very first experiments on alpha-particle scattering performed by Chadwick in Rutherford's laboratory. These experiments gave values for the nuclear charge in the atoms of copper, silver and platinum (29.3, 43.3 and 77.4) which coincided, within the limits of experimental error, with the atomic numbers of these elements in Mendeleev's Table (29, 47 and 78 respectively). It followed from this, and from later experiments, that the nuclear charge was always equal to the atomic number of the element in the periodic system.

It is also noteworthy that the experiments carried out by Barkla and others on X-ray diffraction by various elements revealed that for all the light elements investigated, the nuclear charge was equal to half the atomic weight. If a difference between half the atomic weight and the atomic number of the element amounting to 0.5 or less is taken to be negligible, then half the atomic weight is equal, with this degree of accuracy, to the atomic number from helium to argon, and only starting with argon does the atomic weight increasingly outstrip (twice) the atomic number of the element. The arrangement of the elements in a periodic table according to their atomic weight, as made by Mendeleev and his predecessors (before atomic numbers and their physical significance were known) acquired a theoretical basis only for the first three periods in the periodic system. The discovery of atomic numbers and the development of the atomic theory provided the Periodic Law, for the whole series, with a new and definitive formulation: the properties of the chemical elements show a periodic change related to their atomic number.

If the theory of atomic structure proved to be an ally of the Periodic Law, the periodic system from its side played an exceptionally important role in the development of the atomic theory. Moreover, the question of atomic structure itself arose only after the discovery of the Periodic Law. Nevertheless, the "bricks" from which the atom could be built up only became known some 30 years after the discovery of the periodic system of the elements. The concept of elementary electric charge was first formulated clearly by Helmholtz in 1881, but the electron itself—one of these "bricks", was only discovered by J. J. Thomson in 1897. The other "brick"—the atomic nucleus, as already mentioned, was discovered by Rutherford in 1911. Following the discovery of radioactivity (Becquerel, 1896) and the formation of helium as the result of radium decay (Ramsay and Soddy, 1903) it became evident that the elements could be transmuted one into the other, thus confirming the genetic interconnection of the elements, their mutual kinship. In 1913 Niels Bohr put forward the theory of the hydrogen atom. The hydrogen atom, with its electron levels, proved, in a sense, to be a prototype of all the elements in the periodic system. In 1924 Born and Heisenberg extended the theory of the hydrogen atom to the alkali metal atoms. In 1926 Heisenberg, using quantum mechanics as a basis, solved the problem of the helium atom, and then between 1926–1930 the theoretical problem of the atom with many electrons was solved.

The Pauli exclusion principle (1925), according to which an atom cannot have more than one electron characterised by the same set of four quantum numbers, the number n being able to have the values of 1, 2, 3, 4 etc., the quantum number l which can have values 0, 1, 2 ... $(l - 1)$, the quantum number m which can have values l, $(l - 1)$ ... $-l$ and the quantum number s which can be $+\frac{1}{2}$ or $-\frac{1}{2}$ (inserted by Ed. of Translation), the position of the electron in the atom is determined. This set of quantum numbers, together with Pauli's principle and the postulate that the

ground state of each atom is the state with the lowest energy, give the physical foundations of the periodic system of the elements. It follows from the values established in the quantum atomic theory and the relationship of the quantum numbers and the Pauli principle that, for a given value of the so-called principal quantum number n, which may be 1, 2, 3, 4, etc., the maximal number of electrons in an atom cannot exceed the value $2n^2$, i.e. 2, 8, 18, 32 etc. These electrons form a closed electron shell and are distributed among subgroups with the maximal number of electrons in each orbital being equal to $2(2l + 1)$ where the quantum number l has the values 0, 1, 2 ... $(n - 1)$. The electrons with the quantum numbers $l = 1$, 2, 3 etc. are called s-, p-, d-, f- etc. electrons, respectively.

It follows from the above formulae that the single-quantum shell of the atom ($n = 1$) contains two s-electrons. This shell cannot accommodate more than two electrons and is therefore a closed electron shell which is first filled in helium the atom and then remains unchanged throughout Mendeleev's Table. The two-quantum shell can accommodate six p-electrons in addition to the two s-electrons. This gives a second closed eight-electron shell, which is completed in neon and remains, like the single-quantum shell, closed throughout the Mendeleev Table. The next, three-quantum, shell contains a maximum of 18 electrons: two s-electrons, 6 p-electrons and 10 d-electrons. It was found that only the heavier elements, starting with copper (atomic number 29), possessed the maximal number of electrons, viz. 18. In the three lighter elements, argon, potassium and calcium (atomic numbers 18, 19 and 20) the still incomplete eight-electron third shell already showed the properties of a closed shell, as witnessed by the chemical and physical properties of the Ar atom and the K^+ and Ca^{++} ions.

This and similar facts can be explained as follows. In passing from an element with the atomic number N to the next heavier element N + 1, i.e. with an increase in the nuclear charge and the number of electrons by unity, the "(N + 1)-th" electron occupies the lowest possible energy level. The observed sequence of filling the electron orbitals of the first 20 elements (ending with Ca) indicates that the 19th electron in potassium and the 20th electron in calcium are not d-, but s-electrons, i.e. they are placed in the four-quantum shell which corresponds to the lowest energy; this also follows from the theoretical model of the K and Ca atoms. The d-orbital of the three-quantum shell only begins to fill starting with the next element, scandium (atomic number 21), which is complete in copper, as has already been mentioned. The irregularity with which this orbital is filled, determined each time by minimizing the energy of the atom, explains all those anomalies which are observed in the properties of the elements from scandium to copper. A similar irregularity in the filling of electron orbitals underlies the anomalies in the elements from yttrium to palladium, in the rare earth elements—from the 58th element, cerium to the 70th, ytterbium in which the 32-electron shell with $n = 4$ is first completed, and in the group of heavy elements starting with actinium (atomic number 89).

The discovery of isotopes and the insight into the structure of atomic nuclei played a significant part in the understanding of the structure of the system of the elements and the relationship between the atomic weight and the atomic number of the elements. The problem of the isotopes first arose after the discovery of radioactive elements—the number of products of the radioactive decay of uranium and thorium exceeded the number of free places in Mendeleev's Table. The only course open was to place the elements with similar chemical properties but different atomic weights into one space. Soddy, in 1910, called such variants of the element isotopes. It is interesting to note that the thought of the possible existence of isotopes had been voiced, in passing, by a number of nineteenth century scientists. Thus, for example, Butlerow, addressing the Russian Physico-Chemical Society in 1881 said: "... Most atomic weights approximate whole numbers to such an extent that it can hardly be considered fortuitous. Could it not be supposed that under certain conditions atomic weights might actually be expressed by whole numbers (related to H = 1), i.e. that the atomic weights represent values which, under certain conditions, can change within certain limits?" Isotopes proved not to be an exclusive feature of radioactive elements only. Already in 1912 J. J. Thomson found that there were two varieties of neon atoms, with atomic weights 20 and 22. Now we know that each element consists of a certain number of stable and radioactive isotopes.

It is also known that in addition to isotopes there are also isobars—isotopes of different elements which, however, have the same atomic weight. Their existence demonstrates particularly clearly that it is not the atomic weight but the atomic number of an element, i.e. the nuclear charge and hence the number of electrons in the atom, which determines the chemical and other properties of the element. In particular, the chemical properties of the elements, according to the atomic theory, are determined by the outer electrons of the atom and their energetics. The periodicity of the chemical and other properties of the elements is a direct consequence of the periodicity in the arrangement of the orbitals and sub-orbitals in the electron shells of the atoms.

Isotopes also played a big part in the creation of the theory of the atomic nucleus which, in turn, was of the greatest significance in interpreting the structure of the periodic system of the elements, in particular the relationship between the atomic weight and the atomic number of the elements. Nuclear forces acting between the nucleons—the component parts of the nucleus, protons and neutrons, which at a certain ratio between the number of protons and neutrons bind them into a whole—the atomic nucleus. However, besides the forces of attraction between the protons in the nucleus there are also forces of electrostatic repulsion, which make the nucleus less stable. When the number of protons in the nucleus is small the nucleus may remain stable even with an excess of protons since the nuclear forces are several times stronger than the repulsive forces. The light isotope of helium ^3He has such a nucleus, which consists of one neutron and two protons. The isotopes of all the elements following helium, however, are unstable when the number of protons exceeds the number of neutrons and this explains the fact that the higher the atomic number of the element, i.e. the larger the number of protons, the more does the number of neutrons in the nucleus of its stable isotopes exceed the number of protons.

We can thus see that the theory of atomic structure, of its electron shells and its nucleus, proved to be the physical basis upon which the periodic system of the elements rests. All the difficulties in arranging the elements within the system and the contradictions which arose during the first stages of constructing the system disappeared in the light of the atomic theory. At present the periodic system of the chemical elements forms the foundations on which rests all our science, the guiding light illuminating the progress of science in the future.

The role of the Periodic Law in the advancement of science was utterly clear to Mendeleev from the first years

of the existence of his periodic system of the elements. Addressing the Chemical Society in England in 1889 he referred to the Periodic Law as an "instrument of enlarging our mental horizon" and said that "the law of periodicity enabled us to perceive undiscovered elements at a distance which formerly was unaccessible to chemical vision".

The Periodic Law gave an impetus to the advance of inorganic chemistry. It had an enormous and decisive significance for the development of the atomic theory and the atomic nucleus, for nuclear physics and nuclear chemistry. It is exceptionally important for the development of geochemistry, geology, crystallography, mineralogy and metallurgy. It is a guiding light in catalysis and the consideration of the rates of chemical reactions. There is no branch of science where the Periodic Law does not exert its influence.

The whole world celebrates gratefully the centenary of Mendeleev's achievement and recalls the names of all those whose endeavours and genius have put before us the Periodic Law in all its majesty and brilliance.

Kinetics and Mechanism of Three-body Recombination of Atoms and Radicals

A.D.Stepukhovich and V.M.Umanskii

The review gives a general account of the results of numerous studies on the simplest atomic and radical reactions which are experimentally found to follow third-order kinetics. A large number of experimental results, arranged systematically in tables and graphs, are quoted and discussed. The principal characteristics of the properties of the reactions of this class (negative temperature dependence of the rate constant, different efficiencies of third bodies, relation between the efficiency and structure, etc.) are analysed. The possible interpretation of these processes on the basis of the simplest theoretical postulates—kinetic collision theory, theory of absolute reaction rates, and other equilibrium theories—are considered.
The bibliography includes 203 references.

I. INTRODUCTION

The hypothesis that elemenatry trimolecular reactions should be encountered very rarely because of the low probability of true three-body collisions arose already in the early stage of the development of chemical kinetics. Thus, according to Trautz [1], trimolecular reactions of the type A + B + C → product do not exist and pseudotrimolecular processes actually involve a complex mechanism: (1) A + B ⇌ AB; (2) AB + C → product. The rate-determining stage in the complex process is the second reaction, which does not affect the rapidly established equilibrium of the first stage. The kinetics of the oxidation of NO and of the formation of nitrosyl bromide and chloride were in fact interpreted from this standpoint.

The statistical calculations of Bodenstein [2], Tolman [3], Kassel [4], and Steiner [5-7] showed that, despite certain difficulties, a quantitative treatment of such reactions is indeed possible on the basis of the hypothesis that a three-body collision takes place in two stages: initially a pair (doublet) is formed and then a triplet following the approach of a third particle. Kassel [4] showed that, by taking into account the interaction between real gas molecules, it is possible to explain the characteristics of the temperature variation of the rate constant of a trimolecular reaction. The rate constant is written in the traditional form:

$$k = z_{\text{eff}} = Ae^{-E/RT} = ze^{-E/RT} \quad , \qquad (1)$$

where A and E are the pre-exponential factor and the activation energy for the trimolecular reaction and z, the number of three-body collisions per cm^3 per second, is calculated from the formulae of Tolman or Kassel:

$$z = 8\sqrt{2}\,\pi^{3/2}d_{12}^2 d_{23}^2 \delta \sqrt{kT}\left(\frac{1}{\sqrt{\mu_{12}}} + \frac{1}{\sqrt{\mu_{23}}}\right) N_1 N_2 N_3 \quad , \qquad (2)$$

$$z = 8\pi l_0^2 \sqrt{\frac{2\pi kT}{\mu}}\left(1 + \frac{\varphi_0}{kT}\right)\left[\int_0^{\rho_0} e^{-E(r)/kT} r^2 dr\right] N_1 N_2 N_3 \quad , \qquad (3)$$

where d_{12} and d_{23} are the gas-kinetic diameters of the doublets, μ_{12} and μ_{23} their reduced masses, N_1, N_2, and N_3 the numbers of molecules per cm^3, l_0 the distance between the particles forming the doublet, ρ_0 the distance between the centre of gravity of the doublet and the third particle, φ_0 the potential energy of the doublet, and $E(r)$ the potential energy at a distance r.

In the theory of equilibrium reaction rates [8,9] the formation of an activated complex from the free reacting molecules also may be preceded by a stage of the equilibrium formation of the binary complex AB with the subsequent formation of the trimolecular complex ABC as a result of the addition of the particle C (AB + C → ABC). The fundamental hypothesis is that equilibrium exists between the complex ABC and the initial reactants, the first equilibrium stage not affecting the equilibrium between the activated complexes and the starting materials A, B, and C. This permits a formal representation of the complex process as an elementary trimolecular reaction. Since three-body collisions between particles occur very rarely, it follows that, for trimolecular reactions to have rates which can compete with bimolecular reactions under certain conditions, they must have low activation energies or actually negative temperature coefficients, as happens in three-body recombination. The hypothesis that simple trimolecular reactions exist has become firmly established in chemical kinetics in connection with the study of the simplest process—the formation of diatomic molecules by the recombination of the atoms (H, O, Br, I, and others). By analysing the potential energy curves for the interaction between atoms, Born and Franck [10], Herzfeld [11], and Polanyi [12] showed that the formation of a stable molecule by the recombination of atoms requires the collision of the mutually approaching atoms with a third particle capable of absorbing the excess energy of the molecule just formed and thus enabling it to be stabilised "in the potential well"†. The transfer of excess energy from the excited molecule to the third particle may depend on the structure of the latter, in particular on the presence in its energy spectrum of resonating levels capable of accepting the excitation energy (vibrational or electronic energy) of the molecule in a collision of the second kind. This may account for specific effects of third bodies, without resorting to hypothesis that the specificity is due to the formation of complexes or intermediate compounds between one of the atoms or radicals and an external particle. The specificity of the effect then follows from the characteristics of the transformation and transfer of the energy of the excited particle, i.e. the transformation of its energy into one of

†Boltzmann [13] drew attention to this even earlier.

the forms of the internal energy of the third particle (vibrational, rotational, etc.), which means that the specificity follows from purely physical considerations. The mechanism of the recombination of atoms or radicals via energy transfer to a third particle is sometimes called in modern literature the "ET mechanism" (the energy transfer mechanism) [14].

The experimental study of the rate constants for three-body recombination of atoms shows that at moderate temperatures they are generally of the order of 10^{15} cm^6 $mole^{-2}$ s^{-1} and are characterised by low negative temperature coefficients, i.e. low negative activation energies in the range 0–5 kcal $mole^{-1}$. However, in some cases much higher rate constants have also been obtained experimentally for atomic three-body recombination reactions, indicating the specificity of the effect of third bodies. These data could not be explained within the framework of the ET mechanism. Furthermore, this mechanism, when applied to the specific effect of third bodies, had already encountered serious criticism in the early work of Rabinowitch [15]. A radical–molecular complex mechanism, called for brevity the RMC mechanism, has been proposed to explain the existence of more powerful effects of third bodies on the recombination of atoms or radicals. In three-body recombination reactions of atoms or radicals involving an RMC mechanism, the participation of a third particle in the process involves its ability to form reversibly with one of the radicals intermediate complexes having an excess excitation energy. This energy may be evolved in collisions between the excited complex and the third particle, after which the normal complex interacts with the radical to yield the product and the chemically unchanged third body. The RMC mechanism can provide a natural explanation of the specific effect of third bodies through the concept of reaction complexes, i.e. within the framework of the concept of homogeneous catalysis, which may accelerate the recombination and can account for the widespread occurrence of recombination with participation of third bodies, which play the role of process catalysts.

The question of the competition between ET and RMC mechanisms in each particular case can be resolved in principle by comparing the lifetimes of the corresponding intermediate species [14]. For example, in the recombination of atoms in the presence of fairly complex (or chemically active) third bodies the intermediate compound of the atom and the third body may be longer-lived thereby facilitating the reaction by the complex mechanism; on the other hand, the recombination of complex radicals in the presence of a simple third body will evidently be faster when the ET mechanism operates. However, these are unusual "limiting" cases. It may be that the lifetimes of the complex formed in the first stages of both mechanisms are comparable on *a priori* grounds and it is difficult to decide qualitatively what are the true relative contributions of the recombination mechanisms (for example in reactions with participation of simple unsaturated molecules).

Below we shall discuss in greater detail the experimental data for three-body recombination reactions of atoms and radicals on the basis of the collision theory, the theory of absolute reaction rates, and certain modifications of these theories.

II. EXPERIMENTAL DATA FOR THREE-BODY RECOMBINATION

During the past ten years special reviews have been devoted to experimental studies on three-body recombination reactions of atoms [16–19]. The most important general features of chemical processes of this type are discussed in the present review. We shall not be concerned with the problem of the three-body recombination of charged particles (ions and electrons), about which many experimental and theoretical papers have also been published recently [20–27,31].

The principal difficulty in the study of three-body recombination is usually the problem of obtaining a fairly high concentration of free atoms. The rapid increase of the number of studies on the kinetics and mechanism of three-body recombination from the middle of 1950's up to the present time is mainly due to the successful assimilation of new effective methods for the production of free atoms. These are flash photolysis [28–31] and the method of shock tubes [31–33]. While the method of flash photolysis permits the direct measurement of the rate constant for the recombination of atoms, in shock tube experiments measurements are made (at high temperatures) of the reverse reaction, i.e. thermal dissociation, and the results must be recalculated in terms of equilibrium constants. Flash photolysis alone is applicable over a fairly narrow range of low temperatures. However, the combined use of flash photolysis together with the shock tube method permits [34] measurements of the rate of recombination at much higher temperatures (the shock tube being used to heat the dissociation gas).

The two methods described are at present the most important in the study of dissociation and recombination processes. Apart from these, the free atoms of light elements are frequently produced by an electrode or electrodeless gas discharge (see for example papers by Canadian workers [35–39]). There exist also a number of different methods for the recording of the concentrations of atoms. Among these the ESR method [40,41], the method of "titration" using a rapid side reaction [42–46], and others have found successful application.

1. Absolute Rate Constants for Three-body Recombination of Atoms‡. Effectiveness of Various Particles as Third Bodies

The interest in three-body recombination reactions of atoms arose to the first place in connection with the problem of the recombination of hydrogen atoms. In the 1930's an extensive series of measurements of the rate constant for this reaction was made close to room temperature (Table 1). The results of these measurements show marked discrepancies because of the imperfection of the method under both static and flow conditions. Nevertheless a great achievement of these early studies was the formulation of the problem of the relative efficiencies of various particles as "third bodies" in the recombination process. However, the initial data on this problem proved to be extremely contradictory: while Steiner in several experimental and theoretical studies [5–7] insists that the

‡The available literature data for the rates of three-body recombination of identical atoms are expressed in two different ways: either in terms of the accumulation of molecules, $d[A_2]/dt = k[A]^2[M]$, or in terms of the consumption of atoms, $-d[A]/dt = k'[A]^2[M]$, where $k' = 2k$. In the present review all the numerical constants refer to the first equation, i.e.

$$k = \frac{1}{[A]^2[M]} \frac{d[A_2]}{dt}.$$

hydrogen atom is less effective than the hydrogen molecule (k_H is not more than 10% k_{H_2}), Senftleben and Reichemeier [47,48] quote $k_H/k_{H_2} \simeq 2000$. At the same time in a series of papers Amdur [49-53] asserts that the effectiveness of the H and H_2 species is comparable and that there are no grounds for expecting a significant difference between them.

Table 1. Rate constants for the recombination of hydrogen atoms: $k = \frac{1}{(H)^2(M)} \frac{d(H_2)}{dt}$.

*Most investigators [65-68] who measured the rate of recombination over a fairly wide range of temperatures (mainly 3000-5000°K) noted a decrease of the rate constant, on raising the temperature, in accordance with a T^{-1} law when M is an inert gas. However, Gardiner and Kistiakowsky [64] failed to observe any significant temperature variation in the range 3000-4500°K.

**The values quoted refer to the recombination of deuterium atoms.

***This value was obtained at 1700°K.

It follows from general theoretical considerations [9,54] that a third body M capable of chemical interaction with the recombining atoms (which is the case when M = H) should as a rule constitute a more effective third body. When applied to the reaction under consideration, this point of view is satisfactorily confirmed by later experiments at high temperatures (Table 1, see also Dixon-Lewis et al. [55]) the more self-consistent results of which show that k_H exceeds k_{H_2} on the average by one power of ten. This apparently contradicts the self-evident physical consideration that a larger number of degrees of freedom in the particle M should favour a more effective removal of energy from the recombining pair during its stabilisation in a three-body collision, increasing thereby the rate constant [56]. However, this is true only when particles M which are chemically inert to the recombining particles are compared. In this case the formation of a fairly stable compound H_3 in the interaction between H and H_2 is unlikely (H_2 may be regarded as an inert third body); therefore the above qualitative estimate is inapplicable and the high effectiveness of H as the particle M becomes quite understandable (see also for comparison the data on the recombination of atomic oxygen in Table 2).

The recombination of iodine and bromine atoms has been fairly thoroughly investigated over a wide range of conditions (Tables 4 and 6-8). In practice the role played by the three-body recombination reactions of halogen atoms in photochemical reactions of the type $H_2 + X_2 \rightarrow$ product, where X_2 is a halogen, is very important. The first data on the recombination Br + Br + M → product were in fact obtained by studying the kinetics of the photochemical reaction between H_2 and Br_2. [70-74] The classical experiments of Rabinowitch and coworkers [75-79], designed to investigate the photochemical steady states, marked the beginning of the systematic investigation of the three-body recombination of halogen atoms (iodine and bromine). In these experiments the wide differences between the effectiveness of various atoms and molecules as third bodies were noted for the first time, the absolute values of the rate constants (on the average 10^{15} $cm^6\ mole^{-2}\ s^{-1}$) proving significantly higher than would follow from initial theoretical estimates by Bodenstein [2]. At the same time Rabinowitch [15] suggested that the very high effectiveness of certain complex molecules (he used benzene in his experiments) may be attributed to the formation of a relatively stable atomic-molecular complex.

The dependence of the rate constant on the molecular complexity of the inert third body, mainly on the number of its degrees of freedom responsible for the energy transfer, was particularly clearly demonstrated in the work of Russell and Simons [80]; these workers quote rate constants for the recombination of iodine in the presence of more than thirty different inert gases (Table 4). For example, toluene proved to be 60 times more effective and mesitylene 110 times more effective than argon. Russell and Simons [80] made another interesting observation: they noted that the rate constants vary regularly with the boiling point, critical temperature, and ionisation potential of the inert gas, i.e. with the parameters characterising the strength of intermolecular forces. Fig. 1 illustrates this relation for the variation of $\lg k$ with the boiling point of the substance M as an example.

The existing data for the rates of recombination of the atoms of various halogens on contact with the same inert gas species show that the rate constants are higher for heavier atoms but the differences are not very great. The rates of recombination of I and Br atoms on contact with the same third body are virtually the same over a wide range of experimental conditions [81].

A large number of experimental studies on three-body recombination were stimulated also by interest in the study of chemiluminescence in gases: for example, Berkowitz et al. [82] showed that the intensity of the yellow luminescence of nitrogen depends on the consumption of free N atoms by a third-order rate law with a velocity constant of 7×10^{14} ($\times 10^{\pm 2}$) $cm^6\ mole^{-2}\ s^{-1}$ (see also Reeves et al. [83]); the greenish yellow luminescence of air is due [84] to a trimolecular reaction with participation of O and NO; the

*In Kaufman's review [18] $k = 9.8 \times 10^{14}$ was adopted as the best value for $O + O + O_2 \rightarrow 2O_2$ at room temperature. This is lower by a factor of five than the value obtained by extrapolation of the results of measurements in shock tubes.

**The method developed by Kiefer and Lutz [102] permitted the direct measurement of the rate of recombination in shock tubes, instead of its calculation from the rate of the reverse reaction via the equilibrium constant.

intensity of the red-orange luminescence arising from the products of an electric discharge in chlorine also follows a trimolecular law, $\mathcal{J} = k(Cl)^2(Cl_2)$, the $Cl_2(A^3\Pi_{1u}^+)$ molecule being identified as the source of the luminescence [85]. The study of such systems, mainly by producing free atoms from a discharge, has yielded important data on the rates of recombination of oxygen and nitrogen atoms (Tables 2 and 3). The tables also present the results of experiments in shock tubes.

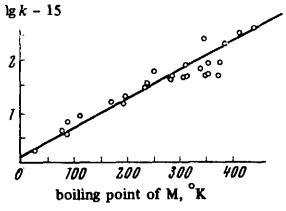

Figure 1. Variation of the rate constant for the recombination of iodine atoms with the boiling point of the substance M. [80]

Examination of the rate constants for the three-body recombination of oxygen atoms at low temperatures (Table 2) shows that they are of the order of 10^{14}–10^{15} when M is an inert gas. Kaufman [18] believes that the best value is 9.8×10^{14} for M = O_2 at room temperature. As the temperature rises, there is a tendency for the constant to fall, which is clearly demonstrated by the results of experiments in shock tubes. The specific effects of various third bodies are also clearly revealed. Table 2 lists the experimental rate constants for the formation of ozone: on the average they are somewhat smaller and are of the order of 10^{13}–10^{14}.

Table 3 lists the rate constants for the recombination of nitrogen atoms on contact with various third bodies. Their order of magnitude differs little from the corresponding values for the recombination of oxygen atoms (at low temperatures), but they vary less markedly with temperature.

Table 3. Rate constants for the recombination of nitrogen atoms*.

*The table shows that most investigators found a very small temperature coefficient for this reaction. In the earliest experiments of Forst et al. [107] it was found that $k \propto T^{-4}$ for M = CH_3Cl and CH_3CN.

2. Three-body Recombination involving Di- and Triatomic Particles

Compared with the recombination of atoms, trimolecular reactions in the gas phase with participation of di- and tri-atomic particles, which play an important role in many atmospheric processes, chemiluminescence, and others,

have been less thoroughly investigated and information about them has begun to accumulate mainly in recent years (Table 8). Among processes in this category, the reaction $H + O_2 + M \rightarrow HO_2 + M$, which plays a major role in the kinetics of complex chemical processes, has been most thoroughly investigated. For example, the phenomenon of the upper explosion limit in the chain process of hydrogen combustion and also the classical example of the inhibition of the photochemical reaction between H_2 and Cl_2 by the addition of oxygen are in fact associated with this reaction. The inhibiting effect of O_2 is explained by the fact that the active chain radical (the H atom) combines with O_2 in a three-body collision, yielding the relatively inactive HO_2 radical, which cannot regenerate the H atom at low temperatures [108,109].

*The results of some studies [79,80,120,125,128] were not corrected for the rapid reaction $2I + I_2 \rightarrow 2I_2$. Therefore the rate constants for relatively ineffective third bodies may deviate from the true values.

**Measured at 60°C

***The values for 50°C are quoted. When M = NO, the rate of reaction is too high for a reasonably accurate determination of the constant.

The $H + O_2 + M \rightarrow$ product reaction was investigated by many workers [110–118] and experimental constants for this reaction, in good mutual agreement, are now available: measurements of Clyne and Thrush [113] in the range 250–800°K and of Getzinger and Schott [115] in the range 1150–1850°K. An interesting feature of this reaction [109,118,119] is a very pronounced catalytic effect of water vapour ($k_{H_2O}/k_{Ar} \simeq 30$ and hardly changes with temperature). This makes it difficult to investigate the upper limit (and particularly its temperature variation), since the presence of even small traces of water vapour in the reaction zone can significantly lower it. Semenov [108] believes that in this case there is a possibility of an unusual chemical interaction involving the formation of the complex $H.H_2O$.

The rates of reactions of this type (Table 5) have values which are on the whole in the same range of orders of magnitude as the rate of atomic recombination. The negative temperature coefficient in these reactions is fairly small.

3. Temperature Variation of the Rate Constant

An interesting and important feature of three-body recombination reactions, which distinguishes them from other elementary reactions, is a negative temperature coefficient of the rate constant, i.e. a negative effective activation energy $E = RT^2(d \ln k/dT)$. This fact has been established quite reliably for the vast majority of reactions of this class (see Tables 1–3, 5, and 6 and Fig. 2). Qualitatively the two possible two-stage recombination mechanisms can account for the negative activation energy. It arises because the probability of the breakdown of the intermediate complex increases with temperature faster

Table 6. Experimental temperature variation of the rate constants for the three-body recombination of iodine atoms (the constants are expressed in cm^6 $mole^{-2}$ s^{-1} and the activation energies E in cal $mole^{-1}$).

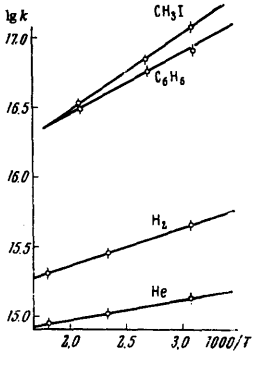

Figure 2. Temperature variation of the rate constant for the recombination of iodine atoms at moderate temperatures [122].

than the probability of the two-body collisions in both stages of the process.

The development of the experimental shock tube technique greatly extended the range of the known temperature variation of the constants. The results of the measurements of the variation of k with T are usually expressed either in terms of the exponential function $k = Ae^{-E/RT}$ ($E < 0$) or in terms of the power function $k = B/T^n$ ($n > 0$) [or $k = B'(T_0/T)^n$] (Table 6). However, more careful measurements showed [135,136] that there is a difference between the parameters E and n obtained at low (flash photolysis) and high (shock tubes) temperatures. Thus Russell [135] concluded that in the formula $k = B/T^n$ for the recombination of I and Br atoms in the presence of inert gas species at high temperatures one should use the average value $n = 1.5$, while at low temperatures the experimental data are best described by the same formula but with $n = 3$. These values are only approximate and are by no means consistent with all the experimental data. It is difficult to speak of the exact values of n or other parameters, since the results obtained at high temperatures may involve considerable errors and do not agree well with one another (see Table 6). However, there is no doubt about the actual complexity of the temperature variation, but it must now be recognised that hardly any elementary chemical reactions may be more or less satisfactorily characterised in terms of the Arrhenius function (or even less so a power function) with constant parameters over a wide range of temperatures [137] §.

The absolute values of the effective activation energies in these reactions are low and vary from zero to (minus) 5 kcal $mole^{-1}$. For example, Strong et al. [126] obtained the following activation energies in the flash photolysis of halogen–inert gas mixtures in the temperature range 25–160°C: −1.4, −2.0, and −1.2 kcal $mole^{-1}$ respectively for the recombination of I atoms in argon, Br atoms in argon, and Br atoms in molecular oxygen. Analysis of the experimental data carried out by Bunker and Davidson [17] showed that the negative temperature coefficient is higher for the gases which are more effective at low temperatures Hence here again there is a correlation between E and the boiling points, critical temperatures, etc. This conclusion is not confirmed by the earlier results of Russell and Simons [80], which are less reliable as regards the temperature variation, since these workers did not allow for the high effectiveness of I_2 as a third body (see p. 597).

According to Husain and Pritchard [138], the variable negative activation energy can be readily interpreted in terms of the ET mechanism if it is assumed that the collision with a third particle leads to the deactivation of the already formed excited ("latent") molecule only when the energy of the relative motion of the recombining particles lies in the range between two critical values ϵ_0 and ϵ_1 (above ϵ_1 there is no deactivation). Then the recombination rate constant should be

$$k = z[\exp(-\epsilon_0/RT) - \exp(-\epsilon_1/RT)] \quad (4)$$

Differentiation of this expression shows that k will decrease with increasing temperature if $\epsilon_0 < RT$ and $\epsilon_1 - \epsilon_0 \ll RT$. It is reasonable to put $\epsilon_0 = 0$; then if one adopts, for example, $\epsilon_1 = 0.1$ and 0.5, we obtain for the recombination

§In the present case one of the possible reasons for this is also the fact that the relative contributions of the ET and RMC mechanisms may vary with temperature.

reaction respectively $E_{300-400} = -0.68$ and -0.51 kcal mole^{-1} and $E_{1000-2000} = -2.72$ and -2.53 kcal mole^{-1} (the subscripts to E denote the temperature ranges). The numerical values thus obtained are extremely plausible, despite the simplified nature of the model: they give a temperature coefficient of the right order of magnitude, the absolute value of which increases at high temperatures in agreement with the results of the majority of the experiments.

4. Energy Distribution Among Recombination Products. Repeated Dissociation and Its Effect on the Temperature Variation of the Rate Constant

In the light of the latest experimental and theoretical data for energy transfer processes, it is fairly reliably known that the conversion of vibrational energy into translational energy, i.e. a process of the type

$$A_2'(v = n) + M \rightarrow A_2'(v = n - 1) + M + Q$$

(a single prime denotes a vibrationally excited molecule) is extremely difficult and is much slower than the transition from one vibrational level to another. The effective deactivation of A_2' requires a very large number of thermal collisions, i.e. it takes place with a very long relaxation time. Therefore it is logical to expect that an elementary exothermic reaction leads to the formation of vibrationally excited molecules, which are then gradually deactivated by collisions with the inert gas molecules. This is confirmed by a series of experiments with elementary bimolecular and termolecular reactions of the type $A + BC \rightarrow AB' + C$ and $A + B + C \rightarrow AB' + C$. For example, according to data of McGrath and Norrish [139], the reaction of atomic oxygen with ozone takes place as follows: $O + O_3 \rightarrow O_2'(v = 17) + O_2$. Cashion and Polanyi [140-143] and also Charters and Polanyi [144], who studied the reaction $H + Cl_2 \rightarrow HCl' + Cl$, arrived at analogous conclusions: the energy distribution among the products formed proved to be displaced from the Boltzmann distribution towards higher vibrational levels. Among termolecular reactions, we may quote as an example the recombination of nitrogen atoms, for which it has been shown [141,145,146], that the N_2' molecule forms at the level with $v = 4$. Villermaux [147] investigated from this standpoint the recombination of hydrogen atoms by a thermal-kinetic method, which is based on the following simple idea: if the energy evolved in the recombination is instantly transferred to translational-rotational degrees of freedom, then the rate of evolution of heat should be equal to the rate of disappearance of atoms (known from other experiments); otherwise the rates are different. The experiments in fact showed that the latter is the case.

Polanyi [148] suggested that, since the recombination product is a vibrationally excited molecule A_2, its repeated dissociation (redissociation) at higher vibrational levels may play an important role. Polanyi made an approximate calculation of the probability of repeated dissociation at 300° and 600°K, assuming that the distance between adjacent vibrational levels close to the dissociation threshold is constant and that there exists a characteristic probability of the change in the quantum number by the same amount, which is independent of temperature. Calculation showed that the total probability of redissociation at all levels in the second and third collisions is 0.175 at 300°K and 0.29 at 600°K. This corresponds to a decrease with increasing temperature in the component of the recombination which definitely contributes to the negative temperature variation of the rate constant. Polanyi obtained an effective activation energy $E = -0.85$ kcal mole^{-1} in the range 300–600°K. The value thus predicted is smaller by a factor of 2–3 than the experimental activation energy, but it may be that, as a result of the above assumptions, it constitutes a lower limit.

Repeated dissociation is only one of the factors contributing to the negative temperature variation, but it is evident that, when this phenomenon is correctly taken into account, complete understanding of the experimental values may be greatly facilitated.

5. Deviations from the Termolecular Law. Anomalously High Efficiencies of Certain Third Bodies

The first experiments on the recombination of atoms showed that the termolecular law holds exactly. However, in 1954–1955 Christie and coworkers [121,149], having revised the results of their earlier study [120] on the recombination of iodine atoms in the presence of noble gas atoms by experiments over a wider range of conditions, observed deviations from the simple relation $d[I_2]/dt = k_M[I]^2[M]$ when the concentration ratio $[I_2]/[M]$ was varied (Fig. 3).

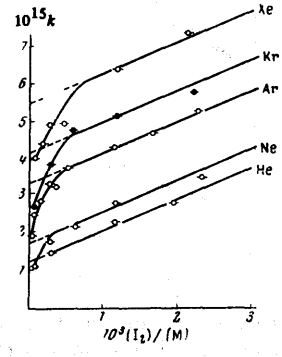

Figure 3. Deviations from the termolecular law in the recombination of iodine atoms [150].

The experimental results showed that the effective rate constant for the formation of molecules is a linear function of the ratio $[I_2]/[M]$ over a wide range of the latter, the relation showing a sharp variation at low values of $[I_2]/[M]$.

In the first series of experiments [120] the variation of the rate constant with $[I_2]/[M]$ was apparently masked by a "thermal effect". Since the recombination process is exothermic, the gas mixture is heated in the course of this process. The exact value of the heat evolved ΔQ depends on the average wavelength of the light absorbed; if we adopt $\Delta Q = 60$ kcal per mole of iodine as the maximum value and assume that the process is adiabatic, we can estimate the increase of temperature: $\Delta T = 3 \times 10^4 \Delta[I]/c_V[M]$, where $\Delta[I]$ is the change in the concentration of free iodine atoms and c_V the heat capacity of the third body M which is present in excess. For a monatomic gas, $\Delta T = 10^4\Delta[I]/[M]$ and, when $[M] = 100$ mmHg and $[I]_0 = 0.1$ mmHg, we obtain $\Delta T = 10$ deg after complete recombination. The direct effect of this temperature rise is hardly significant, but the temperature gradient thus

produced may be important [80]. This thermal effect, which increases with $[I_2]/[M]$, is revealed by a decrease of the observed rate constant during the recombination, compensating thereby the true increase of the constant as $[I_2]/[M]$ is raised. To explain the last finding, the rapid reaction $I + I + I_2 \rightarrow I_2' + I_2$ was postulated. When this and the process $I + I + M \rightarrow I_2 + M$ are taken into account, the kinetic law changes:

$$\frac{d[I_2]}{dt} = k_M[I]^2[M] + k_{I_2}[I_2][I]^2 = k_{init}[I]^2[M] , \quad (5)$$

$$k_{init} = k_M + k_{I_2}[I_2]/[M] , \quad (6)$$

where k_M and k_{I_2} are the true termolecular constants for the third bodies M and I_2 respectively and k_{init} is the effective rate constant determined experimentally in the initial stage of the recombination. Eqn. (6) shows that this constant does indeed vary linearly with $[I_2]/[M]$ and the fact that the straight lines in Fig. 3 are parallel confirms satisfactorily that the slope is related solely to the effectiveness of the I_2 molecule as third body and is independent of the nature of the inert gas M. The slope of the straight lines in Fig. 3 corresponds to $k_{I_2} \simeq 8.5 \times 10^{17}$ cm^6 mole^{-2} s^{-1} at room temperature, which is approximately 260 times higher than k_{Ar} (by a factor of 650 according to the data of Bunker and Davidson [127]). Evidently such high effectiveness of I_2 cannot be explained solely by an increase of the kinetic collision cross-section. However, as early as 1932, Rollefson and Eyring [151] predicted theoretically the possibility of the existence of relatively stable triatomic halogen molecules. The hypothesis of the formation of an I_3 molecule of this kind in the recombination of iodine atoms explains satisfactorily the anomalously high effectiveness of I_2 as the third body M. According to Semenov's estimate [108], the above experimental results correspond to $\Delta E \simeq -6$ kcal mole^{-1} as the energy of formation of I_3 in the reaction $I + I_2 \rightleftharpoons I_3$; Bunker and Davidson [17] quote for the same reaction $\Delta H^\circ = -5.3$ kcal mole^{-1} and $\Delta S^\circ = -20$ e.u.¶.

The rate constant k_{I_2} falls with temperature much faster than those for less effective third bodies (Table 6): at 1300°K the ratio k_{I_2}/k_{Ar} no longer exceeds 30. [133] This fact is in good agreement with the general tendency towards an increase of the negative temperature coefficient with increase of the effectiveness of recombination described in Section II, subsection 3.

For the recombination of Br atoms, it has also been reliably established that the species $M = Br_2$ is distinguished by enhanced effectiveness, although not to the same extent (Tables 7 and 8); an even smaller relative effect is observed [45,152] for $M = Cl_2$ in the reaction $Cl + Cl + M \rightarrow$ product and, finally, there exist only qualitative data indicating that in the recombination of F atoms molecular fluorine is somewhat more effective than argon [153].

The deviation of the rate constant from Eqn. (6) at low values of $[I_2]/[M]$ (Fig. 3), observed by Christie and coworkers [121,149], probably demonstrated for the first time a breakdown of the equilibrium distribution in the recombination of atoms. Generalising the various experimental data, Christie [150] concluded that the deviations from linearity may be attributed to the retardation of the vibrational deactivation of the excited molecule I_2' (formed in the recombination) as the concentration of I_2 diminishes. Although it is known that iodine molecules are initially formed at high vibrational levels, it is nevertheless always postulated that, of the two possible processes

$$I + I + M \rightarrow I_2' + M , \quad (a)$$

$$I_2' + M \rightarrow I_2 + M , \quad (b)$$

the rate-determining stage is the recombination (a), i.e. it is assumed that process (b) is fairly rapid. This assumption is justified if various gases have the same effectiveness in the two processes. If, however, molecular iodine is much more effective (by a factor of 10^4 and more) than an inert gas in the deactivation of I_2', then process (b) proceeds mainly in the following way even at very low values of $[I_2]/[M]$: $I_2' + I_2 > 2I_2$ ($v < 3$); when the contribution of $M = I_2$ to the overall rate of recombination (a) is negligibly small, then process (b) may become the rate-determining stage under the condition $k_b[I_2'][I_2] < k_M[I_2][M]$. Thus a deviation from linearity occurs when $([I_2]/[M])_{dev} = k_M[I_2]/k_b[I_2']$ and, under the initial experimental conditions, $([I_2]/[M])_{dev}$ should be proportional to k_M, as found experimentally (Fig. 3).

*The results quoted were obtained from a study of the photochemical reaction $Br_2 + Cl_2 \rightarrow$ product by comparing the effectiveness of Br_2 and Cl_2 with that of CO_2, using for the latter the result of Rabinowitch and Wood [77] (the direct determination was difficult in view of the heterogeneity of the thermal reaction).

**This result deviates markedly from the data of other workers; possibly, the method used here may yield relatively unreliable results in the presence of excited species [45].

***Measured at 229°K.

However, Nikitin [164,165] believes that for the recombination reactions under conditions of flash photolysis this interpretation is incorrect; according to his estimate, in this case (recombination of iodine) the disequilibrium arises due to the retardation of the transition between the excited and ground electronic states of I_2. In the formation of the system $I_2'-I_2$ there arise electronic levels strongly differing from those for two isolated I_2 molecules

¶Here the situation differs from that which obtains in the recombination of H atoms (see p. 597), since the diatomic product molecule is the chemically active third body. It would be interesting to carry out experiments designed to investigate the effectiveness of free halogen atoms as the third body M.

and there is a high probability of non-adiabatic transitions in the region where the energy levels of the complex I_2'–I_2 come very close together. In the interaction of I_2 with an inert gas atom one cannot expect a pronounced change in the position of the electronic levels; this accounts for the large difference between the effectiveness of the relaxation of I_2' on collision with M = I_2 and inert gas atoms.

Table 8. Rate constants for the recombination of halogen atoms at high temperatures.

Third body, M	T, °K	$10^{-15}k$, cm^6 mole^{-2} s^{-1}	Refs.	Third body M	T, °K	$10^{-15}k$, cm^6 mole^{-2} s^{-1}	Refs.

	2100	0.17	160				

The constants for the midpoint of the temperature range of the measurements are quoted in the table.

It is noteworthy that the very high effectiveness is observed also in other cases where there is a possibility of a chemical bond: for example, with M = NO in the recombination reactions of halogen atoms (Table 4).

6. Effect of the Third Body in the Recombination of Alkyl Radicals

Since alkyl radicals are fairly complex species, in their recombination there is a relatively high probability of their stabilisation as a result of internal energy redistribution; nevertheless at low pressures the role of deactivation in collisions with a third body increases, leading to significant deviations towards a third-order process. The kinetic mechanism of such reactions is usually expressed in terms of the energy transfer mechanism (ET); then the general equations show that the effect of the third body begins to operate at higher pressures the lower its deactivating capacity. Furthermore, this effect becomes more pronounced with increase in temperature due to the decreased life-time of the complex R_2^*, which demonstrates the significant role which it may play in high-temperature pyrolytic processes.

Numerous experiments [166–174] have now yielded a fairly large number of quantitative data for the simplest process of this type—the recombination of methyl radicals:

$$CH_3 + CH_3 \underset{k_B}{\overset{k_A}{\rightleftharpoons}} C_2H_6^*,$$

$$C_2H_6^* + M \xrightarrow{k_C} C_2H_6 + M,$$

whence the rate of accumulation of ethane is:

$$\frac{d[C_2H_6]}{dt} = \frac{k_A k_C}{k_B + k_C[M]}[CH_3]^2[M]. \quad (7)$$

Under the condition $k_C[M] \ll k_B$, a third-order process is realised:

$$\frac{d[C_2H_6]}{dt} = \frac{k_A k_C}{k_B}[CH_3]^2[M] = k_{eff}[CH_3]^2[M] \quad (8)$$

Ingold and Lossing [166] measured mass-spectrometrically the rate of recombination of methyl radicals produced by the thermal decomposition of dimethylmercury and found that the rate has a negative temperature coefficient, without observing at the same time deviations from a second-order process as the helium pressure changed from 18.5 to 4.8 mmHg; this contradicts both the observed negative temperature coefficient and the low deactivating capacity expected for helium. Indeed, as was to be expected, repetition of the observations [167] revealed a linear variation with [He]. Although the negative temperature coefficient of the rate (according to Ingold and Lossing, $E = -2.2$ kcal mole^{-1}) is satisfactorily consistent with the known general properties of three-body recombination reactions, this phenomenon in the recombination of CH_3 radicals can be explained in another way not involving a third-order process [175].

The effect of the third body in this reaction was studied by Kistiakowsky and Roberts [168] and almost simultaneously by Dodd and Steacie [169] in experiments on the photolysis of acetone. These experiments showed that at temperatures in the range 150–250°C the deviations become significant at pressures of about 10 mmHg, which agrees well with the theoretical prediction of Marcus [172] concerning the existence of a transition region near 5 mmHg. According to Dodd and Steacie [169], the rate of spontaneous dissociation of $C_2H_6^*$ at 250°C is not greater than 6×10^7 s^{-1} (lifetime $\geq 1.6 \times 10^{-8}$ s) and increases with increasing temperature, and for the effectiveness of various third bodies in the deactivation of $C_2H_6^*$ these workers found the following values (relative to acetone): Ar(< 0.03), CO_2 (0.03), C_4F_{10} (0.2), $CF_3.C_6F_{11}$ (0.3), C_6H_6 (1.0), and acetone (1.0) at a temperature near 250°C. The absolute values of the effective third-order rate constants are then much higher than for the recombination of atoms.

Among the later investigations, the experiments of Toby and Weiss [173] on the photolysis of azomethane yielded important results. Azomethane proved to be a deactivating agent less effective by a factor of approximately three than acetone, which made it possible to extend the range of investigation of the effect of the third body to higher pressures. Carbon dioxide and sulphur hexafluoride were also investigated as third bodies, and their effectiveness in relation to azomethane proved to be 0.04 and 0.24 respectively.

Numerous experimental data on the recombination of CH_3 radicals in the transition region were analysed by Kondrat'ev [176]. This analysis led to the most reliable values of the kinetic characteristics of the process.

