Kinetics of Homogeneous Reactions in Reaction Vessels with Ideal Mixing (Open Systems)

I.P.Skibida, Z.K.Maizus, and N.M.Emanuel'

The main kinetic features of chemical reactions occurring in flow systems with complete mixing are surveyed. The advantages are discussed of conducting a reaction in a flow system with stirring as compared with reactions under static conditions in a laminar flow. Considerable attention is paid to the establishment of oscillatory (pulsating) régimes. The dependence of the steady-state concentrations on the reaction conditions is examined, as also the kinetics of the establishment of a steady-state. A considerable part of the review is devoted to investigating the possibilities presented by open systems for studying the mechanism of chemical reactions and determining the rate constants of individual elementary stages in complicated chain processes. A list of 70 references is included.

I. INTRODUCTION

Investigations of the kinetics of reactions in open systems, with continuous supply of the starting materials and withdrawal of the reaction products, arouse great interest in connection with the opportunities created for studying the mechanism of chemical reactions. These investigations are also of fundamental value because data on the mechanism and kinetics of reactions occurring in an open system are necessary for the design of present-day automatically controlled technical processes.

When a process is conducted under static conditions, certain quantities of starting materials are introduced into the system, and then undergo several chemical changes. In this case both the starting materials and the reaction products remain within the system: i.e. they do not leave

the reaction zone. The process is complete in a time determined by the quantity of starting materials taken and the rate constants of their conversion. The steady state, which is reached in some cases, represents the establishment of thermodynamic equilibrium. In an open system the unlimited supply and withdrawal of all the components of the reaction make it possible to establish a steady state differing from the thermodynamic equilibrium and characteristic not only for reversible but also for unidirectional reactions.

Processes with continuous supply and withdrawal of reactants can be conducted in two fundamentally different ways—under conditions of ideal (or complete) displacement and under conditions of ideal (complete) mixing†.

A vessel having ideal displacement is a reaction vessel into which a mixture of the reactants is introduced, and the reaction mixture is removed when a particular degree of conversion has occurred. Diffusion of the reactants in a vessel of ideal displacement should be reduced to a minimum. The composition of the reaction mixture in a given element of volume is determined solely by the extent of chemical reaction and varies along the length of the vessel. The residence time of all species in the reaction zone (the "contact time") is the same. Henceforward reactions occurring in vessels with ideal displacement will be termed "reactions in a flow".

The study of reactions in a flow is greatly complicated at high temperatures by convection currents and the presence of temperature gradients.

The second type of reaction vessel for conducting a reaction in a flow system is a "vessel with ideal mixing" (a "gradient-free reaction vessel"). In a vessel with ideal mixing the composition of the reaction products at a given time should be kept uniform throughout the volume by diffusion or by special mixing of freshly arriving substances with the partly reacted mixture. Such systems are also termed "open systems", since, in contrast to reactions in a streamlined flow, any given element of volume of the reaction mixture is "open" to freshly arriving substances. Change in the composition of the reaction mixture occurs not only as a consequence of chemical reaction but also as a result of the additional introduction of starting materials and reaction products from adjacent volumes. The residence times of species in the vessel are not the same. The mean residence time τ of species in the reaction volume is taken to be the reciprocal of the rate of supply of the starting materials to unit volume: i.e. $\tau = V/u$, where V is the volume of the reaction vessel and u the volume rate of supply of the reactants.

Both principles of an unenclosed system—reaction vessels of ideal displacement and of ideal mixing—are used in chemical technology. The latter are employed particularly in heterogeneous catalytic reactions and in other reactions involving solid particles, occurring in a "fluidised bed".

Several other chemical reactions can be more suitably conducted either in a laminar flow or with some definite degree of diffusion, which eliminates laminarity but does not guarantee complete mixing. However, it is fairly difficult to achieve conditions of complete laminarity and especially of a specified degree of diffusion, and in some cases, therefore, it is preferable to conduct the processes in several reaction vessels of ideal mixing connected in series.

† There may also be intermediate types of reaction vessels, with breakdown of laminar flow but not complete mixing.

To study reaction mechanisms it is also more convenient to use a "gradient-free reaction vessel", since the study of reactions in a streamlined flow requires either the careful elimination of or allowance for diffusion, the latter leading to rather unwieldy equations, which cannot be integrated in quadratures even for simple types of reactions.

The use of flow systems with complete mixing to investigate the kinetics of chemical reactions was initiated in 1905 by Bodenstein's work[1] on the kinetics of the reaction $H_2 + I_2 \rightleftharpoons 2HI$.

Conducting a reaction in a gradient-free reaction vessel enables the set of differential equations to be reduced to a set of algebraic equations, which considerably simplifies the task of determining the rate constants of complicated reactions.

Conducting a process in an open system has a further advantage over reactions under static conditions and in a laminar flow: it becomes possible to study processes over a considerably wider temperature range, since the continuous supply of starting materials to the system eliminates the possibility of the starting materials being completely burned up.

The present review will give an account of the main kinetic laws of homogeneous reactions occurring under conditions ensuring complete mixing with continuous supply and removal of substances to and from the reaction zone. We shall not discuss the kinetics of the series of heterogeneous processes in a flow examined in the works of Boreskov, Slin'ko, Temkin, Ioffe, Panchenkov, Nagiev, and other authors[2-6].

II. STEADY STATE IN AN OPEN SYSTEM

Various types of reaction vessel, with and without stirrers, can be used[7,8] to investigate homogeneous reactions in a flow with complete mixing, depending on the type of reaction and the necessary range of variation in flow rates.

For very rapid processes the completeness of mixing can be judged from the kinetics of the accumulation of reaction products being independent of the rate of mixing. With slower processes a method can be employed[9,10] in which a solution of a substance A, which undergoes no chemical change under the experimental conditions, is fed at a constant rate into a vessel filled with the pure solvent. The kinetics of the accumulation of this substance in the system will be described by the differential equation

$$\frac{d(a/a_0)}{dt} = \frac{u}{V} - \frac{u}{V}\left(\frac{a}{a_0}\right) \qquad (1)$$

where a_0 is the concentration of A in the solution fed into the vessel, u the volume flow rate, and V the volume of the system. Integration of Eqn. (1) yields

$$\ln\left(\frac{a_0}{a} - 1\right) = -\frac{u}{V} \cdot t \qquad (1a)$$

which describes the kinetics of the accumulation of A in the system. The slope of the semilogarithmic plot of $\ln[(a_0/a) - 1]$ against t will give the specific rate of supply of the starting materials to the system. Agreement between the experimental value of u/V and the value calculated from the known volume of the reaction vessel and the bulk rate of supply of A to the system indicates that mixing is complete in the vessel.

If a reaction occurring in an open system involves no change in volume, the concentrations both of the starting materials and of all intermediate and final products of the reaction will cease to change some time after the start of

the process: i.e. steady-state concentrations of all the components of the reaction are reached‡. A steady state can be defined as a state in which it is impossible to distinguish any macroscopic changes in the system[11]. Under these conditions the sum of the rates of formation of a product and of its supply to the reaction vessel is equal to the sum of its rates of consumption and removal from the reaction zone.

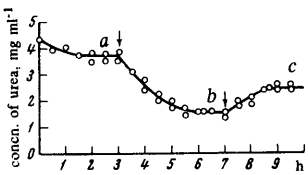

Figure 1. Steady-state concentrations of urea during its decomposition: a) in absence of an enzyme; b) in the presence of additions of an enzyme; c) on deactivation of the enzyme by $AgNO_3$ solution.

Establishment of a steady state in an open system has been observed with several simple and complicated reactions. Examples are the inversion of cane-sugar[9], the initiated polymerisation of styrene[12], the enzymic decomposition of urea[13] (Fig. 1), the decomposition of potassium persulphate catalysed by sulphuric acid[14], and the autoxidation of several hydrocarbons and their derivatives[15-17] (Fig. 2).

1. Time of Establishment of Steady State

If the concentration of a reaction product is zero at the start of a continuous process, the time of establishment of a steady state will depend solely on the rate of supply of the starting materials and the rate constants of the process[14]. The time for establishment of steady-state concentrations of the starting materials will differ from the corresponding time for the reaction products.

Let us examine the kinetics of the establishment of steady-state concentrations of starting material and reaction product in the case of a simple first-order reaction $A \xrightarrow{k_1} B$. The rate of consumption of the starting material A in the system is

$$\frac{da}{dt} = -\left(k_1 + \frac{u}{V}\right)a + \frac{u}{V}a_0.$$

Solution of this equation with the initial conditions $a = 0$ at $t = 0$ yields

$$-(k_1 + u/V)t = \ln\frac{(u/V)a_0 - (k_1 + u/V)a}{(u/V)a_0} = \ln\left(1 - \frac{a}{\bar{a}}\right) = \ln(1-\alpha) \quad (2)$$

where α is the degree of conversion and $\bar{a} = a_0 u/V[k_1 + (u/V)]$ is the steady-state concentration of A. It is seen that the time required to reach any given degree of conversion (e.g. $a = 0.99\bar{a}$, where $\bar{a}$ is the steady-state concentration) depends on the rate of flow and the rate constant k_1:

$$t_{99\%} = \frac{4.6}{k_1 + u/V}. \quad (3)$$

Conversion to 50% of the steady-state value is achieved at

$$t_{50\%} = \frac{0.639}{k_1 + u/V}. \quad (3a)$$

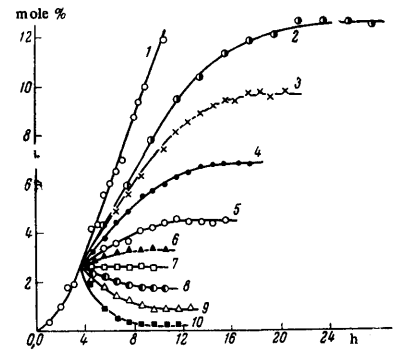

Figure 2. Kinetic curves for the accumulation of adipic acid by the oxidation of cyclohexanone in a reaction vessel of ideal mixing at 110°C with various rates of flow (h^{-1}): 1) 0; 2) 0.04; 3) 0.08; 4) 0.118; 5) 0.24; 6) 0.35; 7) 0.47; 8) 0.55; 9) 0.79; 10) 1.18.

We may note here that, when a first-order reaction is carried out in an open system, the time required to reach a definite degree of conversion of the starting material ($a = \alpha\bar{a}$) is independent of the concentration of A in the solution supplied to the vessel. This is analogous to the fact that under static conditions the time for a definite percentage conversion of the starting material to be achieved is independent of its initial concentration, being determined solely by the rate constant of the process.

The rate of accumulation of the final product B in a first-order reaction is given by the differential equation

$$\frac{db}{dt} = k_1 a - \frac{u}{V}b.$$

In this case

$$1 - \frac{b}{\bar{b}} = e^{-(u/V)\cdot t} - \frac{u}{Vk_1}e^{-(k_1+u/V)t}. \quad (4)$$

When a steady-state concentration of A ($a = 0.99\bar{a}$) is reached with $u/V = k_1$, we have $1 - (b/\bar{b}) = 0.09$: i.e. the steady-state concentration ($b = 0.99\bar{b}$) will not yet have been reached. Calculation based on Eqn. (4) with $u/V \simeq k_1$ shows that the time required for a steady-state concentration of the product B to be established will be approximately double the time required to reach a steady-state concentration of the starting material A.

For a reaction A + B → F with a rate constant of 0.002 M^{-1} min^{-1}, the time required for establishment of the steady-state concentration of a starting material has been shown to be 4τ, and that for the reaction product 6τ (calculations approximate to 1%).[12]

‡ If the system undergoes a change in volume, steady-state concentrations may not be achieved.

In the case of the polymerisation of styrene in the presence of benzoyl peroxide it has been found[12] that a steady-state concentration of styrene is reached in a time 7τ which is independent of the order of the reaction (the order may vary during the process and with different initial conditions). The calculations were based on the known rate constant for the consumption of styrene during polymerisation at 80°C.

2. Kinetics of Establishment of Steady State

The transition from one steady state to another with change in the conditions under which the process is occurring is of considerable interest. It is found that in several cases such transitions are not accomplished monotonically[8,13,14,18,19]: before the new steady state is reached the concentrations of the substances may pass through a maximum or a minimum. Two different phenomena are possible (see Fig. 3).

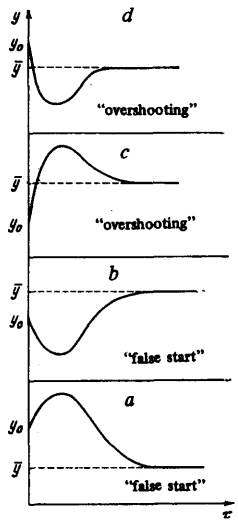

Figure 3. Diagrammatic representations of "overshooting" and "false start" phenomena when a reaction occurs in a vessel of ideal mixing.

1. In the phenomenon of the "false start" an initial change in some parameter of the system is immediately followed by a change in the concentration of the product in the opposite direction to that of the new steady-state concentration. Thus if the initial steady-state concentration of a substance A is a_0, and its new steady-state concentration a_1, a "false start" will give $(da/dt)_{t=t_0} < 0$ when $a_0 - a_1 < 0$ (a minimum is observed on the curve), or $(da/dt)_{t=t_0} > 0$ when $a_0 - a_1 > 0$ (a maximum is observed on the curve).

2. In the "overshooting" phenomenon the initial change in the concentration of a substance is towards the new steady-state concentration: with $a_0 - a_1 < 0$ we have $(da/dt)_{t=t_0} > 0$, and with $a_0 - a_1 > 0$ the derivative $(da/dt)_{t=t_0} < 0$. At a certain time the concentration of the reaction product exceeds the steady-state value (or is lower than the latter), and only by passing through a maximum (or minimum) is the steady-state value reached.

The conditions under which a "false start" or "overshooting" occurs have been determined for a first-order reversible reaction $A \rightleftharpoons B$ and the consecutive reaction $A \rightarrow B \rightarrow C$ when the rates of supply of starting material and of removal of reaction products differ greatly[14] and also when they are the same[8].

Let us examine in rather greater detail the possibility of the occurrence of a "false start" and "overshooting" on the kinetic curves for the accumulation of reaction products in the consecutive reaction $A \xrightarrow{k_1} B \xrightarrow{k_2} C$ with identical rates of supply and removal of all products[8]. In this case, denoting the concentrations of A and B by x and y, we can write down the set of differential equations

$$\frac{dx}{dt} = -(k_1 + u/V)\,x + \frac{u}{V}\tilde{x}_0 \qquad (5)$$

where $\tilde{x}_0$ is the concentration of the component A in the solution fed to the vessel, and

$$\frac{dy}{dt} = k_1 x - (k_2 + u/V)\,y\,. \qquad (6)$$

Introducing the new variables $\Delta x = x - \bar{x}$ and $\Delta y = y - \bar{y}$ (where $\bar{x}$ and $\bar{y}$ are the steady-state concentrations of A and B respectively), and remembering that

$$\frac{d\bar{x}}{dt} = -(k_1 + u/V)\,\bar{x} + \frac{u}{V}\tilde{x}_0 = 0 \qquad \frac{d\bar{y}}{dt} = k_1\bar{x}_0 - (k_2 + u/V)\,\bar{y} = 0$$

we can reduce the differential equations (5) and (6) to the form

$$\frac{d\Delta x}{dt} = -(k_1 + u/V)\,\Delta x \qquad (7)$$

$$\frac{d\Delta y}{dt} = k_1\Delta x - (k_2 + u/V)\,\Delta y. \qquad (8)$$

Integration of (7) and (8) will give

$$\Delta x = \Delta x_0 e^{-(k_1+u/V)(t-t_0)}$$

$$\Delta y = \frac{k_1\Delta x_0}{k_2-k_1}\{e^{-(k_1+u/V)(t-t_0)} - e^{-(k_2+u/V)(t-t_0)}\} + \Delta y_0 e^{-(k_2+u/V)(t-t_0)}$$

where $\Delta x_0 = x_0 - \bar{x}$ and $\Delta y_0 = y_0 - \bar{y}$ are the deviations in the concentrations x and y in the system from the steady-state values at $t = t_0$ (where t_0 corresponds to the instant of transition from the continuous régime, change in the rate of flow, etc.).

The derivative

$$\frac{d\Delta y}{dt} = (k_2 + u/V)\left[\frac{k_1\Delta x_0}{k_2-k_1} - \Delta y_0\right] e^{-(k_2+u/V)(t-t_0)} - \frac{k_1\Delta x_0}{k_2-k_1} e^{-(k_1+u/V)(t-t_0)}$$

can vanish as $t \to \infty$, which corresponds to the establishment of a steady state, and also when

$$(t-t_0) = \frac{1}{k_2-k_1}\ln\left\{\left[1 - \frac{\Delta y_0\,(k_2-k_1)}{k_1\Delta x_0}\right]\frac{k_1+u/V}{k_1+u/V}\right\}. \qquad (9)$$

If Eqn. (9) is satisfied, extremal values appear on the kinetic curves for accumulation of the intermediate substance.

Analysis of Eqn. (9) together with the differential equation (8) will give the following conditions for the appearance of "overshooting" and a "false start" on the kinetic curve for the accumulation of the intermediate B in the above consecutive reaction[8].

1. If $\Delta x_0 > 0$ and $\Delta y_0 > 0$ at zero time, a "false start" with a maximum on the curve may be observed at values of $u/V < (k_1\Delta x_0/\Delta y_0) - k_2$.

2. With $\Delta x_0 < 0$ and $\Delta y_0 < 0$ a "false start" with a minimum may be observed at velocities

$$u/V < \frac{k_1 \Delta x_0}{\Delta y_0} - k_2 .$$

3. When $\Delta x_0 > 0$ and $\Delta y_0 < 0$ "overshooting" with a maximum can be observed throughout the range of variation in u/V, and when $\Delta x_0 < 0$ and $\Delta y_0 > 0$ "overshooting" with a minimum on the kinetic curve can occur.

The phenomena of a "false start" and "overshooting" have been observed experimentally in particular on the kinetic curve for the accumulation of sulphuric acid (the final product of the decomposition of potassium persulphate (Fig. 4*a*) accompanied by the liberation of atomic oxygen[14])

$$K_2S_2O_8 + H_2O \rightarrow K_2SO_4 + H_2SO_4 + O$$

and also in the enzymic decomposition of urea in the presence of urease and additions of silver nitrate, causing inactivation of the enzyme[13], as well as in the complicated chain oxidations of n-decane and ethylbenzene by atmospheric oxygen (Fig. 4*b*).[8]

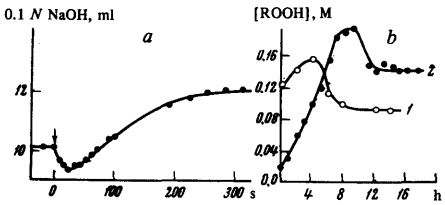

Figure 4. (a) "False start" on kinetic curve for accumulation of sulphuric acid during decomposition of aqueous potassium persulphate solution in reaction vessel of ideal mixing. The arrow indicates the instant at which the rate of diffusion changes. (b) Kinetic curves for accumulation of hydroperoxides in the oxidation of n-decane in a reaction vessel of ideal mixing at 140°C: 1) "false start"; 2) "overshooting".

The possibility of the appearance of "overshooting" and "false starts" on kinetic curves for the consumption of starting material in an open system has been examined in a previous paper[20]. If the reaction is of the first order (see above) the derivative

$$-\frac{d\Delta x}{dt} = \Delta x_0 (k_1 + u/V) e^{-(k_1 + u/V)/(t - t_0)}$$

is able to vanish only at $t = t_\infty$, i.e. in a steady state. At all values of $t \neq t_\infty$ the concentration of the starting material either increases monotonically when $\Delta x_0 < 0$ or falls monotonically when $\Delta x_0 > 0$. Consequently the concentration of the initial reactant can only vary monotonically on passing from one stationary state to another: the occurrence of any extrema is then impossible. This holds for a non-autocatalytic reaction of any order[20].

In fact, for a reaction of the nth order we have

$$\frac{d[A]}{dt} = -k_1[A]^n - (u/V)[A] + (u/V)[A]_0$$

and when $d[A]/dt = 0$ the second derivative

$$\frac{d^2[A]}{dt^2} = [-k_1 n [A]^{n-1} - u/V] \frac{d[A]}{dt} \equiv 0$$

which corresponds to the establishment of a steady state. Thus the kinetic curve for the consumption of A cannot pass through extrema.

In autocatalytic reactions, unlike those of simple types, "overshooting" and "false start" phenomena can be observed even on the kinetic curves for the consumption of the starting material[20]. Actually, if the starting material A is consumed autocatalytically by interacting with the reaction product B, its rate of accumulation in the system is described by the differential equation

$$\frac{d[A]}{dt} = -k_1[A][B] - \frac{u}{V}[A] + \frac{u}{V}[A]_0 .$$

At the instant at which $d[A]/dt = 0$ the second derivative

$$\frac{d^2[A]}{dt^2} = -k_1[A]\frac{d[B]}{dt} - \left[k_1[B] + \frac{u}{V}\right]\frac{d[A]}{dt}$$

may differ from zero if at this instant $d[B]/dt \neq 0$. In this case the kinetic curve for consumption of A will pass through a maximum or a minimum before a steady state is attained.

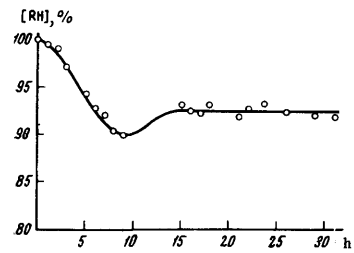

Figure 5. "Overshooting" on kinetic curve for consumption of ethylbenzene by oxidation in an open system at 118°C with a rate of flow of 0.102 h^{-1}.

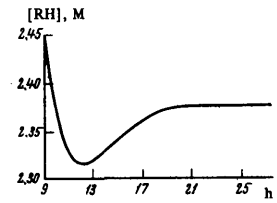

Figure 6. Kinetic curve for consumption of starting material in catalysed oxidation, calculated on M-20 electronic computer with [RH] = 5.2 M, [$CoSt_2$] = 0.006 M, and $u/V = 5 \times 10^{-5}$ s^{-1}.

The phenomenon of "overshooting" has been observed, for example, on the kinetic curve for the consumption of ethylbenzene during its autoxidation by oxygen (Fig. 5).[10]

The possibility of the appearance of extrema on kinetic curves for the consumption of the starting material has been shown also in the catalysed oxidation of hydrocarbons

in the presence of cobalt stearate[21]. The mechanism of the process in this case is represented by the scheme

$$RO_2^{\cdot} + RH \rightarrow ROOH + R^{\cdot} \quad (k_1)$$

$$ROOH + CoSt_2 \rightleftarrows ROOH \cdot CoSt_2 \quad (k_2,\ k_3)$$

$$ROOH \cdot CoSt_2 + CoSt_2 \rightarrow RO^{\cdot} + Co(OH)St_2 + CoSt_2 \quad (k_4)$$

$$ROOH + Co(OH)St_2 \rightarrow CoSt_2 + H_2O + RO_2^{\cdot} \quad (k_5)$$

In an open system the oscillations are maintained indefinitely. When malonic acid was replaced by malic acid, for example, oscillation at two frequencies was observed[29] under certain conditions (Fig. 8).

The very fact that periodic chemical reactions can occur is very interesting from the points of view both of chemical kinetics and of biology. Among the clearest periodic processes in biology are the biological systems for recording

The dependence of the steady-state concentration of radicals $\bar{n}$ on the initial concentration of inhibitor i_0 is found by solving the cubic equation

$$\bar{n}^3 - \frac{1}{k_6}\left(\frac{2k_2k_3[RH]}{(k_3 + u/V)} - \frac{u}{V} - \frac{uk_5}{Vk_i}\right)\bar{n}^2 + \\ + \frac{u}{Vk_6k_i}\left(k_i \cdot i_0 - \frac{2k_2k_3[RH]}{(k_3 + u/V)} + \frac{u}{V} - \frac{w_0k_i \cdot V}{u}\right)\bar{n} - \frac{u \cdot w_0}{Vk_ik_6} = 0 . \quad (11)$$

Equation (11) has three positive roots $\bar{n}_1$, $\bar{n}_2$, $\bar{n}_3$ (three steady states of the process) provided that

$$\frac{V}{u}\left[\frac{2k_2k_3[RH]}{(k_3 + u/V)} - \frac{u}{V}\right] > \frac{k_5}{k_i} .$$

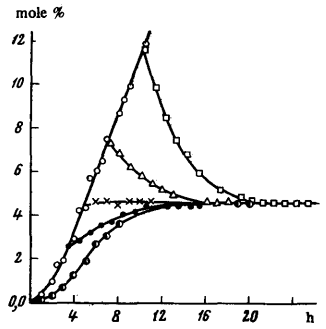

Figure 9. Kinetic curves for the accumulation of adipic acid during the continuous oxidation of cyclohexanone at 110°C with a rate of flow of 0.265 h^{-1}.

However, analysis shows that one of the solutions is unstable. The dependence of the steady-state concentration of the primary intermediate product, the hydroperoxide ROOH (the concentration of hydroperoxide is proportional to the concentration of radicals n), on the initial concentration of the inhibitor[42] is shown graphically[44] in Fig. 10. The section afb corresponds to the steady state $\bar{n}_1$, and the section cd determines $\bar{n}_3$. The state $\bar{n}_2$ (branch blc) is unsteady and is not realised.

Experimental data on the dependence of the steady-state concentration of a reaction product on the initial conditions have been obtained in an investigation of the inhibited oxidation of n-decane[42]. The steady-state hydroperoxide concentration is found to depend on the initial concentration

with change in the inhibitor concentration right until the latter corresponds to point b. At this inhibitor concentration the steady state of the system changes in the direction indicated by the arrow. Thus it is seen that, with the same inhibitor concentration in the solution fed to the vessel and different initial hydroperoxide concentrations in the system ($[ROOH]_0$ = 1.2 mole % and 0), two markedly different steady states are attained. The broken section b–c defines the magnitude of the unstable steady state. In the oxidation of n-decane containing hydroperoxide from the start, breaks are observed close to the critical inhibitor concentration on the kinetic curve of the hydroperoxide (sections a–b on the curves in Fig. 12).[42]

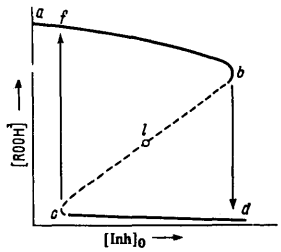

Figure 10. Dependence of steady-state concentration of hydroperoxide on initial concentration of inhibitor in a continuous process of oxidation (calculated results).

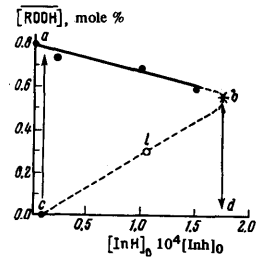

Figure 11. Dependence of steady-state concentration of hydroperoxide on concentration of 1-naphthol and initial hydroperoxide concentration in the system during the oxidation of n-decane with continuous supply of a solution of 1-naphthol in n-decane, at 135°C with rate of flow 1.45×10^{-4} s^{-1}.

With certain initial conditions[34] auto-oscillations can be expected also in a first-order exothermic reaction A → B under non-isothermal conditions.

Auto-oscillations can occur when the process can be described by a set of non-linear differential equations.

The possibility of the occurrence of oscillations has since been discussed theoretically for a large number of systems. In particular, detailed analysis has shown[35-37] that oscillations are impossible under isothermal conditions in systems in which only simple types of reactions take place. Only the presence of an autocatalytic stage or of a wall reaction can lead to the appearance of oscillations[37].

In the system

$$A_1 + M_1 \rightarrow M_2 + B_1$$
$$A_2 + M_2 \rightarrow M_3 + B_2$$
$$A_3 + M_3 \rightarrow M_1 + B_3$$

where the M_i are catalysts, damped and undamped oscillations are possible if the number of components in the reaction exceeds 3.

The occurrence of oscillations about a steady-state value has been discussed in detail for a consecutive reaction comprising n stages, all of which are autocatalytic, taking place in an open system[38]. It is shown that harmonic oscillations about a steady-state value should be observed if the number of consecutive stages does not exceed 3. If the number of stages does exceed 3, anharmonic oscillations are produced owing to the superposition of oscillations. The occurrence of oscillations, and also their frequency and amplitude, depend on the rate of supply of the starting materials to the system and on the initial conditions.

A detailed discussion of oscillatory phenomena in chemical and biological systems will be found in Ref. 39.

IV. DEPENDENCE OF STEADY-STATE CONCENTRATION ON CONDITIONS OF PROCESS

The steady-state concentration is determined by the parameters of the system (temperature, pressure, presence of a catalyst or an inhibitor, and also the rate of flow).

The change in the steady state produced by addition of a catalyst to a system has been shown, for example, in the enzymic decomposition of urea[13] and the decomposition of aqueous potassium persulphate solutions catalysed by silver sulphate[14]. It was shown in the former case[13] that different steady-state concentrations of urea are established in the system depending on the degree of inactivation of the enzyme by silver nitrate solution (Fig. 1). In the decomposition of potassium persulphate in aqueous solutions a change in the steady-state concentration of sulphuric acid (a reaction product) has also been observed on the addition of a catalyst (silver sulphate) to the system[14].

It is interesting that, if a reversible reaction is taking place in an open system, addition of a catalyst not only increases the rate of establishment of equilibrium, as occurs in a closed system, but also leads to a shift in the thermodynamic equilibrium[13a]. This phenomenon has been investigated theoretically[13a] for the first-order reversible reaction A ⇌ B.

Variation in temperature also influences the steady-state concentrations in a system. For example, the mean degree of vinyl polymerisation falls with rise in temperature[40] (this parameter is a function of the concentration of the monomer).

1. Dependence of Steady-State Concentration on Initial Conditions

For most reactions, having highly diverse mechanisms, the steady-state concentration under gradient-free conditions is independent of the concentration of products in the system at the instant of transition to a continuous régime. In the simplest case, when a substance A is consumed by a first-order reaction having a rate constant k_1, we have for the rate of the process the equation

$$\frac{da}{dt} = -(k_1 + u/V)a + (u/V)a_0 . \qquad (10)$$

Integration gives

$$-(k_1 + u/V)a + (u/V)a_0 = [(u/V)a_0 - (k_1 + u/V)a_1]e^{(k_1+u/V)t}$$

where a_1 is the concentration of A in the vessel at time $t = 0$. As $t \rightarrow \infty$ a concentration $\bar{a}$ is reached, which remains unchanged with time (steady-state concentration), and is given by

$$\bar{a} = \frac{(u/V)a_0}{(k_1+u/V)} .$$

This is independent of a_1, and is determined by the values of k_1 and u/V.

The same formula for $\bar{a}$ can be obtained by equating the derivative da/dt in Eqn. (10) to zero.

More generally we can write for the accumulation in an open system of a substance X, formed at a rate w_f and consumed at a rate w_u, the equation

$$\frac{dx}{dt} = w_f - w_u + (u/V)x_f - (u/V)x .$$

In this case the steady-state concentration $\bar{x}$ (determined from the condition $dx/dt = 0$) is given by

$$\bar{x} = \frac{w_f - w_u}{u/V} + x_0$$

being dependent only on x_0, the rates of formation and consumption of X, and the rate of flow, but not on the concentration of X in the vessel at the start of the continuous process.

The fact that the steady-state concentration is independent of the initial conditions can be illustrated, for example, by the series of kinetic curves for the accumulation of adipic acid in the autoxidation of cyclohexanone, obtained with different initial degrees of oxidation (Fig. 9).[15]

Autocatalytic reactions in which two stable steady states can occur depending on the initial conditions constitute an exception. This case has been analysed in the literature[14,34,41-43].

The possibility of more than one steady state appearing in such a system has been investigated in detail by Andreev[41] on the basis of an actual scheme for the oxidation of hydrocarbons in the presence of inhibitors which terminate the oxidation chains

$$RH \rightarrow RO_2^{\bullet} \qquad (w_0)$$
$$RO_2^{\bullet} + RH \rightarrow ROOH + R^{\bullet} \qquad (k_2)$$
$$ROOH \rightarrow RO^{\bullet} + {}^{\bullet}OH \qquad (k_3)$$
$$RO_2^{\bullet} + RO_2^{\bullet} \rightarrow \text{chain termination} \qquad (k_4)$$
$$RO_2^{\bullet} + \text{Inh} \rightarrow \text{chain termination} \qquad (k_i) .$$

The dependence of the steady-state concentration of radicals $\bar{n}$ on the initial concentration of inhibitor i_0 is found by solving the cubic equation

$$\bar{n}^3 - \frac{1}{k_5}\left(\frac{2k_2k_3[RH]}{(k_3+u/V)} - \frac{u}{V} - \frac{uk_5}{Vk_t}\right)\bar{n}^2 + \\ + \frac{u}{Vk_5k_t}\left(k_t \cdot i_0 - \frac{2k_2k_3[RH]}{(k_3+u/V)} + \frac{u}{V} - \frac{w_0k_t \cdot V}{u}\right)\bar{n} - \frac{u \cdot w_0}{Vk_tk_5} = 0 . \quad (11)$$

Equation (11) has three positive roots $\bar{n}_1$, $\bar{n}_2$, $\bar{n}_3$ (three steady states of the process) provided that

$$\frac{V}{u}\left[\frac{2k_2k_3[RH]}{(k_3+u/V)} - \frac{u}{V}\right] > \frac{k_5}{k_t}.$$

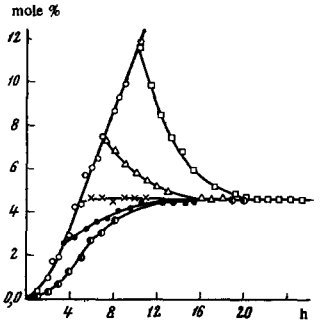

Figure 9. Kinetic curves for the accumulation of adipic acid during the continuous oxidation of cyclohexanone at 110°C with a rate of flow of 0.265 h^{-1}.

However, analysis shows that one of the solutions is unstable. The dependence of the steady-state concentration of the primary intermediate product, the hydroperoxide ROOH (the concentration of hydroperoxide is proportional to the concentration of radicals n), on the initial concentration of the inhibitor[42] is shown graphically[44] in Fig. 10. The section afb corresponds to the steady state $\bar{n}_1$, and the section cd determines $\bar{n}_3$. The state $\bar{n}_2$ (branch blc) is unsteady and is not realised.

Experimental data on the dependence of the steady-state concentration of a reaction product on the initial conditions have been obtained in an investigation of the inhibited oxidation of n-decane[42]. The steady-state hydroperoxide concentration is found to depend on the initial concentration of hydroperoxide in the system. Fig. 11 illustrates experimental results on the inhibited oxidation of pure n-decane and of n-decane containing 1.2 mole % of the hydroperoxide before the start of the reaction. The point a on this diagram indicates the steady-state hydroperoxide concentration in the absence of inhibitor, this being 0.8 mole % under the experimental conditions. If the pure hydrocarbon is being oxidised, the steady state of the system at high inhibitor concentrations is represented by the section c–d. At an inhibitor concentration corresponding to point c a sharp change occurs in the steady state of the system, in the direction indicated by the arrow. If the hydrocarbon contains a certain quantity of the hydroperoxide $[ROOH]_0 > a$ at the start of the reaction, the concentration of hydroperoxide in the steady state will vary along the section a–b with change in the inhibitor concentration right until the latter corresponds to point b. At this inhibitor concentration the steady state of the system changes in the direction indicated by the arrow. Thus it is seen that, with the same inhibitor concentration in the solution fed to the vessel and different initial hydroperoxide concentrations in the system ($[ROOH]_0$ = 1.2 mole % and 0), two markedly different steady states are attained. The broken section b–c defines the magnitude of the unstable steady state. In the oxidation of n-decane containing hydroperoxide from the start, breaks are observed close to the critical inhibitor concentration on the kinetic curve of the hydroperoxide (sections a–b on the curves in Fig. 12).[42]

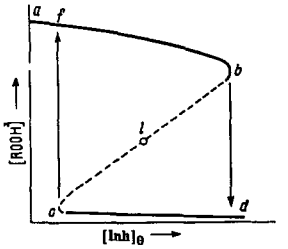

Figure 10. Dependence of steady-state concentration of hydroperoxide on initial concentration of inhibitor in a continuous process of oxidation (calculated results).

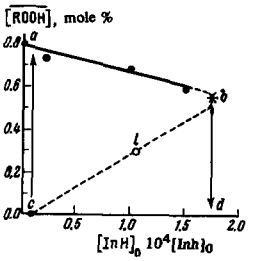

Figure 11. Dependence of steady-state concentration of hydroperoxide on concentration of 1-naphthol and initial hydroperoxide concentration in the system during the oxidation of n-decane with continuous supply of a solution of 1-naphthol in n-decane, at 135°C with rate of flow 1.45×10^{-4} s^{-1}.

With exothermic processes different steady states can be established according to the initial conditions even for simple types of reactions. The occurrence of two greatly differing régimes when a reaction is conducted under adiabatic conditions in a gradient-free reaction vessel was first established by Zel'dovich[43] for thermal ignition. It has been shown[34] that different steady states may be established, depending on the initial conditions, when a first-order exothermic reaction is conducted under non-isothermal conditions in a gradient-free vessel.

Thermal ignition phenomena with a sharp transition from a steady state to a non-stationary régime are inherent in exothermic processes even under static conditions. However, open systems are distinguished by sharper boundaries between ignition and a steady state. When exothermic processes are conducted in open systems, the possibility arises of determining the true concentration limit of ignition (this is impossible under static conditions because the mixture is consumed).

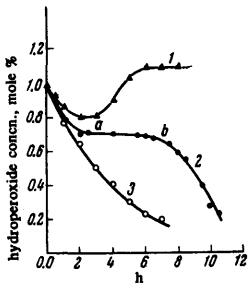

Figure 12. Kinetic curves for the accumulation of hydroperoxide in the oxidation of n-decane containing an initial hydroperoxide concentration of 1.0 mole % at 135°C with a rate of flow of 1.45×10^{-4} s^{-1}, and with different inhibitor concentrations (M) in the solution fed into the vessel: 1) 4.0×10^{-4}; 2) 4.1×10^{-4}; 3) 4.3×10^{-4}.

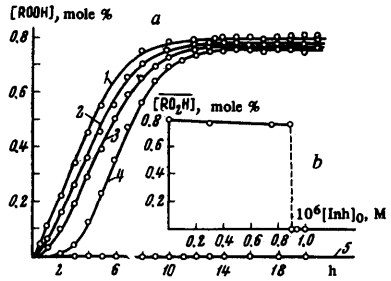

Figure 13. (a) Kinetic curves for the accumulation of hydroperoxide in the continuous oxidation of n-decane at 120°C, with rate of flow of 0.53 h^{-1}, in the presence of 1-naphthol (M): 1) 0; 2) 3×10^{-6}; 3) 7.5×10^{-6}; 4) 9.0×10^{-6}; 5) 9.05×10^{-6}. (b) Dependence of steady-state concentration of hydroperoxide on initial concentration of 1-naphthol.

A greater sharpness of critical transitions in open than in static systems has been observed also in an investigation of the inhibited oxidation of n-decane[45]. The inhibitors used were 1-naphthol and tri-(3,5-di-t-butyl-4-hydroxybenzyl)amine, under identical temperature conditions in open and static systems. When the process is conducted continuously a very sharp transition is observed from the autocatalytic reaction to the steady-state reaction at a critical inhibitor concentration[45] (Fig. 13). Under the same conditions in a closed system the induction period of the process increases linearly with increase in the inhibitor concentration, and limiting phenomena are not observed[42] (Fig. 14). The causes of the sharpness in the transitions in open systems have been analysed[42].

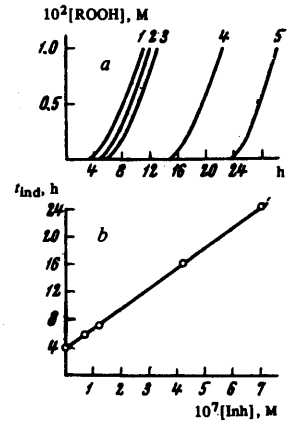

Figure 14. (a) Kinetic curves for the accumulation of hydroperoxide in the oxidation of n-decane under static conditions at 120°C with different initial concentrations (M) of inhibitor (1-naphthol): 1) 0; 2) 8×10^{-7}; 3) 1.2×10^{-6}; 4) 4.1×10^{-6}; 5) 7×10^{-6}. (b) Dependence of induction period on inhibitor concentration.

2. Dependence of Steady-state Concentration on Flow Rate

The variation in steady-state concentrations with change in the rate of supply of the starting materials has been discussed in the greatest detail in the literature. It has been shown for simple reactions (of the first, second, and third order) that increase in the rate of supply of starting materials (and of withdrawal of reaction products) diminishes the steady-state concentration of reaction products, while that of the starting materials increases monotonically[46].

As example let us examine the reaction $A \xrightarrow{k_1} C$, where conversion of A into the product is a first-order reaction. Then the variation in the concentrations of A and C will be described by the differential equations

$$\frac{d[A]}{dt} = -k_1[A] - \frac{u}{V}[A] + \frac{u}{V}[A]_0$$

$$\frac{d[C]}{dt} = k_1[A] - \frac{u}{V}[C],$$

where u is the bulk rate of supply of the substances, V is the volume of the system, $[A]_0$ is the concentration of A in the solution entering the vessel, and [A] and [C] are the instantaneous concentrations of A and C in the solution.

In the steady state $d[A]/dt = d[C]/dt = 0$, and the steady-state concentrations are

$$[\bar{A}] = \frac{(u/V)[A]_0}{(k_1 + u/V)} \qquad (12)$$

$$[\bar{C}] = \frac{k_1[\bar{A}]}{u/V} = \frac{k_1[A]_0}{(k_1 + u/V)} \qquad (13)$$

With increase in u/V the steady-state concentration of C will fall, while that of A will increase, since the factor $u/V(k_1 + u/V)$ increases with increase in u/V.

Analogous equations can be written for second- and third-order reactions[9,46].

The steady-state concentration of the intermediate product in a consecutive reaction will depend in more complicated fashion on the flow rate.

With increase in the rate of supply of the starting materials the steady-state concentration of the intermediate in the consecutive reaction A → B → C first increases and then falls. This extremal dependence on u/V is due to the fact that increasing this parameter produces an increase in the steady-state concentration of the initial substance A, which results in an increase in the concentration of B, while the more rapid removal of B from the system tends to diminish its steady-state concentration.

This can be illustrated by the interaction of the iron(III) ion with the thiosulphate ion[47]

$$2Fe^{3+} + 2S_2O_3^{2-} \rightarrow 2Fe^{2+} + S_4O_6^{2-}.$$

The reaction involves intermediate formation of an unstable complex between these two ions. Determination of the concentration of this complex has shown that its steady-state concentration passes through a maximum with increase in the rate of flow (Fig. 15).

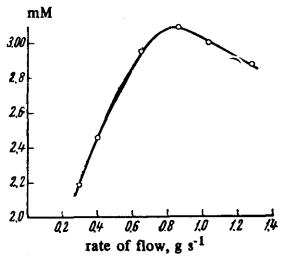

Figure 15. Dependence of steady-state concentration of intermediate complex in the reaction of Fe^{3+} with the thiosulphate ion on rate of supply of $S_2O_3^{2-}$ (rate of supply of Fe^{3+} constant at 0.388 g s^{-1}).

The rate of flow at which the maximum steady-state concentration of the intermediate is reached will depend on the rate constants of its formation and consumption[48]. In the simple consecutive reaction $A \xrightarrow{k_1} B \xrightarrow{k_2} C$, for example, the variation in the concentration of the intermediate substance B is given by the differential equation

$$\frac{d[B]}{dt} = k_1[A] - k_2[B] - \frac{u}{V}[B].$$

The steady-state concentration of B is

$$[\bar{B}] = \frac{k_1 \frac{u}{V}[A]_0}{(k_1 + u/V)(k_2 + u/V)}. \qquad (14)$$

It is seen from Eqn. (14) that the steady-state concentration $[\bar{B}] \rightarrow 0$ as $u/V \rightarrow 0$ and as $u/V \rightarrow \infty$. Since $[\bar{B}]$ has some value different from zero within the range of variation of u/V from 0 to ∞, the steady-state concentration of B must pass through a maximum with increase in u/V. Differentiating $[\bar{B}]$ with respect to u/V, we obtain

$$\frac{d[\bar{B}]}{d(u/V)} = \frac{[A]_0 k_1 [k_1 k_2 - (u/V)^2]}{(k_1 + u/V)^2 (k_2 + u/V)^2}.$$

The dependence of $[\bar{B}]$ on u/V will pass through a maximum when $d[\bar{B}]/d(u/V) = 0$, i.e. at a rate of flow $u/V = \sqrt{k_1 k_2}$.

If more than one intermediate is formed in the system, the steady-state concentration of each product should pass through a maximum, and that of the first intermediate should be reached at higher rates of flow than that of the second intermediate[8]. Thus in the consecutive reaction $A \xrightarrow{k_1} B \xrightarrow{k_2} C \xrightarrow{k_3} D$ the maximum steady-state concentration of B is reached at a rate of flow u/V satisfying the condition $d[\bar{B}]/d(u/V) = 0$. For the steady-state concentration of the second intermediate C we have

$$\frac{d[C]}{dt} = k_2[B] - k_3[C] - u/V[C]; \quad [\bar{C}] = \frac{k_1[\bar{B}]}{k_3 + u/V}.$$

At the maximum in $[\bar{B}]$, when $d[\bar{B}]/d(u/V) = 0$, we find that

$$\frac{d[\bar{C}]}{d(u/V)} = -\frac{k_1[\bar{B}]}{(k_3 + u/V)^2} + \frac{k_1}{(k_3 + u/V)} \cdot \frac{d[\bar{B}]}{d(u/V)} < 0,$$

i.e. $[\bar{C}]$ is a diminishing function of u/V. This implies that the maximum value of C is reached at lower values of u/V than is $[\bar{B}]_{max}$.

The above rules for the variation in steady-state concentrations of final and intermediate products and of starting materials with rate of flow, derived for simple reactions, are maintained for more complicated processes.

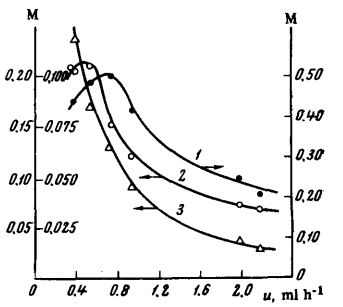

Figure 16. Dependence of steady-state concentrations of oxidation products on rate of supply of ethylbenzene at 118°C: 1) hydroperoxide (right-hand scale); 2) 1-phenylethanol (outer left-hand scale); 3) acetophenone (inner left-hand scale).

An example is the liquid-phase oxidation of ethylbenzene in the presence of azoisobutyronitrile as initiator[17]. The process goes by a chain mechanism with the following sequence of products

ethylbenzene → α-hydroperoxide → 1-phenylethanol → acetophenone

Thus two intermediate products—the hydroperoxide and the carbinol—and one final product—acetophenone—are formed in the system. Investigation of the oxidation of ethylbenzene in a gradient-free reaction vessel has shown that with increase in the flow rate the steady-state concentrations both of the hydroperoxide and of the carbinol pass through a maximum (Fig. 16). In complete agreement with what

has been stated above, the maximum steady-state concentration of the alcohol is reached at lower rates of flow than is that of the hydroperoxide. The steady-state concentration of the ketone falls monotonically with increase in u/V (Fig. 16).

Systems can also exist in which the above variation in steady-state concentration with rate of flow does not occur. Among them are processes involving the intermediate formation of complexes, e.g. by the scheme

$$\begin{aligned} A &\rightarrow B \quad (k_1) \\ B + C &\rightleftarrows D \quad (k_2, k_{-2}) \\ D &\rightarrow E \quad (k_3) \ . \end{aligned}$$

If equilibrium is established sufficiently rapidly and is not disturbed, either by conversion of D into E or by withdrawal of D from the system, i.e. provided that

$$k_3[D] \ll k_{-2}[D] \gg \frac{u}{V}[D]$$

the steady-state concentration of B will not pass through a maximum[49]. The steady-state concentration of A in such a system is

$$[\bar{A}] = \frac{(u/V)[A]_0}{(k_1 + u/V)}$$

while the rate of change in the concentration of B is described by the differential equation

$$\frac{d[B]}{dt} = k_1[A] - k_2[B][C] + k_{-2}[D] - \frac{u}{V}[B].$$

When thermodynamic equilibrium is maintained $k_2[B][C] = k_{-2}[D]$ and $d[B]/dt = k_1[A] - (u/V)[B]$. The steady-state concentration of the intermediate B

$$[\bar{B}] = \frac{k_1 V}{u}[A] = \frac{k_1[A]_0}{k_1 + u/V}$$

increases steadily with decrease in u/V, tending to $[A]_0$, and does not pass through a maximum.

The absence of a maximum steady-state concentration of an intermediate product has been shown for the oxidation of n-decane catalysed by cobalt stearate[21,49]. As already mentioned above (Section II, 2), breakdown of the hydroperoxide (intermediate product) in this process is preceded by formation of the complex ROOH.$CoSt_2$. Fig. 17 shows that the plot of [ROOH] against u/V does not reach a maximum down to relatively small rates of flow. The absence of a maximum is indicated also by the fact that in the uncatalysed oxidation of n-decane a maximum is reached at $u = 2.5$ ml h^{-1}. Yet it can be shown that increasing the rate of initiation by adding cobalt stearate should shift the maximum to higher rates of flow. Thus if ROOH is formed and consumed by a chain mechanism (with rate constants k_2 and k_3 respectively), the rate of flow at which a maximum steady-state concentration of the hydroperoxide is reached is

$$\frac{u}{V} = \sqrt{\frac{k_3 k_3}{k_6}}\sqrt{w_i}$$

(k_6 being the recombination constant of $RO_2^{\cdot}$ radicals), and increases with increase in the rate of initiation. Calculation of the scheme of catalysed oxidation (Section II, 2) on an M-20 electronic computer, with the equilibrium

$$ROOH + CoSt_2 \rightleftarrows ROOH \cdot CoSt_2$$

maintained, showed that the steady-state concentration of ROOH does not pass through a maximum up to 88% conversion of the starting material.

Variation in the rate of supply of the starting materials affects not only the steady-state concentrations of the individual reaction products but also the proportions of the products, since change in u/V influences the steady-state concentration of the final products to a far greater extent than that of the intermediates. This effect is especially clearly developed in the oxidation of cyclohexanone by oxygen at 110°C.[15] With change in the rate of supply of cyclohexanone from 0.079 to 1.175 h^{-1} the steady-state concentration of the hydroperoxide changes from 0.298 to 0.242 mole %, i.e. by a factor of 1.2, whereas the steady-state concentration of adipic acid changes by a factor of 12.

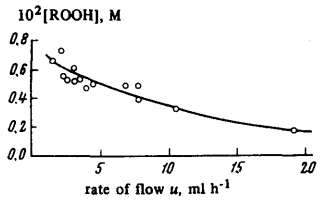

Figure 17. Dependence of steady-state hydroperoxide concentration on rate of flow in the oxidation of n-decane catalysed by cobalt stearate ($[CoSt_2]_0$ = 0.006 M) in a reaction vessel of ideal mixing at 130°C.

Furthermore, when cyclohexanone is oxidised in a gradient-free reaction vessel, the extent of oxidation of adipic acid to carbon dioxide is considerably diminished. If with 4.5 mole % of adipic acid the rate of evolution of carbon dioxide per mole of adipic acid is 0.124 mole h^{-1} under static conditions, in an open system it is only 0.032 mole h^{-1}.

In general in the consecutive reaction $A \xrightarrow{k_1} B \xrightarrow{k_2} C \xrightarrow{k_3} D$ increase in the rate of supply of the starting materials will enrich the mixture in the intermediate products. Thus the concentration of C in the steady state is given by

$$k_2[\bar{B}] - (k_3 + u/V)[\bar{C}] = 0, \text{ whence } \frac{[\bar{B}]}{[\bar{C}]} = \frac{(k_3 + u/V)}{k_2}.$$

With increase in u/V the ratio $[\bar{B}]/[\bar{C}]$ increases: i.e. the relative content of B in the mixture of reaction products is increased.

This conclusion may not apply to more complicated reactions, such as the oxidation of organic compounds[10]. Analysis of a process of oxidation involving chain branching by the reaction $ROOH \xrightarrow{k_3} HO^{\cdot} + RO^{\cdot}$ and quadratic recombination of radicals ($RO_2^{\cdot} + RO_2^{\cdot} \xrightarrow{k_6}$ products) shows that the ratio of the steady-state concentrations of the hydroperoxide (ROOH) and a product C, the latter formed from the hydroperoxide by a molecular mechanism (constant k) and consumed by a chain mechanism§ (constant k_4), is given by

$$\eta = \frac{[\overline{ROOH}]}{[\bar{C}]} = \frac{k_3 \cdot k_3 k_4 [RH]}{k k_6 (k + u/V)} + \frac{u/V}{k}$$

§ If the reaction product is not used up or is consumed by a molecular mechanism, this scheme yields a result identical with that obtained from consideration of a simple consecutive reaction.

in which k_2 is the rate constant of chain propagation $RO_2^{\cdot} + RH \rightarrow ROOH + R^{\cdot}$. It is seen from this expression that the ratio of the steady-state concentrations increases at small rates of flow, but with further increase in u/V it falls. The maximum value of η is attained at the rate of flow

$$u/V = \sqrt{\frac{k_2 k_3 k_4 [RH]}{k_6}} - k.$$

Thus with consecutive chain reactions variation in the flow rate over a certain range may result in enrichment of the mixture with the first intermediate, and over another range enrichment with the second intermediate. The concentration ratio of intermediate and final products increases steadily, as with simple consecutive reactions[10].

With variation in the rate of supply of ethylbenzene the ratio of the steady-state concentrations of the hydroperoxide and 1-phenylethanol formed by its oxidation passes through a maximum (Fig. 18).[17] At the same time the ratio of the steady-state concentrations of the hydroperoxide and of acetophenone (AcPh) increases monotonically, as can be seen from the following data

u, ml h^{-1}	0.40	0.55	0.75	0.95	2.0	2.2
$[\overline{ROOH}]/[\overline{AcPh}]$	5.2	5.7	8.1	9.3	15	15.7

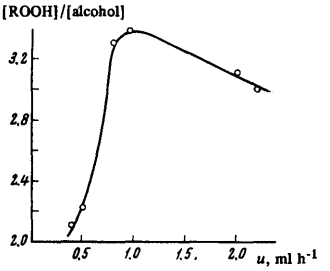

Figure 18. Dependence of ratio of steady-state concentrations of hydroperoxide [ROOH] and 1-phenylethanol on the volume flow rate of ethylbenzene to a reaction vessel with ideal mixing at 118°C.

In concluding this Section it is appropriate to mention that the maximum steady-state concentration attainable in an open system is always lower than the maximum concentration of a product under static conditions with the same process conditions. Thus in the consecutive reaction $A \xrightarrow{k_1} B \xrightarrow{k_2} C$ the steady-state concentration of the final product C

$$[\overline{C}] = \frac{[A_0] k_1 k_2}{(k_1 + u/V)(k_2 + u/V)}$$

is always lower than the maximum possible concentration $[C] = [A]_0$ under static conditions, and tends to it as the rate of flow diminishes. The maximum possible steady-state concentration of the intermediate product B, attainable at a rate of flow $u/V = \sqrt{k_1 k_2}$, is

$$[\overline{B}]_{max} = \frac{[A]_0 \cdot k_1}{(\sqrt{k_1} + \sqrt{k_2})^2}.$$

Yet for the maximum concentration of this product under static conditions[11] we have

$$[B]_{max} = [A]_0 \left(\frac{k_2}{k_1}\right)^{k_1/(k_2 - k_1)}.$$

Writing $k_2/k_1 = \kappa$, we find that the ratio of the maximum concentration of B under static conditions to its maximum concentration in an open system is

$$y = \frac{[\overline{B}]_{max}}{[B]_{max}} = \frac{\kappa^{\frac{\kappa}{1-\kappa}}}{(\sqrt{\kappa} + 1)^2}.$$

Hence it follows[10] that at all values of κ the function $y = y(\kappa)$ is less than unity: i.e. $[B]_{max}$ always exceeds $[\overline{B}]_{max}$.

The calculations given here are valid, of course, only for a simple consecutive reaction. The influence of further complication of the system on the ratio of the maximum concentrations in open and closed systems requires special examination.

V. DEPENDENCE OF REACTION VELOCITY ON FLOW RATE IN VESSELS HAVING IDEAL MIXING

The rate of change in the concentration of any substance in an open system, as already mentioned above, is given by

$$\frac{d[C]}{dt} = w_f + w_u - \frac{u}{V}[C]$$

In the steady state $(u/V)[C] = w_f - w_u$. Thus the product of the rate of supply of the starting materials by the steady-state concentration of a given substance gives the rate of accumulation of this substance in the reaction. In an open system, as under static conditions, the reaction velocity changes with the extent of the process.

For reactions of the first, second, and third order the reaction velocity (the rate of consumption of the starting material) is a maximum at the maximum concentration of the starting materials[46]. In this case, therefore, the maximum reaction velocity is reached with the maximum possible rates of supply of the starting materials. In practice, however, such rates are used very rarely, owing to the difficulty of isolating the reaction products from dilute solutions.

Let us examine the variation with the rate of flow in the rates of accumulation of intermediate and final products in the consecutive reaction $A \xrightarrow{k_1} B \xrightarrow{k_2} C$.[8] The steady-state concentration of the intermediate product B is (see Section IV, 2)

$$[\overline{B}] = \frac{[A]_0 k_1 \cdot u/V}{(k_1 + u/V)(k_2 + u/V)}.$$

Hence its rate of accumulation

$$\frac{u}{V}[\overline{B}] = \frac{[A]_0 k_1 (u/V)^2}{(k_1 + u/V)(k_2 + u/V)}$$

increases monotonically with increase in the rate of supply of the starting materials, as in the case of the reaction $A \rightarrow B$, where B undergoes no further change.

For the final product C we have correspondingly

$$\frac{u}{V}[\overline{C}] = \frac{[A]_0 k_1 k_2 u/V}{(k_1 + u/V)(k_2 + u/V)}; \quad \frac{d(u/V\,[C])}{d(u/V)} = \frac{[A]_0 k_1 k_2 [k_1 k_2 - (u/V)^2]}{(k_1 + u/V)^2 (k_2 + u/V)^2}$$

It is seen that, when $u/V > \sqrt{k_1 k_2}$, the derivative

$$\frac{d\left(\frac{u}{V}[\bar{C}]\right)}{d(u/V)} < 0$$

and the rate of accumulation of the final product falls with increase in u/V. When $u/V < \sqrt{k_1 k_2}$, we have

$$\frac{d(u/V\,[\bar{C}])}{d(u/V)} > 0,$$

i.e. the quantity $[\bar{C}]u/V$ increases with increasing rate of supply of the starting materials. Thus the dependence of rate of accumulation of the product C on u/V passes through a maximum at $u/V = \sqrt{k_1 k_2}$. This same rate u/V corresponds to the maximum steady-state concentration of the intermediate product (Section IV, 2).

If in a consecutive reaction A → B → C the product B is formed autocatalytically from its precursor, not only the rate of accumulation of C but also that of B and even the rate of consumption of A should pass through a maximum with increase in the rate of flow[8]. An extremal dependence of the overall rate of the process and the rate of accumulation of each product on the rate of supply of the initial substances is observed in an open system whenever the kinetic curve for accumulation of the given product under static conditions is S-shaped.