When the reactions of ethyl and more complex radicals are examined, the situation becomes somewhat more complicated. Qualitatively it is clear that the effect of the third body can operate here at even lower pressures; furthermore, the recombination is accompanied by disproportionation reactions, which complicate the composition of the products.

In experiments on the photolysis of diethylmercury, Bradley et al. [177] investigated the kinetics of the interaction of ethyl radicals and the composition of the products; the effect of the third body becomes clearly apparent at low pressures of M = Ne. However, the authors' interpretation of the experimental data in this region is incompatible

with the energy transfer mechanism. The authors' treatment is based on the postulate that the three-body recombination of C_2H_5 radicals is an independent reaction which takes place simultaneously with bimolecular recombination and disproportionation. Then the composition of the products is a linear function of pressure of the following form:

$$\frac{[\text{butane}]}{[\text{ethane}]} = \frac{1}{R} + \frac{k_{tr}}{k_r + k_d} \cdot \frac{1+R}{R}[M]. \quad (9)$$

where k_r and k_d are the rate constants for the bimolecular recombination and disproportionation reactions, k_{tr} is the three-body recombination rate constant, and $R = k_d/k_r$, which is equal to the ratio [ethane]/[butane] in the absence of the termolecular process. Extrapolation using Eqn. (9) to [M] = 0 yields R and then

$$\frac{k_{tr}}{k_r + k_d}.$$

However, the initial postulate of the separate occurrence of bimolecular and termolecular recombination of radicals gives rise to objections. It leads to the conclusion that at fairly high pressures three-body recombination will completely "suppress" bimolecular recombination, while experiments in fact show that the third-order law is fulfilled only at extremely low pressures. It is most likely that, as in simpler cases, these reactions are part of the same process, the order of which may change with pressure:

$$C_5H_5 + C_2H_5 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} C_4H_{10}^* ,$$

$$C_4H_{10}^* + M \xrightarrow{k_2} C_4H_{10} + M ,$$

$$C_2H_5 + C_2H_5 \xrightarrow{k_3} C_2H_6 + C_2H_4$$

and the ratio of the product concentrations can also be expressed in terms of the relation

$$\frac{[\text{butane}]}{[\text{ethane}]} = \frac{k_1 k_2}{k_3} \frac{[M]}{k_{-1} + k_2[M]} ,$$

which is probably the true one. This relation is close to linearity only when $[M] \ll k_{-1}/k_2$; on the other hand, extrapolation to [M] = 0 when experimental points relatively far from this value are available may lead to considerable errors. When $[M] \to 0$, we have [butane]/[ethane] $\to k_1k_2[M]/k_{-1}k_3 \to 0$ provided that all the important elementary stages are incorporated in the mechanism quoted above.

It is remarkable that at very much higher pressures, when the ET mechanism gives rise to a second-order process, there is a possibility in principle of the simultaneous occurrence of three-body recombination, but solely by an RMC mechanism, i.e. with a different rate constant. In other words, we are dealing with the possible occurrence of a second transition (in the sense of a change in reaction order) pressure range. Unfortunately so far there are no data on the kinetics of radical recombination under conditions where this effect might be expected to occur.

There is extremely little information about the role of third bodies in the reactions of more complex radicals. However, theoretically for each case of this kind it is possible to predict a pressure range where the kinetic order of the recombination process should change [197].

III. INTERPRETATION OF EXPERIMENTAL DATA

Many theoretical papers on the problem of the three-body recombination of atoms have now been published. These studies are concerned both with the discussion of the general dynamics of the interaction of three atoms in the course of recombination and with the analysis of the possible two-stage process mechanisms from the standpoint of the classical and quantum mechanics and statistical physics. Modern theories of atomic recombination have been reviewed [165,203]. Here we shall consider only the possibility of the interpretation of the kinetics of three-body recombination on the basis of the simplest theoretical concepts—the kinetic collision theory and the activated complex method.

1. The Collision Theory

As for other elementary gas-phase reactions, the first attempt at the interpretation of the experimental data on three-body recombination involved the use of the Arrhenius formula (1). Before the discovery and systematic investigation of the negative temperature dependence, it was usually assumed that $E = 0$ in this formula, in the belief that the addition of free atoms or more complex paramagnetic species with unpaired spins does not require activation energy. The problem thus reduced to the calculation of the pre-exponential factor in formula (1), which is identifiable with the number of triple collisions z (possibly with an accuracy to within the steric factor $s \leq 1$, so that $A = sz$). According to Bodenstein's earliest estimate [2],

$$\frac{\tau_{12}}{\tau_\lambda} \simeq \frac{d}{\lambda} , \quad (10)$$

where τ_{12} is the duration of the ordinary (two-body) collision, τ_λ the time taken for the particle to traverse its free path, λ the mean free path, and d the diameter of the molecule. However, the fraction of the total time during which the molecule formed collides is approximately equal to the ratio of the number of three-body collisions to the total number of collisions. At atmospheric pressure it amounts to 1/1000; nevertheless Rabinowitch's experiments [75-79] showed that three-body recombination takes place more effectively.

Tolman [3] based his interpretation on the calculation of the average lifetime of the pair formed in the two-body collision when the particles approach one another to a distance not greater than δ. Then the number of elastic collisions of all the particles in an ideal gas can be calculated from Eqn. (2) if the steric factors are neglected.

Other workers proposed different versions of the calculation of the number of three-body collisions, differing mainly in the model adopted: for example, according to Herzfeld [11], the same formula is obtained but δ is treated as the average diameter of the colliding particles; according to Syrkin [178], a three-body collision occurs when all the particles are within a sphere of radius r and the formula differs somewhat from Eqn. (2). Thus all the formulae contain an undetermined parameter which characterises in one way or another the effective region of operation of intermolecular forces. In Tolman's equation (2) this parameter (δ) is defined as the maximum distance between particles 1 and 2 and 1 and 3.

It should be noted that, in the recombination of atoms in collisions with not unduly effective inert gas species even the above simplest formula gives rise to fairly good agreement with the experimental rate constants when a reasonable value of δ is chosen [108,179]. This applies of course only to the absolute value of the constant and agreement is observed only close to room temperature.

Over a wider range, Eqn. (2) is naturally inconsistent with experiment, since it does not constitute a general expression for the rate constant; this is evident if only from the fact that it predicts an increase of the rate constant with temperature as $\sqrt{T}$†. Furthermore, the interpretation of the higher effectiveness of certain third bodies (for example, benzene or a number of other hydrocarbons) on the basis of formula (2) alone would require anomalously high kinetic diameters [180]. Rabinowitch [15] gave a detailed interpretation of his own experiments and those which he carried out together with Wood [76-79] on the recombination of atoms (A + A → product), using the simple collision theory and thus avoiding the difficulties associated with the indeterminacy of the kinetic diameter of the excited molecule $d_{A_2^*}$ in Steiner's treatment [6]. When the two possible recombination mechanisms were taken into account, i.e. (A + A) + M → product and (A + M) + A → product, the total number of three-body collisions leading to recombination was obtained:

$$z = 4\sqrt{2}\,\pi d_{AM}^2 d_{AA}^2 \frac{RT}{m_A}\sqrt{\frac{m_A + m_M}{m_M}}\,N_A^2 N_M (2\tau_{AA} + \tau_{AM})\beta \quad , \quad (11)$$

where τ_{AA} and τ_{AM} are the lifetimes of the corresponding complexes and β is the effectiveness (the "steric factor")‡. Assuming that the experimental rate constant is equal to the number of collisions determined in this way, Rabinowitch calculated from the experimental data the value of $(2\tau_{AA} + \tau_{AM})\beta$. In Table 9 these values are quoted together with later results for A = I; they are somewhat too high, but in general they express correctly the tendency for the given quantity to increase on going to more complex third bodies.

This simple analysis of the recombination process in three-body collisions clearly shows that the high effectiveness of the latter (relative to Bodenstein's initial estimate) depends not so much on the diameter as on the large difference between the distance over which the interaction begins and the distance of closest approach of the particles. Rabinowitch's explanation of the much higher values of τ calculated from experiments with benzene and pentanes, based on "sticky" collisions between the atom and M, is more likely than the possibility of anomalously large cross-sections of the vibrational deactivation of A_2^* by these molecules (ET mechanism).

In the more general form, when account is taken of all possible mechanisms of the termolecular reaction A + B + C → product and the steady-state concentrations of the binary complexes AB, BC, and CA are calculated initially, the model of an elastic spherical collision leads to the following formula for the experimental rate constant [181]:

$$k = s_C z_{AB.C} z_{AB} \tau_{AB} e^{-E_C/RT} + s_A z_{BC.A} z_{BC} \tau_{BC} e^{-E_A/RT} + s_B z_{CA.B} z_{CA} \tau_{CA} e^{-E_B/RT} \quad , \quad (12)$$

Here z_{AB}, $z_{AB.C}$, etc. are the numbers of two-body collisions between the initial particles and between the binary complex and the third particle, τ_{ab} etc. are the lifetimes of the corresponding binary complexes, which are equal to the reciprocals of their decomposition rate constants, and s are steric factors. Incidentally, even this simple treatment shows that, in general, with a rigid model the steric factors for trimolecular reactions should be lower than for bimolecular reactions [182]. Indeed, Eqn. (12) shows that $s_C = s_{AB} s_{AB.C}$ if AB etc. are species actually produced in the process, the formation of which is characterised by a particular steric factor in each case.

Table 9. Experimental values of $10^{13}(2\tau_{AA} + \tau_{AM})\beta$ (seconds).

A	Third body M										Refs.
	He	H_2	Ar	N_2	O_2	CH_4	CO_2	C_5H_{12}	neo-C_5H_{12}	C_6H_6	
Br	0.64	1.2	2.0	3.2	4.5	3.4	6.9				15
I	1.2	1.7	5.0	7.3	12.5	9.6	20.0			84	15
I			3.0					36	32		125

Then $s_{AB.C}$ is the steric factor of the AB + C collision under the condition that AB has in fact formed, i.e. it expresses the conventional probability of the configuration AB...C. Since, from their nature, both s_{AB} and $s_{AB.C}$ are less than unity, it is clear that s_C is less than s_{AB}. If the effective activation energies E_A, E_B, and E_C are low, the steric factors, which are themselves functions of temperature, may have a marked influence on the temperature variation of the rate constant [182,183].

The explanation of the properties of three-body recombinations based on the simple kinetic model involving collisions of structureless particles is of course primitive and constitutes only a first approximation. However, in many simple systems it leads to reliable estimates and helps in extracting useful information from experimental data.

However, we may mention here one difficulty which is common to all three-body recombination theories and which has still not been completely overcome–the problem of the so called "statistical factor". Let us consider as an example the thoroughly investigated recombination of iodine atoms. It is known [184] that two I atoms in the ground electronic state $^2P_{3/2}$ may interact with formation of molecules in the states $^1\Sigma_g^+$, $^1\Pi_u$, and $^3\Pi_{2u,1u}$ whose potential energy curves have minima. The assumption that recombination can give rise only to the ground molecular state $^1\Sigma$ would imply the introduction of a statistical factor of 1/16 in the expression for the rate constant; allowance for other electronic states increases this factor. According to Rabinowitch [15], the interaction of recombining atoms begins at very long distances, for which the energy differences between the curves are very small, so that the perturbing effect of the third body may ultimately lead to a transition from the unstable to a stable curve and then in general any collision of two atoms in the presence of an approaching third particle may be effective for stabilisation and all statistical limitations should be removed. Probably this is an overstatement, but so far there exists no single view concerning this problem and various workers make different allowances for the statistical effect.

†Strictly speaking in a real gas the temperature variation of z according to Eqn. (2) is less pronounced because the diameters vary in accordance with Sutherland's formula:

$$d^2 = d_\infty^2\left(1 + \frac{C}{T}\right) \quad .$$

‡In a more general derivation account must of course be taken of the fact that $\beta \neq$ const for the two types of collisions, i.e. the corresponding factor should be replaced by $2\tau_{AA}\beta_1 + \tau_{AM}\beta_2$. The experiments of Christie et al. [120] showed that in the recombination of iodine $\beta_1 < \beta_2$ (the best values are $\beta_1 = 0.04$ and $\beta_2 = 0.7$).

2. Three-body Recombination of Particles and the Theory of Equilibrium Reaction Rates. Application of the Surface Potential Function. Certain Modifications of the Collision Theory and Analysis of the Trajectories

The determination of the rate constant for an elementary chemical process by methods of the transition state theory (TST) requires detailed information about the interaction between the reacting particles. This interaction is usually represented by a potential energy surface [185].

Both the general methods of construction and the properties of potential surfaces are well known as are the solutions for many specific problems within the framework of TST; [9,186] therefore we shall confine ourselves here to certain general features characteristic of the class of reactions with which we are dealing.

It has been shown [9] that in many cases the state of a three-atom system having minimum potential energy is colinear—all three atoms are located on a single straight line (we may note that in systems with an inert third atom there is also a possibility that other configurations are effective in stabilising the molecule formed). For a colinear system, the construction of a potential energy surface is particularly convenient, and the process may be readily interpreted. Fig. 4 presents such surfaces, describing the combination of atoms A + B + C → AB + C in two cases: when the atoms B and C interact to a considerable degree and when they almost do not interact at all.

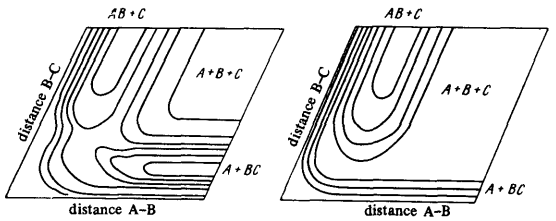

Figure 4. Potential energy surfaces for three-body recombination reactions: *a*) atoms B and C interact chemically; *b*) atoms B and C scarcely interact.

The flat "plateau" in the upper right-hand corner corresponds to the completely dissociated state; if the two atoms form a bond, then a deep "valley" is obtained in the figure, which is parallel to the corresponding coordinate axis when the distance from the third body is very large. Let us consider the first case. If the representative point rolls from the plateau straight into the AB + C valley, then transverse motions, i.e. vibrations, can return it to the plateau and the reaction will not occur. A stable molecule is formed only when the point rolls into the AB + C valley at an appropriate angle, i.e. with a sufficient store of translational and vibrational energy, and crosses the ridge into the product valley; then the translational energy is transformed into vibrational energy. If B and C interact fairly strongly, then the valley parallel to the abscissa axis is deeper and the ridge separating it from the product valley is relatively low, which leads to high effectiveness of C as the third body. It is precisely this case that is realised, for example, in the recombination H + H + H → product (cf. Section II, subsection 1). On the other hand, if the third atom is inert (Fig. 4*b*), the A + BC valley is shallow, the plateau is very wide, and for the reaction to occur the point must reach the region with curved equipotential lines (pathway 1): otherwise the point will be "reflected" from the lower edge of the valley (pathway 2). This imposes more severe limitations on the angle at which the point would leave the plateau, significantly reducing thereby the probability of the reaction. Gershinowitz [187] constructed the exact potential energy surface for the particular case of the H + H + He collision; the probability of the reaction was indeed found to be relatively low. A similar study was also made by Rabinowitch [15].

Eyring et al. [54] calculated the rate constants for the recombination of three hydrogen atoms by TST methods:

$$k = \gamma \frac{g^{\neq}}{g_i} \cdot \frac{[2\pi(m_1+m_2+m_3)\,kTh^{-2}]^{3/2}\prod_{j=1}^{3}(1-e^{-h\nu_j/kT})^{-1}}{(2\pi m_1 kTh^{-2})^{3/2}(2\pi m_2 kTh^{-2})^{3/2}(2\pi m_3 kTh^{-2})^{3/2}} \cdot \frac{8\pi^2 \mathcal{J}^{\neq} kT}{h^2 \sigma^{\neq}} H\bar{v} \cdot \quad (13)$$

In this formula the superscript ≠ denotes quantities referring to the activated complex, γ is the transmission coefficient, g the electronic degeneracy, $\mathcal{J}^{\neq}$ the moment of inertia, ν_j the vibration frequency, $\sigma^{\neq}$ the symmetry number, and $\bar{v} = (kT/2\pi\mu)^{1/2}$ the average velocity with which the point intersects the symmetry axis of the corresponding potential energy surface [9,186]. The factor H constitutes the vibrational component of the partition function of the activated complex, which is responsible for the energy distribution in the latter leading to reaction. Eqn. (13) follows from the more general formula derivable from TST for the rate constant of any trimolecular reaction [8]:

$$k = \gamma \frac{kT}{h} \frac{Q_{(A\ldots B\ldots C)^{\neq}}}{Q_A Q_B Q_C} e^{-E_0/RT} \quad (14)$$

where $Q_{(A\ldots B\ldots C)^{\neq}}$, Q_A, Q_B, and Q_C are the partition functions of the activated complex and the total partition functions of the initial species and E_0 is the zero-point activation energy.

Eyring et al. [54] constructed the potential energy surface on the assumption that in the H–H interaction the Coulombic integral amounts to 14% of the total bond energy § and is independent of the distance. This assumption is permissible, since in calculations of this kind only a relatively small region of the configurational space near the activated state is important (incidentally, this is why analogous assumptions are possible also for certain other parameters). Several additional assumptions concerning the geometry and frequencies of the activated complex permitted the complete calculation of the rate constant, which proved to be 3.1×10^{15}. Eyring et al. [54] also considered the possibility of a different configuration of the activated H...H...H complex—in the form of an equilateral triangle. Then the rate of formation of H_2 proved to be less; nevertheless the correction for the possible non-linear configuration may bring still closer together the theoretical and experimental values.

The application of TST methods makes it particularly convenient to consider the problem of the pre-exponential factor associated with the rate constant as expressed by the Arrhenius formula (1) or obtained directly from formula (14). The point is that, for a wide class of reactions with low activation energies, it is in fact the variation of the pre-exponential factor (or more correctly the steric factor) that is responsible for the temperature variation of the rate constant at fairly high temperatures. This effect

§The possibility of making such estimates has already been discussed [108] (Appendix II).

of the pre-exponential factor may be very large. For example [182], in the general case of a trimolecular reaction (between complex species) the pre-exponential factor in Eqn. (14) varies with temperature as $\varphi(T)/T^5$, where $\varphi(T)$ denotes the contribution of the vibrational partition functions; thus if the vibration frequencies are high, the pre-exponential factor decreases with temperature in proportion to $1/T^5$.

The method developed by Stepukhovich and co-workers [188-192] for bimolecular reactions permits the calculation of the pre-exponential and steric factors provided that the geometry and the frequencies of the activated complexes are known (or postulated), without the necessity of knowing the activation energy. This method is applicable also to trimolecular reactions. Since the number of three-body collisions varies with temperature as $\sqrt{T}$, one can write according to Eqn. (2).

$$E_{exp} = E_0 + \frac{1}{2}RT \ , \qquad (15)$$

$$E_{exp} = E_0 + RT^2 \frac{d \ln A^{\neq}}{dT} \ , \qquad (16)$$

where $A^{\neq}$ is the pre-exponential factor in Eqn. (14); then comparison of this equation with the formula $k = sze^{-E/RT}$ yields the following expression for the steric factor:

$$s = \gamma \frac{kT}{h} \frac{1}{z} \frac{Q_{(A\ldots B\ldots C)^{\neq}}}{Q_A Q_B Q_C} \exp\left\{\frac{1}{2} + T\frac{d}{dT} \ln \frac{Q_{(A\ldots B\ldots C)^{\neq}}}{Q_A Q_B Q_C}\right\} \ . \qquad (17)$$

Stepukhovich and Umanskii [182] applied this method and Eqn. (17) in the approximate calculation of pre-exponential and steric factors and the rate constants for the three-body recombination of halogen atoms in collisions with inert gas atoms on the basis of the hypothesis of a triangular configuration of the activated complex. It was assumed that the bond between the halogen atom and the inert gas atom is of the van der Waals type and that the energy of this bond is approximated by the 12-6 Lennard-Jones potential [193,194]:

$$\varepsilon(r) = 4\varepsilon_0 \left[\left(\frac{\sigma_0}{r}\right)^{12} - \left(\frac{\sigma_0}{r}\right)^{6}\right] \ , \qquad (18)$$

where ϵ_0 is the depth of the potential well and σ_0 the distance over which the potential becomes zero (attraction and repulsion forces are equal). In order to estimate σ_0 and ϵ_0 for halogen atoms, values taken from the viscosity data for the nearest inert gas were used, the interaction parameters being calculated according to the following rules [193]:

$$\sigma_0^{12} = \frac{1}{2}(\sigma_0^1 + \sigma_0^2); \ \varepsilon_0^{12} = (\varepsilon_0^1 \varepsilon_0^2)^{\frac{1}{2}}. \qquad (19)$$

Assuming that the position of the inert gas atom in the complex corresponds to the lowest potential energy of the system, it is possible to determine the characteristic vibration frequencies of the weak van der Waals bonds:

$$\nu = \frac{1}{2\pi}\sqrt{\left(\frac{\partial^2 e}{\partial r^2}\right)_{r_0}/\mu} = \frac{3 \cdot 2^{1/3}}{\pi\sigma_0}\sqrt{\frac{\varepsilon_0}{\mu}} \ , \qquad (20)$$

where $r_0 = 2^{1/6}\sigma_0$ is the equilibrium interatomic distance.

The steric factors calculated by Eqn. (17) for the reactions 2I + M → product and 2Br + M → product proved to be similar and of the order of 10^{-3} at room temperature, i.e. indeed lower than for bimolecular reactions between atoms. This was in fact to be expected on the basis of of what has been said in Section II, subsection 2. Furthermore, the steric factors were found to increase approximately linearly with temperature, which is contrary to their behaviour in bimolecular reactions. From the standpoint of thermodynamics, such variation indicates that the entropy of activation increases with temperature, i.e. the configurational disorder of the activated complex increases to a greater extent than the disorder of the initial state. Within the framework of the concept of two stages in trimolecular reactions, this implies that the second stage, in which the activated complex is formed from a large number of species and breaks down like a complex species, is rate-determining. The higher is the temperature, the more rapid is the breakdown of the complex. An increase of temperature has the same effect as in monomolecular reactions, although the latter have a positive entropy of activation. The classical pre-exponential factor $A = sz$ increases with temperature together with the steric factor.

We shall now examine the contradictions to which Semenov drew attention [108] using as an example the reaction $Br_2 + M \rightleftharpoons 2Br + M$. It consists in the fact that the equilibrium constant for this process calculated from the ratio of the rate constants for the forward and reverse stages is consistent with the experimental value only under the condition that the steric factor for the dissociation reaction is 10^2, which is unlikely on physical grounds. Indeed, per molecule $k_{rec} \simeq 10^{-32}$ and for binary collisions $z_2 \simeq 10^{-10}$, so that we should have

$$K = \frac{(Br)^2}{(Br_2)} = \frac{s_2 z_2 e^{-Q/RT}}{k_{rec}} \simeq s_2 \cdot 10^{22} e^{-Q/RT} \ , \qquad (21)$$

where Q is the heat (however, in this expression it is assumed that $E_{rec} \simeq 0$, so that $E_{diss} = Q$). At the same time, the equilibrium constant is well known from independent data:

$$K = \frac{(Br)^2}{(Br_2)} \simeq 10^{24} e^{-Q/RT} \ . \qquad (22)$$

The above contradiction can be simply and naturally resolved in the light of the concept of steric factors. The equilibrium constant must be written in the form

$$K = 10^{24} e^{-Q/RT} = \frac{k_{diss}}{k_{rec}} = \frac{s_2 z_2}{s_3 z_3} \frac{e^{-E_2/RT}}{e^{-E_3/RT}} = \frac{s_2 z_2}{s_3 z_3} e^{-Q/RT} \ . \qquad (23)$$

Assuming that z_2 and z_3 are 10^{-10} and 10^{-32} respectively, we obtain for the ratio of the steric factors corresponding to dissociation and recombination $s_2/s_3 \simeq 10^2$, which can be accounted for by the above calculations, showing that $s_3 \simeq 10^{-3}$. The point is that at moderate temperatures the steric and energy factors approximately cancel out¶:

$$\frac{1}{s_3} \simeq e^{-E_3/RT} \ ,$$

and because of this the rate constant is indeed of the same order of magnitude under these conditions as the classical (Tolman) number of collisions [Eqn. (2)]. This fact, already mentioned in section III, subsection 1, can now be fully understood†.

The method described was also used [183], with a somewhat modified model of the activated complex, to interpret the trimolecular homogeneous chain termination reaction $H + O_2 + M \rightarrow HO_2 + M$ in the chain hydrogen combustion process [108,109,118]. The rate constant calculated for this reaction with M = Ar agrees very well with the experimental data of Clyne and Thrush [113] (Table 5). We may

¶For the recombination of halogen atoms in collisions with inert gas atoms, $E_0 = 2-3$ kcal mole^{-1}.

†Keck [195] showed by a statistical procedure that the rate constant for the recombination process at low temperatures must be close to the classical number of three-body collisions.

note that this calculation allows some improvement in the solution of the problem of the temperature variation of the upper explosion limit, which is regulated by the competition between this reaction and the chain-branching reaction $H + O_2 \rightarrow OH + O$.

Umanskii and Stepukhovich [196] calculated the kinetic characteristics of certain other reactions of the type $A + BC + M \rightarrow ABC + M$. An analogous approach may be employed to interpret the effect of the third body in the recombination of radicals at low pressures, where the rate is determined by the "pure" third-order constant. Umanskii and Stepukhovich [196,197] suggested that in the second stages of radical recombination by ET and RMC mechanisms the same activation complex is formed. Then the three-body recombination rate constants (at low pressures) are

$$k^{ET} = A^{\neq}\left(\frac{E^*}{RT}\right)^{m-1}\frac{1}{(m-1)!}\ , \qquad (24)$$

$$k^{RMC} = A^{\neq}\exp\left(\frac{\Delta E}{RT}\right)\ , \qquad (25)$$

the expressions involving the same pre-exponential factor $A^{\neq}$ defined by the TST formulae. E^* is the energy distributed among m internal degrees of freedom in the first stage of the ET mechanism and ΔE the energy of formation of the radical-molecular complex.

It is qualitatively clear that the energy transfer mechanism is more likely in the recombination of complex radicals, since it postulates the formation of an intermediate compound with a larger number of internal degrees of freedom and consequently with a longer lifetime (at least in the case of simple third bodies).

Here the concept of the "loose" activated complex was employed [194,198,199]. It is now generally accepted that in bimolecular radical recombination reactions a complex of this kind is in fact involved. Nevertheless in the early studies [15] it was shown that, whereas the number of two-body collisions of relatively simple particles may be fairly well estimated on the basis of rigid molecular models, it is evident that no three-body collisions can involve absolutely rigid molecules. This applies to an even greater extent to complex polyatomic species‡.

On the basis of these considerations, the third-rate order rate constant for the symmetrical recombination of certain alkyl radicals with straight-chain [200] and branched-chain [200] structures and the rate constants for unsymmetrical recombination [197] were calculated. In the latter case it was found that, if in the reaction $R' + R'' + M \rightarrow$ product, the recombining radicals differ markedly in the degree of their complexity, the rate constant may greatly exceed the geometrical mean of the constants for the symmetrical recombination reactions $R' + R' + M \rightarrow$ product and $R'' + R'' + M \rightarrow$ product. The pre-exponential factors for all these reactions proved to be very similar. The steric factor was found to be lower than for atomic recombination due to increase in steric hindrance. Generalising the results of the above discussion of steric factors for three-body recombination reactions involving various species, one may conclude that the following characteristic features obtain:

Recombination of atoms: $s \simeq 10^{-3};\ \frac{ds}{dT} > 0$,

Recombination of atoms with simple molecules: $s \simeq 10^{-3} - 10^{-4};\ \frac{ds}{dT} \simeq 0$,

Recombination of complex radicals: $s \leqslant 10^{-5};\ \frac{ds}{dT} < 0$.

‡The considerations adduced above concerning the relation between the steric factors for trimolecular and bimolecular reactions do not of course refer to the free activated complex model.

The knowledge of the calculated third-order rate constants permit the prediction of the pressure ranges where the order of the reaction changes provided that the experimental second-order rate constants describing the recombination at high pressures [197] are known. The characteristic transition pressure is higher the higher the temperature and the simpler the recombining radicals and the third body.

Examination of the elementary step characteristic of TST, with the aid of the potential energy surface was subsequently applied also in combination with various simplified interaction models whereby the dynamics of three-body collisions may be described mathematically. We may note, for example, the idealised theory of atomic recombination proposed by Jepsen and Hirschfelder [201]. In this theory the calculation of the rate of recombination of atoms in a colinear three-body collision requires the determination of the individual collision trajectories in order to find the fraction of activated complexes decomposing into recombination products. These authors examined an idealised interaction potential for three atoms located on a single straight line in the form

$$V = v(r_{12}) + v(r_{23})\ , \qquad (26)$$

the potential $v(r)$ being approximated by the rectangular potential well model. The potential energy surface corresponding to this model is shown in Fig. 5*a* in skewed coordinates (the angle between the axes is 60°, since the masses of all three atoms are assumed to be identical).

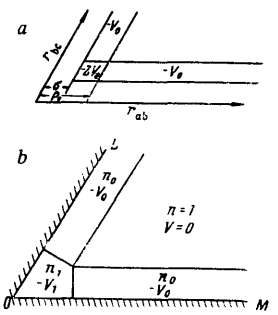

Figure 5. Potential energy surface in the idealised theory [201].

The surface consists of a plateau in the upper right-hand corner (dissociated state), two "trenches" with sheer walls parallel to the coordinate axes (two possible associated states), and a "well" in the lower left-hand corner of the diagram (activated complex or a metastable triatomic molecule). However, in order to facilitate the calculations, a somewhat different surface was employed (Fig. 5*b*) and for the sake of generality the depth of the well V_1 was assumed to be arbitrary. The motion of the representative point with a specified energy E over such a surface exhibits complete analogy with geometrical optics if a refractive index $n = [(E - V)/E]^{1/2}$ is assigned to each part of the surface. This motion is characterised by a linear trajectory which undergoes reflection and refraction at the discontinuities in the potential. It is limited by the internal region of the angle *LOM* in Fig. 6*a* ("the region of motion"), and the trajectories can be studied particularly

conveniently when this region is expanded on the kaleidoscope principle (Fig. 6*b*). The task thus reduces to the determination of the flux of representative points per unit time across the DB_0E line which ensures recombination, i.e. the corresponding trajectories no longer re-emerge from the region of bound states.

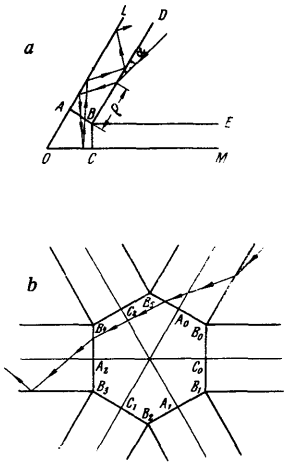

Figure 6. Idealised theory[201]. Trajectory of the representative point: *a*) in the "region of motion"; *b*) in the expanded form.

The aim of any treatment of this kind reduces to finding a formula for the frequency of the effective three-body collisions where only the masses and diameters of the reacting species are included as parameters (we may recall that simple kinetic formulae for the number of three-body collisions contain an undefined parameter characterising the region of operation of intermolecular forces). In his discussion of the contribution of essentially simultaneous three-body collisions to the overall rate of recombination, Smith[202] holds the same view. For a symmetrical description of the motion of three particles in a six-dimensional space, we must construct three three-dimensional cylinders representing the pair interactions between atoms (a "cut off" potential of pair interaction is considered). These cylinders intersect in the region S near the origin of coordinates where all three species interact simultaneously. In those parts where there is no interaction the trajectory is linear and it can enter the region S either directly ("pure" three-body collision) or indirectly, passing first through one of the cylinders and forming a diatomic complex before collision with a third particle. The determination of an effective collision cross-section requires the determination of a geometrical section through the region S. Smith[202] gives an approximate estimate of this section for the case where two of the three reacting atoms are identical. Comparison of the results of the calculations with the experimental data of Christie et al.[121] for the reaction 2I + M → product (Table 4) showed that at 293°K the effectiveness of the simultaneous three-body collisions in the recombination is of the order of 10^{-2}–10^{-3} (1/44 for M = Xe and 1/720 for M = He), the effectiveness being greater the closer is the mass of the third body to that of the recombining atom.

Polarography of Benzenoid Aromatic Hydrocarbons

S.I.Zhdanov

This review summarises the results of the study of the reduction and oxidation in protogenic, aprotic, and strongly acidic solutions of benzenoid polynuclear aromatic hydrocarbons whose molecules do not contain electrochemically active substituents. The characteristic features of the adsorption of aromatic hydrocarbons on mercury and various other metals are noted. The bibliography contains 167 references.

I. INTRODUCTION

The investigation of the problem of aromaticity[1,2], resulting to a considerable extent from the outstanding progress in the field of quantum chemistry, has led to the publication of a large number of papers on the study of the polarographic properties of aromatic compounds. This is due primarily to the fact that the polarographic method is an extremely convenient method for studying the mechanism of electrode processes and can be successfully used to verify theoretical conclusions by correlating polarographic half-wave reduction and oxidation potentials ($E_{1/2}$) with the energy parameters of the molecules, obtained by quantum-chemical calculations. It is now an appropriate time to systematise this extensive published material, which includes valuable information of interest to a wide circle of chemists. These papers have of course been examined in reviews devoted to the polarography of organic compounds, but the treatment has been incomplete[3-8]. The most successful review of these papers is that of Peover[9], but this is published in a source not readily available to Soviet readers, and a number of problems were not examined in it.

The present review to some extent fills this gap. It includes papers on the polarography of only those benzenoid aromatic hydrocarbons which do not contain electrochemically active substituents, and also on the polarography of unsaturated compounds, but only to the extent necessary for an understanding of the phenomena examined. A review of papers on the polarography of non-benzenoid aromatic hydrocarbons was published separately[10].

II. MECHANISM OF REDUCTION

The reduction of unsaturated and aromatic hydrocarbons at a dropping mercury electrode is generally studied in a supporting electrolyte of tetra-alkylammonium salts, most frequently $(C_4H_9)_4NI$, since in solutions of these salts the processes taking place at the most negative potentials can be studied. The second electrode is usually a layer of mercury in contact with the solution being studied; the potential of the second electrode is measured relative to an aqueous saturated calomel electrode. When the values of $E_{1/2}$ are compared, it is not necessary to allow for the inter-phase potential at the interface between the aqueous KCl solution and the non-aqueous $(C_4H_9)_4NI$ solution.

To establish the mechanism of the electrode processes and in particular to obtain the polarographic characteristics ($E_{1/2}$), which can be correlated with the energy parameters of the molecules, it is very important to carry out the studies in solvents with low proton activity ("availability"). It was in so-called aprotic solvents that the stages of reversible electron transfer with the formation of fairly stable hydrocarbon anion radicals, almost uncomplicated by subsequent irreversible reactions of protonation, dimerisation, or disproportionation, were revealed. This behaviour is in complete accordance with the general empirical rules formulated by Stackelberg[11,12] (see also Ref. 3) on the basis of extensive experimental material.

1. The stage of electron transfer is reversible if the geometric structures of the starting material and product do not differ significantly.

2. The stage is irreversible if it is accompanied by the formation of stable σ bonds, for example C–H (protonation) or C–C (dimerisation) bonds.

3. The stage is irreversible if it is accompanied by rupture of a stable σ bond, for example the bonds C–Hal in halogen derivatives, O–O in peroxides, and N–O in hydroxylamines.

4. The stage is irreversible if it is accompanied by the attachment of a proton to a heteroatom with the formation of N–H or O–H bonds, since these bonds are kinetically labile.

The study of aprotic solvents in the polarography of organic compounds was begun by Wawzonek and coworkers[13-18]. Wawzonek was the first to use a dioxan–water (3 : 1) mixed solvent[13-15], and subsequently acetonitrile, dimethylformamide[16,17], and tetramethylurea[18].

Many other authors used solvents which are not strictly aprotic: 75% dioxan[18-34], 85% dioxan[35,36], 96% dioxan[23,25-27,37], 75% ethanol[36,38], ethylene glycol monomethyl ether (cellosolve)[39-41], 50% isopropyl alcohol[42], a tetrahydrofuran–water mixture (3 : 1)[43], and ethylenediamine[44]. Other authors, like Wawzonek, used purely aprotic solvents: dimethylformamide (DMFA)[45-60], acetonitrile[61,62], and

tetrahydrofuran[63]. Purely dioxan solutions have not yet been used in polarography, because of the very low electrical conductivity. DMFA is most frequently used. Similar polarographic properties are shown by tetramethylurea, but this solvent has not found extensive application.

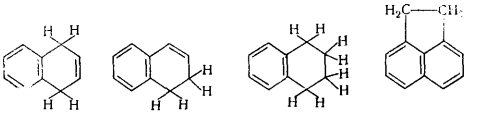
Simple unsaturated and aromatic compounds are reduced at a dropping mercury cathode in the range of high cathode potentials. Compounds whose molecules contain a single non-activated multiple bond[13] or benzene ring[14] are not reduced at all at a dropping mercury cathode in a range of potentials which can be measured. Aliphatic unsaturated compounds with conjugated bonds undergo two-electron reduction in 75% dioxan[20]. For allene ($CH_2=C=CH_2$), $E_{1/2}$ = -2.33 V, for butadiene ($CH_2=CH-CH=CH_2$), $E_{1/2}$ = -2.63 V, etc.

Vinylacetylene ($CH\equiv C-CH=CH_2$) gives two two-electron waves with $E_{1/2}$ = -2.44 V and -2.62 V. The first wave corresponds to the reduction of the triple bond to a double bond, and the second wave corresponds to the reduction of the butadiene produced. Thus the reduction of unsaturated compounds involves the hydrogenation of multiple bonds. Reduction is complete when the compound contains one or several non-conjugated and non-activated multiple bonds.

The reduction of compounds with multiple bonds activated by conjugation with phenyl rings takes place in exactly the same way[13,20]. In these compounds, the multiple bonds undergo electrochemical hydrogenation, whereas the phenyl rings are not attacked. Reduction is complete when the compound does not contain multiple bonds conjugated with other multiple bonds or with phenyl rings.

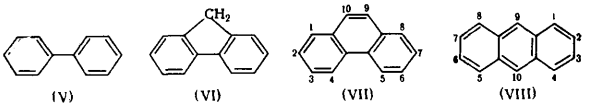
Increase in the conjugation facilitates reduction: $E_{1/2}$ becomes less negative in the series styrene ($Ph-CH=CH_2$), 1,1-diphenylethylene ($Ph_2=C=CH_2$), stilbene (Ph-CH=CH-Ph), triphenylethylene ($Ph_2=C=CH-Ph$), and tetraphenylethylene ($Ph_2=C=C=Ph_2$). The double bond is activated to a greater extent and is therefore more readily reduced when the two phenyl groups are arranged symmetrically with respect to the double bond (stilbene), than when they are arranged unsymmetrically (1,1-diphenylethylene). Styrene is more readily reduced than β-methylstyrene ($Ph-CH=CH-CH_3$), the effect of the methyl group being considerable ($\Delta E_{1/2} \simeq 200$ mV). 1,4-Diphenylbutadiene (Ph-CH=CH-CH=CH-Ph) gives only one wave corresponding to two-electron reduction. Thus this compound is attacked in the 1,4-position, and the molecule of the product contains one of the double bonds in the middle of the carbon chain, not conjugated with either of the two phenyl rings. Phenylacetylene ($Ph-C\equiv CH$) and diphenylacetylene ($Ph-C\equiv C-Ph$) have more negative $E_{1/2}$ values than styrene and stilbene, and they therefore undergo immediate four-electron reduction with the formation of ethylbenzene and bibenzyl respectively.

An analogous picture is observed in the reduction of aromatic hydrocarbons[14]. In the naphthalene molecule, only one double (more accurately aromatic) bond is hydrogenated. From this it follows that the reduction product is 1,5-dihydronaphthalene (I), in whose molecule the double bond is not conjugated with the phenyl ring. 1,2-Dihydronaphthalene (II) is reduced to tetralin (III), which does not exhibit electrochemical activity:



(I) (II) (III) (IV)

Acenaphthene (IV) is reduced in the same way as naphthalene: it gives only one two-electron wave. Biphenyl (V) and fluorene (VI) are hydrogenated in the 1,4-position.



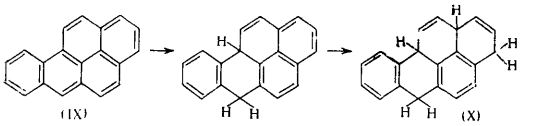
(V) (VI) (VII) (VIII)

The molecules of the products of the two-electron reduction contain only isolated double bonds and a phenyl ring.

Phenanthrene (VII) gives two two-electron waves, the value of $E_{1/2}$ for the second wave being close to the value of $E_{1/2}$ for 9,10-dihydrophenanthrene, and also biphenyl and fluorene. On this basis, the first wave for phenanthrene is attributed to the reduction of the double bond in the 9,10-position, and the second wave to reduction similar to the reduction of biphenyl and fluorene.

Anthracene (VIII) gives one two-electron wave, from which it follows that it is characterised by hydrogenation in positions 9 and 10 with isolation of the two phenyl rings.

Other polynuclear aromatic hydrocarbons studied by Wawzonek (chrysene, pyrene, 1,2-benzanthracene, 1,2,5,6-dibenzanthracene, and 3,4-benzpyrene) give multi-wave polarograms with characteristic rapid breakdown of the molecule into isolated double bonds and phenyl rings. Thus of the ten aromatic bonds in 3,4-benzpyrene (IX)



(IX) (X)

only two are reduced, with the formation of compound (X), where the molecule contains two isolated phenyl rings and two isolated bonds.

The values of $E_{1/2}$ for the waves corresponding to the reduction of unsaturated and aromatic compounds are independent of pH (at pH > 7). The slope of the straight line obtained by plotting $\lg i/(i_d - i)$ against E is 0.06-0.07 V, that is it, as it were, corresponds to the theoretical slope (0.059 V) for a reversible potential-determining one-electron reaction. On this basis, Wawzonek[13] proposed the following mechanism of reduction:

$$R + e = R^{\cdot-} \text{ (reversible potential-determining state)} \quad (1)$$
$$R^{\cdot-} + e \rightarrow R^{2-} \text{ (irreversible stage)} \quad (2)$$
$$R^{2-} + 2H_2O \rightarrow RH_2 + 2OH^- \text{ (irreversible rapid stage)} \quad (3)$$

A second possible mechanism:

$$R + e = R^{\cdot-} \quad (1)$$
$$R^{\cdot-} + H_2O \rightarrow RH^{\cdot} + OH^- \quad (4)$$
$$RH^{\cdot} + e = RH^- \quad (5)$$
$$RH^- + H_2O \rightarrow RH_2 + OH^- \quad (6)$$

was also examined[13], but it was rejected, since for this mechanism $E_{1/2}$ should have been dependent on pH, and this is not observed experimentally. Subsequent studies showed, however, that most compounds are nevertheless reduced according to the second mechanism.

Considerable progress in the study of the mechanism of the reduction of aromatic and unsaturated compounds has been made by applying quantum-chemical calculations to polarographic data. The foundations for this work were laid in a short note published by Maccoll[64]. By developing Hückel's idea of the existence of a relationship between the

energy of the lowest vacant π electron molecular orbital, into which the molecule can accept one or two electrons, and the ease of attachment of alkali metals to aromatic compounds, Maccoll observed a relationship between the reduction potential of an aromatic compound and the energy of the lowest vacant molecular orbital (MO).

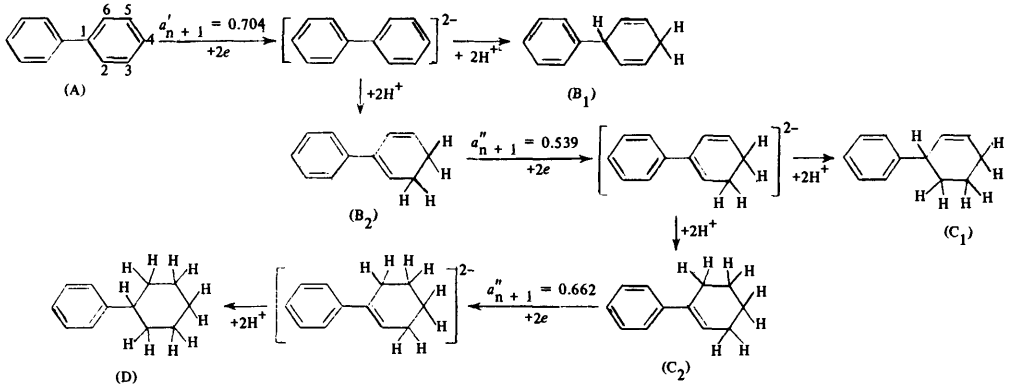
The best known subsequent papers are those of Hoijtink. In his first paper[22] he derived the relationship between $E_{1/2}$ and energy of the lowest MO:

$$E_{1/2} = a_{n+1}\beta - 1.05 \qquad (7)$$

(where a_{n+1} is a coefficient characterising the energy of the lowest vacant MO, β the exchange or resonance integral, and 1.05 the value of $E_{1/2}$ for the first wave of triphenylmethyl, taken as standard), and also put forward arguments which make it possible on the basis of these data to predict the direction of the process. Since $\beta < 0$ ($\beta \simeq -2.27 \pm 0.07$ eV [22]), the value of $E_{1/2}$ is more negative, the larger a_{n+1}.

Eqn. (7) is useful chiefly because it can be used to calculate $E_{1/2}$ for the starting material and the assumed products of the two-electron reduction. If the product has a more negative $E_{1/2}$ value than the starting material, the polarogram will show two two-electron waves; if it has a less negative $E_{1/2}$ value, one four-electron wave will be produced. Thus if the value of a_{n+1} for the starting material is greater than the value of a_{n+1} for the product, four-electron reduction ($n = 4$) should take place immediately.

The calculation also makes it possible to make predictions regarding the structure of the product. If we accept the mechanism of reduction proposed by Wawzonek[13] (reactions 1–3), the structure of the product (intermediate or final) will be determined by the distribution of the π electrons over all the carbon atoms of the framework of the molecular doubly-charged anion R^{2-} and the radical-anion $RH^{\cdot}$, since their protonation (reaction 3) will have the greatest probability at the carbon atom at which the negative charge is a maximum[64]. Hoijtink states[22] that consideration of the other mechanism (reactions 1, 4–6) leads to the same results. For example, for the reduction of biphenyl:



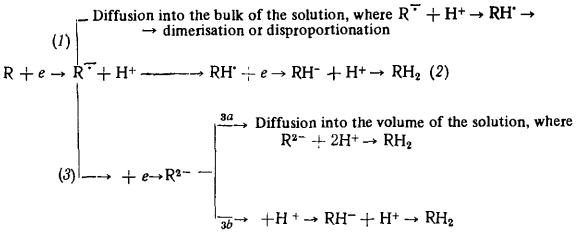
Calculations show that $a'_{n+1} > a''_{n+1}$ and $a'_{n+1} > a'''_{n+1}$. Thus all three substances, that is A, B_2, and C_2, should give a single reduction wave. Moreover, according to the calculation, in the AH^- anion obtained by the attachment of the first proton to the doubly-charged anion A^{2-}, the π electron density should be the same at the carbon atoms in positions 1, 3, and 5. Since positions 3 and 5 are identical, one third of the biphenyl (A) should be reduced to B_1, and two thirds to B_2. Of these two products, only B_2 can undergo further reduction, since B_1 contains only isolated double bonds. Thus the number of electrons in the second stage of the reduction, calculated on the biphenyl, is $n_2 = n_1 2/3 = 4/3$. For the same reasons, half of the intermediate product B_2 is reduced to the product C_1, which does not show polarographic activity, and half is reduced to C_2, which undergoes reduction to the polarographically inactive product D. The number of electrons in the third stage is $n_3 = n_2 1/3 = 2/3$, and the overall wave should correspond to the transfer of $n_{total} = n_1 + n_2 + n_3 = 2 + 4/3 + 2/3 = 4$ electrons. A mixture of products consisting of equal quantities of B_1, C_1, and D should be formed.

This examination was carried out for 12 aromatic hydrocarbons, and very good agreement was obtained between the values of $E_{1/2}$ and the experimental values[14] if allowance is made for the approximate nature of the method of calculating the values of a_{n+1} and the derivation of Eqn. (7).

An analogous approach was used in the examination of the reduction of diphenylpolyenes[37] with general formula $Ph-(CH=CH)_m-Ph$ ($m = 2-6$). For all the compounds studied, $a'_{n+1} < a''_{n+1} < a'''_{n+1}$ etc. Thus the diphenylpolyenes give separate waves for the reduction of individual double bonds.

Application of Wawzonek's mechanism led Chopard-dit-Jean and Heilbronner[65] to the conclusion that there is a difference in the mechanisms of reduction of alternant (for example naphthalene) and non-alternant (for example azulene) aromatic hydrocarbons. In their opinion, alternant hydrocarbons always give two-electron waves, whereas non-alternant hydrocarbons may give one-electron and two-electron waves. Hoijtink and coworkers[25] criticised this view and showed that in an aprotic medium both alternant and non-alternant hydrocarbons give a first one-electron wave. When even weak proton donors (e.g. water) are added, this wave in most instances becomes a two-electron wave. The first wave for azulene, however, even under these conditions, remains a one-electron wave, the reason for which will be examined below.

On the basis of these experimental results, the following general mechanism was proposed



In contrast to the mechanism of Laitinen and Wawzonek, it is assumed that $E_{1/2}$ for the attachment of the first electron is less negative than $E_{1/2}$ for the attachment of the second electron (path 3). On the other hand, $E_{1/2}$ for $RH^{\cdot}$ is always less negative than $E_{1/2}$, since a_{n+1} for this species is smaller than that for the original molecule R. Thus in the absence of proton donors, or when the protonation of the radical-anion $R^{\cdot-}$ is too slow (path 1), the attachment of only one electron takes place at the potentials of the first wave; the radical-anions formed diffuse into the bulk of the solution, where they are slowly protonated and either dimerise or disproportionate. At more negative potentials, the second electron is attached (path 3), and the doubly-charged anion is protonated. The second wave often corresponds to the transfer of more than one electron. This means that R^{2-} has a higher affinity for the proton and is able to undergo protonation in direct proximity to the electrode. If the new molecule RH_2 can undergo further reduction, this process also increases the second wave. The electron affinity of $R^{\cdot-}$ is less than that of RH_2 for, for example, perylene, coronene, fluoranthene, azulenes, and decacyclene.

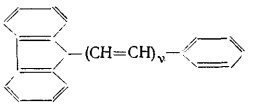
If the rate of protonation of the anion-radical $R^{\cdot-}$ is greater than the rate of diffusion of $R^{\cdot-}$, the $RH^{\cdot}$ radicals formed close to the electrode add on a second electron, the first wave is increased, and the wave for the reduction of $R^{\cdot-}$ at more negative potentials disappears. Path 3 can of course still be realised at these potentials, since in the final analysis increase in the cathode potential makes path 3 more rapid than path 2.

In experiments with the addition of weak proton donors, an intermediate case, where the rates of the diffusion and protonation of $R^{\cdot-}$ are commensurate, has been realised. As a result of simultaneous reduction by paths 1 and 2, the first wave acquires an intermediate height ($2 > n > 1$).

To obtain more information on the mechanism a detailed study has been made of the influence of the concentration of proton donors and the concentration of depolariser on the form of the waves and the magnitude of $E_{1/2}$.[25] An approximate method involving the use of the Nernst equation and the material balance equations was used to derive equations for the wave and $E_{1/2}$, which were compared with experiment. It is obvious that this derivation is inapplicable, if the transfer of both the first and the second electrons takes place reversibly. It has been shown[26] that the Nernst equation can be used if the rates of electron transfer in both directions are appreciably greater than the rates of the diffusion and attachment of protons to the anions.

Analysis of the properties of the waves for hydrocarbons in the presence of weak proton donors, again by an approximate method, made it possible to obtain relationships which correspond, qualitatively at least, to the experimental results. In this way, the new mechanism has to a large extent been confirmed.

In subsequent work, Hoijtink[26] extended the measurements to 1-phenyl-*p*-biphenylenepolyenes, 1-phenyl-*p*-(2,3-benzo)-biphenylenepolyenes, and dibiphenylenepolyenes in 75% and 96% dioxan. In 96% dioxan, the compounds studied gave polarograms with either two one-electron waves or one two-electron wave. It was shown that in the first instance the reduction takes place by Hoijtink's mechanism[25]. In the second instance, two mechanisms are possible: Hoijtink's mechanism (high proton affinity of $R^{\cdot-}$, leading to rapid protonation of $R^{\cdot-}$ and slow reduction of $RH^{\cdot}$) and the mechanism of Laitinen and Wawzonek (electron affinity of $R^{\cdot-}$ greater than that of R). Hoijtink was able to show that here the reduction (two-electron) takes place by the mechanism of Laitinen and Wawzonek. He observed the following relationship: the values of $E_{1/2}$ for both waves of 1-phenyl-*p*-biphenylenepolyenes (XI):



(XI)

become less negative with increase in the length of the polyene chain (with increase in ν), but in such a way that the difference in $E_{1/2}$ decreases. At $\nu = 6$, the values of $E_{1/2}$ for the two waves coincide. Analysis of the properties of the waves by means of a method similar to that just described showed that for substances which give two-electron waves in 96% dioxan, the reduction takes place by the mechanism of Laitinen and Wawzonek.

These results show that in the electrochemical reduction of hydrocarbons, direct transfer of electrons to the molecule being reduced takes place with the formation of radical and molecular carbanions. These anions are unstable towards protonation, but it might be expected that they would have appreciable stability in aprotic media. Various compounds, even in 96% dioxan, that is in a medium which is not strictly aprotic, give two one-electron waves on the polarograms. The radical-anions are evidently fairly stable even under these conditions. The direct observation of the formation of radical-anions and the study of their properties was of considerable interest. This problem was solved in two ways: by electrolysis in acetonitrile or DMFA[16] and by reaction with alkali metals in dimethoxyethane or tetrahydrofuran[66,67].

In acetonitrile and DMFA, a number of the compounds studied form one-wave polarograms ($n = 2$ for styrene, triphenylethylene, and tetraphenylethylene), whereas stilbene, anthracene, and 9-anisylidenefluorene give two waves of unequal height[16]: the first wave is appreciably higher than the second and on the addition of water or benzoic acid (in lower concentration) the first wave increases until it becomes the only wave.

Electrolysis of solutions in acetonitrile or DMFA on a large stationary mercury cathode in all instances produces an intense colour in the solution, characteristic of solutions of radical-anions. The products of the electrolysis of stilbene in DMFA were found to contain 1,2,3,4-tetraphenylbutane, which is evidently obtained by dimerisation of the radical-anions. Further proof of the existence of stable radical-anions was provided by the isolation of dicarboxylic acids from the products of the electrolysis of stilbene in the presence of carbon dioxide.

The reaction of metallic sodium with an aromatic hydrocarbon in dimethoxyethane or tetrahydrofuran gives a salt-like compound of sodium and the hydrocarbon, in which the hydrocarbon forms the anionic part. These compounds

are readily soluble in dimethoxyethane and in tetrahydrofuran and are completely or partly (for the disodium compound) dissociated.

Use has been made[66,67] of the fact that a solution of sodium biphenyl can be used to titrate solutions of other hydrocarbons which have a higher electron affinity than biphenyl. If the potential of the indicator electrode is measured, it is possible to determine the normal potentials of the hydrocarbons (relative to the potential of biphenyl). If the potential for the transfer of a second electron is sufficiently high, the titration may also give the radical-anion and the doubly-charged anion. Experiment showed that the values of the normal potentials obtained in this way are close to the values of the polarographic $E_{1/2}$, the difference in the values of $E_{1/2}$ for the first and second stages amounting to 0.4–0.6 V. The absorption spectra of the radical-anions of aromatic hydrocarbons have been measured[68] and it has been shown[69,70] that these spectra can be interpreted by the methods of quantum chemistry.

The spectra of the radical-anions on the one hand and of the doubly-charged anions on the other[71] have characteristic absorption bands, all the bands being displaced towards longer wavelengths with increase in the length of the conjugated system of double bonds (from stilbene to diphenyldodecahexaene). The reactions of radical-anions with aromatic hydrocarbons exhibiting a less negative half-wave potential have also been studied by EPR spectroscopy[60].

In their discussions, Hoijtink and coworkers suggested that the transfer of electrons to the hydrocarbon molecule and the hydrocarbon radical-anion takes place reversibly; the reversibility was proved by the methods of classical polarography (form of the wave). More rigorous proof can be obtained by alternating-current polarography, in which the reversible processes are characterised by the Faraday current peaks, which exhibit definite properties[72–74]. Hoijtink and coworkers studied the reduction of aromatic hydrocarbons and diphenylpolyenes in DMFA by alternating-current polarography and obtained the following results[47,48,51,57,75].

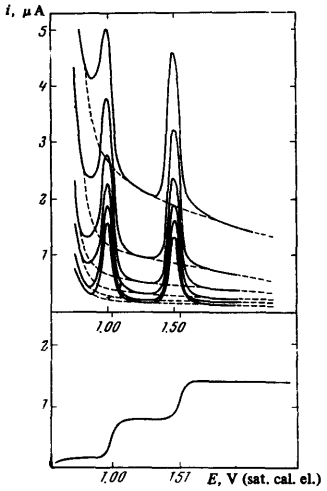


Figure 1. Alternating-current and classical polarograms for dibiphenyleneethylene in dimethylformamide. Frequency, Hz (from lower curve to upper): 32.1, 43.1, 62.5, 94.0, 174, and 392 (published data[47]).

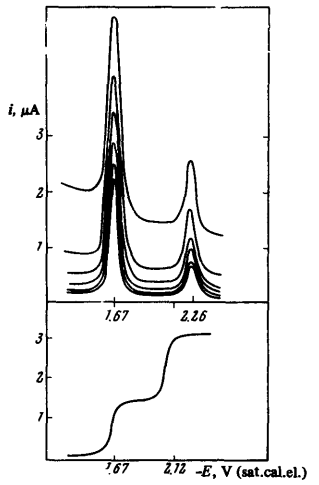

Figure 2. Analogous data for perylene in dimethylformamide.

The properties of the radical-anions of α,ω-diphenylpolyenes and tetraphenylcumulenes, that is compounds of the type $Ph_2=C=C=C=C=Ph_2$ (tetraphenylbutatriene) were studied in exactly the same way[71]. It was observed that the difference in the normal potentials of the first and second one-electron stages (and hence $\Delta E_{1/2}$) for these compounds is much smaller (~ 0.20 V) than that for aromatic hydrocarbons (0.4–0.6 V). The cumulenes are reduced much more readily than the polyenes, since the conjugation in the former is stronger. Polarographic study of tetraphenylbutatriene in DMFA and in aqueous dioxan solutions[53–55] confirmed these results. The intermediate products are tetraphenylbutadiene and tetraphenylbut-1-ene, in which the double bonds are conjugated with the phenyl groups and are reduced further. The final products are tetraphenylbut-2-ene (with an isolated double bond) and tetraphenylbutane.

The alternating-current polarograms for solutions of dibiphenyleneethylene (Fig. 1) and dibiphenylenebutadiene show two Faraday current peaks, corresponding to the two waves on the classical polarograms; on the alternating-current polarograms for aromatic hydrocarbons (tetracene, perylene, fluoranthene, anthracene, coronene, pyrene, 1,2-benzpyrene, and naphthalene) the second peak is always lower than the first peak (Fig. 2)[47]. Judging from the frequency dependence of i_f for both peaks of dibiphenyleneethylene and dibiphenylenebutadiene, both electrons are transferred reversibly. The second electron in the reduction of aromatic hydrocarbons is transferred irreversibly. It is suggested that the irreversibility of the transfer of the second electron for aromatic hydrocarbons is due to R^{2-} protonation, which, thanks to the high proton affinity of R^{2-}, takes place rapidly even in DMFA.

The first stage in the reduction of α,ω-diphenylpolyenes in DMFA is also reversible[48]. On the classical polarograms, however, the first wave is appreciably higher than the second (with the exception of stilbene, whose polarogram consists of two waves of equal height), and on going to higher α,ω-diphenylpolyenes, a tendency for the first wave to increase further at the expense of the second is observed. The second peaks on the alternating-current polarograms of all α,ω-diphenylpolyenes decrease with increase in the frequency of the applied alternating potential, indicating that the second stage of the reduction is irreversible (due to the protonation of R^{2-}). The increase in the first wave at the expense of the second is related to the protonation of the radical-anions $R^{\cdot-}$; the proton affinity of $R^{\cdot-}$ increases with increase in the number of double bonds in the α,ω-diphenylpolyenes. These experiments, however, do not give an unambiguous indication of the reason for the irreversibility of the second stage of the reduction, since it may also be due to slow transfer of the second electron to the radical-anion $R^{\cdot-}$. It has been pointed out[51] that the kinetics of this stage may be influenced by the structure of the electrical double layer.

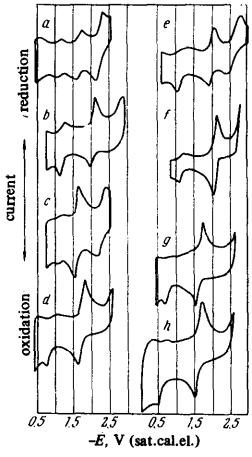

Figure 3. Cyclic polarograms in 0.1 M $(C_4H_9)_4NClO_4$ in dimethylformamide on a stationary platinum electrode for the two-electron reduction of: *a*) perylene; *b*) pyrene; *c*) tetracene; *d*) fluoranthene; *e*) 1,2-benzanthracene; *f*) coronene; *g*) acenaphthylene; *h*) acridine. 50 pulses per second (published data[76]).

It was later confirmed by cyclic volt-ammetry with a platinum electrode[76] or hanging mercury drop electrode[77] that the first stage in the reduction of polynuclear aromatic hydrocarbons (perylene, pyrene, tetracene, and various others) in an aprotic medium is reversible, whereas the second stage is partly or completely irreversible; the anodic branch of the cyclic volt-amperogram shows a clearly defined peak due to oxidation of the radical-anion, whereas the peak for the oxidation of the doubly-charged anion is either very small or completely absent (Fig. 3).

The question of whether it is possible in principle to achieve the electrochemical preparation of triply-charged radical-anions of aromatic hydrocarbons by the attachment of three electrons is of considerable interest. It has been reported[78] that the electrolysis of tetracene in acetonitrile at −2.5 V gives radical species whose EPR signal differs from that of the singly-charged tetracene radical-anion. Hoijtink[57] showed by alternating-current polarography that these experiments actually gave the singly-charged dihydrotetracene radical-anion. The alternating-current polarogram of tetracene shows two Faraday current peaks, corresponding to the first and third waves on the classical polarogram of tetracene. This means that the second stage of the reduction of tetracene is irreversible, because of the rapid protonation of R^{2-} with the formation of dihydrotetracene, whose molecule still contains the naphthalene aromatic system. The third wave on the classical polarogram and the second peak on the alternating-current polarogram thus correspond to the transfer of a single electron to the dihydrotetracene molecule with the formation of the radical-anion. This of course does not mean that the formation of triply-charged radical-anions is in general excluded, but the probability of their production is low, because of their extremely high proton affinity.

We see that the application of the methods of quantum chemistry makes it possible to predict the path for the reduction of complex aromatic and unsaturated compounds. In practice, however, the most probable route is not always realised. For example, according to theory, biphenyl should undergo four-electron reduction in one wave with the formation of a mixture of three substances[22], whereas the experimental results[14] show that it gives only one two-electron wave.

To explain these discrepancies, Hoijtink introduced the idea that the electrical field of the double layer on the electrode or of the counter-ions in solution (primarily protons) influences the electron density distribution in the doubly-charged hydrocarbon anions, determining the nature of the product in the first stage of the reduction[79,80]. In the Soviet literature, this view is held in particular by Bezuglyi[81-83]. Calculations showed[79] that up to a field strength of 1.5 V/Å the negative charge in the doubly-charged naphthalene anion remains greatest in the peri-positions (1,4 or 5,8), whereas in the doubly-charged anions of anthracene, phenanthrene, pyrene, and terphenyl, under the influence of the electric field, the negative charge may be greatest at positions which are not the positions at which it is a maximum in the absence of the field. The change in the reaction centre in the doubly-charged anion takes place at a field strength of about 0.6 V/Å for anthracene, at a strength of about 0.2 V/Å for phenanthrene, and at the even smaller strength of 0.12 V/Å for terphenyl. Thus if the aromatic hydrocarbon is reduced in a protonic solvent and its doubly-charged anion is protonated on the electrode surface, the electric field at the electrode can in principle influence the direction of the process. For example, for anthracene it has been shown theoretically that the primary product is 9,10-dihydroanthracene at field intensities below 7×10^7 V/cm, and 1,4-dihydroanthracene at higher field intensities. In the first instance the molecule has two isolated benzene rings, and under the conditions of polarography, 9,10-dihydroanthracene will be the final product. In the second instance, the molecule of the product still contains a naphthalene system and an isolated double bond. A second wave due to reduction of the naphthalene group should therefore be observed. Hoijtink pointed out the generality of the mechanism of the electrochemical, chemical, and catalytic hydrogenation of aromatic and arylethylenic hydrocarbons (with the primary attachment of one or two electrons to the molecule being reduced). On this basis, he introduced into the analysis of the experimental results data on not only the electrochemical reduction (primarily polarographic data), but also

on chemical reduction (by alkali and alkaline earth metals in inert and proton-active solvents) and on catalytic hydrogenation. These results for the most part agree with the conclusions of the theory. By comparing the compositions of the products obtained under different conditions with the theoretical schemes, it is possible to estimate the magnitude of the electric field gradient under the conditions of a given experiment. For example, the catalytic hydrogenation of anthracene in a solvent of low dielectric constant gives a mixture of 9,10-dihydroanthracene and 1,2,3,4-tetrahydroanthracene, whereas more severe hydrogenation conditions give a mixture of symmetrical and unsymmetrical octahydroanthracenes. This means that the intensity of the field acting on the doubly-charged anion under these conditions is $(6-7) \times 10^7$ V/cm.

From this interesting and important work it follows that the reduction of even fairly simple aromatic hydrocarbons is a complex process. Thus if an organic compound gives a polarogram with two two-electron waves, determination of the nature of the product in the first stage of the reduction is not sufficient to enable a definite conclusion to be reached regarding the nature of the product in the second stage of the reduction. In general, the second wave may be produced as a result of the change in the nature of the product from the first reduction stage with increase in the electric field strength close to the electrode. In principle, this change may also take place without visible transformation of the polarogram. Thus the study of the mechanism of the reduction of complex organic compounds should combine a study of the nature of the influence of many factors with an analysis of the products obtained (see for example Refs. 84 and 85).

A number of papers have been devoted to a more detailed study of the action of proton donors on the reduction of aromatic compounds in an aprotic medium. Schwabe and Schmidt[36] found that when water is added to a dioxan solution of anthracene, fluorene, and pyrene, the first one-electron wave increases at the expense of the second, so that when the concentration of ethanol is sufficiently high, the polarogram shows only one two-electron wave.

Given and Peover[4,49,50] made a detailed study of the influence of various proton donors on the polarography of aromatic hydrocarbons and found that the most convenient proton donor is phenol, which is a sufficiently powerful donor, but which does not give a hydrogen liberation wave. Benzoic acid and HI are inconvenient, because in their solutions the hydrogen liberation waves mask the waves due to the reduction of the aromatic hydrocarbons. Acetic acid is used as an even stronger proton donor. The proton-donating properties of water are too weak, so that its action is appreciable only at high concentrations.

By analysing the form of the first wave for a number of aromatic compounds in the presence of a proton donor at concentrations sufficiently high for the first wave to be a two-electron wave, Given and Peover established that in DMFA the protonation is brought about by undissociated molecules of the proton donor (MA) and not by solvated protons. This conclusion cannot be regarded as proved for all proton donors used, however.

The nature of the action of proton donors depends on the nature of both the proton donor and the depolariser. Given and Peover distinguish various possibilities.

1. If the addition of the proton donor leads to the protonation of the anion-radical $R^{\cdot-}$ produced by attachment of the first electron, the first wave increases at the expense of the second until the latter disappears completely, since the radical $RH^{\cdot}$ is reduced more readily than the original molecule. Most aromatic hydrocarbons behave in this way.

2. If only the doubly-charged ion R^{2-} produced after the attachment of the second electron is protonated fairly rapidly, the first wave remains unchanged on the addition of the proton donor (the anion-radical $R^{\cdot-}$ is too weak a base), but the second is displaced towards less negative potentials. This behaviour is characteristic of quinones.

3. If the original molecule R is protonated, a new wave corresponding to the reduction of the protonated complex is produced in the range of less negative potentials. This behaviour is observed for aromatic carbonyl compounds.

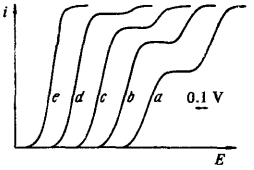

Figure 4. Influence of increase in the concentration of water on the polarogram for anthracene: *a*) 96% dioxan; *b*) 92% dioxan; *c*) 89% dioxan; *d*) 75% dioxan; *e*) 96% dioxan + 2×10^{-4} M HI (published data[25]).

4. The protonation of the doubly-charged anion makes more extensive (multi-electron) reduction possible. When the proton donor is added, the second wave is not only displaced towards less negative potentials but also undergoes an increase in height. Sometimes, additional waves appear. This behaviour is observed for pyrene, perylene, and phenanthrene.

5. If dimerisation of the radical-anions or radicals plays a significant part in the electrode process, a complex picture is observed on the introduction of proton donors. Sometimes, between the two original waves there appears a new wave, which increases with increase in the concentration of the proton donor at the expense of the second wave (benzaldehyde and xanthone in the presence of phenol).

This summary shows that experiments with the addition of proton donors in general do not contradict Hoijtink's scheme for the reduction of aromatic hydrocarbons. In fact, it may be considered that these experiments provide further important evidence in support of the scheme.

Grodza and Elving[56,86] tried to apply various criteria of classical polarography to the determination of the mechanism of the reduction of arylethylenes in ahydrous DMFA and in DMFA–water mixtures (80% or 90% DMFA). The experimental results for styrene, stilbene, 1,1-diphenylethylene, triphenylethylene, and tetraphenylethylene do not satisfy completely any of the postulated mechanisms. These authors consider, however, that the idea that the mechanism of the reduction changes along the polarographic wave corresponds most closely to the experimental results. At the foot of the wave, the reduction is preceded by protonation of the hydrocarbon molecule, whereas close to the limiting current plateau it is followed by protonation of the carbanions ($R^{\cdot-}$ or R^{2-}). Nevertheless, the mechanism involving preliminary protonation of the hydrocarbons in an aprotic medium can hardly be accepted. The authors themselves attribute their lack of success in attempts to

establish the mechanism reliably to the influence of the structure of the electrical double layer, for which it is difficult to allow.

Experiment indicates[87] that aprotic media show different efficiencies in increasing the difference in $E_{1/2}$ for the separate stages of the reduction (differentiating action). Thus for 9,10-anthraquinone and its derivatives in alkaline aqueous-alcoholic or aqueous-dioxan solutions, $\Delta E_{1/2}$ = 0.16–0.18 V; in acetonitrile in a supporting electrolyte of $(C_2H_5)_4NClO_4$, $\Delta E_{1/2} \simeq 0.5$ V; and in DMFA in the same supporting electrolyte, $\Delta E_{1/2} \simeq 0.7$ V. The phenomenon must undoubtedly be attributed to the difference in the rates of protonation of the carbanions. The magnitude of $\Delta E_{1/2}$ is influenced not only by the solvent, however, but also by the dissolved electrolyte. For example, for the same derivatives of 9,10-anthraquinone in DMFA in a supporting electrolyte of LiCl, $\Delta E_{1/2} = 0.30$ V, and in a supporting electrolyte of $(C_2H_5)_4NClO_4$, $\Delta E_{1/2} = 0.70$ V. It has been suggested that the influence of the electrolyte is also manifested in a displacement of the acid-base equilibrium, but it is of course not excluded that it is due to some extent to the influence of the change in the structure of the electrical double layer. Moreover, as shown by Peover and Davis[88], the association of the carbanions with the counter-ions of the electrolyte may have a significant influence. Ion association is responsible for the displacement of the wave towards less negative potentials, and the effect may be considerable. Thus for R^- the change from Li^+ to $(C_4H_9)_4N^+$ gives an effect of about 40 mV, whereas for R^{2-} it amounts to 300–600 mV. An even greater effect is produced by positive cations. For example, Nd^{3+} cations at a concentration of 2×10^{-3} M displaces the first wave for quinone by 550 mV, and the second by as much as 950 mV. Thus $\Delta E_{1/2}$ for the change from Li^+ to $(C_4H_9)_4N^+$, according to the data of Peover and Davis[88], decreases, whereas according to the data of Kheifets and Bezuglyi[87] it increases. The reason for the discrepancy in these result is not known.

The radical states postulated for the reduction of aromatic hydrocarbons have been studied many times by EPR spectroscopy[46,58,60]. It has been shown that the electrolysis of solutions of anthracene, anthraquinone, and benzophenone in an aprotic medium at the potentials of the limiting current of the first wave gives solutions with a high concentration of radical-anions[46]. The final products, however, were the dihydro-derivatives. This means that the radical-anions do not undergo dimerisation, but are protonated and undergo further electrochemical reduction. The radical-anions (unlike the radicals, whose EPR spectra are not recorded) are fairly stable, and although it is not stated in the works cited, their stability is undoubtedly due to the presence of the charge, which provides significant hindrance to both disproportionation and dimerisation.

In an elegant piece of work, Umemoto[60] used the EPR method to investigate the fate of the radical-anions in the bulk of the solution. The radicals were generated in an electrochemical cell, from which the solution was circulated along a capillary passing through the resonant cavity of the EPR spectrometer. The kinetics of the disappearance of the radical-anions were studied in the stationary solution (after the flow of solution through the capillary had stopped). The concentration of water was varied over a wide range (0–40%). The radical-anions in the bulk of the solution are protonated $R^- + H_2O \rightarrow RH^{\cdot} + OH^-$ and either are reduced at the electrode (if the radicals reach it, for example, in the cell) or remove an electron from another R^- radical-anion: $RH^{\cdot} + R^- \rightarrow RH^- + R$ (disproportionation). This reaction is possible since the $RH^{\cdot}$ radical has a greater electron affinity than the R^- radical-anion. Kinetic study showed that the reaction of the RH radicals with the R^- radical-anions is the only route by which the radical-anions disappear in the bulk of the solution.

III. REDUCTION IN STRONGLY ACIDIC MEDIUM

A solution of perylene in concentrated sulphuric acid shows absorption in the EPR spectrum similar to the absorption of a solution of the R^- radical-anion. The ultraviolet spectra of solutions of perylene in concentrated sulphuric acid and of its radical-anion in tetrahydrofuran[89] are also very similar. The suggestion that the radical-anions are formed in the sulphuric acid solutions is rejected on the basis of the fact that the reduction of perylene in these solutions corresponds to a polarographic wave for which $E_{1/2}$ is less negative by 0.5 V than $E_{1/2}$ for the triphenylcarbonium ion. Moreover, $E_{1/2}$ for the radical-anion of perylene (second wave for perylene) is more negative by 0.7 V than $E_{1/2}$ for the triphenylmethyl radical. Thus in solutions of perylene in sulphuric acid, singly-charged cations or the products of the attachment of protons (proton complexes) are formed[89].

Subsequent studies[90] showed that the proton complexes of aromatic hydrocarbons RH^+ in the presence of oxidising agents (oxygen, sulphuric acid, etc.) may be converted into R^+ cations, for example according to the reaction:

$$RH^+ + O_2 \rightarrow R^+ + HO_2^{\cdot} . \qquad (8)$$

If oxygen is removed from the solution, the hydrocarbon cations are slowly converted into proton complexes. The polarograms for solutions of perylene, tetracene, anthracene, and 3,4-benzpyrene in a mixture of trifluoroacetic acid and boron trifluoride, free from oxygen, each show two waves (Fig. 5)[91]. The first wave, lying in the range of negative potentials, is assigned to the reduction of hydrocarbon cations

$$R^+ + e \rightarrow R \qquad (9)$$

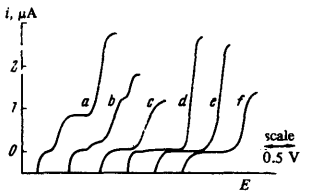

Figure 5. Polarograms for 10^{-3} M solutions of perylene (*a*), tetracene (*b*), anthracene (*c*), 3,4-benzpyrene (*d*), pyrene (*e*), and 1,2-benzanthracene (*f*) in $CF_3COOH + H_2O.BF_3$ (29 mole %) (published data[91]).

For the same concentrations of the hydrcarbons, the heights of the first waves differ considerably, due to the difference in the stabilities of the cations in the absence of oxygen. For this reason, the polarograms for pyrene and 1,2-benzanthracene do not show the first waves at all.

The second waves in most instances are twice as high as the first. This is observed particularly clearly in the polarograms for perylene, which is converted completely

into the cationic state. Thus the second wave is assigned to the two-electron reduction of the proton complexes RH^+:

$$R + H^+ \rightarrow RH^+ \quad (10)$$

$$RH^+ + e \rightarrow RH^\cdot \quad (11)$$

$$RH^\cdot + H^+ \rightarrow RH_2^{+\cdot} \quad (12)$$

$$RH_2^{+\cdot} + e \rightarrow RH_2 \quad (13)$$

From these studies it follows that the hydrocarbon cations are reduced more readily than the corresponding proton complexes. The proton complexes of hydrocarbons with linearly fused rings (anthracene, tetracene, and 1,2-benzanthracene) are reduced much more readily ($\Delta E_{1/2} \simeq 0.2$–$0.4$ V) than hydrocarbons with rings fused in angular fashion (pyrene, 3,4-benzpyrene, and perylene). It is suggested that the greater stability of the proton complexes of angular hydrocarbons to reduction is related to the more even distribution of the positive charge in the RH^+ cations of these hydrocarbons

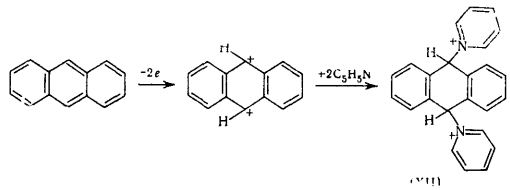
The electrolysis of a solution of perylene in trifluoroacetic acid containing a small quantity of H_2SO_4 (a relatively weakly oxidising medium) at the potentials of the limiting current of the first wave gave the original hydrocarbon—perylene[92]. This confirmed the suggestion that the first wave corresponds to the reduction of the R^+ cation.

IV. MECHANISM OF OXIDATION

The mechanism of the electrochemical oxidation of aromatic hydrocarbons has been studied by modern methods exclusively in an aprotic medium [62,77,93-105]. Either 0.1–2 M sodium perchlorate or 0.1 M tetraethylammonium perchlorate have been used as supporting electrolyte. Oxidation has been studied at vibrating[93,102], stationary[62,94,104], or rotating[77,95-97,99-101,103,105] platinum electrodes. Ag/Ag^+ or aqueous saturated calomel electrodes have been used as reference electrodes. With the latter, precautions were taken to prevent the entry of water into the solutions being studied.

Lund[93] found that a large number of aromatic hydrocarbons give normal or deformed oxidation waves, which he attributed to the removal of two electrons from the highest occupied molecular orbitals, the process involving only one benzene ring of the polynuclear hydrocarbon. Thus tetracene gives a second wave with approximately the same $E_{1/2}$ value as 5,12-dihydrotetracene, close to $E_{1/2}$ for a 2,3-dialkylnaphthalene. In lund's opinion, normal waves are given only by compounds for which the products of the two-electron oxidation are stable. For example, the product of the oxidation of indene, in Lund's opinion, is indane, that is a stable product, whereas the product of the oxidation of fluorene—presumably a derivative of dihydrofluorene—has a marked tendency to polymerise, so that the electrode is insulated from the solution by a layer of insoluble polymer. Other authors[77,96] also attribute the distortion of the waves to the adsorption of oxidation products on the electrode.

The removal of two electrons previously localised on one or two carbon atoms should lead to the formation of a doubly-charged carbonium cation. For example, for anthracene the charges are localised in positions 9 and 10. In the presence of electron donors such as pyridine, the doubly-charged cation is stabilised by the attachment of two molecules of the electron donor in the 9 and 10 positions:



(14)

(XII)

Preparative electrolysis of anthracene in acetonitrile in the presence of pyridine did in fact give 9,10-dihydroanthranyldipyridinium diperchlorate (XII). This compound contains only isolated benzene rings, so that it is not oxidised further (at the oxidation potential of anthracene). According to Lund's data, the $E_{1/2}$ values for the oxidation waves for aromatic alcohols[106] and the original aromatic hydrocarbons are very close, and on this basis he concluded that the first stage in the oxidation of the aromatic alcohols also involves the removal of two electrons from the aromatic rings.

The behaviour of aromatic hydrocarbons differs considerably for electrochemical reduction and oxidation. The attachment of a second electron takes place at a much more negative poential than that of the first, whereas in oxidation, two electrons are removed at the same potential. However, since the highest occupied and lowest vacant molecular orbitals in alternant hydrocarbons are positioned symmetrically with respect to the energy level of the atomic orbital (taken as zero), we should expect the aromatic hydrocarbons to show analogous behaviour during reduction and oxidation, that is successive removal or attachment of two electrons at significantly different potentials[77]. More distinct waves for the oxidation of aromatic hydrocarbons were obtained with a rotating indicator electrode[95,97] than with a vibrating electrode[93]. The electrolysis of anthracene in acetonitrile in the absence of pyridine gave the dimeric product bianthrone[98]. It has been possible to record the EPR spectra of the radical-cations produced in the oxidation of methoxybenzene[99] and 9-arylaminoanthracenes[105].

Study of the oxidation of aromatic hydrocarbons by cyclic volt-ammetry[62] showed that more positive $E_{1/2}$ values are obtained by using fast voltage sweeps than by using slow sweeps. The difference is attributed to the influence of conjugated chemical reactions of the radical-cations, which is felt when slow sweeps are used but not when fast sweeps are used. According to these results[62], the radical-cations are much less stable with respect to reaction with the solvent (their lifetime is of the order of several milliseconds) than the radical-anions produced during reduction.

According to the results[77] of the study of the oxidation of 60 hydrocarbons, the polarisation curves recorded by the classical polarograph give distinct first waves, whose slope (60–80 mV) corresponds to that for a reversible one-electron process. For *p*-phenylenediamine and its *N,N'*-tetramethyl derivative, alternating-current polarography showed a high degree of reversibility for both one-electron oxidations. Anilines give distinct one-electron waves, and also waves corresponding to further oxidation at more positive potentials. When pyridine is added, the first wave becomes a two-electron wave, probably as a result of an increase in the rate of the removal of a proton from the radical-cation. For dibenzanthracene, dibenzpyrene, 3,4-benzpyrene, and pyrene, the first waves are again one-electron waves. Other hydrocarbons give many-electron

waves; for example, the first wave for anthracene corresponds to the transfer of five electrons. In the work cited[77] various hydrocarbons were also studied by cyclic volt-ammetry with a stationary platinum electrode. The radical-cations of different hydrocarbons have different stabilities. Thus 9,10-dimethylanthracene at a rate of change of potential equal to 10–20 V min^{-1} shows a peak corresponding to the reduction of the radical-cation. The doubly-charged cation is even less stable. The radical-cation of anthracene is less stable than that of its 9,10-dimethyl derivative. The oxidation products of 1,2,5,6-dibenzanthracene are very unstable. Many-electron waves are observed when the product of the subsequent transformation of a very unstable radical-cation, which is produced by removal of the first electron, can undergo further oxidation at the potential of formation of the radical-cation. These results show that the removal of two electrons produces the same situation as the attachment of electrons: the successive removal of two electrons, sometimes complicated by chemical transformation of the radical-cation.

The radical-cations of aromatic hydrocarbons are more stable in methylene chloride than in acetonitrile[104]. For 9,10-diphenylanthracene, rubrene, and 1,3,6,8-tetraphenylpyrene, cyclic volt-ammetry with a stationary electrode has shown completely reversible one-electron processes, whereas for tetracene and anthracene, rapid chemical reactions take place under these conditions.

In the preceding section of this review it was shown that in strongly acidic media (concentrated sulphuric acid or a mixture of trifluoroacetic acid and boron trifluoride) the radical-cations of various hydrocarbons are fairly stable. The stability is apparently due to the difficulty of removing a proton from the radical-cation in strongly acidic media. From this it may be concluded that in aprotic solvents the low stability of the radical-cations is probably due to the possibility of proton removal

$$M^{\cdot+} \rightarrow R^{\cdot} + H^{+} \qquad (15)$$

The radicals formed may undergo subsequent reactions (dimerisation, disproportionation, oxidation). The study of the stages involved in the oxidation of aromatic hydrocarbons may apparently be more successful in strongly acidic than in aprotic media. If the reaction

$$R^{\cdot+} + e \rightarrow R \qquad (9)$$

studied in strongly acidic media, and

$$R \rightarrow R^{\cdot+} + e \qquad (16)$$

studied in aprotic media, are completely reversible, the $E_{1/2}$ values of the corresponding waves should be the same. Unfortunately, the $E_{1/2}$ values can be compared only very roughly, since the $E_{1/2}$ values for reaction (9) in strongly acidic media were measured either relative to the mercury bottom[92] or relative to the potential of the start of the dissolution of mercury[91], whereas the $E_{1/2}$ values for reaction (16) in aprotic media were measured either relative to an Ag/Ag^{+} reference electrode (with fast potential pulses)[62] or relative to an aqueous saturated calomel electrode (with slow potential pulses)[77]. The errors become even greater due to neglect of the interphase potentials. The difference in the $E_{1/2}$ values is greater than the maximum possible errors, however. Thus for perylene, according to a rough estimate, $E_{1/2}$ (sat. cal. el.) is +0.1V for reaction (9) and +1.04 V for reaction (16). This discrepancy is possibly due to the fact that the processes taking place are actually more complex than at present assumed.

From the foregoing it follows that for an exact comparison of the $E_{1/2}$ values of oxidation with other molecular parameters it is necessary to determine $E_{1/2}$ by cyclic volt-ammetry with fast potential pulses, as in Ref. 62.

V. CORRELATION OF THE VALUES OF THE HALF-WAVE POTENTIALS

At the present time, in the polarography of aromatic and unsaturated hydrocarbons, extensive use is made of correlations between the values of the half-wave potentials and various molecular constants. The most important of these is undoubtedly the correlation of the half-wave potentials with the energies of molecular orbitals. This has made possible a fairly rigorous verification of the conclusions reached by applying quantum-chemical calculations to the molecules of aromatic and unsaturated hydrocarbons. It has been correctly noted[107] that the application of correlation relations makes it possible to predict $E_{1/2}$ values for compounds which have not been studied, and also to find molecular parameters which are not readily obtainable by other methods, such as ionisation potentials and electron affinities. Thus the study of correlation relations is stimulating further experimental and theoretical studies in this field.

Correlations are most successful when the mechanism of reduction or oxidation is the same for the series of compounds being considered and particularly when these processes are reversible. This last feature is necessary for the application of the relationships for thermodynamically reversible processes.

The idea forming the basis of the correlation of $E_{1/2}$ with the energies of molecular orbitals was formulated by Maccoll[64], who extended to the electrochemical reduction of aromatic hydrocarbons Hückel's concept of the relationship between the energy of the lowest vacant molecular orbital and the ease of attachment of alkali metals to aromatic hydrocarbons. In both instances, one or two electrons (from the alkali metal or the electrode) are transferred to the lowest vacant antibonding molecular orbital. The reversible reduction potential is related to the changes in enthalpy (ΔH) and entropy (ΔS) by the familiar relationship

$$nFE_0 \quad \Delta H - T\Delta S \,. \qquad (17)$$

It is subsequently pointed out that ΔH depends on the energy required for the transfer of one or two electrons to the lowest vacant orbital, that is it is related to the coefficient a_{n+1} in the expression for the energy of the lowest vacant orbital. Comparison of the $E_{1/2}$ values found by Wawzonek and Laitinen[13,14] with the coefficients a_{n+1} calculated by the simple Hückel molecular orbital method (Fig. 6) showed a fairly good linear relationship between these quantities.

This idea was used by Lyons[108] to predict the influence of substituents on the value of $E_{1/2}$ by calculating the change in the energy of the lowest vacant molecular orbital on introduction of the substituent. If the energy of the lowest vacant molecular orbital is increased, reduction is made more difficult, and vice versa. For example, for the introduction of a methyl group into the pyridine ring, theory predicts a displacement of $E_{1/2}$ by 30 mV towards more negative potentials.

Pullman and coworkers[109] verified the correlation of $E_{1/2}$ with a_{n+1} for a large number of compounds (alternant aromatic hydrocarbons and unsaturated compounds). It was found that the plot of $E_{1/2}$ against a_{n+1} cannot be represented by a single straight line for all groups of com-

pound. The linear relationship is observed most rigorously for condensed benzenoid hydrocarbons. Linear condensation of the benzene rings leads to a decrease in a_{n+1} and to an increase in the ease of reduction. The easier reduction of anthracene compared with phenanthrene indicates that the energy of the lowest vacant orbital is greater in phenanthrene. This correlation predicts that for benzene the half-wave potential should be about -3.6 V, This explains why benzene cannot be reduced by direct transfer, whereas reduction by the most active alkali metal—lithium—takes place when it is produced electrochemically[44,110]. The data of phenylethylenes and phenylacetylenes do not fall within the $E_{1/2}$–a_{n+1} correlation for benzenoid hydrocarbons[109]. They lie on an independent straight line, with the exception of the results for tetraphenylethylene. The deviation of this group of compounds from the general straight line is related[109] to the limited accuracy of the calculation of a_{n+1}.

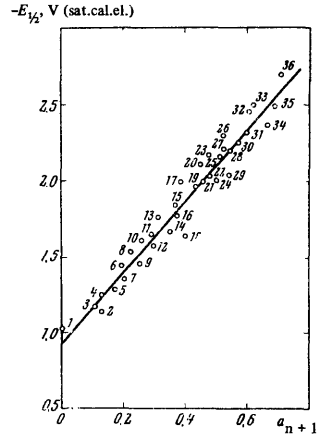


Figure 6. Dependence of the half-wave potentials (in aqueous dioxan) on the coefficient a_{n+1}: *1*) triphenylmethyl; *2*) 1,4-dibiphenylenebutadiene; *3*) 1,6-dibiphenylenehexatriene; *4*) 1-phenyl-12-biphenylenedodecahexaene; *5*) 1-phenyl-8-biphenyleneoctatetraene; *6*) 1,12-diphenyldodecahexaene; *7*) 1-phenyl-6-biphenylenehexatriene; *8*) 1,10-diphenyldecapentaene; *9*) 1-phenyl-4-biphenylenebutadiene; *10*) 1,8-diphenyloctatetraene; *11*) acenaphthylene; *12*) anthanthrene; *13*) 1,6-diphenylhexatriene; *14*) perylene; *15*) 1,2-benzpyrene; *16*) fluoranthene; *17*) 1,4-diphenylbutadiene; *18*) azulene; *19*) anthracene; *20*) pyrene; *21*) 1,2-benzanthracene; *22*) 1,2,5,6-dibenzanthracene; *23*) 1-phenylbutadiene; *24*) 4,5-benzpyrene; *25*) stilbene; *26*) chrysene; *27*) 2,2′-binaphthyl; *28*) quaterphenyl; *29*) coronene: *30*) 1,1-diphenylethylene; *31*) terphenyl; *32*) phenanthrene; *33*) naphthalene; *34*) styrene; *35*) triphenylene; *36*) biphenyl (published data[2]).

The fact that tetraphenylethylene does not fall within the correlation for the unsaturated compounds is tentatively attributed to the non-coplanarity of this compound, as a result of which the conjugation is is weakened, the lowest vacant orbital is raised, and the reduction is made more difficult. Other authors[27,31,82,111,112] have also drawn attention to the part played by coplanarity. Thus according to Hoijtink's data[27], the molecules of such aromatic hydrocarbons as 9,9′-bianthryl, rubrene, and 1,1′-binaphthyl are also non-coplanar, their structure being much closer to one in which the separate parts of the molecule joined by simple C–C bonds are mutually perpendicular, since the $E_{1/2}$ values almost coincide with those for anthracene, tetracene, and naphthalene. The effect of departure from coplanarity in the arylethylene series has been studied in more detail. Pointeau and de Villepin[111] calculated the dependence of the energy of the lowest vacant orbital for biphenyl derivatives on the angle between the planes of the two rings and compared the results with experimental measurements. In the calculations it was assumed that the energy of the orbital is a sinusoidal function of the angle between the rings. The calculation showed that even fairly marked departure from coplanarity gives a scarcely perceptible effect. Thus for rotation of the rings through 20° we should expect a change in $E_{1/2}$ by only 40 mV. The departure from coplanarity was brought about by the introduction of substituents into the ortho-position. The expected effect could not be detected, however, since it was masked by the effects of the substituents.

The effect of the departure from coplanarity is also revealed[82] by comparing the $E_{1/2}$ values for two aromatic compounds with the same number of benzene rings, of which one is condensed, so that the molecule must be planar, whereas the molecule of the other contains a simple C–C bond, about which rotation of sections of the molecule can take place. It is true that the molecules of these compounds also differ in the number of π electrons, so that the effect of coplanarity cannot be established in pure form. Nevertheless, this comparison is useful. Thus $E_{1/2}$ for naphthalene is less negative by 95 mV than $E_{1/2}$ for biphenyl; for anthracene and terphenyl, $\Delta E_{1/2} = 445$ mV, and for tetracene and quaterphenyl, $\Delta E_{1/2} = 630$ mV. The values of $E_{1/2}$ were taken from Bergman's papers[39,40].

Phenylacetylenes are less readily reduced than phenylethylenes[109]. This phenomenon is due to the greater localisation of electrons on the triple bond and the consequent raising of the lowest vacant orbital.

A detailed derivation of the relationship between $E_{1/2}$ and a_{n+1} was first tiven by Hoijtink and van Schooten[22].