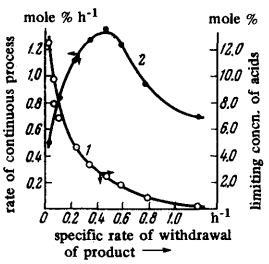

Figure 19. Dependence, on specific rate of supply of cyclohexanone during its continuous oxidation at 110°C, of: 1) steady-state concentration of adipic acid; 2) rate of accumulation of adipic acid.

In the oxidation of cyclohexanone in an open system the rate of accumulation of adipic acid first increases with increase in u/V, passes through a maximum, and then falls[15] (Fig. 19). Analogous extremal variations in the rate of consumption of hydrocarbon and of accumulation of each of the reaction products with increase in u/V have been observed also in the oxidation of n-decane at 140°C (Fig. 20).[8] It is seen from Fig. 20 that the rates of accumulation of all the products of the reaction pass through a maximum, including the rate of accumulation of the first intermediate product, the hydroperoxide. The maxima in the rates of accumulation of all the products with variation in the flow rate are displaced relative to each other, being reached at different flow rates.

With the simple consecutive reaction $A \xrightarrow{k_1} B \xrightarrow{k_2} C \xrightarrow{k_3} D$ as example it has been shown[10] that the maximum rates of accumulation of the individual reaction products should be observed at different values of u/V. For the accumulation of C and D we can write the differential equations

$$\frac{d[C]}{dt} = k_2[B] - (k_3 + u/V)[C] = 0; \quad \frac{d[D]}{dt} = k_3[C] - \frac{u}{V}[D] = 0.$$

Hence the rates of accumulation of these products are

$$\frac{u}{V}[\bar{C}] = \frac{k_2[\bar{B}]\,u/V}{(k_3 + u/V)}; \quad \frac{u}{V}[\bar{D}] = k_3[\bar{C}] = \frac{k_2 k_3 [\bar{B}]}{(k_3 + u/V)}$$

The maximum rate of accumulation of D is reached when

$$\frac{d}{d(u/V)}\left[\frac{[\bar{B}]}{(k_3 + u/V)}\right] = 0;$$

and the maximum rate of accumulation of C when

$$\frac{d\left[\frac{u}{V}[C]\right]}{d(u/V)} = k_2 \frac{u}{V} \frac{d}{d(u/V)}\left[\frac{[\bar{B}]}{(k_3 + u/V)}\right] + \frac{k_2[\bar{B}]}{(k_3 + u/V)} = 0.$$

At the point $d(u[\bar{D}]/V)/d(u/V) = 0$ we have $d(u[\bar{C}]/V)/d(u/V) > 0$: i.e. the maximum rate of accumulation of C is reached at higher values of u/V than is that of D. If one of the stages in the sequence or all of the stages in this process are autocatalytic, the maximum rates of accumulation of individual products are also observed at different rates of flow.

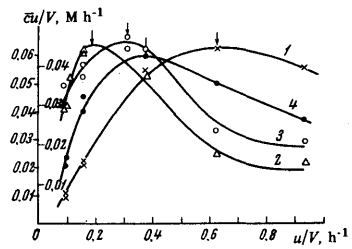

Figure 20. Dependence, on rate of supply of n-decane during its oxidation in reaction vessel of ideal mixing at 140°C, of rates of accumulation of: 1) hydroperoxides (outer scale); 2) acids (outer scale); 3) ketones (inner scale); 4) alcohols (inner scale).

As already remarked above, the maximum rate of accumulation of any final product of a simple consecutive reac- A → B → C is reached at the same rate of supply of the starting materials as is the maximum steady-state concentration of the intermediate which is the immediate precursor of the given final product (see above), independently of whether B can be consumed only by conversion into C or in more than one way. This property of an open system has yielded a possible method for determining the routes by which the final reaction products are formed.

The method consists in comparing the maximum rates of accumulation of the final products and the steady-state concentrations of the intermediates with variation in the flow rate. If these maxima are reached at the same flow rate, the intermediate can be regarded as the direct precursor of the given final product[8].

However, this method of determining the paths by which the final products are formed is not general, and requires careful analysis of the mechanism and the conditions under

which the process is conducted. Thus in the autocatalytic consecutive reaction A → B → C → D, where the reaction product B accelerates consumption of C, the maximum rate of accumulation of D and the maximum steady-state concentration of C should be reached at different values of u/V. However, some modification of the method enables the paths by which D is formed to be determined even in this case[10].

Analysis of the scheme for a chaim oxidation in the liquid phase, where the product D is formed by a chain mechanism involving free peroxy-radicals $RO_2^{\cdot}$ formed by the breakdown of B (with a rate constant k_2'), shows that the rate of accumulation of D in this case is $u[\bar{D}]/V = k_3[\bar{C}][RO_2^{\cdot}]$, or $u[\bar{D}]/V = k_3(k_2'[\bar{B}][\bar{C}]/k_6)^{1/2}$, since with quadratic recombination of radicals (rate constant k_6) we have $[RO_2^{\cdot}] = (k_2'[\bar{B}]/k_6)^{1/2}$.

Since the amount of B is affected by change in the flow rate, the maxima in the relations $u[\bar{D}]/V = f_1(u/V)$ and $u[\bar{C}]/V = f_2(u/V)$ will not coincide. However, if a substance which will ensure a sufficiently rapid rate of formation of radicals $RO_2^{\cdot}$ is added to the system together with the starting materials, so that $w_i > k_2'[\bar{B}]$, we have

$$u/V\,[\bar{D}] = k_3[\bar{C}][RO_2^{\cdot}] = \frac{k_3[\bar{C}]}{\sqrt{k_6}}\sqrt{w_i}$$

By varying the initiator concentration so that w_i remains constant with variation in the flow rate, these maxima can be made to coincide.

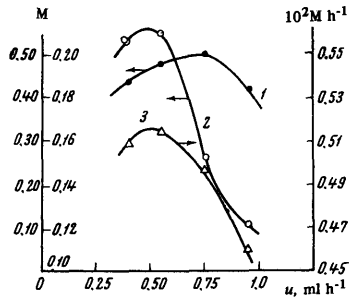

Figure 21. Dependence, on rate of supply of ethylbenzene at 118°C, of: 1) steady-state concentration of hydroperoxide; 2) steady-state concentration of 1-phenylethanol; 3) rate of accumulation of acetophenone.

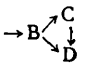
The method has been tested for the oxidation of ethylbenzene[17]. (Preliminary experiments had shown that acetophenone was formed directly from 1-phenylethanol, not by decomposition of the hydroperoxide—see below.) Fig. 21 illustrates the dependence of the rates of accumulation of acetophenone and of the steady-state concentrations of ethylbenzene hydroperoxide and 1-phenylethanol on the rate of supply of ethylbenzene. The rate of initiation of chains was maintained constant to ±4% while u/V was varied from 0.096 to 0.041 h^{-1}. It is seen from Fig. 21 that the maximum rate of accumulation of acetophenone is reached at the same value of u/V as is the maximum steady-state concentration of 1-phenylethanol.

When the final product in a complicated consecutive-parallel reaction is formed by two or more parallel routes, it is also possible to establish these paths. Thus it has been shown[10], for example, that in the consecutive-parallel reaction



the maximum steady-state concentration of B is reached at the same value of u/V as is the total rate of accumulation of the products C and D.

VI. USE OF REACTIONS IN VESSELS HAVING IDEAL MIXING AS METHOD OF INVESTIGATING THE MECHANISM OF CHEMICAL REACTIONS

Study of the kinetics of reactions in vessels with ideal mixing enables the paths by which the final products are formed to be assessed from the dependence of the steady-state concentrations of the intermediate substances and the rates of accumulation of the final products on the rate of flow. However, this is not the only possibility for studying reaction mechanisms and rates of formation of products provided by open systems.

One of the greatest advantages of open systems is that the use of gradient-free reaction vessels makes it possible to study a reaction under perfectly constant experimental conditions, for variation in the conditions during an experiment makes it difficult to interpret the results. The influence of such factors as the pH of the medium, the dielectric constant, etc. is far more easily established when the reaction is conducted in an open system, where constant conditions can be maintained as long as desired.

Such systems present a considerable advantage also for the study of rapid chemical reactions. This method has been used, for example, to study the rapid interaction of iron(II) ions with sodium thiosulphate[47]. The reaction involves the intermediate formation of a violet complex. Under static conditions the coloration disappears extremely rapidly, and it is practically impossible to obtain the spectrum of this compound. Conducting the reaction in an open system with solutions of sodium thiosulphate and of an iron salt fed separately to the vessel enabled the spectrum of the intermediate complex to be obtained. At sufficiently high rates an intense violet coloration was established, which was stable with time and enabled the absorption spectrum of the complex to be recorded. The lifetime of the complex was found to be 10 s.

The attainment of steady-state concentrations when chemical reactions are conducted in gradient-free reaction vessels simplifies mathematical analysis of the set of kinetic equations describing the process. This in turn considerably facilitates the task of determining the rate constants for reactions of differing order from known concentrations of the reaction components.

1. Determination of Rate Constants for Simple Types of Reactions

The rate constants of first-order reactions in open systems can be determined quite simply[50] both from the steady-state concentration of starting material or final product (see Eqns. 12 and 13) and from the time required to reach half the steady-state concentration (Eqn. 3a). These formulae do not take into account a possible change in volume during the reaction. Yet most first-order reactions in the gas phase involve a change in volume. Use

of the formulae (13) and (12) then becomes impossible because of the inequality in the rates of withdrawal of products and supply of starting materials, so that the formula

$$k_1 = \frac{(u/V)[A]_0 - (u/V)_1[\bar{A}]}{[\bar{A}]}$$

where u/V is the rate of supply and $(u/V)_1$ the rate of withdrawal of the starting material A from the system, must be applied[51].

It is thus sufficient to know merely the speed of the gas on entering and on leaving the vessel in order to determine the rates of the process. Nevertheless, a change in volume during the process greatly increases the difficulty of studying reactions in a laminar flow system, since it is then necessary to know the law governing the change in volume throughout the length of the vessel.

As example of the determination of a first-order rate constant we can cite the gas-phase decomposition of chlorocyclohexane (A), which is accompanied by the evolution of elementary chlorine[52]. Progress of the reaction was followed from the change in concentration of chlorine. Since the process involves a change in volume, the rate of withdrawal of chlorine from the system is not equal to the rate of supply of chlorocyclohexane. The rate of change in the chlorine concentration can be written

$$\frac{d[Cl_2]}{dt} = k_1[A] - \frac{u_{Cl_2}}{V}[Cl_2]$$

where u_{Cl_2} is the space velocity of removal of chlorine from the system. After a steady-state chlorine concentration has been established, when $d[Cl_2]/dt = 0$, the constant k_1 is determined by means of the formula

$$k_1 = \frac{u_{Cl_2}}{V}\frac{[\bar{Cl}_2]}{[\bar{A}]}.$$

The value obtained for the decomposition rate constant of chlorocyclohexane was identical with that determined previously under static conditions, which indicates that reaction rate constants can be determined by this method.

A similar study has been made of the pyrolysis of ethyl acetate, which is also a first-order reaction accompanied by a change in volume[53]. The rate constant was determined over the temperature range 376–531 °C, and it was found that the activation energy varied with temperature.

The possibility of determining the rate constants of bimolecular reactions has been examined in detail for the reaction $A + B \xrightarrow{k} C$. In this case k can be determined by measuring the concentration of at least one of the substances present in the system (e.g. C), provided that the initial concentrations a_0 and b_0 of A and B in the mixture entering the vessel are known, together with the rate of supply of A and B to the system[50]. Thus if A and B enter the system with different space velocities u_A and u_B, while the reaction product is removed from the system at the rate $u = u_A + u_B$, the constant is determined by means of the formula

$$c = \frac{(V/u)\ k\ (u_A \cdot a_0 - u \cdot c)\ (u_B \cdot b_0 - u \cdot c)}{u^2}.$$

The rate constant of a bimolecular reaction in a gradient-free reaction vessel was first measured by Bodenstein[1], as already mentioned.

Use of a reaction vessel with ideal mixing facilitates the task of determining the rate constants not only of simple but also of complicated, multistage reactions, among which are consecutive, parallel, and consecutive–parallel reactions.

The individual rate constants of each process can be determined for a series of parallel reactions. In one of the simplest cases, e.g. when several parallel reactions

$$\begin{aligned} A_1 + B &\rightarrow C_1 \quad (k_1)\\ A_2 + B &\rightarrow C_2 \quad (k_2)\\ &\cdots\\ A_n + B &\rightarrow C_n \quad (k_n) \end{aligned}$$

are occurring in a system, each of the constants can be determined by conducting the process with various rates of supply of the starting materials, only the steady-state concentration of these substances being measured. In fact, the rate of change in the concentration of B is

$$\frac{d[B]}{dt} = -k_1[A_1][B] - k_2[A_2][B] - \ldots - k_n[A_n][B] - \frac{u}{V}[B] + \frac{u}{V}[B]_0. \quad (15)$$

When $d[B]/dt = 0$, this equation is converted into an algebraic equation, in which all the k_i can be determined provided that there are n such equations. If the parallel reactions take place in the gas phase and are accompanied by change in volume, the formulae for calculating the individual constants are somewhat complicated[51].

The rate constants of parallel reactions have been determined for the gas-phase decomposition of isopropyl and s-butyl chloroformates, which is accompanied by change in volume[52,53]. When the gaseous compounds are heated to high temperatures, they may undergo either substitution or decomposition with formation of alkenes; in the case of the s-butyl ester, two stereoisomeric compounds—*cis*- and *trans*-but-2-ene—can be formed. Conducting these processes in an open system has enabled the rate constants of each of the parallel stages to be determined at various temperatures.

In the case of a simple consecutive reaction of the type $A \xrightarrow{k_1} B \xrightarrow{k_2} C$ with the same rate of supply of the starting materials, both constants can be determined from the steady-state concentrations of the initial and intermediate substances (A and B) by means of the equations¶

$$-k_1[\bar{A}] - \frac{u}{V}[\bar{A}] + \frac{u}{V}[A]_0 = 0 \quad (16)$$

$$k_1[\bar{A}] - k_2[\bar{B}] - \frac{u}{V}[\bar{B}] = 0. \quad (17)$$

If the concentration of the intermediate cannot be measured, the constants k_1 and k_2 can be determined from the steady-state concentrations of the final reaction product (C) with various rates of supply of the starting materials, by means of the formula

$$[\bar{C}] = \frac{k_1 k_2 [A]_0}{(k_1 + u/V)(k_2 + u/V)}$$

or

$$\frac{1}{u/V}\left\{\frac{1}{[\bar{C}]} - \frac{1}{[A]_0}\right\} = \frac{1}{k_1 k_2}(k_1 + k_2) + \frac{1}{k_1 k_2} \cdot \frac{u}{V}.$$

In the latter case, by plotting

$$\frac{1}{u/V}\left(\frac{1}{[\bar{C}]} - \frac{1}{[A]_0}\right)$$

against u/V, we can determine k_1 and k_2 separately.

Determination of the rate constants for all stages in a process is possible also when a common component takes

¶ Use of an analogous method under static conditions necessitates the graphical differentiation of the kinetic curves for the consumption of A and the accumulation of B, which diminishes the accuracy of the constants obtained.

part in every stage in a consecutive bimolecular reaction[54]. The possibility of determining rate constants for consecutive bimolecular reactions has been examined in detail for chlorinations represented by the scheme

$$A + B \xrightarrow{k_1} A_1$$
$$A_1 + B \xrightarrow{k_2} A_2 \text{ etc.}$$

In this case the constant k_1 can be determined from the formula

$$k_1 = \frac{u}{V \cdot a \cdot x}(1-a) \qquad (18)$$

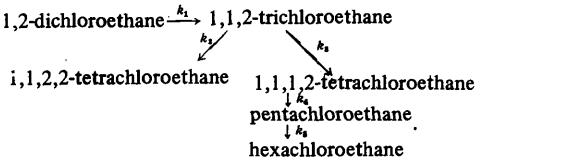
where a is the steady-state mole fraction of A in the reaction vessel, while x is the number of moles of chlorine which have reacted per mole of the initial substance A consumed. The value of x is given by the sum of the mole fractions of all the chlorinated reaction products multiplied by the appropriate coefficients:

$$x = a_1 + 2a_2 + 3a_3 + \ldots + na_n$$

The constant k_2 can be determined if the steady-state mole fractions of A and A_1 are known:

$$k_2 = \frac{u}{V} \cdot \frac{1}{a_1 x}(1-a_1-a_2). \qquad (19)$$

The above formulae (18) and (19) have been used to determine the rate constants for the chlorination of 1,2-dichloroethane at 100°C, which is represented by the scheme



The constants k_1, k_2, and k_3 were determined in the chlorination of 1,2-dichloroethane, and it was shown that 1,1,2,2-tetrachloroethane does not undergo further chlorination. The constants k_4 and k_5 were measured in the chlorination of 1,1,2-trichloroethane[55] and of 1,1,1,2-tetrachloroethane[56] under analogous conditions.

Conducting a process in open systems enables not only the rate constants but also the order of the reaction to be determined. If a reaction of the nth order with respect to some component, e.g. $nA \rightarrow B$, is conducted in an open system with different rates of supply $(u/V)_1$ and $(u/V)_2$ of the starting materials, the steady-state concentrations $[\bar{A}]_1$ and $[\bar{A}]_2$ are given by

$$k[\bar{A}]_1^n = \left(\frac{u}{V}\right)_1 ([A]_0 - [\bar{A}]_1) \qquad (20)$$

$$k[A]_2^n = \left(\frac{u}{V}\right)_2 ([A]_0 - [\bar{A}]_2) \qquad (21)$$

Dividing Eqn. (20) by (21) term by term and taking logarithms, we obtain

$$n \lg \frac{[\bar{A}]_1}{[\bar{A}]_2} = \lg \left\{ \frac{u_1}{u_2} \cdot \frac{([A]_0 - [\bar{A}]_1)}{([A]_0 - [\bar{A}]_2)} \right\},$$

the slope of the plot of $\lg([\bar{A}]_1/[\bar{A}]_2)$ against the right-hand side of this equation giving the order n of the reaction.

Determination of the order of a reaction is a far more laborious task in open systems than under static conditions, since it requires many experiments to be made, whereas under static conditions a kinetic curve with a practically unlimited number of points is obtained in one experiment. Nevertheless, in several complicated processes the order with respect to some component is better determined in open systems. Among such reactions are all those processes in which change in the composition of the product during the reaction changes the apparent order of the reaction.

Thus, for example, the order of the polymerisation of styrene in the presence of an initiator—benzoyl peroxide—has not been accurately established. From some results it has been assumed that the reaction is of the first order with respect to the monomer, whereas other results indicate an order of 1.5. Study of this process in open systems has shown[12] that the apparent order of the reaction with respect to the monomer varies from 1.18 to 1.36 depending on the composition of the reactant mixture.

A property of open systems which is among the most valuable for the study of reaction mechanisms is the possibility of investigating the reaction over a wider temperature range—both downwards and upwards—than under static conditions.

When reactions are studied in open systems, it becomes possible to conduct processes at very small degrees of conversion, which cannot be used under static conditions because of analytical difficulties. The practically unlimited volumes of gases or liquids leaving the reaction vessel in open systems make it possible to accumulate analytically detectable amounts of products even at low degrees of conversion. As a consequence, the temperature of the reaction can be considerably lowered in comparison with static conditions.

At the same time the continuous supply of starting materials to the system prevents them from being completely burned out, so that reactions in open systems can be conducted at considerably higher temperatures than under static conditions. Thus in an investigation[52] of the thermal decomposition of chlorocyclohexane in the gas phase in a flow-type reaction vessel with stirring, it proved possible to raise the temperature from 385°C (the maximum temperature at which the decomposition of this substance had been studied under static conditions) to 476°C, i.e. by almost 100 deg. Study of the decomposition of ethyl acetate in open systems over a wide temperature range enabled a change in mechanism of pyrolysis with rise in temperature to be detected[53]: at high temperatures (above 500°C) the activation energy of pyrolysis is 44 kcal mole^{-1}, but when the temperature is lowered to 376–414°C the activation energy falls to 41 kcal mole^{-1}.

The possibility of determining rate constants for simple types of reactions, as well as for parallel and consecutive reactions, is undoubtedly a merit of open systems. In most cases, however, especially for simple types of reactions, these constants can easily be determined also under static conditions.

The advantage of "open" systems over all other methods of conducting a process is shown most clearly when it is necessary to study complicated reactions. Variation in conditions during the process (e.g. change in the ionic strength of the solution, the dielectric constant, the pH, etc.) makes the determination of rate constants under static conditions extremely inaccurate, and interpretation of the results difficult. To maintain the ionic strength, pH, etc. constant under static conditions special methods are used (e.g. buffer solutions or continuous titration of the solutions during the process, which changes the volume of the system and thereby introduces additional difficulties).

Open systems enable a process to be conducted under conditions which remain unchanged for a long time, so that the reaction velocity can be measured accurately with the composition of the reaction mixture rigidly fixed. An

example is provided by the bromination of acetone under conditions of ideal mixing[57]. The rate constant of this process, determined from the scheme for a simple consecutive reaction, varies considerably with the extent of reaction, so that it was concluded that this reaction is more complicated than the scheme adopted in the literature.

2. Determination of Rates of Reactions involving Reactive Intermediates

The method described above for determining the rate constants of individual stages in parallel and consecutive reactions cannot always be used to determine the rates of chain reactions involving active intermediate species, whose concentration is often impossible to measure.

The kinetics of the accumulation of an intermediate B in consecutive chain reactions, e.g. $A \xrightarrow{RO_2^\cdot} B \xrightarrow{RO_2^\cdot} C$, in an open system is described by the equation

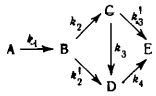
$$\frac{d[B]}{dt} = k_1[RO_2^\cdot][A] - k_2[RO_2^\cdot][B] - \left(\frac{u}{V}\right)[B] = 0. \qquad (22)$$

If the steady-state concentration of the initial substance A is known, Eqn. (22) can be used, together with the equation

$$\frac{d[A]}{dt} = -k_1[RO_2^\cdot][A] - \frac{u}{V}([A] - [A]_0) = 0 \qquad (23)$$

for the consumption of A, to determine the products $k_1[RO_2^\cdot]$ and $k_2[RO_2^\cdot]$, and hence the separate rates of formation and consumption of B for a given rate of supply of the substances.

In general, if the number of unknown rate constants exceeds the number of component concentrations which can be measured, it is impossible to determine the rates of formation and consumption of a substance from an experiment conducted at a single rate of flow. For example, the sequence of reactions



in the steady state can be described by a set of five equations with six unknown constants, and it becomes possible to determine all the constants only by conducting the reaction with several different velocities. In several cases, however, change in the rate of flow has a complicated effect on the concentration of free radicals, and separate determination of the rates of formation and of consumption of intermediates becomes impossible.

The rates of formation and consumption of products in chain reactions are now being very successfully measured by a kinetic method of labelled atoms, in which small additions of intermediates labelled with a radioactive isotope are introduced into the system[58]. However, the method is quite laborious, and involves isolation of the given intermediate from a complicated mixture of reaction products, which is often a quite difficult task. Use of the labelled atoms method in an open system[59] makes this problem slightly easier.

A new method has recently been suggested for determining the rates of formation of intermediates[60]. It consists in conducting the reaction in an open system until a steady state is established. From then a certain quantity of the intermediate, whose rates of formation and consumption are to be measured, is added to the reaction vessel together with the starting material. The bulk rate of supply of the substance to the vessel should not be varied. In this case the steady-state concentrations of the initial substance and of the branched product (and hence also the steady-state concentration of free radicals) remain unchanged, since the rate of supply of the starting materials is constant. The difference in the steady-state concentrations of the intermediate established in the two cases enables its rates of formation and consumption in the system to be determined†.

In the consecutive reaction $A \xrightarrow{RO_2^\cdot} B \xrightarrow{RO_2^\cdot} C$ the steady-state concentration of B when only the initial substance A is fed to the system is given by the equation

$$k_1[RO_2^\cdot][\bar{A}] - k_2[RO_2^\cdot][\bar{B}] - \frac{u}{V}[\bar{B}] = 0 \qquad (24)$$

but when solutions containing additions of B at concentration $[B]_0$ are supplied we have

$$k_1[RO_2^\cdot][\bar{A}] - k_2[RO_2^\cdot][\bar{B}]_1 - \frac{u}{V}[\bar{B}]_1 + \frac{u}{V}[B]_0 = 0. \qquad (25)$$

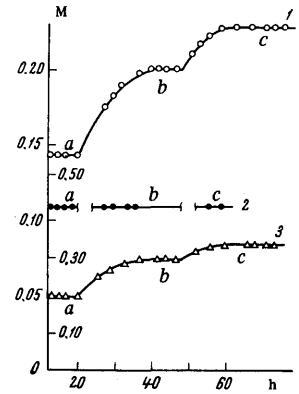


Figure 22. Oxidation of ethylbenzene in reaction vessel of ideal mixing at 118°C, with rate of flow 0.102 h^{-1}, during supply of ethylbenzene (sections a) and of 0.106 M and 0.17 M solutions of 1-phenylethanol in ethylbenzene (sections b and c). Kinetic curves for the accumulation of: 1) alcohols (outer scale); 2) hydroperoxides (inner scale); 3) ketones (outer scale).

As mentioned above, the steady-state concentrations of A and $RO_2^\cdot$ are not affected by supplying to the system a solution containing B. Solution of Eqns. (24) and (25) gives

$$\left(1 + \frac{k[RO_2^\cdot]V}{u}\right) = \frac{[B]_0}{[\bar{B}]_1 - [\bar{B}]} \qquad (26)$$

For a first-order reaction $[\bar{B}]_1 - [B]$ can be plotted against $[B]_0$, the slope giving $k_2[RO_2^\cdot]$, from which $k_1[RO_2^\cdot]$ can be calculated, as well as the ratio of the rate constants for formation and consumption of B. If B is consumed by an nth-order reaction, Eqn. (26) becomes

$$\frac{k_2[RO_2^\cdot]V}{u} = \frac{[B]_0 + [\bar{B}]^n - [\bar{B}]_1^n}{[\bar{B}]_1 - [\bar{B}]} \qquad (27)$$

† This method cannot be used if addition of the intermediate has a substantial effect on the rate of chain branching.

Use of this method to study the autoxidation of n-decane and ethylbenzene has yielded the ratios of the rate constants for interaction of $RO_2^{\cdot}$ radicals with the alcohol, the hydroperoxides, and the hydrocarbon[60-62]. For example, the rate of formation of 1-phenylethanol in the oxidation of ethylbenzene has been determined from experiments in which 0.106 M and 0.17 M solutions of the alcohol in ethylbenzene were supplied to the vessel. Fig. 22 shows that the steady-state concentrations of the alcohol (*1*) and of acetophenone (*3*) increase. The constancy of the hydroperoxide concentration (*2*) indicates that the concentration of radicals remains unchanged for all additions of the alcohol. The steady-state concentrations of 1-phenylethanol (B) obtained are plotted in Fig. 23 as $[\bar{B}]_1 - [\bar{B}]$ against $[B]_0$. From the slope of the straight line obtained it was calculated that $k_2[RO_2^{\cdot}] = 0.15\ min^{-1}$. The same method has been used to measure the rates of formation and consumption of products of the oxidation of n-decane catalysed by cobalt stearate. In this process the greater part of the alcohols, ketones, and acids were shown to be formed directly from the $RO_2^{\cdot}$ radicals[63], not by decomposition of a hydroperoxide (as occurs in the absence of a catalyst[44]).

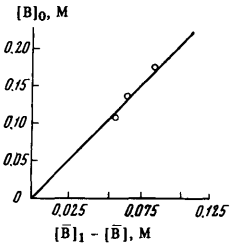

Figure 23. Dependence of difference between the steady-state concentrations of alcohols in experiments with supply of 1-phenylethanol ($[\bar{B}]_1$) and of pure ethylbenzene ($[\bar{B}]$) on concentration of 1-phenylethanol ($[\bar{B}]_0$) in solution supplied to vessel at 118°C, rate of flow 0.102 h^{-1}.

The variation in the steady-state concentration of the final product C, formed from B, with variation in the concentration of B in the solution fed to the vessel enables the rate of formation of C from B to be determined even if C is formed by several parallel routes. Actually, the rate of accumulation of C when the pure starting materials are supplied is

$$\frac{d[C]}{dt} = w_f^1 + k[RO_2^{\cdot}][\bar{B}] - \frac{u}{V}[\bar{C}] = 0$$

and when a solution of B is supplied to the system we have

$$\frac{d[C]}{dt} = w_f^1 + k[RO_2^{\cdot}][B]_1 - \frac{u}{V}[\bar{C}]_1 = 0,$$

where w_f^1 is the rate of formation of C from all products other than B. Hence the rate of formation of C from B is

$$k[RO_2^{\cdot}][B] = \frac{(u/V)([\bar{C}] + [\bar{C}]_1)[\bar{B}]}{([\bar{B}]_1 + [\bar{B}])} .$$

In this way the rate of formation of acetophenone (the final product in the oxidation of ethylbenzene in the absence of a catalyst[17,62]) from 1-phenylethanol has been calculated from the steady-state concentrations of acetophenone at various concentrations of the alcohol in the solution fed to the vessel, and oxidation of 1-phenylethanol has been shown[62] to be the only route by which the ketone is formed during the oxidation of ethylbenzene.

The mixture of reaction products often contains not only various functional derivatives but also a large number of isomeric products differing not only in the structure of the carbon skeleton but also in the position of the functional group in the molecule. When a reaction is conducted under static conditions it is extremely difficult to determine the rates of formation and consumption of each isomer, primarily because each such isomer must be isolated from the complicated mixture of reaction products. Conducting the process in an open system enables the rates of consumption of each of the isomers to be determined by analysing the total content of isomers in the system[64,65].

Let various isomeric products B_1, B_2, ..., B_n be formed in a reaction. It is required to determine the rate constant for consumption of a component B_K. Then for the total rate of accumulation of the isomers we have

$$\frac{d[B]}{dt} = \sum_{j=1}^{n} k_j[\bar{A}_j] - \sum_{\substack{i=1 \\ (i\neq k)}}^{n} k_i[RO_2^{\cdot}][\bar{B}_i] - k_k[RO_2^{\cdot}][\bar{B}_k] - \frac{u}{V}\sum_{\substack{i=1 \\ (i\neq k)}}^{n}[\bar{B}_i] - \left(\frac{u}{V}\right)[\bar{B}_k] = 0 \qquad (28)$$

When the isomer B_K is fed to the system at a concentration $[B_k]_0$, the steady-state concentrations of all isomers other than B_k remain unchanged, and the total accumulation of isomers will be described by the set of equations

$$\frac{d[B]}{dt} = \sum_{j=1}^{n} k_j[\bar{A}_j] - \sum_{\substack{i=1 \\ (i\neq k)}}^{n} k_i[RO_2^{\cdot}][\bar{B}_i] - k_k[RO_2^{\cdot}][\bar{B}_k]_1 + \frac{u}{V}\sum_{\substack{i=1 \\ (i\neq k)}}^{n}[\bar{B}_i] - \frac{u}{V}[\bar{B}_k]_1 + \frac{u}{V}[B_k]_0 = 0 . \qquad (29)$$

Subtracting Eqns. (28) from (29), we obtain

$$-k_k[RO_2^{\cdot}]([\bar{B}_k]_1 - [\bar{B}_k]) - \frac{u}{V}([\bar{B}_k]_1 - [\bar{B}_k]) + \frac{u}{V}[B_k]_0 = 0$$

$$k_k[RO_2^{\cdot}] = \frac{u}{V}\frac{-[\bar{B}_k]_1 + [\bar{B}_k] + [B_k]_0}{[\bar{B}_k]_1 - [\bar{B}_k]} = \frac{u}{V}\left\{-1 + \frac{[B_k]_0}{[\bar{B}_k]_1 - [\bar{B}_k]}\right\}$$

but

$$[\bar{B}_k]_1 - [\bar{B}_k] = \sum_{\substack{i=1 \\ (i\neq k)}}^{n}[\bar{B}_i] + [\bar{B}_k]_1 - \sum_{\substack{i=1 \\ (i\neq k)}}^{n}[\bar{B}_i] - [\bar{B}_k] = [\bar{B}_1] - [\bar{B}]$$

where $[\bar{B}]_1$ and $[\bar{B}]$ are the total concentrations of all the B isomers. Hence

$$k_k[RO_2^{\cdot}] = \frac{u}{V}\left\{-1 + \frac{[B_k]_0}{[\bar{B}]_1 - [\bar{B}]}\right\} .$$

The method was used to determine the reactivities of the isomeric decanols[65] in the oxidation of n-decane at 140°C. After a steady-state concentration of the alcohols had been established with pure n-decane supplied to the vessel (Fig. 24, curve *1*, section *1*), the supply was begun of n-decane containing 0.205 M decan-2-ol. After a new steady-state had been established (straight line *1*, *2*), the supply of decan-2-ol was terminated, and the supply was begun of a similar solution of decan-4-ol (straight line *1*, *3*), followed by decan-5-ol (*1*, *4*).

Since the steady-state concentrations of the total alcohols were the same with all three alcohols supplied to the

vessel, it could be concluded that all the decanols had the same reactivity towards the $RO_2^{\cdot}$ radical.

---o0o---

The purpose of the present review was to examine the kinetics of reactions occurring in vessels having ideal mixing, and the opportunities which such systems present for studying the mechanism of complicated chemical reactions. Among a large amount of published information, therefore only those papers have been considered which make it possible to formulate or substantiate certain general features of open systems.

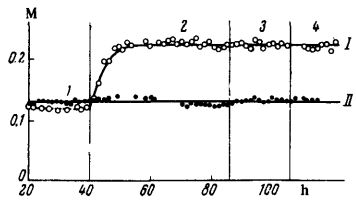

Figure 24. Steady-state concentrations of alcohols (I) and hydroperoxides (II) during the oxidation of n-decane in an open system at 140°C with a rate of flow of 0.0027 min^{-1}, during supply of: 1) n-decane containing no alcohol; 2) 0.205 M solution of decan-2-ol in n-decane; 3) 0.205 M solution of decan-4-ol in n-decane; 4) 0.205 M solution of decan-5-ol in n-decane.

Investigation of reaction kinetics in vessels having ideal mixing enables very important conclusions to be reached for the selection of reaction conditions for particular processes. Thus if the rate of accumulation of a product passes through a maximum, the maximum rate of the process can be permanently maintained by conducting it in vessels of ideal mixing. In this case the process is more suitably conducted in an open system than under static conditions[18,66].

Sometimes it is important to vary the reaction conditions during a process in order to obtain maximum yields, and this can be done especially conveniently by conducting the reaction in several vessels of ideal mixing connected in series. This procedure often enables the efficiency of a process to be increased considerably[66-70]. For example, in the sequence of processes

$$A + B \rightarrow X$$
$$X + B \rightarrow Y$$

represented in particular by chlorination, the product X is obtained in highest yield if the volumes of all the reaction vessels are the same. If primary and secondary products are formed by two parallel reactions of different order

$$2A + B \rightarrow X + Y$$
$$A + B \rightarrow Z$$

the highest yield of X is obtained by steadily increasing the volume from one reaction vessel to the next[18].

Most complicated reactions (consecutive and consecutive-parallel) involve many stages, each characterised by a definite activation energy, so that certain temperatures are required for the reactions. The possibility of varying the temperature during a process may lead to a very considerable increase in the yields.

The effect of variation in temperature has been demonstrated[18] for a model reaction represented by the scheme

$$\begin{array}{ccccc} A & + & B & \xrightarrow{2} & X \xrightarrow{4} Y \\ \downarrow 1 & & & & \downarrow 3 \\ P & & & & Q \end{array}$$

occurring in two reaction vessels of ideal mixing connected in series, Y being the required product. It was shown by calculation that, with the same temperature in the two reaction vessels, the yield of the final product cannot exceed 20-25%, whereas maintaining different temperatures in the two vessels makes it possible to increase the yield to 60%, i.e. by factors of 2.5-3.[18]

Another example of the favourable effect of change in temperature during a process is the catalytic oxidation of sulphur dioxide to sulphur trioxide[68,69]. If a definite degree of conversion (e.g. 97%) is specified, and the reaction is conducted in several vessels of ideal mixing connected in series and maintained at different temperatures, the quantity of catalyst used can be considerably diminished. In one reaction vessel of ideal mixing at 447.6°C the consumption of catalyst with 97% conversion is 0.633 m^3 h $kmole^{-1}$. If, however, the process is conducted in two series-connected reaction vessels, so that 92% conversion is achieved in the first vessel at 480°C, while in the second vessel complete oxidation of the dioxide to sulphur trioxide occurs at 447.6°C, the consumption of catalyst per kilomole of sulphur dioxide per hour with an overall degree of conversion of 97% is only 0.0577 m^3, i.e. one-eleventh.

In several cases it is extremely useful to conduct polymerisation processes in open systems. The constancy of the monomer concentration with time in an open system should lead to a narrower molecular-weight distribution[14,70], but, on the other hand, the unequal residence times of the polymeric species in the reaction zone tends to broaden the molecular-weight distribution. Which of these factors predominates will depend on the lifetime of the growing polymer chain.

Synthesis of Thioamides

K.A.Petrov and L.N.Andreev

Exhaustive data are given on methods for the synthesis of thioamides, which have now found wide application in synthetic practice, in medicine, biology, and analytical chemistry, in the foodstuffs and metallurgical industries, and in other fields. Attention is paid mainly to methods for preparing thioamides from nitriles and amides and by the Willgerodt-Kindler reaction. This is the first review of the synthesis of thioamides to be published in the Soviet literature. The list of references contains 378 items.

INTRODUCTION

Thioamides are reactive compounds which, because of the diversity of their chemical properties, find wide application in technology[1-6], in agriculture[7-12], and in synthetic practice and medicine. They are used as vulcanisation accelerators[13-15], additives to lubricating oils, corrosion-inhibitors for metals[16-19], flotation agents[1-6], insecticides and fungicides, preservatives[20-26], medicinals for the treatment of poisoning by salts of heavy metals, starting materials for the preparation of certain vitamins (e.g. B_1), and other pharmaceutical preparations[26-38].

Thioamides have been studied in detail: more than 400 representatives of this group have been synthesised, and about 500 papers and patents have been published. However, this information is scattered among many periodicals, and is difficultly accessible. The Soviet literature contains no review papers on the chemistry of thioamides, apart from a publication on the use of thioacetamide to replace hydrogen sulphide[39] in the analysis of metals. The foreign literature contains publications of a review character[40-45], but they are either out of date or incomplete. These are the reasons for the publication of the present review.

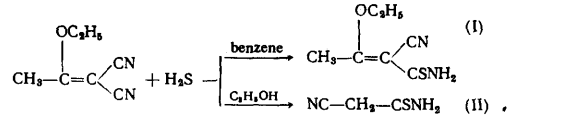
1. PREPARATION OF THIOAMIDES BY THE REACTION OF NITRILES WITH HYDROGEN SULPHIDE

Various method of preparation have been suggested for thioamides. The most convenient of them is based on the reaction of nitriles with hydrogen sulphide, since it uses readily available materials and there are practically no by-products[46-70]:

$$RCN + H_2S \rightarrow RCSNH_2$$

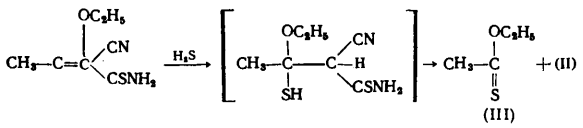
As early as 1841 the first member of the group—thiobenzamide—was obtained by this method[71]. The reaction between nitriles and hydrogen sulphide is usually conducted in various solvents and in the presence of amines, both of which influence the yield of thioamides. Among solvents which have been used are ethanol (aqueous or absolute)[72-79], aromatic hydrocarbons, dioxan, acetone[51-53,80], chloroform[81], pyridine[82,83], and in some cases water[80]. The nitrile solution was saturated with hydrogen sulphide usually at 0°C or room temperature (sometimes at 60°C [73]), a high concentration of hydrogen sulphide promoting better formation of thioamides[73]. After saturation the reaction mixture was either left at room temperature for a few days, or heated at 80–100°C,[84,85] sometimes at 100–150°C, for 6–10 h.

In isolated cases the solvent used has a substantial influence on the character of the products. Thus 1-ethoxyethylidenemalononitrile is able to give various reaction products with hydrogen sulphide depending on the solvent[86]: in benzene α-cyano-β-ethoxythiocrotonamide (I) is formed, whereas in ethanol cyanothioacetamide (II) is obtained:



The difference in the course of the reaction is explained by the differing solubility of the product (I) (formed initially

in both cases), which is insoluble in benzene and is precipitated, whereas it dissolves slightly in hot alcohol and reacts with hydrogen sulphide:



Ammonia, diethylamine, triethylamine, trishydroxyethylamine, and alkali-metal and ammonium hydrogen sulphides are used as catalysts[84,87,88]. When primary and secondary amines are used, mono- and di-substituted thioamides respectively are formed[49,50,89,90]. Hydrogen sulphide adds to nitriles especially readily in the presence of pyridine and of triethylamine[82,83].

Under otherwise similar conditions†, the yield of a thioamide depends on the nature of the nitrile: aliphatic nitriles usually add hydrogen sulphide with greater difficulty than do aromatic nitriles. The yields of aliphatic thioamides are increased by conducting the reaction at elevated temperatures and pressures. In the case of aromatic nitriles the yields are greatly affected by substituents in the aromatic ring: thus under identical conditions yields were obtained of 100% *o*-chlorothiobenzamide, 95% phenylthioacetamide, 94% thiobenzamide, 90% *p*-methoxythiobenzamide, 86% thionicotinamide, 81.5% *p*-aminothiobenzamide, 80% *p*-acetamidothiobenzamide, 70% *p*-ethylsulphonylthiobenzamide, 70% 3,4-dimethoxythiobenzamide, 65.5% thiopicolinamide, 60.5% dithioterephthalamide, and 48.5% *p*-chlorothiobenzamide[91].

The nature of the nitrile influences not only the yield of thioamide but also the reaction velocity. In the preparation of aromatic thioamides from benzonitriles containing various substituents in the ring, the following relative reaction velocities were obtained at 60°C and 1.75 atm (rate of addition of hydrogen sulphide to benzonitrile itself taken as 100): *m*-bromo 831, *p*-iodo 518, *p*-chloro 493, *p*-bromo 451, *p*-methyl 51.9, and *p*-methoxy 41.6.[92]

The action of hydrogen sulphide on dinitriles under the same conditions yields bisthioamides. Cyanogen reacts with hydrogen sulphide in the presence of bases to form dithio-oxamide (rubeanic acid $C_2H_4N_2S_2$)[58,92-100]. The reaction is conducted by saturating alcohol with the gaseous reactants or by mixing cyanogen with liquid hydrogen sulphide[27,58,92,100], the latter component being taken in excess in both cases. Cyanothioformamide is formed as an intermediate in the reaction[58], and has been isolated by carrying out the reaction in alcoholic solution with excess of cyanogen[97]. Sometimes potassium hydrogen sulphide[96] or the sodium compound[93,94,100] is used instead of hydrogen sulphide.

Dithio-oxamide has been obtained also by treating ethyl cyanoformimidate NC.C(:NH).OC_2H_5 or diethyl oxalyldiimidate C_2H_5O.C(:NH).C(:NH).OC_2H_5 with hydrogen sulphide in the presence of bases[101]. It has been proposed to obtain rubeanic acid on an industrial scale by passing a mixture of cyanogen and hydrogen chloride with stirring into an alkaline aqueous solution (pH 7–9) of sodium hydrogen sulphide at temperatures below 50°C:[93]

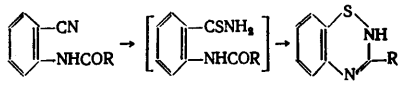
$$(CN)_2 + 2H^+ + HS^- \rightarrow H_2NCSCSNH_2.$$

No secondary products are formed in this case, unlike the process considered earlier. The initial mixture of cyanogen and hydrogen chloride is obtained by the interaction of chlorine and hydrogen cyanide at a high temperature in tubes filled with wood charcoal[93].

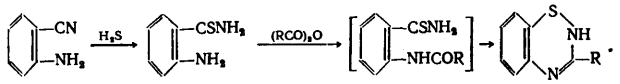
The reaction between a nitrile and hydrogen sulphide can be accomplished also in the absence of a solvent, by using the liquid reactants under pressure[85,102]. Hydrohalic acids[103] or an aluminosilicate[102] are used as catalyst in this case, besides amines. When liquid hydrogen sulphide and a liquid nitrile are used, the reaction is conducted at 50–60°C, a high yield of the thioamide being obtained. In the presence of an aluminosilicate catalyst the reaction between nitriles and hydrogen sulphide takes place under considerably more severe conditions (249–260°C)[102,104].

Under pressures of ~ 8500 atm hydrogen sulphide adds to nitriles at 80–100°C even in the absence of catalysts[85]. Thus acetonitrile and hydrogen sulphide at 80°C give thioacetamide (83%) and a certain quantity of by-products, mainly diethyl trisulphide. The temperature of the reaction must be carefully controlled, since hydrogen sulphide already acts as a reducing agent at 125–150°C.

Several nitriles, e.g. those of alanine, glycine, and *N*-acylanthranilic acids tend to cyclise when an attempt is made to prepare thioamides from them[105]. When an acylaminobenzonitrile is treated with hydrogen sulphide, ring closure occurs with the formation of thiadiazines[105]:

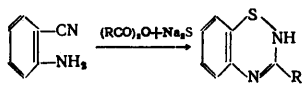


where R = CH_3, C_2H_5, $CH(CH_3)_2$, or C_4H_9. The same heterocycle can be obtained from the nitrile of unacylated anthranilic acid by treating with the anhydride of a carboxylic acid its reaction product with hydrogen sulphide (*o*-aminothiobenzamide):

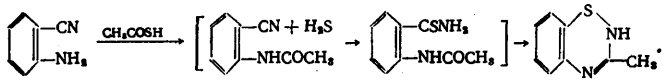


When the reaction is conducted in alcoholic–ammoniacal solution, too, cyclic products are formed. In the presence of an amine instead of ammonia an acyclic product can sometimes be isolated. Thus a small quantity of the non-cyclic thioamide of *N*-acetylanthranilic acid has been isolated from the reaction mass resulting from the interaction of *o*-acetamidobenzonitrile with hydrogen sulphide in the presence of trishydroxyethylamine; even in this case, however, the main product of the reaction was a cyclic thioamide.

The action of sodium sulphide and the anhydride of a carboxylic acid on an amino-nitrile gives a good yield also of the corresponding thiadiazine[105]:



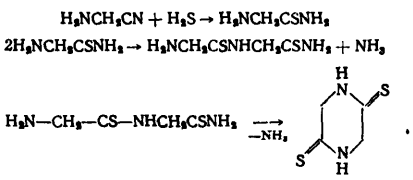
The reaction is conducted in sealed tubes at 100°C. Cyclic thioamides have been obtained also by interaction between *o*-amino-nitriles and thiolic acids in acid medium under pressure[105]:



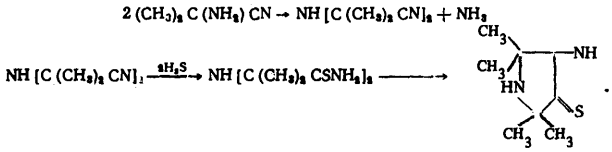
Cyclisation occurs also when hydrogen sulphide acts on aminoacetonitrile or α-aminopropionitrile in ammoniacal alcoholic solution containing ammonium sulphate, with the formation respectively of 2,5-dithionopiperazine and 3,6-dimethyl-2,5-dithionopiperazine respectively, but the

†The course of the reaction is greatly influenced by, for example, the degree of reagents and solvents.

yield is low in both cases. It is assumed that the normal thioamide is formed initially, and ammonia is eliminated from two molecules thereof with ring closure‡:

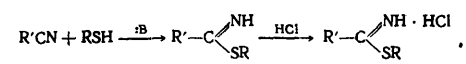


α-Aminopropionitrile reacts with hydrogen sulphide under the above conditions to form mainly aminobispropionitrile. Other α-amino-nitriles do not give dithionopiperazines at all on reaction with hydrogen sulphide. Thus α-aminoisobutyronitrile gives under the same conditions a crystalline product $C_7H_{14}N_2S$, for which the structure 2,2,4,4-tetramethyl-5-thionoimidazoline was proposed:

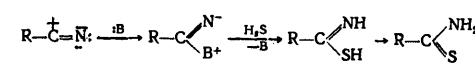


This scheme is supported by the fact that iminodi-isobutyronitrile on treatment with hydrogen sulphide yields the same cyclic product. 2-(*N*-Acetylsulphanilamido)benzonitrile on treatment with hydrogen sulphide in pyridine at 100°C gives the normal, acyclic thioamide[106].

An interesting variant of the reaction of hydrogen sulphide with nitriles is that of perfluoroalkylnitriles with thiols and hydrogen sulphide. Perfluoronitriles add thiols in the presence of amines to form perfluorothioimides, from which perfluoroalkylthioamides and dithiocarboxylic esters are formed by the action of hydrogen sulphide[107]:



The mechanism of the reaction of nitriles with hydrogen sulphide has not been adequately studied. With a tertiary amine as catalyst this reaction is assumed to go according to the scheme[44]



If the reaction is catalysed by a primary or a secondary amine or by ammonia, it is supposed that an amidine is formed initially, and interacts with the hydrogen sulphide to give the thioamide:

There is some indication that amidines could be isolated[89] and that they are converted into thioamides by the action of hydrogen sulphide (see below). However, these schemes probably represent only secondary reactions between hydrogen sulphide and nitriles in the presence of amines. Such reactions include also the formation of imidic esters when alcohols are used as solvent, especially as, like imides, these compounds are converted into thioamides by the action of hydrogen sulphide.

‡The interaction of thioamides with primary amines is known to liberate ammonia and involve ring closure. In the present case one thioamide molecule reacts as a primary amine, while the other acts as a thioamide.

It may be postulated that hydrogen sulphide adds directly to nitriles to form thiolomides, which then isomerise into thioamides:

Such an assumption is supported by the fact that hydrogen sulphide reacts with nitriles at elevated temperatures and pressures to form thioamides even in the absence of amines. The role of amines as catalysts appears in the formation with hydrogen sulphide of hydrogen sulphides, which, because of the greater polarity of the bond, add to nitriles considerably more easily than does hydrogen sulphide itself.

2. PREPARATION OF THIOAMIDES BY THE REACTION OF AMIDINES, AMIDOXIMES, AND IMIDIC ESTERS WITH HYDROGEN SULPHIDE

As shown earlier, amidines and imidic esters§ are intermediates in the preparation of thioamides from nitriles and hydrogen sulphide. Therefore the reactions under consideration can be regarded as variants of the reaction of nitriles with hydrogen sulphide. They involve the intermediate addition of hydrogen sulphide at the multiple bond in the imino-compounds with formation of unstable products, which are then converted into the thioamides.

Both unsubstituted[117,118] and substituted[118-123] thioamides have been obtained by these methods. The following dithio-oxamides (percentage yields in parentheses)—*NN'*-dibutyl (70), *NN'*-diethyl (45), *NN'*-bis-3-methoxypropyl (60), and *NN'*-bis-2-hydroxyethyl (8.5)—have been isolated by saturating alcoholic solutions of the oxamidine derivatives with hydrogen sulphide[123]. *N*-Substituted thioamides are obtained also by heating *N*-substituted amidines with hydrogen sulphide at 100°C.[124] Hydrogen sulphide acts on *NN*-diphenyloxamidoxime $(C_6H_5)_2N.CO.C(:NOH).NH_2$ in ammoniacal solution to give the corresponding thioamide[125] $(C_6H_5)_2N.CO.CS.NH_2$

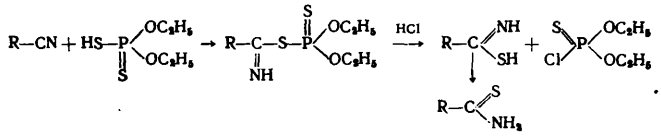
An interesting example of the use of imidic esters to obtain thioamides is the preparation of dithio-oxamide by the reaction of hydrogen sulphide with ethyl oximidate, which is readily formed from cyanogen chloride and ethanol, the yield of the thioamide being 90%:[101]

3. PREPARATION OF THIOAMIDES BY THE REACTION OF NITRILES WITH THIOPHOSPHORIC ACIDS AND THIOAMIDES

A variant of the reaction of nitriles with hydrogen sulphide is the addition of thiophosphoric acids and thioamides to nitriles. These two groups of reagents serve in such cases as sources of hydrogen sulphide. *OO'*-Diethyl hydrogen dithiophosphate has been used as the thio-

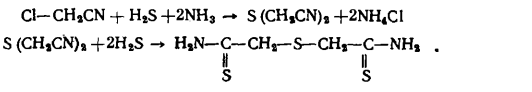
§Imidic esters are easily obtained by saturating a dry equimolecular mixture of the nitrile and the alcohol with dry hydrogen chloride[108-116].

phosphoric acid¶. The addition product is cleaved at the sulphur-phosphorus bond:

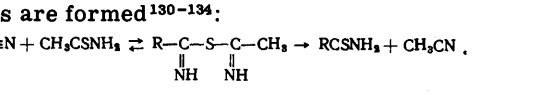


The yield of thioamides reaches 50–90%.[128]

Chlorothioacetamides, inaccessible by other methods, can be obtained[44,129]. In their synthesis, e.g. by the addition of hydrogen sulphide to chloroacetonitrile in the presence of ammonia, a sulphide is first formed, and is then converted into a bisthioamide[128]:

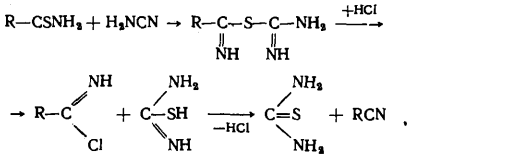


The reaction of nitriles with thioacetamide involves an intermediate stage in which mixed anhydrides of thioimidic acids are formed[130–134]:



When the low-boiling acetonitrile is distilled off, the equilibrium is shifted to the right, and good yields (63–87%) are obtained of a thioamide containing more atoms than the original. Benzonitrile reacts less smoothly with *N*-substituted thiobenzamides.

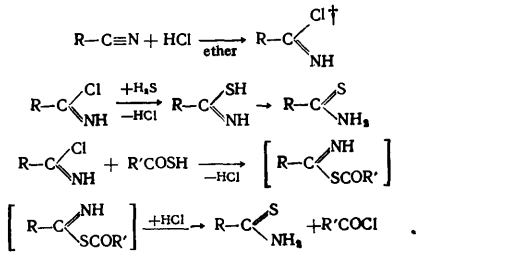
Unsubstituted thioamides react with cyanamide in warm alcoholic solution, giving a good yield of thiourea:



Interaction of these reactants in cold alcoholic solution in the presence of a mineral acid forms in good yield a salt of thiodiformamidine $NH_2C(:NH)SC(:NH)NH_2$. The same product can be obtained by the reaction of thiourea with cyanamide.

4. PREPARATION OF THIOAMIDES BY THE REACTION OF IMIDOYL CHLORIDES WITH HYDROGEN SULPHIDE AND THIO-ACIDS

Thioamides are formed[135] by the reaction of nitriles with hydrogen chloride and hydrogen sulphide or a thioacid:



¶ For the preparation of dithiophosphates see Refs. 126 and 127.

†Doubt has recently been cast on the formation of imidoyl chlorides in this way: formation of a complex of the nitrile with hydrogen chloride is regarded as more probable[136].

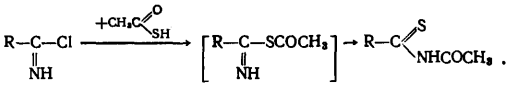
These reactions can likewise be regarded as a variant of the addition of hydrogen sulphide to nitriles, distinguished by the use of hydrogen chloride instead of ammonia as catalyst. Other hydrohalic acids also catalyse the interaction of hydrogen sulphide with nitriles: thuse use of hydriodic and hydrobromic acids as catalysts for the reaction conducted in sealed tubes at 32–50°C gave yields of thioamides of 51–93% with various nitriles[103].

Another product of the reaction, besides those given in the scheme, is the di-imidoyl sulphide, probably formed by reaction between the nitrile and the thioamide:

The relative proportions of thioamide and di-imidoyl sulphide depend on those of the reactants: the more nitrile is present, the higher the yield of the di-imidoyl sulphide.

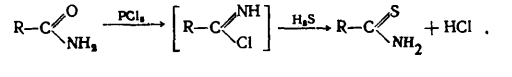
The yield of a thioamide depends on the nature of the thiolic acid and the nitrile, under otherwise similar conditions. The yield of thiobenzamide was 75% when thioacetic acid was used, 100% with thiobenzoic acid; on the other hand, interaction of *p*- and *m*-nitrobenzonitrile with acetothiolic acid gave 40% and 6% yields respectively of thiobenzamide derivatives. Some nitriles, e.g. *p*-tolunitrile and naphthonitrile, give hardly any thioamide under these conditions. A by-product in the preparation of thiobenzamide was dibenzimidoyl sulphide $C_6H_5C(:NH)SC(:NH)C_6H_5$, which is formed in good yield when benzonitrile is treated with thioacetic acid. Thiobenzoic acid gives less by-products than does thioacetic acid.

When thioacetic acid is used, an *N*-acetylthioamide may be formed as a by-product, probably by isomerisation of an intermediate product[137–139]:

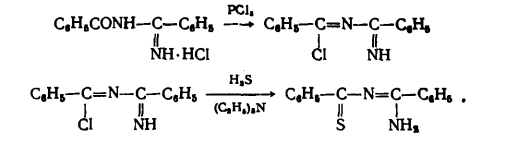


This rearrangement can be avoided by conducting the process at room temperature.

A somewhat similar method is the reaction of amides with phosphorus pentachloride and hydrogen sulphide in an inert solvent[81,140,141], in which thioamides are formed. Imidoyl chlorides are also formed as intermediates in this case:

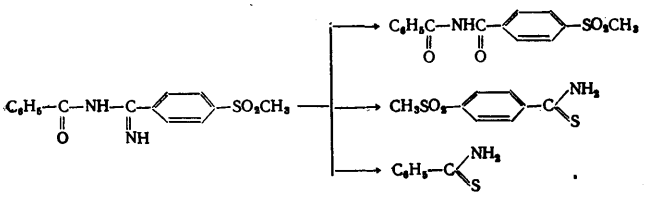


When amides containing hydroxy- and amino-groups are used, these groups are protected by treatment with toluenesulphonyl chloride. This method has been used for the preparation of thiophenacetin *p*-$C_2H_5OC_6H_4NHCSCH_3$, *p*-acetylthioacetanisidine *p*-$CH_3COC_6H_4NHCSCH_3$, *p*-phenylene-*NN'*-bisthioacetamide *p*-$CH_3CSNHC_6H_4NHCSCH_3$, and thioacetamide-trimethylpyrogallol. *N*-Thiobenzoylbenzamidine has been prepared from *N*-benzoylbenzamidine[81]:

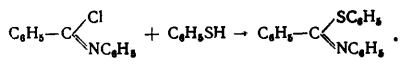


N-Thiobenzoylanisoylamidine and *N*-thiobenzoyl-*p*-chlorobenzamidine have been obtained in the same way, in yields of 48% and 26% respectively[81]. However, three products

were obtained from *N*-benzoyl-*p*-methylsulphonylbenzamidine, owing to cleavage and hydrolysis:

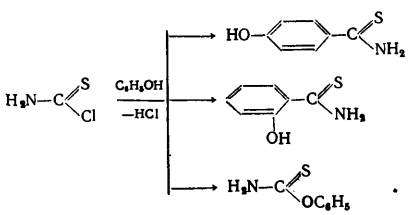


The action of arenethiols on imidoyl chlorides yields isothioamides (thiolimidic esters):



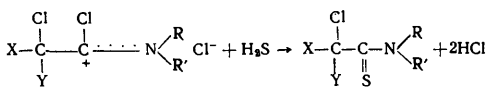
p-Tolyl *N*-*p*-tolylthiobenzimidate has been obtained from *N*-*p*-tolylbenzimidoyl chloride and toluene-*p*-thiol[141].

In several cases thiocarbamoyl chlorides are used for the synthesis of such compounds. Thus the reaction of thiocarbamoyl chloride with phenol has yielded thiosalicylamide, *p*-hydroxythiobenzamide, and phenyl thiocarbamate[141]:

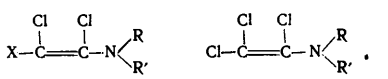


Analogous methods have been used to obtain *N*-thioacylthiocarbanilic esters[142], di-imidoyl sulphides[143,144], and several other derivatives[145].

The reaction of imidoyl chlorides with hydrogen sulphide in many cases enables thioamides to be obtained which are difficultly accessible by other methods. Thus α-chlorothioacetamides are obtained from α-chloroiminium chlorides and hydrogen sulphide[146]:

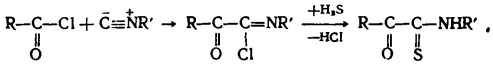


Iminium chlorides have been obtained by the addition of hydrogen chloride to 1,2-dichloro- and 1,2,2-trichlorovinylamines:



The iminium chlorides used for the preparation of trichlorothioacetamide were formed by the addition of chlorine to the above chlorovinylamines. Iminium chlorides are prepared also by the action of carbonyl chloride on *NN*-disubstituted amides of carboxylic acids.

Difficultly accessible *N*-substituted α-oxothioamides have also been prepared by the reaction of imidoyl chlorides[147,148]:



5. PREPARATION OF THIOAMIDES BY THE REACTION OF AMIDES WITH PHOSPHORUS PENTASULPHIDE

The interaction of amides of carboxylic acids with phosphorus pentasulphide involves exchange of oxygen for sulphur with formation of thioamides:

This method, first proposed in 1878, is among the most frequently used for obtaining unsubstituted and substituted thioamides[149,150]. In the latter case substituted amides must be taken:

where R, R′ = H, Alk, Ar.

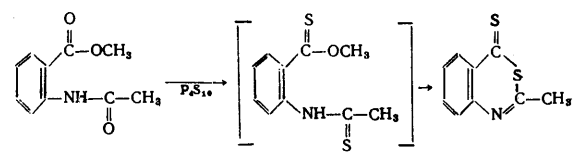
When unsubstituted amides are used, nitriles are obtained as by-products, pr bably owing to decomposition of the resulting thioamide under the influence of phosphorus pentoxide[151,152]:

This side-reaction is sometimes so rapid that the amide is converted—not into the thioamide—but into a good yield of the nitrile[153]. Side-reactions go less vigorously with secondary[48,153-156] and tertiary[73] amides; aromatic amides react more smoothly than do aliphatic amides.

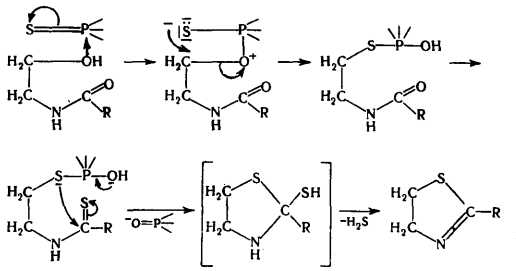
Various thioamides have been obtained by this method[157-179]. The process is conducted with heating, mostly in benzene, toluene, xylene, and tetralin; tetrahydrofuran, dioxan, and other ethers are also used as solvents. The reactions between phosphorus pentasulphide and amides are very rapid, being complete in a few minutes[150].

If the reaction between an amide and phosphorus pentasulphide is conducted in the presence of a primary or a secondary amine, *N*-mono- and *NN*-di-substituted thioamides can be obtained under suitable conditions. In this way *N*-substituted and *NN*-di-substituted thioformamides have been obtained by a one-stage process[180].

Depending on the amount of phosphorus pentasulphide taken, diamides can yield either mono- or bis-thioamides. For example, with a molar ratio of 2,4-diacetamidotoluene to phosphorus pentasulphide of ~ 2 : 1 a mixture of mono- and bis-thioamides (7 : 2) is formed[181]. Similarly, *N*-phenyloxamide yields the corresponding monothio- and dithio-compounds $C_6H_5NHCOCSNH_2$ and $C_6H_5NHCSCSNH_2$,[154] where further treatment of the former compound with phosphorus pentasulphide converts it into the latter, *N*-phenyldithio-oxamide. Oxanilides $C_6H_5NHCOCONHC_6H_5$ behave in the same way. The preparation of ethyl thio-oxanilate $C_6H_5NHCSCOOC_2H_5$ showed that the ester group does not influence the results of the reaction[154,182,183]. An exception to this rule is the reaction of methyl *N*-acetylanthranilate with phosphorus pentasulphide, accompanied by replacement of oxygen by sulphur in both amide and ester groups with cyclisation of the product to 3,4-dihydro-2-methylbenzo-3,1-thiazine-4-thione:

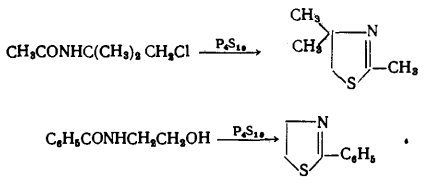


Formation of a thiazoline by the action of phosphorus pentasulphide of an *N*-2-hydroxyethylbenzamide is represented by the scheme[184,185]



The yield of thioamides obtained by treating substituted benzamides with phosphorus pentasulphide is greatly affected by the nature of the substituents. Thus treatment of *m*- and *p*-nitrobenzanilides with phosphorus pentasulphide in boiling xylene gives 70–90% yields of the corresponding thioamides; under the same conditions the aminobenzanilides form thioamides in only 5% yield[169]. Similar results were obtained in toluene, reaction being rapid with the nitro-derivatives and slow with the amino-derivatives. No thioamide is formed when *pp'*-dinitrooxanilide is treated with phosphorus pentasulphide in xylene for 7 h, the nitro-groups undergoing reduction to amino-groups[186]. However, no systematic study has yet been made of the influence of substituents on the yield of thioamides.

The reaction of phosphorus pentasulphide with certain *N*-substituted amides (containing a functional group in the β-position with respect to the nitrogen atom) is sometimes accompanied by cyclisation[184,187]:



In this example formation of 2-phenylthiazole is accompanied by that of a cystamine derivative $(C_6H_5CONHCH_2CH_2S)_2$.[184]

With hydantoins phosphorus pentasulphide yields thiohydantoins, whose specific action is weaker and less prolonged than that of the corresponding derivatives of barbituric acid[188].

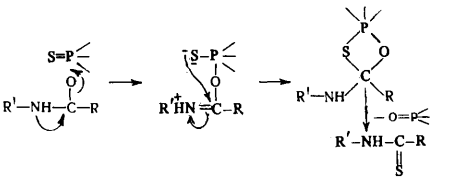
The yield of thioamides obtained from amides and phosphorus pentasulphide is appreciably increased by the presence of oxides or carbonates of alkaline-earth metals[189]; potassium sulphide also has a favourable effect[165]. In the latter case a suspension or a solution of the amide in xylene was treated with the carefully mixed finely ground phosphorus pentasulphide and potassium sulphide in amounts sufficient for the formation of potassium thiophosphate: $P_2S_5 + 3K_2S \rightarrow 2K_3PS_4$ (sometimes a slight excess of potassium sulphide is taken). This reaction goes especially well in pyridine[190].

In order to eliminate the inconvenience of working with a mixture of two solids (potassium sulphide and phosphorus pentasulphide), amides were treated with salts of thiophosphoric acid, this method giving yields of ~ 80% of thioacetamide[191,192]. An 80% yield of thioacetamide was also obtained by treating acetamide with a mixture of phosphorus pentasulphide and potassium sulphide (in the molar ratio: 1.5 : 5).[103]

The yield of thioamides depends on the nature of the initial amide. For example, treatment of acetamide in benzene with a mixture of phosphorus pentasulphide and potassium sulphide gave an 80% yield of thioacetamide, whereas the yield of isovaleramide was 0.4% (the main product being the nitrile).[103]

Thioamides can be obtained by the action of phosphorus pentasulphide on amides also in the absence of solvents[149,153-156,162-164]. In this case equimolecular quantities of the amide and phosphorus pentasulphide are melted together, and the thioamide is extracted from the resulting resinous mass with a suitable solvent. The yield of thioformamide prepared in this way is ~ 50%.[121]

The mechanism of the interaction of amides with phosphorus pentasulphide has not been established exactly. The reaction is presumably represented by the scheme[193]



6. PREPARATION OF THIOAMIDES BY REACTION WITH ALUMINIUM AND IRON SULPHIDES

Thioamides are formed by the action of aluminium sulphide on amides, nitriles, and ammonium salts[194-196], 1 or 2 moles of water being added to the mixture when an amide or a nitrile is used. This is usually added as water of crystallisation (e.g. $Na_2SO_4.6H_2O$). The process is conducted in a sealed tube or an autocalve at 200–250°C for ~ 90 min. When ammonium salts are used, water is not required.

Aromatic and aliphatic thioamides are obtained in good yields by this method[194].

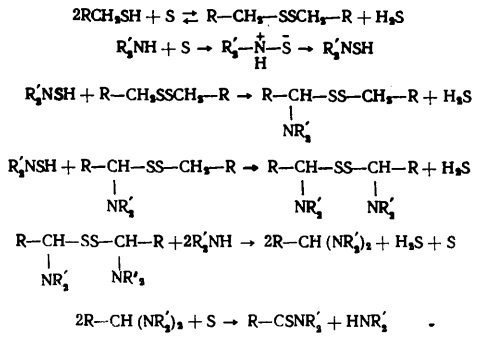
Sulphides of other metals, e.g. iron, can be used instead of aluminium sulphide[195].

7. PREPARATION OF THIOAMIDES BY THE WILLGERODT–KINDLER REACTION

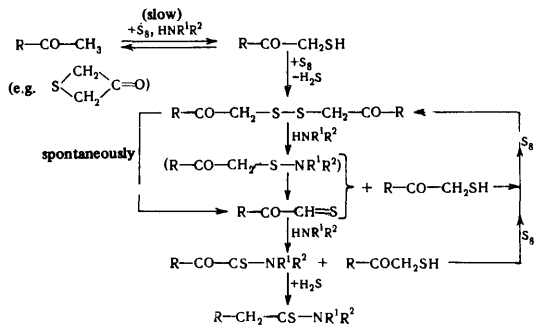
There exist several modifications of this method for obtaining thioamides—(*a*) reaction of sulphur with ketones or aldehydes in the presence of an equimolecular quantity of an amine[165,197-200], (*b*) direct oxidation of the amine by sulphur[201,202], and (*c*) interaction of sulphur with an alkyne and ammonia[203,206]—these three variants being included under the combined term the Willgerodt–Kindler reaction[207-227].

Several reviews have been devoted to this reaction[207-209,228,229], and special papers have been published on its mechanism[209,230-232]. However, the mechanism of the Willgerodt reaction is still not clear. Thiols are probably formed as intermediates, and are converted into thioamides[228]:

The conversion of thiols into thioamides takes place when both sulphur and an amine are present. The formation of thioamides is represented by the scheme



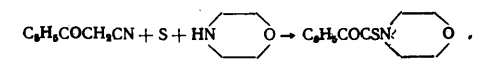
A rather different assessment of the mechanism of the Willgerodt–Kindler reaction has recently been expressed[224] in connection with an investigation of the formation of a thioamide from 3-oxothietan, a secondary amine, and sulphur:



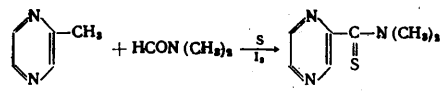
where R = CH_3. According to this scheme the reaction begins with formation of an α-mercapto-ketone, this being the rate-determining stage. The disulphide, which is formed very readily, passes via the oxosulphenamide into an oxo-thial. In the presence of an amine the oxo-thial undergoes disproportionation by the Cannizzaro reaction with formation of the α-mercapto-ketone and an α-oxo-thioamide, the latter then being reduced to the required thioamide.

There are also other interpretations of the mechanism of the Willgerodt–Kindler reaction. In this connection the view of several authors[165,182] must be accepted, that this reaction, which is characterised by a great variety of starting materials and process conditions, does not fit into a single mechanism.

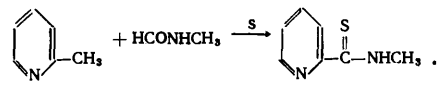
NN-Disubstituted thioamides can be obtained in good yield from aromatic aldehydes[212]. Under the conditions of this reaction diketones are reduced to monoketones, which then give thioamides[215]. α-Cyano-ketones form α-oxo-thioamides with loss of one carbon atom[216]:



Variants of the Willgerodt–Kindler reaction have been described in which certain heterocyclic compounds, dimethylformamide, and iodine are involved in the reaction[209,217,218]. Thus the *NN*-dimethylthioamide of pyrazine has been obtained from methylpyrazine, dimethylformamide, and sulphur in the presence of iodine[219]:

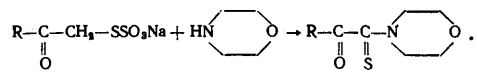


while the use of 2-methylpyridine and methylformamide yields *N'*-methylpyridine-2-thioamide[220]:



In this way quinaldine is converted into quinoline-2-thioamide. The reaction does not take place when anthranilic acid, *o*-aminophenol, sulphanilic acid, 2-aminothiazole, 2-amino-1,3,4-thiadiazole, or 2-aminopyridine is used as the amine component[221].

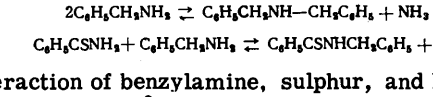
S-Acylmethyl thiosulphates form with amines good yields of *NN*-disubstituted α-oxo-thioamides[233,234]:



It has since proved possible to bring into reaction with sulphur secondary and tertiary alcohols, thiols, disulphides, imines, alkenes[206], diazo-ketones[200], Schiff bases[210], and also $\alpha\beta$-unsaturated acids[232] (in the last case thioamides are obtained having one carbon atom less than in the initial acid)[235–242].

Thioamides are formed when amines are heated with sulphur even in the absence of carbonyl compounds[210,243–253]. Heating benzylamine with sulphur in a sealed tube at 180°C gives a 91% yield of thiobenzamide:

Copious evolution of ammonia occurs when this reaction is conducted in an open vessel[207]:



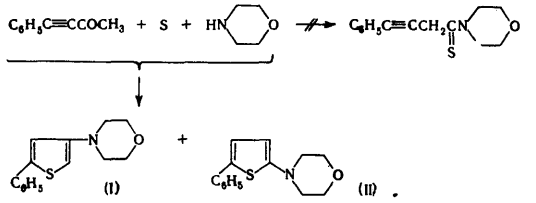
The interaction of benzylamine, sulphur, and lead monoxide in benzene at 20°C gives bisthiobenzamido-disulphide:

A modification of the Willgerodt–Kindler reaction in which an enamine is one of the components is of practical interest, the process being conducted in a polar solvent at room temperature. Thioamides in yields of ~ 75% are formed[222,223]:

Thioamides are formed by the action of sulphur on unsaturated hydrocarbons in the presence of ammonia or an amine. The reactions are conducted in dry solvents at 50–300°C, gaseous ammonia or a low-boiling amine (e.g. methylamine) being used under pressure. In this way the interaction of acetylene, sulphur, and ammonia (or an amine) in dioxan or pyridine at 50–100°C has been applied to the preparation of thioacetamide[249], dithio-oxamides, and other thioamides[203,204,250–253].

The interaction of styrene and sulphur in the presence of morpholine gives a 52% yield of phenylthioacetomorpholide[190], whereas in the presence of benzylamine the main product is phenylacetic acid contaminated by *N*-benzylthiobenzamide. Phenylthioacetomorpholide is obtained in 20% yield also by the action of sulphur on phenylacetylene and morpholine[232,254].

It has recently been shown that acetylenic ketones do not yield thioamides—as has hitherto been supposed—but isomeric thiophen derivatives[211]:



The ratio of the isomers (I) and (II) thus obtained is 9 : 1.

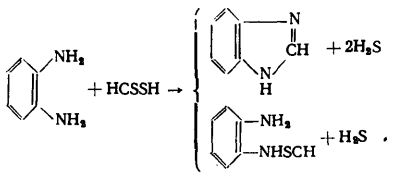
8. PREPARATION OF THIOAMIDES BY THE THIOACYLATION OF AMINES

The thioacylation—analogous to acylation—of amines often results in the formation of thioamides in very good yields. Carbodithioic acids[255-257], their salts[258-264], esters, and chlorides, as well as *O*-esters of carbothionic acids[261 265-268], are used as thioacylating agents. Depending on the reagent used, hydrogen sulphide, thiols, hydrogen chloride, and alcohols are also isolated in this reaction. The amines used are ammonia and primary and secondary amines.

An example of thioacylation by means of thiocarbonyl chlorides is the reaction of thiobenzoyl chloride with aniline to form thiobenzanilide[269]. This method is of no practical value because of the relative inaccessibility of thiocarbonyl chlorides[270]. Carbodithioic acids and their salts are used considerably more often‡. For example, sodium cyanodithioformate, obtained from carbon disulphide and sodium cyanide, gives with diethylamine and dimethylamine the *NN*-dialkylamides of cyanothioformic acid[273].

Potassium dithioformate‡ reacts with an aqueous solution of an amine at room temperature to form an *N*-substituted thioformamide; with water-insoluble amines the reaction is conducted in organic solvents (ether, chloroform, dioxan[262,274]). The yield of thioformamide obtained by the action of ammonia on dithioformic acid reached 30%, higher than in its preparation from formamide and phosphorus pentasulphide[262]. Aniline and 6-aminoquinoline give the corresponding substituted thioformamides in theoretical yields. The reaction does not take place with indole, diphenylamine, or *N*-methylaniline[262].

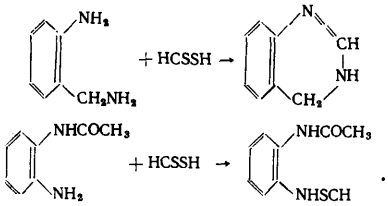
Diamines form with carbothioic acids unstable compounds, which readily undergo cyclisation. Thus *o*-phenylenediamine in aqueous solution at 10°C gives an unstable product, which at room temperature is rapidly converted into benzimidazole[262], though other results indicate that *N*-*o*-aminophenylthioformamide is produced in this case[271,272]:



‡The preparation of the initial carbodithioic acids and their derivatives has been studied in very great detail[228, 229,271,272].

Cyclisation does not occur when dithioformic acids act on 4,5-diamino-6-methylpyrimidine[262] or on 4-amino-5-aminomethyl-2-methylpyrimidine[275-277], because of the feebly basic character of the amino-groups in the starting materials.

o-Aminobenzylamine and *o*-aminoacetanilide with dithioformic acid give quantitative yields of dihydrobenzopyrimidine and stable *N*-*o*-thioformamidoacetanilide[262]:



5-Thioacylpyrimidines, which are not formed from 5-acylpyrimidines and phosphorus pentasulphide, are easily obtained by this method[262,274-291].

m-Tolyldithioacetic acid forms with 1-methyl-1-phenylhydrazine the corresponding hydrazide[292]:

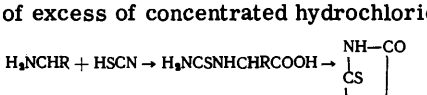
By the action of aqueous solutions of salts of dithioacids on amines in the presence of an aqueous solution of iodine and potassium iodide *N*-substituted thioamides are formed in yields of 95–100%.[258,293] It is supposed that thioacylsulphenamides are formed initially, and split off sulphur to give the thioamides:

Thus addition of a solution of an *N*-substituted dithiocarbamate and iodine or 10% sodium hypochlorite solution (in equimolecular quantities) to excess of concentrated ammonia produces an *NN*-dialkylthioacylsulphenamide, which on prolonged standing or on heating passes into an *N*-substituted thiourea[294]:

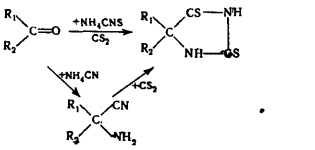
N-Chloropiperidine gives with salts of dithio-acids a quantitative yield of *N*-2′-thiofuroylpiperidine and *N*-thiobenzoylpiperidine. Here, too, sulphenamides are probably formed as intermediates[258,295].

Carbodithioic esters[255,256,296] are often used for the thioacylation of amino-acids[229,255,297-299]§ and the synthesis of purine derivatives[286], vitamin B_1,[274] and other biologically active substances. Equimolecular quantities of carboxymethyl dithiobenzoate and aminoacetic acid interact in

§Amino-acids are thioacylated also by the action of ammonium or potassium thiocyanate in acetic anhydride at 60–80°C, 1-acetyl-2-thiohydantoins being formed, from which the free 2-thiohydantoins can be isolated by the action of excess of concentrated hydrochloric acid[300]:



where R = H or CH_3. Ammonium thiocyanate acts on ketones in carbon disulphide to form dithiohydantoins[301,302]:



an aqueous solution of a base at room temperature to give a 90% yield of thiobenzoylglycine[299]:

$$C_6H_5CSSCH_2COOH + H_2NCH_2COOH \rightarrow C_6H_5CSNHCH_2COOH .$$

Similarly, the interaction of carboxymethyl dithiobenzoate and anthranilic acid gives a good yield of thiobenzoylanthranilic acid[299].

DL-Lysine interacts with carboxymethyl phenyldithioacetate to give a monoacylated derivative, probably $C_6H_5CH_2CSNH[CH_2]_4CH(NH_2)COOH$ (the product gives a positive ninhydrin reaction¶). No racemisation was observed in the thiobenzoylation of the L-stereoisomers of alanine, valine, isoleucine, and leucine[256]. Diethyl aminomalonate is more conveniently thiobenzoylated in pyridine to which triethylamine has been added[297]. The thiobenzylation of diamines gives good yields of polymethylenebisthiobenzamides $C_6H_5CSNH[CH_2]_xNHCSC_6H_5$ (x = 1–6). An α-aminoisobutyrate does not undergo thiobenzoylation, probably owing to steric hindrance[255,256].

Carboxymethyl dithioacetate as thioacylating agent is added in excess (10%) to a solution of the sodium salt of the amino-acid in alcohol[303-305]. N-2-Arylethylthioamides $RCSNHCH_2CH_2C_6H_5$ have been obtained by this method in yields of 86–99%.[306]

Thiobenzamides are formed in good yields by the reaction of dithioic esters with morpholine and with aniline[256]. Carbothionic esters RCSOR′ react similarly with amines[256,307,308]. In this way a phenylthiohydrazide has been obtained from phenylhydrazine and a carbothionic ester[263], the reaction being conducted in ether or excess of phenylhydrazine. The interaction of ethyl thiobenzoate with excess of 2-aminoethanol and isopropylamine respectively has given N-2-hydroxyethylthiobenzamide and N-isopropylthiobenzamide in yields of 53% and 63%.[261]

Good thioacylation results have been obtained by the interaction of carbothionic esters with substituted anilinomagnesium bromides[309,310]:

$$RO{-}C_6H_4{-}CS{-}OC_2H_5 + BrMgNHC_6H_4OR' \rightarrow RO{-}C_6H_4CS{-}NHC_6H_4OR' + C_2H_5OMgBr.$$

A convenient thioacylating reagent is a thioacylsuccimide, obtained in good yield by reaction of an aromatic unsubstituted thioamide with succinyl chloride[311]:

$$ArCSNH_2 + ClCOCH_2CH_2COCl \rightarrow ArCS{-}N\begin{matrix}CO{-}CH_2\\ |\\ CO{-}CH_2\end{matrix}$$

Unsubstituted thioamides are also thioacylating agents. Under mild conditions they undergo transamidation with primary aliphatic amines to form N-alkylated thioamides. This has been termed the Wallach reaction[312]. Several derivatives of dithio-oxamide have been obtained in this way, the two unsubstituted thiocarbamoyl groups being involved in the reaction[313]:

$$2R{-}CH_2{-}NH_2 + H_2N{-}CS{-}CS{-}NH_2 \rightarrow R{-}CH_2{-}NH{-}CS{-}CS{-}NH{-}CH_2{-}R + 2NH_3$$

where R = COOH, SO_3H. Only the thiocarbamoyl group is involved in the reaction of monothio-oxamide with aliphatic amines[143,312]. Morpholine reacts with dithio-oxamide to give N-morpholinodithio-oxamide[44,313], and other thio-oxamides have recently been obtained by this method[314]. Amino-acids also can be thioacylated with dithio-oxamide[315]. NN-Dimethylthioformamide gives amidines with amines[316].

Substituted thioformamides are obtained in good yield by the interaction of chloroform, an amine, and hydrogen sulphide in alkaline solution[317]. It is assumed that dichlorocarbene is formed initially from the chloroform (by α-elimination), and then reacts according to the equation

$$:CCl_2 + R'R''NH + 2SH^- \rightarrow R'R''N{-}CSH + H_2S + 2Cl^- .$$

9. PREPARATION OF THIOAMIDES BY THE REACTION OF ISOTHIOCYANATES WITH ORGANOMETALLIC COMPOUNDS, C–H ACIDS, AND ENAMINES

These reactions are employed considerably more rarely than those considered earlier for the preparation of thioamides. They are based on the addition of nucleophilic reagents at the multiple bond in an isothiocyanate, and in this respect show great similarity to the corresponding reactions of isocyanates:

$$R{-}\overset{\delta+}{N}{=}\overset{\delta-}{C}{=}\overset{\delta-}{S} + R'{-}\overset{\delta+}{X} \rightarrow R{-}N{=}\underset{R'}{\overset{|}{C}}{-}SX \xrightarrow[-OHX]{H_2O} R{-}NHC{=}\underset{R'}{\overset{|}{S}}$$

where X = M, H. The symbol X denotes a metal when an organometallic compound[318-333] or a C–H acid in the form of its sodium or lithium salt is used, and hydrogen in the case of an enamine.

The reaction between isothiocyanates and organometallic compounds was first studied by the use of Grignard reagents. Thioamides are obtained in good yield by the action of Grignard reagents on phenyl isothiocyanate followed by hydrolysis of the addition products[258,318-320]:

$$C_6H_5N{=}C{=}S + CH_3MgI \rightarrow C_6H_5N{=}C(CH_3){-}S{-}MgI \rightarrow C_6H_5NHCSCH_3 .$$

The action of dimethyl sulphate on the addition product of phenylmagnesium bromide and phenyl isothiocyanate gave an S-methyl derivative of an isothioamide[321]:

$$C_6H_5{-}N{=}C(C_6H_5){-}S{-}MgBr + (CH_3O)_2SO_2 \rightarrow C_6H_5N{=}C(C_6H_5)SCH_3 .$$

N-Substituted thioamides of valeric acid were obtained in 90% yield by the reaction of n-butylmagnesium bromide with isothiocyanates[322]. Phenylmagnesium bromide reacts with phenyl isothiocyanate to give thiobenzamide in 88% yield[288].

Isothiocyanates react with excess of a Grignard reagent at high temperatures to give other products. Thus a 45% yield of o-phenyldiphenylmethylaniline was obtained from phenyl isothiocyanate and phenylmagnesium bromide[323].

Bifunctional thioamides are formed by the interaction of sodium alkyls with phenyl isothiocyanate[325-328]:

$$\overset{\delta-\ \delta+}{RCH_2Na} + C_6H_5N{=}\overset{\delta+\ \delta-}{C{=}S} \rightarrow RCH_2\underset{NC_6H_5}{\overset{||}{C}}SNa \xrightarrow[-H]{+Na}$$

$$\rightarrow \underset{Na}{\overset{\delta-}{RCH}}{-}\underset{NC_6H_5}{\overset{||}{C}}{-}SNa \xrightarrow{C_6H_5N=C=S} \underset{\quad C{-}SNa}{\overset{NC_6H_5}{\overset{||}{RCH}}} \xrightarrow[-2NaOH]{+2H_2O} \underset{\quad CSNHC_6H_5}{\overset{CSNHC_6H_5}{RCH}} .$$

$$\underset{\quad C{-}SNa}{\overset{NC_6H_5}{\overset{||}{RCH}}}$$

1,2-Addition products of sodium to alkenes react with isothiocyanates to form disodium derivatives, which can be hydrolysed to bisthioamides[327,334]:

$$2C_2H_5NCS + (C_6H_5)_2CNa{-}CNa(C_6H_5)_2 \rightarrow C_2H_5N(Na)CSCSN(Na)C_2H_5 + (C_6H_5)_2C{=}C(C_6H_5)_2$$

$$2C_2H_5NCS + (C_6H_5)_2CNaCH_2CH_2CNa(C_6H_5)_2 \rightarrow (C_6H_5)_2{=}\underset{CSN(Na)C_2H_5}{\overset{|}{C}}{-}CH_2CH_2(C_6H_5)CSN(Na)C_2H_5 .$$

¶ Boiling amino-acids with an aqueous solution of ninhydrin (indane-1,2,3-trione hydrate) produces a blue coloration.

Organolithium compounds also can be used as the organometallic compounds. Thus 3-methyl-2,2-diphenylbut-3-enothioanilide was isolated after reaction with phenyl isothiocyanate of the organolithium compound obtained from the corresponding alkene and lithium[327], a 57% yield of thiobenzamide after reaction with triphenylsilyl isothiocyanate[329], and *N*-phenylthiobenzamide when phenyl isothiocyanate was used [with phenyl-lithium][330]:

$$C_6H_5Li + C_6H_5NCS \rightarrow C_6H_5N(Li)CSC_6H_5 \xrightarrow{H_2O} C_6H_5NHCSC_6H_5 + LiOH .$$

Triethylaluminium (or a mixture of ethylaluminium dichloride and diethylaluminium chloride) gives with aliphatic and aromatic isothiocyanates a series of thioamides of propionic acid in yields of 58–96%.[331,332]

Phenyl isothiocyanate reacts with sodium tetrahydroborate to form thioformanilide[333,335]:

$$C_6H_5N{=}C{=}S + NaBH_4 \rightarrow [C_6H_5{-}NHCS{-}BH_3Na] \xrightarrow{H^+} C_6H_5NH{-}\underset{\underset{S}{\|}}{C}{-}H .$$

Isothiocyanates react with C–H acids in practically the same way as with organomagnesium compounds, since these acids are usually employed in the form of their alkali-metal salts[324,336–350]:

$$R'{-}\underset{R''}{\overset{R}{C}}{-}Na + R'''NCS \rightarrow R'{-}\underset{R'}{\overset{R}{C}}{-}\underset{\underset{S}{\|}}{C}{-}N(R'''){-}Na \xrightarrow[-NaCl]{+HCl} R'{-}\underset{R'}{\overset{R}{C}}{-}\underset{\underset{S}{\|}}{C}{-}NR''H .$$

Triphenylmethylsodium reacts with isothiocyanates, e.g. with allyl isothiocyanate to form *N*-allyltriphenylthioacetamide[328].

Sodiomalonic ester gives with *p*-phenylene di-isothiocyanate in absolute alcohol the sodium salts of mono- and di-addition products, from which acidification yields diethyl *N*-*p*-isothiocyanatophenylthiocarbamoylmalonate (*a*) and tetraethyl *p*-phenylene-*NN'*-bisthiocarbamoylmalonate (*b*):[348]

$$S{=}C{=}N{-}C_6H_4{-}NH{-}CS{-}CH(COOC_2H_5)_2 \quad (a)$$

$$(C_2H_5OCO)_2CH{-}CS{-}NHC_6H_4NH{-}CS{-}CH(COOC_2H_5)_2 . \quad (b)$$

Sodioacetoacetic ester forms only the monoaddition product, which breaks down in alcoholic solution at room temperature into ethyl acetate and ethyl *N*-*p*-isothiocyanatophenylthiocarbamoylacetate[349,350]:

$$S{=}C{=}N{-}C_6H_4NHCS{-}\underset{COOC_2H_5}{\overset{COCH_3}{C}}{-}H \rightarrow S{=}C{=}N{-}C_6H_4NHCS{-}CH_2COOC_2H_5 + CH_3COOC_2H_5 .$$

Sodium acetylacetonate reacts with aryl isothiocyanates in absolute alcohol to form *NN'*-diarylated bisthioamides of malonic acid[349].

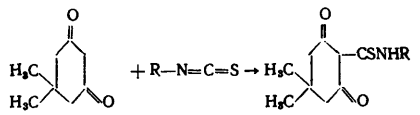
The sodium salt of acetylthioacetanilide reacts with phenyl isothiocyanate to give the dianilide of acetylmalonodithionic acid[350]:

$$CH_3{-}\underset{\underset{O}{\|}}{C}{-}\underset{\underset{Na}{|}}{CH}{-}\underset{\underset{S}{\|}}{C}{-}NHC_6H_5 + C_6H_5N{=}C{=}S \rightarrow CH_3{-}\underset{\underset{O}{\|}}{C}{-}\underset{CSNHC_6H_5}{\overset{CSNHC_6H_5}{C}}{-}H .$$

Other derivatives of malonodithionic acid have been obtained by using substituted phenyl isothiocyanates under the same conditions.

Cyclic C–H acids also react with isothiocyanates to form thioamides. In this way good yields of variously substituted anilides of pyrrolecarbothionic acid have been obtained by the use of pyrrole[351].

The addition of isothiocyanates to dimedone in acetonitrile in the presence of a small amount of alkali[352] leads to the formation of a thioamide in 60% yield:

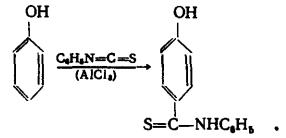


where R = C_6H_5, *p*-ClC_6H_4, *p*-$NO_2C_6H_4$, 1-naphthyl. The reaction does not take place in ethanol[353].

Alkali-metal cyanides give with isothiocyanates *N*-substituted cyanothioformamides, which react with hydrogen sulphide to produce *N*-substituted dithio-oxamides[354]. The best yields of thioamides are obtained with potassium cyanide:

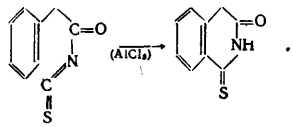
$$KCN + R{-}NHCS \rightarrow R{-}NHCSCN \xrightarrow{H_2S} R{-}NH{-}CS{-}CS{-}NH_2 .$$

Alkoxyphenyl isothiocyanates form with sodium cyanide alkoxylated cyanothioformamides, which are converted by hydrogen sulphide into alkoxyphenyldithio-oxanides[355]. Isothiocyanates react with phenols in the presence of aluminium chloride[356–359], with the formation not of thioneurethanes but of thioamides:



Thioamides are formed with phenyl ethers (and also ethyl phenyl sulphide) and phenyl isothiocyanate[360].

In the presence of aluminium chloride phenylacetyl isothiocyanate undergoes intramolecular rearrangement to give a 40–70% yield of homomonothiophthalamide[361]:

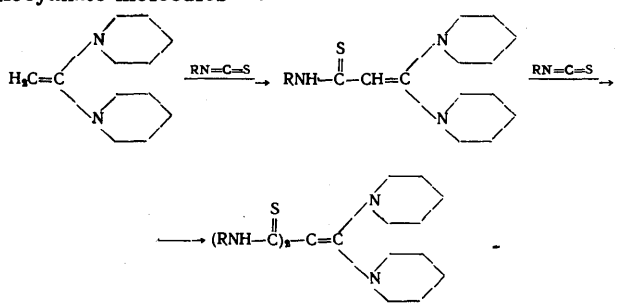


Isothiocyanates react in the presence of aluminium chloride also with aromatic hydrocarbons[362].

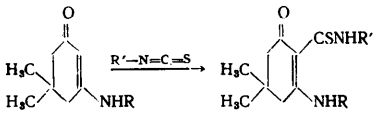
Enamines react with aryl isothiocyanates to form amides of β-aminocycloalkenecarbothioic acids, which are readily saponified to thioamides of β-oxo-carboxylic acids[363–365]:

$$H{-}C{=}C{-}NR_2''' \xrightarrow{R''''{-}N{=}C{=}S} R''''{-}NH{-}\underset{\underset{S}{\|}}{C}{-}\underset{R'}{\overset{R''}{C}}{-}NR_2''' .$$

The enamine of 1,1-dipiperid-1'-ylethylene adds two isothiocyanate molecules[366]:

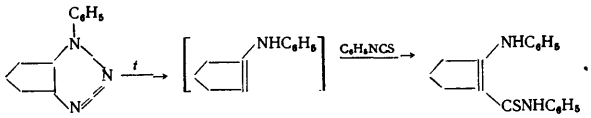


where R = Ar, Alk. Cyclic enamines also react with isothiocyanates[352]:



where R = H, CH_3 and R′ = C_6H_5, p-ClC_6H_4, p-$NO_2C_6H_4$.

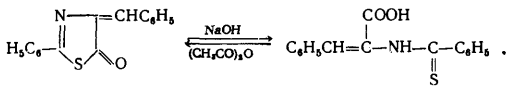
Substituted Δ^1-triazoles react with isothiocyanates to form thioamides (yield 50–99%):[367–370]



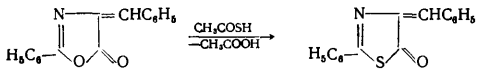
10. PREPARATION OF THIOAMIDES BY THE CLEAVAGE OF HETEROCYCLES

Certain heterocyclic compounds (derivatives of thiazole and oxazole) can undergo cleavage under the influence of alkaline reagents or hydrogen sulphide, thioamides being formed[371–374].

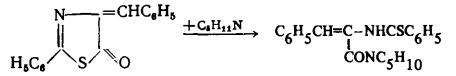
When 4-benzylidene-2-phenylthiazol-5-one is boiled with dilute caustic soda, α-thiobenzamidocinnamic acid $C_6H_5CH{:}C(NHCSC_6H_5)COOH$ is formed[371]. This reaction is reversible, heating the resulting substituted cinnamic acid with acetic anhydride giving an 85% yield of the original thiazolone[371]:



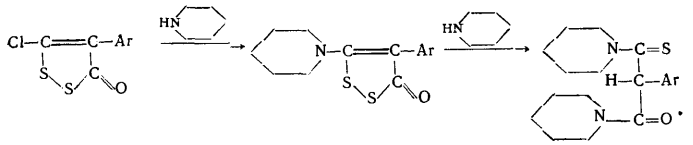
The original 4-benzylidene-2-phenylthiazol-5-one was prepared by the reaction of 4-benzylidene-2-phenyloxazol-5-one with thioacetic acid[371]:



Heating this thiazolone with piperidine gives an N-piperidyl derivative of α-thiobenzamidocinnamic acid in 60% yield:

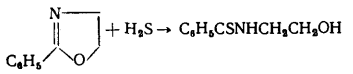


Mixed thioamide–amides of arylmalonic acids are obtained by the action of amines on 4-aryl-3-chloro-5-keto-1,2-dithioles[373]:

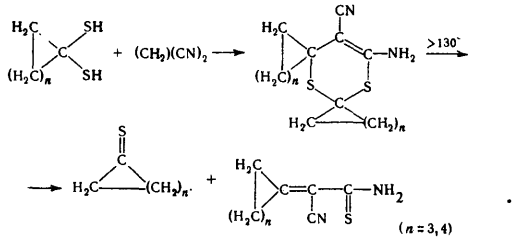


Similarly, N-α-thiobenzamidodihydrocinnamoylpiperidine is obtained from 4-benzyl-2-phenylthiazolone.

Thioamides are formed also by the cleavage of oxazolines by hydrogen sulphide. Treatment of a solution of 2-phenyloxazoline in methanol with ammonium sulphide (or ammonium hydroxide and hydrogen sulphide) gave N-2-hydroxyethylthiobenzamide (yield 77%):[261]

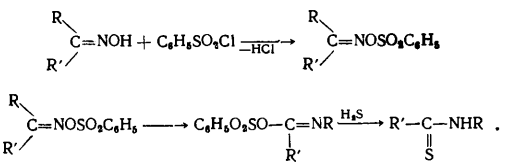


Substituted 1,3-dithi-ins, formed from *gem*-dithiols and malononitrile, when heated decompose into thioketones and thioamides[374]:



11. CONVERSION OF BENZENESULPHONATES OF KETOOXIMES INTO THIOAMIDES

Benzenesulphonates of ketoximes, formed by the action of benzenesulphonyl chloride on the ketoximes in pyridine, are converted in the presence of hydrogen sulphide, as a result of spontaneous Beckmann rearrangement into sulphonimidates, into good yields of N-substituted thioamides[375–378]:



A great variety of thioamides have been obtained by this method using aliphatic, cyclic, aromatic, and mixed ketoximes.

Chemical Properties of 1,3-Dioxans

I.Apok, M.Bartok, R.A.Karakhanov, and N.I.Shuikin

A detailed description is given of the chemical properties of 1,3-dioxans. Special attention is paid to their thermal and catalytic reactions, and also to the preparation from them of various 1,3-bifunctional aliphatic compounds. Detailed consideration is given to the hydrolysis and the alcoholysis of dioxans, and their interaction with derivatives of carboxylic acids and also with certain inorganic compounds containing labile halogen atoms, etc. The mechanism of the various reactions of 1,3-dioxans are surveyed and discussed in detail on the basis of numerous examples. The bibliography contains 155 references.

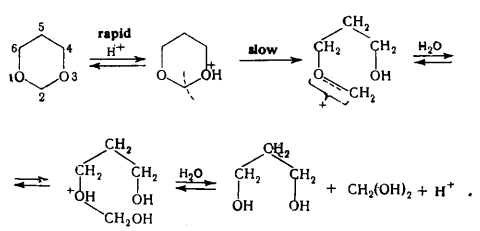
I. INTRODUCTION

The widespread application of the Prins reaction[1] has enabled alkenes[2], obtained in the petroleum-chemical industry, to be used for the single-stage synthesis of several valuable products—1,3-dioxans, diols, unsaturated alcohols, etc.—which can be employed directly as solvents, antiknock compounds, or as intermediates for the synthesis of medicinal preparations, plastics, etc. Publication of a review[2] was followed by considerable progress in the synthesis of 1,3-dioxans, connected in great measure with the use of solid electrophilic catalysts such as mineral acids on carriers (natural and synthetic aluminosilicates) and ion-exchange resins. The use of solid catalysts and flow-type apparatus in particular permitted a considerable simplification in the technology and improvement in the efficiency of the manufacture of 1,3-dioxans. The great quantity of new data which have been published on the transformations undergone by 1,3-dioxans are undoubtedly worthy of special discussion.

Most of the papers and patents which have been published recently have been concerned with the thermal and catalytic cracking of dioxans, and also their conversion into 1,3-bifunctional aliphatic compounds. Special attention will be paid to this question in the present review.

II. HYDROLYSIS OF 1,3-DIOXANS

The vapour-phase catalytic cracking of dioxans in the presence of water vapour involves chemical processes yielding products whose formation can be explained by hydrolysis of the dioxans and accompanying secondary reactions. Like the hydrolysis of acetals[3,4], that of 1,3-dioxans[5-13] is a second-order unimolecular reaction, since its rate is determined by the rate of formation of a carbon cation[12], the reaction being represented by the scheme:



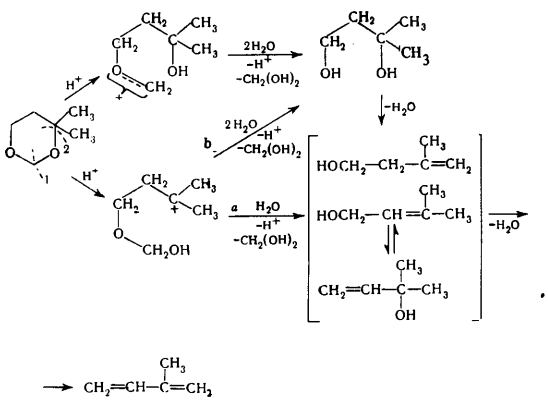
The first stage in the reaction involves addition of a proton, and is followed by slow cleavage of the 1,2- or 2,3-carbon–oxygen bond with formation of a carbon cation, which reacts with two water molecules to give an oxo-compound and a diol.

The above scheme shows that the hydrolysis of 1,3-dioxans in the presence of acid catalysts yields mainly the corresponding 1,3-diols, derivatives thereof[2,5-21], and oxo-compounds. The yield of diols varies within wide limits, since the reaction is reversible, and also because the diols undergo partial dehydration under the conditions of hydrolysis. The equilibrium can be shifted towards the diols by adding alkenes to the reaction mixture[2,14], when the formaldehyde resulting from hydrolysis reacts with the alkene to form the initial dioxan. The yield of 1,3-diol is considerably increased.

Depending on the structure of the 1,3-dioxans, under certain conditions hydrolysis leads directly to formation of conjugated 1,3-dienes[22-26]. This process occurs especially easily with 4,4-dialkyl-1,3-dioxans, hydrolysis of which involves rupture of the 3,4-carbon–oxygen bond as well as the usual cleavage of the 1,2- or 2,3-bond.

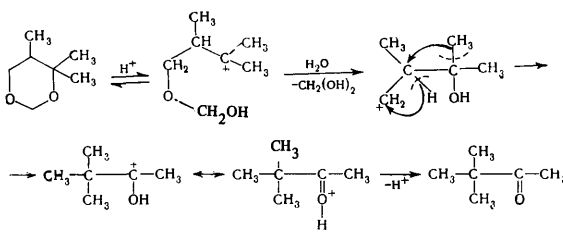
Stabilisation of the tertiary carbon cation which is formed[18,27], ultimately yielding a conjugated diene, can probably be achieved in two ways—(*a*) by loss of a proton

and formation of an unsaturated alcohol, and (*b*) by addition of two molecules of water with formation of a tertiary diol:



Alcoholysis of 4,4-dimethyl-1,3-dioxan gave a 30% yield of the corresponding tertiary ether[20,28,29], whose formation can be explained by interaction of the corresponding carbonium ion with the alcohol.

Many workers have studied the hydrolysis of polyalkylated dioxans. Thus a 50% yield of pinacoline was obtained by treating 4,4,5-trimethyl-1,3-dioxan with a 20% solution of hot hydrochloric acid[26,30], but the reaction mechanism was not discussed. The reaction can probably be represented by a double 1,2-type of rearrangement with migration of a hydride anion in the first stage and of a carbanion in the second stage:



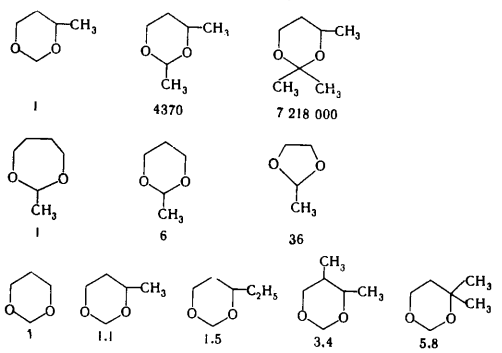
The action of dilute mineral acids (hydrochloric, sulphuric) on 4,4,5-trimethyl-1,3-dioxan gives a 50% yield of 2,3-dimethylbuta-1,3-diene[22,25,26]. The hydrolysis of 1,3-dioxans obtained from polyols leads to the formation of 1,3-dioxolans, which are in equilibrium with the initial dioxans[31]. Phenyldihydropyran has been obtained[32] by hydrolysis of 4-2'-hydroxyethyl-4-phenyl-1,3-dioxan and dehydrocyclisation of the resulting unsaturated diol.

Ion-exchange resins (Amberlite IR-120, Dowex 50-WX-4) are good catalysts for the hydrolysis of 1,3-dioxans[15,33]. Thus the latter have been used to effect the partial hydrolysis of the acetal of pentaerythritol[15]. A patent reports use of the boron trifluoride–ether complex for the hydrolysis of 4,4-dimethyl-1,3-dioxan, when isoprene was obtained as a result of hydrolysis and dehydration[24].

Skrabal[5] and Leutner[6,7] studied the kinetics of the hydrolysis of cyclic acetals in the presence of hydrochloric acid at room temperature. To obtain comparative data they examined the hydrolysis of cyclic acetals containing five-, six-, and seven-membered rings. Table 1, which we have compiled from the work of Leutner and of Gershkovich[18], enables us to compare the stability of various cyclic acetals and ketals under conditions of acid hydrolysis and to reach certain conclusions. Table 1 shows that increase in the number of alkyl radicals in position 2 of the dioxan ring produces a sharp increase in the rate of hydrolysis of the 1,3-dioxans, which enables us to trace the rule in the sequence formal–acetal–ketal (first series).

The authors showed also that the rate of hydrolysis of cyclic acetals increases as the ring becomes smaller (second series). Alkyl radicals in position 4 of the ring have a considerably smaller effect on the rate of hydrolysis (third series). The effect of aryl radicals in position 2 of the 1,3-dioxan ring was studied by Ceder[8], who showed that the rate of hydrolysis of 2-substituted 1,3-dioxans increases in the sequence—2-methyl < 2,2-diphenyl < 2-phenyl < 2-methyl-2-phenyl < 2,2-dimethyl < 2-β-styryl.

Table 1.



* The numerals below the formulae denote relative rates of hydrolysis in the given series.

Thus electron-donor substituents in position 2 increase the rate of hydrolysis of 1,3-dioxans by facilitating the formation of a carbonium ion.

Bender and Silver[10] have studied the effect of substituents in a 2-phenyl ring on the rate of hydrolysis of dioxans. They have shown that hydrolysis is accelerated by *ortho*- and *para*-hydroxyls. It is possible that direct intramolecular action of the hydroxyl on the dioxan ring takes place in the case of 2-*o*-hydroxyphenyl-1,3-dioxan. However, a high rate of hydrolysis is found also with 2-*p*-hydroxyphenyl-1,3-dioxan, where intramolecular interaction of this kind is impossible. In general these facts can obviously be explained by the strong electron-donor effect of the phenoxide ion formed under the experimental conditions[10].

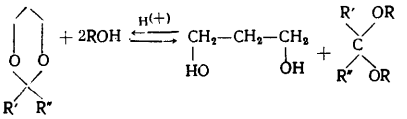
The kinetics and the mechanism of the hydrolysis of 1,3-dioxans have been discussed by Laurent et al.[9] and also by Aftalion et al.[11-13] on the basis of a large amount of experimental data. From their results they calculated several thermodynamic constants—enthalpy, activation energy, etc.—and found the hydrolysis to be endothermic, with an activation energy of approximately 26 cal mole^{-1}.

1,3-Dioxans containing electron-acceptor substituents in position 2, obtained from diols and chloral, are extremely resistant to hydrolysis, since the electron-acceptor groups prevent formation of a carbonium ion[17]. In some cases hydrolysis of the dioxans can be catalysed by traces of carbon dioxide[7]. Thus 5,5-dimethyl-1,3-dioxan-2-spirocyclopentane in an aqueous medium containing a mere trace of carbon dioxide gives 2,2-dimethylpropanediol and cyclopentanone. However, this course of reaction was not observed with the ketals of cyclohexanone and acetone.

The difference in behaviour between the dioxans was explained[33] by internal strain. Transition of a carbon atom from the tetracovalent state (ketal) to the trigonal state (cyclic ketone) is energetically more favourable in the case of cyclopentanone than with cyclohexanone[34]. The same reasons can obviously explain the hydrolysis of the acetals of 2,2-dimethylpropane-1,3-diol when they are boiled in 1,4-dioxan solution even in the absence of traces of mineral acids[15].

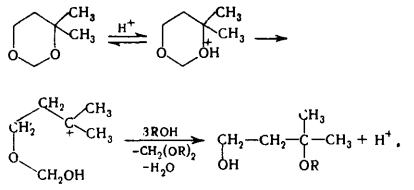
III. ALCOHOLYSIS OF 1,3-DIOXANS

1,3-Diols are obtained in good yield by the reaction between 1,3-dioxans and alcohols in the presence of acidic and electrophilic catalysts[2,27,29,35-41]:

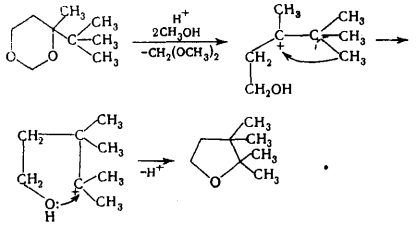


where R′, R″ = H, Alk and R = Alk. Acetals formed at the same time as the diols can be distilled from the reaction mixture, which shifts the equilibrium completely towards formation of diols. The mechanism of this reaction is analogous to that of the hydrolysis of 1,3-dioxans in the presence of acids.

Under certain conditions the alcoholysis of dioxans containing a quaternary carbon atom may lead to the formation of dienes[29,42,43], accompanied by ethers of tertiary alcohols[20,28,29]. The reaction mechanism probably includes formation of a carbonium ion[18,27]:



Korotkov et al.[27] report the formation of tetrahydrofuran compounds by the alcoholysis of 1,3-dioxan derivatives. The reaction involves cleavage of a carbon–oxygen bond adjacent to a tertiary carbon atom, followed by a retropinacoline rearrangement, leading to formation of a tetrahydrofuran ring:

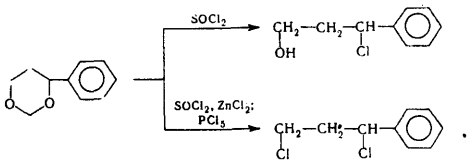


IV. INTERACTION OF 1,3-DIOXANS WITH INORGANIC COMPOUNDS CONTAINING LABILE HALOGEN ATOMS

Little work has been done on the reactions of 1,3-dioxans with inorganic halogen compounds. In 1912 the first study was made of the interaction of 1,3-dioxan with bromine, when a heavy oil, slowly decomposed by water, was formed[44]. The chlorination of 1,3-dioxans in the absence of moisture produced polychlorinated dioxans[2], whereas in aqueous solution 1,3-diols were formed in good yield.

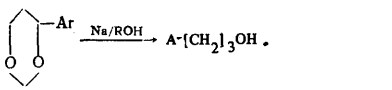
The chlorination of 4,4-dialkyl-1,3-dioxans in sodium carbonate solution produces 1,3-diols[45], one of the hydroxyls being attached to a tertiary carbon atom[46]. Compounds having this structure cannot be obtained by the hydrolysis of 1,3-dioxans, since under the conditions of the reaction the diols formed as intermediates are readily dehydrated to unsaturated alcohols and dienes.

In a large excess of thionyl chloride, as well as in the presence of concentrated hydrochloric acid, 3-phenyl-3-chloropropanol[46] is formed from 4-phenyl-1,3-dioxan, whereas in carbon tetrachloride a 50% yield of 1-phenyl-1,3-dichloropropane is obtained. Replacing the thionyl chloride by phosphorus pentachloride increases the yield to 95%:[46]

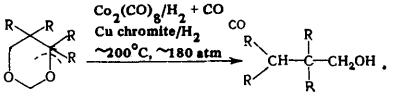


V. HYDROGENOLYSIS OF 1,3-DIOXANS

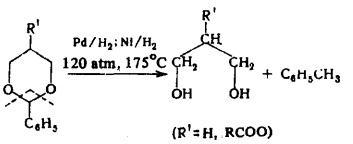
The hydrogenolysis of 1,3-dioxans leads to the formation of alcohols, the corresponding diols, or their monoethers depending on the conditions and the catalyst chosen and also on the structure of the initial compounds. This reaction has been widely studied by many investigators under various conditions in the presence of a large number of catalysts. Thus the hydrogenolysis of 1,3-dioxans has been investigated in the presence of metallic sodium in alcohol[32,47-53], Raney nickel[54,55], nickel[56], palladium[57-60], and platinum[61] catalysts, and also copper chromite[2,40,53,62-65] and octacarbonyldicobalt[66]. The changes undergone by 4-arylated dioxans have been investigated in the presence of metallic sodium and 2,6-dimethylheptan-4-ol, when the corresponding primary alcohols were obtained in yields exceeding 80%:[32,47-53]



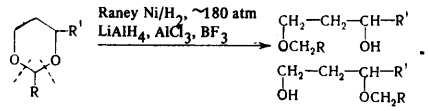
It was shown also that the hydrogenolysis of 1,3-dioxans containing mono- or poly-alkyl or -aryl substituents in positions 4 and 5 of the dioxan ring, on copper chromite or in the presence of octacarbonyldicobalt, leads to the formation of primary alcohols having an iso-structure[2,40,53,62-66]:



However, the use of metallic catalysts—nickel, palladium—for the hydrogenolysis of dioxans makes it possible to obtain 1,3-diols in good yield[56-60], whereas on platinum under analogous conditions the dioxan ring remains unchanged[61]:

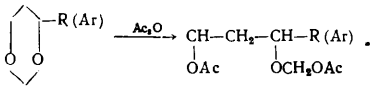


The hydrogenolysis of 1,3-dioxans in the presence of a Raney nickel–aluminium catalyst at high pressures leads to the formation of 1,3-alkoxyalkanols [54,55]. Similar results have been obtained with lithium tetrahydroaluminate and aluminium chloride, or the boron trifluoride–ether complex, as catalyst [67–70]:



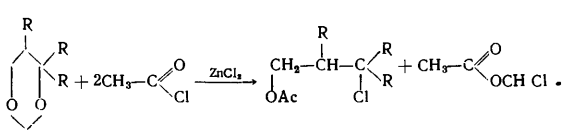
VI. REACTIONS OF 1,3-DIOXANS WITH DERIVATIVES OF CARBOXYLIC ACIDS

Many papers have been published on the reaction between 1,3-dioxans and acetic anhydride. This usually results in ester derivatives of a 1,3-diol in yields reaching 80%:[40,71–77]



Ness et al.[71] showed that, after the dioxan ring has been opened, the acetoxymethoxy-group adds to a secondary carbon atom. Results obtained by other workers[40,72–77] show that the dioxan ring is opened in only one way, whereas according to Shorygina[46,78] the esterification of 4-phenyl-1,3-dioxan may involve cleavage of the acetal ring at two bonds.

In the presence of electrophilic catalysts the chlorides of carboxylic acids open the dioxan ring to form 3-chloroacetoxyalkanes[79,80]:



These reactions are of industrial value, since the products can be used as plasticisers, solvents, etc.[79,80].

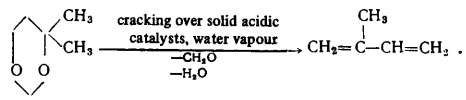
VII. THERMAL AND CONTACT–CATALYTIC REACTIONS OF 1,3-DIOXANS

Several scientific papers and patents have recently appeared on the thermal and catalytic transformations of 1,3-dioxans. These reactions of dioxans are not only of theoretical interest (in connection with the mechanism of the reaction, and the effect of the structure of 1,3-dioxans on the mechanism of catalysis) but also of great practical value. It has been found that good yields of extremely valuable conjugated dienes can be obtained by cracking 4- or 5-mono- or -di-alkyl-1,3-dioxans, synthesised by the Prins method from cheap industrial starting materials (alkenes and formaldehyde), over solid dehydration catalysts of acidic type[27,39,82–124]. The practical value of this reaction stimulated enhanced interest in the changes undergone by 1,3-dioxans, and led to the appearance of numerous publications and patents.

A systematic study of the conditions under which the process could be carried out and also the choice of catalysts was of primary importance for investigating the catalytic cracking of 1,3-dioxans. The pyrolysis of a cyclic acetal, 2-propyl-1,3-dioxan, was first reported by Bilger and Hibbert[81], who showed that, under the conditions of pyrolysis, cyclic acetals are more stable than the isomeric esters. These workers assumed that the reaction takes place by a radical mechanism.