For the change in free energy for the attachment of an electron to a conjugated molecule R, which is related to the reduction potential by Eqn. (17), we can write

$$\Delta G^0 = [\mu^0_R]_{aq} + [\mu^0_{el}]_{Hg} - [\mu^0_{R^-}]_{aq} \qquad (18)$$

where $[\mu^0_R]_{aq}$ and $[\mu^0_{R^-}]_{aq}$ are the chemical potentials of the molecule R and the radical-anion R^- in solution, and $[\mu^0_{el}]_{Hg}$ the chemical potential of the electron in mercury. Eqn. (18) transforms into

$$\Delta G^0 = [\mu^0_R]_g + [\mu^0_{el}]_{Hg} - [\mu^0_{R^-}]_g + [\Delta G^0]_{solv} \qquad (19)$$

where the subscript "g" denotes the gaseous state, and $[\Delta G^0]_{solv}$ is the change in ΔG^0 resulting from the solvation of R and R^-. $[\mu^0_R]_g - [\mu^0_{R^-}]_g$ is equal to the electron affinity of the molecule R in the gaseous state (A). Thus

$$\Delta G^0 = A + [\mu^0_{el}]_{Hg} + [\Delta G^0]_{solv} \qquad (20)$$

But,

$$E = E_0 + \frac{RT}{F} \ln \frac{C_R}{C_{R^-}} = E_{1/2} + \frac{RT}{F} \ln \frac{(i_d - i)}{i} \qquad (21)$$

$$E_0 = \frac{\Delta G^0}{F} = E_{1/2} + \frac{RT}{F} \ln \frac{D_R^{1/2}}{D_{R^-}^{1/2}} \qquad (22)$$

From Eqns. (20) and (22) we have

$$A = FE_{1/2} + RT \ln \frac{D_R^{1/2}}{D_{R^-}^{1/2}} - [\mu_{el}^0]_{Hg} - [\Delta G^0]_{solv} . \quad (23)$$

To the first approximation it may be assumed that $\lg (D_R/D_{R^-})^{1/2}$ and $[\Delta G^0]_{solv}$ are the same for the compounds being considered. We then have

$$A = FE_{1/2} + C . \quad (24)$$

The electron affinity is equal to the negative value of the energy of the lowest vacant orbital $(n + 1)$:

$$\varepsilon = \alpha - a_{i+1}\beta \quad (25)$$

where α is the energy of a π electron localised on an individual carbon atom, β the exchange integral for two neighbouring carbon atoms, and a_{n+1} the numerical coefficient obtained by solving the secular equation in the method of molecular orbitals. Thus

$$-\alpha + a_{n+1}\beta = FE_{1/2} + C . \quad (26)$$

The constants α and C are eliminated by writing the difference for the two compounds:

$$\begin{gathered} -\alpha + a_{i-1}\beta = FE_{1/2} + C \\ -\alpha + a'_{i+1}\beta = FE'_{1/2} + C \\ \hline (a_{n+1} - a'_{n+1})\beta = (E_{1/2} - E'_{1/2})F \end{gathered}$$

or in electron-volts

$$(a_{n+1} - a'_{n+1})\beta = E_{1/2} - E'_{1/2} \quad (27)$$

As standard, it is convenient to take the triphenylmethyl radical, for which $\varepsilon = \alpha$ $(a_{n+1} = 0)$ and $E'_{1/2} = -1.05$ V. By substituting these values in Eqn. (27) we obtain the final expression

$$E_{1/2} = a_{n+1}\beta - 1.05 \quad (7)$$

previously given in the first section.

It can be seen from the discussion that Eqn. (7) is approximate, since assumptions known to be inaccurate were made in its derivation. The change in $\ln (D_R/D_{R^-})^{1/2}$ and $[\Delta G^0]_{solv}$ on going from one compound to another with similar structure, however, is also apparently monotonic, so that $E_{1/2}$ still remains an approximately linear function of a_{n+1}.

Subsequently, attempts were made to analyse the experimental data on the basis of more accurate relationships[113,114]. This gave nothing fundamentally new, however. Moreover, the simple relationship (7) has proved satisfactory. It has been verified many times[22,23,27,29,30,37,52,67,115-121]. Without giving details of these papers, we would point out that a satisfactory correlation is also obtained under experimental conditions in which the reduction is not completely reversible (75% dioxan), apparently because the irreversibility resulting from protonation of the radical-anions has little influence on the value of $E_{1/2}$. When comparing $E_{1/2}$ values it is best to use experimental data obtained under identical experimental conditions, since even apparently insignificant changes in the conditions of the experiment may have a significant influence on the $E_{1/2}$ values, through change in the potential of the reference electrode or diffusion potentials, or through the radical-anions forming ion pairs[88,114] with the counter-ion of the supporting electrolyte.

The correlation given by Eqn. (7) covers not only alternant aromatic hydrocarbons, but also the non-alternant azulene. Azulene, however, shows appreciable departure from this correlation. Thus according to the calculation, $E_{1/2} = -1.87$ V[65] whereas experiment gives $E_{1/2} = -1.64$ V[65]. Various suggestions have been put forward to explain this anomaly. In Hoijtink's opinion[27], this phenomenon cannot be due to the fact that in the approximate calculation by the molecular orbital method used, all the bond lengths in the azulene molecule were taken as equal, since a more rigorous treatment making allowance for the difference in the bond lengths leads to an even greater discrepancy. Hoijtink suggested that the increased ease of reduction of azulene is due to decreased strain of the rings in the azulene molecule when it loses an electron.

In Streitwieser's opinion[2], the correlation can be improved by using a higher value of β for the 9,10 bond (common to both rings).

An even more striking difference between the $E_{1/2}$ values predicted on the basis of correlation (7) and the experimental values is observed for charged non-alternant hydrocarbons—the tropylium and azulenium cations. For these compounds the discrepancy in the $E_{1/2}$ values reached 1.4–1.5 V.

It has been suggested[122] that this anomaly is due to the polarity of the molecules of non-alternant hydrocarbons, leading to a change in the solvation energies of the reacting species and in the electron affinities. For example, on going from the reduction of benzene to the reduction of the tropylium cation these quantities change as follows. Preferential solvation of the product (the R^- radical-anion) is replaced by preferential solvation of the starting material (the tropylium cation). The difference in the solvation energies for these two reactions is about 4 eV, the reduction of the tropylium cation becoming more difficult as a result of the change in the solvation of the components. This effect is masked, however, by the effect of the increased electron affinity of the tropylium cation (by more than 6 eV compared with benzene).

The correlation (7) can be extended to non-alternant hydrocarbons by the introduction of a term allowing for the polarity of the molecule

$$E_{1/2} = a_{n+1}\beta - E^0_{1/2} + kq_r \quad (28)$$

where q_r is the maximal positive charge on a carbon atom of the molecule.

The rule formulated by Hoijtink, according to which the radical RH· of an aromatic hydrocarbon is always reduced more readily than the original hydrocarbon R, may not apply for a non-alternant hydrocarbon, because of the effect of the polarity of the molecule. For this reason, apparently, azulene is reduced more readily than the RH· radical of azulene.

The problem of a possible correlation of the $E_{1/2}$ values of aromatic hydrocarbons with the para-localisation energies has been widely discussed[123-130]. The discussion was initiated by Basu and Bhattacharya[123], who, on the basis of the data of Wawzonek and Laitinen[14] obtained with solutions in 75% dioxan, indicated for the first time the possibility of a correlation between $E_{1/2}$ and the energy of localisation of two electrons in the para-position of the hydrocarbon. A basis for this conclusion was provided by the fact that in 75% dioxan the first wave corresponds to the transfer of two electrons, and reduction generally takes place in the para-position. In fact, they found a satisfactory linear relationship between the $E_{1/2}$ values and the para-localisation energies. Serious objections were raised to this work, however. Pullman and Pullman[124] corrected various para-localisation energy values, and the correlation with $E_{1/2}$ was thereby destroyed. They also pointed out that reduction does not always involve the para-position, and the absence of a linear relationship was demonstrated for a large number of examples. For example, the energy of

para-localisation in polyphenyls remains approximately constant with increase in the number of benzene rings, whereas $E_{1/2}$ becomes less negative. Pullman and Pullman point out that the parallelism sometimes observed between $E_{1/2}$ and the para-localisation energy is possibly due to the fact that the localisation (polarisation) energy is often revealed in the energy of the first vacant orbital. Given's objections [127] reduce to the fact that since in the reduction of aromatic hydrocarbons, two electrons are in fact transferred in stages, the energy of para-localisation is not related to the least negative $E_{1/2}$. It is more correct to expect a correlation of $E_{1/2}$ with the energy of localisation of an electron in an individual position, and this correlation is in fact satisfactory [127]. At present, the correlation of the $E_{1/2}$ values with the para-localisation energies has not been accepted.

By analogy with the correlation of $E_{1/2}$ for the waves for the reduction of aromatic hydrocarbons with the root a_{n+1} of the Hückel secular equation for the first vacant molecular orbital, a correlation was found between $E_{1/2}$ for the oxidation waves and the root a_n for the highest filled bonding orbital [131]. The experimental values of $E_{1/2}$ for oxidation were taken from Lund's paper [93]. A satisfactory correlation was observed (Fig. 7), despite the fact that the waves corresponded to a two-electron oxidation, and, as shown later [62], this oxidation takes place irreversibly because of subsequent rapid transformation of the radical-cations.

Figure 7. Plot of $(E_{1/2})_{ox}$ against a_n for alternant hydrocarbons (circles) and fluoranthene (triangle) (published data [131]).

Since for alternant hydrocarbons the vacant and occupied orbitals are positioned symmetrically with respect to the atomic orbital, that is $a_n = -a_{n+1}$, there is a linear relationship between $E_{1/2}$ for the oxidation and $E_{1/2}$ for the reduction of alternant hydrocarbons [131]. This correlation is important, because it makes it possible to investigate the characteristic features of the behaviour of non-alternant hydrocarbons, which depart even further from this correlation (Fig. 8) than from the linear relationship between $E_{1/2}$ for the reduction or oxidation and a_{n+1} or a_n.

The values of $E_{1/2}$ for the reduction waves have been used to find the electron affinities of the molecules of aromatic hydrocarbons, which are identified with the energies of the first vacant orbital. This possibility was first examined by Lyons [132]. We shall take the derivation of the relationship between $E_{1/2}$ and the electron affinity (A) from Matsen's paper [133].

The electrode processes in the measurement of $E_{1/2}$ for reduction, relative to a saturated calomel electrode, are arbitrarily broken down into the following stages:

$$R_g + e_g \rightarrow R_g^- + A \quad (29)$$

$$R_{soln} + R_g^- \rightarrow R_g + R_{soln}^- + \Delta G^0_{solv} \quad (30)$$

$$e\,(Hg) \rightarrow e_g - 4.54\ eV\ (work\ function) \quad (31)$$

$$Hg_{liq} + Cl^-\ (sat.aq.) \rightarrow (HgCl)_{solid} + e\,(Hg) - 0.56\ eV \quad (32)$$

$$Cl^-\ (sat.aq.) \rightarrow Cl^-\ (sat.aq) + 0.03\ eV \quad (33)$$

$$R_{soln} + Hg_{liq} + Cl^-\ (sat.aq) \rightarrow R^-_{soln.} + HgCl_{solid} \quad (34)$$

$$E_{1/2} = A + \Delta G^0_{solv} - 5.07 \equiv A' - 5.07\ (eV) \quad (35)$$

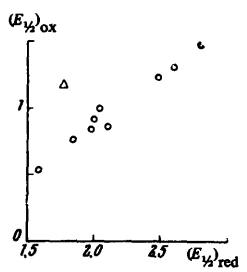

Figure 8. Plot of $(E_{1/2})_{ox}$ against $(E_{1/2})_{red}$ (published data [131]).

The difference in the free energy of solvation ΔG^0_{solv} is determined chiefly by the free energy of solvation of the ion, and can be calculated by means of the Born equation

$$\Delta G^0_{solv} \simeq 27.2\left(1 - \frac{1}{D}\right)\frac{a_0}{\bar{r}}\ (eV), \quad (36)$$

where $\bar{r}$ is the mean radius of the ion, a_0 the Bohr radius, and D the dielectric constant. In a first approximation, $\bar{r}$ is proportional to the cube root of the number of benzene rings in the molecule (p). Thus as $p \rightarrow \infty$ (graphite), $\Delta G^0_{solv} \rightarrow 0$ and $A' \rightarrow A$.

Since a linear relationship exists between $E_{1/2}$ and a_{n+1}, a linear relationship should exist between A' and a_{n+1}. This linear relationship is in fact observed (Fig. 9). Extrapolation of the straight line obtained by plotting A' against a_{n+1} to $a_{n+1} = 0$ (graphite) gave A for graphite (3.8 eV). From this it follows that for graphite $E_{1/2} = -1.27$ V. This value is obviously too negative. Other methods give for graphite $A = 4.39$ eV ($E_{1/2} = -0.68$ V). Finally, from the correlation between the values of A and the spectroscopic characteristics, we have for graphite $A = 4.8$ eV ($E_{1/2} = -0.27$ V). Direct measurements of the reduction potentials of graphite have not been made, but in this connection it may be mentioned that the low current efficiencies in the reduction of benzene by metallic lithium generated electrolytically on graphite were attributed to the partial utilisation of electricity for the hydrogenation of graphite [44]. This suggestion is confirmed by the marked erosion of the graphite cathode, in contrast to the behaviour of a carbon cathode [134].

If the values of A are calculated, it is possible, by comparing them with the $E_{1/2}$ values, to estimate the solvation energy ΔG^0_{solv}. [135] It was established in this way that ΔG^0_{solv} generally decreases with increase in the number of

benzene rings in the molecule of an aromatic compound. For the estimation of the solvation energies, the measurement of the electron affinities of the molecules in the gaseous phase is of considerable importance. Wentworth and Becker[136] suggested a method based on the measurement of the equilibrium constants for the capture of thermal electrons by the gaseous molecules in a gas-chromatographic detector, and observed a good correspondence between the values of A and $E_{1/2}$.

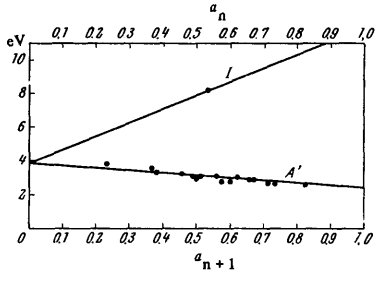

Figure 9. Dependence of the ionisation potential (I) on the energy of the highest filled orbital (the coefficient a_n) and of the apparent electron affinity (A') on the energy of the lowest vacant orbital (the coefficient a_{n+1}) for a number of hydrocarbons with condensed rings (published data[133]).

10)[137]. It has been the subject of a large number of studies[33,39,40,84,93,96,97,99,100,102,109,112,119,138-140]. The slope of the straight line obtained by plotting $E_{1/2}$ against E_ν should be equal to two. A bathochromic shift of the long-wave absorption band (that is towards longer wavelengths) corresponds to a decrease in the difference between the energies of the two orbitals, and a hypsochromic shift corresponds to an increase.

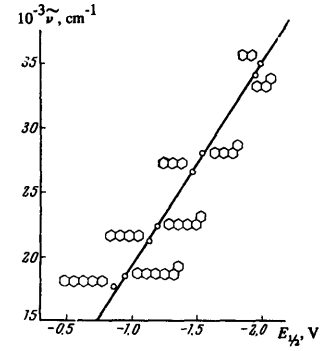

Figure 10. Plot of $\tilde{\nu}$, cm^{-1} against $E_{1/2}$ for the reduction of cata-condensed aromatic hydrocarbons in cellosolve ($\tilde{\nu}$ is the wave number of the p-band in the absorption spectrum) (published data[39]).

The $E_{1/2}$ values for the anodic oxidation waves are used[133] to determine ionisation potentials (I), that is the energies required to remove the least firmly bound electron (to remove an electron from the highest occupied orbital), so that the ionisation potential is equal to the energy of a π electron in this orbital and is an important characteristic of molecules. For graphite, $a_n = a_{n+1} = 0$ and $\Delta G^0_{solv} = 0$ and $A = 1$. Theory predicts that for alternant hydrocarbons the ionisation potential and electron affinity should be symmetric with respect to the work function of graphite (A).

We have seen that the $E_{1/2}$ values for reduction and oxidation contain information on the energy levels of molecules with generalised π electron systems. The same information is carried in the absorption spectra, so that a relationship should exist between the $E_{1/2}$ values and the spectroscopic characteristics of aromatic hydrocarbons. Watson and Matsen[137] were the first to draw attention to this relationship. On absorption of light energy the molecule is excited, and this is reflected in the transfer of an electron from one of the occupied orbitals to a higher vacant orbital. The lowest-energy transfer in the ground state of a molecule takes place from the first occupied orbital to the lowest vacant orbital. For alternant hydrocarbons, $a_n = -a_{n+1}$ and for the energies of the orbitals being considered we can write $\alpha + a_n\beta$ and $\alpha - a_{n+1}\beta$. The difference between the energies of these two orbitals, equal to the excitation energy $h\nu$, is

$$h\nu = -(a_n + a_{n+1})\beta = -2a\beta \quad . \qquad (37)$$

Since there is a linear relationship between a_{n+1} and $E_{1/2}$, there should be a linear relationship between $E_{1/2}$ and the frequency of the absorption band with longest wavelength. This correlation has in fact been observed (Fig.

Attempts have been made to correlate the $E_{1/2}$ values with various other properties of molecules. Thus a correlation has been noted between $E_{1/2}$ and the relative adsorbability of conjugated hydrocarbons on alumina[141]. It has been suggested that the $E_{1/2}$ values for the reduction of vinyl monomers change in the same sense as the ability of the monomer to undergo anionic polymerisation[29,30]. A parallelism has been noted between $E_{1/2}$ for the reduction of aromatic hydrocarbons and their thermal stability[142]. The $E_{1/2}$ values also show a correlation with the values of the g-factor in the EPR spectra of the radical-ions of alternant hydrocarbons[143,144]. The $E_{1/2}$ values have been compared with the carcinogenic activity of aromatic hydrocarbons[118,145]. In the last instance the regularity is not clear. Most carcinogenic substances exhibit both electron-donating and electron-accepting properties, but these functions are less marked for non-carcinogenic compounds[145].

VI. CHARACTERISTIC FEATURES OF THE ADSORPTION OF BENZENOID AROMATIC HYDROCARBONS

The specific electronic structure is also reflected in the adsorption characteristics of aromatic hydrocarbons[146]. Even in early papers it was noted that aromatic compounds are adsorbed much more readily at the mercury–solution boundary than at the free surface of the solution, the electrocapillary maximum being displaced in the cathodic direction[147,148]. The studies dealt chiefly with the hydroxy- and amino-derivatives, so that these experimental facts were interpreted as the result of an intensification of the interaction of the oxygen and nitrogen atoms of the hydroxy- and amino-groups with mercury, because of the flatter orientation of the benzene rings in the adsorbed layer on

mercury. Detailed measurements of the electrocapillary curves in solutions of unsubstituted condensed aromatic hydrocarbons by Gerovich[149-153] show, however, that unsubstituted non-polar aromatic hydrocarbons also displace the maximum of the electrocapillary curve towards more negative values and are preferentially adsorbed on the positively charged surface of the mercury electrode. This suggested that the observed anomalies are related to the adsorption characteristics of the aromatic rings themselves, and not of the polar substituents. In fact, the adsorbability of aromatic hydrocarbons on a positively charged surface increases in the order: benzene, naphthalene, phenanthrene, that is with increase in the number of benzene rings. On the other hand, hydrogenated benzene and naphthalene (cyclohexane and decalin) are adsorbed preferentially on a negatively charged mercury surface and displace the maximum of the electrocapillary curve in the anodic direction, which is characteristic of the adsorption of aromatic compounds[151].

It has been suggested that in the adsorption of aromatic hydrocarbons on a positively charged mercury surface an important part is played by the interaction of the system of π electrons of the hydrocarbon molecule with the positive charges of the mercury surface, with partial transfer of positive charge to the aromatic ring. This interaction is possible only with planar orientation of the molecules of the aromatic hydrocarbons in the adsorbed state. Calculation of the limiting adsorption (Γ_∞) for benzene, naphthalene, and phenanthrene on mercury from electrocapillary measurements showed that with increase in the number of benzene rings, Γ_∞ decreases, so that the area corresponding to one molecule of adsorbate increases[152]. This also confirmed the assumption regarding the flat orientation of the molecules of the adsorbed aromatic hydrocarbons.

Proof of the specific behaviour of aromatic hydrocarbons during adsorption on mercury is also found in work by Blomgren and coworkers[154], in which the dependence of the adsorbability of organic compounds on the solvation energy (solubility) was studied for a large number of substances. Aromatic compounds fall outside the established relationship, and this is again interpreted as due to the influence of the π electronic interaction of the molecules of these compounds with the mercury surface.

This interaction is so marked that it is not eliminated completely when a positive charge is introduced into the molecule of an aromatic hydrocarbon. For example, on going from aniline (neutral medium) to the anilinium cation (acid medium) the adsorption for positive charges on the surface is weakened considerably as a result of electrostatic repulsion but is not eliminated completely[155,156], and the quantity absorbed is almost independent of the potential of the electrode over a fairly wide range (~ 1 V).[157]

Gerovich[151] suggested that the formation of an adsorption layer of aromatic hydrocarbon molecules orientated parallel to the mercury surface should not be accompanied by marked changes in capacity. This suggestion was supported by the fact that the slope of the ascending branches of the experimental electrocapillary curves for solutions of aromatic hydrocarbons are almost the same as those for the solutions of the indifferent electrolyte (Fig. 11).

Direct measurements of the differential capacity showed that for the most positive charges on the surface the differential capacity in solutions of the indifferent electrolyte and the aromatic hydrocarbon coincide[158]. Moreover, in acidic solutions of aniline, from which adsorption of the anilinium cation takes place, the curves obtained by plotting C against E coincide throughout the entire range of potentials[159]. The calculated C–E curves do not coincide with the experimental curves in the range of positive charges on the surface, because of neglect of the π electronic interaction[160,161]. If the hydrogen atoms in the molecules of the aromatic compounds are replaced by fluorine atoms with high electron affinity, the π electron interaction is weakened to such an extent that it is not a decisive factor in the adsorption on mercury[162,163].

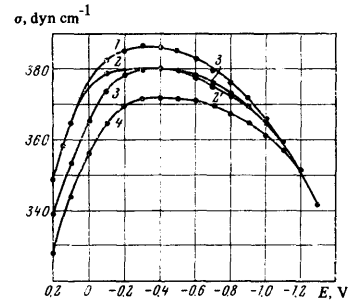

Figure 11. Electrocapillary curves for an aromatic hydrocarbon (naphthalene) in ethanol: *1*) ethanol + 0.1 M NH_4NO_3; *2*) 0.3 M decalin; *3*) 0.05 M naphthalene; *4*) 0.3 M naphthalene (published data[151]).

Under certain conditions the C–E curves for aromatic hydrocarbons, for positive charges on the surface, show peaks, which, however, do not correspond to the adsorption–desorption process (unlike the cathodic peaks). The production of these peaks is related to the re-orientation of the molecules of the aromatic hydrocarbon, that is to the change from a flat orientation for positive charges on the surface to an orientation close to vertical for negative charges on the surface[158,160]. This phenomenon was not detected by a less sensitive method for measuring electrocapillary curves.

The ideas put forward here have been used in an examination of the adsorption of aromatic hydrocarbons on other metals: cadmium[164], gold[165], iron, nickel, copper, and platinum[166]. The study of the characteristic features of the adsorption of organic compounds on metals may be useful in the detection of aromatic properties[167].

In conclusion is should be noted that work on the polarography of aromatic hydrocarbons has had a marked influence on the entire field of the polarography of organic compounds. At the present time, in the study of the mechanism of the reduction of organic compounds, extensive use is made of aprotic media for breaking down multistage processes into individual stages and for revealing the reversible elementary stages; the effect of the addition of proton donors to aprotic media is used to determine the basic nature of the original molecules, radicals, and radical-anions; alternating-current polarography makes it possible to verify more rigorously the reversibility of the electron-transfer stages and to measure the rate constants of these processes; the combination of polarography and EPR spectroscopy is finding application in the electrochemical preparation and study of the properties of radical species. In the study of the mechanism of the oxidation of organic compounds, use is made of experience gained in the study of the oxidation of aromatic hydrocarbons (the

use of acetonitrile as solvent, the rotating platinum microelectrode, and fast potential pulses). The determination of the correlational dependence of polarographic characteristics on molecular constants calculated by quantum-chemical methods has been widely applied.

A review of the published information on the polarography of aromatic hydrocarbons reveals various problems which have been insufficiently studied, and work on these problems should give most promising results.

1. Systematic studies of the path of the electrochemical reduction of various aromatic hydrocarbons and the role of the nature of the solvent and the indifferent electrolyte (the formation of ion pairs and complexes).

2. Deeper study of the mechanism of oxidation of aromatic hydrocarbons.

3. Study of the mechanism of the reduction of aromatic hydrocarbons in strongly acidic media.

4. Study of the correlational relationships, particularly the anomalous relationships (non-alternant hydrocarbons, compounds whose molecules are non-coplanar, etc.) on the basis of more accurate quantum-chemical calculations

5. The development of a theory of the adsorption of aromatic hydrocarbons on metals.

Study of the Mechanism of Homolytic Reactions in Solution by a Combination of Isotopic and Mass-spectrometric Methods

I.P.Gragerov

The use of mass spectrometry for the isotopic analysis of the products of homolytic reactions in deuterated solvents has made is possible to find the ratio of all isotopic forms of the substances studied and has opened up new possibilities in the study of the mechanism of homolytic reactions.
The present review examines critically work carried out by this method. These studies have made it possible to investigate the properties and regular features of the behaviour of various kinds of hydrocarbon radical in various solvents; have led to the discovery of reliable criteria for distinguishing free-radical processes from homolytic reactions taking place in the reaction complex without the liberation of radicals; and have made possible a deeper study of the mechanism of a number of types of free-radical reaction—the photolysis of organic halides and their reactions with metals, the thermal decomposition of benzoyl peroxide, diazo-compounds, and azo-compounds, various reactions of organometallic compounds, and processes of hydrocarbon oxidation. The bibliography contains 144 references.

I. INTRODUCTION

Since 1960, studies of the mechanism of homolytic reactions in solution by means of deuterium have been combined, on an increasing scale, with analysis of the products by low-voltage mass spectrometry. In this method (see for example Refs. 1 and 2), the ionising voltage in the mass spectrometer is reduced, so that the minimal number of fragment ions is formed. In a number of instances it is possible to obtain mass spectra corresponding to the molecular ions of isotopic forms of the compounds being analysed and to find the ratio of these forms directly from the ratio of the intensities of the corresponding peaks. These data have proved to be more valuable for an understanding of reaction mechanisms than previously available information on only the total concentration of deuterium in the products.

The considerable volume of work which has now been carried out by means of a combination of the isotopic and mass-spectrometric methods, and the importance of the results, have stimulated the publication of this review. The work examined in it has been directed towards the study of the properties of radicals with different structures, the investigation of the mechanism of a number of specific reactions with the intermediate formation (or assumed formation) of radicals, and the discovery of new criteria for distinguishing reactions involving free radicals from homolytic reactions taking place in the reactive complex. This last requires some explanation.

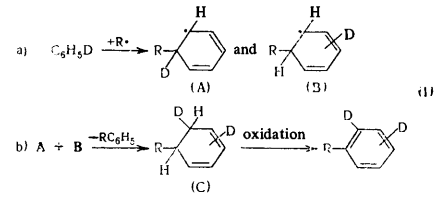
For any homolytic reaction in solution, mechanisms of two types are possible a priori—a free-radical mechanism and a mechanism which does not involve free radicals but which involves the redistribution of the bonds in an intramolecular or intermolecular reactive complex without the liberation of radicals (see for example, Refs. 3–5). It is obvious that the choice between these two possibilities is extremely important for an understanding of the mechanism. It is not always a simple matter to make this choice, however, since the two reaction paths may lead to the same products, and direct methods for detecting radicals are usually insufficiently sensitive, particularly in the most important case of highly reactive radicals. These difficulties have been responsible for a number of errors and contradictions in published data on the mechanism of homolytic reactions in solution and emphasise the importance of the discovery of reliable criteria for distinguishing a free-radical mechanism.

In this review, the results of studies carried out by means of deuterium and mass spectrometry are examined critically and compared with data obtained by other methods.

II. THERMAL DECOMPOSITION OF BENZOYL PEROXIDE AND THE PHOTOLYSIS OF IODOBENZENE. PROPERTIES OF PHENYL RADICALS

The first paper in this field, published by Eliel and coworkers[6], described the thermal decomposition of acyl peroxides. It was found in particular that benzoyl and acetyl peroxides in a solution of benzene C_6H_5D give, among other products, biphenyl and toluene containing the d_2 isotopic forms. This observation provided further confirmation of the processes, established a short time earlier[7], involving the disproportionation of radicals formed by the attachment of phenyl radicals to benzene,

and also proved the analogous reactions with methyl radicals [see scheme (1)]†:



(1)

The origin of the products of the reaction of R· radicals with benzene is now explained on the basis of the disproportionation and also the dehydrogenation and dimerisation of radicals of type (A). It was suggested [6] that the first two of these reactions take place with a kinetic isotopic effect, determining the isotopic effect for the formation of diaryls or alkylaryls (the differences between their isotopic composition and the composition calculated from the original benzene). The existence of this last effect, the presence of the isotopic forms d_2 in the diaryls or alkylaryls obtained in benzene-d_1, and the formation of dihydrodiaryls or dihydroalkylaryls (C) in an inert atmosphere were regarded by Eliel and coworkers [8] as indications that free radicals R· take part in the reactions. We shall return to these indications later, but meantime we would point out that the authors cited were unable to explain the isotopic composition of the biphenyl obtained in experiments with benzoyl peroxide. This was done later (see below).

In subsequent work [9-12], the decomposition of benzoyl peroxide and the photolysis of iodobenzene were studied in benzene C_6D_6 (also containing the d_5, d_4, and d_3 forms), in benzene (C_6D_6 + C_6H_6), or in cyclohexane (C_6D_{12} + C_6H_{12}). The solvents after the experiments, the biphenyls obtained, and the unreacted iodobenzene were subjected to mass-spectrometric analysis.

It was found that the benzenes C_6H_5D and C_6H_6 are formed in the reactions; the ratio of the other forms of benzene remains unchanged; the cyclohexane is enriched in deuterium, but new isotopic forms are not produced; the iodobenzene does not contain the form C_6D_5I and other deuterated forms; the isotopic composition of the biphenyls from the experiments in benzene exhibit characteristic features, which are discussed in detail below.

The thermal decomposition of benzoyl peroxide [6,7,13,14] and the photolysis of iodobenzene [15-18] undoubtedly take place with the intermediate formation of free phenyl radicals. The observations listed above make it possible to reach a number of conclusions regarding the properties of these radicals and the mechanism of the reactions being considered, and to formulate the indications of the participation of free phenyl radicals in homolytic reactions.

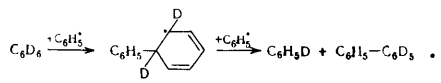
It has often been suggested (see for example Refs. 15, 16, 19-21), that phenyl radicals are capable of removing deuterium from heavy benzene:

$$C_6H_5^{\cdot} + C_6D_6 \rightarrow C_6H_5D + C_6D_5^{\cdot} \quad . \qquad (2)$$

Considerable importance was attributed to this process of "chain transfer" since it was assumed that it increases the "lifetime" of the phenyl radicals and the possibility of their reaction. A consequence of reaction (2) would be the formation of products containing C_6D_5 residues, namely C_6D_5I, $C_6D_5-C_6D_5$, $C_6D_5-C_6D_4H$, etc., formed by the recombination of $C_6D_5^{\cdot}$ with atomic iodine or by attachment to benzene from the medium. The iodobenzene after the experiments did not contain deuterium (see above), however, and the biphenyls did not contain forms with more than five deuterium atoms, and all the deuterium was present in one of the rings. Another consequence of reaction (2) with different isotopic forms of benzene from the medium should have been a change in the ratio of the quantities of these forms (as a result of the kinetic isotopic effect). In actual fact, however, the ratio does not change.

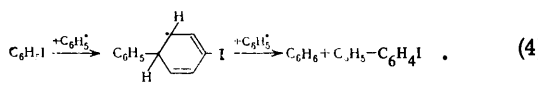
For these reasons it was concluded that "chain transfer" by the phenyl radicals does not take place to a significant extent either in its simplest form (2) or in a later version [20,22,23] involving a π complex of a radical and benzene. An analogous conclusion was reached on the basis of less direct data [24,25].

The formation of benzenes d_1 and d_0 in these experiments was attributed to reactions of type (3) with different isotopic forms of benzene from the medium:



This suggestion agrees with all the observations, since reactions (3) cannot lead to the formation of C_6D_5I or $C_6D_5-C_6D_5$ and should not lead to a change in the ratio of the heavy forms of benzene, since we should not expect significant kinetic isotopic effects in processes involving attachment to different isotopic forms of benzene.

The formation of benzene-d_0, however, cannot be attributed entirely to reactions (3), since in experiments in which the original benzene contained 95% deuterium, this reaction, for all possible values of the kinetic isotopic effect of its second stage, should give more benzene-d_1 than benzene-d_0, whereas the opposite was observed. Thus the formation of benzene C_6H_6 was attributed not only to process (3) but also to an analogous reaction of type (4) or, in the experiments with benzoyl peroxide, to processes of the same kind involving, instead of C_6H_5I, the peroxide or other aromatic compounds not containing deuterium.



(4)

This treatment, in particular, attributed the increase in the ratio C_6H_5D/C_6H_6 with decrease in the concentration of C_6H_5I or peroxide in benzene to the fact that the decrease leads to a decrease in the extent to which reaction (4) takes place. We shall see below that reactions of type (4) must be assumed in order to explain the isotopic composition of the biphenyls formed. It should also be noted that in the photolysis of iodobenzene, iodobiphenyl is in fact obtained [18].

In a medium of cyclohexane, benzenes-d_1 and -d_0 are formed by reactions (5), taking place with a kinetic isotopic effect, which explains the enrichment of the cyclohexane in deuterium after the experiments:

$$C_6H_5^{\cdot} + C_6D_{12} \rightarrow C_6H_5 + C_6D_{11}^{\cdot}; \; C_6H_5^{\cdot} + C_6H_{12} \rightarrow C_6H_6 + C_6H_{11}^{\cdot} \quad . \qquad (5)$$

The magnitude of this effect was found to be 9. It was measured [26] relative to the quantities of C_6H_5D and C_6H_6 formed in the photolysis of C_6H_5I, since it was shown that in a medium of cyclohexane, reaction (5) is the only source of benzenes-d_1 and -d_0.

The behaviour of phenyl radicals in toluene $C_6H_5CD_3$ has not been studied by this method. It will be shown in the next section, however, that a number of radicals which are less reactive than $C_6H_5^{\cdot}$ remove hydrogen from the methyl

†Here and subsequently, one of the possible formulae for cyclohexadienyl radicals is given.

group of toluene. It may therefore be assumed that hydrogen is also removed by phenyl radicals, and that published data [27] which deny this removal are in this respect erroneous.

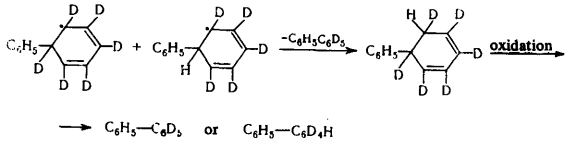
The reaction of the cyclohexyl radicals formed by reaction (5) was not specially studied in the works cited. From this work it followed, however, that C_6H_{11} radicals are not significantly capable of undergoing disproportionation and chain transfer:

$$C_6H_{11}^{\cdot} + C_6D_{11}^{\cdot} \rightarrow C_6H_{11}D + C_6D_{10}$$

$$C_6H_{11}^{\cdot} + C_6D_{12} \rightarrow C_6H_{11}D + C_6D_{11}^{\cdot} \qquad (6)$$

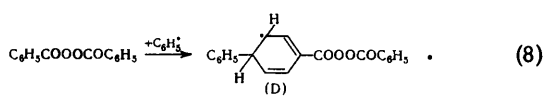
since the cyclohexane after the experiments did not contain the form $C_6H_{11}D$. This conclusion was later confirmed (see section III).

The isotopic composition of the biphenyls from these experiments shows that these substances are formed not only by the previously accepted schemes of types (3) and (7) involving various isotopic forms of benzene, but also by other paths. This followed from the results of a calculation which showed that the isotopic composition of the biphenyls obtained by schemes (3) and (7) or their combination differs from that observed experimentally: in the biphenyls the proportion of the d_0, d_1, and d_2 forms is higher, and among the other forms the proportion of d_5 is lower than that given by calculation. Allowance for kinetic isotopic effects does not give agreement between the calculated and experimental results.



(7)

The experimental results can be explained, however, if it is assumed that in addition to reactions (3) and (7), the photolysis of C_6H_5I involves the disproportionation of iodohydrobiphenyl radicals, formed according to scheme (4), with isotopic forms of hydrobiphenyl radicals, formed by reaction (3). Calculation shows that this process leads to a decrease in the proportion of the biphenyl-d_5 in the biphenyls-d_3, -d_4, and -d_5. Moreover, it leads to the formation of the iodobiphenyl-d_1. The latter, and also the iodobiphenyl-d_0, give on photolysis the radicals $C_6H_5C_6H_3D^{\cdot}$ and $C_6H_5C_6H_4^{\cdot}$, which, like phenyl radicals, remove hydrogen and deuterium from the medium, giving the biphenyls-d_0, -d_1, and -d_2. In the experiments with benzoyl peroxide, the isotopic composition of biphenyl is explained analogously: in addition to reactions (3) and (7), the process involves attack by the phenyl radicals on the peroxide (and other aromatic compounds present), for example:



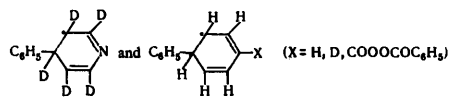
(8)

The radicals (D) after dehydrogenation and disproportionation give phenyl-substituted benzoyl peroxides-d_0 and -d_1, decomposition of which leads to the formation of $C_6H_5C_6H_4^{\cdot}$ and $C_6H_5C_6H_3D^{\cdot}$ radicals, which remove hydrogen and deuterium from the medium with the formation of the biphenyls-d_0, -d_1, and -d_2.

It will be shown below that the isotopic composition of the products of many reactions involving $C_6H_5^{\cdot}$ radicals in benzene are explained analogously.

Thus the isotopic composition of biphenyl results from the reactions of free radicals of various types. In biphenyl there is an increase in the concentration of the d_0, d_1, and d_2 forms, and a decrease in the concentration of the d_5 form. There characteristic features of the isotopic composition, as shown by Gragerov and coworkers (see for example, Refs. 10, 11, 27, 38, 74, 112), can be used to distinguish reactions involving $C_6H_5^{\cdot}$ free radicals in benzene from reactions taking place in the reactive complex. Another indication, as is clear from above, is the appearance of the benzenes-d_1 and -d_0 in benzene and cyclohexane after the experiments. It will be shown below that reactions which do not involve free radicals do not lead to the formation of the benzene-d_1 and -d_0 and give biphenyl with composition corresponding to that of the benzene solvent.

The thermal decomposition of benzoyl peroxide in heavy pyridine was studied recently [28] and it was shown that there is an extensive analogy in the reaction mechanisms in pyridine and in benzene. As in a medium of C_6D_6, the reaction gave the benzenes-d_1 and -d_0 and the products of the reaction of the C_6H_5 residues with the solvent—phenylpyridines, and also biphenyl. These results were attributed to the free-radical mechanism of the process. It was confirmed by the isotopic composition of the phenylpyridine and biphenyl, which could be explained only by assuming reactions, similar to those examined above, undergone by radicals of type (9), formed by the attachment of C_6H_5 to the isotopic forms of pyridine and the aromatic compounds present in the system



(9)

The experiments showed that the benzenes-d_1 and -d_0 are not formed by direct removal of hydrogen from pyridine:

$$C_6H_5^{\cdot} + NC_5D_5 \rightarrow C_6H_5D + NC_5D_4^{\cdot} \qquad (10)$$

since the reaction was not accompanied by a change in the ratio of the quantities of its isotopic forms and did not give heavy bipyridyls (the probable products of the attachment of pyridyl radicals to pyridine). The formation of the benzenes-d_1 and -d_0 was attributed to the dehydrogenation of radicals (9) by phenyl radicals.

III. PHOTOLYSIS OF ORGANIC HALIDES AND THE PROPERTIES OF THE CORRESPONDING RADICALS

The free-radical mechanism of the photolysis of organic halides is firmly established [11,16,18,29,30], and this reaction provides a convenient and general source of free radicals. It is used in studies carried out by means of deuterium and mass spectrometry to investigate the properties and the mechanism of the reactions of hydrocarbon radicals. Simple aliphatic, substituted phenyl, aryl, and arylalkyl radicals and various radicals stabilised by conjugation have been studied in various solvents. A summary of the reactions studied and references to the corresponding literature are given in the Table.

The chief result of these studies is the establishment of the extensive similarity between a number of radicals and phenyl radicals and the discovery of the general regular features of their behaviour and of criteria which make it possible to detect the participation of free hydrocarbon radicals in reactions whose mechanism has not been established. Specific properties have been found only for the

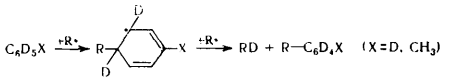
benzyl and cyclohexyl radicals, which will be examined separately.

The R' radicals studied (with the exception of the benzyl and cyclohexyl radicals), in the reactions given in the Table, give the hydrocarbons RD and RH. As with the phenyl radicals, the isotopic composition of the benzene, toluene with deuterium in the ring, and naphthalene after the experiments remains the same as that for the original solvents, whereas cyclohexane and toluene with deuterium in the methyl group are usually enriched in deuterium. The products of the direct removal of hydrogen from benzene by R' radicals are not obtained.

Reactions involving the photolysis of organic halides (the symbol + denotes that the reaction has been studied).

Halides	Heavy solvents: benzene	cyclohexane	deuteromethyltoluene	toluene with deuterium in the ring	naphthalene	triphenyldeuteromethane	References
p-$C_6H_5C_6H_4I$	+	+	+	−	−	−	31–33
	+	+	+	+	−	−	34
	+	+	+	+	−	−	34
	+	+	+	−	−	−	34
	+	+	+	+	+	−	31–33
	+	−	−	−	−	−	35
$C_6H_5CH_2I$	+	+	+	+	−	+	32,33,36
$(C_6H_5)_2CHBr$	+	−	−	−	−	−	35
$CH_2{=}CH{-}CH_2I$	+	+	+	−	−	−	35
	+	+	+	−	+	+	32,33,36
CH_3I	+	+	−	−	−	−	12,37–39
C_2H_5I	+	+	−	−	−	−	12,37–39

These facts were interpreted by assuming that the radicals R', like phenyl radicals, remove hydrogen directly from cyclohexane and the methyl group of toluene, but not from benzene, the toluene ring, or naphthalene. They add on to the latter and remove hydrogen from the resulting radicals of the cyclohexadienyl type, according to a scheme analogous to (3), for example:



(11)

This course of the reactions is confirmed by the fact that in a number of instances, products of the type RC_6D_4X have been isolated or their formation established from the mass spectra. Their isotopic composition, like the composition of the biphenyl formed by the reaction of phenyl radicals with benzene (section II), usually differed from that calculated entirely according to a scheme of type (11): the products contained less than the calculated quantity of the d_4 form and more than the calculated quantities of the d_0 and d_1 forms [12,34,37–39]. These characteristic features of the isotopic composition were explained by assuming that the formation of these substances, in addition to reactions of type (11), also involves processes of type (1b) including a disproportionation stage.

The hydrocarbons (RH + RD) obtained in these reactions contain much more of the d_0 than d_1 form even in experiments with highly deuterated solvents. As with the phenyl radicals, this was explained by assuming that the hydrocarbons RH are obtained not only by the above reactions with heavy solvents, which give the compounds RD and RH, but also by the reaction of the R' radicals with the original aromatic halides and other light aromatic compounds [according to a scheme analogous to (4)] or by the direct removal of hydrogen from aliphatic halides, other aliphatic compounds present in the system, and aliphatic substituents in the aromatic rings.

These data made it possible to formulate criteria for the participation of R' free radicals in reactions whose mechanisms have not been established. These are: 1) the appearance of the hydrocarbons RD and RH in reactions in a medium of heavy benzene, cyclohexane, toluenes with deuterium in the ring or in the methyl group, and naphthalene; 2) the presence in the products of the type $R{-}C_6H_5$, obtained in heavy benzene, of larger quantities of the isotopic d_0 and d_1 forms and smaller quantities of the d_5 form than expected by calculation according to a scheme of type (11).

Benzyl radicals in aromatic media behave like the other radicals examined above. Unlike the latter, however, they do not remove hydrogen at 30–40° from the methyl group of toluene or from cyclohexane (but they remove it from the C–H group of triphenylmethane). Thus not all of the critieria for a free-radical mechanism, formulated above, apply to benzyl radicals.

It was found that cyclohexyl radicals cannot remove hydrogen at 30–40°C from benzene, toluene, cyclohexane, naphthalene, or the CH groups of triphenylmethane, either directly or through intermediate attachment to aromatic rings. Thus the method examined here cannot be used to indicate these radicals.

It should be noted, however, that the properties of cyclohexyl radicals raise a number of problems. For example, the reason for their low reactivity compared with benzyl radicals, and the mechanism of formation of light cyclohexane and cyclohexene obtained by photolysis of iodocyclohexane in heavy media [33,36], are not understood. This makes it uncertain whether the photolysis of $C_6H_{11}I$ does in fact give free radicals C_6H_{11}, particularly in view of the recent report [40,41] that the cyclohexyl radicals obtained by the photolysis and thermal decomposition of $Pb(C_6H_{11})_4$ and $Pb_2(C_6H_{11})_6$ in benzene remove hydrogen from the medium. It should be remembered, however,

that the $C_6H_{11}^{\cdot}$ radicals formed by the removal of hydrogen from cyclohexane under the influence of phenyl radicals do not disproportionate and do not remove hydrogen from cyclohexane [12]. The same was found for the $C_6H_{11}^{\cdot}$ radicals produced by the action of naphthyl radicals on cyclohexane [31-33]. Thus the properties of cyclohexyl radicals require further study.

Some other remarks and comparisons may be made regarding these data.

The study of 2,4,6-trialkylphenyl radicals was of interest in connection with the fact that steric hindrance can alter the properties of radicals considerably. The data show, however, that the properties of these radicals are qualitatively analogous to the properties of $C_6H_5^{\cdot}$ radicals.

Allyl radicals, as expected (but contrary to certain published work [42]), are much more reactive than benzyl radicals. It is difficult to reconcile their ability to remove hydrogen from cyclohexane with the data in Ref. 43 and with some of the data in Ref. 42.

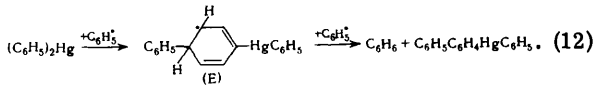
The reaction of diphenylmethyl radicals with benzene contradicts the data of Ref. 44, which are apparently erroneous in this respect. It must be assumed that these radicals, like benzyl radicals, do not react at low temperatures with cyclohexane and the methyl group of toluene.

IV. VARIOUS REACTIONS OF ORGANOMETALLIC COMPOUNDS

The mechanism of the photolysis of diphenylmercury was not elucidated completely by a large number of studies, carried out in particular by the isotopic method. Thus in Refs. 15, 19, 21, 22 it was concluded that this reaction in benzene takes place by a free-radical mechanism, whereas in Refs. 45 and 46 it was concluded that the reaction takes place in the reactive complex, without the liberation of radicals. The photolysis in cyclohexane and cyclohexene was explained by means of a free-radical scheme [46,47].

The use of a combination of the isotopic and mass-spectrometric methods showed [12,37-39] that the photolysis in benzene or in cyclohexane takes place by a free-radical mechanism, and also made it possible to determine various details of the mechanism.

In heavy solvents it was established that the benzenes-d_1 and -d_0 are formed, and this provided proof that $C_6H_5^{\cdot}$ radicals take part in the reaction. The fact that the form C_6H_6 predominates in the experiments in benzene was attributed, as with the photolysis of iodobenzene and the decomposition of benzoyl peroxide, to the fact that this form, unlike C_6H_5D, is obtained not only by a reaction of type (3) with the forms of benzene from the medium, but also by a reaction analogous to (4), involving diphenylmercury:



(12)

Further proof of the free-radical mechanism of the photolysis of diphenylmercury in benzene is provided by the characteristic features of the isotopic composition of the biphenyl produced. This does not contain biphenyls with more than five deuterium atoms and contains more of the d_0, d_1, and d_2 forms, and less of the d_5 form, than required by calculation according to reactions (3), (7), or their combinations, with any possible kinetic isotopic effects. This observation was attributed to the fact that the disproportionation of type (7) involves the radicals (E), which do not contain deuterium, and this leads to a decrease in the concentration of the d_5 form in the biphenyl obtained and to the appearance of $C_6H_5C_6H_4HgC_6H_5$ and $C_6H_5C_6H_3DHgC_6H_5$ molecules, which on photolysis give $C_6H_5C_6H_4^{\cdot}$ and $C_6H_5C_6H_3^{\cdot}$ radicals; the latter remove hydrogen and deuterium from the medium, with the formation of the biphenyls-d_0, -d_1, and -d_2.