Hamamoto and Mitsutani[122] investigated metal oxides and sulphates as catalysts. As the active component of the catalyst for the preparation of dienes from 1,3-dioxans many workers have used phosphoric acid, its acid salts, organic and inorganic phosphates on carriers and in their absence[27,39,82–112,114–124]. The carriers used have been graphite[82], coke[118], silica gel[84,90,104,114], silica–alumina[115,116], neutral silicates[101,105,108], kaolin[98], zeolite[114], kieselguhr[90,97,121], pumice[90], titanium dioxide[102,107–110], quartz[103,108–112], glass wool[105,108–110], aluminium oxide[84,90,114], silicon carbide[100,106,108–110], diatomite[99], and also mixed carriers[97].

An extremely interesting report has appeared on the transformation of 4,4-dimethyldioxan when passed together with triethyl phosphate through a tube containing silica gel heated to 400°C.[120] 4-Alkyl, 4,4-dialkyl-, and 4,5-polyalkyl-1,3-dioxans form dienes in yields which reach 90% depending on the reaction conditions[27,39,82–124]:



Water vapour is most often used as "diluent" in these processes, and plays an important part in maintaining the equilibrium of the acid phosphates in the catalytic decomposition of dioxans[94,115]. Nitrogen and the vapours of organic solvents are also employed as diluents[84,102,121]. The pyrolysis of 1,3-dioxans has been investigated over a wide range of temperatures of 150° to 450°C. The best results have been obtained at 200–350°C. There are indications that the relative proportion of side and secondary reactions increases as the period of contact becomes longer, the process shifting towards formation of isobutene or leading to the production of polymers of dienes and formaldehyde[94,117]. The pyrolysis of 1,3-dioxans has been investigated at atmospheric or nearly atmospheric pressures, but in several cases in which diluents were used the partial pressure of dioxan was 50–100 mmHg.

The effect of the nature of the catalyst and of the conditions of cracking has been investigated in detail for the conversion of 4,4-dimethyl-1,3-dioxan into isoprene[94,115,116,122,123]. The course of the reaction was shown to be greatly influenced by the nature of the carrier, its composition, and its structure, and also by the quantity of active component and the conditions under which the catalyst had been prepared (e.g. the temperature of ignition), as well as by the reaction temperature, the space velocity, etc.

In the cracking of 4,4-dimethyl-1,3-dioxan acidic carriers exhibit catalytic activity even in the absence of an active phase. In this case, however, the process exhibits poor selectivity towards formation of isoprene, the main product being isobutene[94,115]. Aluminium silicate, B_2O_3.Al_2O_3, Al_2O_3, SiO_2, $ZnO–SiO_2$, $Cr_2O_3.Al_2O_3$, and metal sulphates also catalyse the cracking of dimethyldioxan[94,113,115,122], the yield of isoprene being small.

A catalyst obtained by impregnating aluminium silicate with acid phosphates and then igniting possesses quite different properties. Both the yield and the selectivity are increased.

The properties of a catalyst depend substantially on the composition of the carrier. Thus increasing from 5% to 10% the alumina content of the carrier leads to a diminution in the selectivity and the stability of the catalyst[115].

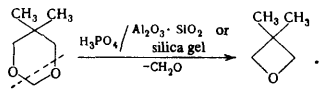
The explanation is that increase in the basicity of the carrier is accompanied by a change in the composition of the phosphate polymers formed on the catalyst surface during its ignition.

Another factor determining the activity and the selectivity of a catalyst is the concentration of active phase on the surface of the carrier and the associated proton acidity of the catalyst[116]. With increase in concentration of the active phase up to 4% a slow linear increase in proton acidity is observed; but with further increase in concentration the slope of the curve becomes greater. On the other hand, the activity and the selectivity of the catalyst with respect to isoprene increase rapidly over the section corresponding to saturation of the catalyst surface by phosphate polymers, i.e. up to 4–5% of the active phase; with further increase in concentration of the active phase and the associated acidity of the catalyst, the increase in activity and selectivity slows down, and constant values are reached[116].

1,3-Dioxans are regarded[116] as undergoing conversion both on Brønsted and on Lewis acid centres. However, the roles of the two types are different[115]. The formation of isoprene is attributed to the action of Brønsted acid centres, while the conversion of dioxan into isobutene and carbon is ascribed mainly to reaction on Lewis acid centres. Reversible adsorption of dioxans on the Brønsted centres is effected by oxygen atoms of basic character, and as a result intermediate ionic complexes are formed on the surface. These complexes break down to form dienes.

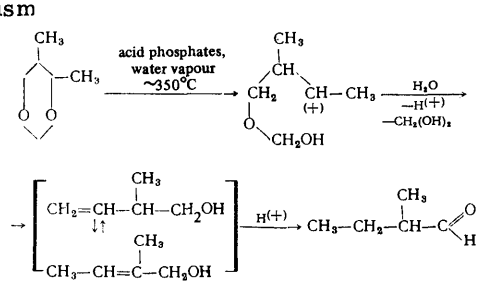
Cleavage of a carbon–carbon bond, with formation of carbon and isobutene, takes place independently of the formation of isoprene[14,115,116]. It is catalysed by both Brønsted and Lewis acid centres, but the chemisorption of dioxans on the Brønsted centres prevents this reaction[116]. Therefore variation in the number of Brønsted acid centres has a great effect on selectivity, whereas the total conversion is little affected by this factor.

In the cracking of alkyl-1,3-dioxans good yields of oxetans are obtained as well as dienes[89,124,125]. Under certain conditions oxetans can be prepared practically exclusively by means of this reaction[124]:



Little study has been made of the effect of the structure of the initial 1,3-dioxan on the course of reactions leading to the formation of oxetans. However, there are grounds for supposing that an important part is played by the symmetry of the dioxan molecule and the peculiar stability of the 3,3-dialkyloxetans formed in the series of alkyl-substituted oxetans[124].

The cracking of 4-methyl- and 4,5-dimethyl-1,3-dioxans on solid acid catalysts yields an alkylcarbinol[91,126] and isovaleraldehyde[127] depending on the space velocity, by the mechanism



VIII. CATALYTIC ISOMERISATION OF 1,3-DIOXANS

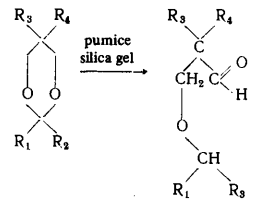
1. Heterogeneous Catalytic Isomerisation

The literature contains a large amount of experimental information on the heterogeneous catalytic isomerisation of 1,3-dioxans[125,128–131]. The isomerisation takes place by an ionic mechanism on weakly acid catalysts[125,128,129], and by a radical mechanism under thermal conditions[130,131].

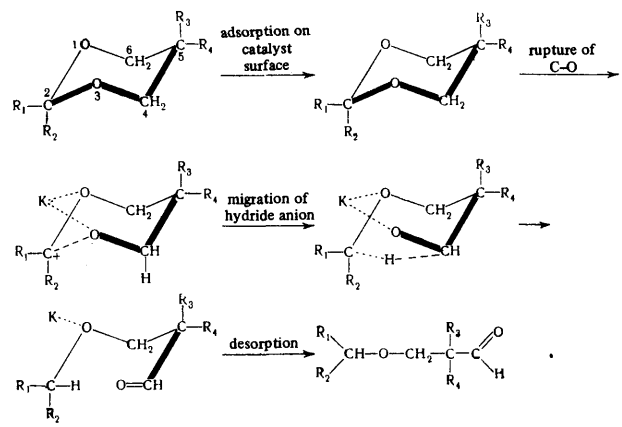
(*a*) Isomerisation by an ionic mechanism

Acid catalysts accomplish the cleavage of open-chain acetals with the formation of vinyl ethers and alcohols[132–139].

Rondestvedt and Mantell[125,128,129] note that 2,5,5-trialkyl-1,3-dioxans undergo isomerisation on pumice and silica gel into good yields of β-alkoxy-aldehydes:



The dioxan is assumed to be adsorbed on the acid centres of the catalyst in the chair conformation, and the resulting ionic compound is stabilised by migration of a hydride ion. The reaction mechanism can probably be represented by the scheme:



(i) Adsorption. Increasing the bulk of substituents prevents two-point adsorption of 1,3-dioxans. The size of the substituents R_1 and R_2 plays an especially important part. If R_1 in a dioxan ring in the chair conformation is considerably larger than R_2, it will occupy an equatorial position, which will prevent two-point adsorption of the dioxan on a catalyst surface, owing to repulsion of R_1 from the surface. The repulsion is eliminated on the migration of R_1 to the axial position. The energy required for such migration (1–4 kcal mole^{-1}) will depend on the difference in size between R_1 and R_2, and can be balanced by the difference in energy of repulsion between the substituents R_1, R_2 and the surface. If R_1 is an aromatic substituent, the attraction of its π-electrons to the acid centres of the surface will facilitate two-point adsorption. Electron-acceptor substituents in the aromatic ring, by diminishing the

electron density of the ring, prevent formation of a complex on the catalyst surface, whereas electron-donor substituents facilitate adsorption. Substituents containing unhindered oxygen and nitrogen atoms of basic character, located in the acetal ring, diminish the probability of oriented adsorption and thereby prevent isomerisation.

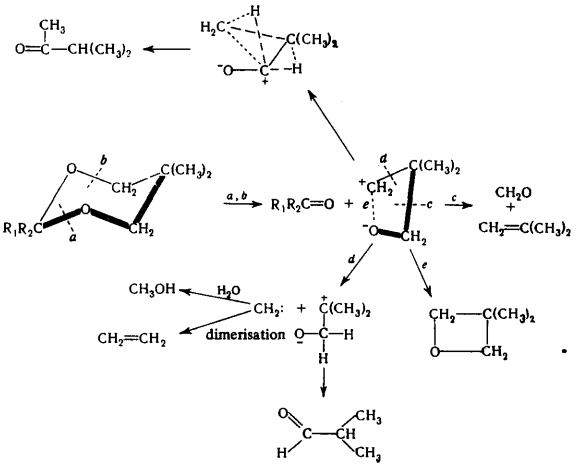
(ii) Rupture of carbon–oxygen bond and stabilisation of carbonium cation. The second stage of the reaction involves heterolytic rupture of the 2–3 carbon–oxygen bond with formation of a carbonium ion having the positive charge on the $C_{(2)}$ atom. The ability to form a cation depends on the size and the nature of the substituents attached to the $C_{(2)}$ atom. The diminution in the tendency of cyclic acetals to isomerise in the sequence—ketal > alkylacetal > formal—is associated with the formation and stabilisation of the carbonium cation, and serves to confirm the above hypotheses (see Sections II and III). The ease of isomerisation of 2-phenyl-1,3-dioxans depends on the nature of the *para*-substituent in the benzene ring. Electron-donor and electron-acceptor substituents respectively promote and impede isomerisation of 2-phenyl-1,3-dioxans, which in the absence of such substituents are extremely reactive.

The similarity in the first stages in the mechanisms of hydrolysis and isomerisation on weakly acidic catalysts (formation of a carbonium cation) explains the absence of isomerisation in 4,4-dialkyl-1,3-dioxans. Apart from obvious stereochemical considerations, it must be borne in mind that published data indicate[18,27] that 4-alkyl substituents facilitate cleavage of the 3–4 carbon–oxygen bond by diminishing the possibility of rupture of the 2–3 carbon–oxygen bond, which excludes the possibility of isomerisation. It must also be noted that the literature contains data on the successful isomerisation only of symmetrical 1,3-dioxans, for which cleavage of the 1–2 and 2–3 carbon–oxygen bonds is equally likely.

(iii) Migration of hydride anion from $C_{(4)}$ to $C_{(2)}$. Such migration accompanying cleavage of the 2–3 carbon–oxygen bond can be explained from the fact that aliphatic acetals form vinyl ethers on stabilisation of the carbonium cation formed during rupture of the carbon–oxygen bonds[132–139]. The cracking of six-membered cyclic acetals on weakly acidic catalysts yields alkoxy-aldehydes. In the latter case the catalyst ensures transfer of a hydride ion from $C_{(4)}$ to $C_{(2)}$, which is favoured also by the geometry of the intermediate complex. The constriction of the 1,3-dioxan ring at the oxygen atoms in the chair conformation brings the $C_{(2)}$ atom closer to the axial hydrogen atom attached to the $C_{(4)}$ atom, as a result of which the hydride ion migrates from $C_{(4)}$ to $C_{(2)}$ with cleavage of the 2–3 carbon–oxygen bond.

(iv) Desorption. The character of the transformation is greatly affected by the rate of desorption. A high rate at this stage favours smooth isomerisation, whereas slow desorption leads to resinification and deactivation of the catalyst. Thus the lone pairs of electrons in the case of 2-*p*-dimethylaminophenyl-1,3-dioxan or the presence of unhindered oxygen atoms in substituents in the dioxan ring prevent the isomerisation of these compounds owing to their strong adsorption.

Study of the secondary products enables conclusions to be drawn on the mechanism of the side-reactions. A detailed investigation of the products from 5,5-dimethyl-1,3-dioxan has shown that, besides the expected alkene and oxo-compound, catalysis yields substances whose formation can be explained by the scheme:

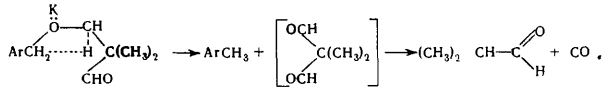


The main reaction via the zwitterion is (*d*), leading to the formation of isobutyraldehyde instead of the formaldehyde and isobutene expected according to reaction (*c*).

Besides compounds of the type $R_1R_2C:O$ (*a*–*b*) the reaction products were found to include formaldehyde, isobutene, isobutyraldehyde, isopropyl methyl ketone, $\alpha\alpha$-dimethylpropionaldehyde, methanol, 3,3-dimethyloxetan, ethylene, propene, and also hydrocarbons having a longer carbon chain than in the initial dioxan, with in rare cases vinyl ethers. Reaction (*e*) corresponds to closure of the zwitterion. Thus the ketal of cyclohexanone gives a 10% yield of the dimethyloxetan, whereas in the case of the initial ketal of cyclopentanone only traces of the dimethyloxetan were detected in the catalyst.

Under analogous conditions the seven-membered dioxetans are converted mainly into tetrahydrofuran derivatives, this reaction probably also involving the intermediate formation and closure of zwitterions. The detachment of a methylene radical by reaction (*d*) is confirmed by the presence of C_6 hydrocarbons among the products.

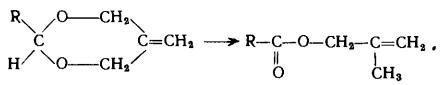
The by-products of the cracking of 2-aryl-1,3-dioxans include also toluene. The formation of toluene is probably accompanied by that of dimethylmalonaldehyde, which is decarbonylated to isobutyraldehyde:



It is very probable that benzaldehyde also is formed.

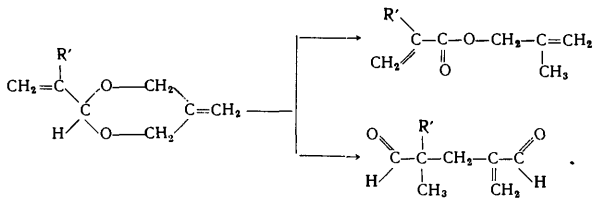
(*b*) Thermal isomerisation of 1,3-dioxans

An interesting case of the isomerisation of 1,3-dioxans on glass beads was observed by Weiss et al.[130,131], who found that with 5-methylene-1,3-dioxans the principal final products were methylallyl esters. Isomerisation into such esters is possible only with dioxans that contain a 2-hydrogen atom:



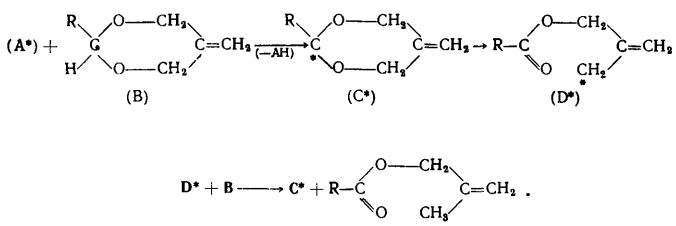
The nature of the 2-substituent has a fundamental effect on the character of the transformation of dioxans, but methylallyl esters are formed in all cases. If the substituent R

is a vinyl group, parallel formation of a dialdehyde takes place:

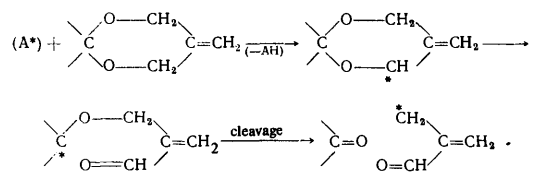


The presence of two 2-alkyl substituents stabilises the dioxan molecule. It must be noted that a radical mechanism has been suggested[140-146] for the conversion of acetals into esters. There appears to be no need[130] to introduce a free radical into the reaction medium to initiate the reaction, for the structure of the initial dioxan and diacetyl, containing double bonds of allyl type[130,131,140,141], creates favourable conditions for the occurrence of a radical reaction under the thermal conditions described.

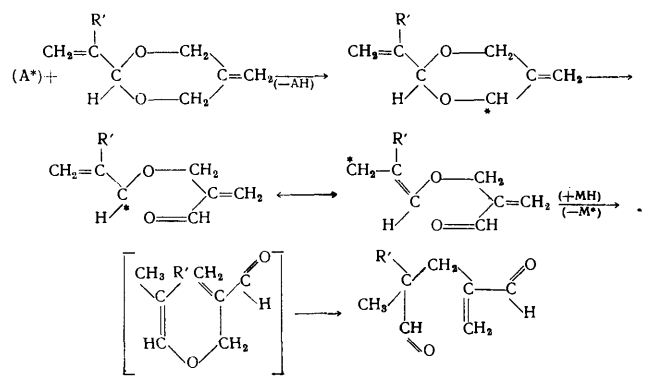
The reaction proceeds according to the scheme



The dioxan molecule undergoes cleavage if the primary act is attack on the quaternary carbon atom:

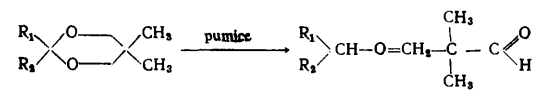


With 5-methylene-2-vinyl-1,3-dioxan as initial compound, however, analogous attack on the quaternary carbon atom leads to the formation of a dialdehyde:



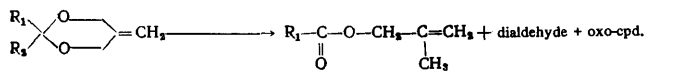
The possibility of the existence of an allyl vinyl ether—the hypothetical intermediate compound—represents a new concept in the field of radical reactions. Analogous views have been expressed earlier in the case of ionic reaction[147,148]. It is interesting to compare the results obtained by Rondestvedt[125,128,129] with those of Weiss et al.[130]. The tendency of 5,5-dimethyl-1,3-dioxans to isomerise increases with the structure of the initial oxo-component of the dioxans in the sequence—$\alpha\beta$-unsaturated aldehydes < aliphatic aldehydes < aromatic aldehydes < ketones—whereas 5-methylene-1,3-dioxans show an increase in activity in the reverse sequence—ketones < aliphatic aldehydes < aromatic aldehydes < $\alpha\beta$-unsaturated aldehydes[130]—see Tables 2 and 3. This is explained by differences in the structure of the 1,3-dioxans and in the mechanism of isomerisation.

Table 2. Ionic heterogeneous catalytic isomerisation.



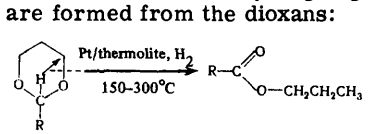
R_1	R_2	Unchanged dioxan, %	Yield based on dioxan converted, mole %		Isomerisation temp., °C
				$R_1-\underset{\underset{O}{\|}}{C}-R_2$	
$CH_2=CH-$	H	100	0	0	480
H	H	37	60	—	400—440
$(CH_3)_2CH-$	H	16	82	—	410
CH_3-	CH_3-	12	51	31	360
	H	0	>80	—	400
	H	0	75—80	5	400
	$-(CH_2)_5-$ O	0	80	10	390

Table 3. Radical heterogeneous catalytic isomerisation at 450°C.



R_1	R_2	Unchanged dioxan, %	Yield based on dioxan converted, mole %		
			methylallyl ester	dialdehyde	$R_1-\underset{\underset{O}{\|}}{C}-R_2$
$CH_2=C(CH_3)-$	H	8	39	13	47
$CH_2=CH-$	H	26.5	26	46	18
	H	41.5	79	—	17
$(CH_3)_2CH-$	H	58	97.5	—	1
	H	67	88	—	1.5
H	H	74	62	—	—
CH_3-	CH_3-	78.5	—	—	
	$-(CH_2)_5-$	100	—	—	0

An interesting possibility of isomerisation has been observed[149] with 2-alkyl-1,3-dioxans on platinum deposited on thermolite (1). In a stream of hydrogen good yields of propyl esters are formed from the dioxans:



2. Homogeneous Catalytic Isomerisation of 1,3-Dioxans

Esters are formed by the transformation of 1,3-dioxans in the presence of organic peroxides or by the action of ultraviolet radiation on these acetals[144,146]. The first stage in the reaction is regarded as involving detachment of hydrogen from the $C_{(2)}$ atom of the dioxan ring, this being followed by cleavage of a carbon–oxygen bond and formation of an ester molecule. 4-Methyl-2-phenyl-1,3-dioxan yields mainly n-butyl benzoate, the isobutyl ester being formed in smaller amount[144]:

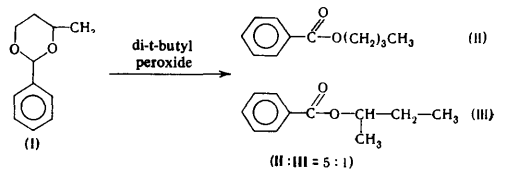


Table 4. Homogeneous catalytic isomerisation.

Dioxan	Catalyst	Reaction conditions	Reaction products	Ref.
IV	di-t-butyl peroxide	132°C 18 h		144
I	ditto	135°C 18 h	II III ratio I:II=5:1	144
	ultraviolet + acetone + t-butyl alcohol	20–40 h		146
	ditto	ditto		146

A similar distribution of products is observed in the isomerisation of mixed open-chain acetals in the presence of d-t-butyl peroxide, the course of the reaction being determined by the ability of the intermediate radicals formed to be stabilised by hyperconjugation[145]. Table 4 gives comparative data obtained for the isomerisation of 1,3-dioxans.

IX. POLYMERISATION AND OXIDATION OF 1,3-DIOXANS

The polymerisation, the copolymerisation, and also the oxidation of 1,3-dioxans have been very little studied. Strepikheev and Volokhina[150] investigated the possibility of their polymerisation in the presence of camphorsulphonic acid and obtained negative results. However, five-, seven-, and eight-membered cyclic acetals are in considerable measure polymerised under analogous conditions, the stability of the acetal ring increasing—and the tendency to polymerisation decreasing—with rise in temperature. These workers also found that the tendency to polymerise diminishes with decrease in the size of the ring in series of cyclic acetals, in the sequence—8 > 7 > 5 > 6—little difference in capacity for polymerisation being found between the five- and seven-membered rings. The enthalpy of cyclisation of acetals[151] also diminishes with the size of the ring, in the sequence 8 > 5 > 7 > 6. These results enable an assessment to be made of the relative tendency of cyclic acetals to polymerise.

The patent literature contains reports of the polymerisation and copolymerisation of 1,3-dioxans[79,152,153]. Peroxides, $\alpha\beta$-unsaturated esters, and their polymers have been obtained by the oxidation of 2-alkylene-1,3-dioxans in the presence of oxygen and cobalt(II) ions[154]. A good yield (~ 95%) of a benzoic ester has been obtained[155] by the reaction between *N*-bromosuccinimide and 2-phenyl-1,3-dioxan:

Methods for the Determination of Water in Substances in Different States of Aggregation

V.A.Drozdov, A.P.Kreshkov, and S.I.Petrov

The most important data on methods widely used at present to determine the concentration of moisture in substances in different states of aggregation are examined. The bibliography contains 715 references.

IV. Physical and physicochemical methods for the determination of water 52

I. INTRODUCTION

Since the publication of Mitchell and Smith's monograph[1], the Karl Fischer method for the determination of water has been improved, and new chemical, physical, and physicochemical methods for its determination, which have been widely used in various fields of science, industry, and the new technology, have been described.

Simultaneously, the requirements made of the methods themselves have become more severe, since the modern tendency in analytical chemistry is directed towards automation of the continuous control and regulation of technological processes, with minimal expenditure of effort on the actual analysis. This has led to the introduction and development of completely new and highly sensitive methods of analysis, such as infrared spectroscopy, coulometry, gas-liquid chromatography, etc.

Published reviews[2-30] of methods for the determination of water do not claim to examine this problem exhaustively.

In the present paper an attempt has been made to give a complete review of all methods for the determination of water in substances in different states of aggregation.

II. METHODS FOR THE DETERMINATION OF WATER BASED ON ITS SEPARATION

1. The Drying Method. The simplest and oldest method for the determination of water is based on the drying of the specimen to be analysed to constant weight. The water content is estimated from the loss in weight. The rate and efficiency of dehydration are determined by a number of factors: the way in which heat is supplied to the specimen being tested, the rate of removal of the water liberated, the establishment of an optimal temperature of drying, at which decomposition of the specimen being analysed is not observed[31,32], the state of the water molecules in the material being studied, and also diffusion conditions.

The drying process is influenced considerably by the depth of the layer and the friability of the specimen[33]. The reproducibility of the results depends on such factors as the design of the drying oven, the nature of the material from which the drying vessel is made, and the shape of the evaporation dishes. The rate of removal of water from the surface of a solid phase is a function of the water vapour pressure and the temperature of drying.

When moist organic substances are heated, changes in the weight of the substance being analysed may be due not only to the liberation of water, but also to the liberation of CO_2, CO, H_2, and CH_4. In the analysis of thermally unstable inorganic compounds (iron and aluminium sulphates), selective absorbers for water and sulphur dioxide are used.

The temperature at which the specimen is heated during drying is determined by the nature of the substance being analysed.

In addition to the determination of water of crystallisation in salts[34], the drying method can be used with different degrees of accuracy for the determination of the concentration of water in cheese[35], jam[36], sheeps' milk cheese[37], tungstosilicates[38], xanthates[39], wood[40,41], castor beans[42], grain and grain products[43,44], clay[45], natural glasses[33], cadmium thiobarbiturate[46], [iron ore] charges[47], carbon black[48], the raw material for opium[49], meat products[50], brown coals[51,52], nuts, raisins, and poppyseed[53], dried fruit[54], and malt[55].

In order to use lower temperatures for drying and hence prevent thermal decomposition of the specimen, the use of infrared radiation and reduced pressure has been proposed for the determination of water in salts[56,57] and serum[58,59].

By combining the drying oven and analytical balance, it is possible to determine losses in weight during drying, with elimination of the operations involving the transfer of the specimen to a desiccator, and the time required to cool the substance being analysed.

A number of authors have proposed the more rapid determination of water by the drying method using a combination of hot air circulation, infrared radiation, vacuum drying ovens, and special evaporating dishes. The methods cover the analysis of grain, starch, and foodstuffs[60-62], pharmaceutical products[63], fertilisers[64], grain and coffee[65], dried grapes[66], and hops[67].

New apparatus and procedures for studying the mechanism of the drying of colloidal capillary-porous materials have been published[68]. The British Standards Institute has published standards for vacuum drying ovens[69].

Various techniques[70], attachments, and automatic instruments for the determination of water by drying have been described[17,71-83].

The drying method has found most extensive application in the determination of hydrate water in inorganic compounds. The method is less satisfactory for organic compounds. The sources of error encountered in the drying method have been examined[84].

The drying method is time-consuming, has a low accuracy when the water concentration is low, and for practical utilisation it requires the establishment of standard conditions for each specific instance. A number of the proposed improvements (infrared radiation, vacuum drying apparatus, automatic balances, etc.), however, make it possible to reduce the time required for the determination of water to 15–20 min. The error in weighing determines the limit of the minimal quantities of water which can be detected. The chief disadvantage of the method is that it cannot distinguish between water and other volatile substances present. The drying method is irreplaceable, however, for the routine determination of water in heterogeneous materials (fresh fruit, grain, silage, etc.). The drying method can serve as a relative criterion in the development of new and improved methods for the determination of water.

2. The Sorption Method. The sorption method for the determination of water is based on the use of sorbents to trap water vapour removed by a current of carrier gas, with gradual heating of the substances being analysed. The absorption tube containing the sorbent is weighed before and after the passage of the carrier gas, and the increase in weight gives the water concentration.

Various solid and liquid reagents have been used as absorbents: $CaCl_2$, P_2O_5, $CoCl_2$, drierite, anhydrone, sulphuric acid phosphoric acid, etc. The characteristics of various drying agents have been compared[85].

Dry air or argon are often used as carrier gas. The choice of carrier gas for a particular example of the determination of water is determined by the nature of the substance being analysed.

The sorption method is used for the determination of water in liquid and gaseous chlorine[86], liquids[87], silicate and carbonate minerals[88,89], beryllium carbide[90], wool[91], and potassium fertilisers[92], and for the determination of oxides and water in metal powders[93] and cable insulating paper[94]. In the simultaneous determination of water and CO_2 in rocks and minerals[89], a mixture of sodium carbonate and asbestos is used as absorbent to trap CO_2.

The sorption method is regarded as superior to the drying method, but it is very tedious and time-consuming, and cannot be automated. The accuracy of the method depends on the nature of the substance being analysed, the concentration of water being determined, the sensitivity of the analytical balance, and the selective absorbing power of the sorbent. By varying the absorbent, it is possible to carry out the separate determination of water and thermal decomposition products. The sorption method is also used as a means of separating water for its subsequent determination by chemical and physicochemical methods.

3. The Distillation Method. A weighed specimen of the substance being analysed is boiled in a special apparatus with an excess of a liquid which is immiscible with water (C_6H_6, toluene, xylene, CCl_4, tetrachloroethane, dioxan, perchloroethylene, aniline, mineral oils, petroleum fractions, etc.). The mixture of vapours distilled is condensed in a special distillate receiver, the liquids separate into layers, and the volume of distilled water is read off from the meniscus. The choice of solvent and the time for which the specimen is boiled are determined by the ease with which the boiling liquid penetrates into the pores of the finely ground specimen. The solvent chosen should distil in the form of an azeotropic mixture at a temperature at which chemical reactions do not take place. By creating an inert gas atmosphere in the distillation apparatus it is possible to avoid redox processes.

The accuracy of the determination of water by the distillation method depends to a considerable extent on the design of the condensate trap and the boiling assembly. Various trap designs cater for instances when the boiling liquid is lighter or heavier than water. Highly accurate results can be obtained by fine graduation of the measuring vessels and by placing the traps in a thermostat. In order to reduce the consumption of solvent during the determination and hence decrease the error in the determination due to the mutual solubility of the liquids, traps capable of returning part of the distilled liquid, after separation into layers, into the boiler assembly have been proposed.

The use of different solvents makes possible the separate determination of moisture and water of crystallisation in the same material. When azeotropic distillation with benzene and xylene are used for calcium sulphate and superphosphate fertiliser specimens, both free water and water of crystallisation are removed using xylene, whereas only free water is removed using benzene[95].

The time required for the distillation varies from 15–30 min to several hours, and is determined by the properties of the material being studied (solid or liquid, degree of subdivision, solvent chosen, temperature of distillation, etc.).

An extensive review of literature on the distillation method has been given in a paper[96] which describes the history of the development of the distillation method, gives various designs of distillation assembly, and examines critically a large number of practical examples of the use of the method. The construction of apparatus for the distillation is being constantly improved[96-108].

Satisfactory results have been given by the distillation method in the determination of water in soap[109-111], printing dyes[109], sugar-containing products[112], food products[113-115], silage[116], gypsum and superphosphates[95], furfural[117], diesel fuel, petrol, and sump oils[106], glycols and glycerol[118], diethylene glycol[119], polyethylene glycol[120], textile materials[101], petroleum and petroleum products[121], polycaprolactam[122], and DDT and HCCH emulsions[123]. A USSR State Standard has been published on the distillation method[124].

The distillation method uses simple apparatus, and all the operations are straightforward. Analytical chemists often use this method when the drying and sorption methods are inapplicable, and also when it is necessary to obtain comparative results in the development of new methods for the determination of water. In the last instance, the distillation method serves as a criterion. When the concentration of water in the substances being analysed is low, the distillation method is combined with other chemical and physicochemical methods of analysis.

III. METHODS FOR THE DETERMINATION OF WATER BASED ON THE USE OF CHEMICAL REACTIONS

1. Gas-volumetric methods. Calcium hydride reacts vigorously with water with the liberation of hydrogen, which can be measured quantitatively by volumetric or manometric methods. If the water to be determined is first extracted with a solvent, the reaction can be used for the quantitative determination of water. The solvent should be inert towards CaH_2. The first material to be proposed as extracting agent for water was degassed ethanol[125-127], and this was subsequently replaced by dioxan and pyridine[128,129].

Calculation of the thermodynamic potentials of the CaH_2–H_2O system has shown [130] that different quantities of hydrogen are liberated, depending on the temperature. In gas-volumetric determinations, strict control of the conditions of the analysis is necessary. The method can then be used for the quantitative determination of water with satisfactory accuracy in a variety of substances: inorganic crystal hydrates, liquid fuels, furfural, petroleum products, uranium hexafluoride, etc. [131-139]. The determination of traces of water vapour in gases has been described [140]. The calcium hydride method is the subject of a USSR State Standard [141].

The formation of acetylene by the reaction of water with CaC_2 has been made the basis of a method for the determination of water in substances in different states of aggregation. Since alcohols react with CaC_2 to form C_2H_2, they are unsuitable for use as media in the analysis. Inert solvents are recommended. The quantity of acetylene liberated can be measured by gas-volumetric methods, from the increase in pressure in the system, from the loss in weight of the reagent after volatilisation of the C_2H_2, by flame intensity measurements, or by measuring the quantity of oxygen required for combustion of the acetylene. In a number of instances it is considered more rational not to carry out the reaction between CaC_2 and the water-containing liquid in a heterogeneous system, and the preliminary extraction of the water by an inert carrier gas is recommended.

The carbide method for the determination of water has a number of disadvantages and limitations [130,139,142] and requires strict control of the conditions during the analysis. The method is used for the rapid determination of water in various materials: liquid coking and pyrolysis products [136], furfural [117], ores, brown coals [143], gypsum [144], rubber [146], ethyl acetate and chloroaldehyde [146], soils and building materials [147], industrial oils [148], cresol [149], metallurgical slags [150], hydrocarbons [151], leather, paper [152], grain [152,153], groats [154], peat, and wood [155].

The carbide method cannot be used for the determination of water in substances which react with CaC_2, CaO, or $Ca(OH)_2$.

Some authors consider that magnesium nitride is more convenient for the analysis than CaC_2, since the ammonia formed can be determined quantitatively by acid-base titration. Ethanol, dioxan, and a CH_3OH–C_2H_5OH mixture have been recommended as media. The analysis can be carried out in an ordinary Kjeldahl apparatus. High accuracy can be achieved in the determinations if the water is removed beforehand from the materials being studied, using a carrier gas. The method cannot be used to analyse substances which liberate NH_3 when heated. Temperature has a significant influence on the course of the reaction between Mg_3N_2 and water [130].

Noteworthy papers have been published on the use of magnesium nitride for the determination of water in divinyl distillate [156,157], gases [158], spirits and eau de Cologne [159], and transformer oil [160].

Tserevitinov's method for the determination of active hydrogen has been modified for the determination of water. The substance to be analysed is dissolved in pyridine or other inert solvent which does not react with CH_3MgI. Various compounds which contain active hydrogen atoms or which react with the Grignard reagent interfere in the determination of water. Tserevitinov's method has been proposed for the determination of water in oil [161] and gypsum [144].

Among other gas-volumetric methods, mention must be made of the determination of combined water in silica gel using diborane [162] and in solvents using alkali metals and their alloys.

Gas-volumetric methods (particularly the carbide and hydride methods) are distinguished by the rapid reaction of the reagent with the water being determined, and they have found extensive application in technology, as a result of the variety of methods for measuring the gas liberated. The required speed, accuracy, and sensitivity can be achieved.

2. Titrimetric Method. The Karl Fischer method [1] occupies a unique position among titrimetric methods for the determination of water. Study of the nature of the Karl Fischer reagent has established [163-165] that the quantity of methanol taking part in the titration has a significant influence on the results of the water determination. The titre of the reagent is a function of the ratio $H_2O : CH_3OH$. It has been proved experimentally [166] that for a solution of the reagent containing no methanol the ratio of the reacting I_2 and H_2O is 1 : 0.53, and that this ratio increases when CH_3OH is added. At a CH_3OH concentration of 24 vol.%, the ratio is equal to 1 : 1.5, and it subsequently remains almost constant over a considerable range (as far as 70%). When the reaction medium contains a large quantity of CH_3OH or C_5H_5N, additional complications, depending on the quantity of water being titrated, are observed. The deviations from the ratio 1 : 1.5 are greater, the smaller the quantity of water being titrated. The following equation has been proposed [11]

$$2H_2O + 4CH_3OH + 3C_5H_5N \cdot SO_2 + 3I_2 + 6C_5H_5N \rightarrow$$
$$\rightarrow 2C_5H_5N\begin{matrix}CH_3\\SO_4H\end{matrix} + C_5H_5N\begin{matrix}CH_3\\SO_4CH_3\end{matrix} + 6C_5H_5N \cdot HI .$$

The observed dependence of the water equivalent of the Karl Fischer reagent on the ratio $CH_3OH : C_5H_5N$ requires that the titration be carried out correctly. The standardisation of the Karl Fischer reagent and the determination of water must be carried out in a methanol + pyridine mixture with the same composition as that used for the Karl Fischer reagent. The value for the blank titration of the solvent cannot be found by titrating a smaller quantity and then multiplying the results of the titration by an appropriate factor.

The Karl Fischer reagent is prepared by mixing all the components together at the same time [1,166] (in this instance, however, the reagent may undergo a considerable loss of activity during storage [167]) or by mixing methanol and pyridine solutions of sulphur dioxide and iodine before use [168-172]. To decrease the time required for the preparation of the reagent, a simplified method for dehydrating the components with bromine or chlorine has been described [173]. It has been recommended [168] that the titration be carried out by dissolving the specimen to be analysed in a pyridine–methanol solution of sulphur dioxide. The titrant is a methanol solution of iodine.

A large number of attempts have been made by research workers to replace the components of the reagent in order to make it cheaper and to achieve greater stability. The replacement of pyridine by hexamethylenetetramine has been proposed [168], but sparingly soluble reaction products are formed. The replacement of methanol by the monomethyl ester of ethylene glycol [174] gives a more stable reagent, which has been shown to have valuable qualities [175]. It has been reported [176] that methanol can be replaced by chloroform. The preparation of an improved and stabilised reagent has been described [177].

For work in inert solvents (dioxan, benzene, CH_3CN, etc.), the use of a chloroform solution of bromine and sulphur dioxide has been proposed [178]. Substances containing HO-groups cannot be titrated with the recommended reagent. Pyridine and HCOOH also interfere.

The preparation of an improved reagent [179], designed for the determination of water in caprolactam and alcohols [180,181], has been patented. An alkoxide, phenoxide, or salts of organic acids are added to the reagent to combine with the hydrogen ions formed during the analysis. Patents [182-184] have recommended the addition to the reagent of one or more of the products of the spontaneous reaction which takes place in the reagent in the absence of water (NaI, pyridinium hydrogen, di-iodide, and secondary or tertiary amines).

The working solution is standardised by titrating accurately weighed specimens of H_2O in an inert solvent [163,164] or mixed solvent $C_5H_5N + CH_3OH$ (3 : 7) [11]. If the reagent is standardised using a standard solution of water in methanol, the determination gives its apparent water number [185], which may not coincide with the true value. It is recommended that the modified reagent be standardised using accurately weighed specimens of water or by titrating accurately measured volumes of aqueous solutions of methanol or ethanol.

Crystal hydrates have been used to standardise the Karl Fischer reagent [1,186,187].

Allowance must be made for the temperature factor [188] when the temperature of the surrounding medium during the standardisation differs from the temperature at which the analysis is carried out.

Methanol and its mixtures with pyridine, ether [189], chloroform [190], or propanol [172] are most frequently used as media for the titration. Ethylene glycol and glycerol are used only if it is necessary to determine water in gases after its absorption by these solvents. Dioxan has also been recommended [163,164,191,192]. Chloroform is usually employed for substances insoluble in methanol [193-195]. Toluene is used [196] if water is being determined after azeotropic distillation. Formamide [197], because of its high dielectric constant, is an excellent solvent and extracting agent. Acetic acid [170,197] or its mixtures with pyridine [198] are used for special purposes.

The use of *N*-ethylpiperidine as catalyst to increase the rate of the reaction between H_2O and the titrant has been recommended [199].

The analytical control of the Karl Fischer reagent has been described [200]. The spent reagent can be regenerated [11].

A variety of methods are used to detect the equivalence point in the titration. The technique of visual titration has been described in detail [1]. A new feature in this field is the attempt to introduce indicators [201-203]. Various modifications of the visual titration technique have been examined [204,205].

A photometric method for the detection of the equivalence point has been proposed for the determination of water in coloured liquids [167,206-209].

Electrometric titration is widely used to detect the equivalence point. Direct and back potentiometric titration using a bimetallic electrode couple has been described [1,210]. The so-called "dead stop" method of titration is most widely used [1,211,212]. The mechanism of the titration using polarised electrodes has been examined [213]. The sharp change in current strength at the equivalence point can be recorded using a qualitatively-operating electric eye [214]. The development of electronic apparatus has led to the production of various automatic assemblies [215-220].

There is a wide range of apparatus for electrometric Karl Fischer titration [216-234] by macro-, semimicro-, and micro-methods with complete or partial automation. In addition to standard cells attached to the titrator, various original modifications of the cell vessels and pipettes have been described [222,235-241].

Coulometric titration with the Karl Fischer reagent, based on the electrolytic generation of iodine, has been recommended for the automatic continuous control of traces of water [242-252].

Titration with the Karl Fischer reagent is used for the determination of water in various forms in the following inorganic substances: liquid ammonia [1,253], hydrogen fluoride [254,255], crystal hydrates [182,256], concentrated sulphuric [204] and nitric acids and their mixtures [257,258], ammonium perchlorate [259], uranium tetrafluoride and uranium oxide [260], mineral pigments [261], contaminated acids in sulphonation processes [262], minerals [263], calcium chloride [264], titanium(III) and vanadium(III) chlorides [265], pigments and paints [266,267], sodium tetraborate [268], granulated fertilisers [269-271], the inorganic components of solid rocket fuel [272], complex salts [273], inorganic reagents [274], and sulphuryl chloride derivatives [275].

In the determination of water using the Karl Fischer reagent, it is necessary to make allowance for the reaction of the components of the reagent with various inorganic compounds [1,261]. Thus in the determination of water in iron(III) salts a redox reaction takes place, but this can be prevented by adding 8-quinolinol [276] and carrying out the titration in quinoline.

The total concentration of water in sulphuric acid is usually determined by titrating in pyridine or a mixed pyridine + dioxan solvent, in order to reduce to a minimum the participation of methanol in the reaction. Water in fuming nitric acid is determined by titration in dimethyl formamide + pyridine [257] or dichloroethane [258]. An original method has been proposed for the determination of water and alkali metal oxide with selenium and tellurium [277].

Unsatisfactory results are obtained in the direct titration of anhydrous sodium carbonate [278], sodium carbonate, borate, and perborate, glycerophosphate, $CaCO_3$, calcium and magnesium oxides, hydrogen carbonate [63], acid salts, and $CuSO_4.5H_2O$ [279]. In these instances, preliminary xylene distillation of H_2O or its extraction with methanol [280], tetrahydrofuran, or dioxan [279] are recommended. The quantity of basic substance passing into solution during extraction is determined by titration with acid.

It is possible to determine water by direct titration in a number of organic compounds: salts of organic acids [164], sodium alkylarylsulphonate [281], dynamite glycerol [282], amines and amides [1,166,204], rubber [283,284], medical raw materials [285], pharmaceutical products [286-292], alkaloids [170,175,288], antibiotics [288,293,294], vegetable oils [195,295,296], solvents [171,204,264,297,298], powders and explosives [272,282,292,300], petroleum and petroleum products [301-303], insulating and lubricating oils [304-306], insecticide aerosols [307], oils and fats [195,261], aviation fuel [190], xanthates [308], potassium xanthate [168], cellophane [208], polymers and plastics [292,309-311], polyvinylpyrrolidone [312], vitamin C [168], milk powder and cheeses [313], starch [197,314], leather and tanning agents [315-317], dried vegetables [197,318], grain products [25,319], textile materials [320,321], soap and wetting agents [322], coals [204,323], formaldehyde polymers with low molecular weight [324], seeds [325], treacle [326,327], honey [328], cocoa [329], chocolate [330], flour and flour products [331,332], hydrocarbons [303], glycol and glycerol frost-resistant solvents [118], vinyl esters [322], ketones [234-336], tributyl phosphate and kerosene [337], ion exchange resins [338], laminated polyamides [339], aerosol coatings [340], malt [55], serum [59], gelatin [341], and alginates [342].

The determination of water by the Karl Fischer method in aldehydes and ketones requires appropriate modifications [1,334-336,343]. Ascorbic acid is oxidised by the reagent to dehydroascorbic acid, and quinone is reduced to hydroquinone. Thiols are oxidised slowly, but their influence can be eliminated by adding alkenes before the titration.

Various silanols react quantitatively with the Karl Fischer reagent [344,345]. The determination of H_2O in silicones in the presence of silanols has been examined [346].

In the determination of water in gases, for example hydrocarbons [347-350], hydrogen chloride [351], the atmosphere of furnaces used for the annealing of porcelain and enamel [352], oxygen, nitrogen, and other gases [350,353], the gases are bubbled through anhydrous methanol and the absorbed water is determined by titration.

In evaluating the Karl Fischer titration, it should be noted that the method is applicable to the direct determination of water in quantities varying from one part per million to 100% in all types of compound which do not react with the components of the reagent. In order to achieve the highest sensitivity in the determination, it is recommended that the solvent (preferably a pyridine + methanol mixture) be titrated first, followed by analysis of the specimen in the same medium. Direct titration gives the total concentration of water (free and combined). The Karl Fischer titration is readily automated. The coulometric method for the generation of iodine for the Karl Fischer reagent has made possible the continuous automatic regulation and control of moisture content in industry. In view of the universal and highly sensitive nature of the method, it is often used as a standard in the development of new methods for the determination of moisture.

Among other titrimetric methods, mention must be made of those based on the reaction of water with various inorganic chlorides and organic acid chlorides. The hydrogen chloride liberated is distilled off and titrated. Of the readily hydrolysed chlorides, aluminium chloride has proved the most suitable.

The acetyl chloride method [354] is convenient for the determination of water in substances which present difficulties in the Karl Fischer method. The method is based on the difference in the behaviour towards water and alcohol shown by acetyl chloride, prepared in dioxan, toluene, or CCl_4. In the first instance, 1 mole of water liberates 2 moles of titratable acids (CH_3COOH + HCl) whereas in the second instance 1 mole of CH_3OH liberates 1 mole of acid (HCl). When the reaction of the reagent with water-containing inert solvents is complete, the excess of CH_3COCl is treated with alcohol and titrated with alkali solution. A blank titration is carried out for the calculations.

The method is used to determine water in liquid hydrocarbons, esters [354], gaseous hydrocarbons [355], acetone [354,356], edible oils, margarine, and fats [357], alcohols [358], and coals [359].

CH_3OH cannot be used as extracting agent in the acetyl chloride method, because it reacts with CH_3COCl. Formic acid, aldehydes, and high concentrations of lower alcohols and glycols interfere in the determination. Strong amines and esters which are readily hydrolysed in the acidimetric titration may distort the results of the analyses considerably.

The use of *p*-nitrobenzoyl chloride [360], lauryl chloride, stearyl chloride, or benzoyl chloride in place of acetyl chloride has been proposed, but these are not all successful. Studies have shown [361] that the addition of organic bases facilitates the rapid and quantitative hydrolysis of acid chlorides by water.

Succinoyl dichloride has been used as hydrolytic reagent for the determination of the water content of gases and crystal hydrates [362,363].

The hydrolysis of acid anhydrides and chlorides can be used for the determination of water. The use of acetic [364] and benzoic anhydrides for this purpose has been described. The water to be determined is collected in a 1:3 anhydride + pyridine mixture by azeotropic distillation, for example with dioxan or toluene, after which the hydrolysis is carried out and the excess of the anhydride is eliminated using aniline. A blank titration is carried out for the calculation. The time required for the hydrolysis is reduced considerably if catalysts ($HClO_4$ or 2,4-dinitrobenzenesulphonic acid [365]) are added to the reaction mixture.

The reaction of sodium alkoxide with water has been used to determine small quantities of water in alcohol, dioxan, crotonylidene-acetone, and anthraquinone [366]. The sodium hydroxide liberated reacts further with ethyl acetate to form CH_3COONa, and the excess of sodium alkoxide is determined by titration.

Lead tetra-acetate in benzene solution reacts with water to form PbO_2, which is determined iodometrically [367].

Organic compounds of the alkali metals (triphenylmethylsodium) react vigorously with water. Since organic compounds of the alkali metals are coloured, and the products of their reaction with water colourless, water can be titrated without using indicators [368].

By making use of the limited mutual solubility of the liquids in the presence of water, it is possible to determine water in furfural by titration with a mixture of hexanol and cotton-seed oil [369], in blood and biological materials with xylene [370], and in crystal hydrates with a mixture of C_2H_5OH and 2-methylpropanol [371]. Extensive material on the determination of the moisture content of substances by titration of the water has been published [372].

Papers have been published on the determination of water in organic compounds by a new chemical method based on the hydrolysis of t-butyl vanadate in the presence of NH_3 or acridine [373,374]. The precipitate formed in the reaction—a salt of vanadic acid—is determined by titration with a solution of Mohr's salt. The method can be used to determine water in hydrocarbons, alkyl halides, esters, ketones, benzaldehyde, and pyridine. A semi-automated version of the method has been proposed.

A method for the determination of water in alcohols has been developed, based on the hydrolysis of dimethyl oxalate in alkaline solution [375].

Water can be determined by acid-base titration in non-aqueous media. Thus water has been determined by titration in anhydrous sulphuric acid [376,377]. $HClO_4$ was used as titrant.

Other titrimetric methods have found less extensive practical application than the Karl Fischer method, due to the characteristic features of the reagents. The most widespread is the acetyl chloride method, use of which is recommended when the Karl Fischer method is inapplicable. The most promising method is that based on the hydrolysis of t-butyl vanadate.

3. Gravimetric Methods. Methods for the quantitative determination of water have been based on the water-removing properties of anhydrous copper sulphate (in alcohols, aldehydes, and acids). Aluminium and magnesium ethoxides react with water to form equivalent quantities of the hydroxides, which are determined by weighing. Large quantities of water in alcohols and in mixtures of alcohol with benzene, petrol, and trichloroethylene are determined by making use of the hydrolysis of

ethyl formate. The product is weighed as sodium formate.

The determination of water in bromine is based on the oxidation of sulphur dioxide by bromine in the presence of water. The sulphate formed is determined gravimetrically [378].

Water at concentrations of 10–100 mg per 100 ml specimen can be determined in the organic solvents ether, $CHCl_3$, CCl_4, and hydrocarbons using an ethereal solution of LiBr, which reacts with water to precipitate $LiBr.H_2O$, determined by weighing [379].

An automatic gravimetric hygrometer for the determination of moisture in gases has been described [380].

Gravimetric methods find only limited application, because of the tedious nature of the operations, the time required, and the specific character of the method.

IV. PHYSICAL AND PHYSICOCHEMICAL METHODS FOR THE DETERMINATION OF WATER

1. Methods Based on Measurement of the Specific Gravity, Viscosity, Angle of Rotation of Polarised Light, Refractive Index, Mutual Solubility, Etc. Methods recommended for the determination of water have been based on measurement of the specific gravity of the substance being studied (determination of water in alcohols [381]), measurement of the viscosity (in acetone, alcohol [382], concrete, cement, and other building materials [383]), and the ability of an optically active water-containing substance to rotate the plane of polarisation of plane-polarised light to an extent proportional to the water concentration (determination of water in sugar refinery pulp [384] and in sugar [385]). A refractometric method can be used to determine water in two- and three-component systems (analysis of furfural [117], sugar products [54,386], mixtures of formaldehyde and HNO_3 [387], and C_2H_5OH and ethyl cellosolve [388]). Methods of analysis making use of the difference in the temperatures of boiling sugar sap and the vapour [389], the thermal conductivity of gases [390], the critical temperature of mixing of liquids (determination of water in aniline [391]), the change in pressure accompanying the freezing of water (in air [392] or gases [393]) and the change in the specific enthalpy of the moist material during the desorption of water [394] have been described. Surface moisture can be determined by weighing the specimen in air and in two liquids which have different densities and which are miscible with water [395,396].

In the determination of the moisture content of gases, extensive use is made of the "dew point" method [397,398], for which a large number of instruments, constructed on different principles, have been described: with thermoelectric cooling [399,400], with cooling in a Dewar vessel [401], pneumatic [402], with electrical contact [403], and with photoelectric recording [404]. A method [405] and apparatus [406] for controlling the moisture content of organic solvents, based on measurement of the concentration of water in the vapour above the solvent, have been patented. The moisture content of board and other porous materials is determined by measuring the equilibrium vapour pressure [407].

In the utilisation of the psychrometric method for the determination of the moisture content of gases, particular attention is being paid to the theoretical principles of the method [398,408], particularly at high temperatures [409]. Various psychrometers have been described [404,410-412].

2. Methods Based on Measurement of the Dielectric Constant. The determination of H_2O in various materials is based on measurement of the dielectric constant (DC) of the system. The DC of water (80.57) differs significantly from that of other solvents. The theoretical principles of the method based on DC measurements have been described [413,414]; the empirical relationship $DC = f(H_2O)$ is used for each specific water-containing system. The sensitivity of the determination when the DC of the solvent is sufficiently constant may reach several parts per million. Measurements of the DC losses are more sensitive.

For the determination of water in hydrocarbons, dioxan, which is a common cosolvent for H_2O and hydrocarbons, is recommended, since the DC of dissolved and emulsified water are quite different [415]. Measurements of the DC of an emulsion of NaOH solution in transformer oil have been given [416]. The method is widely used to control the concentration of water in petroleum and petroleum products [417-426]. Continuous measurement and recording are possible even at water concentrations reaching 60% [427]. The measurements are often carried out by comparing the DC of water-containing petroleum and anhydrous petroleum [428-430]. The determination of water in hydrazine and phenylhydrazine [431], monohydric and polyhydric alcohols [432], pyridine bases [433], ethyl acetate [434,435], dioxan [433], the diethyl ether of diethyleneglycol [436], the three-component methanol–propan-2-ol–water system [437], and mineral oils [438] has been described.

For multi-component systems, determination of water by loss measurements is in most instances impossible, since the dielectric loss factor may be altered for reasons other than a change in the water concentration [413].

To determine water in solids, use is made of preliminary extraction by a solvent [414], for example in the determination of water in soil [439], spinach [440], quartz sand, manganese ores, coal, clay [441], wheat, ammonium sulphate, etc. [442]. The limits of applicability of the method involving preliminary extraction are made narrower when the extracting solvent does not extract water completely, or when complete extraction takes a long time. This has led to the development of the immersion method [443]. The substance being analysed is immersed in a liquid with known DC value, and the final DC of the system is measured. The H_2O concentration is found from a calibration curve. This method has been proposed for the analysis of inorganic fertilisers [443,444].

Water can be determined in many materials by immersing electrodes directly in the substance being studied: molecular sieves [445], grain [445-448], hops [446], peat [449], soil [450], packing materials [451], tobacco [452-454], [iron ore] charges [455], textile fibres [456], loose materials [457,458], moulding mixtures [459,460], paper and cardboard [461], granulated materials, Nitrophos [462], and trinitrotoluene [463]. In some instances it is necessary to keep the pressure of the electrodes on the material being studied strictly constant [452].

The dielectric loss method is particularly promising for the analysis of loose materials. Thus it is possible to measure the moisture content of pigments without weighing a specimen [413].

Special cell designs have been developed, making it possible to determine the concentration of water in films [413,464]. A portable hygrometer for the determination of the moisture content of air from DC measurements has been described [465,466]. An analyser for the continuous determination of moisture in gases containing HF has been described [467].

Various types of apparatus for carrying out the determination have been described [17,421,468-475].

3. Methods Based on Measurement of the Electrical Conductivity. The moisture content of

gases absorbed by a solvent is determined by measuring the electrical conductivity of the water-containing extracting agent [476]. Sulphuric acid is used as absorbent for the moisture in natural gas [477]. The electrical resistance of LiCl is a function of the moisture content of the gas in contact with the salt [478].

The moisture content of soil [479] is determined by measuring the electrical resistance of a mixed solvent saturated with NaCl after the extraction of water from the soil. The measurement of the moisture content of transformer oil from the change in the electrical resistance of a fabric placed between perforated metal plates has been described [480]. Specific resistance measurements have been used for the continuous control of the moisture content of the rocket fuel dinitrogen tetroxide [481]. The method involving electrical conductivity measurements has been used to determine water in liquids—hydrogen fluoride [482,483], propane [484], petroleum residue [485], and pyridine [486].

The continuous determination of the electrical conductivity of solids can be carried out usually at high water concentrations. The electrical conductivity depends on the source voltage, the shape and arrangement of the electrodes, the chemical composition of the material, temperature, the degree of uniformity, the state and the distribution of the water, the degree of polarisation, the state of the surface of the individual granules and pieces and the degree of compactness and contact in the material [17]. Methods and apparatus have been described for the rapid determination of moisture from electrical conductivity measurements in sawn timber and wood [487-489], salt [490], leather [491], chromium oxide [492], paper, textiles [493], peat [494], copra [495], and chromatograms [496].

In radiosondes, moisture is determined using a hygrometer element of oxidised aluminium, whose resistance is a function of the moisture content of the atmosphere [497].

Various forms of apparatus have been described [10,17,21,469-471,488-501].

4. Electrometric Methods. The coulometric method is based on the determination of the quantity of electricity required for the electrolysis of water absorbed by a thin film of absorbent (H_3PO_4, H_2SO_4, or their mixtures, P_2O_5, KOH, K_2CO_3, etc.) [502-511] from a measured quantity of gas. In the analysis of liquids [503,512-515] and solids [17,503], the water is first transferred to the gaseous phase by evaporation or by using a current of heated dry gas [512]. The quantity of current used in the electrolysis is recorded graphically from a curve giving the change in current, by means of integrators [17,514], or from the magnitude of the current [515]. The rate of carrier gas [flow] depends on the design of the recorder, the nature and moisture content of the specimen, and the weight taken. For solids, a method involving the extraction of moisture by a gas, combined with heating by high-frequency currents, has been described [17,512,513].

Procedures [516,517] and apparatus have been described for determination of moisture by comparing the pressures of the gas being analysed and a reference gas for the same resistance of the hygroscopic film.

The efficiency of analysers for the determination of water in gas streams and liquid streams has been studied [518].

The coulometric method can be used to determine water in cracking gases, petrol vapour, natural gas [504,519], air [520], aromatic hydrocarbons [521], organic liquids [512,514,516], the technological product streams in petroleum refineries [522], circulating freon refrigerant [516,517], and solids [523,524].

Water in ϵ-caprolactam can be determined polarographically [525,526]. It is suggested that water in various organic compounds can be determined by the reaction of the substance with phenylchloro-oxophosphorus, which leads to an increase in the polarographic current of the solution at a given potential [527]. An improvement of the method has also been determined [528].

5. Optical Methods. Water in liquid products can be detected qualitatively using indicator paper [529-531] impregnated with salts $CoCl_2$, $CuBr_2$, BiI_3, SbI_3 or mixtures $K_3Fe(CN)_6 + CoCl_2$, $K_2CrO_4 + MnCl_2$ + resorcinol, activated silica gel treated with $CoBr_2$ solution [532], or molecular sieve A [533].

The change in the colour of solutions of a number of compounds as a result of hydration of the reagent can be used for colorimetric analysis. Thus cobalt compounds can be used to determine water with satisfactory accuracy in $CHCl_3$, salicylaldehyde, crotonaldehyde, and benzaldehyde [534], acetone [534-536], Cl_2CF_2, Cl_3CF, $ClCF_3$, petrol, methyl chloride [537], refined sugars [538], alcohols, acetone, ethyl acetate [539], maize, and Indian corn [540]. Water in solid specimens is extracted beforehand using a solvent.

With increase in the concentration of water in alcohol, there is an increase in solubility and a development of the colour of $K_2Cr_2O_7$ [541], and in reactive fuels, hexachlorane, and turbine oils a similar effect is shown by the dye Methylene Blue [542,543]. The concentration of H_2O is determined from the decrease in the colour of the Karl Fischer reagent after passage of the moist gas through the reagent [544].

The oxidising properties of $K_2Cr_2O_7$ are used to determine water in various biological materials [545]. The intensity of the colour of the reduced form of chromium depends on the water concentration. Using a scale of standards, it is possible to determine moisture using anhydrous copper sulphate [546,547].

Ether and ketones saturated with anhydrous LiCl acquire the orange-red colour characteristic of $LiCuCl_3$ in the presence of H_2O and copper perchlorate [548]. Moisture can alter the colour of solutions of chloranilic acid [549], hexanitrobenzene [550], complexes of diethylaluminium hydride with isoquinoline [551], and an acetone solution of anhydrous copper chloride [536].

Water in gaseous nitrogen can be determined by vacuum spectrophotometry in the ultraviolet range [552].

Various reagents ($SiCl_4$ [553] and $TiCl_4$ [554]) in contact with water-containing solvents form stable suspensions of hydrolysis products, whose light absorption depends on the moisture content.

The moisture content of monomers is determined by measuring the optical density of specimens cooled to −50°. The turbidity is proportional to the water content [555]. The turbidity at a CH_3COOH–toluene interface can be used to determine the concentration of moisture in the acid [556].

The turbidimetric method is used to determine water in methyl and ethyl thiols [557] and in fuels for aviation turbines [558]. The moisture content of gas is measured from the light extinction of the aerosol formed by passing the moist gas through oleum [559]. Water in liquid hydrocarbons [554] and motor fuel [560] can be determined nephelometrically.

Infrared spectroscopy can be used to determine water in gases, liquids, and solids over a wide range of water concentrations. The choice of analytical absorption band is determined by the chemical composition of the substance being analysed and the concentration of water being determined. At high concentrations of water (fractions of one percent and above) the bands in the range 5100–5300 cm^{-1} and 7100–6200 cm^{-1} due to the overtones and combination

frequencies of the stretching and bending vibrations of the HO groups of the water molecules are used[20,561-574]. The weak absorption bands at 1550–1650 cm^{-1} and 3590–3710 cm^{-1} due to the symmetric bending and asymmetric stretching vibrations of the HOH and HO groups are used to determine traces of water[575-582].

Infrared spectroscopy is widely used to determine water in various organic liquids: alcohols[561,575,577,582-585], glycols[561,582], dioxan[561,582,586,587], ketones[573,575,577,582,583,586,588], 1,1-dimethylhydrazine, diethylenetriamine, monomethylhydrazine[562,563,589], glycerol[565,583], esters[573], aldehydes[580], benzene, toluene, xylene[590], CCl_4[586,587,590,591], chloroform[582,586,587], ethyl bromide[589], homologues of pyridine[592], aniline[582,586,587], tetrabutyl phthalate[578], tetrahydrofuran[587], tributyl phosphate[593], dimethyldioxan[581], freon-22 refrigerant[594], organic solvents[585-599], and lubricating oils[600]. The limits of sensitivity of the determination of water in non-associated solvents and the relationship between the limits of sensitivity and the transmission coefficient of the background have been examined[590].

The methods of molecular spectroscopy are extremely effective and make it possible not only to determine the concentration of water in organic solvents but also to obtain considerable information on its state in solution, the bonds formed with the solvent molecules, and processes of hydration and extraction[20,601].

Special procedures are required for the determination of water in strongly corrosive inorganic liquids. Thus in the determination of water in liquid sulphur dioxide the NaCl or KCl cells are fitted with polyethylene and lead linings[576]. The conditions for the determination of water in liquid bromine[579,602] and fuming nitric acid[571] have been examined in detail.

Alkali metal halide discs, suspensions in Nujol, or solutions in D_2O have been proposed for the analysis of salts[568]. Methods have been developed for the determination of water of crystallisation[564,566,570,595,603], and water in carbohydrates[604] and milk fat[605].

In the analysis of vegetable materials by infrared spectroscopy the water is extracted beforehand with methanol[606], and in the analysis of coffee the water is separated by azeotropic distillation with dioxan[113]. The determination of water in complex minerals[607], silicates[568], silica gel[574], polymers[608], elastomers[609], films[569,596], and aluminium acetylsalicylate[610] has been described.

Infrared spectroscopy is sometimes used to analyse the products of the reaction of water with various reagents—2,2-dimethoxypropane[595] (acetone and CH_3OH are formed) and CaC_2, which liberates acetylene[609,611]. Various forms of apparatus have been described[12,83,571,583,584,595,608,609].

Infrared hygrometers for measuring the moisture content of air have been described[612,613]. The conditions for the analysis of gases at elevated temperatures and pressures have been examined[614].

6. NMR Spectroscopy. Nuclear magnetic resonance (NMR) can be used to measure the moisture content of liquids and solids. The determination of the moisture content of solid, loose, and fibrous materials is based on the fact that the water molecules are relatively mobile compared with the molecules of the main hydrogen-containing substance, so that the proton absorption curve obtained on a low-resolution instrument has the form of a very broad signal, on which the narrow line from the protons of water is superimposed[615,616]. At a concentration of water greater than 10%, the amplitude of the signal is linearly dependent on the moisture content[617-619]. At lower water concentrations, the bonding between its molecules and the adsorbent changes, and the dependence of the amplitude of the signal on the water concentration becomes more complex. In such instances, a calibration curve is used. Various instruments have been described[12,620-624].

The determination of water by the EPR method in wood, cellulose, fruit, starch[618,619,625-627], pectin[618], nylon[628], various granulated materials[619], peat[629], corn syrup and chewing gum[630], and a moving stream of coal[631] has been described. Small concentrations of water can be measured by determining the width of the absorption line[618]. The relaxation times have been used to determine the concentration of water in hardened epoxide resins and polyamides[632].

High-resolution NMR spectroscopy can be used to determine H_2O in acetone[633] and other liquids[634]. The dependence of the magnitude of the chemical shift of the protons of the water on its concentration can be used to determine water in, for example, CH_3CN, piperidine[635], and tributyl phosphate[636].

The NMR method is effective in the study of the sorption of water on various materials. It makes it possible to measure moisture contents over a wide range, rapidly, accurately, and without decomposition of the specimens. The control of technological processes from moisture content measurements is possible[621,622,637].

7. The Chromatographic Method. The chromatographic determination of water can be carried out either by direct separation of a mixture or by chromatographic study of the products of the previous reaction of appropriate reagents with water. The first version is carried out by the gas-liquid method, which is used to analyse mixtures with high water content. The liquid phase may consist of polyethylene glycol on refractory brick[638], Teflon[639,643], or porous glass[644], stearic or 12-hydroxystearic acids[645], and diiso-octyl phthalate on teflon[646], and tetrahydroxyethylenediamine on chromosorb[562]. The following reagents have been recommended for the determination of water by the second method: CaC_2[151,639,647-651], $LiAlH_4$[652], $NaAlH_4$[653,654], CaH_2[639,647,655], organic isocyanates[647], 2,2-dimethoxypropane[656,659], and lead tetra-acetate[660]. The gases formed and the organic liquids are analysed by absorption or gas-liquid chromatography.

The determination of water in the following materials has been described: butane[638], alcohols[661], mixtures of NH_3 and amines and mixtures of ethanol and butanol and ammonium carbonate[640], methanol, ethanol, CH_3COOH[641], pyridine[641,662], aliphatic acids[645], hydrocarbons[151,652,646], gases[654,663], hydrazine, monomethylhydrazine, 1,1-dimethylhydrazine, diethylenetriamine, and their mixtures[562,664], mixtures of the gases H_2, O_2, N_2, CH_4, and CO[651], pharmaceutical products[665], liquid alkenes, diene monomers, and various oxygen-containing compounds[653,666], sodium acetate and copper sulphate (with preliminary extraction of the water by methanol)[624], CH_3OH–aldehyde mixtures[644,650], the products of the manufacture of C_6H_5OH from isopropylbenzene[667], fruit[668], and water in the moon's crust[669].

Water in gases and hygroscopic liquids can be determined by reverse chromatography: a moist carrier gas with a water concentration greater than that of the substance being analysed is used, so that negative peaks appear on the gas chromatogram[670].

8. Other Methods. When a beam of β- or γ-radiation is passed through a material of uniform density,

a decrease in the intensity of the radiation beam is observed, depending on the moisture content. This phenomenon is used for the quantitative determination of the moisture content of soils, building materials and other loose materials, asphalt, wood[671,672], textiles[673], and petroleum[674]. A portable instrument for this purpose has been described[675].

A new method has been proposed for the determination of water in methanol[676] using kryptonates. In the presence of water, ^{85}Kr is liberated, and this is removed by a stream of nitrogen into a counting chamber and determined quantitatively.

Methods have been described for the determination of water by the third-component method using a radioactive substance in crystal hydrates[677,678], pharmaceutical products[679], sesame oil[680], silica gel, and iron ores[678]. The concentration of water in synthetic pigments and biopolymers can be determined by mass-spectrometric measurements after deuterium exchange[681].

A method for the determination of moisture has been based on the ability of hydrogen atoms to weaken a beam of fast neutrons[10,671]. The results of the measurements are little influenced by the salt content and density of the material and are not influenced by temperature and the moisture distribution. The use of the neutron method to measure the moisture content of lime raw materials[682], concrete[683,684], soil[684], wood, sand, moist salts[685,686], and lamp black[687] has been described. The development of a neutron moisture meter whose operation does not depend on the density of the material has been described[688-690].

The use of an ultrasonic method for the determination of small quantities of water in CH_3OH has been proposed[691].

It has been suggested that very small quantities of water can be determined by hygrophotography. An illuminated light-sensitive plate (a double complex of mercury and silver iodide) can undergo a restoration of colour with time. Moisture increases the rate of this process, and this makes possible the quantitative and qualitative determination of water in alcohols, medical products, soil, etc.[692-697].

A number of papers[698-700] and a draft standard[701] have been published on the determination of the moisture content of petroleum products and reactive fuel by centrifuging. Glass-fibre filters have been recommended for the determination of H_2O in sludges[702].

The absorption of radiowaves in the centimetre range by water has been made the basis of a method for the determination of moisture in polymers[703], foodstuffs[704,705], clay, sand, coal, tobacco, fertilisers, and oil[705]. Various moisture meters have been described[704-706].

The determination of water from the extinction of the luminescence of 4-chloro-2-sulphobenzalacetophenone in hydrocarbons has been described[707,708].

The thermal characteristics of the medium can be used as criteria for the determination of moisture in capillary-porous[709,710], dispersed, and fibrous[711] materials, magnesium perchlorate[712], sulphuric acid[713], fluorocarbons[714], and unsaturated hydrocarbons[715].

A review of methods for the determination of water by physical and physicochemical methods shows that these methods extend considerably the possibilities for the control and automation of production, are extremely rapid, and also extremely effective in the study of the state of water in substances in different states of aggregation.

Organic Compounds in the Solar System

B.Yu.Levin

Information about the presence of organic and carbon-containing compounds in planets and their atmospheres, in comets, and in meteorites is reviewed. Data on organic compounds present in meteorites are the most important. Numerous studies on such compounds in recent years have led to a significant advance in our knowledge about their nature. In particular, "primary" organic compounds preserved within mineral grains have been detected. These proved to be the compounds which should have been formed in maximum amounts under quasi-equilibrium conditions in the system carbon-hydrogen-oxygen. This finding is based on both theoretical and experimental data. The data concerning the presence of organic compounds in the protoplanetary cloud are used to assess the possible history of these compounds on earth. The bibliography incorporates 108 references.

1. INTRODUCTION

The existence of organic compounds in the solar system is one of the most important problems of cosmochemistry, since it is most closely related to the problem of the origin of life on earth and the formation of petroleum deposits on the latter. Modern data indicate not only a wide distribution of organic compounds in most of the bodies of the solar system but also the fact that these compounds may have entered into the composition of our earth in great abundance during its formation.

For a long time panplanetary cosmogony was ruled by hypotheses according to which the earth and other planets were formed from incandescent gaseous nuclei. At a temperature of several thousands of degrees organic compounds cannot exist and therefore these hypotheses led to postulates that organic compounds were produced on the previously formed earth after it had cooled sufficiently. Following Mendeleev, the formation of methane as a result of the action of hot steam on metal carbides was regarded as the beginning of this process.

During the last twenty years a radical change in the hypotheses concerning the "initial" state of planetary matter took place in planetary cosmogony: all modern cosmogonic hypotheses postulate the aggregation of planets from a cold gas-dust cloud surrounding the sun at one time. Organic compounds must also have been present in this cloud. Furthermore, in most recent investigations it was shown that various organic compounds, including some which were extremely complex, were present in the protoplanetary cloud at concentrations virtually corresponding to thermodynamic equilibrium.

Since carbon-containing compounds are an essential component of the "raw material" from which organic compounds are formed, the problem of the presence of these in various bodies of the solar system will also be touched upon.

2. ORGANIC COMPOUNDS IN PLANETS

The simplest carbon compounds enter into the composition of all planetary atmospheres when these exist at all. Such compounds are detected spectroscopically. The amount of a particular gas in the atmosphere can be estimated, if only approximately, from the intensities of the absorption bands. Usually the amount is expressed in terms of the thickness of a homogeneous layer of gas at standard temperature and pressure (s.t.p.). For gases with absorption bands in parts of the spectrum accessible to measurement and which are possible components of the planetary atmosphere, the absence of appreciable bands in the spectrograms of the planet permits the determination of the upper limit to the content of the gas in the atmosphere. Frequently this upper limit has been significantly reduced as apparatus was improved.

Spectroscopic data on the composition of planetary atmospheres serve as the initial basis for theoretical calculations of thermodynamic equilibrium in a mixture of gases of this kind and for the determination of the possible concentrations of other more complex molecules.

The hypotheses concerning the presence of carbon compounds, including organic compounds, within the planets themselves are based on indirect considerations. For the giant planets and their satellites, calculations involving models of their internal structure are based on data concerning their average density and on the equations of state for various substances, indicating an appreciable content of light compounds, among which the most important are organic and related compounds. The hypotheses concerning the presence of organic compounds within the planets of the earth group are based on considerations associated with the history of their development.

Spectroscopic observations show that the atmospheres of the giant planets Jupiter, Saturn, Uranus, and Neptune contain much methane and the atmospheres of the first two also contain ammonia. The amounts of these gases above the cloud level forming the visible surface of these planets are listed in Table 1. The increase of the amount of methane on going from Jupiter to Neptune is due to a change in the structure of the atmosphere associated with the reduction of temperature. The absence of ammonia from the atmospheres of Uranus and Neptune is accounted for by its freezing at the lower temperature of the cloud layer in these planets.

Hydrogen, which constitutes the main or at any rate an important component of these atmospheres, has scarcely any spectroscopic effect. Therefore our knowledge about its content above the cloud layer is poor even for Jupiter. Errors in the determination of the equivalent width of the quadrupole band lines of molecular hydrogen in the Jupiter spectrum are such that, even after new laboratory studies of these lines, the amounts of hydrogen found above the cloud layer of Jupiter vary from 30 to 200 km† [3,4]. The models of the part of the Jupiter atmosphere above the cloud level differ correspondingly [4,5]. In their spectroscopic observations of Jupiter, Spinrad and Trafton [4] did not observe absorption bands due to CH_2, NH_2, O_2, HNO, HDO, HCN, C_2H_2, HCO, and H_2O, but they do not quote data concerning the upper limits to their contents. Owen [6] compared the Jupiter spectrum in the near infrared with the laboratory spectra of a number of molecules and obtained the upper limits to their contents, which are listed in Table 2.

Table 1. Composition (cm at s.t.p.) of the atmospheres of the giant planets above the cloud level from spectroscopic data [1,2].

Gas	Jupiter	Saturn	Uranus	Neptune
CH_4	15 000	35 000	~350 000	~600 000
NH_3	700	<250		
O_2		<0.1	<0.1	
SO_2		<0.01	<0.01	

The occasional appearance of a red-brown colour of certain features of Jupiter (in particular the so called red spot) has been attributed from the beginning of the 1950's to the formation in the atmosphere of various organic molecules [7-11]. Urey [7] quotes as an example the following possible compounds: yellow diazomethane (CH_2N_2), red tetrazine ($C_2H_2N_2$), yellow azomethane [$(CH_3)_2N_2$], and yellow cuprene [$(C_2H_2)_x$]. However, it did not prove possible to obtain direct spectroscopic evidence for the presence of particular organic molecules on Jupiter.

In laboratory experiments, where a corona discharge was created in a simulated Jupiter atmosphere [12], the formation of the following molecules was observed: HCN, CH_3CH, C_2H_2, C_2H_4, and C_2H_6. In other experiments [13], where the simulated Jupiter atmosphere was subjected to hard ultraviolet irradiation (λ = 584 Å), the formation of methane, ethylene, and propane was observed. Saslaw and Wildey [13] also discussed theoretical chemical models of the upper Jupiter atmosphere postulating various chains of reactions between hydrocarbon molecules and ions. The equilibrium concentrations of a number of molecules in the upper layers of the Jupiter atmosphere, calculated on various assumptions concerning their temperature, are listed by Lippincott et al. [11]

Despite the enormous pressure, amounting to millions and tens of millions of atmospheres, in their interior, the giant planets have a low average density (0.7–2.2 g cm^{-3}). Calculations of the internal structure of these planets show that Jupiter contains about 80% of hydrogen and Saturn about 60%, the remainder of the mass of these planets being made up of helium, rocky materials, and also various light compounds such as methane, ammonia, carbon dioxide, water, and others. The average densities of Uranus and Neptune show that these planets contain little hydrogen and consist almost entirely of light compounds such as methane, ammonia, carbon dioxide, and others (with an admixture of rocky materials). When account is taken of the enormous mass of the giant planets, it is found that the overall mass of the light compounds which they contain, including organic compounds, is dozens of times greater than the mass of the earth. There is no doubt that these organic compounds are of a abiogenic origin.

† According to Owen's new determination [18], the amount of hydrogen is 85 ± 15 km.

Table 2. Upper limits to the contents of certain gases in Jupiter's atmosphere above the cloud level from spectroscopic data [6].

Gas	Upper limit to content, cm at s.t.p.
CH_3NH_2	800
C_2H_4	200
C_2H_6	250
SiH_4	2000
CH_3D	3000
HD	50000

The abundance of light compounds in the giant planets is associated with the abundance in the universe of the chemical elements which enter into the composition of these light substances. The most abundant element in the universe is hydrogen (60 wt.%, i.e. about 86% in terms of the number of atoms); the second place is occupied by the chemically inert helium (38 wt.% or about 14% in terms of the number of atoms). Next we have carbon, nitrogen, and oxygen, constituting altogether about 1.2 wt.% or 0.1% in terms of the number of atoms. The total number of atoms of all the remaining chemical elements taken together is only 0.8%. When gas with the cosmic composition (or a composition close to the latter) comes under the influence of fairly low temperatures permitting the formation of molecules, hydrogen molecules (H_2) are formed in the greatest amount, in the second place are compounds of hydrogen with C, N, and O atoms, such as methane, ammonia, and water, and finally in the third place there are compounds of carbon, nitrogen, and oxygen with one another, such as carbon monoxide, carbon dioxide, and CN. Thus the total cosmic abundance of chemical elements predetermines the abundance of carbon-containing and in particular organic compounds in cold cosmic bodies, whose matter has not been subjected to pronounced fractionation.

Organic compounds probably enter into the composition not only of the giant planets but also of their satellites. Unfortunately the average densities are known, if only approximately, for only five of the largest satellites of the giant planets (the four Galilean satellites of Jupiter and Titan—the largest satellite of Saturn), from which an indirect assessment of their composition may be made. The two satellites closest to Jupiter have a rocky composition and the two more distant ones (among the Galilean satellites) and Titan consist of 50% of rocky material and of 50% of light substances. These light substances probably include various organic compounds. An indirect indication

of this may be the presence on Titan of a methane atmosphere (possibly containing also ammonia) discovered by Kuiper in 1944.

We shall now consider the planets of the earth group. As early as the 1930's, the infrared spectrum of Venus revealed absorption bands which proved to belong to the carbon dioxide molecule. The amount of carbon dioxide present above the cloud layer forming the visible surface of Venus corresponds to a layer about 2 km thick (at s.t.p.). Kuiper, using spectroscopic data, found the upper limits to the possible contents of a number of other gases (Table 3).

Table 3. Composition of the atmosphere of Venus above the cloud level from spectroscopic data[1,14].

Gas	Amount, cm at s.t.p.
CO_2	200 000
CO	<3
N_2O	<100
CH_4	<20
C_2H_4	<3
C_2H_6	<1
NH_3	<4

Until recently the thickness and composition of the atmosphere under the cloud layer were unknown. In October 1967 the remarkable landing on Venus of the Soviet automatic station Venus-4 established that the carbon dioxide content is 90 ± 10%.[15]

Assuming a considerable concentration of water vapour in the atmosphere of Venus, Wildt put forward the hypothesis that the cloud layer of this planet consists of condensates of formaldehyde and its polymers. However, subsequently this hypothesis was abandoned. In the first place the attempts undertaken by Wildt himself to find the formaldehyde band in the ultraviolet part of the spectrum were unsuccessful. In the second place the water vapour content proved to be very small: in all several tens of grammes per cm^2. At present it is believed that the clouds most probably consist of crystals of ordinary ice.

At one time it was suggested that the entire surface of Venus is covered by a continuous ocean preventing the formation of carbonate rocks from the carbon dioxide atmosphere. Whipple and Menzell put forward the hypothesis of a soda water ocean, i.e. water saturated with carbon dioxide. Hoyle, believing that many organic compounds must have formed even in the protoplanetary gas–dust cloud under the action of various types of hard solar radiation, suggested the possibility of the existence of a petroleum ocean evolved from the inner parts of Venus. Both these hypotheses were rejected when several years ago radioastronomical measurements of the intrinsic thermal radio emission from Venus showed that its temperature is about 600°K. However certain investigators suggested that this temperature does not refer to the surface but the upper ionosphere of Venus. However, measurements by the automatic station Venus-4 showed that the temperature increases on going deeper into the atmosphere, reaching more than 500°K at the surface.

Since at the high temperature of the Venus atmosphere thermochemical equilibrium must be established rapidly, Mueller[16] estimated the possible content in this atmosphere of various hydrocarbons and found that it must be negligibly small. Recently this was confirmed by new more complete calculations‡ [11,17].

Studies of the spectrum of Mars for a long time failed to yield any information about the composition of its atmosphere. It was not until 1947 that weak carbon dioxide bands were observed in the infrared part of the spectrum. According to the latest data[18], the amount of carbon dioxide in the Mars atmosphere corresponds to a layer 75 ± 15 m thick (at s.t.p.). Spectroscopic estimates of the upper limits to the possible contents of other gases are listed in Table 4. Until recently it was believed that the atmosphere of Mars is thinner by a factor of 10 than the earth atmosphere and under such circumstances carbon dioxide would constitute less than 10 wt.%. The main component was believed to be molecular nitrogen, which is not revealed in the part of the spectrum accessible to observations. However, during recent years the application of new methods of observation resulted in a lower estimate of the density of the Martian atmosphere and a corresponding increase in the importance of carbon dioxide. Finally, in 1965 studies carried out with the aid of the American automatic station Mariner-4 showed that the Martian atmosphere is thinner than the earth atmosphere by a factor of 100 and therefore carbon dioxide constitutes not less than 50% and possibly the entire 100% of the atmosphere.

Table 4. Composition of the Martian atmosphere from spectroscopic data[19].

Gas	Amount, cm at s.t.p.	Gas	Amount, cm at s.t.p.
CO_2*	4500±2500	NH_3	<0,1
H_2O**	$(14\pm7)\cdot10^{-4}$	NO_2	$<1\cdot10^{-3}$
O_2	<2	N_2O	<0.08
O_3	$<4\cdot10^{-4}$	NO	<20
CH_3CHO	$<6\cdot10^{-3}$	H_2S	<7.5
CO	<1	H_2CO	<0.3
CH_4	<0.1	COS	<0.2

*According to Owen's new data[18], the amount of carbon dioxide is 7500 ± 1500 cm.
**Precipitated water. The amount varies both in space and in time.

The problem of the presence of an atmosphere on the planet Mercury, which is closest to the sun, remains to a large extent obscure. Polarimetric observations indicated the existence of an atmosphere with a mass of 3 g cm^{-2} (on earth about 1000 g cm^{-2}), but there was no spectroscopic confirmation of its existence. In 1963 V. I. Moroz observed a slight increase in the intensity of the carbon dioxide bands in the infrared spectrum of Mercury relative to that of the moon (in the latter case the carbon dioxide bands are due to the presence of carbon dioxide in the terrestrial atmosphere).

For a long time it was believed that one side of Mercury is always turned towards the sun and therefore it might have been supposed that in the night hemisphere of the

‡ In all these calculations models of the Venus atmosphere postulating an unduly high pressure at the surface and an unduly high nitrogen content were employed. However, the conclusion concerning the negligibly low concentration of hydrocarbons is almost independent of these initial data and remains valid also for the true atmosphere of this planet.

planet, under the conditions of a constant low temperature, there are frozen volatile substances. However, radar observations showed that Mercury rotates about its axis with a period amounting to two thirds of its period of rotation about the sun. In agreement with this finding, radio-astronomical observations, permitting an estimate of the surface temperature to a depth of several meters, do not reveal an appreciable difference between the day and night hemispheres. Thus the possibility of the existence of frozen volatile substances is completely excluded for the major part of the surface of Mercury, with the possible exception of the polar regions whose temperature remains unknown.

We have no information about the presence of organic compounds on the moon, which lacks an atmosphere. Only theoretical considerations concerning their possible presence have been put forward. Thus Sagan[20], believing that a reducing atmosphere consisting mainly of methane, ammonia, and water existed at one time on the moon, put forward the hypothesis that organic substances formed in this atmosphere under the action of solar ultraviolet radiation may have persisted in the upper layer of the moon. In an atmosphere with this composition fairly complex organic molecules with molecular weights up to 100 are formed under the action of ultraviolet radiation (and electric discharges): amino-acids and other organic acids, pyrroles, pyridines, and simple hydrocarbons and their polymers (see, for example, Miller[21] and Miller and Urey[22]). According to Sagan's estimate, the amount of amino-acids with a molecular weight of about 100 alone, formed during ten million years in an atmosphere opaque to ultraviolet rays, may be of the order of 5 g cm^{-2} (for a quantum yield of 10^{-6}). The heavy molecules produced must have sunk towards the surface and then on to the surface itself where they were protected by the atmosphere from the destructive short-wavelength radiation. As the atmosphere became dissipated, ultraviolet radiation must have partially decomposed the organic molecules, while some may have been converted into more complex compounds (for example, polypeptides may have been formed from the amino-acids). Sagan believes that organic compounds on the moon were protected from complete degradation under a layer of meteoritic material and have persisted up to the present time on the elevated "mainland" parts of the lunar surface, while in the sections corresponding to the "seas" they were destroyed by the lava flow.

However, the picture drawn by Sagan is probably incorrect for a number of reasons. Firstly, recently serious doubts have been expressed concerning the hypothesis that the primary atmospheres of earth type planets and the moon consisted mainly of methane, ammonia, and water. Data on the oxidation equilibrium between gases and silicate melts showed that, for the evolution of methane to occur, the melts must have contained metallic iron, which is in fact not the case. Gases of the same composition as those evolved from volcanos[23] must have been evolved from the basalt magmas. Consequently the lunar atmosphere must have consisted of water, carbon dioxide, sulphur dioxide, molecular hydrogen, and carbon monoxide. Secondly, the density of the atmosphere at the surface of the moon can have scarcely exceeded one millionth part of the density of the present day terrestrial atmosphere at the surface[24], i.e. was the same as the density of the terrestrial atmosphere at the height of about 150 km. This density is altogether too low both for the formation of a sufficient number of organic molecules and for their protection from solar ultraviolet radiation after they have sunk to the lunar surface. Thirdly, impacts of meteorites of various dimensions keep "ploughing up" the surface layer of the moon to a depth of several metres and therefore favourable conditions for the protection of organic matter do not exist there.

Gilvarry[25,26] goes much further than Sagan and suggests that biogenic organic substances may be present on the moon. He is the only astronomer who suggests that real seas, in which even life may have existed, were present at one time on the moon. Gilvarry starts from the unlikely hypothesis of extremely rapid evolution of water from the interior of the moon and greatly overestimates the possible duration of its persistence on the lunar surface. This hypothesis has not found any supporters.

There exists, however, another theoretical possibility of the presence on the moon of considerable amounts of organic compounds, including hydrocarbons. It is associated with the presence of these substances in meteorites (see section 4) and, judging from all available data, in the materials from which earth type planets and the moon aggregated. As noted by Wilson[27], if the average hydrocarbon content in meteorites (about 0.01%) is assumed for the primary material of the earth and the moon and account is taken of the fact that only part of these may have been converted into liquid hydrocarbons by cracking in the interior parts of these bodies, then the amount is still sufficient to account for the origin of all petroleum accumulations on earth. Wilson put forward the hypothesis that the lunar seas are covered by the asphalt remaining after the evaporation of lighter hydrocarbons which emerged in the form of petroleum from the interior of the moon. Wilson's hypothesis was objected to by Mueller, who is a supporter of the biogenic hypothesis of the origin of petroleum. However, Wilson's quantitative estimates are quite correct. Nevertheless there is a serious astronomical basis to doubts concerning the possibility of such large petroleum outflow on the surface of the moon.

As a result of the extremely low thermal conductivity of the surface layer of the moon, the daily temperature variation penetrates only to a depth of about 0.5 m; at greater depths the temperature remains always constant. In the equatorial zone this constant subsurface temperature is about −30°C and in the polar regions it is considerably lower. As a result of the constant increase of temperature with depth, a temperature of 0°C is attained at a depth of 2–4 km in the equatorial zone and at a depth of 15–20 km in the polar regions. The existence of a layer of subzero temperatures implies the great probability of the existence of a layer of permafrost. In the polar regions of the moon not only water vapour arising from the interior but also carbon dioxide can freeze in this layer. The permafrost layer must prevent the outflow on to the lunar surface of non-biogenic "petroleum" and in general the evolution and dissipation of volatile organic compounds; their presence in large amounts in the interior layers of the moon appears very likely. However, the properties of the lunar surface, its dielectric constant and low reflectivity, have been successfully explained by astronomers on the basis of the silicate nature of its composition without resorting, like Wilson[27], to the asphalt or petroleum coke hypothesis.

It should be added that under the layer of subzero temperatures there must exist a fairly thick layer in which water may exist in the liquid state. The permafrost layer (if it does exist on the moon) is self-sealing, i.e. all cracks in it are rapidly eliminated. A coating is obtained which does not permit the escape to the outside even of gases and therefore it allows the existence of a kind of "internal atmosphere"[28]. The only case of the evolution of gases from the interior of the moon was observed by Kozyrev in 1959. In one of the spectrograms of the moon which he obtained

there is an emission band extremely similar to the most intense C_2 band which is also observed in the spectra of comets.

All that has been said above concerning the possibility of the existence on the moon of a permafrost layer, containing and retaining organic compounds, applies to a considerable extent also to Mars.

3. ORGANIC COMPOUNDS IN COMETS

Apart from the giant planets, the solar system contains yet another type of bodies consisting mainly of volatile materials, namely comets. The solid nuclei of the comets are small, usually between several hundred metres and several tens of kilometres in diameter and consist of "ice" comprising different gases with an admixture of involatile rocky materials (10–30 wt.%). In their structure the comet nuclei must resemble enormous lumps of snow (however, these are black and not white) rather than blocks of ice. They move around the sun along extended orbits and most of the time they remain far from it. The temperature of the nucleus is then extremely low and therefore gases are not evolved from the latter. On approach to the sun, the surface layers of the nucleus are beginning to heat up and the evolved gases form an atmosphere which is continually dissipated—the head of the comet and the tail.

Spectroscopic observations on the heads and tails of comets reveal the presence of C_2, C_3, CN, CH, OH, NH, NH_2, CO, and N_2. Until recently it was believed that all these chemically unstable radicals are generated as a result of the photodissociation of chemically unstable parent molecules evolved (desorbed) from the comet nuclei. Methane, ammonia, carbon dioxide, and water were postulated in the first place as parent molecules of this kind. However, the problem of the parent molecules is much more complex.

Donn and Urey[29] put forward the hypothesis of the presence in the comet nuclei of considerable amounts of frozen unsaturated radicals. However, subsequently they changed their view. Even under laboratory conditions radicals are frozen only with considerable difficulty and under natural conditions they could enter into the composition of comet nuclei only in a small amount. Donn[30] estimated this amount as approximately 1%.

Delsemme and Swings[31,32] believe that the wide variety of volatilities of the hypothetical parent molecules enumerated above is incompatible with the results of observations on comets, which indicate that the ratio of the amounts of different molecules varies little with the distance of the comet from the sun, i.e. with the temperature of the surface of the nucleus. Therefore they suggest that the molecules in the comet nuclei are present in a hydrated form (such as $CH_4.6H_2O$), which gives rise to similar volatilities of all the compounds. Although their initial evidence appears unsound (the differences in volatility will be rapidly compensated during evaporation by the generation of various concentration gradients in the surface layer of the nucleus), the idea of an abundance of water in comet nuclei is probably valid. In recent years it was established that the lines due to atomic oxygen observed in the spectra of comets do not originate from the superposition of the luminescence of the terrestrial atmosphere but are due to the comets themselves. Oxygen atoms are produced as a result of the photodissociation of water.

The comet nuclei were formed at extremely low temperatures and therefore it may be suggested that initially they consisted of amorphous matter with a disordered arrangement of a wide variety of molecules, radicals, and atoms[33]. Subsequently the radioactive elements entering into the composition of the involatile fraction must have heated the central part of the nucleus to a temperature of about 50°K or above and must have caused the evaporation (sublimation) of the most volatile components and their diffusion through the porous material of the nucleus and condensation in the cold outer layers[34]. During this process the initial composition and structure of the material of the nucleus might have changed significantly.

Observations on some of the radicals contained in the comet atmospheres make it possible to establish the lifetimes of the parent molecules from the instant of their evolution from the comet nucleus to their photodissociation. In particular the lifetimes of molecules giving rise to C_2 and CN do not exceed 1–3 h at a distance of one astronomical unit from the sun.

Potter and Del-Duca[35] made laboratory measurements of the ultraviolet absorption cross-sections (in the region 4000–1300 Å) for ethylene, acetylene, methane, acetonitrile, monocyanoacetylene, dicyanoethylene, dicyanogen, methylamine, hydrazine, ammonia, hydrogen peroxide, and water, and using data on the ultraviolet emission intensity of the sun, found the lifetimes of these molecules in the interplanetary space. It was found that the lifetimes of molecules whose decomposition can give rise to C_2 and CN amount to tens and hundreds of hours at a distance of one astronomical unit from the sun, which is inconsistent with the astronomical data. Consequently C_2 and CN are formed by the photodissociation of some other uninvestigated molecules (for example, molecules, which are stable only at low temperatures) or they are formed not by photodissociation but as a result of another process, for example molecular collisions in the immediate vicinity of the nucleus.

Laboratory studies of Stief and De-Carlo[36] showed that, from the purely spectroscopic point of view, the parent molecule of C_2 may be acetylene (C_2H_2) or an acetylene molecule, but not ethylene or ethane. However, according to Potter and Del-Duca[35], acetylene must be excluded because its lifetime in the radiation field of the sun is much too great.

Stief and De-Carlo also found that NH observed in comets cannot form as a result of the photodissociation of ammonia (NH_3), but can be produced by the dissociation of hydrazine (N_2H_4) or some other related molecule.

Thus, although the presence of organic molecules in the nuclei of comets is not subject to doubt, only the first steps have been taken so far in the determination of their exact nature. A fairly complete idea about the organic compounds in the nuclei of comets will probably be derived in the next few years by direct analysis of the matter from the nuclei by means of automatic apparatus mounted on a space rocket which will be sent to intercept the comet.

4. ORGANIC COMPOUNDS IN METEORITES

The meteorites falling on earth are fragments of asteroids, i.e. bodies located at the boundary between the zone of the earth type planets and that of the giant planets. In the regions of the planetary system remote from the sun there exist probably objects of meteorite dimensions consisting of "ice" comprising different gases, i.e. similar to the nuclei of comets. However, bodies moving in the region of the earth orbit, i.e. in the vicinity of the sun, consist of refractory substances—silicates and iron–nickel alloy.

All meteorites contain at least a small amount of carbon and carbon compounds, including organic compounds. In particular, gases evolved when meteorites are heated contain carbon dioxide, carbon monoxide, methane, and ethane (together with molecular hydrogen, hydrogen sulphide, and sulphur dioxide). However, there exist chondrites of a rare type (about 30 are known) containing several per cent of organic compounds. These are known as carbonaceous chondrites. Carbonaceous chondrites contain carbon, predominantly in the form of high-molecular aromatic compounds and also in the form of bitumen-like material. In addition they contain hydrated minerals and free sulphur. The material of carbonaceous chondrites was never heated to temperatures in excess of 200–300°C. Mason's review[37] is specially devoted to carbonaceous chondrites.

Wiik[38] showed that carbonaceous chondrites can be naturally divided into three types, differing in the content of volatile substances and structure. The average carbon and water contents (expressed as percentages) are as follows:

	type I	type II	type III
C	3.5	2.5	0.5
H_2O	20.1	13.4	1.0

(The maximum observed carbon content is 4.83%).

Carbonaceous chondrites of type I have a composition very similar to that expected for a solid condensed in the protoplanetary cloud. Even the content of widely distributed elements is almost identical with the "cosmic" abundance, while in meteorites of other types there is a smaller or greater deficit. Carbonaceous chondrites contain large amounts of primary inert gases, i.e. gases captured from the surrounding medium in the formation of the meteorite material (and not evolved in consequence of radioactive breakdown). It is now believed that, of all the substances at present available to us, carbonaceous chondrites of type I are closest to the primary matter from which the planets of the earth type are formed.

The presence of organic compounds in carbonaceous chondrites was established as early as 1834 by Berzelius, who, however, found it difficult to identify them because of the complexity of their structure and the small amount available for analysis. In the XIXth century investigations consisted mainly in the isolation of organic compounds by sublimation or by extraction with solvents such as alcohol or petrol. The amount of bituminous substance isolated rarely exceeded 1% of the total weight of the specimen. However, the major part of the carbonaceous substance consists of a black carbon-like material which is not acted upon by solvents. It has been frequently called graphite or amorphous carbon. As early as 1864, however, Cloëz, who studied the meteorite Orgueil showed that this black substance is an organic complex. He isolated it by dissolving the inorganic component and obtained 6.4% of an insoluble residue. He assumed that this residue is a complex mixture of compounds with a high molecular weight. It is now known from X-ray diffraction data that the black substance in all carbonaceous chondrites is amorphous and consists of an aromatic polymer[39].

After a break of more than half a century, studies on the organic material in carbonaceous chondrites were resumed in the 1950's. Mueller[40] irradiated with ultraviolet light 20 carbonaceous chondrites and found that 19 of them do not fluoresce. Hence he concluded that they do not contain free hydrocarbons with an atomic ratio $H:C > 1.4$. However, further studies showed that luminescent extracts can be obtained from all carbonaceous chondrites. Mueller extracted organic compounds from the Cold Bokkeveldt meteorite by means of organic solvents. The substance extracted after the removal of sulphur crystals (10–12%) proved to have the following composition: C 19.8%; H 6.7%; N 3.2%; S 7.2%; Cl 4.8%; O and other elements 40.0%; ash 18.3%; the presence of chlorine is interesting. In contrast to solutions of terrestrial minerals of biological origin, which are always optically active, the solution of the extracts from the Cold Bokkeveldt meteorite showed no optical rotation within the limits of accuracy of the apparatus (0.02°). Mueller concluded that the organic substance from the meteorite consists of complex organic acids with different solubilities. They were produced by non-biological polymerisation in a gaseous medium containing nitrogen, sulphur, and chlorine. Judging from the difficulty of the dissolution of silicates, this substance envelops the strong particles.

Boato[41] studied the isotope composition of carbon and hydrogen from 12 carbonaceous chondrites and found appreciable differences between individual meteorites and in certain cases also between different parts of the meteorite. This is the result of fractionation processes or chemical reactions in the early stages of the formation of the meteorite.

At the beginning of the 1960's Calvin[42] and Briggs[43] showed that organic substances can be extracted from carbonaceous chondrites not only with organic solvents but also with water. The infrared and ultraviolet spectra of the extracts from the Orgueil, Murray, and Alais meteorites investigated by Calvin showed that they contain a wide variety of organic compounds including hydrocarbons and heterocyclic bases. Cytosine was found in the extract from the Murray meteorite[42]. On the other hand, no amino-acids were found in the aqueous extracts. On the basis of the infrared and ultraviolet spectroscopic data and data obtained by paper chromatography, Briggs[44] suggested that the extracts from the Mokoia meteorite contain purine or the related imidazole compound and also conjugated cyclic systems. He attributed the solubility in water to the presence of polar groups, such as carboxy- and hydroxy-groups and amines. He also found no indication of the presence of amino-acids.

An enormous explosion of interests in carbonaceous chondrites was stimulated by the work of Nagy and coworkers published in 1961.[45,46] In the first of these Nagy, Meinschein, and Hennesy[45] present the results of mass-spectrometric analyses of the linear and cyclic hydrocarbons from the Orgueil meteorite. They investigated a number of fractions distilled at temperatures between 100° and 400°C. Having found a similarity in the positions of the maxima on the distribution curves with respect to the carbon number for various hydrocarbons from the meteorites and from substances of biological origin—oils and sea deposits—the authors regarded this as evidence for the occurrence of biological processes "outside the limits of the earth", i.e. in the parent bodies from which the meteorites were derived.

In the second paper Lakus and Nagy described the results of the microscopic study of the Orgueil and Ivuna meteorites. They assert that both meteorites contain an enormous amount of microscopic particles (about 10 μm) resembling fossil seaweed, pollen, or spores. They amount to thousands per milligramme. These particles, which have come to be called "organised elements", are dyed by biological stains. Referring to the previous paper, in which it was claimed that biochemical compounds were observed, the authors expressed the view that the "organised elements" are indeed petrified unicellular micro-organisms.

As pointed out correctly by Briggs[47], to establish the biological nature of the organic material from meteorites, "it is necessary to show that the composition of the mater-

ial is identical with that wihch can be obtained on breakdown of a terrestrial cellular life form. If the composition is different, it follows that the material is either of an abiogenic nature or that it originates from an extraterrestrial life form having a chemical composition different from that of the terrestrial life forms familiar to us. If this latter hypothesis is adopted, it is impossible to employ merely the presence of organic matter in meteorites as a criterion of extraterrestrial biogenic processes, since evidently one can say about any chemical substance that it is part of a completely unknown and hypothetically alien life form. The last consideration is important, since it is difficult to doubt that in many of their properties the meteoritic organic compounds do not resemble terrestrial biological residues".

As regards the "organised elements", the attempts to revive the micro-organisms from meteorites proved unsuccessful[48] and the investigations had to be based merely on their morphology which is a very indefinite and unreliable procedure.

The conclusions of Nagy, Meinschein, and Hennessy were objected to by Anders[49] on several counts, who emphasised that despite their captions, the mass spectra quoted by these workers for the range C_{15}–C_{30} do not refer to the pure hydrocarbons (straight-chain alkanes and mono-, di-, and tri-cycloalkanes), including also the degradation products of heavier molecules with masses up to 600. He noted that the curves for the oil and sea deposits differ appreciably from one another and therefore there is no standard curve characteristic of hydrocarbons of biological origin. Anders also pointed out a number of possibilities of contamination of the meteorite by terrestrial biogenic hydrocarbons: as a result of contact with the hands, the "respiration" of the porous meteorite during changes in atmospheric pressure, etc. He concluded his paper with the following words: "even if it should be possible to prove a close resemblance in the distribution of compounds, as opposed to cracking patterns, a logical difficulty remains: it must also be proved that a similar distribution could not have arisen in the solar nebula by purely inorganic reactions. Like all negative proof, this is impossible to obtain. A far more promising approach would be to look for optical activity in meteorite hydrocarbons. Optical activity is a universal and indispensable property of life as we know it and its discovery in meteorites would go a long way toward convincing sceptics such as myself of the onetime existence of life on the meteorite parent bodies".

It is therefore difficult to convince the investigators of meteorites of the possibility of the existence of life on their parent bodies, which would imply a complete revision of the modern hypotheses concerning the origin and history of these bodies. Nevertheless, as far as the astronomical and cosmochemical data are concerned, there is no justification for such revision.

The critical remarks of Anders were published together with the reply of Nagy, Meinschein, and Hennessy which they conclude with the hope that their further results would completely confirm their preliminary conclusions. In Urey's words[50], these authors were very surprised by the reaction to their paper from meteorite experts. They believed that they had made an interesting discovery which would be accepted without objection.

In 1962–1963 a vigorous controversy developed around the work of Nagy and coworkers. In March 1962 a series of articles were published in Nature (No. 4821) on this question (Urey; Briggs, and Kitto; Fitch, Schwarcz, and Anders; Bernal; Nagy, Klaus, and Hennessy). In May 1962 a special conference devoted to the "organised elements" was held in New York (for the conference report, see Urey[51]). A number of papers have been published both by the supporters of the biological origin of the particles discovered and by their opponents, who explain them away by the unusual forms of natural minerals or by contamination by terrestrial particles of biological origin—pollen, pores, etc.

Klaus and Nagy discovered several types of "organised elements". Fitch and Anders[52–54] divided these elements into two groups: particles with a very complex structure and particles with a much simpler structure. There is no doubt about the latter that they belong to the meteorite itself. However, Fitch and Anders and also Mueller[55,56] showed that the Orgueil and Ivuna meteorites contain microscopic hexagonal crystals of troilite (FeS), which resemble the hexagonal "organised elements" described by Klaus and Nagy. By centrifuging in heavy liquids the meteorites ground to a powder, as was also done by Klaus and Nagy to concentrate the "organised elements", Fitch and Anders also found spherical particles resembling the spherical "organised elements", but which they showed to be supercooled drops of sulphur and hydrocarbons. As regards the group of particles with complex morphology which resemble terrestrial micro-organisms both in structure and in the remaining properties, there are grounds for the belief that their presence in the Orgueil meteorite (probably only in a few individual lumps of the meteorite) is a result of contamination.

The experiments of Imshenetskii and Abyzov[57] showed that not only stone but also iron meteorites are completely permeable to soil micro-organisms. It is therefore not surprising that Roy found Johnstown achondrite to be contaminated with two types of terrestrial bacteria and Oro and Tornabene[58] isolated three types of terrestrial bacteria on the Murray and Mokoia carbonaceous meteorites. These meteorites were stored simply wrapped up in paper. A lump of the Orgueil meteorite, which these authors also investigated, was preserved in a museum in a sealed glass vessel and no contamination with micro-organisms could be observed. In all the remaining cases of the observation of bacteria in meteorites, it was asserted without sufficient evidence that bacteria brought by the meteorite from space had been revived. The contamination of meteorites by terrestrial bacteria results at the same time in contamination by terrestrial biogenic organic substances, which may be erroneously assumed to belong to the meteorites themselves§.

Both Briggs and Anders and Fitch noted that the attribution of a biological origin to the "organised elements" on the basis of morphological data is unconvincing, since it is based to a large extent on subjective assessments. Later Urey[50] in his review on the hypothetical presence of biogenic substances in meteorites¶ also wrote that "to a chem-

§ In one of the lumps of the Mokoia meteorite which was contaminated with pieces of wood, spores, and radiolaria after falling, Mueller[60] found a resinous substance which subsequent investigations showed to be identical in composition with the substance exuded from the root of the tree on which the meteorite had fallen.

¶ Urey's review has the unfortunate title "Biological Material in Meteorites", which creates the impression that the author firmly admits the biogenic nature of the organic compounds from meteorites. Recently Urey et al. published a special note[59], in which they emphasise that they do not regard the biogenic origin of these compounds as proved, but at the same time they find that there is no adequate proof for their abiogenic nature.

ist, morphological forms appear to be an unsatisfactory basis for identification of biological remains because so many artifacts of approximately the size of micro-organisms, can be made both from organic material and inorganic material". At the same time Urey noted that the evidence in favour of the presence of organic substances is such that if terrestrial objects and not meteorites were concerned there would be no question about their validity. In the case of meteorites, as pointed out both by himself and Anders and Fitch, further objective study of the factual data is essential.

It was indeed essential both because of the exceptional importance of the problem of the existence of extraterrestrial life and because it might reveal the weak points of the method used previously to establish the presence of life residues in terrestrial specimens. An extremely important step was taken in 1965 when Anders and coworkers succeeded in obtaining proof that the organic compounds found in meteorites might have arisen in the protoplanetary cloud without any participation of biological processes (see below). As regards the "organised elements", nowadays almost everyone admits that the part of these belonging to the meteorite itself is abiogenical in nature and consists of complex crystals and mineral grains or hydrocarbon droplets, while the remainder are a result of the contamination of the meteorite by earth spores, pollen, etc.

In 1962–1965 a series of studies on the organic material in carbonaceous chondrites was carried out by Vdovykin[61]. These investigations dealt both with the bitumen-like material extracted by solvents and with the high-molecular insoluble phase. Luminescence analysis of the extracts obtained by cold extraction with various solvents by Florovskaya's method revealed the presence in these materials of reducing, neutral, and acid organic compounds: oils, neutral and acid resins, and humic components. The content of oils was 45–75% and that of asphaltenes 9–20%. The study of the fluorescence band spectra established the presence of condensed aromatic hydrocarbons[62].

The high-molecular phase constituting more than 90% of the carbonaceous substance was investigated by X-ray diffraction, electron diffraction, and microdiffraction methods. This phase consists mainly of an amorphous organic substance in which crystalline polymers are encountered and also very small inclusions with some order in the arrangement of carbon atoms. A gradual transition of the high-molecular phase of the carbonaceous substance into carbon black, and subsequently to graphite was noted. This phase, consisting of highly condensed aromatic compounds, is present also in achondrites and in the graphite inclusions in iron meteorites.

During these years a large number of papers were also published abroad and their number continues to grow. These studies dealt with the aromatic and aliphatic compounds in the bitumen-like (extractable) and high-molecular phases of the carbonaceous substance and also with compounds containing sulphur, nitrogen, and the halogens. Hayes[63] reviewed systematically the work published in 1953–1966. Information about this work, including the bibliographical references, is also available in Vdovykin's book[61]. Many organic compounds have been observed with absolute certainty but for others there are discrepancies in the results.

An example of the pitfalls encountered in the analysis of organic compounds in meteorites is provided by the history of the detection of amino-acids in them. Thus Degens and coworkers reported the observation of sugars and amino-acids in a number of carbonaceous and ordinary chondrites[64,65]. On this basis, Degens[66] speaks of a genetic relation between the organic material from meteorites and from sea deposits.

However, Oro and Skews[67] soon detected the same amino-acids as those found in meteorites on the skin of human fingers and actually in similar relative amounts. It was found that the amounts of amino-acids detected in meteorites can be fully accounted for by the amino-acids present in the fingerprints remaining after the meteorites have been handled. Therefore Oro believes that his data support the results of Calvin[42] and Briggs[44], who failed to detect amino-acids in meteoritic organic materials (see also Ref. 68). Probably their detection in other investigations[64–66] can be accounted for by the contamination of the specimens studied.

A pitfall of another kind is clearly demonstrated by the study of the isotopic composition of hydrogen carbon, and sulphur from the organic material in four carbonaceous chondrites carried out by Briggs[68]. He observed enrichment in deuterium and sulphur-34 and depletion in carbon-13. As regards the enrichment in deuterium and depletion in carbon-13, this substance resembles terrestrial materials, but the enrichment in sulphur-34 is contrary to what is observed on earth. Therefore Briggs believes correctly that his results confirm the extraterrestrial origin of the substance which he investigated. However, if only hydrogen and carbon were studied, the opposite conclusion would probably have been arrived at!

The application of the ESR method led to the detection of free radicals in the carbonaceous material in meteorites[61,69,73]. It was found that the concentration of free radicals is 10^{16}–10^{17} per gramme of carbon. Repeated measurements after the irradiation of the meteorites with X-rays established that the free radicals are associated with aromatic structures. Soviet investigators attribute the formation of radicals to the effect of cosmic radiation. According to French scientists, the carbonaceous components of the meteorite material are at least partly of biological origin. However, Urey[50] in his discussion of this finding also pointed out that free radicals might have arisen in the abiogenic material of meteorites under the influence of the radiation to which they were subjected in the interplanetary space. Schulz and Elofson[73], who investigated the Orgueil meteorite, carbonised the carbonaceous material at different temperatures and concluded that this meteorite had never been subjected to a temperature in excess of 300°C. They note that the presence of free radicals can be explained in different ways and that an abiogenic origin is also possible.

The studies discussed above led to a significant advance of our knowledge about organic compounds in meteorites but did not and could not provide a definite answer to the question of their biogenic or abiogenic nature. At the same time experimental studies, begun even earlier, continued to reveal new possibilities in laboratory abiogenic synthesis[12,21,22,42,43,74–84].

Perhaps one of the main difficulties arises in connection with the explanation of the abiogenic origin of saturated hydrocarbons. In meteorites they are mainly of the unbranched type, although abiogenic synthesis usually yields a mixture of branched and unbranched compounds. At the same time saturated hydrocarbons in most terrestrial organisms are unbranched. Only Wilson[74] succeeded in obtaining by an abiogenic procedure similar high-molecular hydrocarbons on the surface of a salt solution by passing an electric discharge through a mixture of methane, ammonia, and hydrogen above the solution. It is also known that thin films of waxy material are formed in electron microscopes on surfaces subjected to the action of an electron beam.

Similar waxy coatings were observed on the surface of cosmic dust[85]; they probably consist of a hydrocarbon polymer formed in the interplanetary space under the action of radiation.

Vigorous controversy has developed on the question of the optical activity of the organic compounds from meteorites[86-90] (see also Refs. 61 and 63). The rotation of the plane of polarisation is extremely rarely observed in the products of non-biological laboratory processes, but is a characteristic feature of all substances of biological origin and therefore the detection of rotation in extracts from carbonaceous chondrites would be important evidence in favour of the biogenic nature of these extracts, but would still not constitute incontrovertible proof of this. Since the time when Mueller's work was carried out, the precision of measurements increased, but later observations also led to the conclusion that the extracts have no optical activity. The reported low optical activity in certain meteoritic extracts is probably associated with the surface contamination of the specimens by fingerprints.

An important stage in the investigation of the nature of the organic material in meteorites was reached with the work of Anders and his coworkers. These investigators succeeded in obtaining data on the composition of the organic compounds which were contained within the mineral grains and therefore had not lost their volatile components, in contrast to the remaining larger portion of organic material in the meteorite. The composition of this substance is similar to that observed for the equilibrium distribution in carbon-rich carbon–hydrogen–oxygen mixtures. Therefore Studier et al.[91] suggested that the organic substances present in meteorites were formed in the interplanetary cloud and were then captured on formation of the parent bodies from which the meteorites originated. Initially this concept was based on theoretical calculations of the equilibrium concentrations of various compounds in the system carbon–hydrogen–oxygen and was then supported by experiments.

The basic idea of their investigation was as follows. During the course of the last few millions of years of their existence, the meteorites were heated to 250–300°K each time they passed through the perihelion. Therefore the most volatile substances could persist only in a few "secluded" corners within the mineral grains, while the less volatile substances persisted also in the form of surface coatings and in the interstices between the grains. Carbonaceous chondrites contain traces of primary inert gases firmly retained within the mineral grains. These gases were captured from the primary gas phase (from the protoplanetary cloud or, in the view of certain investigators, from some atmosphere) during the formation of the carbonaceous chondrites or the minerals included in them. The above investigators made an attempt to elucidate whether other volatile substances were captured at the same time.

Volatile substances were evolved in a vacuum at low temperatures from freshly ground specimens of three carbonaceous chondrites. The fractions evolved at different temperatures (up to 140°C) were investigated using a mass-spectrometer, whereby mass spectra up to a mass number of 500 could be studied. The substances which could be identified on the basis of 28 individual analyses are listed in Table 5†.

The new measurements emphasised the predominance of aromatic hydrocarbons compared with aliphatic hydrocarbons. An important discovery was that the amount of ethane is smaller by a factor of at least 1000 than of methane. From the analysis of these results, the authors concluded that the volatile compounds which they detected do indeed represent little changed residues of the primary gaseous medium in which the carbonaceous chondrites were formed and on this basis they endeavoured to elucidate the origin of the organic compounds. Two alternative hypotheses are possible: (a) a non-equilibrium process associated with some high-energy source (for example Mueller–Urey reactions presupposing irradiation with ultraviolet light or charged particles), or (b) an equilibrium process presupposing reactions in the gaseous medium under conditions of thermodynamic equilibrium.

Table 5.*

*The approximate abundances are denoted by one or two plus signs. The compounds which were looked for but not found are denoted by the minus sign and those detected on extraction with solvents are denoted by the letter *E*. The question mark denotes tentative compounds.

The non-equilibrium process is to a high degree non-selective with respect to the formation of particular compounds. In all the numerous experiments on this process it was found that methane is always accompanied by light alkanes, aliphatic compounds predominate over aromatic compounds, complex aromatic compounds, for example coronene, could not be detected at all, and the amount of branched alkanes obtained was considerably greater than that of the straight-chain isomers. Thus this process cannot explain the data obtained for the meteorites: neither the high methane : ethane ratio nor the absence of propane, butane, and pentane, nor the predominance or aromatic compounds, nor the high straight-chain alkane : branched-chain alkane ratio.

In recent years the equilibrium process did not attract attention, since thermodynamic calculations for the gas having the cosmic composition, i.e. with a very high hydrogen content, showed that in this way it is possible to obtain only traces of complex organic compounds. The first step in the demonstration of the possibilities of this process were taken by Suess[92], who pointed out that, in a gas depleted in hydrogen by a factor of 100 compared with the

† Studier et al.[91] quote the values of m/e for several dozen peaks in the mass spectra which were not identified.

cosmic abundance, complex organic compounds can form by equilibrium reactions. Subsequently this was fully confirmed by computer calculations[93,94] of the equilibrium concentrations of all the main components produced in the system carbon–hydrogen–oxygen and also of a representative group of more than 100 compounds present in small amounts. The concentrations of compounds containing nitrogen, sulphur, and chlorine in addition to carbon, hydrogen, and oxygen were also calculated. A wide range of temperatures and pressures was considered: from 300° to 1000°K and from 10^{-6} to 300 atm. The results for the carbon–hydrogen–oxygen mixture are presented in the form of a ternary diagram in Fig. 1. The straight lines separate the regions in which particular compounds predominate. The straight line in the centre of the diagram indicates the position of the "asphalt threshold", above which the concentration of aromatic compounds increases by a factor of 10^{20}–10^{30}, until finally these compounds become the main components of the system (Fig. 2). The curved lines in the lower part of the diagram correspond to the equality of the free energies of carbon in the gaseous mixture and the free energy of graphite (dashed line for 500°K and continuous line for 700°K). Above this line, complete thermodynamic equilibrium requires the formation of graphite. However, since the activation energy required for its formation is very high, considerable amounts of resins and asphalts accumulate before this happens. The points *A*, *B*, *C*, and *D* in Fig. 1 indicate the compositions of the mixtures for which the concentrations of a number of compounds have been published[93,94] (500°K and 1 atm). With these four compositions, it was found that many compounds which are biologically important, such as ribose, glycerol, and derivatives of adenine, cytosine, glycylglycine, and serine, are present at concentrations less than 10^{-35}.