The isotopic composition of the undecomposed biphenylmercury residue was also studied, and it was found that it does not contain deuterium. These results are of interest in connection with the fact that the introduction of tracer from the benzene into the diphenylmercury during photolysis was considered [15,21,22] to be one of the most important proofs of the existence of "chain transfer" of phenyl radicals (see section II). The introduction was not confirmed in subsequent work by the same authors [45,46].

Recently, they returned again [41,48] to the study of the photolysis and thermal decomposition of diphenylmercury, and also the photolysis and thermal decomposition of tetraphenyl-lead and hexaphenyldilead in heavy benzene, this time using the isotopic and mass-spectrometric methods. It was established that the reactions give the benzenes-d_1 and -d_0 and biphenyls of three kinds: unlabelled—A, labelled in one ring—B, and labelled in two rings—C. The mechanism of these reactions was examined for the example of the photolysis of diphenylmercury. The biphenyl A, in the opinion of the authors cited, is obtained as a result of the intramolecular decomposition, catalysed by mercury, of part of the diphenylmercury, with recombination of the radicals on the metal surface. We have seen, however, that another explanation for the appearance of this biphenyl is possible.

The formation of the biphenyl B was attributed to two mechanisms—decomposition in the reactive complex and free-radical reaction according to schemes (3) and (7)—and the production of the biphenyl C was attributed to free-radical "chain transfer" (2) and attachment of the radicals $C_6D_5^{\cdot}$, $C_6D_4H^{\cdot}$, etc., formed according to scheme 2, to the isotopic forms making up the heavy benzene.

It was later shown [49] that the biphenyls A, B, and C are also obtained in the photolysis and thermal decomposition of triphenylbismuth in heavy benzene, and the same explanations were put forward.

The formation of the biphenyl C in photolysis at low temperatures and the conclusion, on this basis, that "chain transfer" of phenyl radicals takes place do not agree with the work on the photolysis of diphenylmercury [11,37-39] or with other data on the behaviour of phenyl radicals in heavy benzene (see section II). The following considerations also cast doubt on the correctness of this observation. The isotopic composition of the biphenyl C can readily be calculated from the composition of the benzene solvent. The results of the calculation, however, show a marked lack of correspondence with the composition found in the works cited. It may therefore be assumed that that part of the work which refers to the production of the biphenyl C and the "chain transfer" in the photolysis is erroneous. It is not excluded, however, that "chain transfer" is observed at high temperatures, under the conditions of the thermal decomposition.

The decomposition and oxidation of diphenylzinc in heavy benzene have been studied [50,51]. Both reactions led to the appearance of the benzenes-d_1 and -d_0 and gave the biphenyls A and B, together with a small quantity of C in the thermal decomposition. The formation of the biphenyl A was attributed to intramolecular decomposition or oxidation of $Zn(C_6H_5)_2$, and the formation of the biphenyl B was attributed to reaction between the solvent and $C_6H_5^{\cdot}$ radicals

formed on decomposition or oxidation. Under the conditions of the thermal decomposition, the diphenylzinc underwent isotopic exchange with benzene. It must therefore be assumed that the biphenyl C was obtained by reaction between the solvent and labelled phenyl radicals from the organometallic compound, which had undergone partial exchange.

It was recently established [28] that the photolysis of diphenylmercury in heavy pyridine takes place by a free-radical mechanism. All that has been said regarding the decomposition of benzoyl peroxide in pyridine (section II) applies to the mechanism of this reaction.

V. REACTIONS OF DIAZO- AND AZO-COMPOUNDS

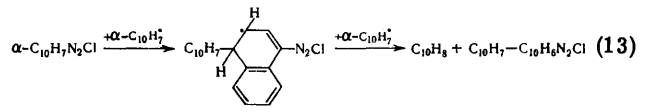
Despite extensive published material [3,14,30,52-55], the participation of free radicals in the thermal decomposition of diazonium salts was disputed—evidence was published for [30,56,57] and against [58] this suggestion. The same is true of the thermal decomposition of nitrosoacetanilide (NAA) [14,30,53,55] and phenylazotriphenylmethane (PAT) [59]: evidence has been put forward for [60-70] and against [8,22,58] a free-radical mechanism. Confirmation was also required for the free-radical mechanism of the Gomberg–Bachmann reaction [14,30,52,53,55,71,72]. The mechanism of the arylation of benzene by aromatic amines under the influence of isopentyl nitrite in neutral medium [73] was not studied. Studies of these reactions by a combination of the isotopic and mass-spectrometric methods are discussed below.

The decomposition of phenyldiazonium fluoroborate and chloride was studied in various deuterated solvents [9,10,12,38,39,74,75]. In benzene, cyclohexane, toluene $C_6D_5CH_3$, bromobenzene, and chloroform, the fluoroborate did not give the benzenes-d_1 and -d_0, and the biphenyl obtained in a medium of benzene had an isotopic composition corresponding to the combination of the C_6H_5 residues from the salt and from the solvent. Thus $C_6H_5^{\cdot}$ radicals do not take part in the decomposition of $C_6H_5N_2BF_4$. $C_6H_5^{+}$ ions (whose reactions were detected in some examples of the decomposition of the fluoroborate [76,77]) apparently do not take part in the decomposition either, since it may be assumed that these ions, like Alk^+ ions, which remove hydrogen from Alk–H molecules [78,79], react with the solvents to give the benzenes-d_1 and -d_0. The decomposition of $C_6H_5N_2BF_4$ takes place in the reactive complex.

The decomposition of $C_6H_5N_2Cl$ in the same solvents, on the other hand, gave the benzenes-d_1 and -d_0, and the biphenyl obtained in a medium of benzene had the isotopic composition characteristic of free-radical reactions. Thus $C_6H_5^{\cdot}$ free radicals take part in this reaction. Their yield, however, is much less than that in the other reactions examined, since the yield of benzenes-(d_1 + d_0) is unusually small. The process probably takes place in two directions—by the free-radical mechanism and in the reactive complex—with the latter direction predominating.

In the decomposition of $C_6H_5N_2BF_4$ in heavy pyridine and α- and β-picolines with deuterium in the methyl group, all the indications of the participation of $C_6H_5^{\cdot}$ free radicals were observed (the formation of the benzenes-d_1 and -d_0, and the characteristic isotopic composition of the phenylpyridine), whereas in the decomposition of $C_6H_5N_2Cl$ they were observed only in a medium of picolines. The fluorobenzene and chlorobenzene formed in these reactions did not contain deuterium.

The intermediate formation of free radicals was established in the thermal decomposition of α-naphthyldiazonium chloride [32,33,80] in heavy benzene, cyclohexane, and naphthalene. The reaction led to the formation of the naphthalenes-d_1 and -d_0, obtained by direct removal of hydrogen from cyclohexane and according to schemes of types (11) and (13):



$$\alpha\text{-}C_{10}H_7N_2Cl \xrightarrow{+\alpha\text{-}C_{10}H_7^{\cdot}} C_{10}H_7\text{-}N_2Cl \xrightarrow{+\alpha\text{-}C_{10}H_7^{\cdot}} C_{10}H_8 + C_{10}H_7\text{–}C_{10}H_6N_2Cl \quad (13)$$

The last reaction is analogous to scheme (4).

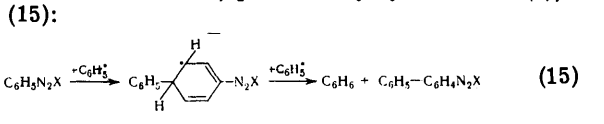
The chloronaphthalene from these experiments did not contain deuterium, so that it was not formed by chlorination of the naphthalene by atomic chlorine. The chloronaphthalene was possibly obtained in the "solvent cage":

$$\alpha\text{-}C_{10}H_7N_2Cl \xrightarrow{-N_2} (\alpha\text{-}C_{10}H_7^{\cdot} + Cl^{\cdot}) \rightarrow \alpha\text{-}C_{10}H_7Cl \quad (14)$$

and the low yields may be due to the fact that most of the radicals leave the "cage" and do not give this substance. It is not excluded that some chloronaphthalene is obtained by a reaction which does not involve free radicals, as with the halogenobenzenes.

To explain these results, it was suggested [75] that the free-radical mechanism of decomposition of diazonium salts plays a greater role, the more stable the radicals formed, and that this stability is determined not only by their chemical character but also by solvation. It was still not clear, however, why the decomposition of $C_6H_5N_2Cl$ in pyridine takes place by a reaction which does not involve free radicals.

The decomposition of NAA and PAT in heavy benzene or cyclohexane [81] takes place by a free-radical mechanism. It gave benzenes-d_1 and -d_0, presumably by reactions (3), (5), and (15):



$$C_6H_5N_2X \xrightarrow{+C_6H_5^{\cdot}} C_6H_5\text{-}N_2X \xrightarrow{+C_6H_5^{\cdot}} C_6H_6 + C_6H_5\text{–}C_6H_4N_2X \quad (15)$$

X = –OCOCH$_3$ or –C(C$_6$H$_5$)$_3$

to which, in the case of PAT, was added reaction with the triphenylmethanes formed in the experiments:

$$C_6H_5^{\cdot} + (C_6H_5)_3CH \text{ (or } (C_6H_5)_3CD) \rightarrow C_6H_6 \text{ (or } C_6H_5D) + (C_6H_5)_3C^{\cdot} \quad (16)$$

The latter were evidently obtained by the removal of hydrogen or deuterium from radicals of the cyclohexadienyl type by $(C_6H_5)_3C^{\cdot}$ radicals according to schemes of types (3) and (15) with $(C_6H_5)_3C^{\cdot}$ instead of $C_6H_5^{\cdot}$ in the second stages. The formation of triphenylmethanes confirmed indirectly the free-radical mechanism of the decomposition of PAT. Direct confirmation was obtained by the EPR method, which made it possible to identify the triphenylmethyl radicals.

Eliel and coworkers [8] found, however, that in the decomposition of NAA and PAT in benzene-d_1, biphenyl is obtained without a kinetic isotopic effect and does not contain the d_2 form, and the products of the reactions in an inert atmosphere do not contain dihydrobiphenyl. This absence of the "indications of the participation of free radicals in the reactions" (see section II) was interpreted as proof that the decomposition of NAA and PAT takes place by a mechanism which does not involve free radicals.

We cannot agree with this intrepretation. It has been correctly noted [64] that all the above "indications" of Eliel and coworkers are the result of disproportionation of radicals of the cyclohexadienyl type (see section II). Their presence proves that the reactions take place by a free-radical mechanism, but their absence merely indicates that disproportionation does not take place.

It has also been demonstrated[81] that disproportionation does not take place, since the biphenyls obtained in the work cited contained the forms from d_5 to d_2 in the ratio corresponding to that calculated according to scheme (3).

Disproportionation of radicals of the cyclohexadienyl type is apparently suppressed by more rapid reactions involving dehydrogenation and combination with $(C_6H_5)_3C^\cdot$ or $C_6H_5-N=N-O^\cdot$ radicals, which are formed in appreciable concentrations, because of their relative stability[64,68].

The biphenyls in the experiments being discussed[81] contained larger quantities of d_1 and d_0 forms relative to those calculated according to scheme (3), and a source of these forms, in addition to reactions (3), is provided by the thermal decomposition of $C_6H_5C_6H_4N_2X$ molecules formed according to scheme (15), and the removal of hydrogen and deuterium from the medium by the $C_6H_5C_6H_4^\cdot$ radicals produced (see section II). Thus the isotopic composition of the biphenyls also indicates that the thermal decomposition of NAA and PAT takes place by a free-radical mechanism.

Of the Gomberg–Bachmann reactions, the reactions of $C_6H_5N_2Cl$, α-$C_{10}H_7N_2Cl$, and p-$C_6H_5C_6H_4N_2Cl$ with aqueous alkali in benzene and cyclohexane have been studied[10,12,38,39,74] and the free-radical mechanism of these reactions has been proved. Like other free-radical processes, the reactions led to the formation of the benzenes-d_1 and -d_0, the naphthalenes-d_1 and -d_0, and the biphenyls-d_1 and -d_0 respectively, obtained by the direct removal of hydrogen from cyclohexane by the radicals according to schemes of types (3) and (11) and by reactions analogous to reactions (13) and (15). The biphenyl from the experiments with $C_6H_5N_2Cl$ in benzene contained smaller quantities of the d_5 form and larger quantities of the d_0, d_1, and d_2 forms relative to those calculated according to scheme (3), and this again indicated that the reaction takes place by a free-radical mechanism. In the experiment with $C_6H_5C_6H_4N_2Cl$, in accordance with the free-radical scheme, one of the products was terphenyl.

The reaction of aromatic amines $ArNH_2$ with isopentyl nitrite was studied in heavy benzene, cyclohexane, or naphthalene[82] with the compounds aniline, p-nitroaniline, p-anisidine, α-, and β-naphthylamines, p-aminobiphenyl, and γ-aminopyridine. A free-radical mechanism was found for all these reactions: the products contained the compounds ArD and ArH, formed, as usual, by the removal of hydrogen from cyclohexane by Ar$^\cdot$ radicals according to reactions of type (11) with benzene or naphthalene and also ArH formed by the removal of hydrogem from isopentyl nitrite and its reaction products by the radicals, and also by a reaction analogous to reaction (11), but with the original amines instead of benzene or naphthalene. The last reaction, in the case of aniline, should give aminobiphenyl, which, by reacting with isopentyl nitrite, leads to the formation of the biphenyls-d_1 and -d_0. These were in fact found in the experiment with aniline in benzene in quantities greater than that calculated according to scheme (11). In the other experiments the isotopic composition of the products of the arylation of benzene coincided with that calculated according to this scheme. Thus in this instance, as in the decomposition of NAA and PAT, the disproportionation of radicals of the cyclohexadienyl type is not significant. This reaction is apparently suppressed by the more rapid dehydrogenation, possibly under the influence of isopentyl nitrite or its decomposition products.

The radicals β-$C_{10}H_7^\cdot$, p-$O_2NC_6H_4^\cdot$, p-$CH_3OC_6H_4^\cdot$, and γ-$NC_5H_4^\cdot$, obtained by the reaction of the corresponding amines with isopentyl nitrite, were first studied in the work cited by means of a combination of isotopic and mass-spectrometric methods. From the foregoing it follows that their behaviour in benzene, cyclohexane, and naphthalene does not differ from that of other aryl or simple alkyl radicals.

In the work cited it was suggested that diazo-hydroxides are formed in intermediate stages:

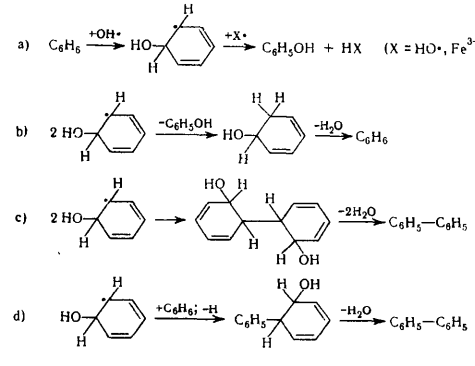
$$ArNH_2 + C_6H_{11}ONO \xrightarrow{-C_6H_{11}OH} ArNHNO \rightarrow Ar-N=N-OH \quad . \qquad (17)$$

The same substances are obtained in the first stages of the Gomberg–Bachmann reaction. The similarity in the mechanisms of the two reactions was recently confirmed[83] by the fact that in the reaction of aniline with isopentyl nitrite in benzene the EPR method established the existence of the same radicals $C_6H_5-N=N-O$, which were recently assumed[72] to be intermediate products of the Gomberg–Bachmann reaction.

VI. PROCESSES OF HYDROCARBON OXIDATION

It has been shown by isotopic and mass-spectrometric methods[12,38,84,85] that in the oxidation of a mixture of benzenes C_6D_6 and C_6H_6 by potassium permanganate in acid medium or by ammonium peroxosulphate catalysed by Ag^+ ions, the unreacted hydrocarbon residue does not contain the benzene-d_1. It was assumed that radicals are formed in the intermediate stages of the oxidation of organic compounds by permanganate (for example Refs. 86 and 87) and by peroxosulphate (for example Ref. 88). The results given above show that in the examples being considered these radicals cannot be $C_6H_5^\cdot$ radicals. On the other hand, the radiolysis of dry benzene ($C_6D_6 + C_6H_6$) gave biphenyl with the isotopic composition corresponding to a free-radical scheme of formation, confirming the previously assumed (for example Ref. 89) participation of $C_6H_5^\cdot$ radicals in this reaction.

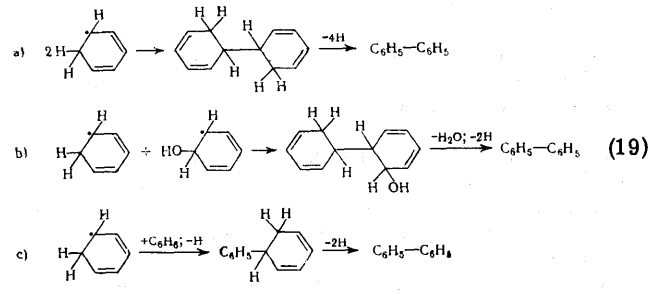
$C_6H_5^\cdot$ radicals are not obtained in the oxidation of heavy benzene by Fenton's reagent or pernitrous acid or in the radiolysis of a degassed water–benzene mixture[12,84,85,90]. These data refuted the commonly encountered schemes for radiolysis and oxidation by Fenton's reagent involving the participation of phenyl radicals (for example Refs. 91–94), assumed to be produced by the removal of hydrogen from benzene by OH$^\cdot$ radicals. We give below alternative schemes (for example Refs. 93–96) in which OH$^\cdot$, like other radicals, do not remove hydrogen from benzene, but add on to it:



(18)

The isotopic composition of the products of these reactions made it possible to refine these schemes and to obtain new data on the mechanism.

The composition of the biphenyls concided with that calculated for reactions (18*c*) or (18*d*). For the radiolysis, it made it possible to reject another possible mechanism—the formation of biphenyl from $C_6H_7^{\cdot}$ ($C_6D_7^{\cdot}$) radicals, assumed to be formed [97,98] by the attachment of hydrogen atoms from the water to benzene:

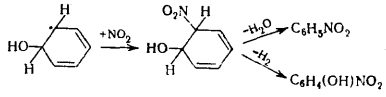


(19)

since the isotopic composition of the biphenyl differed sharply from that calculated according to schemes (19). Disproportionation of the radicals $C_6H_7^{\cdot}$ and $C_6D_7^{\cdot}$ does not take place either. This would have given (after dehydrogenation of the C_6H_7D disproportionation product) the benzene-d_1, which was not detected.

The phenol obtained in oxidation with Fenton's reagent had an isotopic composition close to that calculated according to scheme (18*a*) but markedly different from that corresponding to scheme (18*b*) with allowance for the dehydrogenation of dihydrophenol. Thus disproportionation of the hydrophenol radicals (18*b*), if it takes place at all, does not take place to a significant extent. This is apparently related to the high concentration of oxidising agents (Fe^{3+}, H_2O_2) in the reaction system; these rapidly dehydrogenate the radicals according to reaction (18*a*). The results obtained confirm schemes (18*a*), (18*c*), and (18*d*).

It has been suggested [99] that in the reaction of benzene with pernitrous acid, nitrobenzene and nitrophenol are formed according to the scheme:

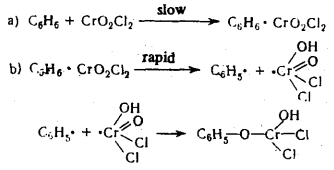


(20)

The isotopic composition of the reaction products showed that the removal of water and hydrogen takes place with a kinetic isotopic effect and therefore takes place in the slow stages of reactions (20). Another possible mechanism for the formation of nitrophenol—hydroxylation of nitrobenzene—cannot be distinguished from mechanism (20) on the basis of the results being discussed. It should be noted that a mechanism which does not involve free radicals is also possible for oxidation by pernitrous acid [12] and that the results being discussed do not make it possible to choose between this and scheme (20).

In the mechanism of the oxidation of hydrocarbons by chromyl chloride (Etard's reaction), the problem of the nature of the first, most important, oxidative stage, which is complete with the formation of an insoluble complex of the hydrocarbon and CrO_2Cl_2, was unresolved. Ionic (for example Ref. 100), radical [101-103], and molecular [104] mechanisms were proposed for this stage. It was recently shown [103] that the free-radical scheme agrees with all published data, but direct confirmation was given only in Refs. 9, 10, 12, 32, 38, 105. In these experiments, mixtures of light and heavy benzene, toluene, and naphthalene or solutions of toluene, diphenylmethane, biphenyl, naphthalene, anthracene, and phenanthrene in heavy benzene or in heavy cyclohexane were subjected to incomplete oxidation. It was found that the unreacted residues of the oxidised hydrocarbons contained their d_1 isotopic forms, indicating the intermediate formation of the radicals corresponding to the hydrocarbons. The oxidation of toluene and diphenylmethane in benzene gave further proof of the intermediate formation of benzyl and diphenylmethyl radicals—the isolation of benzophenone and triphenylcarbinol, which are products of the oxidation of diphenylmethane and triphenylmethane, formed by the addition of the $C_6H_5CH_2^{\cdot}$ or $(C_6H_5)_2CH^{\cdot}$ radicals to benzene according to scheme (11).

In the works cited and in Ref. 106 it was established that a kinetic isotopic effect is not observed in the oxidation of benzene and naphthalene by CrO_2Cl_2, but that this effect is observed in the oxidation of toluene and triphenylmethane. The reaction scheme finally proposed is given below for the example of benzene:



(21)

(22)

Analogous reactions take place with the second molecule of the oxidising agent. Reaction (22) competes with the usual reactions of $C_6H_5^{\cdot}$ radicals in benzene—reaction (3), which gives benzene-d_1, and reaction (7). In some instances, for example in the oxidation of toluene and triphenylmethane, the slow stage is stage (21*b*), and this leads to a kinetic isotopic effect.

The participation of free radicals in Etard's reaction was recently confirmed directly by the EPR method [107].

VII. REACTIONS OF ORGANIC HALIDES WITH METALS

The participation of free radicals in the mechanism of the reactions of organic halides with metals is often assumed, but it has been demonstrated convincingly in only a few studies. Studies of the reactions of magnesium, lithium, sodium, potassium, and copper with organic halides by a combination of isotopic and mass-spectrometric methods are discussed below. These studies not only proved that these reactions involve free radicals, but also revealed many aspects of their mechanisms.

A number of authors (for example Refs. 108 and 109) assumed on the basis of indirect data that reactions of this kind involving magnesium take place by a free-radical mechanism. This was subsequently confirmed more convincingly [110,111], but it was still not clear whether this mechanism was general and whether it still holds in the presence of ether, in which preparative syntheses are usually carried out.

In the study of the reaction of magnesium with iodobenzene in heavy benzene or cyclohexane [9,10,12,38,39,112], the substances A isolated directly from the reaction mixture and the substances B obtained by the action of water on the residue from the complete separation of compounds A were analysed separately. Benzenes-d_0 and -d_1 were found in the compounds A, indicating that the free radicals $C_6H_5^{\cdot}$ take part in the reactions. The formation of the radicals was explained by the scheme:

$$C_6H_5I + Mg \rightarrow C_6H_5^{\cdot} + MgI^{\cdot} \rightarrow C_6H_5MgI \qquad (23)$$

and the formation of the benzenes-d_1 and -d_0 was explained by the usual schemes (3), (4), and (5). In the biphenyl A from the experiments in benzene, the proportions of the

forms from d_5 to d_2 corresponded to those calculated according to scheme (3), whereas the proportions of the d_1 and d_0 forms were found to be much greater. Thus reactions of type (3) provide the main source of the biphenyls from d_5 to d_2, and the disproportionation (7) is not significant. The formation of the biphenyl-d_0 was attributed to the reaction:

$$C_6H_5MgI + C_6H_5I \rightarrow C_6H_5{-}C_6H_5 + MgI_2 \quad (24)$$

and the formation of the biphenyls-d_1 and some -d_0, as in other examples of reactions involving phenyl radicals in benzene, was attributed to the removal of hydrogen or deuterium from the medium by $C_6H_5C_6H_4^{\cdot}$ radicals. The latter were produced from iodobiphenyl [formed by reaction (4)] by a scheme similar to schemes (23) or (26) (see below).

The benzene B was formed by the reaction

$$C_6H_5MgI + H_2O \rightarrow C_6H_6 + MgIOH \quad . \quad (25)$$

It did not contain deuterium, indicating the absence of isotopic exchange between C_6H_5MgI and benzene (discovered earlier [113]). The biphenyl B from the experiment in benzene was apparently obtained analogously from $C_6H_5C_6H_4MgI$. It contained a small quantity of deuterium, probably as a result of isotopic exchange between $C_6H_5C_6H_4MgI$ and biphenyl A under the severe conditions of the separation of the latter. The compounds B obtained in benzene or cyclohexane included hydrogen (H_2 + HD). The formation of HD molecules was attributed to the dehydrogenation of radicals of the hydrobiphenyl type by the species $MgI^{\cdot}$ or to the removal of hydrogen from cyclohexane by these species and reaction of the resulting MgID molecules with water. The existence of compounds of the type MgIH was recently confirmed [114]. The biphenyls A and B from the experiments in cyclohexane did not contain deuterium, since they were formed by reaction (24) and by the reaction of $C_6H_5C_6H_4MgI$ with water.

It may be noted that the possibility of formation of radicals by reactions of type (23) has been doubted (see for example Refs. 109 and 110) and it has been suggested that the radicals are obtained in processes described by overall equations of type (24). Special experiments [115] confirmed that reaction (24) takes place by a free-radical mechanism. This does not alter the essential features of the interpretation given for the mechanism of reaction of iodobenzene with magnesium, but only modifies stage (24), interpreting it as a radical reaction:

$$C_6H_5MgI + C_6H_5I \rightarrow MgI_2 + 2C_6H_5^{\cdot} \quad (26)$$

It must be assumed that most of the $C_6H_5^{\cdot}$ radicals formed according to this scheme combine in a "solvent cage", and this explains the high percentage of the d_0 form in the biphenyl obtained in benzene C_6D_6 according to reaction (26) and in the biphenyl A.

Returning to process (23) and the analogous reaction of $C_6H_5C_6H_4I$, we may note that their free-radical mechanism was assumed [12] because it was impossible to explain the formation of hydrogen HD without assuming the participation of $MgI^{\cdot}$ radicals. $MgI^{\cdot}$ radicals may also be obtained, however, by the thermal decomposition of organomagnesium compounds (see below and Ref. 116). Thus the free-radical nature of reaction (23) and its analogues has not yet been proved.

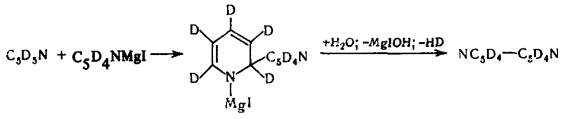
It has been shown [33, 115] that the free-radical mechanism of the reaction of magnesium with iodobenzene is preserved in the presence of ether. Free-radical mechanisms were also found for the reactions of magnesium with α-iodonaphthalene in heavy benzene, with p-iodobiphenyl in heavy benzene mixed with ether and in heavy cyclohexane mixed with ether, and with benzyl chloride in heavy benzene mixed with ether. These reactions gave naphthalenes-d_1 and -d_0, biphenyls-d_1 and -d_0, and toluenes-d_1 and -d_0 respectively. Moreover, terphenyl was obtained in the experiments with iodobiphenyl in benzene/ether, and diphenylmethane and bibenzyl were obtained in the experiments with benzyl chloride.

The mechanism of these reactions is analogous to that examined above: the hydrocarbons RD and RH were obtained according to schemes (11), (5), and (4) with light aromatic compounds and by removal of hydrogen from ether by the radicals. Terphenyl and diphenylmethane were formed according to schemes of type (11), and bibenzyl was formed by the combination of benzyl radicals. The radicals were apparently produced by reactions analogous to reactions (26) and possibly (23).

The reaction of iodobenzene with magnesium in heavy pyridine takes place in unique fashion [28]. At 60° the isotopic composition of its products and its mechanism are analogous to the composition of the products and the mechanism of the decomposition of benzoyl peroxide and the photolysis of diphenylmercury in pyridine (sections II and IV). At 120°, the ratio of the isotopic forms in the solvent changes, and phenylpyridines containing more than four deuterium atoms, and heavy bipyridyls, are formed. These characteristic features were attributed to processes which begin on heating and which involve and exchange of MgI residues from the organomagnesium compounds for the hydrogen of the pyridine and phenylpyridine:

$$C_6H_5MgI + C_5D_5N \rightarrow C_6H_5D + C_5D_4NMgI$$
$$C_5D_4NMgI + C_6H_5C_5D_4N \rightleftarrows C_5D_4HN + IMgC_6H_4C_5D_4N$$

and the formation of the bipyridyls was attributed to the reaction:



or to the addition of pyridyl radicals of thermal origin to pyridine.

These explanations were confirmed by the fact that the reaction between C_6H_5MgI and heavy pyridine at 120° gave the same products and isotopic compositions with the same characteristic features as in the reaction of C_6H_5I with magnesium.

The reactions of C_6H_5MgBr with $CoCl_2$, AgBr, $CuCl_2$, $PtCl_4$, $HgBr_2$, $FeCl_3$, $SnCl_4$, and $CrCl_3$ in a medium of heavy benzene mixed with ether were studied [117]. The published data on the mechanism of reactions of this type (for example Refs. 118–124) contain a number of contradictions. It was moreover not clear whether free radicals take part in the reactions.

The formation of free radicals was established in all these reactions, since they gave the benzenes-d_1 and -d_0 and biphenyls containing deuterium. Most of the biphenyls consisted of the d_0 form. In a number of instances their isotopic composition could not be explained without assuming the disproportionation of radicals of the hydrobiphenyl type, produced in intermediate stages of the formation of the biphenyls.

The source of the radicals was detected in experiments with $HgBr_2$ and $SnCl_4$, where the chief products were stable diphenylmercury and tetraphenyltin. It must be assumed that the radicals were obtained at the stage involving the formation of these organometallic compounds, since their decomposition did not take place. It is possible

that other organometallic compounds, which are assumed to be intermediate products of these reactions [118], are obtained by a free-radical mechanism. The decomposition of at least some of them [119-121,125] also probably involves radicals.

The fact that the d_0 form predominates in the biphenyls obtained in these experiments can be attributed to the fact that most of the biphenyls are obtained from phenyl residues which have not become free radicals. These radicals have combined in the reactive complex, in a "solvent cage" or on the surface of the metals. Only a small percentage of C_6H_5 residues were liberated, and these gave the deuterated biphenyls.

In the work cited it was also shown that the benzenes-d_1 and -d_0 are formed when a solution of C_6H_5MgBr in a mixture of heavy benzene and ether is heated to 50° or oxidised with atmospheric oxygen.

The participation of free radicals in the reactions of organic halides with alkali metals has not been extensively studied. The recently proposed [126] simple radical scheme:

$$ArX + M \rightarrow Ar^{\cdot} + MX;\ 2Ar^{\cdot} \rightarrow Ar - Ar \qquad (27)$$

cannot now be accepted, since it has been established that organometallic compounds are formed in intermediate stages of the Fittig reaction. The alternative scheme [127,128]

$$\text{a) } ArX + 2M \rightarrow ArM + MX$$
$$\text{b) } ArM + ArX \rightarrow Ar{-}Ar + MX \qquad (28)$$

does not exclude the production of radicals in the formation of organometallic compounds or in their reaction with the aryl halides [129]. Radicals were found in various examples of the Wurtz reaction [130,131], but not in the Fittig reaction [9,112].

The study of the reaction of lithium with fluorobenzene in heavy benzene [132,133] showed that the reaction gives the benzenes-d_1 and -d_0, and the ratio of the other forms of benzene remains unchanged. This proved the participation and reaction of $C_6H_5^{\cdot}$ radicals, since phenyl-lithium does not undergo isotopic exchange with benzene [134]. The participation of radicals was confirmed by the isotopic composition of the biphenyl, which was found to be characteristic for the free-radical mechanism (see sections II–IV). In heavy cyclohexane with heating, the benzenes-d_1 and -d_0, and biphenyl, are formed. Biphenyl is not obtained at 20°, so that the process stops at the stage of C_6H_5Li formation. Under these conditions also, the benzene-d_1 was not obtained.

These results show that $C_6H_5^{\cdot}$ radicals are produced by the reaction of C_6H_5Li with C_6H_5F, giving biphenyl, and not in the formation of C_6H_5Li.

The course of this reaction was represented by schemes (28*a*), of form (26) with the participation of C_6H_5Li and C_6H_5F, by the reaction:

$$2C_6H_5^{\cdot} \rightarrow C_6H_5{-}C_6H_5 \qquad (29)$$

and by schemes (3), (5), and (4), and also by analogous reactions of fluorobiphenyl, formed according to the last scheme.

The $C_6H_5^{\cdot}$ radicals obtained by a reaction of type (26), apparently recombine chiefly in a "solvent cage". Thus most of the biphenyl is of the d_0 form.

In the benzenes-(d_1 + d_0) the proportion of the benzene-d_1 is much less than that in other reactions involving $C_6H_5^{\cdot}$ radicals. This was explained by assuming that in addition to the usual routes, the benzene-d_0 is obtained by the reaction:

$$C_6H_5F + C_6H_5Li \rightarrow \langle\bigcirc\rangle + C_6H_6 + LiF\ . \qquad (30)$$

The study of the mechanism of the reaction of iodobenzene with sodium is complicated by isotopic exchange of phenylsodium with benzene [19,112]:

$$C_6H_5Na + C_6D_6 \rightleftarrows C_6H_5D + C_6D_5Na \qquad (31)$$

which, like the reactions of phenyl radicals, gives the benzene d_1. Analogous processes involving biphenyl distort its isotopic composition.

It has been shown [132,133], however, that after several hours at room temperature, without mixing, exchange is not observed, but that under these conditions in benzene, the d_1 and d_0 forms appear, and the ratio of the other forms remains unchanged, and in the biphenyl obtained the ratio of the isotopic forms is that characteristic for a radical mechanism. All this shows that the reaction involves $C_6H_5^{\cdot}$ free radicals. This conclusion was confirmed by experiments in heavy cyclohexane.

The reaction mechanism must be represented by schemes analogous to that assumed for the reaction of fluorobenzene with lithium. As in the experiments with lithium, the proportion of the d_1 form is unusually low in the benzenes-(d_1 + d_0) formed, and this was attributed to a reaction of type (30) involving iodobenzene and phenylsodium. The course of these processes has been convincingly proved [135].

These data show that the conclusion in Ref. 112 that the reaction of sodium with iodobenzene does not involve free radicals is incorrect.

It was stated above that the isotopic exchange of hydrogen between C_6H_5Na and C_6D_6 is not observed in the absence of mixing. This was attributed to the fact that benzene does not penetrate, or penetrates very slowly, into the thickness of the layer of phenylsodium and NaI surrounding the metal granules, or into the inner layers of the phenylsodium crystals. Thus exchange takes place only on the surface and remains insignificant. This interpretation is confirmed by the fact that mixing, which leads to mechanical breakdown of the above layer and to subdivision of the phenylsodium crystals, and also increase in the duration of contact between C_6H_5Na and C_6D_6, and heating, facilitate the exchange. The latter is observed from the appearance of deuterium in the benzoic acid obtained from phenylsodium and from the redistribution of deuterium (which often reaches random distribution) between the isotopic forms of benzene and biphenyl. The exchange of phenylsodium with benzene does not reach equilibrium, however, even under severe conditions, and part of the benzoic acid remains light. The other part consists of the set of isotopic forms corresponding to random distribution.

These observations confirmed the early assumptions [127,128,136,137] regarding the existence of the above layer, difficult to penetrate, on the surface of the sodium granules, and demonstrated the poor penetrability of the C_6H_5Na crystals with respect to benzene.

In the works cited [132,133], the reactions of fluorobenzene with sodium and potassium were also studied, and it was shown that they involve free radicals.

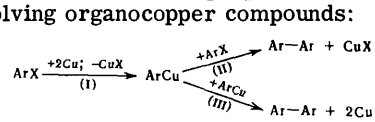
Subsequently, various examples of the Fittig and Wurtz reaction were studied [133-138] and it was found that a free-radical mechanism is extremely probable for the reaction of sodium with *p*-iodobiphenyl, α-iodonaphthalene, 9-iodophenanthrene, iodomesitylene, 2,4,6-triethyliodobenzene, 2,4,6-tri-isopropylbromobenzene, benzyl bromide, diphenylbromomethane, and triphenylchloromethane in heavy benzene or cyclohexane and for the reaction of sodium with ethyl iodide in a medium of heavy naphthalene. All these reactions gave hydrocarbons RD and RH corresponding to

the halides taken, and did not show signs of isotopic exchange between the compounds R–Na and the solvents; this exchange, like the reaction of R· radicals, might give RD molecules.

In the work cited it was also shown that the triphenylmethyl radicals, like many aryl and alkyl radicals, remove hydrogen from benzene. This reaction apparently involves an intermediate addition stage of the type corresponding to reactions (3).

In the interpretation of the mechanism of the reaction of aryl halides with copper (the Ulmann reaction) it was assumed that the halide forms on the metal surface a polar complex which attacks a second halide molecule [139,140], or that the reaction under the influence of copper gives free radicals, which react to give the final products [141,142], or, finally, that organocopper compounds are formed in some stages of the process [139]. Strong support was recently obtained for the last view.

The participation of radicals was proved [133,143] for the reaction of copper with iodobenzene, *p*-iodobiphenyl, and α-iodonaphthalene in a solution of heavy benzene or cyclohexane. The reactions gave benzenes, biphenyls, and naphthalenes-d_1 and -d_0, and the biphenyl isolated in the experiments with C_6H_5I in benzene had an isotopic composition corresponding to a free-radical mechanism of formation. The hydrocarbons (d_1 and d_0) obtained in benzene contained much more of the d_0 form than in other free-radical reactions. Here, as in the reaction of aryl halides with lithium or sodium, the hydrocarbons-d_0 are apparently formed not only from the usual sources of hydrocarbons-d_1 and -d_0 [reactions of types (3), (4), (5), and (11)], but also by reactions of type (30), which at the high temperature of the experiments (210–230°) become possible for organocopper compounds. The work cited adopted the scheme previously proposed [144] for the Ulmann reaction involving organocopper compounds:



(32)

with the refinement that stages I, II, or both involve the intermediate formation of aryl radicals. These processes apparently take place in such a way that only some of the radicals move from the surface into the solution. Thus the greater part of the diaryls formed does not contain deuterium. The reactions III probably take place in the reactive complex [144].

VIII. POSSIBILITIES AND LIMITATIONS OF THE METHOD

In conclusion we shall examine the extent to which the regular features of the behaviour of radicals and the criteria for a free-radical mechanism, discussed in this review, are of general importance.

These regular features and criteria were established for various hydrocarbon radicals—alkyl, aryl with different numbers of rings, arylalkyl (including such stable radicals as triphenylmethyl), and sterically hindered. It may be assumed that the great majority of hydrocarbon radicals show analogous behaviour. Differences in behaviour may be expected only for the radicals showing greatest steric hindrance (for example 2,4,6-tri-t-butylphenyl), since for these radicals, addition to aromatic rings and dehydrogenation and disproportionation of the addition products should be difficult. This is also to be expected for radicals which are unable to add on to aromatic systems for other reasons.

Dehydrogenation of type (11) may be brought about not only by R· radicals, but also by other radicals or oxidising agents X present in the system. As a result of this competition, the formation of the compounds RD may be suppressed by the preferential formation of the compounds XD, and one of the criteria for a free-radical mechanism is not observed. This possibility is apparently rarely realised, and was not observed in any of the works cited, even in the oxidation of hydrocarbons by chromyl chloride (section VI), when the concentration of the strong oxidising agent was high. The probability of complications of this kind is particularly great for R· radicals with low activity.

The formation of RD molecules may be prevented by the reaction of R· radicals with X· radicals produced simultaneously. This requires the collision of two short-lived species, however, and this process usually cannot compete with a reaction of type (11), in which R· adds on to the solvent, which is present in high concentration, and reacts with relatively stable radicals of the cyclohexadienyl type. The reaction of R· with X· (and the suppression of one of the criteria for a free-radical mechanism) may play a significant role in systems where the X· radicals have a low activity and their concentration is high.

Another complication is associated with the fact that disproportionation of type (1*b*) always competes with dehydrogenation of type (11) under the influence of R· radicals or other radicals or oxidising agents. A result of the competition may be the suppression of disproportionation. This leads to the non-observance of its consequences, for example a decrease in the concentration of d_5 form and an increase in the concentration of d_2 form in compounds of the type $R–C_6H_5$, formed by the reaction of R· radicals with benzene. Sections V and VII examined several examples of this kind, but it was shown that in these instances also, it is possible to reach reliable conclusions regarding the free-radical mechanism of reactions from the isotopic composition of the compounds of the form $R–C_6H_5$.

The suppression of disproportionation, as already noted, leads to the disappearance of the criteria for a free-radical mechanism proposed by Eliel and coworkers, since these are all consequences of the disproportionation.

It was shown above that most of the radicals which have been studied remove deuterium from heavy cyclohexane and the methyl group of heavy toluene, giving hydrocarbons RD (and RH). This criterion of a free-radical mechanism is convenient for the most reactive radicals, but not, for example, for benzyl radicals.

All the material of the present review shows that the method described for detecting free radicals and for studying the mechanism of free-radical reactions gives reliable results for a wide range of reactions with the participation of assumed participation of hydrocarbon radicals in solvents of different character. The applicability of this method to the study of radicals of other types has not yet been established.

Progress in the Chemistry of Primary Aliphatic Nitroamines

A.L.Fridman, V.P.Ivshin, and S.S.Novikov

Methods of making primary aliphatic nitroamines are considered. In addition to the well-known traditional methods for the preparation of nitroamines, little known methods for making them are examined and prospects for their further development are discussed.
This review is the first attempt in the world's literature to systematise the wealth of published material on primary aliphatic nitroamines. The literature is covered up to the end of 1967 or beginning of 1968. There is a bibliography of 207 references.

CONTENTS

I. Introduction 640
II. Methods of making primary nitroamines 640
III. Physical properties and structure 644
IV. Chemical properties 646
V. Analytical determination 651
VI. Certain aspects of practical use 651

I. INTRODUCTION

The progress in the chemistry of aliphatic nitro-compounds has stimulated interest in the nitroamines. This is shown by the large number of journal papers and patents published in recent years. The interest in the chemistry of aliphatic primary nitroamines arose not only because of the most interesting conversions of these compounds[1-3], but also the wide range of practical applications[4-11].

Isolated facts about the methods of preparation and properties of the primary aliphatic nitroamines can be found in monographs and review papers devoted to the nitro-compounds[1,12-14]. However, many of these papers are out of date or do not give sufficiently complete information about primary aliphatic nitroamines. There is no previous review paper on nitroamines in the Russian literature.

The present review surveys the published information on aliphatic primary nitroamines up to the end of 1967. In doing this the classical studies of Franchimont and his students and also other work on nitroamines carried out at the end of the last century is cited only where necessary and for the purpose of completeness in the material given. The early studies on nitroamines were surveyed more completely in 1912 by Baker[1].

Historically, two main periods can be distinguished in the development of the chemistry of the primary aliphatic nitroamines. The first began in 1888, when Franchimont synthesised methyl nitroamine[15,16], and continued for 20–25 years. This period is characterised by the appearance of fundamental studies on the nitroamines by such investigators as Franchimont[16-28], Klobbie[16,17,21,26], van Erp[27,29,30], Romburgh[31,32], Hantzsch[33-37], Baker[1,38,39], and others[40-45]. After 1915 until the nineteen-forties there was little interest in the nitroamines. But in 1948–1952 a long series of papers by Lamberton and coworkers[2,46-55] appeared, as well as interesting papers by Wright and coworkers[56-60], the work of McKay[61-74], and others[75-80]. Interest in nitroamines was reawakened and has not diminished since.

II. METHODS OF MAKING PRIMARY NITROAMINES†

Most of the known methods of making nitroamines can be divided into four groups: (1) the nitration of amines with preliminary protection of the amino-group; (2) the nitration of *N*-dichloroamines (Smart and Wright's method); (3) synthesis of nitroamines from nitroguanidine; and (4) direct nitration of amines by certain nitrating agents. There are also a few methods which at present are not of a general nature.

1. Nitration of Amines with a Previously Protected Amino-Group

Primary nitroamines, with rare exceptions, are readily decomposed by concentrated acids and cannot be obtained by the nitration of corresponding amines with nitric acid or its mixture with sulphuric acid. For the successful nitration of an amino-group it must first be protected. There are four main stages in the preparation of primary nitroamines by this method: (1) introduction of a protective grouping into the amino-group; (2) nitration of the protected amine; (3) removal of the protective grouping; and (4) isolation of the nitroamine.

Acetyl, formyl, oxalyl, alkoxycarbonyl, carbonyl, picryl, tosyl, and cyanoethyl groups can be used as the protective groupings.

The simplest of the primary nitroamines—methylnitroamine—was synthesised by the introduction of the oxalyl group into methylamine[21]:

$$CH_3NH_2 + (COCl)_2 \rightarrow (CH_3NHCO)_2 \xrightarrow{HNO_3} \left(\begin{array}{c} NO_2 \\ | \\ CH_3NCO \end{array}\right)_2 \xrightarrow{NH_3,\ ether}$$

$$\rightarrow \begin{array}{c} NO_2 \\ | \\ CH_3NH \end{array} \cdot NH_3 \xrightarrow{HCl} \begin{array}{c} NO_2 \\ | \\ CH_3NH. \end{array}$$

† Here and subsequently primary aliphatic nitroamines are being discussed, therefore the term "aliphatic" is often omitted.

The protection of amines by the oxalyl group is general and is used for the synthesis of a series of primary nitroamines and also of ethylenebisnitroamine[21,43,81]. The symmetric dialkyloxamides are readily nitrated with nitric acid or nitrating mixture. An example is the nitration of polynitroalkyloxamides[82-84]:

$$\begin{matrix}OCOC_2H_5\\OCOC_2H_5\end{matrix} + 2H_2NCH_2CH_2C(NO_2)_3 \rightarrow \begin{matrix}OCNCHH_2CH_2C(NO_2)_3\\OCNHCH_2CH_2C(NO_2)_3\end{matrix} \rightarrow$$

$$\xrightarrow{HNO_3+H_2SO_4} \begin{matrix}OCN(NO_2)CH_2CH_2C(NO_2)_3\\OCN(NO_2)CH_2CH_2C(NO_2)_3\end{matrix}.$$

The removal of the oxalyl group proceeds smoothly under the action of ammonia or boiling water.

Franchimont and his students[16,85] used an alkoxycarbonyl group as well as oxalyl as a protecting group in the nitration of amines. The method of preparing primary nitroamines through alkylnitrourethanes was subsequently perfected and developed and is now very important.