Unfortunately only one of these four mixtures, mixture *O* (Fig. 1) with the ratios C : H : O = 1 : 1 : 1.33, lies above the "asphalt threshold". Studier, Hayatsu, and Anders[91] selected the compounds for which concentrations in excess of 10^{-10} had been calculated and, having arranged them in descending order, compared them with their own results (Table 6). It was found that all nine compounds which are the most abundant in mixture *C* are present in carbonaceous chondrites. The next two compounds, ethane and ammonia, were not found despite a thorough search. The upper limit of the ethane content thus found, 10^{-2} of the methane content, is higher by a power of ten than the calculated concentration. Of the remaining five compounds, only xylene was detected. Its detection is probably due to the characteristics of the sensitivity range of the mass spectrometer. In general there is a remarkable qualitative agreement between the theoretical distribution and the results of the experimental study of the volatile compounds from meteorites.

Having established that at least the major part of organic compounds in meteorites were formed in an equilibrium process, Studier, Hayatsu, and Anders posed the question of the time and place of their formation. Since meteorites are fragments of asteroids, there are three possibilities:

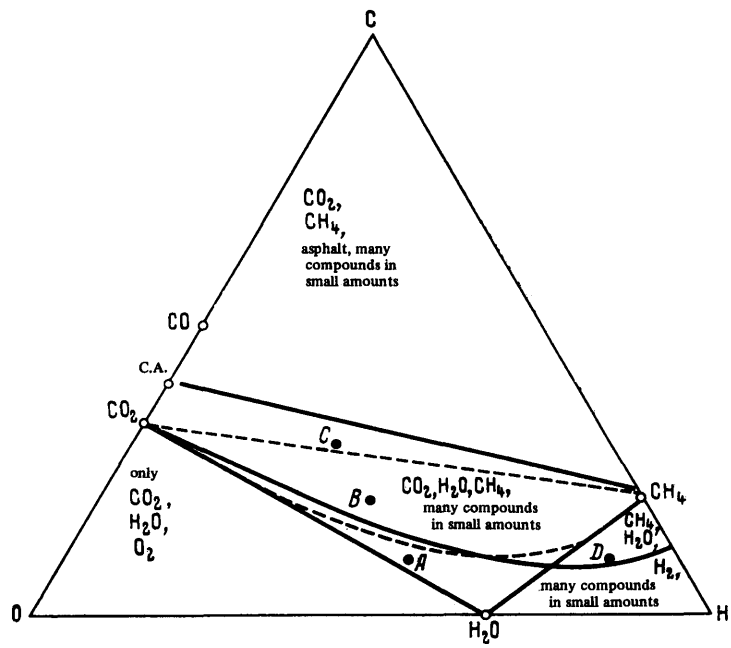

Figure 1. Ternary diagram for the system carbon–hydrogen–oxygen with the indication of the "asphalt threshold" (straight lines in the centre of the diagram) and the lines corresponding to the equality of the free energy of carbon in the gas mixture and the free energy of graphite (curved lines in the lower part of the diagram) at 500°K (dashed line) and 700°K (continuous line). The point C.A. on the O–C line indicates the ratio of the cosmic abundances of these elements.

(1) the transient atmosphere of asteroids (because of their low mass, asteroids do not have a permanent atmosphere); (2) the "internal atmosphere" (see p. 67); (3) the protoplanetary cloud. The first two possibilities must be rejected, since, in order to explain the amount of organic compounds present in meteorites, an impossibly large mass of the atmosphere is necessary—between 100 and 1000 kg of carbon dioxide and methane per cm^2. At the same time the formation of the organic compounds in the protoplanetary cloud is quite possible. The cloud having the cosmic composition coincides almost completely with the point H in Fig. 1, i.e. its composition occurs in the region where hydrogen, carbon, and oxygen are almost entirely present as H_2, CH_4, and H_2O. Along the C–O line the cosmic ratio of the abundances of these elements is represented by the point C.A. The selective loss of hydrogen alters the composition of the mixture along the C.A. line (not shown in Fig. 1) and at about 500°K the "asphalt threshold" is crossed by the mixture.

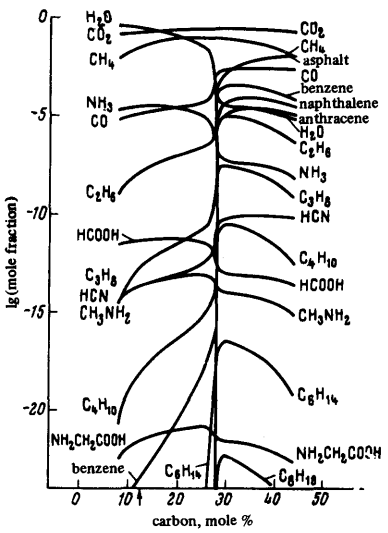

Figure 2. Variation of the concentrations of a number of organic compounds on crossing the "asphalt threshold".

The paper of Studier, Hayatsu, and Anders was very sharply critisised by Urey and Lewis and by Burlingame and Schnoes, but the criticism received an entirely convincing answer[95–97]. Urey and Lewis rejected the possibility of using the results of the calculation of equilibrium concentrations on the assumption that there is no graphite. However, in their reply Studier, Hayatsu, and Anders were already able to confirm the absence of free carbon by their experimental results obtained in the study of the attainment of equilibrium in the system carbon–hydrogen–oxygen[98]. They employed CO–H_2 mixtures, since in the temperature range 1000–200° and at moderate pressures carbon monoxide is the dominant form of carbon in the cosmic gas. In the first 15 experiments molecular hydrogen was employed but subsequently 38 experiments were carried out using molecular deuterium (D_2) to avoid the risk of contamination. The mixture compositions ranged from the atomic ratios C : H : O = 1 : 1 : 1, which corresponds to the "asphalt" region in the ternary diagram, to C : H : O = 1 : 500 : 1, which is close to the cosmic value. The principal aim of these experiments was to test the hypothesis that the formation of free carbon is inhibited kinetically, so that there arises a metastable distribution of compounds with a high proportion of aromatic components. In some series of experiments pure gas mixtures were employed and in others the catalytic effects of powders consisting of iron and stone meteorites were examined. The temperature of the gas mixture, which was usually under a pressure of 1–2 atm, was increased in steps and the compounds formed were investigated mass-spectrometrically.

Table 6.

Compound	Calc. concns. for mixture C	Presence in carbonaceous chondrites	Compound	Calc. concns. for mixture C	Presence in carbonaceous chondrites
Carbon dioxide	0.66	+	Anthracene	$2.9 \cdot 10^{-5}$	+
Nitrogen	0.50	+	Ethane	$2.3 \cdot 10^{-5}$	—
Methane	0.24	+	Ammonia	$1.1 \cdot 10^{-6}$	—
Carbon monoxide	$5.3 \cdot 10^{-3}$	+	Xylene	$9.4 \cdot 10^{-8}$	+
Benzene	$6.6 \cdot 10^{-4}$	+	Ethylene	$5.7 \cdot 10^{-9}$	
Naphthalene	$1.4 \cdot 10^{-4}$	+	Acetic acid	$1.2 \cdot 10^{-9}$	
Hydrogen	$1.3 \cdot 10^{-4}$	+	Hydrogen cyanide	$1.4 \cdot 10^{-10}$	
Water	$7.9 \cdot 10^{-5}$	+	Benzoic acid	$1.3 \cdot 10^{-10}$	

The experiments showed that the familiar Fischer–Tropsch reaction:

$$n\,CO + \left(n + \frac{1}{2}x\right) H_2 \rightarrow C_nH_x + n\,H_2O$$

took place. When this reaction is carried out under industrial conditions, the catalysts used are iron, nickel, and cobalt, i.e. precisely the elements which enter into the composition of iron meteorites. Therefore it is not surprising that the meteorite powder has a powerful catalytic effect. Without it a scarcely detectable amount of organic compounds is formed only after prolonged heating, whereas in the presence of the iron meteorite powder a wide variety of complex hydrocarbons are rapidly produced, but not even traces of free carbon were detected.

The distribution of reaction products strongly depended on time and temperature. At low temperatures the reaction did not reach equilibrium. This was shown by the fact that, for the mixture whose composition lies within the "asphalt" region, aliphatic hydrocarbons predominated over the aromatic compounds. At high temperatures and for prolonged reactions the results are closer to equilibrium, when only traces of aliphatic compounds should be detected.

On the basis of their experiments, Studier, Hayatsu, and Anders concluded that the organic compounds present in meteorites can be obtained in two stages: initially the Fischer–Tropsch reaction yields as metastable products straight-chain alkanes, methyl- and dimethyl-alkanes, alkenes, and light aromatic compounds and then equilibrium is partially attained, whereupon the amount of light alkanes falls and that of aromatic compounds and methane increases, with formation of condensed aromatic compounds (but carbon is not formed!).

This two-stage process might have occurred in the protoplanetary cloud having the cosmic composition and there is no need for its depletion in hydrogen, which initially appeared to be essential for the carbon–hydrogen–oxygen

mixture to fall within the "asphalt" region of the ternary diagram. Experiments showed that the first stage (the Fischer–Tropsch reaction) takes place satisfactorily with H:C = 500, which is close to the cosmic value of this ratio. Only during the second stage is it necessary that the composition should be in the "asphalt" region, i.e. in the region where H:C < 4. However, the organic compounds formed in the first stage correspond to H:C ≤ 2; when they condense and are thereby virtually isolated from the hydrogen-rich gas phase, they automatically fall within the "asphalt" region. The organic compounds formed condensed on the surface of dust particles, where the second stage of the process took place.

The experiments of Hayatsu et al.[99] showed that nitrogen-containing organic compounds might have formed in the same two-stage process if the latter took place in the presence of ammonia.

Modern hypotheses concerning the formation of the protoplanetary cloud by separation from the protosun in the final stage of its contraction entail a hot brief initial stage during which carbon must have existed in the form of carbon monoxide. When the cloud cooled, the condensation of metallic and silicate dust particles created catalytic centres for the Fischer–Tropsch reaction between carbon monoxide and molecular hydrogen. Because of the presence in the protoplanetary cloud of nitrogen, sulphur, and chlorine, not only hydrocarbons but a wide variety of organic compounds might have formed. These compounds condensed on the surface of the dust particles and together with them entered into the composition of the parent bodies of the meteorites formed by accretion from the dust component of the protoplanetary cloud. The second stage of the process—the partial attainment of equilibrium—probably occurred within the interior of these parent bodies—in that part of their material which was subjected to even slight heating and which gave rise to carbonaceous chondrites.

Investigators adhering to the idea of the biological origin of organic compounds present in meteorites for some reason do not discuss the question of what were the involatile carbon compounds which entered into the composition of the parent bodies of the meteorites and served, from their point of view, as the raw materials for further biological synthesis. The work of Anders and coworkers shows that the principal features of meteoritic hydrocarbons are characteristic of the abiogenic material synthesised from carbon monoxide and molecular hydrogen.

Studier, Hayatsu, and Anders note that the similarity between meteoritic and terrestrial hydrocarbons, including biogenic hydrocarbons, is frequently exaggerated and also that the importance of this similarity is overestimated. In this connection they point to the work of Friedel and Sharkey[100,101], who showed that the abundance of different isomers in crude petroleum from Saudi Arabia is expressed by the same formula as their abundance in the products of the Fischer–Tropsch reaction. This formula involves only two adjustable parameters, namely the probability of increase in chain length and the probability of chain branching. This shows that the distribution of isomers in crude petroleum is not due to biosynthesis but to catalytic processes and therefore the similarity between terrestrial and meteoritic hydrocarbons does not constitute evidence for the biological origin of the latter. On the contrary, this may be regarded as evidence for a non-biological origin of a considerable proportion of terrestrial petroleum.

Thus considerable advances have now been achieved in the study of organic compounds present in meteorites and the principal features of their abiogenic synthesis in the protoplanetary cloud have been elucidated.

5. ORGANIC COMPOUNDS ON EARTH

The presence of abiogenic organic compounds in meteorites and consequently in the parent bodies of the meteorites (asteroids) makes it virtually certain that these compounds were also present in the material from which the earth accumulated. Judging from type I carbonaceous chondrites, the total mass of the "primary" organic compounds brought to the earth might have exceeded severalfold the mass of water in the oceans[27,102].

However, only a small fraction of the "primary" organic compounds could persist in the course of the formation of the earth and its subsequent evolution. In the first place the "primary" organic material broke down to a considerable extent as a result of the temperature rise accompanying the impact of planetismals against the surface of the growing earth. However, Studier, Hayatsu, and Anders believe that, during the dispersion and cooling of the products of the "explosion" accompanying the impact, new hydrocarbons and other organic compounds might have formed rapidly (as a result of the Fischer–Tropsch reaction and other processes occurring simultaneously). Nevertheless the newly formed compounds and the persisting portion of the "primary" compounds from the protoplanetary cloud were buried in the course of the further growth of the earth underneath the growing outer layers. At the same time the interior of the earth, starting with a depth of the order of 100 km, became hot, initially as a result of the evolution of the energy associated with the accretion process itself and then as a result of the accumulation of heat due to radioactivity. At the present time the temperature of the interior is 2000–4000°C and this should probably result in an almost complete breakdown of organic compounds. The material of meteorites of most types was heated to 500–1000°C and organic compounds are present in the latter in amounts corresponding to hundredths and thousandths of a per cent. (However, it should be noted that, although this content is smaller by 2–3 powers of ten than in carbonaceous chondrites, it is nevertheless of the same order of magnitude as the content of organic compounds in terrestrial rocks, frequently regarded as petroleum bearing.)

The "primary" organic compounds and the compounds formed during the dispersion of material after the impacts of planetismals might have partially persisted only in outer relatively cold layers of the earth. Furthermore new compounds might have been synthesised in these layers from the decomposition products diffusing from the hot interior to the surface. It has been shown experimentally that clays are good catalysts for the Fischer–Tropsch reaction[103].

Thus it appears very probable that a considerable proportion of the pre-biological organic matter on earth was not formed by the Mueller–Urey reaction in the terrestrial atmosphere but by Fischer–Tropsch reactions both in the protoplanetary cloud and during further stages in the evolution of the main bulk of terrestrial material. As early as a few years ago, a number of authors pointed out that the formation of organic compounds must have begun in the protoplanetary cloud[43,47,104–108].

---oOo---

The studies carried out in recent years have significantly extended and deepened our knowledge concerning the presence of organic compounds, ranging from the simplest to the most complex, in various bodies in the solar system. The studies of the organic material from meteorites,

which demonstrate the presence in the latter of very complex organic compounds, frequently encountered in terrestrial biogenic organic materials, are particularly important.

Modern astronomical data quite definitely indicate that meteorites are fragments of parent bodies on which conditions necessary for the occurrence of life did not exist and therefore the organic material of the meteorites has an abiogenic origin. Thus the presence of complex organic compounds in meteorites demonstrates the wide possibilities of abiogenic synthesis of organic compounds under natural conditions.

The data on the organic compounds in meteorites together with the advances in the laboratory synthesis of organic compounds, and in planetary cosmogony as regards the formation of the earth, provide a basis for the revision of our hypotheses concerning the complexity attained by the abiogenic synthesis of organic compounds on earth before the generation of life led to the occurrence of biological synthesis, and also concerning the role of natural abiogenic syntheses at the present time.

The Spontaneous Condensation of Vapour and the Formation of Condensation Aerosols

A.G.Sutugin

The development of the theory of spontaneous condensation of vapour, experimental studies of this phenomenon, and the use of the theoretical results for calculations on the formation of condensation aerosols are reviewed. The difficulty of calculating the free energy of formation of the nuclei of a new phase is examined in detail, and particular attention is paid to the problem of the contribution made by external degrees of freedom to the free energy. The problem of the existence of limiting supersaturation is discussed. Existing methods for the study of spontaneous condensation and the results obtained by these methods are examined critically. The bibliography contains 191 references.

CONTENTS

I. Introduction 79

IV. Experimental studies of the formation of condensation aerosols 87

I. INTRODUCTION

The spontaneous (homogeneous) condensation of vapour, first examined at an early date by Gibbs, has recently been attracting increasing attention from specialists working in various fields of science and technology. Spontaneous condensation takes place in various important technological processes, in powder and vacuum metallurgy, in rocket jets, and in supersonic aerodynamic nozzles. The results obtained in the study of the condensation of vapour are important for an understanding of the mechanism of other first-order phase changes taking place in the solidification of alloys, boiling, cavitation, the crystallisation of polymers, the devitrification of glasses, and the separation of phases on a spinodal; the results are also important for the theory of the equation of state of gases. The number of papers devoted to this problem is increasing, and there is also an increase in the number of different views regarding fundamental problems of the theory, such as the determination of the free energy of nucleus formation, the accomodation of molecules on the surface of the nuclei, and the influence of the association of the condensing vapour. Reviews on this problem, published chiefly in other countries, generally do not deal objectively with some aspects. In the last two decades, new experimental methods for studying spontaneous condensation have appeared, but the results of these studies have been inadequately dealt with in the review literature. At the same time, experimental practice is requiring the development of theoretical methods of calculation which will make it possible to predict the course of the production of the particle distribution with respect to dimensions in condensation aerosols, since it is only when such methods have been developed that deliberate control of this process will be possible. The present review is devoted to a critical examination of modern theories of spontaneous condensation, experimental methods of study, the relationship between theory and experiment, and methods for calculating the microscopic model of aerosol formation.

II. THE PRESENT STUDY OF THE THEORY OF SPONTANEOUS CONDENSATION

The theory of spontaneous nucleus formation in a supersaturated vapour, developed by Volmer[1], Farkas[2], Becker and Doring[3], and in its most elegant and complete form by Zel'dovich[4,5] and Frenkel'[6,7], has long since become classical, and has been described in many reviews and monographs[8-10]. This theory is based on the model first proposed by Szilard and Farkas[2], according to which a supersaturated vapour consists of a mixture of single molecules and molecular aggregates (clusters), which, according to Frenkel', can be regarded as the nuclei of a new phase. In the present review the term "nucleus" will be used only to denote aggregates of supercritical dimensions, that is dimensions at which the aggregates are stable and the probability of their growth is greater than the probability of their volatilisation. According to the general theory of thermodynamic fluctuations, the number of aggregates decreases exponentially with increase in their free energy of formation ΔG. In an unsaturated vapour, the dependence of ΔG on the dimensions of the aggregate decreases monotonically, and in the supersaturated vapour it has a minimum corresponding to the dimensions of the critical cluster. In the classical theory we can express the probability $W_g(t)$ of finding a cluster at moment of time t at a certain point on the g axis (g is the number of molecules in the nucleus) by the equation for a Markovian process:

$$\frac{dW_g(t)}{dt} = \alpha_{g-1}W_{g-1}(t) - (\alpha_g + \beta_g)W_g(t) + \beta_{g+1}W_{g+1}(t) \qquad (1)$$

where α and β are the rate constants for the reactions $A_g + A_1 \rightarrow A_{g+1}$ and $A_{g+1} \rightarrow A_g + A_1$, and A_g and A_1 represent clusters consisting of g molecules and a single molecule. Under equilibrium conditions:

$$\beta_g = \alpha_{g-1}W^0_{g-1}/W^0_g \qquad (2)$$

where $W_g^0 = c_1 \exp(-\Delta G_g^0/kT)$, ΔG_g^0 is the equilibrium value of the free energy of formation of the aggregate, and c_1 the concentration of molecules. By substituting the values of W and β, and replacing the finite differences $\alpha_{g+1} - \alpha_g$ and $\beta_{g+1} - \beta_g$ by differentials, we transform Eqn. (1) into the form

$$\frac{\partial W(g,t)}{\partial t} = \frac{\partial}{\partial g}\left\{\alpha_g \frac{\partial W(g,t)}{\partial g} + \alpha_g \frac{W(g,t)}{kT}\frac{\partial(\Delta G_g)}{\partial g}\right\}. \quad (3)$$

This is essentially the Fokker–Planck equation for the diffusion of the aggregates along the g axis. It was first derived by Frenkel'. To determine the number of aggregates reaching supercritical dimensions in unit time, J, it is assumed that the process is a steady-state process, that is the quantity c_1 is kept constant, and the clusters are removed from the system when their dimensions exceed the critical dimensions g^*. We then have

$$\alpha_g \frac{\partial W(g)}{\partial g} + \alpha_g \frac{W(g)}{kT}\frac{\partial(\Delta G_g)}{\partial g} = -J. \quad (4)$$

Various authors have solved this equation and obtained a result which can be written in the general form:

$$J = 4\pi r^{*2}(p/\sqrt{2\pi mkT})\, c_1 Z \exp(-\Delta G^*/kT) \quad (5)$$

where $p/\sqrt{2\pi mkT}$ is the number of collisions undergone by the molecules of the vapour with unit area of the cluster surface, p the pressure and m the mass of a molecule of the vapour, and Z the non-equilibrium Zel'dovich factor—$Z = (\Delta G^*/3\pi kTg^{*2})^{1/2}$.

This factor is of the order of 10^{-1}–10^{-2} and characterises the deviation of the concentration of the clusters from the equilibrium value. Various expressions for J are given in the Table.

The equations given in the Table show that J depends to a marked extent on the magnitude of the supersaturation S. We can therefore speak of the "critical supersaturation", that is the supersaturation at which the rate of nucleus formation becomes appreciable. The critical supersaturation is usually taken to be that corresponding to a rate of formation of nuclei equal to 1 cm^{-3} s^{-1}. For water vapour saturated at room temperature, a change in supersaturation of 15% close to the critical value produces a change in J by a factor of $\sim 10^8$, and this makes it possible to find S_{cr} from comparatively rough determinations of the concentration of the aerosol produced in the experiment. Volmer and Flood[22] obtained for the magnitude of the critical supersaturation the expression

$$\lg S_{cr} = \sqrt{\frac{1{,}44}{\lg A}}\left(\frac{M}{\rho}\right)\left(\frac{\sigma}{T}\right)^3 \quad (6)$$

where A is the pre-exponential factor in Eqn. (5) for the rate of nucleus formation.

A key feature of the theory is the determination of the free energy of formation of the cluster. In the classical theory it is assumed that ΔG can be represented as the sum of two terms—a bulk term and a surface term:

$$\Delta G = Ag + Bg^{2/3} \quad (7)$$

where $A = kT \ln S$, $S = p/p_0$, p_0 is the equilibrium pressure of the vapour at the given temperature,

$$Bg^{2/3} = 4\pi r^2 \sigma, \quad (8)$$

and σ is the surface tension, and it is assumed that the cluster has macroscopic values for the surface tension and the density ρ. This last assumption has been criticised many times. Attempts to calculate ΔG without apriori assumptions regarding the values of σ and ρ for the material of the nucleus can be divided into two main groups. In the first group, the authors have tried to express σ and ρ as functions of the dimensions of the nuclei, and in the second, various attempts have been made to calculate ΔG without the apriori assumption that this quantity can be divided into bulk and surface contributions.

Equations for the rate of nucleus formation*.

$J = a_c N^{4/3}(p/R)^2(2M\sigma/\pi)^{1/2}\exp[(-16\sigma^3M^2/3kp^2R^2T^2\ln^2 s)] \equiv \equiv A_\Phi \exp(-\Delta C_\Phi/kT) \equiv J_\Phi$	1, 5, 7, 12
$J = g^{*4/3}Z_\Phi$	3
$J = a_c(2M\sigma/N\pi)^{1/2}(p_0/kT)^2\rho^{-1}g^{*-2/3}\exp[(-\Delta H_\Phi/kT)(1-3g^{*-1/3}+2g^{-1*})]$	13
$J = A\exp[(-\Delta G_\Phi/kT)(1-2\sqrt[3]{4}g^{*-1/3}+4g^{*-1})]$	14
$J = a_c Np(2\pi MkT)^{-1/2}(4\pi d^2c^2)(kTN/\pi M)^{1/2}\exp(-\Delta C_\Phi/kT)$	11
$J = K\exp(-\Delta G_\Phi/kT)\sinh(-\alpha g^{*1/3}/3kT)$, $\alpha g^{*2/3} = 4\pi r^*\sigma$, K is a factor including the rate constant of the reaction, $A_g + A_1 \rightarrow A_{g+1}$	15
$J = J_\Phi/S$	16
$J = J_\Phi \cdot Q_t Q_r/c$	17
$J = J_\Phi Q_t Q_r (c_e/q_t)^2/c$	18
$J = J_\Phi (Q_t Q_r/c)(2\pi^* g)^{-1/2} e^{-\delta}$	19
$J = J_\Phi (Q_t Q_r/c)\, e^{\delta}(2\pi g^*)^{-1/2} S^{-1}$	20
$J = J_\Phi (Q_t Q_r/c)(c/q_t)^2(q^{*4}/S)$ for monatomic molecules	21
$J = J_\Phi (Q_t Q_r/c)(c/q_t q_r)^{1.2}(q^{*4}/S)$ for vapour consisting of linear polyatomic molecules	21
$J = J_\Phi (Q_t Q_r/c)(c/q_t q_r)(q^{*4}/S)$ for nonlinear molecules	21

*Symbols: ρ is the density of the liquid, r^* the radius of the critical nucleus, c the concentration of the molecules of the vapour, c_e the equilibrium concentration of the molecules of the vapour, a_c the accommodation coefficient, M the molecular weight, R the universal gas constant, N Avogadro's number, q_t and q_r the translational and rotational partition functions for the molecules of the vapour, Q_t and Q_r the corresponding partition functions for the critical aggregates, and d the diameter of the molecules of the vapour.

From the theory of the interphase boundary formulated by Gibbs, it follows logically that the surface tension should depend on the curvature of the surface of separation between the phases[23]. Kennan[24] put forward arguments justifying the monotonic decrease in σ with increase in the positive curvature of the surface. A quantitative expression for the relationship $\sigma = f(r)$, where r is the radius of the liquid drop, was first obtained by Tolman[25], who combined the basic equation of Gibbs' theory with the Gibbs–Kelvin equation relating the equilibrium pressure of the vapour above the drop and the curvature of the surface. By neglecting terms containing $1/r$ raised to powers > 1, Tolman obtained the following expression

$$\sigma/\sigma_0 = 1/[1+2(\delta/r)] \quad (9)$$

where δ is a quantity of the order of the interatomic distance, and σ_0 the tension of a flat surface.

Kirkwood and Buff[26] pointed out the inaccuracy in Tolman's arguments, due to the identification of the pressure

in a microscopic drop p' with the pressure in a macroscopic volume of liquid, and calculated the relationship $p'/(r)$ using Kirkwood's statistical theory, according to which the pressure in a liquid is determined by the intermolecular forces, described by the Lennard-Jones equation[27]. By taking account of only the interaction of pairs of nearest neighbours, Kirkwood and Buff obtained the same result as Tolman[25]. An even more rigorous derivation of Eqn. (9) was given by Hill[28]. As shown by Buff and Kirkwood[29], however, mere allowance for the relationship $\sigma(r)$ cannot improve the theory, since it is also necessary to make allowance for the change in the density of the drop with change in dimensions, due to the fact that the thickness of the Gibbs' interfacial layer becomes commensurate with the radius of the drop. Plesner[30] calculated the surface tension and radial density distribution in nuclei with dimensions 3–25 times greater than the dimensions of the molecule. To describe the behaviour in the drop, Plesner used Tonk's equation of state[31] for solid spheres with an attractive potential inversely proportional to the sixth power of the distance. Plesner's result is surprising—the surface tension of these droplets is independent of their dimensions and amounts to $\sim \sigma_0/3$. If we remember that the factor $\exp(-\Delta G^*/kT)$ close to critical supersaturation usually has a value $\sim e^{-50}$, we can see that a change in the surface tension by a factor of 3 corresponds to an increase in the rate of nucleus formation by a factor of $\sim 10^{15}$. Plesner's discovery that σ is independent of the curvature means that within a certain range of dimensions there should be a sharp decrease in σ with decrease in r. Since the relationship $\sigma(r)$ is not observed experimentally as far as values of the curvature equal to 10^6 cm^{-1}, this range must be fairly narrow. All this appears unlikely. An interesting feature is that, according to Plesner, very fine drops, even at their centres, do not have the same densities as macroscopic amounts of the liquid.

Shcherbakov[32,33] pointed out that the excess of free energy in very fine drops relates to the entire volume of the drop, and not merely to its surface. He also found that simple substitution of the relationship $\sigma(r)$ in Kelvin's equation cannot lead to the correct result, and that it is also necessary to introduce into this equation a term containing $d\sigma/dr$. This viewpoint was put forward by both Kelvin and Gibbs, but their opinion was based entirely on intuition. In Shcherbakov's theory, surface tension is regarded as a quantity equal to the excess free energy per unit surface area of the drop. The expression obtained by Shcherbakov for the quantity σ defined in this way has the form

$$\sigma = \sigma_0\left(1 - \frac{2}{kr} + \frac{2}{k^2r^2}\right) \qquad (10)$$

where $(1/k \simeq 0.2\text{–}0.5 \times 10^{-7}$ cm). Because of the third term, which increases with decrease in r, the function $\sigma(r)$ has a minimum, and at very small values of r it increases with decrease in the dimensions. This result does not agree with the results of published work[25-30] or with the conclusion recently reached by Bellemans[34] in a generalisation of the theory of the Mayer–Born–Fuchs equation of state[35] for the case of a system containing an interface of arbitrary curvature.

A monotonically decreasing relationship $\sigma(r)$ is also predicted by the theory of surface tension developed by Cahn and Hilliard[36,37] and Hart[38], based on the idea that the free energy density is a function of the concentration and concentration gradient of the molecules. The quantity ΔG in this theory can be calculated without introducing the surface tension, according to the formula

$$\Delta G = \int_V [f_0(c) + k(\nabla c)^2]\, dV \qquad (11)$$

where ∇c is the concentration gradient of the molecules, and $f_0(c)$ is the Helmholtz free energy for one molecule. On the spinodal, that is the line on the phase diagram whose equation, according to Gibbs, has the form

$$dP\,dV + dT\,dS + \Sigma\, dN\, d\mu = 0 \qquad (12)$$

ΔG becomes zero. As the spinodal is approached, according to this theory, the surface of the clusters becomes diffuse, and their radius tends to infinity. At low supersaturations, the Cahn–Hilliard–Hart theory predicts[38] a rate of nucleus formation close to that obtained from the classical theory. In recent years this theory has been further developed[39-42], and Hart[40] has reached an extremely important conclusion. In the Gibbs' theory of surface tension, the quantity σ is invariant with respect to the position of the interphase boundary in the intermediate range between the phases. For a curved surface, this invariance is not observed, and the calculated value of σ depends on the choice of position for the boundary between the phases. In this instance σ is found from the condition $d\sigma/dR = 0$, where R is the radial coordinate. Hart established that under certain conditions the function $\sigma(R)$ may not have a minimum, that is the free energy of the nucleus cannot always be separated into bulk and surface terms.

In the Cahn–Hilliard–Hart theory it is assumed that the changes in the concentration of the molecules are small at distances close to the value for the radius of action of the intermolecular forces. This assumption has been criticised by Hirth and Pound[43].

Reed[44] calculated the chemical potential of a molecular aggregate consisting of up to eight molecules by finding the sums with respect to states of the aggregates, regarding them as polyatomic molecules. He assumed that the interaction between nearest neighbours in the aggregate is described by the Lennard-Jones equation. Reed's theory is applicable to larger aggregates only with great difficulty, because of the increase in the magnitude of the calculations. In Reed's theory it is possible only to estimate the influence of the presence of isomeric configurations of the aggregates, consisting of the same number of molecules, on their equilibrium concentration. Kilpatrick and Katsura[45] developed a method for calculating the virial coefficients of vapours containing aggregates consisting of several (up to ten) molecules. This makes it possible to calculate the equilibrium values of the free energy of formation of these aggregates. Benson and Shuttleworth[46] calculated the free energy of a cluster containing 13 molecules, assuming that the molecules in the nucleus are close-packed, and making allowance only for the interaction of pairs of nearest neighbours.

In view of the successful development of work on the many-body problem[47], we can expect the development of a nucleus model in which the treatment is not restricted to the interaction of nearest neighbours.

In recent years, the problem of the contribution of the external degrees of freedom of the cluster to its free energy has been widely discussed. This problem was first examined by Frenkel'[48]. Having pointed out that the result obtained by the theory of nucleation without allowance for the contribution made by the rotational and translational movement of the cluster to the value of ΔG has no physical significance, Frenkel' assumed that in order to

take account of this contribution it is sufficient to exclude six internal degrees of freedom. For this purpose he replaced g by $g - 2$ in the expression for ΔG (7). The exclusion of six internal degrees of freedom in order to take account of the external degrees of freedom is quite logical, but for this purpose it would be sufficient to replace g by $g - 2$ only in the first term, that is the bulk term, in expression (7). Frenkel' did not introduce any arguments to explain why he carried out this substitution in both terms; this substitution produces almost no change in the value of ΔG, whereas replacement in only the bulk term would lead to an increase in the rate of nucleation by a factor of $\sim 10^{20}$.

Rodebush[17], in an examination of the problem of the absolute entropy of formation of clusters, also concluded that it is necessary to make allowance for the external degrees of freedom, but he subsequently concluded[40] that this contribution is taken into account automatically in the classical theory. Adams and Band[50] made allowance for the contribution of the translational degrees of freedom, neglecting rotational degrees of freedom. As pointed out by Kuhrt[18], with the introduction of a factor taking account of the external degrees of freedom into the statistical sum, it is necessary at the same time to exclude six vibrational degrees of freedom. The introduction of Kuhrt's correction for the example of the condensation of water vapour at supersaturations close to the critical supersaturation corresponds to an increase in the rate of nucleation by a factor of $\sim 10^8$.

Courtney[16] made allowance for the partial pressure of the clusters in the calculation of ΔG, and this led to an increase in the expression for J given by Frenkel'by a factor $1/S$, which may reach very large values at the concentration of the vapours of non-volatile substances. In his next paper[21], Courtney combined this result with Kuhrt's conclusions[18]. The expression which he obtained is given in the Table.

The problem of the absolute entropy of formation of nuclei was examined in detail by Lothe and Pound[19], Sundquist and Oriani[20], Hirth[51], Feder and coworkers[52], and Russell and coworkers[53]. The last of the works cited gives a logical summary of earlier work and formulates the following scheme, which makes it possible to find the free energy of formation of a cluster: n nuclei, containing g molecules, are formed from ng molecules of the vapour by five processes: 1) the vapour is compressed until saturated; 2) the vapour is condensed to liquid at constant temperature and pressure; 3) the liquid is supercooled to 0°K; 4) the liquid is divided reversibly into n portions; and 5) the clusters are heated to a temperature T.

By writing expressions for the changes in free energy corresponding to these processes, the authors cited[19,20,51-53] obtained an expression for the free energy of formation of a cluster. The equations which they obtained on this basis for the rate of nucleation are also given in the Table. These expressions give values for J which are greater by factors of 10^{17}–10^{18} than those obtained by Frenkel's solution. It should be noted, however, that despite the strictly logical nature of the arguments cited above, the numerical estimates of the influence of the contribution of the external degrees of freedom to the rate of nucleus formation, made in the works cited[19,20,51-53], are of doubtful accuracy. In the calculation of the term corresponding to the fifth stage in the above scheme, the authors cited mechanically applied the formulae for the translational and rotational components of the heat capacity of polyatomic molecules. A cluster, however, is a much looser formation than a polyatomic molecule, since the energy of the van der Waals' forces holding the molecules in the nucleus is much less than the energy of valency bonds. Thus, as pointed out by Vukolovich[54], the rotation of the cluster as a whole can be neglected. The theory developed by Vukolovich for the heat capacity of water vapour containing molecular associates, which ignores the external degrees of freedom of the associates, shows such good agreement with the experimental data that it has been possible on this basis to construct an accurate water vapour phase diagram, which has been widely used for several decades in technical calculations. Hirth and Pound's argument[10] that the rate of nucleus formation may be much less than the calculated value, since the probability of attachment of molecules may decrease considerably with increase in the curvature of the surface, reaching values as small as 10^{-17}, does not appear convincing. It is true, however, that Okuyama and Zung[55] predicted theoretically a decrease in the accommodation coefficient a_c for a drop radius $\leq 10^{-5}$ cm, but in their calculations they ignored the relationship $\sigma(r)$, which may weaken this effect considerably. It follows from the experimental data of Wakeshima and Takata[56] that a_c increases slightly with decrease in r.

Recently, the previously published conclusions[18,19,50-52] were convincingly criticised by Reiss and Katz[57], who showed that there is no justification for the assumption made by Lothe and Pound and subsequent workers that the expression (7) given for the value of the free energy of formation of a nucleus corresponds to an aggregate with a stationary centre of mass. After examining the classical theory in detail, Reiss and Katz concluded that it ignores only the contribution of the translational motion of the centre of mass. It is evident that this feature can be taken into account by introducing Courtney's correction $1/S$ into the expression for J. The other inaccuracy which they detected requires the introduction of a factor V_g/gV_1, where V_g is the volume of a cluster consisting of g molecules, and V_1 the volume of a single molecule. According to the estimates made by Reiss and Katz, this factor has values from 1 to 10.

Courtney[58] pointed out that even if the Lothe–Pound correction is correct, it does not mean an increase in the rate of nucleus formation by a factor as large as 10^{17}, since in this instance the greater part of the mass of the vapour should be present in aggregates with subcritical dimensions. The marked decrease in the concentration of single molecules of vapour resulting from this feature should be accompanied by a decrease in the equilibrium concentration of critical nuclei, and hence by a decrease in J.

In a number of recent papers, the determination of the rate of nucleus formation in first-order phase changes is examined on the basis of the general relationships of the thermodynamics of irreversible processes[52,59], but the conclusions reached in these papers are so general in character that it would be premature to discuss the results obtained in this direction.

The classical theory neglects the heating of the nuclei by the liberated heat of condensation. This is quite justified when the condensing vapour is a small impurity in a noncondensing gas, in which the collision of the molecules of the gas with the nuclei ensures dissipation of the heat of the phase change, but in practice we often have to deal with the condensation of vapour in the absence of a carrier gas, and the neglect of the heating effect becomes unjustified. Russell and Feder[52] solved the problem of nonisothermal formation of nuclei by examining the equation for the two-dimensional diffusion of clusters in the g–ϵ plane, where ϵ

is the thermal energy of the cluster. Similar work was carried out by Bakhanov and Buikov[60].

All the expressions given in the Table describe nucleus formation under steady-state conditions. In a non-steady-state process, however, J is a function of time t. The problem of nucleus formation in non-steady-state conditions, arising in the instantaneous production of supersaturation, has been examined by a number of authors, including Zel'dovich[5], Collins[61], Wakeshima[62,63], Kantrowitz[64], and Frisch[65], who solved a time-dependent equation of form (3), with the assumption that at the initial moment of time the vapour is completely monomolecular and that the diffusion coefficient along the g axis:

$$D = (36\pi)^{1/3} v g^{1/3} p / \sqrt{2\pi m k T} \qquad (13)$$

is independent of g. Here, v is the volume occupied by one molecule in the liquid. The result obtained by these authors can be written in the form

$$J = J_0 \exp(-k^2/zt) \qquad (14)$$

where z is the rate of growth of the particles in molecules per second, and k a constant whose order of magnitude is equal to that of the number of molecules in the nucleus. The specific values obtained by different authors[5,61-64] for the time interval $\tau_{0.9}$ after which J reaches values equal to 0.9 times its steady-state value, differ considerably; the values lie in the range 10^{-5}–10^{-6} s, and $\tau_{0.9}$ increases with decrease in the probability of attachment. Wakeshima[62] and Frisch[65] tried to make allowance for the influence of associates in the vapour on the rate of attainment of the steady-state. Wakeshima found that in this instance the rate of attainment of the steady state is increased, but Frisch reached the opposite conclusion. It should be noted that there is an error, pointed out by Courtney[66], in Frisch's mathematical calculations.

To estimate the time required for steady-state conditions to be established, it is necessary to alter the relationship $J(t)$. It is possible to determine the time interval after which the concentration of critical nuclei reaches, let us say, 50% of its steady-state value. Andres and Boudart[67] solved Eqn. (3) by the method of statistical moments. The values which they obtained for $\tau_{0.5}$ are smaller by an order of magnitude than the values of $\tau_{0.9}$ obtained by other workers[3,62-65]. A simple approximate expression for $\tau_{0.9}$ was obtained by Farley[68]:

$$\tau_{0.9} = 25 g^{*2} \sqrt{2\pi m k T} / 4\pi r^{*2} \rho$$

A third method for studying the problem of the attainment of the steady state involves numerical solution of a system of equations of type (1) for all values of g from 1 to a certain value of $g > g^*$. The first attempts of this kind were made by Christiansen[69] and Turnbull[70], who solved systems of 4 and 25 equations respectively. Courtney[71] used a computer to solve a system of equations describing the changes with time in the concentrations of clusters containing from 20 to 120 molecules. The calculations were carried out for the condensation of water vapour at −10°, −40°, and −60°C and supersaturations of 5.0 and 6.0. Courtney assumed that for nuclei with $g < 20$ the equilibrium concentration is reached instantaneously. Under these conditions, $\tau_{0.95}$ amounted to 1.5–27 μs. This is smaller by a factor of about 2–3 than that obtained from the published relationships[62-65] and is fairly close to the values which can be obtained using Farley's formula[68]. For values of $S = 5$, Courtney obtained values of $\tau_{0.95}$ which were smaller by a factor of ~ 10 than those obtained for $S = 6$. The calculations were carried out with the assumption that $a_c = 1$.

Chakraverty[72] recently solved Eqn. (3) without making any assumptions regarding the quantities α_g and β_g, which were regarded as unknown functions of g. His results show qualitative agreement with Courtney's conclusions[71] and order of magnitude agreement is also observed in the values of τ.

As pointed out by Sutugin and Fuchs[73], steady-state conditions are not attained in practice at very high supersaturations, since the supersaturation changes considerably throughout the entire process of nucleation, whose duration may not exceed 10^{-5} s. Under these conditions, calculation of nucleus formation is possible only by solving a system of equations of type (1). The problem is then simplified, since under conditions of high supersaturation the dimensions of the critical nucleus are very small and the number of equations in the system is also small. Moreover, the total duration of the process becomes commensurate with the time interval within which the nucleus collides with an average of one molecule of the vapour. This makes possible a simple calculation of the quantity of vapour involved in molecular collisions with nuclei with all dimensions represented, and also with the growing supercritical particles, and this makes it possible to avoid the assumption, which is usually made in the classical theory, that the supercritical particles are removed from the system and replaced by an equal mass of vapour.

An attempt to make allowance for the influence of the heat of condensation during the attainment of the steady state was made by Probstein[74], who expressed the probability of volatilisation of a molecule from the growing nucleus as follows:

$$\beta_g' = \beta_g \left[1 + \theta \frac{U_\infty}{RT^2} \right] \qquad (15)$$

where β_g is the probability of volatilisation under isothermal conditions, U_∞ the heat of condensation, $\theta = J_g U_\infty c m / f_g F \alpha_g a_c l$, f_g the distribution function for the concentrations of the clusters, and l the heat capacity. Probstein introduced a new time $t' = t/[1 + U_\infty^2 c_1 m / l a_c R T^2]$ and solved Eqn. (3). The method of solution which he used is analogous to the method of Kantrowitz, but since allowance was made for the heat of condensation it was found that the attainment of the steady state requires a time interval which is several times larger. As pointed out by Feder and Russell[52], a fundamental study of the problem of non-steady-state nucleus formation under nonisothermal conditions requires the solution of a three-dimensional diffusion equation in g–ϵ–t space, and this presents insurmountable difficulties. The approximate estimates which they made showed that the liberation of the heat of condensation during the formation of nuclei in water vapour under the conditions which usually exist in experiments with a Wilson chamber may lead to an increase in $\tau_{0.9}$ by a factor of 2–3 compared with isothermal conditions.

Luke[75] solved the problem of the rate of cooling of hot atoms of a metal suddenly placed in a cold inert gas. When the concentration of metal vapour is low, the excess of thermal energy of the atom is reduced by a factor of 2 in a time interval of ~ 10^{-7} s. From this it may be concluded that if the mass of condensing vapour amounts to only a small fraction of the total mass of the vapour–gas mixture, the liberation of the latent heat of the phase change may not have a marked influence on the value of J.

On going to the problem of limiting supersaturation, it is necessary first of all to note that there are at least two interpretations of this concept. The first interpretation is related to the fact that the dimensions of the cluster

cannot be less than the distance between the centres of the molecules in the liquid (or the solid). This was first pointed out by Frenkel'[7], whose viewpoint was supported by other workers[76-78] who tried to calculate the maximal supersaturation using the Gibbs–Kelvin equation, which obviously cannot be used for this purpose. Bykov and Teverovskii[76] assumed that the weak dependence of the rate of nucleation in water vapour on its supersaturation, observed by a number of workers, can be attributed to the attainment of limiting supersaturation. In Bykov and Teverovskii's own experiments, however, only the magnitude of the critical nucleus calculated according to the Gibbs–Kelvin equation remained constant, and the rate of formation of the nuclei changed considerably with change in the supersaturation.

The second concept of limiting supersaturation is based on the idea that under certain conditions the work of formation of the nucleus should become zero. The theory of second-order capillary effects, developed by Shcherbakov[79] and the Cahn–Hilliard–Hart theory[35-37], in particular, lead to this conclusion. From this concept it follows that the nucleus corresponding to limiting supersaturation may contain tens or hundreds of molecules. The formula put forward by Shcherbakov and coworkers[32,79] for calculating the limiting supersaturation contains the macroscopic density of the liquid. It follows from published work[35-36], however, that as the spinodal is approached the density of the nuclei decreases, approaching the density of the vapour.

A number of authors[80-82] consider that ΔG^* does not become equal to zero even on the spinodal. This view is contrary to Gibbs' classical theory of surface tension. Gibbs[12] in fact showed that the work of formation of a nucleus amounts to $\frac{1}{3}\sigma F$, where F is the surface area of the nucleus. Rusanov[83] pointed out that if σ becomes zero, ΔG should also become zero. Thus this concept should be correct at least for the condensation of vapour close to the critical point.

The conclusion that the minimal nucleus should contain much more than two molecules, that is that there is no vapour pressure with which very small aggregates can be in equilibrium, follows from the work of Shcherbakov[32,33], Bakhanov and Buikov[84], and Cahn, Hilliard, and Hart[35-37]. This conclusion is not completely general, however, since calculations[16,73] have shown that in the supersaturated rarefied vapours of substances with low volatility the minimum of the $\Delta G(g)$ relationship may correspond to dimers or even monomeric molecules. For the condensation of the vapours of these substances with low volatility, the concept of limiting supersaturation can be derived from the following considerations. Let us assume that we have a mixture of the vapour and a noncondensing gas. Let us cool this mixture along the isochore to a temperature at which the critical nucleus contains two molecules. The concentration of the dimer (with the condition that constant supersaturation is maintained) will be determined by the ratio of the rates of formation and breakdown of the dimeric molecules. With decrease in temperature the rate of the first process will decrease comparatively slowly, since the number of collisions between the molecules is proportional to $T^{1/2}$, whereas the second process stops almost completely at a certain temperature (this follows from calculations for rarefied silver vapour[73]). Thus the rate of formation of the critical nuclei—dimers—will first increase due to the decrease in the rate of breakdown, and then decrease as a result of the decreased number of collisions between individual molecules. Limiting supersaturation, at which the rate of nucleus formation is determined exclusively by the frequency of the collisions between individual molecules, can be obtained only in the condensation of a vapour with a sufficiently low partial pressure, otherwise exhaustion of the vapour phase takes place during the cooling of the vapour–gas mixture.

In Kachurin's opinion[85], at high supersaturations the rate of nucleus formation should be appreciably greater than that obtained in the classical theory, since in this instance, in addition to the gradual increase in heterophase fluctuations, we may have conversion of homophase fluctuations (that is fluctuations not exhibiting the structure of the new phase) into heterophase fluctuations. On the other hand, it follows from the Cahn–Hilliard–Hart theory[36-38] that as the spinodal is approached the difference between homophase and heterophase fluctuations should disappear.

As already noted, the classical theory considers only the condensation of a one-component monomolecular vapour. The vapours of most substances, however, consist of mixtures of associates. A generalised equation taking account of the possibility of collision with one another for associates and subcritical nuclei of different dimensions can be written in the form

$$\frac{dW_g}{dt} = -\sum_{j=0}^{N+1} K_{jg}W_g + \sum_{j=0}^{N} K_{gj}W_j, \quad g, j = 1, 2 \ldots N$$

where Kjg is the probability of conversion of nucleus j into g, and K_{gj} the probability of the reverse change. The analytical solution of this equation presents considerable difficulty. Frisch and Willis[86] carried out the analytical solution of a simplified equation describing nucleus formation in a vapour consisting of a mixture of the dimer and monomer. Courtney[21] used numerical methods for the same purpose. According to his results, nucleus formation should take place several times more rapidly in the presence of dimers. As correctly pointed out by Katz and Salsburg[87], however, the authors cited[21,86] neglected the decrease in supersaturation due to the fact that part of the mass of the vapour is included in the dimer. In fact, the equilibrium concentration of critical nuclei is proportional to the concentration of monomolecular vapour [(Eqn. (2)], so that association should decrease the rate of nucleus formation. An analogous conclusion was reached by Sutugin and Fuchs[73], who calculated the condensation of silver vapour for the conditions where an appreciable proportion of the condensing substance is included in subcritical associates.

Nucleus formation in a two-component condensing vapour has been examined theoretically by Neumann and Doring[88] and also by Reiss[89].

In addition to the above theory, based on the Szilard–Farkas model, attempts have been made to develop other theories of phase transformations. Expressions for the equilibrium concentrations of nuclei are obtained in the Mayer–Born–Fuchs equation of state theory[38]. The general form of these expressions is similar to that of Frenkel''s equation for the equilibrium concentration of a nucleus with given dimensions, but the determination of the equilibrium concentrations in the Mayer–Born–Fuchs theory requires extremely tedious calculation of the so-called group integrals, which take account of the contribution of the interaction between pairs of molecules making up the cluster to the statistical sum for the cluster. The problem is complicated considerably by the need to calculate the group integrals for all possible isomeric configurations. Recently, however, considerable progress has been made in this direction. Kilpatrick and Katsura[45] and Barker and Leonard[90] developed a relatively simple method for calculating the group integrals for nuclei

containing up to ten molecules. These authors were able to calculate even the fifth virial coefficient of a gas containing associates. Since during condensation the concentrations of small ($g < 10$) nuclei are almost the same as the equilibrium concentrations, the latest results of the theory of the equation of state may be useful for calculations of nucleus formation at high supersaturations.

In the opinion of Christiansen[91] and La Mer[92], the nucleus of liquid phase in a vapour should contain not more than 4–5 molecules, which is considerably less than the number assumed in the classical theory. They also assumed that for each substance the dimensions of the nucleus should depend very little on temperature, the concentration of the molecules of the vapour, and the supersaturation. Courtney[93] described this model as the "constant-number theory" and pointed out that it should be suitable for the description of nucleus formation in substances with a high intermolecular interaction potential. Sutugin and Fuchs[73] calculated nucleus formation in silver vapour condensing as a result of the cooling in a submerged stream at concentrations of 10^{16}, 10^{15}, and 10^{14} molecules cm^{-3}, and found that the dimensions of the nucleus should correspond to 5–6 molecules for the first two concentrations. For the third concentration, the rate of nucleation became appreciable when the nucleus contained six atoms, after which the cross-section of the nucleus decreased with increase in supersaturation, and for the greater part of the total duration of the process the nucleus consisted of only two atoms. For all three concentrations, the supersaturation increased by several orders of magnitude during nucleus formation. From this it follows that at high supersaturation the dimensions of the nucleus in fact change little.

Independent attempts to develop a theory of nucleus formation which does not make use of the Szilard–Farkas model have been made by Reiss[94] and Hill[95], but the models which they have proposed have been insufficiently developed, and it would be premature to discuss their importance.

Results useful for an understanding of the initial stage of the formation of associates were obtained by Storgyn and Hirshfelder[96], who examined the problem of the lifetime of a combination of two molecules, formed by the collision of two single molecules, or, in other words, the problem of the duration of collisions in pairs. These authors calculated the duration of the collisions of pairs in inert gases, with the assumption that the interaction between the molecules is described by the Lennard-Jones equation. The method which they developed makes it possible to calculate both the kinetics of formation of the dimers and their equilibrium concentration, but only by using computers.

Vukolovich's equation of state theory[54] was used by Nikandrov[97,98] to calculate the concentration of aggregates in water vapour for $S = 1$.

All that has been said in this section refers to the formation of the nuclei of a liquid phase in vapours, but since experimental data indicate that the particles of condensation aerosols are amorphous, particularly when the condensation takes place at high supersaturations[99–103], it may be assumed that in most instances the condensation of a vapour in bulk leads to the formation of nuclei of a liquid phase, which can crystallise only subsequently. According to data obtained by different authors, the condensation of water vapour below −40°C or below −65°C leads to the formation of ice nuclei, but this has been disputed by Dufour and Defay[104], who considered that ice is formed only by the freezing of water droplets produced from the vapour.

Unlike the nuclei of the liquid phase, crystalline nuclei are characterised by anisotropy of the surface energy. Because of the small dimensions of the nuclei, a marked contribution to the surface energy is made by the apices, edges, steps, and fractures on the surface of the faces. The growth of droplet nuclei includes only one process—the adsorption of molecules from the vapour phase—whereas the formation of a crystallite should include four molecular processes: the adsorption of molecules of the vapour on the surface, the nucleation of two-dimensional discs on the surface of the faces, surface diffusion, and the attachment of molecules to elementary steps, the free energy of formation of the crystallite being a monotonic function of the number of molecules of which it is made up. Stranski and Kaischev[105,106] and Carrera and Burton[107] examined the process of crystal formation, taking account of only the formation of two-dimensional discs on the faces, and assuming that in nucleation the concentrations of the clusters are equal to the equilibrium concentrations. An expression for the rate of formation of crystalline nuclei, including a non-equilibrium factor, was obtained by Becker and Doring[3,108], who calculated the bond energy of the nucleus using a model involving the interaction between pairs of nearest neighbours. Taylor[109] solved the problem of the bond energy for the crystalline nuclei of alkali metal halides, containing up to 13 molecules, by means of the quantum theory of first-order perturbations. When calculating the free energy of crystalline nuclei, as for the nuclei of a liquid phase, it is necessary to take account of the contribution made by the external degrees of freedom.

III. METHODS OF CALCULATING THE FORMATION OF CONDENSATION AEROSOLS

In the formation of a condensation aerosol, the formation and condensation growth of nuclei take place simultaneously. The consumption of vapour for the growth of the particles leads to a decrease in the supersaturation, and nucleation stops. Thus the calculation of the number and dimensions of the particles formed should make allowance for both these processes, and also for coagulation at high concentrations of the particles formed.

Calculation methods of this kind are required for comparing theory with experiment, and also for predicting the parameters of aerosols formed in various technological processes.

Existing methods of calculation can be divided into analytical and computational. The analytical method for calculating the formation of an aerosol during the adiabatic expansion of a gas containing the vapour of a condensable substance was first developed by Tunitskii[110], who carried out the simultaneous solution of the equations for conservation of mass of the condensing substance and for rate of formation of nuclei, assuming the temperature to be constant. He obtained two expressions for the number of drops formed. In the derivation of one of these expressions it was assumed that the rate of growth of the drops is determined by a gas-kinetic mechanism, and in the second instance a diffusion mechanism was assumed. Tunitskii also estimated the error introduced by neglecting the heat of condensation.

Oswatitsch[111,112] developed an analytical method for calculating the change in the number of drops and the mass of condensate during the condensation of vapour in a Laval nozzle. For this purpose he carried out the simultaneous solution of four differential equations: the continuity equation and the equations for the preservation of momentum,

preservation of energy, and condensation. The problem of aerosol formation during the adiabatic cooling of a vapour–gas mixture was also solved by Corner[113], and later by Bakhanov and Buikov[60], who took account of heat exchange with the external medium and the change in temperature resulting from the heat of condensation. Any of the steady-state solutions for the rate of nucleus formation can be used in any of the above methods of calculation.

Raizer[114] solved the problem of condensation in a cloud of vapour undergoing adiabatic expansion into a vacuum, but he neglected the liberation of the heat of condensation, and this is inadmissible in the examination of condensation in the absence of a noncondensing gas capable of dissipating the energy of the phase change.

Disadvantages common to all analytical methods of calculation include the need for simplifying assumptions in the derivation, and also the fact that these methods can predict only the number of particles formed and their mean dimensions, and not the parameters of the size distribution. Analytical methods of calculation cannot include an examination of coagulation. In the calculation of the growth of the particles it is necessary to assume that throughout the entire process, growth takes place by a single mechanism, whereas the mechanism changes with increase in the dimensions of the particles. An analytical solution is also impossible if the temperature and concentration are functions of more than one variable[115–117]. Because of these features, methods for the successive calculation of the condensation, in which the duration of the process is broken down into tens or hundreds of intervals or stages, have been widely used. It is assumed that in each range of temperature, the concentration and other significant parameters remain constant, and that they undergo sudden changes on going to the next interval. The number of nuclei formed in each interval, and the growth of the particles previously formed, are calculated.

Amelin[118] described a program for calculating the condensation when a turbulent vapour–gas stream is cooled in a heat exchanger, Griffin and Sherman[119], Stever[120], and Hill, Wittig, and Demetri[121] described in detail stepwise methods for calculating the condensation in Laval nozzles, and Lund and Rivers[122] described methods for calculating the condensation in a Wilson chamber.

In the works cited, the calculations were carried out for situations where the supersaturation depends only on time or only on the coordinate. Higuchi and O'Konski[123] put forward a method for determining the number of nuclei formed in the zone in which a hot inner stream mixed with a cold surrounding gas. They expressed the number of particles formed in unit time by means of the integral $\int_0^\infty J(n)\frac{dV(n)}{dn}dn$, where $V(n)$ is the volume of the mixing zone bounded by a surface with constant value n, that is the ratio, averaged with respect to time, of the weight concentrations of the cold and hot gases. Higuchi and O'Konski neglected the quantity of vapour used up in the growth of the particles, and assumed that the supersaturation falls below the critical value entirely as a result of the dilution of the condensing mixture by fresh portions of cold gas. This is quite justifiable, if the supersaturation exceeds the critical value only in a very small part of the mixing zone of the stream S. If however high supersaturations are reached in the zone in which the hot vapour–gas stream mixes with cold air, the quantity of vapour used up cannot be neglected. Sutugin and Fuchs[73] developed a method for the stepwise calculation of the condensation in the stream, in which the entire mixing zone is broken down into intervals whose boundaries are the n-const surfaces. A program for calculating the formation of an aerosol under conditions in which fresh portions of condensing gas are formed continuously as a result of a chemical reaction in the gaseous phase was compiled by Dunham[124].

Carstens and coworkers[125] carried out a numerical estimation of the decrease in the rate of nucleus formation due to the decrease in the concentration of vapour close to the growing particles, and found that this effect is extremely small.

Friedlander[126] put forward a calculation of the formation of condensation aerosols in a submerged stream by means of the theory of similarity and calculated the dimensionless criteria, whose function should be the dimensions of the particles of the resulting aerosol. Like all methods based on the use of the theory of similarity, Friedlander's method requires the preliminary empirical determination of the dependence of the parameters sought on each of the criteria, the number of which may vary from 4 to 8. It is therefore not surprising that this method has not yet found application.

The formation of aerosols at high supersaturations is often accompanied by coagulation, and, as pointed out by Petryanov and Tunitskii[127], it is coagulation which should determine the degree of dispersion of the aerosols formed under these conditions. As a rule, polydisperse aerosols are formed during spontaneous condensation. A number of recent papers[128–130] are devoted to numerical methods for calculating the coagulation of aerosols by integration of a system of equations of the form:

$$\frac{dn_i}{dt} = \sum_{j+k=i} K_{jk}n_jn_k - \sum_{l=1}^{\infty} K_{jl}n_jn_l$$

where n_i is the concentration of particles formed from i primary particles, and K_{jk} the collisional rate coefficients. The volume of the calculations increases with increase in the degree of coagulation, so that this method cannot be used to calculate the coagulation leading to an increase in the dimensions of the particles by a factor of more than ~ 100. Rosinski and Snow[131] proposed a simplified scheme for the calculation of coagulation. According to the ideas of these authors, the continuous distribution function of the aerosol particles with respect to dimensions is replaced by a discontinuous function, and it is assumed that the aerosol consists entirely of particles in which the numbers of molecules are given by the figures 2^i, where i is an integer. The collisions of particles of the 2^i classes leads to the formation of particles of the 2^{i+1} class. It is then arbitrarily assumed that the collisions of particles of classes 2^i and 2^{i-1} also leads to the formation of particles of class 2^{i+1}, but in an amount corresponding to $(2^i + 2^{i-1})/2^{i+1}$ times the number of particles of class 2^i taking part in the collisions. In the collisions of particles of classes 2^1 and 2^{i-j}, where $j > 1$, however, the dimensions of the former remains unchanged, but their number increases by a factor of $(2^i + 2^{i-j})/2^i$. This scheme was used by Stockham[132] for calculations on silver vapour, and he assumed that the collision of two atoms leads irreversibly to the formation of a twin, etc. As shown by Sutugin and Fuchs[73], this is justifiable only at sufficiently low concentrations of vapour and a high rate of cooling of the vapour–gas mixture, but since the size distribution of the aerosol finally obtained is still determined by the coagulation, Stockham's results are of undoubted value. He found that Rosinski and Snow's scheme correctly predicts the degree of dispersion of the resulting aerosols if values approximately twice those obtained in the formula for the number of collisions between gas molecules are used for the coagulation constant in the

CHEMICAL SOCIETY REFERENCE LIBRARY BURLINGTON HOUSE, W.1

calculations. This last feature confirms Fuchs and Sutugin's theoretical and experimental conclusions[133] that the forces of intermolecular interaction should increase considerably the coagulation constant of highly dispersed aerosols. In later work[73], the value 2.21 was obtained for the factor corresponding to the increase in the rate of coagulation of silver particles as a result of molecular forces.

Strictly speaking, the forces of intermolecular interaction should also influence the condensation growth of highly dispersed aerosols, but the introduction of a correction analogous to Sutherland's correction can hardly be meaningful, since there are almost no data on the magnitude of the condensation coefficient and its dependence on the curvature of the surface on which the condensation is taking place.

IV. EXPERIMENTAL STUDIES OF THE FORMATION OF CONDENSATION AEROSOLS

The aim of the experimental study of this phenomenon may be the determination of the critical supersaturation for a given substance and the temperature dependence of the critical supersaturation, or the determination of the dependence of the rate of nucleation on supersaturation and the influence of various factors on this rate. The development of the size distribution of particles during the formation of a condensation aerosol is of considerable interest.

The chief difference between existing methods for studying spontaneous condensation lies in the methods for the production of the supersaturation in the condensing vapour; this may be brought about by adiabatic cooling of the vapour or vapour–gas mixture (Wilson cloud chamber and Laval nozzle), by heat exchange through the walls of the apparatus, and by mixing gas streams at different temperatures.

The oldest instrument used to study spontaneous condensation is the Wilson cloud chamber[134]. Adiabatic expansion in a Wilson chamber can be brought about by means of a piston, a diaphragm, or a bellows, or by suddenly connecting the working volume to a vacuum reservoir. A number of workers have studied the problem of the adiabatic nature of the expansion taking place in the chamber. Flood[135] concluded that the expansion is adiabatic so long as the volume of the chamber is not less than 1 litre, and the degree of expansion not less than 1.4, but Stachorska[136], using an inertia-free temperature recorder, proved that the expansion is non-adiabatic in a chamber with a volume of 1 litre even for expansions of 1.2, and concluded that it is necessary to use a chamber with a volume of 30 litre, in which Thomson's equation for the adiabatic decrease in temperature is obeyed rigorously. The use of a large chamber is also desirable in order to decrease the loss of vapour and nuclei as a result of diffusional deposition on the walls.

These features restrict the application of the Wilson chamber to the range of low supersaturations. Since at supersaturations which are not too much greater than the critical supersaturation the number of nuclei formed is limited, it is necessary to take careful precautions to remove foreign condensation nuclei (including ions) from the chamber. For this purpose the chamber is filled with a filtered gas; before the start of the main measurements, several successive expansions are carried out, and the foreign condensation nuclei become larger as a result of the condensation of vapour, and are deposited on the floor of the chamber. Ions are removed by applying an electrical field.

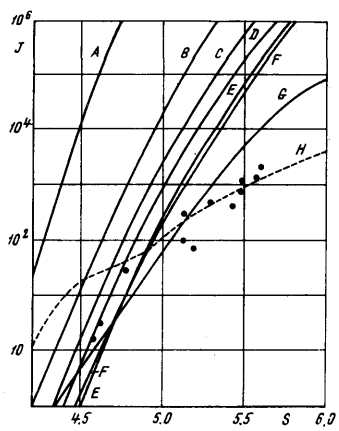
Since the end of last century, the Wilson chamber has been used many times to determine the critical supersaturation in the vapours of water, alcohols, and various other liquids, and the data obtained by its use over several decades were assumed to provide irrefutable proof of the correctness of the classical theory. Recently, however, a different viewpoint has been put forward[137–139]. Mason[137], in an examination of data on critical supersaturation obtained by Wilson and Powell[140], Volmer and Flood[141], Frey[142], Sander and Dahmkohler[143], Barnard[144], and Pound and coworkers[138], pointed out that Wilson and Powell[140] used an unsatisfactory method for detecting the start of condensation, and that the other authors cited[141–143] took inadequate measures to eliminate foreign condensation nuclei. In the much more thorough work of Barnard[144], Pound and coworkers[138], and Madonna and coworkers[139], the experimental values of the critical supersaturation coincided with the theoretical values only at temperatures $< 260°C$. Pound and coworkers[138] and Madonna and coworkers[139], like Mason[137], consider that in all work on the study of spontaneous condensation in the Wilson chamber, condensation on ions or foreign particles was in fact observed. Hollomon and Turnbull[145] found that the Volmer–Flood formula effectively predicts the critical supersaturation in the vapours of water and a number of organic liquids. Clark and Rodebush[146] found that different values are obtained for the critical supersaturation in water vapour when He or N_2 are used as inert gas. Madonna and coworkers[139] observed the same effect for the condensation of water vapour in O_2 and N_2, but Courtney[147] did not observe this effect. The scatter in the experimental values of the critical supersaturation in Courtney's work, however, was very high, even in the same carrier gas.

A number of papers have been devoted to a comparison of experimental data on the rate of nucleation with steady-state solutions of the classical theory. The rate of nucleation can be measured if the concentration of particles formed and the time interval during which they are formed are known. The first work in this direction[141,142,148,149] suffered from a large number of unsatisfactory experimental features, and the response time of the chambers in these experiments was not determined, so that it is not surprising that their results showed poor agreement with Tunitskii's calculations[110].

Stachorska[150], in a study of the condensation of C_2H_5OH vapour, obtained very good agreement with the results of his own calculations, based on Frenkel''s equation with allowance for the quantity of vapour used up in the growth of the particles. The results of Allard and Kassner[151], Kassner and Schmidt[152], and Schuster and Good[153] show good agreement with the calculations of Courtney[71] and of Lund and Rivers[154]. Although Courtney's calculations[71] were carried out using the Frenkel'–Courtney equation (see Table), whereas Lund and Rivers[154] used the Becker–Doring equation, these two equations differ only in a small numerical factor. At low supersaturations, both equations are readily justified within the limits of experimental error, but at high supersaturations the Frenkel'–Courtney equation is better. The introduction of the Courtney correction $1/S$ would also improve the agreement with theory in Stachorska's experiments, particularly at higher supersaturations, where this correction is greater. The results of the comparison of theory and experiment are given in Fig. 1.

Edwards and Woodbury[155] studied nucleus formation in supersaturated ^4He vapour. Since their experiments were carried out at absolute temperatures of several degrees,

it may be assumed that heterogeneous formation of nuclei did not take place, since at such low temperatures, no substance is capable of generating condensation nuclei. Edwards and Woodbury found that the rate of nucleation is greater by several orders of magnitude than that predicted by the classical theory, and depends to a marked extent on the supersaturation. The number of particles formed in these experiments was very large, and this made it impossible to attribute the results to condensation on ions which might have remained in the chamber after the application of the electric field. This discrepancy is possibly due to anomalous physical properties in liquid helium.



Theoretical and experimental data on the dependence of the rate of nucleus formation in cm^{-3} s^{-1} on the supersaturation for water vapour in an atmosphere of helium at −5°C from various papers. Theoretical curves: A,[143] B,[1] C,[4] D,[68] E,[3] F,[2] and G,[66]. Experimental data: H[152] and solid circles[151].

In the calculation of the rate of nucleation in the works cited, the values of the surface tension for a flat liquid surface were assumed. Pound and La Mer[156] and Byers and Chary[157] compared experimental results with the calculation of $J(S)$ with allowance for the relationship $\sigma(r)$ found by Tolman, and found that the agreement between theory and experiment is lower when allowance is made for this relationship.

Nucleation under non-steady-state conditions was studied by Allard and Kassner[151] using a Wilson chamber with two-stage expansion. The second, slow stage of the expansion was carried out in order to compensate for the increase in temperature resulting from heat exchange. This precaution was necessary, since the duration of the condensation in their experiments was greater than usual. The number of drops formed was recorded by fast cinematography. According to Allard and Kassner[151], the rate of increase in J shows satisfactory agreement with Courtney's calculations[71], but as the vapour is exhausted the rate of decrease in J is less than that given by the calculations. A number of papers[138,139,143] describe the study of the formation of ice crystals in supersaturated water vapour at low temperatures. The formation of the ice crystals was detected from the freezing of supercooled sugar solution placed in the Wilson chamber. The freezing of the solution is initiated by ice crystals deposited from the chamber. Although in the works cited the formation of ice crystals was detected at temperatures below the range between −40° and −65°C, Mason and Maybank[158] and Mason[137] point out that there is no proof that the crystals were formed from the vapour, and not by the crystallisation of nuclei of supercooled liquid. Changes in the mechanism of the formation of nuclei could not be detected[139] in butanol vapour at temperatures as low as −75°C.

Flood[159] studied nucleation in a binary mixture of water and C_2H_5OH vapours and obtained good agreement with the theory of Neumann and Doring[68], but Flood's experiments[159] suffered from all the unsatisfactory features characteristic of early work with the Wilson chamber, so that it must be accepted that further study of nucleus formation in binary mixtures is required.

In concluding the examination of results obtained using the Wilson chamber, it may be noted that work carried out in recent years provides quantitative confirmation of the correctness of the classical theory, and of all the equations, Frenkel's equation with Courtney's correction is satisfied with greatest accuracy.

Recently, the study of condensation in supersonic aerodynamic nozzles has acquired considerable importance. Here, as in the Wilson chamber, supersaturation is established by adiabatic cooling. For all substances except helium, the decrease in the equilibrium vapour pressure due to the decrease in temperature on adiabatic cooling takes place more rapidly than the decrease in the static pressure, so that sufficiently great isoentropic expansion of the vapour–gas mixture or even the pure gas may lead to the production of high supersaturations. If the flow of the stream in a Laval nozzle is not accompanied by condensation, the change in the static pressure (that is the pressure which can be measured by an instrument moving with the stream) is described by the equation for an adiabatic process. The condensation of vapour leads to a sudden increase in pressure, proportional to the mass of the condensed substance, relative to the "dry" isoentropy, and an increase in temperature as a result of the liberation of the heat of condensation. Experimental methods for studying condensation in Laval nozzles are based on measurement of the distribution of the static pressure and temperature along the axis and comparison of the results obtained with the "dry" isoentropy. The magnitude of the deviation of the pressure from the dry isoentropy can be calculated by one of the methods mentioned in section III, and the comparison of the calculated and experimental values forms the basis of methods for verifying theories of condensation. Thus comparison of theory and experiment in this instance is carried out indirectly. Detection of fog formation by optical methods is also used, but since the droplets begin to produce appreciable light scattering only when they reach dimensions of 10^{-6} cm, the formation of the fog is detected with a slight delay, which may amount to 10^{-4} s. This last feature, which is not taken into account, has in turn been responsible for the erroneous opinion that a long time interval is required for the attainment of the steady state in nucleation[160].

Oswatitsch[111] showed that the experimental data of Binnie and Woods[161] and Yellot[162] on the condensation of water vapour can be correctly approximated by the results of theoretical calculations with appropriate selection of the values for the surface tension of water. Gyarmathy and Meyer[163] obtained quantitative agreement between their own analytical calculations based on Frenkel's equation

and experiments on the condensation of sodium and water vapours. Wegener and Pouring[164] established that the results of the study of the condensation of water vapour can be approximated by any of the equations of Frenkel', Yang, Becker and Doring, or Barnard, with the selection of appropriate values for the accommodation coefficient.

A number of papers have described the study of the condensation of nitrogen in Laval nozzles. Comparison of the results of this work with calculations is made difficult by the absence in this instance of a noncondensing gas, so that the heating of the growing particles by the heat of condensation cannot be neglected. Moreover, in the presence of various impurities, such as CO_2 and H_2O, heterogeneous condensation in fact take place[165,166], since the impurities, which condense before the start of the condensation of nitrogen, form condensation nuclei. Thus only the experiments on the condensation of pure dry nitrogen are of interest. Studies of this kind carried out by various authors have given results which show good agreement with one another[167,168]. Some of these data were compared by Griffin and Sherman[169] with the results of a stepwise calculation of condensation using Courtney's equation[16] and were found to show good agreement with these calculations. Quantitative comparison of theoretical calculations with the results of experiments in Laval nozzles leads to the conclusion that the discrepancy does not exceed the error in the calculations and the error in the measurements, which are fairly high. Qualitative agreement between experimental and calculated data was obtained by Norgen[170,171] who collected particles of aluminium and mercury chlorides formed by condensation of the corresponding vapours in a laval nozzle and studied them on an electron microscope. Thomann[172,173] found that crystals of ice with dimensions ~ 14 Å are formed by condensation of water vapour in a supersonic jet.

In addition to condensation in aerodynamic tubes, which have been studied by a number of workers[161-173], condensation in gas streams flowing through a nozzle with small diameter into a high vacuum has been studied intensively in recent years. By using a nozzle cooled with liquid helium it is possible to obtain streams with Mach numbers of up to 100 and a temperature of the order of several degrees Kelvin. An apparatus of this kind has been described in detail by Kantrowitz and Grey[174], and by Becker, Klingerhofer, and Lohse[175]. The flow of H_2, N_2, and He at a pressure of ~ 600 mmHg into a vacuum of ~ 10^{-5} mmHg has been studied[175]. The density of the flowing beams was varied in the range 10^{15}–10^{19} molecules cm^{-2} s^{-1}. It was established that the addition of another gas which does not condense under the conditions of flow to the gas condensing in the nozzle increases by a large factor the mass consumption of the condensing gas on passing through the nozzle. Thus dilution of N_2 with four times its volume of H_2 increased the density of the stream by a factor of 30. The addition of the noncondensing gas evidently facilitates condensation to the extent that it facilitates dissipation of the heat of association. The time required for attainment of the steady state was also estimated, and it was found that its order of magnitude agrees with that predicted by theory.

Henkes[176] used a mass spectrometer to detect the formation of aggregates in the apparatus of Becker, Klingerhofer, and Lohse[175]. He was able to detect aggregates containing up to 550 molecules in an H_2 stream. At the same time he established that the intensity of the electron beam bombarding the molecular beam being studied influences the distribution of the concentration of aggregates in the latter. Leckenby and coworkers[177] passes various gases and gas mixtures from a high-pressure cylinder into a mass spectrometer chamber through a nozzle with diameter 10^{-3} mm and established that aggregates of molecules are formed. When gas mixtures were used, the aggregates also consisted of different molecules. The concentration of aggregates was comparable with the concentration of monomeric molecules. An interesting feature is that for water vapour, aggregates with an even number of molecules were formed in larger quantities than the aggregates with an odd number of molecules. Greene and Milne[178] showed that the addition of 2.5% CO_2 to argon being passed through a nozzle into a mass spectrometer increases the ratio of the concentrations of monomer and dimer in argon by a factor of 3. The authors considered that this proves that the formation of the complexes is not due to the action of the ion source.

The determination of the concentration of aggregates in gases, even when these are not under supersaturation conditions, is of considerable interest for the verification of work on the calculation of the equilibrium concentrations of small aggregates. Bentley[179] used a combination of mass spectrometry and the Kundsen effusion technique to measure the concentration of associates of molecules in CO_2. He showed that the concentrations of the associates are given by power functions of the concentration of the monomer. In particular, he found that $C_2 \sim C_1$,[2,85] $C_3 \sim C_1$,[7,8] and $C_4 \sim C_1$.[11] Bentley showed that CO_2 contains aggregates of up to 23 molecules.

It has not as yet been possible to interpret quantitatively the results of mass spectrometric studies of the formation of nuclei. The attempt made by Dunning[180] cannot be regarded as successful, since he used macroscopic values of the surface tension and density in the calculation of the equilibrium concentrations of these small clusters.

Milne[181] compared the results of mass spectrometric determinations of the formation of dimers during the flow of argon through a molecular nozzle with calculations by the method of Storgyn and Hirshfelder[96] and obtained satisfactory agreement.

Spontaneous condensation during the cooling of a vapour–gas stream in a heat exchanger with turbulent flow was the subject of a theoretical and experimental study by Amelin[118,182]. An ultramicroscope was used to determine the mean dimensions and concentration of droplets of sulphuric acid and glycerol, and the results were compared with those obtained by a theoretical stepwise calculation. It was shown that when Frenkel''s equation is used, satisfactory agreement with experiment is obtained for glycerol, the experimental and theoretical values of the count concentration differing by a factor of not more than 3–4. For sulphuric acid, however, the results of calculations using the Becker–Doring equation gave better agreement with experiment.

A third method for achieving supersaturation in experiments on spontaneous condensation is by mixing streams of gases at different temperatures, with the hotter gas containing the condensing vapour, or by mixing hot vapour with a cold gas by molecular diffusion.

Spontaneous condensation during the mixing of streams at different temperatures was first studied by Fuks and Oschmann[183] and by Petryanov and Tunitskii[127], who used three-way capillaries for the mixing. The inadequate state of development of the theory of turbulent mixing at that time made it impossible to carry out a quantitative interpretation of the results obtained. Some important qualitative conclusions were reached in this work, however. In particular, it was concluded that with increase in the concentration of condensing vapour the rate of nucleus

formation does not increase indefinitely, but reaches a limiting value. Petryanov and Tunitskii[127] also concluded that in the condensation of the vapour of substances with low volatility and very low partial pressures, the formation of aerosols takes place by a coagulation mechanism. This is not always true, however, since Fuks and Sutugin[184], in a study of the condensation of NaCl vapour with a partial pressure of $\sim 10^{-7}$ mmHg, showed that when streams at different temperatures are mixed in a three-way tube, the concentration of the aerosol formed may be very low— $\sim 10^2$ cm^{-3}—and this excludes the possibility of a coagulation mechanism.

An elegant method for studying spontaneous condensation using an immersed turbulent stream was proposed by Amelin[185]. The method is based on the fact that the supersaturation in the mixing zone of the stream at first increases with dilution of the hot gas of the stream, reaches a maximum, and then decreases. By varying the temperature of the flowing stream and the medium, it is possible to achieve conditions under which the supersaturation will exceed the critical value only in a very narrow part of the mixing zone. The critical supersaturation of glycerol vapour[186] determined by this method was found to be close to that calculated by the Volmer–Flood formula. Higuchi and O'Konski[123], using an improved version of Amelin's method, showed that Frenkel's equation very effectively describes nucleation in dibutyl phthalate and glycerol vapours but describes that in sulphur vapour slightly less effectively. The agreement for triethylene glycol was poor, and the authors cited attributed this to the presence of impurities. It should be noted that in their comparison of experiment and theory, Higuchi and O'Konski compared the published values of the surface tension of the substances used with values calculated from experimental data on the rate of nucleation. Since J depends to a very marked extent on σ, there may be considerable discrepancy in J for good agreement in the values of σ. Sutugin and Fuchs[73] studied the condensation of silver vapour in a hot submerged stream of argon. They deposited the aerosols obtained, measured the weight of the deposit and its specific surface, and used these results to calculate the dimensions of the particles and their count concentration. The experimental results were compared with theoretical calculations carried out by means of a theoretical scheme which they developed, using Reed's method[44] to calculate the free energy of the nuclei and the Rosinski–Snow scheme[131] to calculate the coagulation growth of the particles. The partial pressure of silver vapour in these experiments amounted to 0.01–1 mmHg. The nuclei began to be formed in significant quantities at supersaturations of $\sim 10^5$. It was shown that the degree of dispersion of the aerosols formed at high supersaturations is determined by coagulation, accompanied by merging of the particles. It was also shown that the proposed scheme of calculation can be used to predict quantitatively the parameters of the aerosols formed.

Spontaneous condensation during the mixing of coaxial streams at different temperatures in the diffuser of a KUST instrument[187] was studied by Kogan[188] and Rybin[189]. Kogan[188] showed that the introduction of the molecules of various substances decreases the magnitude of the critical supersaturation in diiso-octyl sebacate vapour, in qualitative agreement with Neumann and Doring's conclusion that in binary mixtures the critical supersaturation should be different from that in the pure vapours of each component. Rybin[189] studied the spontaneous condensation of the vapours of a number of organic liquids with low volatility in a KUST instrument. By making use of the equations for the material and heat balances, he calculated the magnitude of the supersaturation achieved with complete mixing of the streams, assuming that mixing precedes nucleus formation, and neglecting the condensation of vapour on the walls during mixing. The values of J calculated from the equations of the classical theory were found to be smaller than the experimental values by several orders of magnitude.

Gen and coworkers[190] studied aerosols formed by the diffusion of aluminium vapour into a cold rarefied inert gas. It was found that the dimensions of the particles decrease rapidly at first with decrease in the concentration of the vapour, and then remain almost unchanged, that is the concentration of the particles at first increased, and then reached a limiting value. The concentration of particles for a given concentration of vapour increased with decrease in the pressure of the inert gas. Turkevitch[191] used an analogous method to study the condensation of silver vapour and showed that the degree of dispersion of the resulting aerosol is determined by coagulation. The increase in concentration with decrease in the pressure of the inert gas was attributed to an increase in the rate of diffusion of the vapour and hence an increase in the rate of cooling.

Higuchi and O'Konski[123] pointed out that it is possible to achieve supersaturation by chemical or photochemical reactions. It has not yet been possible, however, to find a reaction which would take place so rapidly that it would be complete before the start of condensation of the product. In the large number of experiments on the study of condensation with chemical reaction, the latter took place at the same time as nucleation, and the reaction was usually catalysed on the surface of the forming particles. These features make quantitative interpretation of the experiments difficult.

In summarising the examination of the results of the experimental study of spontaneous condensation, it must be accepted that the experimental data confirm the classical Volmer–Frenkel–Becker–Doring–Zel'dovich theory rather than the new Lothe–Pound–Hirth theory. It can also be stated that existing methods for calculating the processes of aerosol formation using the equations of the theory of spontaneous nucleus formation make it possible to predict the parameters of the resulting aerosols with sufficient accuracy for practical purposes.

The Problem of Monatomic Multicharged Ions and the Nature of the Chemical Bond in Inorganic Crystals

A.A.Levin, Ya.K.Syrkin, and M.E.Dyatkina

The review deals with the problem of the chemical bond in inorganic solids on the basis of the analysis of the experimental data. It is shown that thermochemical and crystal-chemical arguments can hardly be regarded as proof of the ionic theory, while data derived by modern methods for the direct estimate of effective charges show quite definitely that the bonds are covalent even in structures such as alkaline earth metal oxides and chalcogenides. The bibliography comprises 116 references.

I. INTRODUCTION

The aim of the present review is to examine the present state of the problem of the nature of the chemical bond in inorganic crystals. Although the concept of the partial covalence of such crystals has now become fairly widespread[1-3], the tendency to regard this "covalent component" as a relatively small correction to the ionic state predominates. One of the reasons for this situation is the traditional belief that the classical ionic theory and its concepts of multicharged ions are consistent with the majority of thermochemical and crystal-chemical data, which are thus regarded as "proof" of the validity of this theory. More detailed analysis shows, however, that in all cases, except alkali metal halides, thermochemical and crystal-chemical arguments are not convincing and in fact it is not experimental data that are consistent with the ionic theory but certain theoretical postulates in the thermochemistry of crystal lattices and in crystal chemistry—branches of science which have developed for half a century under the dominant influence of the ionic concept. Therefore such agreement is not surprising, but, rather than being the foundation of the ionic model, it is its consequence. The relevant questions have been examined in sections II and III of the present review.

On the other hand a fairly large amount of direct experimental data on charge distribution in inorganic solids has now accumulated. These experimental results show that the only inorganic crystalline materials close to a purely ionic state are probably alkali metal halides, for which the ionic theory holds almost completely. In crystals of compounds of "polyvalent" elements the effective charges do not increase but are actually more likely to decrease with increase in formal valence. Thus the effective ionic charges in alkaline earth metal oxides and chalcogenides ($A^{II}B^{VI}$) do not exceed unity in all probability† and in compounds of the type $A^{III}B^{V}$ they are approximately 0.5. In

† However, many workers continue to regard these crystals as purely ionic[4].

compounds more complex than the binary compounds with the composition AB the situation is somewhat more complicated but even in crystals of this kind the effective ionic charges are low‡. Experiments show that the anionic charges never exceed about 1 e, while cationic charges may be somewhat greater. Experimental data on the effective charges are considered in section IV.

The review concludes with section V, where the question of the possible physical cause limiting the effective charge of the atom in a molecule or crystal is discussed. The concluding paragraph deals with the problem of the quantum-mechanical description of the partially covalent state in solids. A fairly typical example, showing how an appreciable departure from a purely ionic structure can lead to a considerable change in the physical properties of the solid, is also quoted there.

II. THERMOCHEMICAL DATA AND THE PROBLEM OF MULTICHARGED IONS

The fundamental thermochemical concept in ionic theory is the so called "lattice energy" (Table 1), i.e. the energy which would be evolved in a hypothetical process involving the mutual approach of ions (including multicharged ions) from infinity to real atomic distances in the crystal. Two properties are then used as the main evidence in favour of the ionic model (Table 1): (1) the similarity of the "theoretical" and "experimental" lattice energies; (2) the sharp increase in lattice energy on going from compounds of "univalent" elements to compounds of "polyvalent" elements, in full agreement with the quadratic relation between the energy of electrostatic attraction and the charge.

Table 1. Theoretical (U_T) and experimental (U_E) lattice energies in crystals*

Crystal	U_T, kcal mole^{-1}	U_E, kcal mole^{-1}	Q, kcal mole^{-1}	E_{atom}, kcal mole^{-1}
NaF	217 [5]	217 [7]	136	180
KF	193 [5]	193 [7]	134	174
RbF	184 [5]	185 [7]	131	170
CsF	176 [5]	173 [7]	127	164
NaCl	185 [5]	185 [7]	98	152
KCl	168 [5]	169 [7]	104	154
RbCl	161 [5]	162 [7]	103	152
MgO	942 [6]	942 [6]	144	239
CaO	865 [6]	853 [6]	152	257
SrO			141	239
BaO	756 [6]	766 [6]	133	235
MgS	807 [6]		83	178
CaS	740 [6]		115	220
SrS	696 [6]		108	200

* The heats of formation (Q) of the compounds and the heats of sublimation of the metals taken from Ref. 8 and the dissociation energies of diatomic molecules taken from the summarising table in Ref. 16 were used to calculate the atomisation energy E_{atom}. Here and henceforth literature references are quoted immediately after the numerical data.

‡ It is superfluous to emphasise that the concept of the essentially covalent structure of inorganic crystals in no way contradicts the generally known experimental facts, for example, Faraday's laws of electrolysis. Furthermore, in solutions we are dealing not with atomic but with solvated ions.

However, simple analysis shows that for compounds of "polyvalent" elements both these properties do not reflect any experimental relations but are a consequence of the definition of the concept of the "theoretical" lattice energy, which is calculated precisely on the basis of the postulate of the ionic nature of the bond.

1. Theoretical Lattice Energy

The theoretical lattice energy U_T is by definition a purely computational quantity which can be formally calculated for any system of real or fictitious charges. Nevertheless the use of this concept in the theory of crystal lattices already involves certain difficulties.

Even within the framework of the postulated ionic model U_T cannot be calculated unambiguously, since in the expression for the theoretical lattice energy§

$$U_T = \frac{MZ^2}{R} - U_{rep.}, \qquad (1)$$

the electrostatic bond mechanism defines only the first term $U_{electr} = MZ^2/R$. The exact form of the second term U_{rep} is unknown (it is specified by the expression for the potential V_{rep}, which takes into account the repulsion between ions at distances smaller than the equilibrium value). Usually any one of the model functions of the following types is employed for the "repulsion" potential:

$$\begin{aligned} &\text{(a) } V_{rep.} = br^{-n} && \text{Born and Lande [9]},\\ &\text{(b) } V_{rep.} = be^{-ar} && \text{Born and Mayer [10]},\\ &\text{(c) } V_{rep.} = \varepsilon + be^{-ar} + cr^{-6} + dr^{-8} && \text{Ladd and Lee [11]}, \end{aligned} \qquad (2)$$

but none of these has a rigorous theoretical foundation and therefore none has any advantages over the others¶. However, the use of different functions (and different parameters a, b, and c, ...) leads to appreciable discrepancies in the corresponding values of U_T (Table 2). This discrepancy amounts to only 1–2 kcal mole^{-1} for alkali metal halides, but increases by a factor of several tens for other compounds.

Table 2. Theoretical lattice energy U_T of crystals according to different calculations

Crystal	Na_2O	K_2O	Rb_2O	MgO	CaO	BaO	ZnO	GeO_2	SnO_2	TiO_2
U_T, kcal mole^{-1}	651 [5]	580 [5]	552 [5]	942 [6]	865 [6]	756 [6]	990 [15]	2534 [18]	2301 [18]	2429 [18]
	600 [17]	529 [17]	508 [19]	907 *	816 *	726 *	917 [19]	3210 [19]	2845 [19]	2958 [19]

* From Ref. 32, Vol. I; according to Baughan's data [14].

§ Here Z is the formal ionic charge, R the anion–cation interatomic distance, and M the Madelung constant, which is 1.64 for a ZnS type lattice and 1.75 for an NaCl type lattice. Eqn. (1) is written in terms of atomic units.

¶ Sometimes it is suggested that Eqn. (b) follows from quantum mechanics and therefore is more justified, than, for example, Eqn. (a). In fact Eqn. (b) is a simplified version of the formula obtained by Unsöld [12] and Brück [13] for the repulsion potential between a positive point charge and a hydrogen-like atom and cannot be applied to real crystals.

The attempts to calculate U_T for the ionic model by the more correct quantum-mechanical procedure also proved to be comparatively successful only for alkali metal halides [20-23]. The results of the calculation [24] for MgO by the same method [20-23] using Watson's functions [25] for O^{2-} ions agree with elementary electrostatic calculations (Tables 1 and 2) only to a first approximation: $U_T^{(1)} = 923$ kcal mole^{-1} and the equilibrium lattice constant $a^{(1)} = 4.23$ Å. In calculations based on a second approximation it was found unexpectedly that the mutual repulsion of ions, which had always been neglected, exceeds in fact by a factor of 2-3 (!) the Born repulsion between anions and cations, so that the more accurate calculation leads to much poorer results: $U_T^{(2)} = 747$ kcal mole^{-1} and the lattice constant $a^{(2)} = 5.5$ Å (against the experimental value $a = 4.21$ Å)†.

2. Experimental Lattice Energy

In the discussion of experimental lattice energies, U_E it is necessary to consider two cases which differ sharply in their physical significance. For compounds of "univalent" elements, U_E is determined with the aid of the Born-Haber cycle from the equation

$$U_э = Q + S + \tfrac{1}{2}D + I_1 - F_1 \qquad (3)$$

where Q is the heat of formation of the compound AB, S the heat of sublimation of the metal A, D the heat of dissociation of the molecule B_2, I_1 the first ionisation potential of the metal A atom, and F_1 the affinity of the non-metal B atom for one electron. For compounds $A^{I}B^{VII}$, all the quantities on the right-hand side of Eqn. (3) are susceptible to direct experimental determination regardless of any hypotheses concerning the nature of the bond between the atoms in the crystal. Thus the heats Q, S, and D and I_1 are obtained by direct thermochemical and spectroscopic measurements [26,27], and the affinity for one electron F_1 can be determined, for example, from data on light-induced ejection of an electron [28]. Therefore in the case of alkali metal halides U_E is a purely experimental quantity and the agreement between U_T and U_E indeed means that the corresponding crystals can be regarded as constructed from the ions Li^+, Na^+, ..., F^-, Cl^-, ...

The situation is quite different for compounds of "polyvalent" elements for example the oxides and chalcogenides of alkaline earth metals or transition metals: Mg, Ca, Ti, V, etc. In this case the "experimental" lattice energy is defined thus:

$$U_E = Q + S + \tfrac{1}{2}D + I_1 + I_2 - F_1 - F_2 \ . \qquad (4)$$

At first sight this expression is constructed in the same way as that for univalent elements. However, in fact there is a profound difference between Eqns. (3) and (4).

† It is remarkable that when account was taken of the repulsion between anions in the calculation of Peterson et al. [23] for sodium chloride, poor agreement between the values of U_T and U_E was again obtained. Thus the calculation to first-order approximation gave $U_T^{(1)}$ (NaCl) = 183 kcal mole^{-1} and $A^{(1)} = 5.4$ Å, while the calculation to second-order approximation (taking into account the repulsion between Cl^- ions) gave $U_T^{(2)}$ (NaCl) = 155 kcal mole^{-1} and $a^{(2)} = 6.77$ Å.

The quantity U_E calculated from Eqn. (4) cannot be regarded as the result of an experimental (if only in principle) Born-Haber cycle, i.e. as a physical quantity susceptible to experimental measurements, since Eqn. (4) includes together with experimentally measured quantities Q, S, D, I_1, I_2, and F_1 also a quantity of a significantly different type. This quantity is the affinity of the atom for a second electron (F_2), which cannot be found by any independent method.

3. Affinity of the Atom for Several Electrons

The reason why F_2 cannot be determined is due to the fact that the affinity for a second electron would have to be understood as the energy of the process

$$B^- + e^- \rightarrow B^{2-} + F_2 \qquad (5)$$

which in reality never takes place‡. The experimental data show that for free atoms such a process cannot in fact occur since the binding energy of even one "superfluous" electron in the singly charged ions O^-, S^-, etc. is low (see section V, 1). On the other hand, there are no direct experimental data which would indicate the existence of monatomic multicharged negative ions in molecules or crystals (see section IV) and theoretical considerations also cast doubt on their existence (see section V).

It is noteworthy that although the concept of affinity for several electrons is usually associated with the thermochemistry of crystal lattices, real thermochemical data by themselves, without the previously adopted ionic concept, do not require the introduction of such a concept at all. The heats of formation and atomisation energies of alkali metal halides and alkaline earth metal oxides and chalcogenides are compared in Table 1. It is evident from this table that the heats of formation of the chalcogenides are close to the heats of formation of the halides and are in no way comparable to the enormous "lattice energies" for doubly charged ions§. Thus the only reason for the introduction of the concept of affinity for several electrons was the attempt to compensate the excessively large attraction energy of multicharged ions in the ionic model, i.e. essentially to adjust the experimental heats of formation to the postulates of the ionic theory (very large negative values must be attributed to the affinity for several electrons [32]).

4. The Reason for the Agreement Between the "Experimental" and "Theoretical" Lattice Energies

The vicious circle indicated above makes it impossible to find U_{exp} by an experimental procedure even within the framework of the ionic model. In order to escape from this vicious circle, it is usually postulated in the ionic

‡ From the standpoint of quantum mechanics, extremely unstable doubly charged ions with a lifetime of the order of 10^{-10} s are possible [29]. According to some data, such ions (with a lifetime of about 10^{-4} s) were recently observed mass-spectrometrically [30], although in another paper [31] doubt was cast on these results. At any rate the presence of such unstable species in no way supports the ionic theory, particularly since doubly charged ions F^{2-}, Cl^{2-}, and Br^{2-} with the same lifetime were observed together with O^{2-} in this investigation [30].

§ The difference between the atomisation energies is of course greater. However, it too is insignificant compared with the difference between the lattice energies.

theory that crystals have a purely ionic structure, and that in Eqn. (4) for any one compound adopted as a standard it is possible to substitute U_T for U_E. Then the corresponding "affinity for two electrons":

$$F_1^0 + F_2^0 = Q^0 + S^0 + \frac{1}{2}D + I_1^0 + I_2^0 - U_T^0 \qquad (6)$$

is adopted as the "experimental" value and is substituted in Born's cycle [formula (4)] for all other compounds. However, it is readily seen that U_E is then given by the equation

$$U_E = U_T^0 + (Q - Q^0) + (S - S^0) + (I_1 + I_2 - I_1^0 - I_2^0) = \qquad (7)$$
$$= U_T + (U_T^0 - U_T) + (Q - Q^0) + (S - S^0) + (I_1 + I_2 - I_1^0 - I_2^0) = U_T + \Delta U ,$$

where the sum of the quantities in brackets (ΔU) is small compared with the first term U_T¶. Thus Eqn. (7) shows that the so called "experimental" lattice energy U_E represents essentially the same "theoretical" energy U_T after it has been only slightly modified by experimental data. Therefore neither the order of magnitude of U_E nor the agreement between U_T and U_E reflect any experimental facts and of course cannot be regarded as proof of the ionic structure of the corresponding crystals.

Although Eqn. (7) makes it possible to explain in broad outline both the order of magnitude of U_E and the approximate agreement between U_E and U_T, it is frequently asserted that the "thermochemical" affinities for several electrons obtained for different lattices are so close that it is bound to imply the reality of multicharged ions. Therefore we shall consider the question of this agreement in detail (for oxygen as an example). In the first place, as shown by Eqn. (6), the quantity $F_1 + F_2$ is not purely experimental but depends on the value of U_T. Therefore, even for the same compound, $F_1 + F_2$ may assume different values depending on which formula is selected for the calculation of U_T. For example, the values of $F_1 + F_2$ for CaO calculated using the theoretical lattice energy[6] U_T(CaO) = 865 kcal mole^{-1} [6] (the Ladd–Lee formula) and the value[14] U_T(CaO) = 816 kcal mole^{-1} (the Born–Meyer formula) are respectively about −190 and about −140 kcal mole^{-1}, i.e. differ by 50 kcal mole^{-1}. A similar discrepancy is found when the same formula is used for different compounds, even when these are of the same structural type. Thus when the Born–Lande formula is applied to CaO, we have U_T = 852 kcal mole^{-1} [15,32] and then $F_1 + F_2$ = −177 kcal mole^{-1}, while for VO we have U_T = 996 kcal mole^{-1} [15,32] and $F_1 + F_2$ = (−220)–(−240) kcal mole^{-1} (the heat of formation of VO has evidently not been established exactly[33]). Consequently the "thermochemical" affinity of oxygen for two electrons can vary within extremely wide limits, from 140–150 kcal mole^{-1} [17,32] to 220–240 kcal mole^{-1} and therefore one can speak of the constancy of this affinity to within 10–15 kcal mole^{-1} only in a very restricted sense for a series of chemically and crystal-chemically similar compounds and under the condition that the same formula is used to calculate U_T.

However, in this case the constancy of the right-hand side of Eqn. (6) is not surprising. It is accounted for simply by the fact that in a series of such compounds the potentials I_1 and I_2 vary in parallel with $1/R_{cation} \propto 1/R \propto U_T$, whereas the heats Q vary within comparatively narrow limits (see, for example, Table 1).

¶ $Q - Q^0$ and $S - S^0$ are usually small (for alkaline earth metal oxides each of these does not exceed about 10 kcal mole^{-1}) and the quantities $U_T^0 - U_T$ and $I_1 + I - I_1^0 - I_2^0$ usually have different signs and cancel out.

5. "Thermochemical" and "Spectroscopic" Affinities for Several Electrons

The agreement between the "thermochemical" affinity for two electrons and the corresponding "spectroscopic" value is sometimes quoted as yet another argument in favour of the ionic theory. The "spectroscopic" value of F_2 is understood as the quantity found by the extrapolation of the spectroscopic values of the ionisation potentials and affinities for one electron and hence independent of lattice energy. However, such arguments, based on the "agreement" between $(F_2)_{thermochem}$ and $(F_2)_{spectr}$ can also be scarcely regarded as convincing. Indeed the "spectroscopic" value of F_2 as well as the "thermochemical" value are not constant but depend on the method of extrapolation. Thus extrapolation for the isoelectronic series from F^- to S^{6+} yields $F_1 + F_2$ = −155 kcal mole^{-1} for the oxygen atom[34]; Glockler's formula[35] $J = \alpha z^2 + \beta z + \gamma$ yields $F_2 \simeq$ −191 kcal mole^{-1},[36] while according to the data of Crossley and Coulson[37], the "spectroscopic" affinity of oxygen for two electrons is estimated as −118.6 kcal mole^{-1}. Since F_1 ranges from 23.5 to 46 kcal mole^{-1} according to different estimates (see Ref. 32, Vol. II), it follows that $(F_2)_{spectr}$ varies in the range 140–200 kcal mole^{-1} and the agreement of this value with $(F_2)_{thermochem}$, which varies in the range 140–220 (240) kcal mole^{-1} can be treated only as agreement with respect to the order of magnitude.

Finally, one must bear in mind that ionisation potentials and affinities for one electron correspond to bound states of the electron in the atom which are physically completely different from the free state corresponding to the hypothetical multicharged ion. From this standpoint, the extrapolation procedure itself for the determination of $(F_2)_{spectr}$ appears altogether fairly doubtful. On the other hand, if one assumes, in accordance with the ionic theory, that the structure of the energy levels of the atom in a compound changes radically, the multicharged ion passing into a bound state, then the use of the energy levels of the free atom in the extrapolation does not appear very logical.

Table 3. Comparison of the theoretical and experimental lattice energies for various crystals

Crystal	U_T, kcal mole^{-1}	U_E, kcal mole^{-1}	Q, kcal mole^{-1}	E_{atom}, kcal mole^{-1}	Crystal	U_T, kcal mole^{-1}	U_E, kcal mole^{-1}	Q, kcal mole^{-1}	E_{atom}, kcal mole^{-1}

PbSe	655	750	18	115	MnO_2	3100 [40]	3670 [40]	124	311

* All the values of U_T and U_E, with the exception of those given individual references, were taken from Yatsimirskii[19]. The heats of formation Q of the compounds and the heats of sublimation of the metals were taken from Ref. 8; the heats of formation of silicon, germanium, and tin compounds were taken from Benson[39].

6. Thermochemical Arguments Against the Ionic Theory

As shown in subsections 3 and 5 in section II (mainly for alkaline earth metal oxides), thermochemical data can never be treated as proof of the ionic theory. For other compounds, the discrepancies between the thermochemical data and the predictions of the ionic model become so large† that they in fact turn into direct arguments against this model.

The theoretical and experimental lattice energies of a number of substances are compared in Table 3. The discrepancy between U_T and U_E reaches in this case an amount equal to the heat of formation of the compounds (or the affinity of the anions for two electrons, if this is preferable) and sometimes actually exceeds it. Evidently, in such a case one is dealing with a sharp discrepancy between experiment and the ionic model.

III. IONIC RADII AND CRYSTAL CHEMISTRY

Classical crystal chemistry with its central concept of ionic radius has always been regarded as closely related to the ionic model; therefore crystal-chemical arguments are usually advanced in favour of this model (see Ref. 41 for example). Three such arguments are most often discussed.

1. The possibility of employing ionic radii, including the radii of multicharged ions, to represent interatomic distances. [If the ions Mg^{2+} and O^{2-} do not exist, then why is $R(Mg^{2+}) + R(O^{2-}) = R(MgO)$?].

2. The relative dimensions of anions, cations, and neutral atoms. [The ionic radius of Mg^{2+} in the MgO structure is $R(Mg^{2+}) = 0.65$ Å and the atomic radius is $R(Mg) = 1.5$ Å; does this not demonstrate that all the valence electrons have been removed from the magnesium ion?].

3. The possibility of explaining the crystal structure on the basis of the Magnus–Goldschmidt "stability limits" [radius ratio rules (Ed. of Translation)]. (Geometry shows that precisely six spheres with a radius of 1.40 Å can be accomodated around a sphere with a radius of 0.65 Å. Does this not confirm that magnesium and oxygen ions in the MgO crystal are spheres with precisely this radius?).

We shall discuss these arguments in succession.

1. Anion–Cation Distances

The generally adopted ("classical") systems of ionic radii[42-50] are well known and agree with one another to within several hundredths of an ångstrom. One of these (Pauling's system) is quoted in the first column of Table 4. In any of these systems the sum of the radii $R(A^{n+}) + R(B^{n-})$ is equal to the interatomic distance and in this sense they all indeed "explain" the experimental data. The problem is, however, how unambiguously ionic radii may be obtained from experimental interatomic distances. We are restricting for the time being the discussion to anion–cation distances; it is easy to show that none of the "classical" scales does in fact follow from experimental data, since comparison of such interatomic distances can in general yield no information about the actual dimensions of the ions. The only experimental relation which follows from a comparison of interatomic distances is the approximate constancy of differences of the following type (Å):

$$\begin{aligned} &R(CaO) - R(MgO) = 0.30, \\ &R(CaS) - R(MgS) = 0.24, \\ &R(CaSe) - R(MgSe) = 0.23, \\ &\ldots\ldots\ldots\ldots \end{aligned} \tag{8}$$

or analogous differences for the same metal atoms (Å):

$$\begin{aligned} &R(MgS) - R(MgO) = 0.50, \\ &R(CaS) - R(CaO) = 0.44, \\ &R(SrS) - R(SrO) = 0.37, \\ &\ldots\ldots\ldots\ldots \end{aligned} \tag{9}$$

Table 4. Various systems of ionic radii (Å)

Pauling's ionic radii (Refs.47-49)		Slater's ionic radii (Refs.51 and 52)		Ionic radii from (Ref.53)		Ionic radii found by Pauling's rule [see (III),5)]	
Li^+	0.60	Li	1.45				
Na^+	0.95	Na	1.80				
K^+	1.33	K	2.20				
Rb^+	1.48	Rb	2.35				
Cs^+	1.69	Cs	2.60				
Be^{2+}	0.31	Be	1.05				
Mg^{2+}	0.65	Mg	1.50	Mg^+	1.35	Mg^+	1.25
Ca^{2+}	0.99	Ca	1.80	Ca^+	1.65	Ca^+	1.55
Sr^{2+}	1.13	Sr	2.00	Sr^+	1.82	Sr^+	1.62
Ba^{2+}	1.35	Ba	2.15	Ba^+	2.01	Ba^+	1.81
F^-	1.36	F	0.50				
Cl^-	1.81	Cl	1.00				
Br^-	1.95	Br	1.15				
I^-	2.16	I	1.40				
O^{2-}	1.40	O	0.60	O^-	0.75	O^-	0.88
S^{2-}	1.84	S	1.00	S^-	1.25	S^-	1.20
Se^{2-}	1.98	Se	1.15	Se^-	1.38	Se^-	1.35
Te^{2-}	2.21	Te	1.40	Te^-	1.40	Te^-	1.55

Eqns. (8) and (9) can perhaps be naturally interpreted as an indication of the approximate constancy of the "dimensions" of atoms—at least in a series of compounds similar in the chemical and crystal-chemical sense. However, even such an interpretation yields only the differences between the corresponding radii (Å):

$$\begin{aligned} &R(Ca) - R(Mg) = 0.23 - 0.30, \\ &\ldots\ldots\ldots \\ &R(S) - R(O) = 0.37 - 0.50 \\ &\ldots\ldots \end{aligned} \tag{10}$$

and not the true "dimensions" of atoms or ions‡. The position does not change when instead of similar compounds one considers compounds belonging to different types (both in the chemical and crystal-chemical sense). As in the previous case, it is readily seen, that a comparison, for example, of the equations (Å)

$$\begin{aligned} &R(Mg) + R(O) = 2.10 && (\text{in MgO}), \\ &R(Na) + R(O) = 2.41 && (\text{in } Na_2O), \\ &R(Mg) + R(F) = 1.98\text{–}2.05 && (\text{in } MgF_2), \\ &R(Na) + R(F) = 2.31 && (\text{in NaF}) \end{aligned} \tag{11}$$

† Provided, of course, that one considers real values and is not satisfied with agreement between the fictitious quantities U_T and U_E to within 15 or 20%! A typical example of such an error is the calculation of the bonding energies of the Mn^{2+} and O^{2-} ions in the MnO crystal[38]. The Heitler–London method yields in this case U_T = 796 kcal mole^{-1}, which is regarded as satisfactory because of the good agreement with U_E = 923 kcal mole^{-1}. In fact the actual accuracy of the calculation is much lower, since the "theoretical" and "experimental" heats of formation differ by a factor of two.

‡ Eqns. (10) show, incidentally, that the very concept of ionic radius is at best valid only to within 0.1 Å. Therefore there is hardly much point in specifying any system of ionic radii with undue precision.

yields nothing except the differences between the ionic radii (Å):

$$\begin{aligned} R(\mathrm{Na}) - R(\mathrm{Mg}) &= 0.31, \\ \cdots\cdots\cdots & \\ R(\mathrm{O}) - R(\mathrm{F}) &= 0.10, \\ \cdots\cdots\cdots & \end{aligned} \qquad (12)$$

although in this case for anions and cations of different valences.

The difficulty pointed out above is general, since any comparison of interatomic anion–cation distances defines the true dimensions of ions only to within an arbitrary constant, which can be added simultaneously to all anionic radii and subtracted from all cationic radii (or conversely). Therefore it is not surprising that, together with the "classical" systems of ionic radii, there may exist also other systems, which differ sharply from the former. One of such "non-classical" systems was recently developed by Slater [51,52] on the basis of calculations of atomic wave functions [54,55] by the Hartree–Fock method and was tested on more than 1200 interatomic distances. This scale restores to a certain extent the system of Bragg radii [56], proposed before the beginning of the "ionic period" in crystal chemistry, and differs from the "classical" scale in that the radii of anions are reduced and those of the cations increased by 0.85 Å. It is remarkable that, although Slater's radii apply not to ions but to neutral atoms, nevertheless with their aid the experimental interatomic distances are satisfactorily reproduced even for crystals such as alkali metal halides.

Table 5. Experimental [52] (in brackets)* interatomic distances and the radii of singly charged ions in $A^{II}B^{VI}$ crystals

$R(B^{1-})$	B^{1-}	$R(A^{1+})$			
		1.35	1.65	1.82	2.01
		A^{1+}			
		Mg^+	Ca^+	Sr^+	Ba^+
0.75	O^-	2.10* (2.10)	2.40* (2.40)	2.57* (2.57	2.76* (2.76)
1.25	S^-	2.60* (2.60)	2.90 (2.84)	3.07 (2.94)	3.26 (3.18)
1.38	Se^-	2.73* (2.73)	3.03 (2.96)	3.20 (3.12)	3.39 (3.31)
1.40	Te^-	2.75* (2.75) wurzite	3.05 (3.17)	3.22 (3.24)	3.41 (3.50)

* The upper number (without brackets) is the sum of ionic radii $R(A^+) + R(B^-)$. [53] The values denoted by an asterisk were used to calculate $R(A^+)$ and $R(B^-)$.

Another similar scale of ionic radii (corresponding to singly charged ions of the "divalent" elements Mg^+, Ca^+, ..., O^-, S^-, ...) was recently examined [53] in connection with the structure of the energy bands in crystals of compounds of the type $A^{II}B^{VI}$. These radii are listed in Table 5, which shows that they too give a good representation of interatomic distances, at least to within a reasonable accuracy of about 0.1 Å (see the footnote on p. 99).

2. Ionic Radii and Anion–Anion Distances

It may prove that the true dimensions of ions can still be derived from purely crystal-chemical data if, instead of anion–cation distances, one uses anion–anion distances and assumes that in certain structures anions can be in contact. Many years ago Lande postulated that such a case is realised in practice, for example in the structures of MgS and MnS and MgSe and MnSe, for which the interatomic distances are as follows (Å):

MgS	2.60	MnS	2.59
MgSe	2.73	MnSe	2.72 .

The approximate equality of the interatomic distances in the sulphides MgS and MnS and also in the selenides MgSe and MnSe enables Lande to assume [57] that the anions in these compounds touch one another and ultimately he obtained the following radii for the anions S^{2-} and Se^{2-}: $R(S^{2-}) = 1.83$ and $R(Se^{2-}) = 1.93$ Å.

However, even this treatment is in all probability incorrect, since the agreement between interatomic distances does not by itself constitute evidence that the anions touch—in any case anions with classical ionic radii. For example, the interatomic distances in binary compounds of the same structural type (NaCl) are [52]§ (Å):

Sm—O	2.49	Np—O	2.50
Pu—O	2.48	Pa—O	2.48
Ce—N	2.50	Gd—N	2.50
Np—N	2.45	Pu—N	2.45

and therefore agree with a precision which is not less than in the previous case. At the same time the O–O or N–N distance in these structures is approximately 3.50 Å, which in no way agrees with the sum of the "classical" ionic radii: $2R(O^{2-}) = 2.80$ Å and $2R(N^{3-}) = 3$ Å. Furthermore, together with such examples, it is not difficult to quote examples of the agreement between distances in structures with different anions and the same cations. For example, the interatomic distances (Å) [52]§ in certain binary compounds of zirconium, tantalum, uranium, and plutonium are

Zr—O	2.31	Zr—N	2.30
Ta—O	2.22	Ta—C	2.22
U—As	2.88	U—Se	2.88
Pu—N	2.45	Pu—C	2.46 ,

If these structures are examined from a purely crystal-chemical standpoint as was done by Lande, it would be logical to assume that the cations are in contact. However, one would then have to adopt for the ionic radii the values $R(Zr) = 1.63$, $R(Ta) = 1.56$, $R(U) = 2.03$, and $R(Pu) = 1.73$ Å, which are completely unacceptable from the standpoint of the "classical" scales (these values lead to the anionic radii $R(O) \simeq R(N) \simeq 0.6$–$0.7$ Å, $R(Se) \simeq 0.85$ Å, etc).

3. "Dimensions" of Ions

The ambiguous nature of any scale of ionic radii leads to the failure also of the second argument in favour of the ionic model. In fact it does not at all follow from experimental data that the "dimensions" of cations are much smaller than the "dimensions" of neutral atoms, while those of anions are much greater. Such a relation is typical only for "classical" scales. On the other hand, in Slater's scale [51,52] ionic radii are almost identical with atomic radii, and in the scale of Levin et al. [53] they differ only slightly from the atomic radii (Table 5). It is noteworthy that the greater anionic radii compared with those

§ Taken from R. W. G. Wyckoff's compilation "Crystal Structures", First Edition, New York, 1948 and checked by the authors against the Second Edition (New York, 1963).

of neutral atoms, required by the classical scale, are not confirmed by calculations of atomic wave functions [54,55]. On the contrary, for halide ions such calculations clearly indicate that the dimensions of the atoms remain unaltered when an electron is attached.

4. Limits of Stability

The Magnus–Goldschmidt limits of stability are usually quoted as the third crystal-chemical argument in favour of the ionic theory. For example, comparison of the O–O distances in the series MgO–CaO–SrO–BaO,

Compound	MgO	CaO	SrO	BaO
O–O distance, Å	2.96	3.40	3.64	3.90

shows that all crystals cannot be represented by close-packed spheres firmly in contact with one another. To explain this fact, it is assumed in classical crystal chemistry that close packing of anions corresponds to the minimum distance between oxygen atoms (in the MgO structure), which is 2.96 Å, and larger distances can be accounted for by the presence of gaps between the anions, which, however, satisfy the familiar "stability limits" [58] for the R(cation)/R(anion) ratio (Table 6).

Table 6. Magnus–Goldschmidt "stability limits" for various structures

Coordination number	Coordination polyhedron	R_A/R_B
2	line	0—0.155
3	triangle	0.155—0.225
4	tetrahedron	0.225—0.414
	square	0.414—0.732
6	octahedron	0.414—0.732
8	cube	0.732—1.000

It is readily seen, however, that these stability limits also cannot be regarded as a confirmation of the validity of the classical ionic radii for at least two reasons. The first is simply that, in fact, the classical ionic radii frequently do not satisfy the Magnus–Goldschmidt rules (Table 7). The second reason consists in the preconception (under the influence of the ionic theory) according to which "large" ions are necessarily assumed to be anions and "small" ions are taken to be the cations [52]. From the purely geometrical standpoint, there is no reason to reject the treatment of structures as close-packed cations (and not anions) [52], for which the stability limits would hold, as it were, "inversely". It is significant, however, that such a view has not merely a geometrical basis. If it is assumed that the negative charge of an atom cannot exceed unity [Sections (IV, 4) and (V, 2)], then we obtain in a natural manner a scale of the radii of singly charged ions of "divalent" elements, already mentioned in Section (III, 1). In this scale the structures of CaO, SrO, BaO, and to a smaller extent MgO consist of close-packed large metallic ions A^+, the octahedral vacancies of which contain the O^- anions, and the stability limits hold in many cases, albeit for the inverse ratio R(anion)/R(cation) (Table 8).

5. Other Methods for the Determination of Ionic Radii

Thus experimental data on interatomic distances do not yield convincing arguments either for or against the ionic theory, so that the classical scales of ionic radii must be regarded not as a basis but as a consequence of the ionic model. This conclusion applies also to other methods for the determination of ionic radii based on attempts to supplement or replace purely crystal-chemical data by other considerations. Such attempts were made at one time by Wasastjerne [42,43] and Pauling [47–49].