N-Alkylcarbamates are usually obtained by the reaction of esters of chlorocarboxylic acids with alkylamines in the presence of alkali[86]. However, often *N*-alkylcarbamates can also be obtained by other methods and they are more accessible than amines. A method of obtaining *N*-alkyl-*N*-nitrourethanes by the alkylation of nitrourethane with diazo-compounds or alkyl halides is interesting in this connection[55,87]:

$$\left.\begin{matrix}RCHN_2 + HN(NO_2)COOC_2H_5\\RCH_2Hal + AgN(NO_2)COOC_2H_5\end{matrix}\right\} \rightarrow RCH_2NCOOC_2H_5.$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad NO_2$$

The production of various polynitroalkyl carbamates by the decomposition of azides of polynitrocarboxylic acids in the presence of alcohols, the reaction of isocyanates with alcohols, etc., has been described[88-96]:

$$RC(NO_2)_2CH_2CH_2CH_3 \xrightarrow{R'OH} RC(NO_2)_2CH_2CH_2NHCOOR' \xrightarrow{HNO_3+Ac_2O}$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad \rightarrow RC(NO_2)_2CH_2CH_2NCOOR'.$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad NO_2$$

The nitration of *N*-alkylcarbamates is usually undertaken under the action of a sevenfold to fifteenfold excess of concentrated nitric acid[16,33,23,85,97]. Curry and Mason[98] proposed a mixture of acetic anhydride with nitric acid, which was more effective than nitric acid alone. This mixture nitrated many alkyl carbamates, including t-butyl carbamate, and also polynitroalkyl carbamates[89], whereas *N*-alkyl carbamates with branched alkyl residues are not nitrated by nitric acid[30]. An attempt to use tetranitromethane for the nitration of alkyl carbamates was unsuccessful[99].

The removal of an alkoxycarbonyl group is usually done under the action of ammonia in ethereal solution:

$$RNCOOC_2H_5 \xrightarrow{NH_3,\ ether} RNH\cdot NH_3 + C_2H_5OCONH_2.$$
$$\quad NO_2 \qquad\qquad\qquad\qquad\quad NO_2$$

Many alkylnitroamines and also ethylene-, trimethylene-, tetramethylene-, and pentamethylene-bisnitroamines were obtained by this method[16,85,100]. Hantzsch and Metcalf[33] obtained *N*-nitroglycine and some of its derivatives in a similar manner. Blomquist and Fiedorek[33] patented a method for making nitrates of nitroaminoalcohols of the type $C_2NOCH(R)CH(R')NHNO_2$.

It was subsequently shown that not only ammonia but also other amines are suitable for splitting *N*-alkyl-*N*-nitrourethanes and that the amination of *N*-alkyl-*N*-nitrourethanes is general and can be used to obtain the amine salts of primary nitroamines[99]. Hexamethylene-1,6-bisnitroamine was made in this way[99].

The hydrolysis of polynitroalkyl-*N*-nitrocarbamates has not been described. Such a study should give interesting information about the effect of electronegative groups on the ease of removal of alkoxycarbonyl groups.

Primary nitroamines are often obtained by the nitration of alkylureas. As long ago as 1888 Franchimont and Klobbie[17] nitrated imidazolid-2-one with nitrating mixture and then decomposed the 1,3-dinitroimidazolid-2-one with water to ethylenebisnitroamine:

$$\begin{matrix}H_2C-N\\|\\H_2C-N\\H\end{matrix}\!\!>CO \xrightarrow{HNO_3+H_2SO_4} \begin{matrix}H_2C-N(NO_2)\\|\\H_2C-N(NO_2)\end{matrix}\!\!>CO \xrightarrow{H_2O} \begin{matrix}NO_2\\|\\HN-CH_2-CH_2-NH\end{matrix}\!\!<\begin{matrix}NO_2\\|\\.\end{matrix}$$

Imidazolid-2-one can also be nitrated with nitric acid[101].

In nitration, monoalkylureas are readily converted into *N*-alkyl-*N'*-nitroureas; nitration of the nitrogen atom connected with the alkyl group does not usually take place[81]. An exception is methylurea, which is converted rather smoothly into *N*-methyl-*N*-nitrourea. The latter can be hydrolysed to methylnitroamine[39].

An interesting paper was recently published on the preparation of the first representative of the *N*-dinitroamine series—methyl-*N*-dinitroamine, obtained by the nitration of methylurea nitrate by a mixture of acetic anhydride and nitric acid[102]:

$$CH_3NHCNH_2\cdot HNO_3 \xrightarrow{HNO_3+Ac_2O} CH_3N(NO_2)(NO_2).$$
$$\quad\ O$$

In nitration, *sym*-dimethylurea is smoothly converted into *NN'*-dinitro-*NN'*-dimethylurea[103]. We note that the nitration of substituted ureas and their derivatives has not yet been sufficiently studied and further investigations in this field can lead to both the development of simple methods for making primary nitroamines and also to the preparation of other interesting compounds. This is shown by the above study by Japanese scientists[102] and also by other investigations[104-106].

The acetyl group is important as a protective group for the nitration of amines. Thus, one of the methods of obtaining ethylenebisnitroamine is based on the introduction of acetyl groups into ethylenediamine followed by the nitration of ethylenebisacetamide with a mixture of nitric acid and acetic anhydride[81]. The acetyl group is readily detached with water, alkali, or ammonia. Methylenebisnitroamine was obtained from methylenediamine in a similar fashion[47]. The synthesis of polynitroalkyl-*N*-nitroamines by the hydrolysis of polynitroalkyl-*N*-nitroacetamides is described in the patent literature[107-109].

Formyl groups are sometimes used instead of acetyl for the protection of amino-groups[110]:

$$H_2C(NHCHO)(NHCHO) \rightarrow H_2C(N(NO_2)CHO)(N(NO_2)CHO) \rightarrow H_2C(N(NO_2)H)(N(NO_2)H).$$

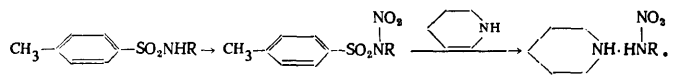
It is worth noting an extremely interesting method for obtaining *N*-alkylacetamides and *N*-alkylformamides, based on the condensation of the corresponding *N*-(hydroxymethyl)amides with nitroalkanes, for example, nitroform:

$$RCONHCH_2OH + HC(NO_2)_3 \rightarrow RCONHCH_2C(NO_2)_3 + H_2O.$$

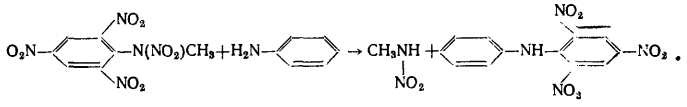
Unfortunately, the nitration of the trinitroethylacetamide and trinitroethylformamide thus obtained has not been described.

Gillibrand and Lamberton used a tosyl group for the protection of the amino-group[55]. The tosyl group is removed under rather severe conditions but the yields of the

primary nitroamines are reasonably high[111]. Piperidine is a convenient reagent for removing the tosyl group[111]:

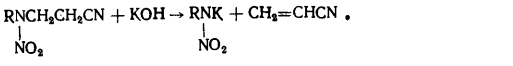


An example of the production of methylnitroamine by the removal of the picryl group from methylpicrylnitroamine under the action of aniline or *p*-toluidine has been described[1]:



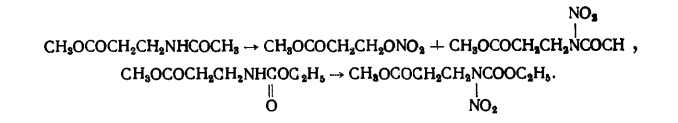
Since alkylpicrylnitroamines are readily obtained in the nitration of alkylanilines or dialkylanilines[12], the method of making primary nitroamines by using a protective picryl group opens up great possibilities.

Kissinger and Schwartz[112] observed the cleavage of 2-cyanoethylnitroamine in alkali into a salt of the nitroamine and acrylonitrile:

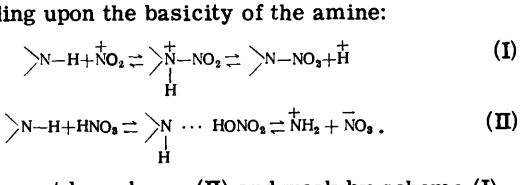


Although only one example of this reaction has been described, the readily accessible β-cyanoethylnitroamines, which are obtainable by the nitration of the corresponding aminonitriles[113,114], can probably serve as the initial compounds for obtaining primary nitroamines.

An analysis of the methods of preparation of primary nitroamines with protected amino-groups shows that the urethane method is the most universal, simplest, and most available at the present time. In every instance there are no indications in the literature of unsuccessful examples of the nitration of *N*-alkylcarbamates or of the removal of alkoxycarbonyl groups from *N*-alkyl-*N*-nitrocarbamates. In this connection it is interesting to compare the nitration of esters of glycine and β-alanine with the use of various protecting groups. Whereas nitration of the *N*-acetyl derivative of the methyl ester of β-alanine gives the *N*-nitroamide in insignificant yield the corresponding urethanes are nitrated quantitatively[115]:



The mechanism of the *N*-nitration of protected amines has not been discussed in the literature and there have not been systematic investigations in this field. A considerable drop in the basicity of the amine generally occurs on the introduction of the above protecting groups. It is well known that in the dialkylamine series strong bases without catalysts are not nitrated at the nitrogen atom, whereas amines of low basicity are nitrated rather readily[116]. Lamberton[2] considers that the reaction can proceed in two ways, depending upon the basicity of the amine:

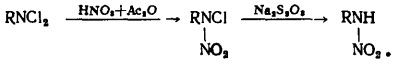


Strong bases react by scheme (II) and weak by scheme (I).

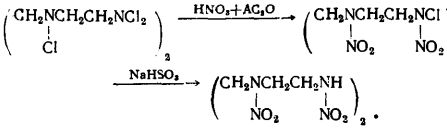
A protected amino-group is a weak base and its nitration can be described by scheme (I). The reversibility of the nitration is evidence for this scheme. It is known that *sym*-dinitrodimethyloxamide in sulphuric acid solution is a source of the nitronium cation and exhibits a nitrating action[117]. Similar examples have been given by Holstead and Lamberton[46].

2. Nitration of *N*-Dichloroamines (Smart and Wright's Method)

In 1948 Smart and Wright[56] proposed a new method for obtaining primary nitroamines. They found that on treatment of *N*-dichloroamines in an excess of acetic anhydride with concentrated nitric acid, chlorine is removed with the formation of *N*-chloro-*N*-nitroamines. In a reducing medium the latter lose a second chlorine atom and are converted into primary nitroamines:

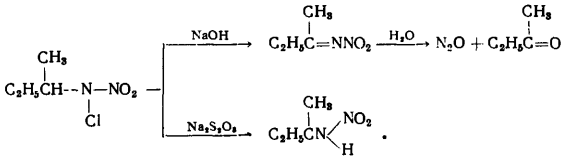


Butylnitroamine, isobutylnitroamine, n-octylnitroamine, ethylenebisnitroamine etc. have been obtained by Smart and Wright's method[56,57]. The example of *N*-hexachlorotriethylenetetramine has shown the possibility of the simultaneous substitution of nitro-groups for the chlorine atoms at primary and secondary nitrogen atoms[57]:

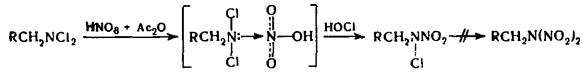


It is noteworthy that an intermediate *N*-chloro-*N*-nitroamine has been isolated in a pure form in only one instance, in small yield[56]. Nevertheless it is evident that *N*-chloro-*N*-nitroamines are more stable in acid than are primary nitroamines, which also ensures that the reaction will take place in the desired direction.

The replacement of a chlorine atom by hydrogen in *N*-chloro-*N*-nitroamines is effected under the action of aqueous solutions of alkalis, sodium hydrogen sulphite, or sodium thiosulphate[56,57]. When the product of the nitration of s-butyldichloroamine was treated with an aqueous solution of alkali the yield of s-butylnitroamine was only 10%, whereas sodium thiosulphate allowed the yield to be raised to 65%. It was thought[56] that depending upon the medium the intermediate *N*-chloro-*N*-nitroamine can be hydrolysed or can undergo intramolecular loss of hydrogen chloride[56]:



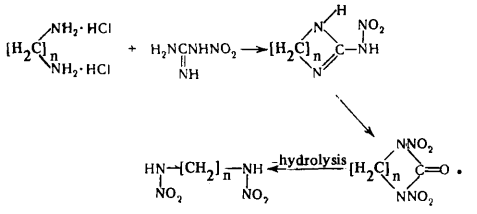
There has not been a thorough study of the mechanism of nitration of *N*-dichloroamines. In one of their papers[56] Smart and Wright suggested that nitric acid forms a complex with the *N*-dichloroamine, the nitrogen of the amino-group acting as a donor and the nitrogen of the nitric acid as an acceptor. The complex which is formed is unstable and readily loses hypochlorous acid to form an *N*-chloro-*N*-nitroamine. Because of the introduction of the nitro-group the *N*-chloro-*N*-nitroamine loses the donor properties and reaction cannot proceed further to form an *N*-dinitroamine:



3. Syntheses Based on Nitroguanidine

Nitroguanidine differs markedly from the primary nitroamines in its properties. Investigations in recent years [61] have shown that this compound should really be given a nitroimine structure. A review by McKay [14] dealt with the chemistry of nitroguanidine. The study of nitroguanidine derivatives has led to the discovery of new original methods of making primary nitroamines, which are also discussed in this section.

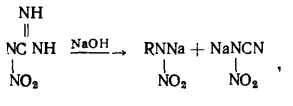
McKay and Manchester [62,63] developed a method for obtaining aliphatic bisnitroamines based on the nitration of the cyclic products of the interaction of diamines with nitroguanidine. The nitro-derivatives obtained are readily hydrolysed to the corresponding nitroamines:



1,2-Bisnitroaminopropane, 1,3-bisnitroaminobutane, and 1,3-bisnitroamino-2-nitroxypropane [62,63] were obtained in a similar manner.

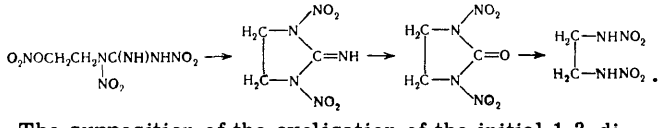
Primary nitroamines were obtained in many other instances. Thus in the cleavage of 2-amino-1-nitro-2-imidazoline a nitroamine salt is formed, the structure of which was proved by subsequent chemical transformations.

1-Alkyl-1,3-dinitroguanidines are split with alkali to salts of primary nitroamines and the extremely interesting, but little studied, cyanonitroamide [118]:



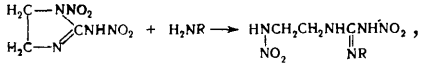
where R = CH_3 and n-C_4H_9.

The decomposition of 1,3-dinitro-1-(2-nitroxyethyl)-guanidine is extremely unusual. When this compound is boiled with water ethylenedinitroamine is isolated in 57% yield [118]:



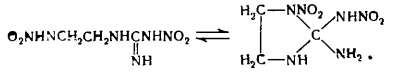
The supposition of the cyclisation of the initial 1,3-dinitro-1-(2-nitroxyethyl)guanidine is confirmed by the similar conversions of other *N*-(2-substituted ethyl)-*N'*-nitroguanidines [118].

In the interaction of 1-nitro-2-(nitroamino)imidazoline with ammonia or amines β-nitroaminoalkylnitroguanidines are formed [65,66,72,73]:



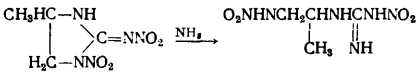
where R = H, CH_3, Ar.

Kirkwood and Wright [119] succeeded in showing that 1-nitro-2-(nitroamino)guanidine exists as two isomers. The position of the equilibrium is shifted to one side or the other depending upon the solvent:

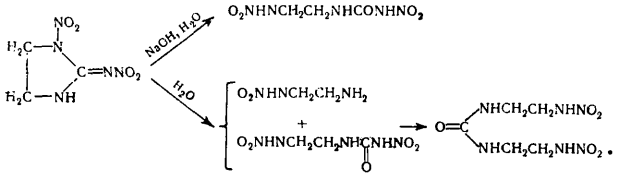


Later McKay [67] gave additional information in support of the existence of linear products.

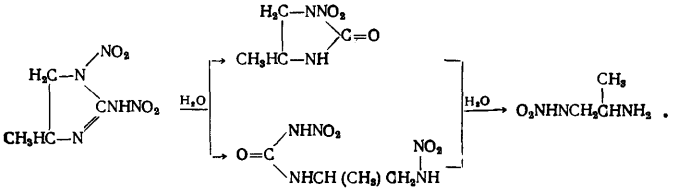
The difference in the opinions of these authors is evidently due to the ease of cyclisation and cleavage of the products of the addition of the amines to 1-nitro-2-nitriminoimidazolid-2-one. This circumstance makes difficult the hypothetical choice of any one structure. However, for certain compounds such a type of linear structure has been shown sufficiently clearly. For example, the product of the addition of ammonia to 4-methyl-1-nitro-2-nitriminoimidazolid-2-one is a linear primary nitroamine [68]:



When treated with alkali, 1-nitro-2-nitriminoimidazolid-2-ones are usually cleaved to primary nitroamines [69,70,120]. When 1-nitro-2-nitriminoimidazolid-2-one is hydrolysed with aqueous alkali, 3-nitro-1-(2-nitroaminoethyl)urea is obtained in good yield. The aqueous hydrolysis of this compound leads to bis-(2-nitroaminoethyl)urea as a result of the reaction of the primary decomposition products [121]:



Two products are also formed in the hydrolysis of 4-methyl-1-nitro-2-nitriminoimidazolid-2-one in water—*N*-2-(nitroamino)ethyl-1-methylnitrourea and 4-methyl-1-nitro-2-imidazoline, and on long boiling with water these are converted into 2-amino-3-nitroaminopropane [71]:



On dissolution in aqueous alkali, 1-nitro-2-propylamino-2-imidazoline is hydrolysed to *N*-2-nitroaminoethyl-*N'*-propylurea [120]. In an acid or alkali medium 1-nitro-2-*p*-acetamidophenylamino-1-nitro-2-imidazoline is hydrolysed to *N*-2-nitroaminoethyl-*N'*-pacetamidophenylurea [70].

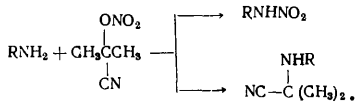
McKay and coworkers [74] described an interesting molecular rearrangement leading to the production of a primary nitroamine.

4. Direct Nitration of Amines

The relative complexity and multistage nature of the methods of synthesis of primary nitroamines are responsible for the search for new, simpler methods for their production. The most tempting was the direct nitration of primary amines.

From this point of view the method developed by Emmons and Freeman for the nitration of amines with acetone cyanohydrin nitrate 1-cyano-1-methylethyl nitrate is interesting [122]. Propyl, butyl, isobutyl, pentyl, and isopentyl nitroamines were obtained in 50–55% yield by this method. The reaction takes place under rather critical

conditions and is accompanied by the formation of aminonitriles:



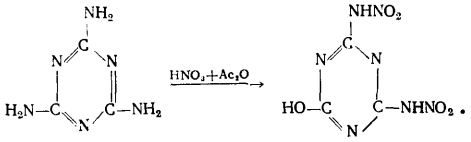
The method is suitable for the nitration of amines having bulky substituents at the α-carbon atom[122].

Another way of obtaining nitroamines was described recently in the patent literature. It is based on the reaction of nitryl fluoride with ammonia or amines in an inert solvent or in the vapour phase[123]. Information is available about the nitrating ability of nitrile chloride in relation to amines[124].

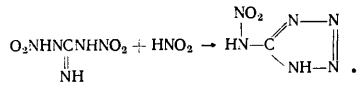
Primary nitroamines can also be obtained in the nitration of amines by acetyl nitrate in the presence of butyllithium[125]. The method is applicable only to compounds containing functional groups indifferent to butyl-lithium. Furthermore the complexity of the experimental conditions (low temperature, atmosphere of dry nitrogen) does not give this method a decisive advantage over the existing ones.

Although the methods of preparation and properties of nitroamides, which are similar in structure to the primary nitroamines, or those of aromatic and heterocyclic nitroamines are not discussed in the present review, we will note that some of these compounds can be obtained by the direct nitration of the corresponding amides and amines with nitric acid or nitrating mixture. Thus nitrourethanes are usually made by the nitration of urethane[47].

Benzosulphonitroamide and *p*-toluene sulphonitroamide are obtained in a similar fashion[126]. Aminopyridines are readily nitrated by nitrating mixture to the corresponding nitroaminopyridines[127]. The nitration of melamine with a mixture of acetic anhydride and nitric acid gives *NN'*-dinitroammeline[128]:



Triacetylmelamine gave nitroammelide. Under the action of nitrous acid, nitroaminoguanidine is converted into 5-nitroaminotetrazole[129,130]:

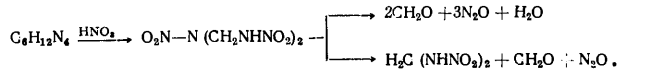


5. Other Methods of Preparation

The formation of nitroamines in the hydrolysis of linear products of the nitrolysis of tertiary amines has been described. Methylenebisnitroamine was first isolated as the barium salt from the pyrolysis products of hexamethylenetetramine[47].

2,4,6-Trinitro-2,4,6-triazaheptane-1,7-diol bistrifluoroacetate can be split by benzylamine to the corresponding amine salt of methylenebisnitroamine[131]. The hydrolysis of the linear products of the nitrolysis of Mannich bases also leads to the production of primary nitroamines[132].

The nitrolysis of hexamethylenetetramine is accompanied by the formation of a primary nitroamine as a side-product[133]. The latter is decomposed completely by hot water but under milder conditions it is hydrolysed to methylenebisnitroamine:



In reacting with nitric acid under mild conditions hexamethylenetetramine dinitrate forms 1,3-dinitro-1,3,5-triazapentane[134].

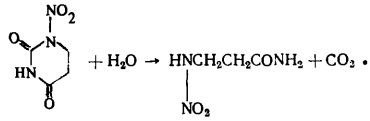
Freeman[135] obtained a series of nitroamines by the reduction of nitroimines with potassium tetrahydroborate or lithium tetrahydroaluminate. This work completed the discussion of the structure of nitroimines to which some investigators had ascribed the structure of pernitrosoketones.

Examples are known of the production of primary nitroamines from the corresponding isodiazotates[136]. However, owing to the difficulty of obtaining the starting compounds this method is not widely used.

Finally, there is a single paper[137] on the production of a nitroamine in low yield by a reaction similar to the Wurtz reaction:

The preparation of primary nitroamines containing other functional groups in the alkyl residue is by the same methods as were given earlier. Naturally, the action of the functional group of the reagents employed for the preparation of the nitroamines must be considered. In particular, aminoalcohols are converted into the nitrates of the nitroaminoalcohols[19,138]. However, under certain conditions the nitrate group can be removed or its formation avoided completely[138,139].

Nitroaminoacetamide is obtained when nitrohydantoin is boiled in water for a long time[92]. Nitroaminopropionamide can be obtained from nitrohydrouracil[20]:



Free nitroaminocarboxylic acids are formed in the hydrolysis of amides with alkali. δ-Nitroaminovaleric and ϵ-nitroaminocapronic acids are obtained in the alkaline hydrolysis of the corresponding *N*-nitrolactams[140]. Propargylnitroamine is obtained by the usual scheme by the nitration of *N*-propargylurethane[141].

III. PHYSICAL PROPERTIES AND STRUCTURE

1. General Characteristics

Primary aliphatic nitroamines are liquids or readily melting crystalline compounds. The first member of the homologous series of monoalkylnitroamines—methylnitroamine—melts at 38°C,[16] ethylnitroamine at 6°C,[16] and the higher homologues are also low-melting or liquid substances. The bisnitroamines are solids whose melting points depend on the number and multiplicity of the methylene groups in the molecule.

Primary nitroamines are weak acids. Thus the pK_a of methylnitroamine is 6.0;[142] its homologues are even

weaker acids. When electronegative groups are introduced into the alkyl chain of the nitroamine the acidic properties increase. The dissociation constants of $\alpha\omega$-bisnitroamines have been determined[143]. A comparison of the pK values obtained with those for $\alpha\omega$-dicarboxylic acids shows that with increase in the number of methylene groups the difference between the first and second dissociation constants decreases in the bisnitroamine series more slowly than in the dicarboxylic acid series (Table 1).

Table 1. Dissociation constants of $\alpha\omega$-dinitroamines and $\alpha\omega$-dicarboxylic acids (20°C).

α,ω-Bisnitroamines	pK_1	pK_2	ΔpK	Acid	pK_1	pK_2	ΔpK
Methylene	5.0	6.6	1.6	Malonic	2.83	5.69	2.86
Ethylene	5.35	6.66	1.31	Succinic	4.22	5.67	1.45
Trimethylene	5.59	6.85	1.26	Glutaric	4.39	5.50	1.11
Tetramethylene	5.87	6.98	1.11	Adipic	4.43	5.49	0.95

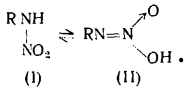
Baly and Desch studied the optical properties of the nitroamines[144]. They showed that the unsubstituted alkylnitroamines have normal molecular refraction.

The use of primary nitroamines as explosives stimulated the study for some of them of the thermochemical, stability and explosive characteristics. The information on these characteristics has been surveyed in Orlova's monograph[145]. Primary nitroamines are relatively stable thermally, the liquid compounds can be distilled under vacuum, and the thermal stability of the crystalline nitroamines is different. Methylenebisnitroamine is of low thermal stability, whereas ethylenebisnitroamine is distinguished by high stability, has good explosive characteristics, and diminished sensitivity to shock[146]. A differential thermal analysis of nitroamines was recently made[147]. Medard determined the heats of formation of ethylenebisnitroamine (25.65 kcal mole^{-1}) and nitroaminoethyl nitrate (45.8 kcal mole^{-1}).[148]

The physiological activity of the primary nitroamines has hardly been studied. There is information on the comparative physiological action on the human organism of nitromethane and methylnitroamine[149]. When the latter is introduced into the human organism it does not produce any changes in the composition and pressure of the blood, that is, unlike nitrates and nitroalkanes it is harmless for man. It was also noted that ethylenebisnitroamine has no harmful action on the human organism[12].

2. Structure and Spectra

The aliphatic nitroamines were first ascribed the structure of the true N-nitro-compounds (I). Later, Hantzsch[34-37] by starting from a formal analogy between the nitroalkanes and primary nitroamines, suggested that the latter exist in two tautomeric forms:



(I) (II)

By this scheme he explained the acidic properties of nitroamines and the formation of O-isomers in the alkylation of the salts of nitroamines. Hantzsch attempted to confirm this concept of tautomerism in a series of nitroamines by physicochemical methods. The evidence in support of tautomerism was that he observed an arrest (the time needed for the displacement of the equilibrium I⇌II) in the precipitation of the ammonium salt of the nitroamine on passing ammonia through a solution of the nitroamine in benzene. Furthermore, he observed a high temperature coefficient of electrical conductivity for salts of the nitroamine in aqueous solution. However, Euler showed[44] that these results cannot serve as proof of the tautomerism of the primary nitroamines.

Thorough physicochemical investigations made recently allowed the nature of the primary nitroamines to be more deeply understood. X-Ray structural analysis of ethylenebisnitroamine showed that the nitro-group in this compound exhibits normal properties, that is, the valence angles are similar to the angles of the nitro-group of p-dinitrobenzene, and the interatomic distances N–O (1.23 Å) in the nitroamine group are equal and comparable with the values for nitromethane[79]. Hence the conclusion that the structure of true N-nitro-compounds is more probable in the un-ionised form for the primary nitroamines. In addition there is a considerable shortening of the C–N and N–N bonds in comparison with the sum of the covalent radii (1.41 and 1.33 Å in comparison with 1.47 and 1.40 Å), and it is concluded that there is an electronic displacement from the nitrogen connected to the nitroamine group leading to the formation of a positive charge, which decreases the radius of the simple (N–C) bond of the nitrogen. The short N–N bond has 15% of the character of a double bond.

The X-ray structural method does not allow the location of the hydrogen atom in primary nitroamines to be determined. More reliable information on this aspect is obtained as a result of the spectroscopic analysis of nitroamines.

A study of the infrared spectra of a series of nitroamines showed that asymmetric vibrations in the range 1630–1550 cm^{-1} range and symmetric vibrations in the 1354–1262 cm^{-1} range are characteristic of the nitro-groups in these compounds. When there are electronegative substituents in the nitroamines the asymmetric vibrations are shifted to the side of higher frequencies[78,150,151]. The band in the 1000–948 cm^{-1} range is assigned to the vibrations of the N–N bond.

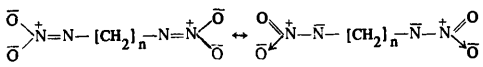
The complexity of the infrared spectra of the primary nitroamines in the 3600–3000 cm^{-1} range required additional confirmation that the bands in this region belong to the vibrations of the NH group. This information was obtained in a thorough study of the infrared spectra of crystalline ethylenebisnitroamine and tetramethylenebisnitroamine and their N-deuteriated analogues[152]. A comparison of the spectra of these nitroamine and their N-deuteriated derivatives allowed the 3240 and 3253 cm^{-1} bands observed in the spectra of ethylenebisnitroamine and tetramethylenebisnitroamine to be assigned to the stretching vibrations of the NH bond which participates in the formation of a hydrogen bond with the nitro-group of a neighbouring molecule in the crystal. In the spectra of the N-deuteriated nitroamines these bands are shifted into the 2400 cm^{-1} region. Bands characteristic for the asymmetric and symmetric stretching vibrations of the CH_2 group appear, which were masked earlier by the intense vibrations of the NH groups. In the spectra of the deuteriated analogues of the nitroamines studied there is also a displacement of the bands assigned to the asymmetric vibrations of the nitro-group, etc.

Hence the infrared spectra also confirm the true nitroamine structure of the primary nitroamines, at least in the un-ionised state.

The ultraviolet spectra of the primary nitroamines have been studied [78,153,155]. A maximum at 232 nm (235 nm in alkaline medium) is characteristic for methylenebisnitroamine in this range. In an alkaline medium there is a bathochromic shift of the maximum [78].

The Raman spectra of the primary nitroamines were studied by Kohlrausch and Wittek [156].

In discussing the structure of the primary nitroamines reference must again be made to the work on the determination of the dissociation constants of the $\alpha\omega$-bisnitroamines (Table 1). Since ΔpK decrease more slowly in the bisnitroamine series than in the dicarboxylic acid series, it was concluded that the effective distance between the charges of the double anions increases more slowly in the bisnitroamine series [143]. In this paper the ionised bisnitroamines are regarded as mesomeric anions. It is thought that the contribution of structure (III) is more characteristic for methylenebisnitroamine than for tetramethylenebisnitroamine.

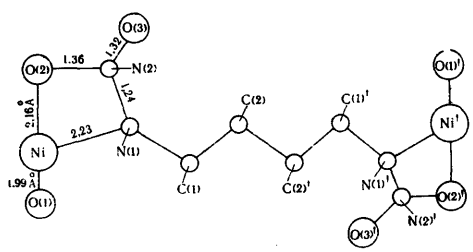


(IV)

It was recently suggested that the lower thermal stability of the primary nitroamines and their salts in comparison with secondary nitroamines is due to the conversion of the primary compounds into the aci-form on heating. Compounds in an aci-form are less stable and easily decompose [147]. However, experimental proof in support of this view has not been forthcoming.

Several studies deal with the explanation of the structure of salts of nitroamines by physicochemical methods. On the basis of an X-ray diffraction analysis of the disodium salt of ethylenebisnitroamine Alentoff and Wright maintain that the anionic centre in this compound is the oxygen atom and not the amine nitrogen [59]. However, the authors think it undesirable to attribute the structure found in a particular example to all the salts of the nitroamines with alkali metals, considering that the compound they investigated could be exceptional owing to the unique symmetry of the anion. Subsequent investigations showed that the salts of the nitroamines have a more complex structure.

In an X-ray diffraction study of the hydrate of the nickel salt of tetramethylenebisnitroamine it was found that in the crystalline state this compound exists in the form of polymeric chains. Each molecule of the ligand joins two nickel atoms with coordination of both nitroamine groups. The nitroamine group acts as a chelate ligand. The oxygen atom (Ni–O 2.16 Å) and the amine-nitrogen atom (Ni–N 2.23 Å) are coordinated so that a four-membered ring is formed with the nickel atom and the other nitrogen atom [157].



It is interesting that the study of the Raman spectra of the potassium salts of methyl- and ethylnitroamines showed that they have the structure of true *N*-nitrocompounds [156]. As already noted, on going from a free nitroamine to its salt there is a displacement of the maximum in the ultraviolet spectrum [78]. A difference was also noted in the infrared spectra of the primary nitroamines and their salts. This all suggests that the nitroamine anion should be regarded as a mesomeric anion with reaction centres at oxygen and nitrogen

IV. CHEMICAL PROPERTIES

The primary nitroamines exhibit high reactivity, which is in many respects similar to that for mono- and polynitroalkanes. Their activity is due to the presence of the labile hydrogen atom of the primary nitroamino-group and also to the nitroamino-group itself. Owing to the labile hydrogen the nitroamines form salts which undergo condensation with formalin‡, the Mannich reaction, add to activated double bonds, are alkylated, etc.

1. Reaction with Bases

Primary aliphatic nitroamines are weak acids and are capable of forming salts with bases. To obtain salts of nitroamines, bases, or metal oxides, carbonates, or alkoxides are used [1]. Potassium, barium, cobalt, zinc, copper, nickel, silver, mercury, lead, ammonium, and many other salts of primary nitroamines are known. In the preparation of salts of nitroamines in water, hydrates are often formed with various water contents in the molecule. Some metal salts of nitroamines are decomposed by boiling water. However, they are usually thermally more stable than the initial nitroamines but more sensitive to shock. In this respect the silver and mercury salts of the nitroamines are especially dangerous. Nitroamine salts are often used for the purification and analysis of nitroamines and also in certain chemical changes.

It is generally accepted that the primary nitroamines are stable in an alkaline medium. The anions of the aliphatic nitroamines do not react with a hot 20% solution of potassium hydroxide and only very concentrated alkali under severe conditions can bring about the decomposition of the primary nitroamines [29,30]. However, Hantzsch long ago observed [33] the decomposition of nitroaminoacetic acid and its derivatives by alkali under relatively mild conditions. These experiments were subsequently reproduced and analysed [51]. It was observed that some primary nitroamines, particularly those with electronegative substituents in the alkyl residue, are capable of decomposition by the scheme

$$RR'CHNHNO_2 \rightarrow RR'C{=}O + N_2 + H_2O$$

under the action of dilute alkali on heating.

Decomposition by this reaction is assisted by an increase in the hydroxide ion concentration, an increase in the concentration of sodium or potassium ions, and an increase in the electrical conductivity of the grouping in the alkyl residue. Furthermore, the presence of hydrogen at the α-carbon atom is important. Compounds without hydrogen in the α-position are stable to alkalis.

‡ Attempts to carry out condensation with other aldehydes were unsuccessful [24].

2. Reactions with Acids

Long ago Franchimont and coworkers[25,31,158] observed that primary nitroamines are decomposed by aqueous sulphuric acid with the formation of dinitrogen oxide and an alcohol:

$$RNHNO_2 \rightarrow ROH + N_2O.$$

Subsequent study of this reaction showed that it is more complex. During acid hydrolysis tetramethylenebisnitroamine forms butadiene and tetramethylene oxide in addition to dinitrogen oxide and butanediol. In the decomposition products of hexylnitroamine there are dinitrogen oxide, hexene, primary and secondary hexyl alcohols, and dihexyl ether[30]. Acetaldehyde was observed in the decomposition products of ethylenebisnitroamine[31].

On the basis of the results obtained in the acid decomposition of primary nitroamines and bisnitroamines it was suggested that the reaction proceeds through the intermediate formation of nitroamide and a carbonium ion[49]:

$$RNHNO_2 + H^+ \rightarrow R^+ + NH_2NO_2.$$

Nitroamide is the source of the dinitrogen oxide and water and the extremely active carbonium ion is stabilised with the formation of an alcohol (reaction with water), alkene (loss of a proton), or other decomposition products as a result of the reaction with nucleophilic reagents present in the reaction sphere.

The reaction of nitroamines with acids is regarded as an electrophilic substitution of the S_E2 type at the amine-nitrogen. The rate of reaction is directly proportional to the concentration of protons and of the primary nitroamine. The accumulation of electron-donating substituents at the nitrogen facilitates the decomposition of the nitroamines.

Further study of the acid decomposition of primary nitroamines was by the example of alkyl derivatives with a branched chain[50]. Such compounds decompose more rapidly than alkylnitroamines of linear structure and furthermore a definite difference in their behaviour in relation to sulphuric and hydrochloric acids is observed at the same pH. The decomposition of isopropyl nitroamine is catalysed by hydrogen sulphite ions.

In one study[50] the hypothesis about the formation of nitroamide at the first stage of acid hydrolysis has been doubted. Hence although there is a definite relation between the rate of decomposition of the primary nitroamines and the concentration of hydrogen ions the reaction is extremely complex and has still not been properly studied. The reaction of primary nitroamines with hydrochloric acid takes place rather smoothly with the formation of alkyl chlorides[49]:

$$RNHNO_2 + HCl \rightarrow RCl + N_2O + H_2O.$$

This is widely used for confirming the structure of the primary nitroamines[62,74,121,159]. The reaction of primary nitroamines with acetyl chloride and thionyl chloride proceeds similarly[14,58].

Primary nitroamines are extremely sensitive to nitric acid. Methyl nitroamine is decomposed by concentrated nitric acid even at 0°C with the formation of methyl nitrate and dinitrogen oxide[1]. Nitrous acid also readily decomposes methylnitroamines in aqueous solution to methanol, dimethylnitroamine and its *O*-isomer[23]. It was suggested that the decomposition proceeds through the intermediate formation of diazomethane[23]:

$$CH_3NHNO_2 + HNO_2 \rightarrow CH_3N{=}NOH + HNO_3,$$
$$CH_3N{=}NOH \rightarrow CH_2N_2 + H_2O,$$
$$CH_3NHNO_2 + CH_2N_2 \rightarrow (CH_3)_2NNO_2 + CH_3N{=}\overset{\overset{O}{\nearrow}}{N}{-}OCH_3.$$

3. Oxidation and Reduction

There has been almost no investigation of the reaction of primary aliphatic nitroamines with oxidants. There is only the statement that primary nitroamines are rather stable to oxidants[1].

The reduction of nitroamines has been studied in greater detail. When reduced with zinc in acetic acid methylnitroamine is converted into methanol, and when reduced with sodium amalgam methylamine is formed[18]; methylhydrazine is liberated by the action of zinc in nitric acid. An alkaline solution of aluminium converts methylnitroamine into methylisodiazotate[161]. In the reduction of ethylenebisnitroamine by zinc in hydrochloric acid a little ethylhydrazine is liberated[160]. It is suggested that the reduction of nitroamines proceeds through the intermediate formation of nitroso-derivatives which are readily isomerised into diazo-compounds. The latter can be isolated from alkaline solutions as diazotates.

4. Reaction with Formaldehyde

One of the characteristic reactions of primary nitroamines is their reaction with formaldehyde. Franchimont[24] first observed this reaction in the presence of bases. It was shown later that bisnitroamines readily form the corresponding nitroaminocarbinols on reaction with formaldehyde[75]:

$$[H_2C]_n(NHNO_2)_2 + CH_2O \xrightarrow{H_2O} [H_2C]_n(N(NO_2)CH_2OH)_2.$$

Only the monomethyl derivative could be isolated for ethylenebisnitroamine[75,81]:

$$O_2NHN{-}[CH_2]_2{-}NHNO_2 + CH_2O \xrightarrow{H_2O} HOCH_2\overset{\overset{NO_2}{|}}{N}{-}[CH_2]_n{-}\overset{\overset{NO_2}{|}}{N}H.$$

The mechanism of formation and the chemical nature of the hydroxymethyl derivatives was thoroughly studied with the aid of potentiometric titration and the analytical determination of formaldehyde[52]. It was shown that the hydroxymethylnitroamines dissociate readily in water with the loss of formaldehyde

$$RNCH_2OH \rightleftharpoons RNH + CH_2O.$$
$$\quad\;|\qquad\quad\;|$$
$$\quad NO_2\qquad NO_2$$

The position of the equilibrium is displaced to the right. Aqueous solutions of the dicarbinol derivatives of ethylenebisnitroamines and trimethylenebisnitroamine can be accurately titrated with potassium hydroxide as free nitroamines; the combined formaldehyde is also readily determined by well known procedures[52].

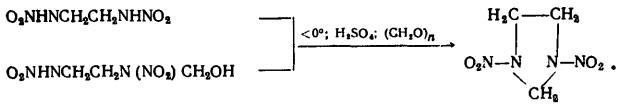
The hydroxymethylenebisnitroamines are more stable in acid solutions, since the electron-withdrawing properties of the nitroamino-group hinder the dissociation of the hydroxyl. Here the loss of a proton seems more hypothetical[52]:

$$RNCH_2OH \rightleftharpoons RNCH_2O^- + H^+.$$
$$\quad\;|\qquad\quad\;|$$
$$\quad NO_2\qquad NO_2$$

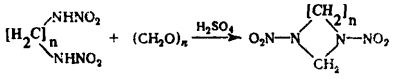
The interaction of nitroamines with paraformaldehyde in organic solvents also leads to the formation of nitroaminocarbinols. In sulphuric acid medium at low temperature methylenebisnitroamines are formed[162]:

$$RNH + [CH_2O]_n \xrightarrow{H_2SO_4} RNCH_2NR.$$
$$\quad\;|\qquad\qquad\qquad\quad\;|\qquad\;|$$
$$\quad NO_2\qquad\qquad\qquad NO_2\;NO_2$$

Ethylenebisnitroamine and its hydroxy-derivative form 1,3-dinitro-1,3-diazacyclopentane under these conditions[162]:

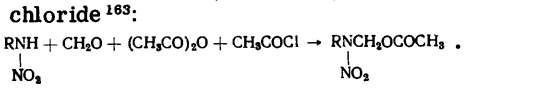


The higher homologues of ethylenebisnitroamine—trimethylenebisnitroamine and tetramethylenebisnitroamine—form 1,3-dinitro-1,3-diazacyclohexane and 1,3-dinitro-1,3-diazacycloheptane respectively in this reaction[80]:



where n = 3 or 4.

In research practice instead of the carbinol hydroxymethylnitroamines their derivatives are often used—acetates, nitrates, and chloromethylnitroamines[163]. The acetates of the nitroaminomethylols are obtained by the direct reaction of nitroamine, formalin, acetic anhydride, and acetyl chloride[163]:

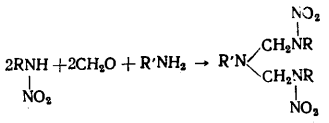


The nitrates of the hydroxymethylnitroamines, which exhibit an alkylating action, are usually of low stability and dangerous to use[164]. Important derivatives of the hydroxymethylnitroamines are the recently discovered *N*-(chloromethyl)-*N*-nitroamines, the chlorine atom of which has a reactivity reminiscent of the chlorine in chloromethyl ethers and is capable of replacement by various functional groups[164].

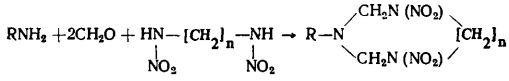
5. Aminomethylation of Primary Nitroamines

The possibility of using the primary nitroamines in a Mannich reaction was first demonstrated by the example of the reaction of methylnitroamine with *N*-hydroxymethylpiperidine[24]. Ammonia was investigated, as well as piperidine, as the amino-component, and methyl-, ethyl- and ethylenebis-nitroamines were also studied as the N–H acid component[25].

In the last 20 years there has been a thorough study of the Mannich reaction in a series of nitroamines. In 1949 Chapman and coworkers showed that for primary amines both of the hydrogen atoms of the latter take part in the condensation[165]:

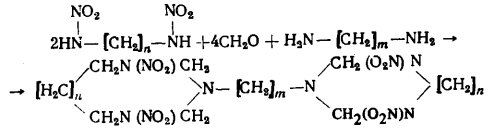


$\alpha\omega$-Bisnitroamines with not more than three methylene groups in a chain form cyclic condensation products[165]:



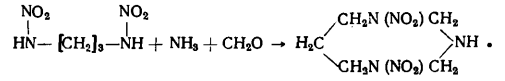
where n = 1–3.

Bicyclic compounds are isolated in the example of diamines[165]:

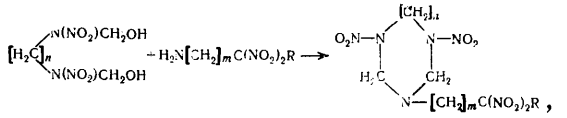


where n = 1–3, m = 2.

The formation of a bicyclic product was also observed in the condensation of ethylenebisnitroamine with ammonia and formalin (n = 2, m = 1)[166], but for trimethylenebisnitroamine a monocyclic product is formed as well as the bicyclic product (n = 3, m = 1)[80]:

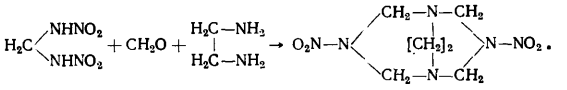


An interesting example of cyclisation was observed in the condensation of bisnitroaminodiols with polynitroalkylamines[167–170]:

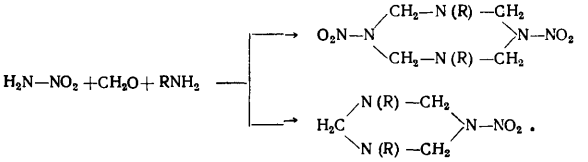


where n = 1 or 2, m = 2–6, R = NO_2 or CH_3.

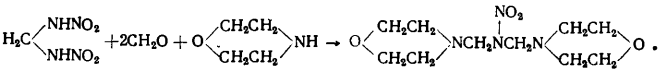
Quite recently[171–173] a new series of studies appeared on the condensation of dinitramines—$O_2NHN[CH_2]_nNHNO_2$, n = 1–4—with formaldehyde and diamines—$H_2N[CH_2]_nNH_2$, n = 2, 3, 4, 6—and also methyl-, ethyl-, butyl-, 2-hydroxyethyl-, hydroxypropyl-, trinitropropyl-, and benzylamines, aniline, phenylenediamine, 3,3-dinitropentamethylene-1,5-diamine, 3,6-dinitro-3,6-diazaoctamethylene-1,8-diamine, bis-2-aminoethyl ether. From a large amount of experimental material it was shown that the basicity of the amines and diamines in the aminomethylation of ethylenebisnitroamine has no effect on the nature of the reaction products. The more basic the amino-component introduced into the reaction the higher the pH of the medium at which formation of the cyclic products takes place. Special attention was paid to the behaviour of methylenebisnitroamine in the Mannich reaction. On reaction with ethylenediamine and formaldehyde at pH 4.6–5.6 it forms 3,7-dinitro-1,5-*endo*-ethylene-1,3,5,7-tetra-azacyclo-octane:



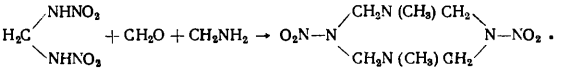
N-Nitroamide is the only nitro-derivative which contains two hydrogen atoms at the nitrogen carrying a nitro-group, therefore the aminomethylation of this compound can proceed in two directions:



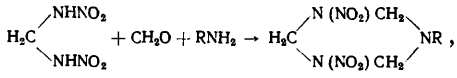
Methylenebisnitroamine is often used as a source of nitroamide, and depending on the conditions of carrying out the Mannich reaction it can function as a bisnitroamine or as a nitroamide[165]. The reaction of methylenebisnitroamine with morpholine and formaldehyde in water or ethyl acetate is:



The formation of derivatives of nitroamide was also observed in an anhydrous medium in the reaction with methyl-, benzyl-, and cyclohexylamines.

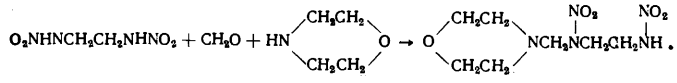


In aqueous medium products are obtained which contain the structural of methylenebisnitroaminemoiety [165].



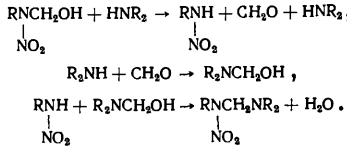
where R = CH_3, $C_6H_5CH_2$.

Linear Mannich bases are formed in the condensation of ethylenebisnitroamine with formaldehyde and morpholine [75]:



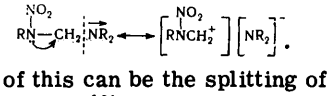
With two moles of formaldehyde and morpholine the reaction proceeds at two nitroamine groups [75].

The mechanism of the aminomethylation of the primary aliphatic nitroamines has been insufficiently studied. Lamberton and coworkers [52] proposed the following reaction scheme:

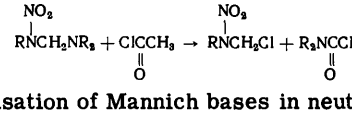


Under the action of alkalis Mannich bases are readily decomposed into nitroamine salts, amines, and formaldehyde; in an acid medium their stabilisation with the formation of the cation $RH(NO_2)CH_2N^+HR_2$ is possible [52].

It is interesting that the Mannich bases obtained from nitroalkanes (especially the mononitroalkanes) differ sharply in their chemical behaviour from the products of the aminomethylation of the primary nitroamines [52]. The former, as is well known, are insoluble in water, readily soluble in organic solvents; they cannot be titrated with alkali. The latter are readily titrated with alkali and soluble in water and other polar solvents. The reason for such a marked difference must, we think, be sought in the mutual influence of the nitroamine and amino-groupings at a single carbon atom. Like *N*-(chloromethyl)nitroamines, where the chlorine exhibits considerable lability on account of the $+M$ effect of the nitrogen atom and the I effect of the chlorine atom, the $+M$ effect of the amine-nitrogen of the nitroamino-group is evidently due to the stabilisation of the carbonium ion:



Confirmation of this can be the splitting of the Mannich bases by acetyl chloride [164]:



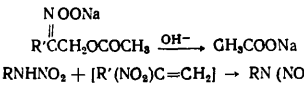
The polarisation of Mannich bases in neutral media is due to their preferential solubility in polar solvents and their ready cleavage by alkalis into their components.

6. Addition at an Activated Double Bonds

Despite the fact that the addition of primary nitroamines to compounds which contain activated double bonds, found in the initial stages of the study, interesting results in this field were also obtained recently. This reaction was first found by Kissinger and Schwartz [112]. The alkenes studied were methyl acrylate, acrylonitrile, acrylamide, methyl vinyl ketone, and diethyl maleate; the nitroamines chosen were methyl-, ethyl-, and butyl-nitroamines and also ethylenebisnitroamines and *N*-methylethylenebisnitroamines. The reaction takes place only in the presence of an alkaline catalyst:

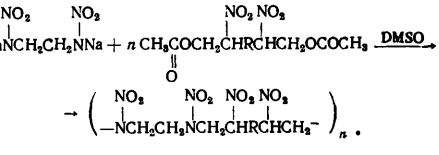
The addition of ethylnitroamine to 2,2-dinitropropanediol acrylate [174] takes place similarly.

Nitroamines are capable of adding to a double bond of nitroalkenes and unsaturated ketones [175,176]. The reaction with nitroalkenes can also take place at the moment of their liberation from nitroalkyl acetates [177]:



An interesting example is the bromodinitroethylation of the alkali salts of nitroamines. In the first stage the reaction proceeds by the cleavage of bromodinitroethyl acetate into *gem*-dinitroethylene and sodium acetate. Subsequently the excess of the nitroamine salt adds to the dinitroethylene to form the corresponding salt of dinitroethylenetriamine. Under the action of a bromonium ion the latter is converted into the corresponding bromo-derivative [178].

The addition of $\alpha\omega$-dinitroamines to the decomposition products of acetates of nitrodiols leads to the formation of polymeric products [179]:



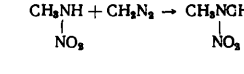
Polymers of high molecular weight are formed on carrying out the reaction in solvents indifferent to an activated double bond. When water, alcohols, or nitro-compounds are used as solvent the chain is broken owing to the addition of solvent molecules at the double bond.

7. Alkylation and Acylation

The alkylation of primary nitroamines is important for finding the structure of nitroamines and their salts and also for the synthesis of secondary nitroamines. In studying these reactions even the first investigators found that in alkylation often a mixture of isomers is formed, the quantitative composition of which depends on the nature of the alkylating agent, the metal cation, and the medium in which the reaction is carried out.

Alkylation of diazoalkanes. The reaction of primary nitroamines with diazoalkanes is of interest from the standpoint of finding the structure of nitroamines by chemical means.

In the treatment of nitroamide with diazomethane the main reaction product is dimethylnitroamine [180]. The latter is also obtained in quantitative yield in the alkylation of methylnitroamine [181]:

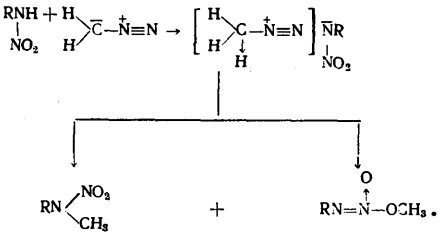


It is interesting to note that the more acid phenylnitroamines are alkylated mainly at the oxygen[181]:

In the alkylation of primary nitroamines with diazoethane ethyl derivatives are formed[57].

In the examples described above the investigators usually either did not note the formation of isomeric products of *O*-alkylation, or they were not investigated closely. More detailed study of the reaction of diazomethane with the isopropylnitroamine suggested the formation of a secondary nitroamine and the isomeric *O*-ester in the ratio 7 : 3.[48,53]

The reaction with diazomethane is usually carried out in non-polar solvents; we think that it can be described by the scheme:



After the release of nitrogen from the intermediate "diazonium" cation the nitroaminium ion can complete the octet of the carbon atom either by the electron pair of the amine nitrogen (when the nitroamine-nitrogen is not solvated), or owing to the electron pair of the oxygen of the nitro-group (when there is partial polarisation of the nitroammonium anion), which also leads to the products of *N*- and *O*-alkylation, or to their mixtures.

Alkylation by alkyl halides and dimethyl sulphate. The alkylation of the salts of nitroamines with alkyl halides has been studied in greater detail than the alkylation of primary nitroamines with diazoalkanes. The direction of the reaction here depends significantly on the nature of the cation. The silver salts of nitroamines usually form *O*-alkylacylnitroamines[30]:

Whereas sodium or potassium salts form *N*-alkylation products preferentially[24,27,182]. Thus the sodium salt of isopropylnitroamine with methyl iodide gives 60% isopropylmethylnitroamine and 9% *N*-isopropyl-*O*-methyl acinitroamine; the silver salt of the same nitroamine forms a mixture of the secondary nitroamine and its *O*-isomer in the ratio 1 : 10. On the basis of the sodium salts isopropyl-, butyl-, and octyl-nitroamines with the corresponding alkyl iodides, di-isopropylnitroamines, dibutylnitroamines, and dioctylnitroamines were obtained in yields of 14, 12, and 32%; the yields of the *O*-isomers were respectively 26, 24, and 30%. It was noted that the sodium salt of cyclohexylnitroamine is not alkylated by cyclohexyl iodide[56].

In the primary dinitroamine series the alkylation of the monopotassium salt of ethylenebisnitroamine with methyl iodide and dimethyl sulphate was studied. In both instances *N*-methyl-*NN'*-dinitroethylenediamine is isolated. In the alkylation of the dipotassium salt of ethylenebisnitroamine with dimethyl sulphate, *NN'*-dinitro-*NN'*-dimethylethylenediamine is formed[38]. The potassium salt of isopropylnitroamine gives equal proportions of the *N*- and *O*-isomers with dimethyl sulphate[183].

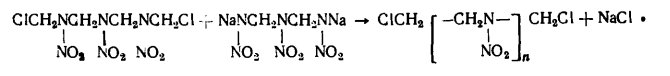
Hence the alkylation of salts of nitroamines with alkyl iodides or dimethyl sulphate often cannot serve as a convenient method for obtaining the secondary nitroamines, but it is completely suitable for the synthesis of *O*-alkylacinitroamines, which are studied as models of the aci-form of the nitroamines[54].

An interesting and practically useful series of papers deals with the alkylation of salts of nitroamines by chloroderivatives containing an active chlorine atom. Picryl chloride and the potassium salt of methyl nitroamine form tetryl in good yield[32]. Ethyl-, propyl-, and butyl-picrylnitroamines can be obtained similarly[26]. *N*-(Chloromethyl)nitroamines and *N*-(nitroxymethyl(-nitroamines react with the sodium salts of nitroamines, the yields of the resulting alkylation products varying from 15 to 81%[184]:

In this reaction a series of $\alpha\omega$-dimethylpolymethylenenitroamines

$$RN(NO_2)[CH_2N(NO_2)]_nR;$$

is obtained; 2,4,7,9-tetranitro-2,4,7,9-tetra-azadecane, and nitroaminoalkyl derivatives of nitrourethane[184]. In the condensation of the disodium salts of dinitroamines with bis-*N*-(chloromethyl)nitroamines polymeric compounds with nitroaza-groupings in a chain are formed[185]:



Acylation of primary nitroamines. Until recently it was thought that acid anhydrides do not attack primary nitroamines[21,24,43]. However, recently Woodcock[75] succeeded in obtaining ethylenebisnitroacetamide in small yields by the action of acetic anhydride on ethylenebisnitroamine.

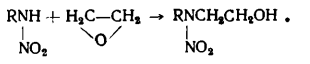
In studies at the end of the last century it was shown that the acid chlorides of organic acids either do not react with primary nitroamines or bring about complete decomposition. Acetyl chloride reacts with the silver salts of methylnitroamine and propylnitroamine with release of dinitrogen oxide[21]. Benzoyl chloride acts similarly on methyl- and isopropyl-nitroamines.

It was found recently that the potassium and silver salts of the esters of *N*-nitroglycine and *N*-nitroalanine are exceptions. They are smoothly acylated at the nitrogen by acetyl chloride, benzoyl chloride, and 3,5-dinitrobenzoyl chloride[115]. The formation of *O*-acylation products is almost not observed.

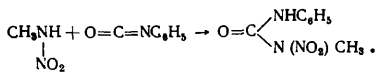
There have been reports of the reasons for such an unusual course of reaction in the failure of Kornblum's rule[186,187] for the alkylation of mesomeric anions. Starting from the fact that the alkali salts of nitroamines react with acylating agents at different rates, and silver salts do not react without catalytic additions of pyridine the investigators suggest that the salts have a chelate, not an ionic, structure. Sodium and potassium salts exist in solution in the form of associates in which the oxygen of the nitro-group is coordinated with metal ions. The silver salts are evidently chelates, therefore acylation is hindered both at nitrogen and at oxygen. The catalytic action of pyridine leads to the breakdown of the complex owing to the formation of a new donor–acceptor bond between the silver ion and the nitrogen atom of the pyridine, as a result of which the nitroamine group is capable of *N*- and *O*-acylation. This point of view satisfactorily explains the effect of the cation in the alkylation of various salts of nitroamines[115].

8. Other Reactions

Primary nitroamines are condensed with ethylene oxide to form the corresponding nitroaminoalcohols[188]:

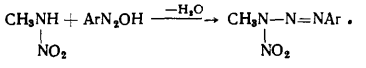


The reaction of methylnitroamine with phenyl isocyanate, leading to the formation of *N*-phenyl-*N'*-nitro-*N'*-methylurea has been described[45]:

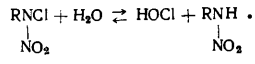


In the action of potassium isocyanate on methylnitroamine free isocyanic acid is released; the formation of the corresponding urea does not take place[45].

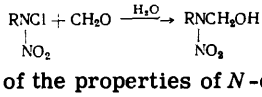
Methylnitroamine reacts with aromatic diazo-compounds. The reaction products in this instance are methylaryl-*N*-nitrotriazenes[189]:



Reference must be made to the production and the study of the properties of the little known *N*-halogeno-*N*-nitroamines. Franchimont and Klobbie[16] did not isolate any individual products from the reaction mixture in the bromination of salts of alkyl nitroamines. Much later Smart and Wright[56], in studying the conversion of alkyldichloroamines to nitroamines expressed the opinion that in aqueous solution there is the equilibrium involving *N*-chloro-*N*-nitroamines:

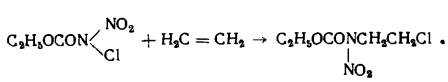


It was recently observed that the chlorine in *N*-chloro-*N*-nitroamines is smoothly converted into the hydroxymethyl group under the action of formaldehyde[190]:

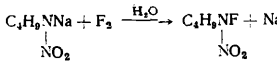


Detailed study of the properties of *N*-chloro-*N*-nitroamines has not been studied in detail nor has the chlorination of primary nitroamines been investigated. However, *N*-chloro-*N*-nitroamines should exhibit extremely interesting chemical properties owing to the strong polarisation of the chlorine atom under the influence of the nitroamino-group, which should lead, in turn, to great lability of the chlorine in reactions with nucleophilic compounds.

In this connection it is interesting to note that primary aromatic nitroamines are readily chlorinated by hypochlorous acid to the unstable *N*-chloro-*N*-nitroamines[191,192]. The production of *N*-chloro-*N*nitrourethane by the action of sodium hypochlorite on a solution of nitrourethane in sulphuric acid and its addition to ethylene and cyclohexene[193]:

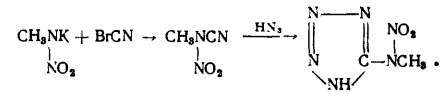


Elemental fluorine reacts readily with salts of nitroamines in an aqueous medium with the formation of *N*-fluoro-*N*-nitroamines. This reaction takes place, for example, with the isomeric butylnitroamines[194]. A thermochemical investigation of the compounds synthesised was also made[195,196].



N-Fluoro-*N*-nitroamines are low-boiling unstable liquids. *N*-Bromo- and *N*-iodonitroamines are unknown.

The reaction of the potassium salt of methylnitroamine with cyanogen bromide, taking place with the formation of *N*-cyanomethylnitroamine has also been described. Without isolating the latter in the pure state it was converted into 5-methyl-5-nitroaminotetrazole by treatment with hydrogen azide[197]:



Methylnitroamine reacts vigorously with methylmagnesium iodide[1] with liberation of gaseous products. The products were not identified.

V. ANALYTICAL DETERMINATION

Four qualitative reactions for nitroamines are known: (1) the Franchimont reaction[23]; (2) Thiele and Lachman's reaction[87]; (3) Bamberger's reaction[198]; and (4) Lieberman's reaction[199]. All these reactions are discussed in sufficient detail in Houben–Weyl's monograph[200].

Quantitative methods of analysis of nitroamines for dinitrogen oxygen liberated in the decomposition of nitroamines by hydrochloric acid and iron(II) chloride and also in a Lunge nitrometer[201]:

If the physicochemical methods of identification of primary nitroamines were developed rather intensively in recent years (see Section III), the chemical methods were perfected very poorly and there have been no significant approaches in this field recently. Mention must only be made of the method of identification of primary nitroamines in the form of *S*-benzylthiuronium salts[55]. The latter are formed in good yields on mixing aqueous solutions of *S*-benzylthiuronium hydrochloride with the sodium salts of primary nitroamines. The *S*-benzylthiuronium salts of the primary nitroamines crystallise well from 50% ethanol and have precise melting points. Thus the *S*-benzylthiuronium salt of methylnitroamine melts at 117°C, that of ethylenebisnitroamine at 125–129°C, and that of benzylnitroamine at 127°C.[55]

VI. CERTAIN ASPECTS OF PRACTICAL USE

Judging by the published information, some of the primary aliphatic nitroamines have definite practical value as explosives. The most important of these is ethylenebisnitroamine, which was manufactured in the U. S. A. on an industrial scale under the commercial name of "Haleite"[101]. Ethylenebisnitroamine was used as a high explosive[4]; it can also be used as a component of missile explosives[5] and as a main or reduced charge in percussion cap–detonators instead of tetryl[5].

Methylnitroamine is a low-melting explosive, more powerful than tetryl but weaker than hexogen[12]. It is recommended for use in explosive compositions mixed with T. E. N.[6]

Nitroaminoethanol nitrate and 1-nitroamino-2-nitroxypropane have been suggested as plasticisers for cellulose nitrate.

In recent years there have been patents on the possibility of using primary nitroamines in rocket technology.

Patents have been granted on the use of nitroamide and several primary alkylnitroamines as monopropellents [123,141]. Ethylenebisnitroamine and its hydrazinium salts are recommended as components of mixed rocket propellents [7,202]. The nitroaza-polymer

$$ClCH_2\left[N(NO_2)CH_2\right]_n CH_2Cl$$

obtained by condensation of a salt of a dinitroamine with a bis-*N*-(chloromethyl)-*N*-nitroamine has been recommended as a binder in solid rocket propellents [185].

Nitroamines have interesting and important prospects for use for other purposes. For example, a patent has been granted for the use of aliphatic nitroamines as weed-killers [203] and as effective plant growth stimulators [8,204,205]. Some of the nitroamines are recommended as additives for diesel fuel to increase the octane number [198], for removing the deposit in internal combustion engines [10], and also special additions in dyeing. Bis-(β-diketones)

E.S.Krongauz and A.M.Berlin

Methods of synthesis of various types (including those containing the ferrocene structure) of bis-(β-diketones) which are of interest as intermediates in organic synthesis, owing to their high reactivity, are described. The physical and chemical properties of these tetraketones, due to their structural features, to the presence of four carbonyl groups in the molecule, and to ketol-enol tautomerism are examined. 119 references.

I. INTRODUCTION

Tetraketones, like other carbonyl compounds, exhibit high reactivity and can therefore serve as intermediates for the synthesis of aliphatic, aromatic, heterocyclic, and high-molecular-weight compounds.

The interest in tetraketones arose in recent years when existing methods for their preparation were perfected and new methods developed. The greatest number of papers relates to the use of tetraketones for the synthesis of new compounds, especially those of the heterocyclic series, which have attracted the attention of both chemists and of investigators in the sciences bordering on chemistry. Tetraketones have been used successfully for the synthesis of a new class of thermally stable polymers containing macromolecules of heterocycles in chains: polypyrazoles, polyquinoxalines, polyquinolines, and also for the obtaining coordination polymers with various metals.

Polycoordination and polyheterocyclisation are comparatively new reactions in macromolecular chemistry and their subsequent development should also extend the regions of use of tetrafunctional compounds, including tetraketones.

The present review considers the most abundant representatives of tetraketones—bis-(β-diketones) of various structures: linear, of the type

$$RCOCH_2CO-Y-COCH_2COR$$

and branched, of the types

$$[(RCO)(R'CO)CH]_2CHR'' \text{ and } (RCO)(R'CO)CH-Y-CH(RCO)(R'CO).$$

Other tetracarbonyl compounds are not considered here, since they have been studied less and are little used.

The review covers the periodical literature on these tetraketones up to 1st January 1968.

II. SYNTHESIS OF BIS-(β-DIKETONES)

1. The $RCOCH_2CO-Y-COCH_2COR$ Type

a. The Claisen condensation. Bis-(β-diketones) of the general formula

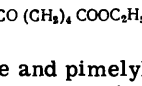
$$RCOCH_2CO-Y-COCH_2COR\ ,$$

can be obtained by two main methods: the Claisen condensation and direct acetoacetylation of aromatic compounds. The most prevalent method is the Claisen condensation, which consists in the treatment of a dicarbonyl compound, usually an ester of a dicarboxylic acid ($R'OOC-Y-COOR'$) with a ketone ($RCOCH_3$) or ethyl acetate in the presence of sodium or potassium amide[1-13]. For example[1]:

$$CH_3OOC-Y-COOCH_3 + 2C_6H_5COCH_3 \rightarrow C_6H_5COCH_2CO-Y-COCH_2COC_6H_5 + 2CH_3OH.$$

Despite its universality this method has several limitations: the Claisen condensation is accompanied by side-processes, which considerably reduce the yield of the final bis-(β-diketone), make it more difficult to isolate in a pure form, and sometimes make the synthesis completely impossible. For example, the Claisen condensation cannot be used for making adipylbisacetophenone and pimelylbisacetophenone ($Y = [CH_2]_4$ and $[CH_2]_5$; $R = C_6H_5$), because under these conditions the Dieckmann reaction takes place more readily, leading to the formation, in the first example, of 2-ethoxycarbonylcyclopentanone in 77% yield[1]:

$$C_6H_5COCH_3 + C_2H_5OCO(CH_2)_4COOC_2H_5 \rightarrow$$



.

Adipylbisacetophenone and pimelylbisacetophenone were obtained by treatment of a suspension of the sodium salt of the ketone in ether with the dichloride of the corresponding

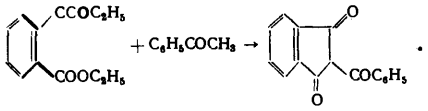
acid[1]. This method was used earlier for the synthesis of certain β-diketones[14-17]. It was then noted that the use of three equivalents of the sodium salt of the ketone per one equivalent of the acid chloride ruled out any possibility of further acylation.

The Claisen condensation also has other limitations: esters of malonic and succinic acids usually undergo an aldol condensation and a Stobbe condensation respectively. For example, with diethyl succinate the condensation with acetophenone leads to the formation of an ester of an unsaturated acid in 92% yield:

$$C_6H_5COCH_3 + C_2H_5OOC(CH_2)_2COOC_2H_5 \xrightarrow{NaH} \rightarrow C_6H_5C(CH_3)=C(COOC_2H_5)CH_2COOC_2H_5.$$

It is interesting to note that in the condensation of di-t-butyl succinate with acetophenone in the presence of NaH succinylbisacetophenone was obtained in 19–34% yield in addition to the half-ester (yield 56–64%).[9]

Several bis-(β-diketones) cannot be obtained by the Claisen condensation owing to the occurrence of intermolecular cyclisation. For example, 2-benzoyl-1,3-diketoindane was obtained in the reaction of diethyl phthalate and acetophenone in the presence of sodium ethoxide[18]:

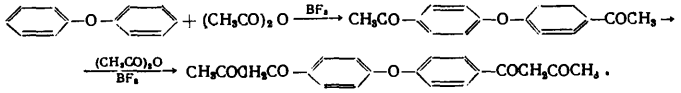


The reactions with acetone and ethyl methyl ketone take place in a similar fashion.

The mechanism of the Claisen condensation in the synthesis of bis-(β-diketones) is analogous to the mechanism of the acylation of ketones by esters. The acylation probably takes place by a three-stage mechanism, as for the formation of acetoacetic ester[15].

b. Direct acetoacetylation. This method is suitable for the synthesis of only aromatic bis-(β-diketones) in which R = CH_3, and Y = an aryl biradical of various structures. The method consists in the direct acetoacetylation of aromatic compounds with two benzene rings by an excess of acetic anhydride in the presence of BF_3.[19,20]

In comparison with the Claisen condensation this method does not require the use of solvents and metallic sodium (or sodium amide), is simple and convenient to use, and gives higher yields and purer bis-(β-diketones). With diphenyl oxide as an example the reaction can be represented by the following overall equation:

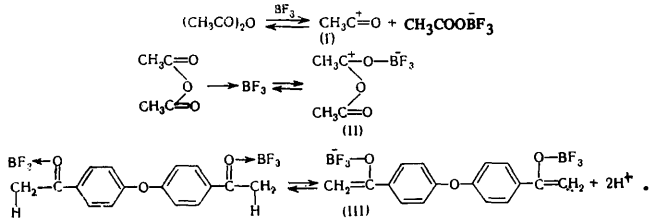


The first stage of the reaction is evidently the formation of diacetyl compounds by a Friedel-Crafts reaction.

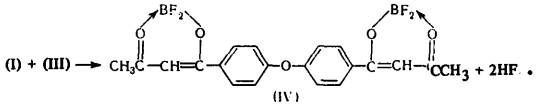
The formation of bis-(β-diketones) from diketones can occur either as a result of their direct *C*-acylation or by the *O*-acylation of the diketone with subsequent *C*-acylation of the resulting ester of the enol form of the diketone[21].

The large consumption of boron trifluoride is probably due to the *C*-acylation of the diketone being connected with the conversion of both the acid anhydride and also the diketone into reactive intermediate compounds, which then participate further in the condensation.

The mechanism of this reaction has not been investigated. Presumably, as for the synthesis of β-diketones[22] the acid anhydride forms a carbonium ion—of type (I) or (II)—and the diketone a complex of the enol type, which by analogy with ordinary enols should correspond to structure (III):



Condensation of the carbonium ion (I) with the enol complex (III) leads to the formation of a complex of the tetraketone (IV):



The *O*-acetylation of a diketone evidently leads to the proton-catalysed enolisation of the diketone accompanied by the acylation of the enol formed. Subsequently *C*-acylation of the ester of the enol form of a diketone by carbonium ions (I) or (II) lead to the formation of an ester of the enol form of a bis-(β-diketone), which after removal of the acid fluoride also forms the complex (IV).[20-22]

In the initial period of the reaction when there is still little acid in the reaction mixture, a bis-(β-diketone) can be formed only by *C*-acylation of a diketone. However, with the accumulation of acid in the reaction mixture formation of a bis-(β-diketone) can also take place indirectly and in the last period of the reaction this second path can become dominant. Since the acid which is formed as a side-product of the reaction catalyses not only the *O*-acetylation of ketones but also their self-condensation (aldol type) the best yields of bis-(β-diketones) were obtained when the rate of introduction of BF_3 into the reaction was maximal[20].

The direct acetoacetylation of diphenyl oxide, diphenylmethane, diphenylethane, diphenyl disulphide, and diphenyl esters of ethylene glycol and diethylene glycol by acetic anhydride in the presence of BF_3 gave the corresponding bis-(β-diketones), the structure of which was confirmed by a counter-synthesis by the Claisen condensation[20].

2. Bis-(β-diketones) of the $[(RCO)(R'CO)CH]_2CHR''$ Type

Bis-(β-diketones) of this type are obtained by the reaction of β-diketones with aldehydes in the presence of the appropriate catalyst[23-39].

The synthesis of bis-(β-diketones) of the $[(RCO)(R'CO)CH]_2CHR''$ type, evidently proceeds through the formation of an intermediate product of the $(RCO)(R'CO)CH{=}CHR''$ type, which adds a second molecule of the β-diketone by a Michael reaction, for example, in the formation of 2-phenyl-1,1,3,3-tetra-acetylpropane during the reaction of equimolecular amounts of benzaldehyde and acetylacetone[23]. In a series of instances, for example, in the reaction of acetylacetone with cinnamaldehyde[24], 2-hydroxynaphthaldehyde[25], or salicylaldehyde[26], the formation of an unsaturated β-diketone $(CH_3CO)_2C{=}CHR''$ was not observed.

Bis-(β-diketones) with a trifluoroacetyl group could not be obtained by this method, evidently because of their hydrolytic cleavage, analogous to that of the simple β-diketones containing a trifluoroacetyl group[26-28].

3. Bis-(β-diketones) of the (RCO)(R'CO)CH–Y–CH(RCO)(R'CO) Type

Bis-(β-diketones) in which R=R'=CH_3 and Y is a single bond are obtained by the reaction of a sodium salt of a β-diketone with iodine in ether and ethanol[40-42].

For the synthesis of bis-(β-diketones) with R=R'=CH_3, Y = $[CH_2]_2$, $[CH_2]_6$, $[CH_2]_{10}$, and 1,4-$(CH_2)_2C_6H_4$ a method suitable for the synthesis of monoalkylated β-diketones RCOCHR"COR' was used, consisting in the alkylation of a β-diketone (sodium salt of acetylacetone) with a dihalogenoalkane[43-48,56,57]. The reaction is usually carried out in a sealed ampoule[46-49] or in a high-boiling solvent[50]. The dihalogenoalkane can act as the solvent, which allows the reaction to be carried out at higher temperatures. However, the presence of a large excess of the dihalide is unfavourable for the reaction since it assists intramolecular condensation.

It was found that the best alkylation conditions are the reaction of acetylacetone (3 moles) with the dihalogenoalkane (1 mole) in a medium of t-butyl alcohol in the presence of sodium t-butoxide (2 moles) under reflux with vigorous stirring[40]. 4,4'-Bis-(2,2-diacetoethyl)biphenyl and 4,4'-bis-(2,2-diacetoethyl)diphenyl oxide were obtained by boiling 4,4'-bis(bromomethyl)biphenyl and 4,4'-bis(bromomethyl)diphenyl oxide with sodium acetylacetonate in acetylacetone[51].

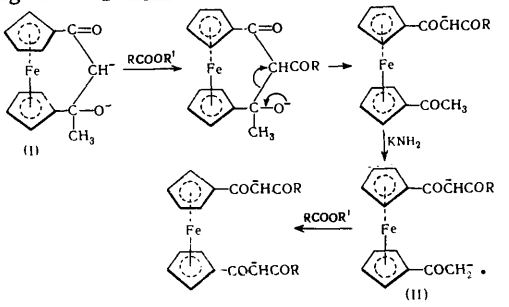
It should be noted that the alkylation of sodium acetylacetonate by dihalogenoalkanes in the synthesis of bis-(β-diketones) takes place exclusively at the carbon atom. Evidently for bis-(β-diketones) a type S_N2 transition state is established preferentially, in which the alkylation is directed towards the less electronegative atom, here carbon.

The observed direction of alkylation agrees with the views of Nesmeyanov and Kabachnik concerning the increasing tendency to reaction with transfer of the reaction centre (from oxygen to carbon) with increase in the ionic character of the bond of an ambidentate anion with a metal. Moreover, in addition to polar factors steric effects have a great effect on the direction of alkylation[52-54].

Neuse and Crossland[57] recently described some ferrocene-containing bis-(β-diketones) having a linear structure of the $RCOCH_2CO–Y–COCH_2COR$ type, where Y = ferrocene.

1,1'-Bis(acetylaceto)ferrocene and 1,1'-bis(benzoylaceto)ferrocene were obtained by a Claisen condensation from 1,1-diacetylferrocene by the method of Hauser and coworkers[16]; 1,1'-bis(formylaceto)ferrocene was synthesised by a modified Schlögl method[17], which included condensation of 1,1'-diacetylferrocene with ethyl formate.

A mechanism has been proposed for the acylation of diacetylferrocene in the presence of potassium amide, which takes place through the formation of the intermediate cyclic carbanion (I) and dianion of the bis-(β-diketone) (II), according to the scheme:



The authors note that the introduction of the second acyl group is easier than the first which can be explained by the better solubility of the dipotassium salt of the dicarbanion (II) compared with the dipotassium salt of the dianion (I), and possibly also the isomerisation of cis-dianion (II) into the trans-configuration as a result of the repulsion of the negative charges of the two side chains[57].

III. PHYSICAL PROPERTIES AND STRUCTURE OF THE BIS-(β-DIKETONES). KETO–ENOL TAUTOMERISM

Most of the bis-(β-diketones) described above are crystalline substances with rather high melting points. The overwhelming majority of the bis-(β-diketones) give a specific cherry-red colour with a methanol solution of $FeCl_3$.

A characteristic feature of the bis-(β-diketones) is the keto–enol tautomerism which has been studied in detail by the example of dicarbonyl compounds[58]. In recent years a significant contribution to the development of a quantitative theory of keto–enol equilibrium by the example of β-diketones has been made by Kabachnik and coworkers[59-62].

Since linear bis-(β-diketones) of the type $RCOCH_2CO–Y–COCH_2COR$ can be regarded as derivatives of benzoyl acetone and branched bis-(β-diketones) of the $[(RCO)_2CH]_2Y$ and $[(RCO)(R'CO)CH]_2CHR'''$ types as 3-substituted acetylacetone. They will possess to a considerable extent the keto–enol equilibrium found for β-dicarbonyl compounds. However, there are some specific features in the keto–enol tautomerism of bis-(β-diketones), owing to the peculiarities of their structure.

As an investigation of their infrared and ultraviolet spectra showed, bis-(β-diketones) of the $RCOCH_2CO–Y–COCH_2COR$ type exist predominantly in the *cis*-enol form in the solid state and in 95% ethanol solution[1]. This is shown by the absence of absorption characteristic for the carbonyl group in the infrared spectra of almost all the bis-(β-diketones) studied (in the range 5.7–5.9 μm), except for oxalyldiacetone and adipyldiacetone. Furthermore, the 16 bis-(β-diketones) studied have either one or two absorption bands of high intensity (in the range 6.2–6.5 μm) ascribable to an enol chelate bond. The absence of hydroxyl absorption in the spectra of ten of the 16 bis-(β-diketones) (2.95 μm region) is evidently due to its displacement and the superposition of the bands of the stretching vibrations of the C–H bonds. A similar effect was observed earlier in the spectra of acetylacetone and other enolised β-diketones, which was explained by the influence of the strong intramolecular hydrogen bonds[22,55,63,64].

The position of the enol-chelate bonds in the infrared spectra is determined by the structural features of the bis-(β-diketones). Thus, the enol-chelate bands in sebacylbisacetone are found at 6.08 and 6.24 μm, and in oxalyldiacetone at 6.25 and 6.33 μm. This displacement is the result of the great degree of conjugation possible in oxalyldiacetone. Replacement of the alkyl terminal groups in the latter by phenyl groups increases the degree of conjugation and correspondingly the oxalyldiacetophenone has an enol–chelate band at 6.25–6.40 μm.[1]

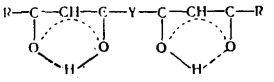
When two β-diketone groups are separated by a methylene chain there is less conjugation. Thus succinyl-, pimelyl-, suberyl-, azeloyl-, and sebacyl-diacetophenone have enol–chelate absorption at 6.20 and 6.34 μm.[1]

The position of the keto–enol equilibrium is significantly affected by the nature of the solvent. It is found that a tendency for bis-(β-diketones) to exist in the keto-form is more pronounced in tetrachloroethylene than in the solid state. As studies of the ultraviolet spectra showed, in

95% ethanol bis-(β-diketones) of this type exist predominantly in the enol form[1]. A displacement of the position of the enol band in the ultraviolet spectra of the bis-(β-diketones) to the side of 310 nm can be qualitatively connected with conjugation, which appears in the presence of terminal phenyl groups and/or phenylene bonds. For example, when R = phenol and Y = a methylene chain, the enol band is noted at ~ 312 nm (succinyldiacetophenone 320 nm, and oxalyldiacetophenone even 333 nm); terephthalyldiacetone has absorption at 340 nm, isophthalyldiacetophenone at 357 nm, and terephthalyldiacetophenone at > 360 nm.

For certain bis-(β-diketones) the enol content has been determined quantitatively from the ratio $\varepsilon_m/\varepsilon_e$ (ε_m is the observable extinction at 310 nm, where the absorption of the keto-form should be insignificant, and ε_e is the extinction of the pure enol), and on the basis of PMR spectra. The calculated concentrations of the enol in 95% ethanol for the following bis-(β-diketones) are: suberyldiacetophenone 77.8%; azelyldiacetophenone 82.8%; sebacyldiacetophenone 88.4%; and 4,4′-bis(acetoacetyl)diphenyl oxide 100%.[1,65]

On the basis of the results of spectroscopic investigations and also the inertness of bis-(β-diketones) of the $RCOCH_2CO-Y-COCH_2COR$ type in certain reactions in which the ketonic form is absent, the following structure was attributed to them:



Evidently, as a result of the enolisation of the bis-(β-diketones) a claw-shaped complex (chelate) is formed and the fractional negative charge arising on the carbon is delocalised between the carbon and carbonyl-oxygen atoms, which leads to the stabilisation of the molecule and a decrease in its reactivity[19].

It should also be noted that the keto-enol equilibrium in the bis-(β-diketones) is extremely stable. Unlike the usual mobile keto-enol equilibrium known in acetylacetone, acetoacetic ester, and other β-diketones, the principal enol form is retained and reacts even in solutions of these bis-(β-diketones).

Bis-(β-diketones) of the $[(RCO)(R'CO)CH]_2CHR''$ type (the so-called branched tetraketones) exist predominantly in the keto-form in the solid state according to the infrared spectra. This is shown by the intense carbonyl absorption at 5.77–5.85 μm and the weak absorption in the 6.25 μm range, characteristic of enol–keto absorption. In the infrared spectra of the bis-(β-diketones) of this type there are maxima at ~ 2.95 μm, corresponding to the vibrations of the strained hydroxyl bonds. In nine examples it was found that the hydroxyl bonds can be shifted, bringing about displacements of the vibrations of the CH-bonds analogous to the displacement observed in the spectrum of acetylacetone and other enolised β-diketones, and also bis-(β-diketones), which form strong intramolecular hydrogen bonds[63,64].

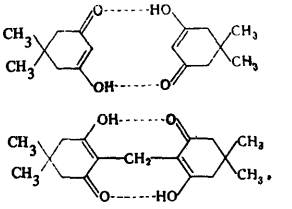
The structure of R and R′ has a considerable influence on the position of the normal carbonyl bond in these bis-(β-diketones). In 11 compounds in which R = R′ + CH_3 five have two carbonyl maxima at 5.78 and 5.85 μm, and six of the compounds have only one intense maximum at ~ 5.85 μm. The compounds

$[(CH_3CO)(C_6H_5CO)CH]_2CHC_6H_5$ and $[(C_6H_5CO)_2CH]_2CH_2$

have two carbonyl group absorption maxima in the ranges 5.83 and 5.94 μm and 5.91 and 5.97 μm, respectively. These changes in the position of the carbonyl bonds are evidently due to an increase in the carbonyl conjugation.

The enol-chelate absorption of these compounds is very weak. Only in three compounds of the $[(CH_3CO)_2CH]_2CHR''$ type, where R″ = 2-ClC_6H_4, 2-CH_3O-C_6H_4, or 2-C_5H_4N, is the intensity of the enol-chelate absorption and carbonyl absorption comparable. The reason for this is not clear. Possibly here there is the effect at all the R″ of these three compounds of heteratoms or substituting groups in the *ortho*-position, which creates steric and/or polar effects favourable for an enol-chelate structure.

In the infrared spectra of solid methylenebis(dimedone) there are present the vibrations of weak intensity of conjugated carbonyl at 5.90 μm and of enol-chelate bonds of high intensity at 6.10 and 6.30 μm. This picture is completely analogous to the dimedone spectrum, which suggested an analogy in their structure: an enol-chelate structure resulting from dimerisation has been proposed for dimedone and an intramolecular enol-chelate structure for methylenebis(dimedone)[63]:



Methylenebis(dimedone) does not form the cherry-red colour characteristic of bis-(β-diketones) with a methanol solution of $FeCl_3$.

An investigation of the ultraviolet spectra of bis-(β-diketones) of the $[(RCO)(R'CO)CH]_2CHR''$ type in 95% ethanol showed the dependence of the extinction coefficient on concentration; in some instances the extinction coefficient increases with increase in concentration—for example, for the compound

3,4-$(CH_3O)_2C_6H_3CH[CH(COCH_3)_2]_2$

—in other instances it decreases as the concentration is raised—for example,

$[(CH_3CO)_2CH]_2CHC_5H_4N$,

—in a third group it is independent of concentration—methylenebis(dimedone) and certain other compounds[40].

Such anomalies, which are explicable for acyclic β-diketones by their low acidity and inability to form enol-chelates[68] unsuitable for finding differences in the spectra of bis-(β-diketones) since they are all capable of forming enol-chelate structures. The differences in the extinction coefficients can be best explained by a change in the conjugation of the enol with change in concentration[67].

A comparison of the ultraviolet spectra of the β-diketones and the related bis-(β-diketones) of the $[(RCO)(R'CO)CH]_2CHY$ type that the latter have much less tendency to enolisation, with the structure and spectroscopic characteristics of the bis-(β-diketones) determined by the nature of R, R′, and the –Y bonds. Thus benzoyldiacetone in 95% ethanol has mixed keto–enol absorption in the 245.5 nm range ($\lg\varepsilon_m = 3.78$) and the pure absorption of the enol form at 310 nm ($\lg\varepsilon_m = 4.14$).[68] The bis-(β-diketone)

$[(CH_3CO)(C_6H_5CO)CH]_2CHC_6H_5$

has only one intense maximum, at 248.5 nm ($\lg\varepsilon_m = 4.30$), which shows the absence of an enol form. Dibenzoylmethane exists in ethanol almost exclusively in the enol form

($\lg \varepsilon_m = 4.36$ at 345 nm and $\lg \varepsilon_m = 3.92$ at 250 nm); tetra-acetylpropane, on the other hand, has intense absorption at 249 nm ($\lg \varepsilon_m \simeq 4.6$) and weak absorption at 340 nm ($\lg \varepsilon_m = 3.0-3.4$).

Hence unlike the $RCOCH_2CO-Y-COCH_2COR$ type of bis-(β-diketones), which exist in the solid state predominantly in the enol form, the bis-(β-diketones) of the $[(RCO)(R'CO)CH]_2CHR''$ type (where $R'' \neq H$) have a much less expressed tendency to enolisation in the solid state.

Bis-(β-diketones) of the $[(RCO)(R'CO)CH]_2Y$ type show great differences amongst themselves in physical properties and structure. Tetrabenzoylethane is hardly enolised at all (there is no absorption at 340 nm, an intense absorption at 247.5 nm, $\lg \varepsilon_m = 4.89$); tetra-acetylethane, on the other hand, has an intense enol-chelate absorption at 6.27 μm but no carbonyl absorption in the 5.85 μm range. Tetra-acetylpropane has maximum absorption of approximately the same intensity both in the range of vibrations of the ketonic groups and in the enol-chelate region.

In an investigation of the PMR spectra of 1,1,2,2-tetra-acetylethane, 1,1,3,3-tetra-acetylpropane and 1,4-bis-(2',2'-diacetoethyl)benzene a signal for a hydroxyl proton of *cis*-enol form was observed. The chemical shifts of the protons of the OH group measured on the δ scale were 16.85, 15.80, and 16.90 respectively. Our calculations showed that the first is 100% *cis*-enol, the second contains 50% *cis*-enol and 50% ketonic form, and the third 20% *cis*-enol and 80% ketonic form. The PMR results are in complete agreement with the results obtained in studying the infrared spectra of these bis-(β-diketones), and also with their reactivity.

For all three types of bis-(β-diketones) the dissociation constants in water–dioxan mixtures with 75 or 50 vol.% dioxan at 30°C were determined using tetramethylammonium hydroxide as a base[69-71].

It was found that linear bis-(β-diketones) of the $[RCOCH_2CO]_2Y$ type are evidently stronger acids than branched ketones of the $[(RCO)(R'CO)CH]_2CHR''$ and $[(RCO)(R'CO)CH]_2Y$ types, as is shown primarily by the fact that the dissociation constants of branched bis-(β-diketones) were so low that they could not be determined in 75% dioxan.

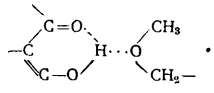
The lower acidity of the branched bis-(β-diketones) is probably connected with the fact that both the β-diketone functions are displaced from the active methylene position. An analogous picture is observed with simple β-diketones: the pK_D of acetylacetone (10.35) in 50% dioxan is less than the pK_D of butylpentane-2,4-dione (12.07).[69]

In general the relative acidity of linear and branched bis-(β-diketones) can be linked with their relative tendency to exist in the enol form in the solid state: linear bis-(β-diketones), which exist in the solid state predominantly in the enol form, are weaker acids than the branched bis-(β-diketones), which have less tendency to enolisation.

In the $C_6H_5COCH_2CO-[CH_2]_n-COCH_2COC_6H_5$ series (n = 4–8) it is interesting to note the peculiar dependence of the value of pK_{D_1} (but not pK_{D_2}) on the chain length *n*. Thus the dissociation of the first proton takes place more slowly for pimelyl ($n = 5$) than for adipyl ($n = 4$), suberyl ($n = 6$) or sebacyl-diacetophenone ($n = 8$) and even more slowly for azelayldiacetophenone ($n = 7$). The difference between the values of pK_{D_1} and pK_{D_2} increases linearly with increase in the chain length from 4 to 8. We were unable to determine pK_{D_2} for azelayldiacetophenone. The fact that the second proton of linear bis-(β-diketones) dissociates with greater difficulty with increase in the chain length, differs from what is to be expected from their behaviour[69].

However, for compounds of the $[(CH_3CO)_2CH]_2[CH_2]_n$ type the second proton dissociates more readily with increase in the chain length: thus the difference between the values of pK_{D_1} and pK_{D_2} equals 4.11 ($n = 0$), 0.49 ($n = 6$), and 0.06 ($n = 10$). The value of pK_D of bis-(β-diketones) of the $[(RCO)(R'CO)CH]_2CHR''$ type is greatly affected by the nature of R, R', and R''. For a given R'' group the derivatives of acetylacetone ($R = R' = CH_3$) have lower pK_D than derivatives of methoxyacetylacetone ($R = CH_3$, $R' = CH_3OCH_2$), although acetylacetone itself has a higher pK_D (10.35) than methoxyacetylacetone (9.66 in 50% dioxan).

To explain this non-correspondence it is suggested that a structure with an intermolecular hydrogen bond between an ethereal oxygen and a chelate hydrogen is formed:



Hence the third oxygen reduces the lability of a proton and increases pK_D itself.

In the bis-(β-diketones) series $[(RCO)(R'CO)CH]_2CHR''$ with $R = R' = CH_3$ the compound with $R'' = 4\text{-}CH_3OC_6H_4$ has a higher value of pK_D than the compound with $R'' = C_6H_5$ (11, 62, and 11.1 respectively), which is attributed to the activating influence of a methoxy-group. An increase in the electronic density at an α carbon atom in relation to the methylene group leads to a decrease in the lability of the proton. The influence of other electron-repelling substituents can be explained similarly[69]. The differences in the structure of bis-(β-ketones) appear not only in the physical properties but also in their behaviour in chemical reactions.

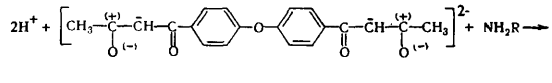
IV. CHEMICAL PROPERTIES OF THE BIS-(β-DIKETONES)

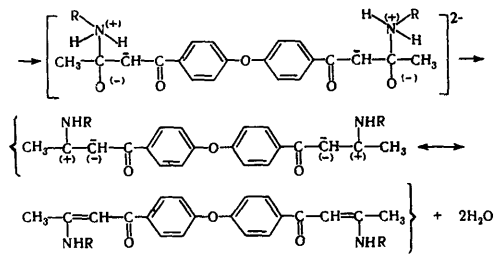
The reactivity of bis-(β-diketones) has been little investigated. As might have been expected from the analogy in structure, the bis-(β-diketones) are greatly reminiscent of β-dicarbonyl compounds. However, there are significant differences in the reactivity of these classes of compounds, which are evidently due to the presence of four carbonyl groups in the molecule of bis-(β-diketones) and of structural features connected primarily with keto-enol tautomerism.

1. Reaction of Bis-(β-diketones) with Amines. Ketoimide–Enamine Tautomerism

The reaction of linear bis-(β-diketones) of the $RCOCH_2CO-Y-COCH_2COR$ type with some aromatic amines has been studied. Thus 4,4'-bis(acetoacetyl)diphenyl oxide reacts vigorously on heating with aniline, 2-naphthylamine, 4-aminobiphenyl, and other amines, forming the corresponding dianils in high yields[72].

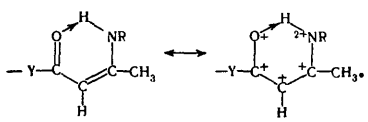
Since the initial 4,4'-bis(acetoacetyl)diphenyl oxide exists predominantly in the enol form, this reaction evidently proceeds owing to polarisation of the bonds of the principal form of the enol, which adds on the amine with subsequent loss of water from the addition product and stabilisation by conjugation:





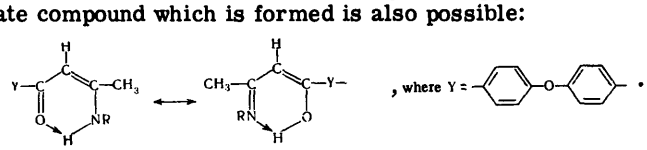
Like the initial 4,4′-bis(acetoacetyl)diphenyl oxide the product of its reaction with an amine can exist in two tautomeric forms, enamine and ketimide:

And, finally, the enamine form, like the enol form of the bis-(β-diketone), forms a pseudoaromatic chelate compound:



The "aromatisation" of the enamine-chelate form with the formation of an aromatic system of 6π-electrons should proceed more readily here than in ordinary enols, since the p-electrons of nitrogen are less firmly held than those of oxygen in the enols.

The existence of intramolecular prototropy in the chelate compound which is formed is also possible:

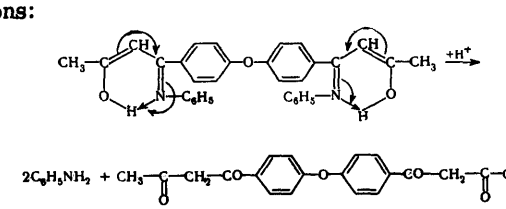


A noteworthy feature, which is characteristic for bis-(β-diketones) and probably for their derivatives, is the complete displacement of the tautomeric equilibrium in solutions, in the solid state, and in melts to the side of one of the possible tautomeric forms.

2. Kolbe Synthesis

Unlike the derivatives of aniline and acetylacetone, the products of the reaction of 4,4′-bis(acetoacetyl)diphenyl oxide with amines are cyclised into derivatives of quinoline with much greater difficulty[72].

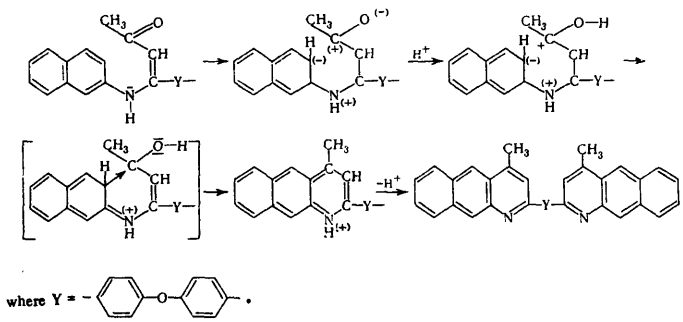
As a result of the reaction the fission of the original dianil into its constituent components is often observed. Evidently, such a direction of reaction can be explained by the fact that displacement of one CH_3 group (acetylacetone) by an aromatic radical (diphenyl oxide residue) leads to the weakening of the nitrogen–carbon bond in the β-arylaminoketone. The presence of an unshared pair of electrons at the nitrogen determines the nucleophilic nature of the NH group and facilitates attack at the side of the hydrogen ions:



The product of the reaction of 4,4′-bis(acetoacetyl)diphenyl oxide with 2-naphthylamine readily undergoes cyclisation under the action of anhydrous HF at 0°C and also on heating with a mixture of 2-naphthylammonium chloride with 2-naphthylamine, forming derivatives of benzoquinoline in ~ 35% yield in both instances. The action of conc. H_2SO_4 brought about hydrammine splitting of the original dianil.

The benzoquinolines obtained by these two methods were not identical in their properties[72]. Evidently under different conditions cyclisation proceeds in different ways.

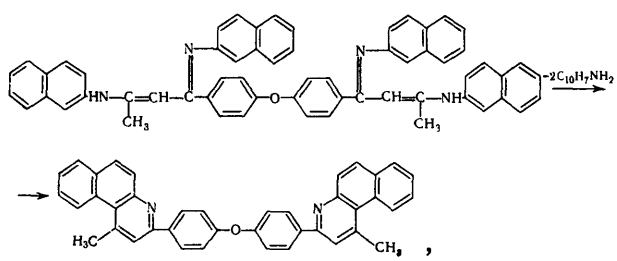
Evidently, under the action of HF a hydroxycarbonium ion is formed which cyclises into an aromatic system when water is lost:



where Y = .

In this system the closure of the naphthalene ring takes place in position 3 and a linear derivative of dibenzo(*g*)quinoline is formed. Its structure is confirmed by the similarity of the ultraviolet spectra of benzoquinoline with the spectra of anthracene, by the characteristic colour of its salts and by fluorescence in ultraviolet light[72].

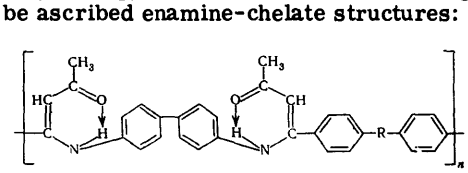
On heating 4,4′-bis(acetoacetyl)diphenyl oxide with 2-naphthylamine in the presence of an equimolecular amount of the amine hydrochloride after Petrov[73], an angular derivative of dibenzo(*f*)quinoline is obtained. Here the reaction evidently proceeds throughout the formation of an intermediate addition compound at the four carbonyl groups:



with subsequent loss of two molecules of 2-naphthylamine.

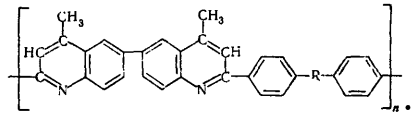
These reactions were extended to aromatic diamines; in particular the reaction of 4,4′-bis(acetoacetyl)diphenyl oxide and 4,4′-bis(acetoacetyl)diphenylethane with benzidine were studied.

Heating a mixture of the initial products leads to the formation of high-molecular-weight polyanils (η_{pr} = 0.6–0.8) which by analogy with the low-molecular-weight products can be ascribed enamine-chelate structures:



where R = –O– or $-[CH_2]_2-$.

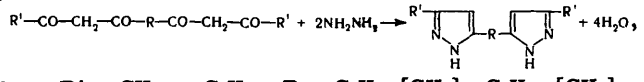
Further heating of the polyanils in a vacuum leads to intramolecular cyclisation and the formation of polyquinolines, with the degree of cyclisation here depending on the temperature and the time of heating in a vacuum[74].



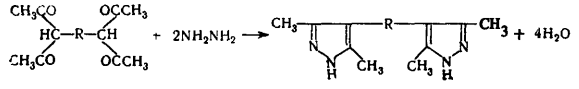
3. Reaction of Bis-(β-diketones) with Hydrazines and Hydrazides of Acids

Bis-(β-diketones) readily undergo condensation, especially with nitrogen-containing compounds (such as hydrazine and its derivatives, hydroxylamine, amidines, urea, etc.), forming addition products at two opposite carbonyl groups of two molecules of the nitrogen-containing compound, with subsequent cyclisation of the addition product and formation of heterocyclic systems: pyrazole, isoxazole, etc. The condensation products, like the original bis-(β-diketones), exhibit tautomerism.

a. Bispyrazoles. 3,5-Bispyrazoles are formed in the reaction of linear and branched bis-(β-diketones) with hydrazine hydrate according to the following scheme[55,75-77]:



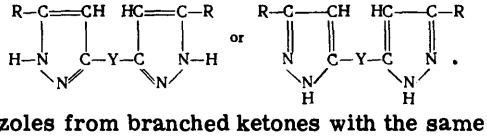
where R′ = CH_3 or C_6H_5; R = C_6H_4–$[CH_2]_2$–C_6H_4, $[CH_2]_3$, C_6H_4–O–C_6H_4, or C_6H_4–S_2–C_6H_4.



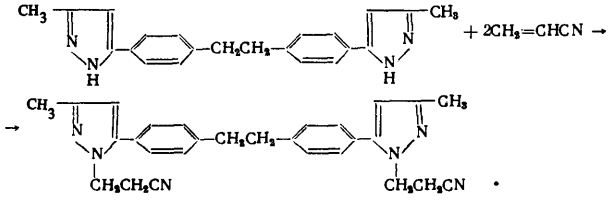
where R = CH_2–C_6H_4–CH_2, $CH_2[C_6H_4]_2CH_2$, or CH_2–C_6H_4–O–C_6H_4–CH_2.

An intermediate product of the reaction is evidently the bishydrazone formed in the reaction of the carbonyl groups of the ketone with the amino-group of the hydrazine, which then closes into a pyrazole ring.

Since the bispyrazoles of linear bis-(β-diketones) have different substituents in positions 3 and 5, two structural isomers are possible:



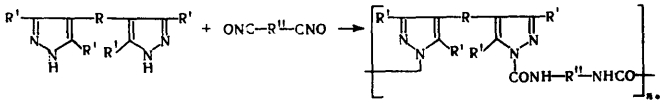
Bispyrazoles from branched ketones with the same substituents do not have isomers, thanks to the symmetry of the molecule. Bispyrazoles, like pyrazoles, form salts with strong bases (for example, hydrochlorides) they are capable of undergoing cyanoethylation, acylation, etc. The cyanoethylation of 4,4′-bis-[3(5)-methylpyrazolyl-5(3)]diphenylethane on heating it with acrylonitrile in an ampoule has been described[75]:



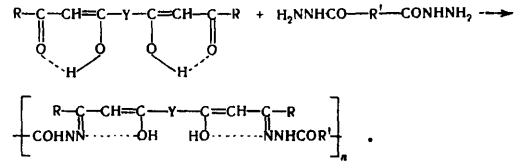
When bispyrazoles react with acetyl chloride, the corresponding *N*-acyl derivatives are formed[75,78-80].

The replacement of the acetyl chloride in this reaction by the acyl chlorides of dicarboxylic acids leads to the formation of polyacylpyrazoles[76].

When di-isocyanates are used instead of the dicarboxylic acid chlorides polymers containing pyrazole rings and amide bonds –CO–NH– in a chain were obtained[87]:



b. Polyacylhydrazones and polyacylpyrazoles of linear bis-(β-diketones). The reaction of linear bis-(β-diketones) with hydrazides of dicarboxylic acids leads to the formation of polyacylhydrazones:

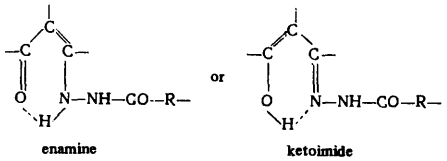


Evidently the formation of polyacylhydrazones takes place analogously to the reactions of monocarbonyl compounds with such reagents as semicarbazide, hydroxylamine, amines, etc., that is, through the addition of the amino-group of the hydrazide at the >C=O bond, with subsequent loss of water. Therefore such reaction will proceed more readily with a ketonic or *trans*-enolic form of a bis-(β-diketone) having a free carbonyl group and with greater difficulty with *cis*-enols in which the carbonyl group is connected by an intramolecular hydrogen bond into a stable six-membered ring.

The polyacylhydrazones which have been formed also have a chelate structure stabilised by an intramolecular hydrogen bond, which is shown by the presence in the ultraviolet spectrum of a polyacylhydrazone of absorption in the range λ_{max} = 335 nm; the band with λ_{max} at 300 nm is ascribed to the presence of a *cis*-enol with a stable hydrogen bond[40].

In the infrared spectrum of polyacylhydrazone as well as an intense absorption band in the 1720 cm^{-1} range attributable to the vibrations of a hydrazide C=O group there is a maximum in the range 1600–1620 cm^{-1} characteristic for a *cis*-enol[75].

The enolisation of polyacylhydrazones can be effected both as a ketomide and as an enamine structure[82]



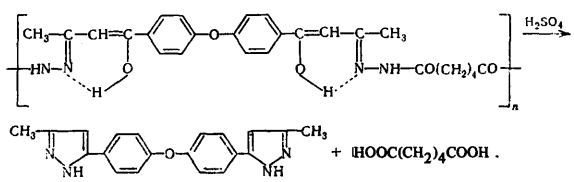
enamine ketoimide

and it is difficult to choose between these. Both these structures are stabilised by intramolecular hydrogen bond, which makes further attack by nitrogen on the carbonyl oxygen more difficult in the formation of a pyrazole ring.

Having investigated the kinetics of the formation of polyacylhydrazones by the example of the reaction of 4,4′-bis-(acetoacetyl)diphenyl oxide with the dihydrazide of adipic

acid in dimethylformamide solution at 90–120° was investigated by ultraviolet spectroscopy. It was shown that under the chosen conditions the process obeys the laws of a first order irreversible reaction. The rate constants and the activation energy of the process (17 kcal mole^{-1}) were determined[83].

The polyacylhydrazones are stable to long boiling in water and also to brief action by conc. H_2SO_4 (5–10 min). After 24 h in a solution in H_2SO_4 at room temperature polyacylhydrazones form the corresponding bispyrazoles and an acid, in quantitative yield:



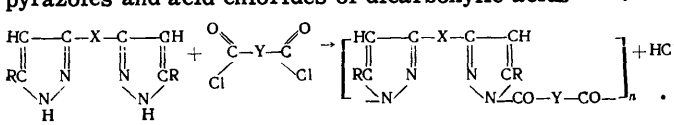
On treating polyacylhydrazones with hot hydrochloric acid the bispyrazolium chloride is formed. Concentrated solutions of alkalis also decompose the polyacylhydrazones.

The structure of the polyacylhydrazones was confirmed by comparing their ultraviolet spectra in H_2SO_4 with the ultraviolet spectrum of a model compound—4,4′-bis(acetoacetyl)diphenylethane acetylhydrazone. The ultraviolet spectrum of the polyhydrazone based on sebacylbisacetophenone in methanol is similar to the spectrum of the model compound in methanol, but has a bathochromic shift of 40 nm.[75]

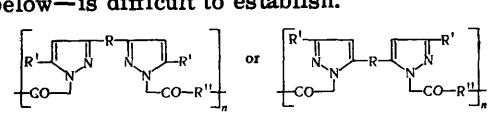
Heating polyacylhydrazones in an atmosphere of inert gas in a vacuum at 200–250°C for 3–5 h leads to the formation of polyacylpyrazoles in quantitative yield. Polyacylpyrazoles are yellow powders soluble in cresol, dimethyl sulphoxide, dimethylformamide, and sulphuric and formic acids.

Polyacylhydrazoles exhibit stability to hydrolysis by boiling water and to the brief action of conc. H_2SO_4. At room temperature polyacylpyrazoles are unchanged after several days action by 25% KOH solution; boiling for 12 h in the same alkali solution leads to complete destruction of the polymer. The bispyrazole formed as a result of hydrolysis is identical with the known product obtained from a ketone and hydrazine hydrate.

The production of bispyrazoles in the hydrolysis of polyacylpyrazoles with almost quantitative yield is confirmation of the structure of the polymers as linear macromolecules with repeated pyrazole rings. Proof of the correctness of the structure attributed to the polymers was also obtained in studying their ultraviolet and infrared spectra and also by counter-synthesis of the polyacylpyrazoles from bispyrazoles and acid chlorides of dicarboxylic acids[84–86]:



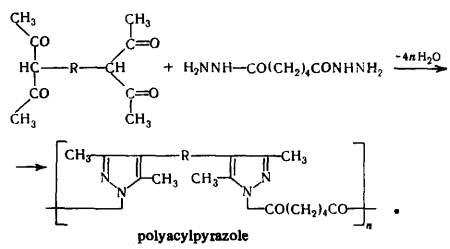
It is noteworthy that the precise position of the enol hydroxyl in bis-(β-diketones)—which determines whether the polyacylpyrazoles formed have one of the two structures shown below—is difficult to establish.



poly-1,3-pyrazole poly-1,5-pyrazole

However, Lowe and Ferguson[87] have shown convincingly that in benzoylacetone the carbonyl adjacent to the phenyl ring is enolised. Therefore of the two possible isomeric structures the poly-1,5-pyrazole structure must be considered the more probable, since linear bis-(β-diketones) can be considered to be analogues of benzoylacetone.

c. Branched bis-(β-diketones). The reaction of branched bis-(β-diketones) with hydrazides of dicarboxylic acids can be effected both in solution and in the melt. Branched bis-(β-diketones), as might have been expected, were much more reactive than the linear ones. 1,4-Bis-(2,2′-diacetoethyl)benzene, 4,4′-bis-(2,2-diacetoethyl)biphenyl, and 4,4′-bis-(2,2-diacetoethyl)diphenyl oxide exist predominantly in the ketonic form and react with adipic hydrazide very vigorously, forming polyacylpyrazoles directly under mild conditions; the intermediate polyacylhydrazones could not be isolated.

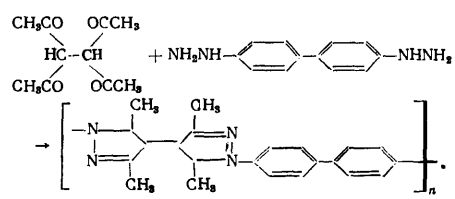


polyacylpyrazole

1,1,2,2-Tetra-acetylethane is an exception to the series of branched bis-(β-diketones), since it exists exclusively in the *cis*-enol form. On reacting with the hydrazide of adipic acid it forms a polyhydrazone comparatively readily, but attempts to cyclise this were unsuccessful. 1,1,3,3-Tetra-acetylpropane behaves similarly: it readily forms a polyhydrazone, which under different cyclisation conditions forms the same product, corresponding to a mixture of 50% polyhydrazole and 50% polyhydrazone.

According to the infrared and PMR spectra this ketone is 50% enolised[51]. However, tetra-acetylethane and tetra-acetylpropane readily form bispyrazoles with hydrazine hydrate, from which the corresponding polyacylpyrazoles were obtained by polycondensation with adipoyl chloride[85].

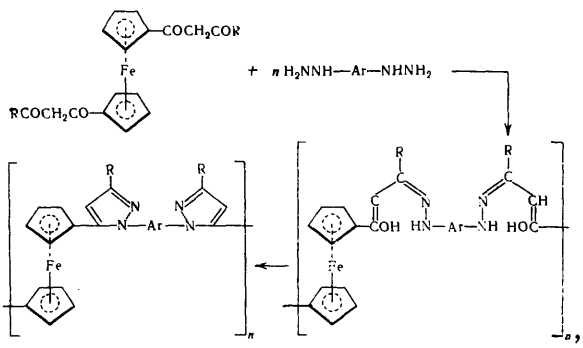
High-molecular-weight thermally stable polyarylenepyrazoles were obtained by heating bis-(β-diketones) with dihydrazines (for example, with 4,4′-dihydrazinobiphenyl). They exhibit high stability to hydrolysis by water and the action of acids and alkalis[88]. Their formation can be represented in general by the following scheme:



The structure of these polymers was demonstrated by the investigations of Mosby[55], and of Schaefer and Bertram[89].

By low-temperature condensation of 1,1′-bis(diketo)ferrocenes with aromatic or pseudoaromatic dihydrazines in solution, Neuse[90] obtained soluble polyhydrazones with a molecular weight of 1500–2000 and a viscosity of ~ 0.1–0.2 dl. g^{-1}. By thermal treatment at 200–240°C these polyhydrazones undergo cyclisation with the formation of

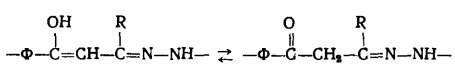
polymers containing pyrazole heterocycles substituted in positions 1 and 5:



where R = H, CH_3, C_6H_5; Ar = *m*-C_6H_4, *p*-C_6H_4, *p*-C_6F_4-C_6F_4-*p*, and *p*-C_6H_4-SO_2-C_6H_4-*p*.

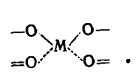
Infusible, but usually soluble, polypyrazoles had a reduced viscosity of 0.15–0.40 dl. g^{-1} and exhibited high thermal stability, exceeding that of other known ferrocene-containing polymers with heterocycles in chains[90].

The investigation of the infrared and electronic spectra of the polyferrocenylhydrazones shows the possibility of the existence in them of keto–enol equilibrium of the type:



and that the formation of a hydrazone includes the predominance of the γ-carbonyl groups of the initial bis-diketo-compound. When R = H the formation of a hydrazone takes place exclusively through the γ-carbonyl; the polymer has weak absorption in the 6.02–6.05 μm range, which is characteristic for aliphatic acyl derivatives of ferrocene in which the Φ–CO–CH_2 group is present. The additional vibrations at 5.75–5.80 μm which show the formation of a hydrazone through the α carbonyl are absent[90].

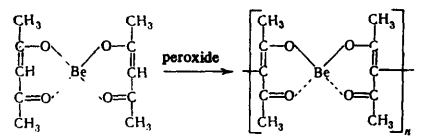
d. Coordination polymers based on bis-(β-diketones). Bis-(β-diketones) of various structure were used in polycoordination which led to the use for the construction of polymeric molecules of coordinate bonds, as well as the ordinary covalent bonds, and to the inclusion of metal atoms in the macromolecule. In this instance the bond between the metal and the ligand is effected through oxygen:



A large number of review articles and original papers deal with the synthesis of coordination polymers are the study of the polycoordination[91–99].

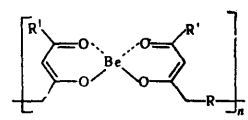
Metals with coordination number 4: copper, beryllium, zinc, magnesium, cadmium, calcium, and also transitional metals: nickel, cobalt, manganese, chromium, titanium, etc., have mainly been used for the synthesis of the coordination polymers.

The production of coordination-chain polymers can be brought about by the reaction of aqueous solutions of salts of the corresponding metals with alcoholic solutions of the bis-(β-diketones)[100] or by heating stoichiometric amounts of the metal acetylacetonate with the bis-(β-diketone) in vacuo or in a high-boiling solvent[101–103]. In the latter procedure the acetylacetone is liberated and a metal derivative of the original tetraketone is formed. Coordination polymers were also obtained by interfacial polycondensation (polycoordination)[104–106] and by polyrecombination of beryllium acetylacetonate[107]:

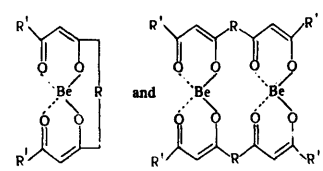


The coordination polymers obtained by the above methods are infusible and insoluble products, which makes it extremely difficult to investigate the mechanism for their formation, and to study their properties and field of application. The molecular weights of these polymers varied within the range 1000–5000, which impeded the appearance of the main polymeric properties: mechanical strength, and ability to form films and fibres.

The coordination polymers of the type:

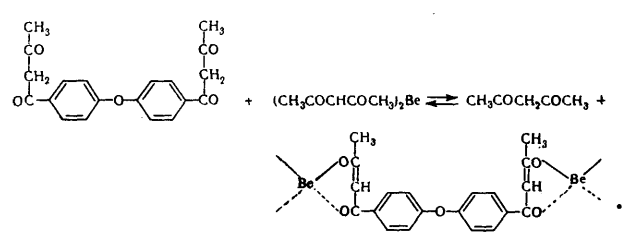


with the highest molecular weights were obtained by the polymerisation of cyclic coordination compounds of beryllium formed in the thermal destruction in vacuo of the low-molecular-weight coordination polymers of the corresponding bis-(β-diketones) and beryllium[13]:



where R′ = CH_3, CF_3; R = $[CH_2]_6$, $[CH_2]_7$, $[CH_2]_{10}$, $[CH_2]_{12}$, $NH[CH_2]_6NH$, $NH[CH_2]_{10}NH$, *p*-$[O(CH_2)_2O]_2C_6H_4$, $O[CH_2]_6O$ (R = CF_3).

The detailed investigation of polycoordination by the example of the reaction of 4,4′-bis(acetoacetyl)diphenyl oxide with beryllium acetylacetonate both in the melt and in solution allowed the main rules for this process to be established. It was found that polycoordination is a form of polycondensation process, which can be carried out at elevated temperature and which is an equilibrium process[101–117]:



Under polycoordination conditions the coordination polymers are capable of undergoing exchange reactions both with the low-molecular-weight product of the polycoordination (acetylacetone) and with low-molecular-weight substances which are similar in chemical nature to the coordination polymer (the acetylacetonate of another metal); exchange reactions also of individual polymeric molecules

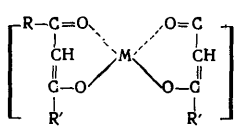
with one another also occur. Finding the main rules of polycoordination made it possible to obtain coordination polymers of high molecular weight[98,99].

A study of the kinetics of polycoordination of 4,4′-bis(acetoacetyl)diphenyl oxide with beryllium acetylacetonate in dimethylformamide solution and in Dinyl showed that this process is a second-order reaction with an activation energy of 25 kcal mole^{-1}.[109]

The properties of the coordination polymers, as for other types of high-molecular-weight compounds, are determined by the flexibility of the polymeric chain, the interfacial interaction, and the stereochemical regularity of the macromolecule. The ionic radius of the metal participating in the formation of the polymeric chain has a considerable effect on the strength of the interchain interaction and the packing density of the macromolecules of coordination polymers of the bis-(β-diketones). When the radius of the metal differs considerably from those of other atoms forming the chain (for the polymers of beryllium) this results in a disturbance of the packing density of the polymeric chains, a weakening of the force of interchain interaction, which in turn determines their best solubility and fusion[112].

The melting point of the coordination polymers of 4,4′-bis(acetoacetyl)diphenyl oxide, 4,4′-bis(acetoacetyl)diphenylmethane and 1,1,2,2-tetra-acetylethane with various metals decreases in the order: Be > Mg > Ca > Zn. The nature of the metal also affects the colour of the polymer[113].

The properties of the coordination polymers of the bis-(β-diketones) depend considerably on the chemical structure of the initial tetraketone, since in all the polymers of the bis-(β-diketones) the same coordination ring



is present, which is a comparatively stable formation in view of the fact that the donor groups coordinated with the metal ion occupy positions fixed relative to one another, the observable differences in the properties of these polymers are determined by the flexibility of the initial ligand and the packing density of the polymeric chains. The flexibility of the bis-(β-diketone) ligand will increase with increase in the number of methylene groups it contains, with decrease in the concentration of aromatic nuclei, with inclusion of aliphatic links between the aromatic nuclei of the tetraketone; the packing density of the polymeric chains will decrease on going from bis-(β-diketones) with aromatic nuclei substituted in the *para*-position, to bis-(β-diketones) with aromatic units substituted in the *meta*-position[99].

An increase in the flexibility of the polymeric chains or a decrease in their packing density owing to the corresponding changes in the structure of the initial bis-(β-diketone) is usually accompanied by a decrease in the thermal stability and an increase in the solubility of the coordination polymers[100,106,111,112].

An improvement in the solubility of the coordination polymers of the bis-(β-diketones) is brought about by the introduction into the ligand molecule of polar substituents on using a six-coordinated metal, four bonds of which participate in the creation of a coordination ring and two are occupied by aromatic radicals[118]. For example, the coordination polymers of terephthalyldiacetoacetic ester with copper, nickel, cobalt, magnesium, zinc, and mercury of the general formula:

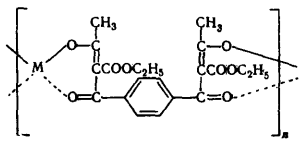


exhibit better solubility than the polymers of terephthalyldiacetone.

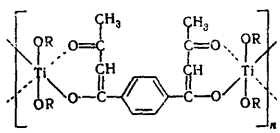
The coordination polymers of tetraethyl and tetra-t-butyl orthotitanates and terephthalyldiacetone of the structure



exhibited solubility in xylene[118].

The infrared spectra of polymeric copper chelates of bis-(β-diketones) have been studied[119].

I. INTRODUCTION

The chemistry of the phosphazenes, derived initially from the work of Liebig[1], has shown considerable developments in recent years, due on the one hand to the scientific interest in this independent class of compounds and on the other to the great practical value of many phosphazene compounds, especially the polymers. A review[2] published in 1943 cited 73 references; the exhaustive review of Shaw and coworkers[3] published 19 years later had 397 references and after four more years the number of publications and communications in this region had increased almost twofold[4].

The reviews published earlier[2-10] did not contain thorough and critical considerations of the phosphazene polymers. The published reviews of phosphazene polymers[11-14] are restricted to an examination of the various types and classes of polyphosphazenes.

In recent years much new material on the synthesis, structure, and properties of polymeric phosphazenes has accumulated and shows the separation of this division of phosphazene chemistry into a separate branch of the chemical science of polymers, a branch which is of independent interest.

The present article is an attempt at a more detailed review of the latest approaches in the chemistry of phosphazene polymers without considering cyclic and linear oligomers and methods of obtaining them, and a new classification for these polymers is also proposed.

II. CLASSIFICATION OF POLYPHOSPHAZENES

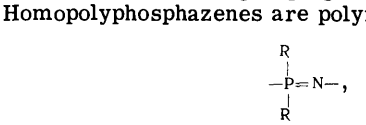
The first attempt at the classification of the phosphazene polymers was made by Shaw[15], who proposed to divide them into two classes: (1) polyphosphazenes obtainable by the polymerisation of cyclic phosphazenes; (2) polyphosphazenes obtainable by polycondensation; the latter, in turn, are subdivided into those which can be synthesised by the homopolycondensation of only phosphazene monomers (for example, phosphams) and the polycondensation of them with other monomers.

Another classification[4] is based on the nature of the substituents connected with the phosphorus atom in phosphazene polymers; according to this they are divided into purely inorganic (polyhalogenophosphazenes, polythioisocyanatophosphazenes) and organo-substituted phosphazenes. However, in using the above two classifications it is difficult to systematise all the various phosphazene polymers.

We think that the appearance in recent years of new and numerous types of phosphazene polymers enables the classification proposed earlier to be reconsidered and the classification adopted to be based on the structure of the macromolecule of the polymers and not on their method of production or the nature of their lateral substituents.

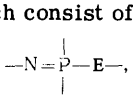
We think that the structural-chemical classification of high-molecular-weight compounds proposed by Korshak[16] is more correct in principle for systemising the polyphosphazenes. In accordance with this principle all the polyphosphazenes can be divided into three large classes: homopolyphosphazenes, heteropolyphosphazenes, and polymers with phosphazene groupings in the side-chain.

Homopolyphosphazenes are polymers of the type

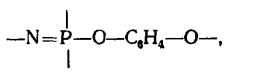


the main chain of the macromolecules of which is constructed from alternating phosphorus and nitrogen atoms, and the lateral radicals can be inorganic (halogens, isothiocyanate groups), or organic, or organoelemental. Examples of homopolyphosphazenes are the polydichlorophosphazene, polydimethylphosphazene, polydialkoxyphosphazenes, etc.

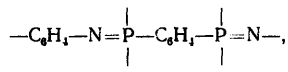
Heteropolyphosphazenes are polymers, the macromolecules of which consist of units of the type



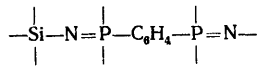
where E represents atoms or groups of atoms other than the phosphazo-group. Examples of the second class of phosphazene polymers include the polyoxyphenyleneoxyphosphazenes



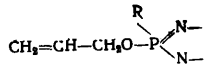
the polyphenylenephosphazenes



and the polyphenylenesilylphosphazenes



Polymers with phosphazene groupings in the side-chain contain macromolecules with a main carbo- or hetero-chain and phosphazene groups in the side-chain. Such polymers are obtained by the polymerisation of unsaturated organic derivatives of phosphazenes, for example:

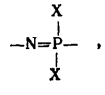


Our proposed classification of the polyphosphazenes is analogous to that generally accepted in the chemistry of organic and organoelemental polymers; it is mainly based on a constant criterion of these polymers—the structure of the macromolecules. This classification allows both the known phosphazene polymers and polymers which may appear in future to be systematised.

III. HOMOPOLYPHOSPHAZENES

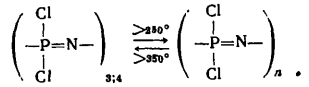
1. Polyhalogenophosphazenes

Linear polyhalogenophosphazenes are inorganic polymers with an elemental unit of the macromolecule of the structure



where X is Cl, Br, or F. These polymers are distinguished primarily by high thermal stability and fire resistance, although they are of limited practical use owing to low stability towards hydrolysis. Nevertheless the finding of the main rules for the formation of halogenophosphazene polymers always was and is still an extremely important task. A knowledge of these rules could open the path to the production of such linear polymers and rubbers with highly elastic macromolecules, combined with good thermal stability, materials which are needed by modern technology.

As long ago as 1870 Wichelhaus[17] observed the formation of a resinous substance on heating hexachlorocyclotriphosphazotriene (HCP). Later, Stokes[18] noted, in studying the polymerisation of cyclochlorophosphazenes with 6–12 atoms in the ring, that it proceeds very slowly at 250°C and rapidly at 350°C, while depolymerisation of the polymer starts at not much above 350°C:



Stokes also noted the decomposition of polychlorophosphazene by hot water.

Schenk and Romer[19] observed the polymerisation of HCP and octachlorocyclotetraphospazotetraene (OCP) from 250° to 350°C and described the physical properties of the polychlorophosphazene rubber, which is colourless when pure, transparent, insoluble in organic solvents, but swells strongly in benzene and is stable in the cold to the action of inorganic acids. Under the action of water this polymer loses its elasticity, being converted into a brittle mass. It was also found that linear oily oligomers can also be converted into a rubber but below 200°C.

Renaud[20–23] studied the polymerisation of HCP and made an X-ray diffraction investigation of the polymers which are formed; according to his results these polymers had an amorphous or a crystalline structure. The effect of the polymerisation temperature on the molecular weight of the polymers formed was noted; their glass formation temperature was −47°C.

Detailed study of the physical properties of the polychlorophosphazene rubber were carried out by Meyer and coworkers[24–27]. Various polyhalogenophosphazenes were examined. Meyer[24] found the most probable position of the phosphorus and nitrogen atoms in the macro-chain. On the basis of the X-ray diffraction investigations of chlorophosphazene rubber, a fibrous structure was proposed for it, amorphous in the unextended state and crystalline when stretched. As was shown, the main valencies of the macromolecule

are arranged in a direction parallel to the axis of the fibre with an identity period of 5.16 Å, which corresponds with two elemental units.

The thermoelastic properties of the polychlorophosphazenes suggest the existence of spiral, flexible, long chains[25–27], with the molecular weight, calculated from the thermoelastic properties, equalling 20 000.

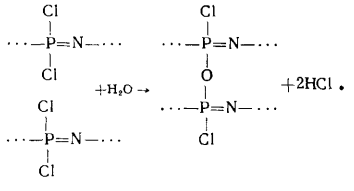
From the X-ray results the P–N–P bond angle in a rubber macromolecule was found to be equal to the N–P–N angle, 124°.[28] From its physico-mechanical properties, freshly-prepared chlorophosphazene rubber is not inferior to organic rubbers[26,27].

Ficquelmont suggested[29] that the polychlorophosphazenes consist of cross-linked macromolecules and the gradual decrease in their elasticity is connected with the crystallisation processes. When heated carefully to 500°C the rubber is converted into a black, infusible, insoluble product. Later[30], a tendency to a more rapid crystallisation of the polymerisation product from pure HCP than of the polymer from a mixture of low-molecular-weight homologues was observed.

In a subsequent paper Ficquelmont[31] noted that the polymerisation of cyclic chlorophosphazenes and the depolymerisation of the rubber are equilibrium processes. Schmitz-Dumont[32,33] concluded that in the polymerisation of HCP and OCP true equilibrium exists only in the gas phase. When cyclochlorophosphazene vapour was heated to 600°C a rubber was not formed, but a mixture of HCP, OCP, and higher homologues in crystalline and liquid states was obtained.

These results were confirmed by Moureu and Ficquelmont[34], who determined the molar heat of vaporisation on the elemental unit $PNCl_2$, equal to 15.5 kcal, and showed the impossibility of reaching high polymerisation coefficients in the gas phase.

Specker[35,36] investigated the physico-mechanical properties of the polychlorophosphazene rubber in the light of Kuhn's kinetic theory. The elasticity modulus was found to be proportional to the temperature in the range from −60° to 160°C, Specker found the elasticity modulus of rubber to be 2–4.2 kgf cm^{-2}. Values of the elasticity modulus close to these limits were also found later[37,38]. The molecular weight of rubber calculated by Kuhn's formula was 80 000, which corresponds to 700 $-PNCl_2-$ units. Specker considers[36] that the increase in the elasticity modulus of polychlorophosphazene is connected not with the crystallisation of the rubber but with the hydrolysis of the polymeric molecules and the formation of a lattice structure:



The first investigations of the kinetics of the thermal polymerisation of HCP were made by Schmitz-Dumont[33]. Systematic and detailed studies in this direction were made by Patat and coworkers[39–42].

Patat and Kolinskii[39] investigated the polymerisation of cyclic chlorophosphazenes in hydrocarbon solvents in the presence of oxygen at 250–350°C. They thought that the oxygen was responsible for the initiation of polymerisation, breaking of the chain, and the cross-linking of the macromolecule. However, it was found later[41] that polymerisation of sufficiently pure cyclochlorophosphazenes in the absence of oxygen takes place by a radical mechanism with homolytic breaking of the P–N bond in the ring as a second-order reaction with an activation energy of 42 kcal mole^{-1}.

Abel[43], who found that the reaction order of block polymerisation of cyclochlorophosphazenes is between 1 and 2, doubted the radical mechanism of this process.

Patat and Derst[42] found that depolymerisation of polychlorophosphazene rubber is a first-order reaction with an activation energy of 26 kcal mole^{-1} and a rate independent of the presence of oxygen. Nevertheless they stated that the depolymerisation had a radical character but with peculiarities connected with the structure of the rubber. They suggested that polychlorophosphazene is constructed from small cyclic molecules connected with one another. Such a structure for the rubber explains its high molecular weight and insolubility. In depolymerisation, as a result of the homolytic breaking of bonds these rings are freed from one another forming small cyclic molecules. The depolymerisation of higher linear halogenophosphazenes can generally be used as an effective method for obtaining the lower cyclic homologues[44,45], the yields of the individual phosphazenes decreasing with increase in the size of the ring, so the amounts of the cyclic tri-, tetra-, penta-, hexa-, and hepta-mers formed in the depolymerisation of the polychlorophosphazene are[44] in the ratio 20 : 15 : 8 : 5 : 1.

In investigating the block polymerisation of HCP at 275–350°C and the hydrolysis of polychlorophosphazenes Gimblett[46] concluded that polymerisation takes place in the gas phase by a radical mechanism and the breaking of the chain is effected in the block as a result of recombination. Chain-transfer reactions should also take place in the block through the polymer molecule with the formation of branch and lattice structures[46]. The effect on the thermal polymerisation of HCP of its concentration, the temperature of the process, and the reactor material has been shown[47]. The polymerisation is described by an S-shaped kinetic curve.

Shaw[48] suggested that if this reaction also involves free radicals their concentration is very low.

The radical mechanism of polymerisation came under even greater doubt after an investigation of the radical polymerisation of industrial HCP under the influence of γ-radiation[49] and of the polymerisation of pure HCP under the action of ultraviolet radiation[50] or of a beam of accelerated electrons[51], since in every instance of polymerisation either polymerisation was not observed or low-molecular-weight oligomers were obtained.

As is well known, cyclochlorophosphazene molecules contain P–N and P–Cl polar bonds. Therefore the initiation of polymerisation is probably connected with the heterolysis of some bond and the ionic initiation of chain growth. This view was first advanced by Konecny and coworkers, who studied the catalytic polymerisation of cyclochlorophosphazenes[52], and by Gimblett[53] who, in studying the thermal polymerisation of HCP, suggested that the act of initiation is the breaking of the P–Cl bond in HCP by the reaction:

$$P_3N_3Cl_6 \rightleftarrows P_3N_3Cl_5^+ + Cl^-,$$

and the chloride ion is responsible for the chain growth.

Further investigations of the electrical conductivity of HCP[54], its ability to form pyridinium salts[55] and pyridine complexes with Lewis acids[56] confirmed the suggestions about the possibility of heterolytic breaking of the P–Cl bond in HCP.

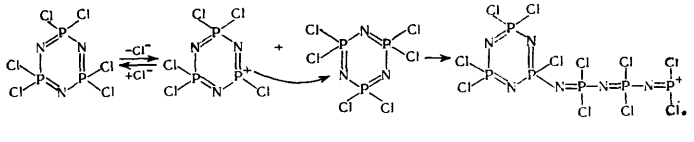
A study of the mechanism of thermal polymerisation of HCP with the aid of the EPR method and by measurements of the capacity, electrical conductivity, and dipole moments of HCP melts at various temperatures, also confirmed the ionic nature of the thermal polymerisation of the cyclochlorophosphazenes[57].

Table 1. Electrical conductivity of $(PNCl_2)_3$ and $[PN(OC_6H_5)_2]_3$, 10^{11} mΩ cm^{-1}.

$P_3N_3Cl_6$		$(PN(OC_6H_5)_2)_3$		$(PN(OC_6H_5)_2)_3$	
°C	conductivity	°C	conductivity	°C	conductivity
120	1.7	120	1.5	163.5	4.8
163	1.7	165	3.5	139	2.4
203	33	203.5	4.3	350	316
253	6250	252	17.7	120	17.7
202	2900				

Measuring the EPR in the range from 25° to 250° did not show free radicals in a melt of the trimer; the dielectric constant alters slightly under these conditions (from 2.52 to 4.85). However, the conductivity changes very sharply, especially above 200°C (Table 1). For comparison, Table 1 gives the change in conductivity of a control compound—hexaphenoxycyclotriphosphazotriene which does not polymerise in the temperature range studied[57].

These results convincingly support an ionic mechanism for the polymerisation of HCP. Unlike Gimblett's hypotheses[53], Allcock and Best[57] consider that the growth of the chain of cyclic cations is brought about by the positive charge on the phosphorus atom, which attacks a nitrogen atom of a new phosphazene ring, starting chain growth:



This mechanism also provides a reason for the formation of a three-dimensional polymer: the terminal group of the growing chain is a ring, which can also undergo electrophilic attack by the growing end of another macrochain, giving the beginning of branching.

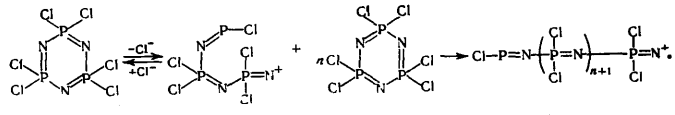
A mass-spectrometric study of the products of the decomposition of cyclochlorophosphazenes by Brion and Paddock[58] showed that a compound of ionic type $P_nN_{n+1}Cl^-_{2n+1}$ is formed predominantly.

Heterolysis of the P–Cl bond in linear molecules of polychlorophosphazenes is evidently also the reason for their depolymerisation at higher temperatures. It cannot be ruled out that this process can be effected at any part of the chain. The following results suggest that polymerisation and depolymerisation of chlorophosphazenes are equilibrium reactions[59]: (1) when held separately at 600°C the linear polychlorophosphazene and a mixture of the trimer with tetramer (HCP and OCP) both form a mixture of linear and cyclic chlorophosphazene oligomers of the same composition[33]; (2) with increase in the temperature the proportion of the polymer in the equilibrium mixture drops and that of the lower rings rises; (3) an increase in pressure favours the formation of a polymer[60]; (4) the polymerisation of cyclic chlorophosphazenes $(PNCl_2)_{3-7}$ is endothermic and ΔH_{polym} decreases with increase in the size of the ring, amounting to 1.39 kcal mole^{-1} for the trimer and 0 for the hexamer[61].

Evidently, as for other inorganic polymers the polymerisation of chlorophosphazenes and depolymerisation of polychlorophosphazenes includes an equilibrium between all the homologues $(PNCl_2)_n$ with n from 3 to 15 000 and the direction of the process is determined by the change in free energy $\Delta G = \Delta H - T\Delta S$, that is, by the change in the entropy and enthalpy of the system[62]. Kinetic factors must also be taken into account[63].

Probably the depolymerisation of polychlorophosphazenes takes place with participation of ionic terminal groups; possibly the high polarity of the bonds in the main chain of the macromolecules of the polychlorophosphazene also permits the rearrangement of the bonds, as is observed with the polysiloxanes[64].

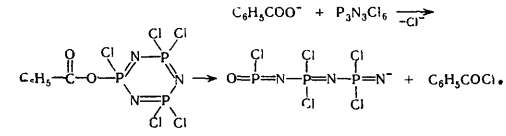
Konecny and Douglas[50] first observed the catalytic action of many organic compounds and metals in the polymerisation of cyclochlorophosphazenes. It was noted that the polymerisation of GCP is also brought about by t-butyl peroxide, but here the catalysis cannot be ascribed to the decomposition of peroxide into radicals, since at 210°C its half-decomposition period is very short whereas the polymerisation occurs in a few hours. The reaction also proceeds similarly in the presence of ammonium persulphate[65]. The investigation of the polymerisation of cyclochlorophosphazenes in the presence of benzoic acid, diethyl ether, and alcohols[52] suggested that the initiating act of chain growth is the heterolysis of HCP molecules (or other rings) at the P–N bond with formation of an active electrophilic centre at the nitrogen atom



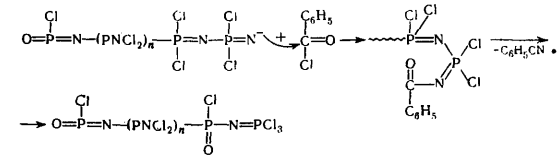
Gimblett found that oxygen does not affect the rate of catalytic polymerisation of HCP in the presence of benzoic acid; this polymerisation can be described by a first-order equation with an activation energy of 27.3 kcal mole^{-1}.[66]

A study of the kinetics of block polymerisation of HCP at 240–250°C showed it to be a second-order reaction with activation energy of 57 kcal mole^{-1}.[67]

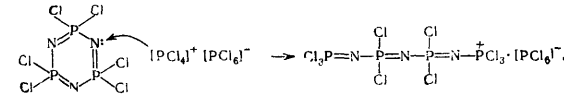
An investigation of the effect of benzoic acid and its salts on the polymerisation of HCP was made[67]. On the basis of the analysis of the volatile products of the polymerisation and of the previously established nature of interaction of salts of benzoic acid and HCP[68] it was suggested that the most probable mechanism includes attack by the benzoate anion on the HCP molecule and its opening by the scheme



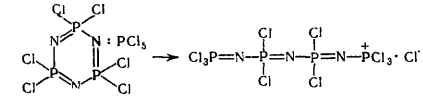
The linear anion formed reacts with HCP molecules starting the chain growth. The breaking of the chain is represented as follows:



This anionic mechanism is evidently specific for the action of benzoic and other carboxylic acids. Sometimes cyclochlorophosphazenes are polymerised in the presence of Lewis acids. The first report of the conversion of cyclic chlorophosphazenes into linear ones on heating with PCl_5, $AlCl_3$, $FeCl_3$, and other chlorides appeared in 1959.[69] Later it was stated in a patent[70] that such a process is brought about by heating cyclochlorophosphazenes in an autoclave at temperatures above 250°C with various iron, phosphorus, aluminium, and antimony chlorides, etc. After Becke-Goering and coworkers[71,72] had established the structure and mechanism of formation of linear chlorophosphazenes, the nature of the processes thus occurring became evident, which for PCl_5 can be represented as follows. Cyclochlorophosphazene (for example, HCP) are attacked by the $[PCl_4]^+$ cation with opening of the ring:

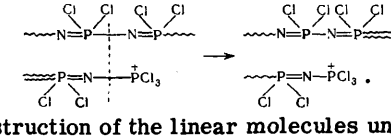


Chain growth takes place similarly with attack by a linear growing cation of the cyclic molecules until disappearance of the cyclophosphazene. Ring opening may precede its formation of a complex with PCl_5:



Here there is a chloride anion instead of a hexachlorophosphate anion. With other chlorides there is evidently similar opening of the rings[73].

Probably the terminal cationic groups of linear molecules react not only with cyclic molecules but also with linear macromolecules especially after the chlorophosphazenes have been used up:



This destruction of the linear molecules under the action of the terminal groups will, as for many polycondensation organic polymers, lead to the formation of an equilibrium mixture containing linear and cyclic chlorophosphazenes[74].

Even in the preparation of chlorophosphazenes by the ammonolysis of PCl_5 part of the linear oligomers can split off cyclised short-chain fragments [75].

Above 250°C equilibrium is reached rather rapidly—after 1–2 h. [70] The amount of chloride in the reaction mixture will determine the molecular weight of the linear chlorophosphazenes which are formed.

Considering the above possibility of polychlorophosphazene distribution as a result both of terminal group reactions and the intrachain rearrangement of bonds, the possibility of interchain exchange leading to the formation of an equilibrium mixture of linear molecules must also be admitted. Catalytic breaking of the macromolecules under the action of other reagents, for example, chlorine, is also possible at the same time.