Table 7. Examples of the breakdown of the Magnus–Goldschmidt rule

Compound	Structural type	Coord. no., coord. polyhedron	$R(A^{2+})/R(B^{2-})$, (Pauling's radii), Å
BeO	wurtzite	4 tetrahedron	0.22
BeS	zinc blende	»	0.17
BeSe	ditto	»	0.16
BeTe	»	»	0.14
MgSe	NaCl	6 octahedron	0.33
SrO	NaCl	»	0.81
BaO	NaCl	»	0.97
PaO	NaCl	»	0.77
UP	NaCl	»	0.75
NpO	NaCl	»	0.79
PuO	NaCl	»	0.77
AmO	NaCl	»	0.77

Table 8. The ratios $R(B^-)/R(A^+)$ for various crystals

Crystal	Structural type	$R(B^-)/R(A^+)$	Crystal	Structural type	$R(B^-)/R(A^+)$
MgO	NaCl	0.55	FeO	NaCl	0.53
CaO	NaCl	0.45	CaO	NaCl	0.54
SrS	NaCl	0.69	NiO	NaCl	0.56
BaS	NaCl	0.60	CdO	NaCl	0.47
BaSe	NaCl	0.69	PaO	NaCl	0.43
BaTe	NaCl	0.70	UO	NaCl	0.44
TiO	NaCl	0.55	NpO	NaCl	0.43
VO	NaCl	0.58	PuO	NaCl	0.43
MnO	NaCl	0.51	AmO	NaCl	0.43

1. Wasastjerne based his treatment on experimental refractive indices and dielectric constants, assuming that the polarisability of ions α is proportional to their volume V, as for the primitive model of the atom considered as an ideally conducting sphere. Subdivision of the experimental distance (A–B) in the proportions $\sqrt[3]{\alpha_A} : \sqrt[3]{\alpha_B}$ is possible and yields a rough estimate of ionic radii; however, for this purpose it is necessary to divide in some way the overall polarisation of the crystal into increments corresponding to the individual ions. Wasastjerne determined the ionic radii assuming essentially that all polarised electrons belong to anions, but it is readily seen that the other hypothesis would lead to the opposite estimates.

2. Pauling's treatment [47–49], based on the postulate that in crystals the anions of the elements in Groups VII, VI, and V and the cation of the elements in Groups I, II, and III are isoelectronic, suffers from the same defect. Furthermore Pauling was forced to construct this scale of ionic radii in two stages. In the first stage he determined the so called "univalent" ionic radii R_1, assuming that the

corresponding anions are isoelectronic with ions of Group VII elements and that the ionic radius is inversely proportional to the Slater charge of external electrons:

$$R_1 = \frac{C}{Z_{\text{nucleus}} - Z_{\text{screen}}} \quad . \qquad (13)$$

However, the resulting interatomic distances differ appreciably from the experimental values (by about 0.5 Å). Therefore in the second stage Pauling modified the "univalent" ionic radii by introducing a correction for the hypothetical contraction of the ions in the crystal.

It is interesting that Pauling's equation (13) combined with the hypothesis that $A^{II}B^{VI}$ crystals contain only the singly charged ions $(A^{II})^+$ and $(B^{VI})^-$ yields satisfactory values for the interatomic distances also without this modification (Table 9). Then the radii obtained for the ions $(A^{II})^+$ and $(B^{VI})^-$ are found to be fairly close to the values obtained earlier [Section (III, 1), Tables 4 and 5].

Table 9. The ionic radii $R(A^+)$ and $R(B^-)$ and interatomic distances in $A^{II}B^{VI}$ crystals obtained by Pauling's equation (13). The experimental interatomic distances are given in brackets

$R(B^{1-})$	B^{VI}	$R(A^{1+})$			
		1,25	1,55	1,62	1,81
		A^{II}			
		Mg+	Ca+	Sr+	Ba+
0.88	O^{1-}	2.13 (2.10)	2.43 (2.40)	2.50 (2.57)	2.69 (2.76)
1.20	S^-	2.45 (2.60)	2.75 (2.84)	2.84 (2.94)	3.01 (3.18)
1.35	Se^-	2.70 (2.73)	2.90 (2.96)	2.97 (3.12)	3.16 (3.12)
1.55	Te^-	2.80 (2.75)	3.10 (3.17)	3.17 (3.24)	3.36 (3.50)

6. X-Ray Diffraction Data and the Ionic Model

The capacity of the atom to scatter X-rays (atomic scattering factor f_0) is roughly proportional to the number of electrons and therefore should be different for the neutral atom and the ion. Since the sublattices consisting of atoms bearing different charges are displaced relative to one another in the crystal structure, one may hope that the degree of ionisation will influence the details of the diffraction pattern. Attempts to test in this way whether or not the true charge distribution is consistent with the ionic model were frequently undertaken (see, for example, the literature review in Section IV in Urusov's thesis[59]) and one of the most typical of such attempts has been described by Raccah and Arnott[60]. Using three different values[61-63] of the atomic [form (Ed. of Translation)] factor for the doubly charged ion O^{2-} and the atomic [form] factor for the doubly charged ion Mg^{2+}, Raccah and Arnott showed that the divergence factor¶ in these three cases varies in the range 1.721–0.681%. For the two latest values[62,63] of the scattering factors of the O^{2-} ion, the R factor proved to be 0.849 and 0.881%. The results constitute at first sight convincing evidence in favour of the ionic model.

¶ The relative difference between the experimental and theoretical X-ray reflection intensities: $R = (\sum_{hkl} |I_E - I_T|)/(\sum_{hkl} I_E)$.

However, more detailed analysis shows that this conclusion is incorrect. In the first place the calculation of the intensities using the atomic factor for the singly charged ion[64] O^- in the same study led to $R = 1.326\%$, which falls precisely between the values of the R factor for the doubly charged ions (here one should also bear in mind that, while using the scattering factor for the singly charged O^- ion, the authors employed for magnesium the "doubly charged" atomic factor, as before).

Furthermore, there is yet another general consideration which makes any attempt to assess the degree of ionic character on the basis of X-ray diffraction data extremely risky. In any X-ray diffraction study the theoretical atomic scattering f_0 curve is always multiplied by a "temperature correction"

$$f_{\text{temp.}} = e^{-B(\sin\vartheta/\lambda)} \qquad (14)$$

(which has a characteristic value for atoms of each kind) taking into account the thermal vibrations of the atoms in the lattice (see, for example, Porai-Koshits[65]). The temperature corrections for each structure are found separately by an experimental procedure, which is in fact carried out precisely to ensure the minimum discrepancy between the intensities I_E and I_T. Since the atomic scattering factor is also fairly satisfactorily represented by the exponential function

$$f_0(\sin\vartheta/\lambda) \simeq (\text{no. of electrons}) \times e^{-A'(\sin\vartheta/\lambda)^2}, \qquad (15)$$

the resulting atomic temperature factor

$$f = f_0 f_{\text{temp.}} \simeq (\text{no. of electrons}) \times e^{-(A+B)(\sin\vartheta/\lambda)^2} \qquad (16)$$

may simulate the scattering factor for an ion of any charge type†.

IV. EFFECTIVE CHARGES AND THE COVALENT NATURE OF THE CHEMICAL BOND

We see that indirect (thermochemical and crystal-chemical) data cannot be regarded as an argument in favour of the ionic model. However, there also exist at present direct methods for the determination of effective charges of atoms in molecules and crystals. The data obtained with the aid of these methods in fact show that the chemical bond in inorganic crystals is significantly covalent‡.

1. Dipole Moments of Diatomic Molecules

The simplest method for estimating the effective charge lies in the measurement of the dipole moment. In a diatomic molecule A–B the effective charge (expressed as a

† A discrepancy may be observed only in the region of very low values of $\sin\theta/\lambda$ (see the plot in Freeman's paper[66]), particularly for amplitudes which are expressed as the differences between the atomic factors for the ions A and B. Such amplitudes are F_{111} for the NaCl lattice and F_{200} for the ZnS lattice. It is remarkable that an accurate estimate of the intensity of the I_{111} reflection for MgO yields an ionic charge $Z \simeq 1.2$–1.3.[59]

‡ Of course, in the assessment of the reliability of each effective charge obtained by a particular method, one must bear in mind that the concept of the effective charge of the atom in the molecule or crystal is itself to some extent arbitrary and only the values which are reproducible when obtained by different methods may be regarded as reliable [see Section (IV, 5)].

fraction of the electronic charge) can be defined by the relation

$$Z = \mu/4.8R, \qquad (17)$$

where the dipole moment μ is measured in debyes and the interatomic distance R in angstroms. The application of Eqn. (17) to the dipole moments of alkali metal halide molecules (in the gas phase) usually yields charges which are fairly close to $Z \simeq 1$. Recently the dipole moments of the diatomic molecules SrO and BaO were determined by microwave spectroscopy and were extrapolated to BeO (Table 10)[67]. Table 10 shows that the corresponding effective charges do not exceed unity, whereas according to the ionic model charges close to two would be expected in this case.

2. Dielectric Properties of the Crystal Lattice and Ionic Charges

The data in Table 10 do not permit the direct assessment of the effective charges in crystals for which the purely ionic state appears to be energetically the most favourable, since the Madelung constant for crystals is significantly greater than unity while the corresponding value for a diatomic molecule is unity. It is interesting, however, that the charges in Table 10 hardly change on transition to the crystal state. One of the most widely known methods for estimating effective charges in this case is based on the investigation of the dielectric properties of the crystal lattice.

Table 10. The dipole moments μ and effective atomic charges Z for certain molecules

Molecule	μ (D)	Z (e)
BeO	6.3	1.00
SrO	8.9	0.97
BaO	7.9	0.85

Szigetti[68] showed, in terms of the rigid and non-overlapping ion approximation, that the difference between the static (ϵ_0) and high-frequency (ϵ_∞) dielectric constants is related to the effective ionic charge Z by the equation

$$\varepsilon_0 - \varepsilon_\infty = \left(\frac{\varepsilon_\infty + 2}{3}\right)^2 \cdot \frac{4\pi Z^2}{\omega^2 V_m} \qquad (18)$$

where m is the reduced mass of the pair of ions A and B, V the volume per AB formula unit, and ω the frequency of the optical branch of lattice vibrations, which can be found by an independent method.

The effective charges "according to Szigetti"[68-78] are listed in Table 11, which shows fairly clearly the discrepancy with the value based on the concepts of the ionic theory.

The effective ionic charges can also be estimated using elastic and piezoelectric properties of crystals. The estimates obtained in this way, $Z_{BeO} \simeq 1$, $Z_{ZnO} \simeq 1$,[81] $Z_{ZnS} = 0.68$,[82] and $Z_{CdS} = 0.73$[83] or $\simeq 1$ [84] confirm the previous data.

3. Spin–Orbit Splitting

A method for estimating effective charges, which is significantly different from the preceding two, is based on the study of the spin–orbit splitting of levels in the valence band of crystals, which is reflected, for example, in a characteristic subdivision of peaks corresponding to interband transitions[85-87].

Table 11. Effective charges* "according to Szigetti"[68-89]

Crystal	Charge	Crystal	Charge	Crystal	Charge	Crystal	Charge
LiF	0.87[68]	RbI	0.89[68]	PbF_2	0.87[71]	BN	1.14[76]
NaF	0.93[68]	CsCl	0.84[68]	BeO	1.1 [72]	BP	0.25[76]
NaCl	0.74[68]	CsBr	0.79[68]	MgO	1.76[68]	InP	0.60[77]
NaBr	0.69[68]	TlCl	1.08[68]		1.20[79]

* For compounds A_2B and AB_2, the effective charge corresponds to the charge at the atom B.

From the standpoint of quantum mechanics, the effective charge of an atom corresponds to the probability p of finding a valence electron at this atom. Spin–orbit splitting is in fact a phenomenon in which the probability of observing the electron at oppositely charged atoms of the crystal is revealed in a fairly direct manner. As a result of the interaction of the spin and orbital momenta, the energy levels of the valence electrons in crystals split[86-88], and each atom makes its own contribution to the overall splitting, proportional to the probability of finding a valence electron at the atom. The resulting splitting Δ can thus be expressed in terms of the splittings for the individual atoms, Δ_A and Δ_B§, in the following form[88]:

$$\Delta \approx p_A \cdot \Delta_A + p_B \cdot \Delta_B, \; p_A + p_B = 1. \qquad (19)$$

All three splittings, Δ, Δ_A, and Δ_B, can be found by an independent method, so that Eqn. (19) makes it possible to determine from experimental data the required probabilities p_A and p_B or, conversely, to compare the experimental splitting Δ_E with the corresponding theoretical value Δ_T calculated with the aid of Eqn. (19) for this or a previously specified effective charge. The corresponding data are presented in Table 12. Comparison of this table

§ We may note that the quantities Δ_A and Δ_B for atoms in a crystal are not necessarily the same as the quantities Δ_A^0 and Δ_B^0 observed in the spectrum of the free atoms. Such agreement occurs at the point L of the valence band (for ZnS type crystals). In the centre of the Γ band $\Delta_A \simeq 3/2\Delta_A^0$ and $\Delta_B \simeq 3/2\Delta_B^0$.

with Table 11 shows that the charges "according to Szigetti", which are of the order of unity for $A^{II}B^{VI}$ compounds and of the order of 0.5 for $A^{III}B^{V}$ compounds, give rise to fully satisfactory agreement between the theoretical and experimental values of spin–orbit splitting.

Table 12. Spin–orbital splitting in crystals*

Crystal	AlAs	GaSb	InAs	InSb	ZnSe	ZnTe	CdSe	CdTe	HgSe	HgTe
Δ_E, eV	0.33	0.75	0.43	0.98	0.35	0.57	0.28	0.55	0.30	0.75
Δ_T, eV	0.33	0.76	0.41	0.89	—	—	—	—	—	—
Δ (B)	—	—	—	—	0.29	0.65	0.29	0.65	0.29	0.65

* For the compounds $A^{III}B^{V}$, the splitting Δ refers to the centre of the zone and for the compounds $A^{II}B^{II}$ to point L. The effective charges used in the calculation of Δ_T for $A^{III}B^{V}$ were taken from Gielisse[76]. The data for the compounds AlAs–InSb were taken from Braunstein and Kane[89] and those for the compounds ZnSe–AgTe from Scouler and Wright[90].

4. X-Ray Spectroscopic Method for the Determination of the Effective Charge

The most direct and convincing evidence against the ionic theory comes, however, from X-ray spectroscopic data for molecules and crystals[91-93]. X-Rays are generated in transitions of outer electrons to inner atomic levels (X-ray emission spectra) and are absorbed in the reverse transitions (absorption spectra). Since the excess charge at the atom (positive or negative) leads to a displacement of the atomic energy levels, the study of the dependence of this displacement on the charge permits the experimental determination of the effective charges of ions in molecules and crystals by comparing their X-ray spectra with those of neutral atoms. The effective charges found by the X-ray spectroscopic method are listed in Table 13, three characteristic features of which are the most important: (1) the "X-ray spectroscopic" effective charges are usually in good agreement with the values estimated by other methods; (2) these charges are close in magnitude to the formal charges of the ionic theory mainly only for compounds of univalent elements; (3) whereas the charges of positive ions may reach fairly high values, those of negative ions do not exceed unity.

The data in Tables 11–13 show that this last property of effective charges is fairly general and is probably particularly important. Its importance is discussed below; here we may note that this feature is confirmed also by more detailed X-ray spectroscopic studies than the investigation of the displacement of the lines in the spectra. In a number of recent studies methods were developed whereby it is possible to assess the general structure of the energy levels and the form of the wave functions of the electrons in molecules and solids. A study of this kind on TiO, for example, showed[97] that the structure of the energy bands of this crystal is best interpreted on the basis of calculations[98] using singly-charged Ti^+ and O^- ions.

5. The Consistency of the Effective Charges and the Concept of the Effective Charge

The data on the effective charges obtained with the aid of the methods discussed above can be objected to on quite natural grounds, associated with the following factors: (1) the inaccuracy of the estimate of the effective charges by each method; (2) the incomplete consistency of different methods with one another; (3) the inadequacy of the concept of the effective charge itself. We shall examine these objections in order to obtain the answer to the question to what extent the effective charges estimated by various "direct" methods correspond to the "true" charges of ions in crystals and consequently to what extent such data really constitute evidence against the ionic theory.

Table 13. Effective charges Z found by the X-ray spectroscopic method*

Crystal	Z	Crystal	Z	Crystal	Z	Crystal	Z
NaF	0.58	MgS	1.05 −1.2	MnS	−0.86 −0.7 [95]	GaSb	0.33 [96]
NaCl	0.92	CaS	−1.1 −0.7 [95]	GeS	−0.71	InSb	0 [96]
NaBr	0.83	BaS	−0.71	SiO_2	1.97	Al_2O_3	1.53 1.77 [96]
NaI	0.75	ZnS	−0.86 −0.66 −0.3 [95]	SiS_2	1.69 −0.81	Al_2S_3	1.26 −1.00
MgF_2	1.30	CdS	−0.81 −1.5 [95]	$FeS_{1,98}$ marcasite	−0.96	Al_2Se_3	1.44
		$FeS_{1,093}$	−0.71 −0.7 [95]	CoS_2	−0.54	Al_2Te_3	1.44
$MgCl_2$	1.50						
$MgBr_2$	1.38	$FeS_{1.018}$	−0.96	NiS_2	−1.1	Mg_2C	0.34
Na_2S	0.75 −0.96	$CoS_{1,09}$	−0.61	MnS_2	−0.15	Li_2Si	−0.09
K_2S	−1.06	NiS	−0.66 −0.7 [95]	SnS_2	−0.54	Mg_2Si	−0.89
Ag_2S	−0.61	CuS	−0.51	AlN	1.32 1.17 [96]	Ca_2Si	−0.89
Cu_2S	−0.61	TiS	−0.61	AlP	0.87 0.87 [96]	Mg_2Sn	0.28
MgO	1.01 0.5 [94]	$TiS_{1.81}$	−0.81	AlSb	0.57 [96]		

* The minus sign denotes throughout the charges of the "electronegative" atom B (obtained from the displacement of the $K_{\alpha_{1,2}}$ doublet for this atom). All the charges, apart from those with individual references, were taken from Refs. 91 and 92.

1. The accuracy of each method may be checked by comparing the charges determined by the same method for different substances, in which the expected charges should have approximately the same value. Comparison of the charges determined, for example, by the method of Szigetti and by X-ray spectroscopic methods for the family of alkali metal halides or alkaline earth metal chalcogenides (Tables 11 and 13) shows that the results usually agree to within about $(0.1-0.3)e$ and therefore each method may be regarded as "accurate" within these limits. For the X-ray spectroscopic method, there exists yet another check, based on the possibility of an independent estimate of the charge at each of the atoms A and B in the binary compound AB. Experiment shows that both charges are usually found to be the same within the accuracy quoted above.

2. The consistency of the effective charges is clearly seen from a comparison of Tables 11–13 and also from Table 14 (taken from Urusov[59]), which lists about ten effective charges in ZnS obtained by a wide variety of methods. These tables show that the effective charges obtained by different methods are as a rule consistent to within the same limits, namely (0.1–0.3)*e*.

Table 14. Comparison of the effective charges in ZnS obtained by different methods

Charge	Method of estimation	References
0.96	Szigetti's method	68
0.85	infrared absorption spectra	74
0.68	measurement of piezoelectric constants	82
0.51	correlation with thermal ionisation of impurities	99
0.8	measurement of hyperfine splitting constant in ESR spectrum of impurity ions	100
0.86	X-Ray spectra	91, 92
0.66		
0.56	measurement of refractions	101
0.5	difference between optical and thermal width of the forbidden gap	102
0.7	study of magnetic susceptibility	103
Mean 0.7±0.2		

3. We shall finally examine the question of the validity of the concept of the effective charge itself, which is important for the understanding of the real significance of various experimental estimates. There is no doubt that the effective charge of an atom in a molecule or crystal is not a physical quantity with a completely valid definition, such as, for example, the mass of the atom or the charge of its nucleus. In fact, effective charges are used for an approximate representation of the real distribution of electron density. In various cases different approximations may be necessary, since, generally speaking, different "effective charges" correspond to different properties. Therefore any experimental method for the estimation of "effective charges" constitutes not only a method of measurement but at the same time also a method for the definition of the concept of the effective charge itself (this explains the discrepancies between the effective charges obtained by different methods). If the effective charges obtained by different methods showed a fairly wide scatter (from zero to the value of the formal valence), then the very concept of a "unique" charge attributable to the atom in the compound would of course lose significance.

However, experiment shows (see paragraph 2) that in fact all these values agree with one another within reasonable limits. Thus reference to the lack of validity of the concept of the effective charge would be justified only if it was possible to exclude altogether this concept from the theoretical scheme of quantum chemistry and the theory of the solid state (and this is scarcely possible at the present time). At any rate, the inaccuracy of this concept cannot serve as a basis for the return to the ionic theory, since the assertion that the charge, say, at the S atom in ZnS is nevertheless −2, already presupposes the use of some definition of the effective charge, for example one of the definitions which have been enumerated. However, experiment shows that *in the same sense* this charge can be much more correctly treated as close to unity.

V. THE PROBLEM OF MULTICHARGED NEGATIVE IONS FROM THE STANDPOINT OF QUANTUM MECHANICS

The small charge of negative ions is a general property of experimental effective charges, as already mentioned above. When Table 13 is examined, it is difficult to avoid the conclusion that it is precisely the impossibility of the attachment to the atom of more than one excess electron that constitutes the physical factor which "regulates" the distribution of charge in molecules and crystals. This conclusion is clearly illustrated in Table 15, which lists the effective charges at the oxygen atom in compounds with a wide variety of compositions and structures.

In this section an attempt is made to show that this conclusion not only follows from experimental data but probably is also a fairly natural consequence of simple theoretical considerations.

Table 15. Effective charges at the oxygen atom[91] in different compounds

Compound	Effective charge	Compound	Effective charge
MgO	1.01	Na_2SiO_3	1.14
SiO_2	0.99	$MgSiO_3$	0.98
Al_2O_3	1.02	$Al_2(SO_4)_3$	0.89
Na_2SO_4	1.09	$Mg(ClO_4)_2$	0.75
Na_3PO_4	1.15	$Al(ClO_4)_3$	0.73
$MgSO_4$	0.88	$Mg_3(PO_4)_2$	0.92
$AlPO_4$	0.94	$KAlSi_3O_8$	1.01

1. Localisation of the Electron and the Bound States

Table 16 lists the experimental values of the first two ionisation potentials and affinities for one electron for a number of "electronegative" atoms. Evidently the electron affinities of all the atoms (except halogens) are smaller approximately by a factor of ten than the ionisation potential, i.e. the binding energy of even one excess electron is always insignificant.

We shall consider this finding from the standpoint of quantum mechanics. The localisation of the electron at the atom (i.e. the presence of a "bound" state in the system electron–atomic residue is possible only when the potential well corresponding to the potential acting on this electron contains a "discrete spectrum" of energy levels¶.

It is known that in any field $U(r) < 0$ which vanishes at infinity, $\lim_{r\to\infty} U(r) = 0$, a discrete spectrum corresponds to negative energies, while a continuous spectrum corresponds to positive energies[104].

Thus Table 16 shows that the dissociation energy of an outer electron depends significantly on the effective charge

¶ The wave functions of a discrete spectrum decay at infinity according to an exponential law, so that the probability of finding an electron outside the atom is very small. On the other hand, the wave functions corresponding to a "continuous spectrum" decay to infinity very slowly. For example, in the case of a coulombic potential they have the asymptotic form[104] $Y_l^m(\theta, \varphi)(1/r)\sin(kr - \pi l/2)$ and decrease as $1/r$. Therefore in the state corresponding to the continuous spectrum the electron can be in no way localised at the atom.

and in the case of negative ions approaches the upper boundary of the discrete spectrum. If it is assumed that the effective charge can have fractional values (as is in fact the case in a molecule or a crystal), then, on the basis of the experimental dissociation energies for $Z = -1, 0, 1, 2, \ldots$, it is possible to plot an $E-Z$ interpolation curve showing the dependence of the energy of the outer electron on the charge at the atom. Curves of this kind for carbon, nitrogen, and oxygen are presented in Fig. 1. Evidently in all cases the $E-Z$ curve crosses from negative energy values to positive values at $Z \simeq -1$, i.e. the electron passes to a state corresponding to a continuous spectrum.

Table 16. Ionisation potentials[27] and electron affinities of various elements

Element	Electron-volts		
	I_2	I_1	F_1
F	34.98	17.42	3.45 [105]
Cl	23.80	13.01	3.61 [105]
Br	19.10	11.84	3.36 [105]
I	19.40	10.45	3.06 [105]
O	35.146	13.614	1.47 [106]
S	23.4	10.357	2.07 [107]
Se	21.5	9.75	1.7 [108]
Te	18.6	9.01	2.2 [108]
N	29.605	14.54	−0.1 [109]
P	19.65	11.0	0.7 [109]
As	20.10	9.87	0.6 [109]

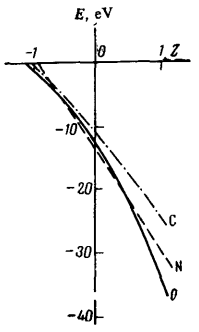

Figure 1.

In this connection one may point to the lack of physical significance of calculations of self-consistent wave functions for ions such as O^{2-}, N^{2-}, etc.[5,110,111] Indeed all such calculations start *a priori* with wave functions having an exponentially decaying radial component of the "Slater" type:

$$R(r) \propto ae^{-ar} \qquad (20)$$

(the parameters of this function are selected by a variational procedure), while functions of this type can be associated only with discrete spectra.

2. Localisation of the Electron in the Case of an Ion in the Lattice

Although Fig. 1 refers to isolated atoms and not to atoms in the lattice, one may assume that the presence of the lattice does not cause any significant change[113]. Fig. 2 presents a schematic curve for the potential U_0 of a given atom B_0 (for example oxygen) and the Madelung potential U_M acting on the electron assuming all the remaining lattice ions to be replaced by point charges. It is evident from Fig. 2 that in the region of B_0 the gradients of both potentials have opposite directions so that the Madelung potential of the lattice weakens rather than enhances the binding of the electron to "its" atom.

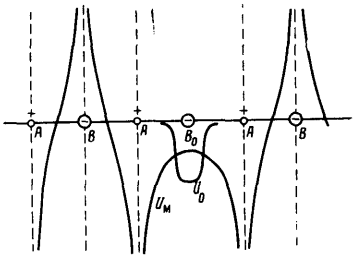

Figure 2.

This consideration can be made more general when account is taken of the fact that in the relevant range of effective charges, $Z_{B_0} \simeq -1$, the U_0 potential becomes of the short-range type and is simulated by a spherical potential well with a rectangular profile[29] (as for the short-range potential of nuclear forces). It is well known that the bound states (states corresponding to a discrete spectrum) in a well of this kind can exist only if the depth of the well u_0 is sufficiently great[104]:

$$u_0 \geqslant \frac{\pi^2\hbar^2}{8ma^2} \qquad (21)$$

(a is the radius of the well).

The experimental fact that the energies of all the outer electrons of all atoms become zero at $Z_{B_0} \simeq -1$ shows that with this effective charge the depth of the well u_0 becomes insufficient to retain the particle. However, it is evident that the Madelung potential U_M (Fig. 2) cannot make the well any deeper, since it reduces the level of its bottom at least to the same extent as it reduces the potential barrier between the atom B and the surrounding atoms A.

It follows from Eqn. (21) that the presence or absence of discrete spectrum levels in the spherical well is determined not only by its depth u_0 but also by its radius a. Therefore one might think that the effect of neighbouring atoms may increase not the depth but the width (radius) of the potential well. Calculation shows, however, that this effect is probably insignificant[112,113].

To make the treatment concrete, suppose that the radius of the well $a = 2$ a.u. $\simeq 1$ Å, i.e. about half the interatomic distance in typical oxides such as MgO. We shall now examine the relation between the depth of the well u_0 and the energy E of the lowest level in this well.

On solving the Schrödinger equation

$$\begin{aligned} &\frac{1}{r}\frac{d^2}{dr^2}(r\psi) + k^2\psi = 0, \quad k = \sqrt{2(u_0 - |E|)}, \quad r \leqslant a \\ &\frac{1}{r}\frac{d^2}{dr^2}(r\psi) - k^2\psi = 0, \quad k = \sqrt{2|E|}, \qquad r > a \end{aligned} \qquad (22)$$

for this potential, it can be shown[104] that the energy of the lowest level is defined as the root of the transcendental equation

$$\sin ka = \pm \sqrt{\frac{1}{2a^2 u_0}} \qquad (23)$$

(the roots with $\cot ka < 0$ must be used[104]). The numerical solution of Eqn. (23) with $a = 2$ a.u. yields the curve relating $|E|$ to u_0 (Fig. 3), which can be more conveniently interpreted as the plot of the opposite function: $u_0 = u_0(|E|)$. We shall now make the reasonable assumption that, for each effective charge Z_B, the outer electron of the atom B is located at the lowest level E in the potential well due to the atomic skeleton and the remaining electrons. Then the dependence on Z of the quantity corresponding to the binding energy $|E|$ may be estimated from the plots in Fig. 1, and, on combining the plots in Figs. 1 and 3, it is easy to find also the relation $u_0 = u_0(Z_B)$. The dependence of the depth u_0 of the potential well on the effective charge of the oxygen atom,

$$u_0(Z) = u_0(|E|), \quad |E| = f(Z) \qquad (24)$$

is shown in Fig. 4. The experimental data allow this curve to be plotted only up to the point $Z = -1$. However, the probable extrapolation of this curve (dashed line) shows that at $Z \simeq -1.2$ the depth of the well u_0 becomes zero. Therefore, even if one assumes that the effect of the lattice can result in a decrease of the radius of the well, with the charge $Z \simeq -1.2$ the volume of the well nevertheless becomes zero and inequality (21) will not hold.

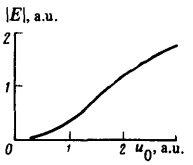

Figure 3.

It must be emphasised yet again that all the arguments adduced above refer only to negative ions. From the standpoint considered, positive ions, both in a free state and in a chemical compound, can have any charge, although excessively large positive charges are unlikely for other reasons. [Section (V, 4)]. Therefore the presence of singly charged ions, say, Ca^+ in CaO, does not contradict chemical facts requiring the presence of the doubly charged ion Ca^{2+}, for example the well known isomorphism of $NaNO_3$ and $CaCO_3$. If it is assumed that the Na atom in $NaNO_3$ indeed exists in the form of the Na^+ ion with a radius of 0.95 Å (which is also not entirely evident), then the similarity of the distances and the isomorphism of both compounds may be attributed to the presence of the doubly charged ions Ca^{2+} and CO_3^{2-} in $CaCO_3$. This leads, however, to an average negative charge at the oxygen atom (about 0.5). This illustrates the obvious fact that polyatomic anions can have charges greater than unity: −2, −3, −4 [for example in $Fe(CN)_6^{4-}$].

3. Other Causes of the Decrease of Ionic Character

The effect involving the "displacement" of the electron to a state corresponding to a continuous spectrum, mentioned above, thus constitutes the principal mechanism restricting the anionic charge to $|Z_{anion}| \simeq 1e$. However, from this point of view, $|Z| \simeq 1e$ must be regarded as only the upper limit of the possible charge. In fact the real charges in compounds can be still lower, due to energy considerations. This conclusion is apparently confirmed by experimental results (see Tables 11–13). In any of the compounds quoted in these tables the charge at the halogen atom may be unity. However, in no case does it actually reach this value. A similar conclusion follows from thermochemical and crystal-chemical arguments. Thus comparison of theoretical and experimental lattice energies of alkaline earth and transition metal halides[32] indicates a considerable departure from the ionic model.

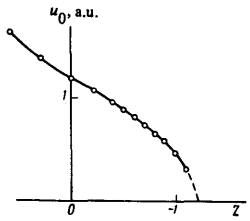

Figure 4.

Such departure from the purely ionic structure, with its characteristic tendency towards close packing, is indicated by much well known crystal-chemical data[58]. Thus, for example, BeF_2 has the open structure of cristobalite, while $BeCl_2$ forms a chain structure. $CaBr_2$ and $CaCl_2$ crystals have a deformed rutile structure with two Ca–Cl distances, namely 2.70 and 2.76 Å. In the $BaCl_2$, $BaBr_2$, BaI_2, $PbCl_2$, and $PbBr_2$ structures each metal atom is generally surrounded by nine halogen atoms at the vertices and at the centre of a trigonal prism, which in the case of $SrBr_2$ is also deformed. Calcium and lead iodides crystalise with the characteristic cadmium iodide layer structure. We may mention, finally, certain facts which suggest that even alkali metal halides are not completely ionic (Tables 11 and 13).

4. Description of the Nature of the Chemical Bond in Partially Covalent Crystals and the LCAO Method

We see that the crystals of inorganic compounds are to a large extent covalent and therefore in conclusion we shall consider the question of the description of the chemical bond in such crystals. The general postulates will be set out using as a typical example alkaline earth metal oxides[53], which makes it possible to demonstrate also how partial covalence can modify the physical properties of a solid.

The very concept of the chemical bond presupposes a definite approach to the theory of the electronic structure

of the molecules or crystals. The principal feature of this approach is that, within the framework of the theory of the chemical bond, we attempt to relate the electronic structure of the entire system to (a) the electronic structure of the constituent atoms of the system and (b) to the interaction of these atoms with one another. In the quantum chemistry of molecules principles (a) and (b) are expressed in the molecular orbital method, where one-electron functions of the entire molecule (molecular orbitals) are derived from the wave functions of the individual atoms (atomic orbitals). From the standpoint of the molecular orbital method, the chemical bond in an individual molecule of the MgO type is described, in the simplest variant, with the aid of a two-centre molecular orbital of the type

$$\psi = c_1\varphi_1 + c_2\varphi_2, \quad c_1^2 + c_2^2 = 1 \qquad (25)$$

$\varphi_1 = 2p_x$ orbital of O atom, $\varphi_2 = 3s$ orbital of Mg atom, where the relative values of the coefficients c_1 and c_2 determine the ionic character of the molecule.

In a coordination crystal of the MgO type individual molecules cannot be isolated. However, this is by no means necessary, since the molecular orbital method is in no way restricted to two-centre two-electron bonds. In this case it is most logical to treat the entire crystal as a giant "molecule" of $N \simeq 10^{24}$ atoms and to use the corresponding one-electron functions as the sum of the atomic orbitals of all the atoms constituting the crystal. This method, which is fully analogous to the LCAO-MO method in molecular theory, is well known in the physics of the solid state under the name "the strong bond method". Although each one-electron function (the so called "Bloch wave function") in the crystal contains a number of atomic orbitals of the order of 10^{24}, the actual application of the strong bond method is greatly simplified by the translational symmetry of the crystal lattice. As a result of the presence of translational symmetry, all the atomic orbitals φ, linked with one another by the translational motion of the lattice R, enter into the one-electron function of the crystal in the form of the combination

$$\psi = \frac{1}{\sqrt{N}} \Sigma_R e^{ikR} \varphi(r - R), \qquad (26)$$

where the summation is carried out over all the lattice sites. If each atom of the crystal has only one atomic orbital (and each unit cell contains only one atom), then Eqn. (26) will be the "true" one-electron function of the crystal (the eigenfunction of the effective one-electron Hamiltonian).

In a more complex case each "kind" of translationally non-equivalent atomic orbital has its own function of the type of Eqn. (26) and the overall one-electron function constitutes a linear combination of similar "basal" Bloch functions. For a crystal of the MgO type such basal Bloch functions are therefore the four functions formed from the $2p_x$, $2p_y$, and $2p_z$ orbitals of the oxygen atom and the ns functions of the metal atoms:

$$\begin{aligned}
\psi_1 &= (1/\sqrt{N}) \Sigma_R \exp(ikR)\, \varphi_1(r - R),\\
\psi_2 &= (1/\sqrt{N}) \Sigma_R \exp(ikR)\, \varphi_2(r - R),\\
\psi_3 &= (1/\sqrt{N}) \Sigma_R \exp(ikR)\, \varphi_3(r - R),\\
\psi_4 &= (1/\sqrt{N}) \Sigma_R \exp(ikR)\, \varphi_4(r - R),\\
\varphi_1 &= 2p_x,\ \varphi_2 = 2p_y,\ \varphi_3 = 2p_z,\ \varphi_4 = ns.
\end{aligned} \qquad (27)$$

Each overall Bloch function for the entire crystal will then constitute a linear combination of these four basal Bloch orbitals with certain coefficients c_1, c_2, c_3, and c_4:

$$\psi = c_1\psi_1 + c_2\psi_2 + c_3\psi_3 + e_4\psi_4, \quad |c_1|^2 + |c_2|^2 + |c_3|^2 + |c_4|^2 = 1. \qquad (28)$$

Fully by analogy with the LCAO-MO method for the MgO molecule, the coefficients c_1, c_2, c_3, and c_4 determine the ionic character of the crystal. Thus with $c_4 = 0$, the Bloch function (28) includes only the atomic functions of the anions. This case, like the case with $c_2 = 0$ in Eqn. (25), corresponds to a purely ionic state. With $c_4 \neq 0$, we have different degrees of covalence as a function of the relative value of the coefficient c_4.

We shall now consider briefly how covalence affects the physical (electrical) properties of the crystals, which depend on the structure of its energy levels.

In order to find the energy levels for the diatomic MgO molecules, it is necessary to set up the "secular" equation

$$\begin{vmatrix} \langle\varphi_1|\hat{H}|\varphi_1\rangle - \varepsilon & \langle\varphi_1|\hat{H}|\varphi_2\rangle \\ \langle\varphi_2|\hat{H}|\varphi_1\rangle & \langle\varphi_2|\hat{H}|\varphi_2\rangle - \varepsilon \end{vmatrix} = 0$$

two roots of which, ϵ_1 and ϵ_2, yield the required levels for the ground and first excited states. Quite analogously, in order to find the energy levels for the MgO crystal by the strong bond method, it is necessary to solve the following fourth-order "secular" equation:

$$Det|\langle\psi_i|\hat{H}|\psi_j\rangle - \varepsilon\delta_{ij}| = 0$$

with the basal Bloch functions (27). Since the latter depend on the vector k, each of the roots $\epsilon = \epsilon_i(k)$ also depends on this "wave vector". Ultimately we obtain 4 N different energy levels, which split into four individual "bands" or "zones": $\epsilon_1 = \epsilon_1(k)$, ..., $\epsilon_4 = \epsilon_4(k)$ (certain bands can of course overlap). In the case of the MgO type crystal under consideration the three bands with the smallest energy (partially overlapping) correspond to the 3 N occupied energy levels and form the so called "valence bands" (altogether in an MgO type crystal consisting of N formula units there are 6 N valence electrons, which occupy 3 N levels in pairs). The fourth band with $\epsilon = \epsilon_4(k)$ corresponds to unfilled, excited states. This is the conduction band and is separated from the valence bands by an energy "gap", called the forbidden gap. The width of the forbidden gap E_g is the most important electrophysical characteristic of the crystal and corresponds to the energy of the first optical transition in the molecule.

If the simplest possible approximation is used to calculate the structure of the energy bands, i.e. the treatment is restricted by (a) taking into account only the valence atomic orbitals and (b) taking into account only the interaction between anions and cations, then $E_g \simeq 11$, 9, 10, and 8.5 eV is obtained respectively for the series MgO–CaO–SrO–BaO.[53] These values are almost the same for the entire series, which is clearly inconsistent with experimental data, since in fact the width of the forbidden gap narrows from 8–9 eV[113,114] to about 4 eV[115] on going from MgO to BaO. It can be shown that, by taking into account the interactions between anions and the interaction of the 2s orbital of oxygen with the ns orbitals of the metal atoms, one cannot alter the variation of E_g in the series of oxides[53], so that the observed narrowing of the forbidden gap appears inexplicable at first sight. However, there is another important factor, which has a very pronounced effect on the width of the forbidden gap and which was not taken into account in the above estimate, namely, comparison of the metal–metal distances in oxides and in metals shows that the distances in the oxides are much shorter than in the pure metals. This fact by itself is not, of course, particularly important, since similar shortening is observed also in other compounds, for example in alkali metal halides. In the latter case, however, such decrease of the A^I–A^I distance does not at all suggest actual interaction

between the metal atoms, which are present in the crystal not in the form of neutral atoms but in the form of ions A^+. From the standpoint of the ionic theory, the oxides $A^{II}O$ constitute a fully analogous example. In all $A^{II}O$ crystals the quantity $2R(A^{2+}_{II})$ is smaller than the metal–metal distance and therefore, from the standpoint of the ionic theory, there is no real interaction between the A^{2+}_{II} ions. The situation is different if it is assumed that the $A^{II}O$ crystals contain only singly charged A^{+}_{II} ions. With the aid of the scale of singly charged ionic radii (see Table 5), it is easy to show that the quantity $2R(A^{+}_{II})$ is smaller than the metal–metal distance only for MgO and perhaps CaO. In SrO and particularly BaO real metal–metal interaction is to be expected and it is not difficult to show that even a very low value of the corresponding resonance integral leads to the required sharp narrowing of the forbidden gap[53].

Metal–metal interaction does not occur in purely ionic crystals and therefore it is to be expected that in the isoelectronic series of alkali metal halides NaF–KF–RbF–CsF a significant decrease of E_g should not be observed. Apparently experimental data[116] confirm this conclusion.

The Steric Structure of Nucleosides, Nucleotides, and Their Derivatives

N.N.Preobrazhenskaya and Z.A.Shabarova

This review deals with the literature data on the conformations and intramolecular interactions of nucleosides, nucleotides, and their derivatives: nucleotide esters, nucleoside cyclic phosphates, oligonucleotides, nucleoside pyrophosphates (including nucleotide coenzymes), ATP, and nucleotidopeptides.
The problem of the degree of bending of the pentofuranose ring and its effect on the orientation of the ring substituents, including the effect on the structure of the *cis*-2',3'-glycol group, which is revealed in a number of specific reactions, is discussed together with the question of the relative positions of the base and sugar in nucleosides. The bibliography includes 268 references.

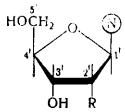
I. INTRODUCTION

During the last decade an enormous amount of data on the properties and structure of nucleosides, nucleotides, and their derivatives has accumulated. It has been established unambiguously that nucleotides are as a rule *N*-glycosides of D-ribose or 2-deoxy-D-ribose†. In all nucleosides the carbohydrate residue is in the cyclic furanose form. The glycosidic centre in the nucleosides has the β-configuration (*trans*-position of C_1,-N and $C_{2'}$-$O_{2'}$ bonds or *cis*-position of $C_{1'}$-N and $C_{4'}$-$C_{5'}$)‡.



R = OH or H, (N) - purine or pyrimidine base

The studies on the determination of the configuration of nucleosides carried out with the aid of refined chemical methods by Todd's school are recognised as classical and are described in a number of reviews including reviews in the Russian language[1-3]. In recent years much attention has been devoted to physicochemical methods for the determination of the configuration of nucleosides, among which NMR spectroscopy[4-8] and spectropolarimetry[9-20] are undoubtedly promising.

At the present time the chemistry of nucleosides has reached a level such that it is necessary to investigate not only the configurations (i.e. the distribution of atoms about the dissymmetric part of the molecule—for example the asymmetric carbon atom or ring), but also the real geometrical formula of the molecules as a whole—their conformation. This problem is particularly important in connection with the study of various polyfunctional derivatives of nucleosides, in which the specific steric structure of the molecule can lead to the interaction and hence the modification of the properties of groups which are not directly linked.

†In this review we shall not deal with synthetic and natural anomalous nucleosides (the "minor" components of nucleic acids and nucleoside antibiotics), among which may be derivatives of sugars other than D-ribose and 2-deoxy-D-ribose and also *C*-glycosides.

‡The following abbreviations have been adopted in the present review: RNA and DNA—ribonucleic and deoxyribonucleic acid respectively; UMP—uridine 5'-monophosphate; ADP—adenosine 5'-diphosphate; ATP—adenosine 5'-triphosphate; NDPS—nucleoside diphosphate sugar; UDPG—uridine diphosphate glucose; NAD—oxidised nicotinamide-adenine dinucleotide; NADP—oxidised nicotinamide-adenine dinucleotide phosphate; NADH—reduced nicotinamide-adenine dinucleotide; FAD—flavine-adenine dinucleotide; THF—tetra hydrofuran; NMR—nuclear (here as a rule proton) magnetic resonance; ESR—electron resonance.

2. RIBOSE AND 2-DEOXYRIBOSE

The form of the nucleoside molecule is to a large extent determined by the conformation of the five-membered carbohydrate ring. The tetrahydrofuran ring, which constitutes the basis of ribose and 2-deoxyribose, is nonplanar like cyclopentane[21], since all its C–C bonds would then have the eclipsed conformation characterised by maximum energy[22]. Due to the effect of the oxygen atom in the furanose ring, more and less stable conformations appear when the ring is bent. It is readily seen that, when the C_2 or C_3 atom deviates from the plane of the ring, a greater number of bonds passes from the eclipsed to the *gauche*-conformation than when the C_1, C_4, or the oxygen atom deviates from the plane of the ring. Accordingly the

conformations with the C_2 or C_3 (or both) atoms outside the ring are more stable.

The deformation of the ring of D-ribose and its 2-deoxy-derivative probably occurs even more readily than in tetrahydrofuran, since the *gauche*-disposition of the OH groups and the CH_2OH group leads to an even greater energy gain, compared with the eclipsed disposition, than the *gauche*-disposition of the hydrogen atoms in tetrahydrofuran. Furthermore, it has been found that the average length of the C_2–C_3 bond in many ribose derivatives is 1.528 ± 0.008 Å[23] (i.e. is close to the value 1.533 ± 0.003 Å found for the ordinary C–C bond[24]). In this case with the eclipsed disposition of the 2- and 3-hydroxyls the distance between their oxygen atoms must be less than 2.5 Å. Since the van der Waals radius of oxygen is 1.40 Å,[25] evidently a planar conformation of the ribose ring is impossible[26].

By analogy with tetrahydrofuran, the most favourable conformations for ribose are those in which the C_2 or C_3 atoms deviate from the average plane of the ring[27,28]. This is the so called primary or main deformation of the furanose ring. The out-of-plane atom (C_2 or C_3) can be displaced to the side where the C_5 atom is located or to the opposite side. This corresponds to possible *endo*- and *exo*-conformations. The deviation of the out-of-plane carbon atom from the average plane of the ring is very considerable: 0.5–0.6 Å. It is interesting that the *endo*-conformation is most often encountered in nucleosides (see Table 1).

Here, however, one should note that the eclipsed or partially eclipsed conformation of the C_2,–C_3, bond in 2-deoxyribose is characterised by a lower strain compared with ribose and can probably actually occur in solution (because there is a hydrogen atom in the 2-position and not an OH group as in ribose). Indeed a conformation of the carbohydrate ring in which the ring oxygen atom is displaced from the average plane of the ring, and not the C_2, or C_3, atom, has been in fact observed with the aid of NMR spectroscopy for a number of deoxyribose nucleosides (thymidine, deoxyuridine, deoxyadenosine 3′-phosphate) (*O-endo*-conformation, see Table 1)[29,30].

Table 1. Conformation of the pentose ring in nucleosides and nucleotides.

Compound	X Ray diffraction data		NMR spectroscopic data	
	conformation	references	conformation	references
Ribose-5-phosphate	C_2,-*endo*	31

Thymidine 5′-phosphate	C_3,-*endo*	55		
Deoxyadenosine 5′-phosphate			O-*endo*	29. 30

*Thymidine is the only nucleoside whose structure was also investigated by ESR spectroscopy[50].

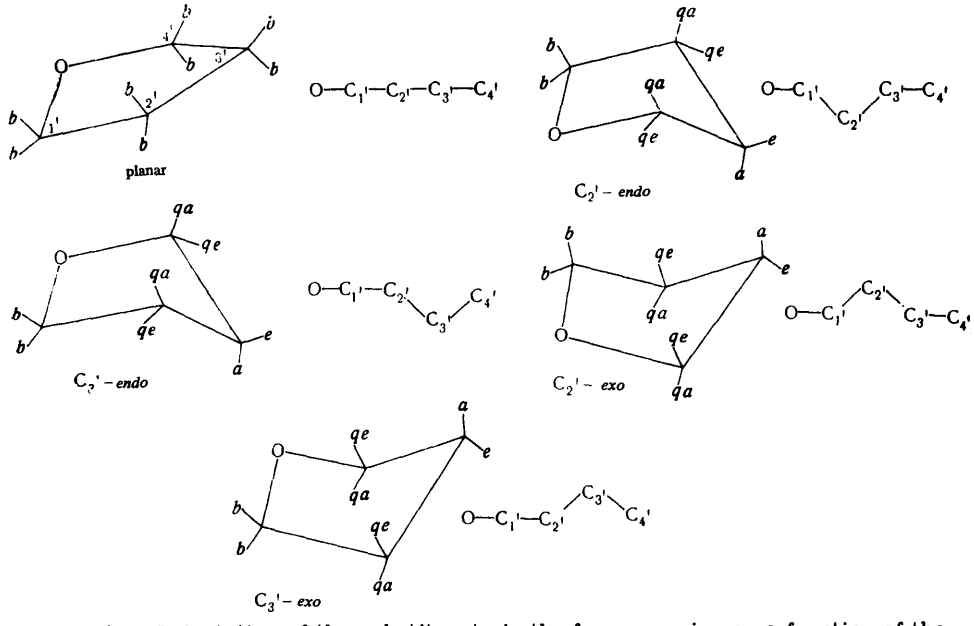

Figure 1. Orientation of the substituents in the furanose ring as a function of the nature of its bending (*a* and *e*—axial and equatorial respectively, *qa* and *qe*—quasi-axial and quasiequatorial, *b*—bisector orientation).

Apart from the primary (main) bending, secondary (minor) bending occurs in the ribose residue of nucleosides: as a rule, the four atoms of the ribose ring, determining its average plane, are also not completely coplanar. However, in this case the deviation is outside the limits of the experimental error, not exceeding 0.05 Å (i.e.8–10% of the primary bending)[38].

The consequences of the bending of the furanose ring in nucleoside are deviations of the C–C and C–O bond lengths from the normal values (up to ±0.11 Å) and of the valence angles from the tetrahedral value (up to ±9°)[21,28-53].

The external angles and bond lengths in the ribose ring also deviate from the normal values. As a result, the substituents at the carbon atoms of ribose are oriented as shown in Fig. 1. Here, however, one should note that, according to NMR spectroscopic data, the orientation of substituents depends to some extent on their nature: in the isomeric 2′- and 3′-*O*-benzylnucleosides the angle of twist between the $C_1,-H_1$, and $C_2,-H_2$, bonds is smaller in the 2′ isomer than in the 3′-isomer[56].

3. CONFORMATION OF THE HETEROCYCLIC BASE

X-Ray diffraction analysis of nucleosides and nucleotides showed that the heterocyclic bases are in many cases almost planar, i.e. the deviations of the ring atoms from the average plane are within the limits of experimental error[32,35,36,45,47,55] (see also Nyburg's review[57]).

However, a number of cases have been described in which the atoms of the base were found to deviate from coplanarity. The bending is particularly pronounced in pyrimidine derivatives. For example, in cytidine[38] and cytidine 3′-phosphate[21,30] the N_1 and C_4 atoms deviate from the average plane of the base to the same side§. The deviations amount to about 0.05 Å, so that the pyrimidine base adopts the form of a shallow boat. In purines the deviations of the heterocyclic ring atoms from the average plane are somewhat smaller.

At the same time the substituents in the heterocyclic rings of nucleotides and nucleosides (the amino-group, oxygen, the methyl group, the C_1, atom of pentofuranose) are displaced from the average plane of the ring very considerably. The O_2 and C_1, atoms (and also the O_4 and C_7 atoms in thymine) deviate to opposite sides[32,36,52]. The displacement of the C_1, carbon atom of ribose from the average plane of the heterocycl probably constitutes a general rule and reaches a considerable magnitude (up to 0.2–0.3 Å).[18,22,34,36,41,47] As a result the glycoside bond forms an angle with the plane of the base[34], which is 3.5° in adenosine 3′-phosphate for example.

4. RELATIVE POSITIONS OF THE BASE AND SUGAR

The relative positions of the base and sugar play an important role in determining the geometrical form of the nucleoside molecule. A clear albeit an incomplete idea of this is provided by the value of the dihedral angle between the average planes of the base and sugar. It is interesting to note that as early as 1947 Astbury believed, on the basis of the X-ray diffraction data obtained by Hendricks[58], that the planes of the heterocyclic base and the carbohydrate in nucleosides are parallel (quoted after Jordan[59]). However, in 1950 Furberg[28] showed that this conclusion is a result of an incorrect interpretation of the experimental data and that in fact the rings in nucleosides are approximately perpendicular to one another. This proved to be true of all the nucleosides and nucleotides investigated hitherto (see Table 2).

Table 2. Dihedral angles between the planes of the base and the sugar in nucleosides and nucleotides.

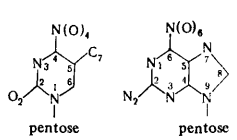
*The dihedral angles for the two conformations existing in a single crystal cell (for further details, see Russ. p. 232).

Evidently, for the same dihedral angle between the planes of the base and sugar, there is a possibility of rotation of the base about the glycosidic bond. Therefore, in order to characterise completely the relative positions of the base and sugar, it is necessary to know the magnitude of the angle of twist φ_{CN}. This is the angle formed by the projections of the bonds $C_1,-O_1$, and N_1-C_6 (for pyrimidines) or N_9-C_8 (for purines). If the N_1-C_6 bond of pyrimidine (or the N_9-C_8 bond of purine) and the $C_1,-O_1$, bond of the sugar are antiparallel, then φ_{CN} is believed to be 0°; positive angles are reckoned clockwise and negative angles anticlockwise looking in the direction from C_1, to N.[39,40]

There exist two regions of φ_{CN} angles in which relatively stable conformations may exist: the region with φ_{CN} about −30° (the *anti*-region) and the region with φ_{CN} about +150° (the *syn*-region). Each of these occupies somewhat more than 90°. Examination of molecular models[60] and also calculations based on the results of X-ray diffraction analysis[61] showed that the barrier between the *syn*- and *anti*-regions is determined by steric interactions between the N_3 atom of the base and the oxygen atom of the pentose ring in purine nucleoside and between the oxygen atom of the 2-oxo-group or the hydrogen at the C_6 atom of the base on the one hand and the oxygen atom of the pentose ring or the oxygen at the C_2, atom of the sugar (the hydrogen at the C_2, atom in deoxyribonucleosides) on the other in pyrimidine nucleosides. For most of the

§In this review the system of numbering of the pyrimidine and purine rings adopted in Chemical Abstracts is employed:



nucleosides and nucleotides investigated, the *anti*-orientation of the base is preferred (see Table 3). The *syn*-orientation is as a rule less favourable sterically. Furthermore, for purine nucleoside in which the C_3, atom deviates from the plane of the sugar and for pyrimidine nucleosides with the C_3,-*endo*-conformation of the sugar, the existence of the *syn*-isomers is altogether impossible[61]. However, it is evident that in pyrimidine O_2-5′-cyclonucleosides and in purine N_3,-5′-cyclonucleosides only the *syn*-orientation of the base is possible in consequence of the formation of an additional ring. This was confirmed by X-ray diffraction analysis[62] (see Fig. 2). Nor can one exclude the possibility that the necessary stabilisation of the *syn*-conformation is achieved in certain cases in the polynucleotide chain[61] or in nucleotidopeptides (see Section 12) due to non-covalent interactions.

*See the footnote to Table 2.

There is a hypothesis that the *anti*-orientation of the base in ribonucleosides may be stabilised by the formation of a hydrogen bond between the 2′-hydroxy-group of ribose and the 2-oxo-group of pyrimidine or the N_3 atom of purine. This hypothesis is supported by a number of factors: (1) the ultraviolet absorption spectra of pyrimidine ribonucleosides change appreciably in a highly alkaline medium; such changes were not observed for the corresponding nucleoside 2′-phosphates[63–68]; (2) the basicity of the heterocycle in ribonucleosides is lower than in the corresponding 2′-deoxyribonucleosides[63,64,68–70]; (3) in the infrared spectrum of 3′,5′-di-*O*-acetyladenosine there is an absorption band corresponding to an intramolecular hydrogen bond; a band of this kind is absent from the spectrum of 2′,5′-di-*O*-acetyladenosine[71]; (4) the 2′-hydroxy-group of the ribose residue in nucleosides is more acid than the 3′-hydroxy-group[67,72–75]—this has a significant influence on a number of reactions: in the methylation of ribonucleosides with diazomethane 2′-*O*-methylnucleosides are formed preferentially[76–79] and in the tritylation of uridine[80–83] and tosylation of 5′-*O*-trityluridine[84] the 2′-hydroxy group is attacked appreciably faster than the 3′-hydroxy group; (5) the study of the rate of hydrolysis of a number of ribodinucleotides also led Witzel to the hypothesis of the existence of the hydrogen bond C_2,–O–H...O=C_2 in pyrimidine nucleosides and C_2,–O–H...N_3 in purine nucleosides[85,86]; (6) in the latest papers from Ts'o's laboratory[87] the results of an NMR spectroscopic comparison of adenosine with 2′-deoxyadenosine and 2′-*O*-methyladenosine and of pyrimidine ribonucleoside 5′-phosphates with 2-deoxyribonucleoside 5′-phosphates are regarded as evidence of the existence of a hydrogen bond between the 2′-hydroxy-group of the sugar and the 2-oxo-group of pyrimidine or the N_3 atom of purine.

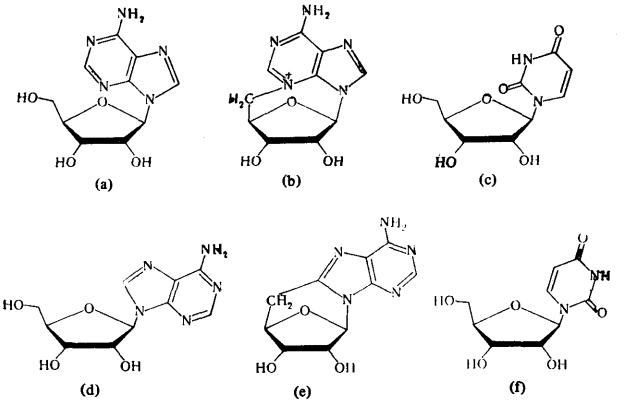

Figure 2. *Syn*- (a, b, and c) and *anti*- (d, e, and f) orientation of the base.

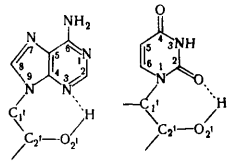
The latter type of hydrogen bond was postulated by Zamecnik[88] in the discussion of the mechanism of the formation of aminoacyl-*t*-RNA from aminoacyladenylates[88].



However, there are a number of data inconsistent with the hypothesis of the existence of such an intramolecular hydrogen bond. Thus in the study of the photochemical addition of water to the 5,6-double bond in pyrimidine nucleosides comparison of the quantum yields for cytidine, 2′-deoxycytidine and cytidine 2′-,3′-, and 5′-phosphates led to the hypothesis that a hydrogen bond forms between the base and the 5′-hydroxy-group of ribose[89,90]. Pitha et al.[91], who observed in the infrared spectra of 2′,3′-di-*O*-substituted nucleosides absorption bands corresponding to a hydroxy-group involved in the formation of a hydrogen bond with the heterocycle, arrived at the same conclusion. Izatt et al. observed a sharp decrease of the acidity of the secondary hydroxyl both in 2′- and in 3′-deoxy-(and methyl-)adenosine and on this basis suggested that a hydrogen bond between 2′- and 3′-hydroxy-groups exists in adenosine[74,75]. It should be noted, however, that this hypothesis does not explain precisely why the 2′-hydroxy-group is the more acid. Finally, on the basis of the determination of the dissociation constants of the 5′-hydroxy-group in the α- and β-isomers of pseudouridine (5-ribofuranosyluracil), Ofengand and Schaefer[92] concluded that the C_5,–O–H...O=C_4 hydrogen bond forms in the natural β-isomer.

5. CONFORMATION OF THE *cis*-GLYCOL GROUP C_2,(OH)–C_3,(OH)

The *cis*-glycol group C_2,(OH)–C_3,(OH) determines a number of important properties of ribonucleosides. Its steric structure can be characterised by the magnitude of the angle of twist φ_{00} between the C_2,–O_2, and C_3,–O_3, bonds. The angle of twist between the true *cis*-bonds is 0°. However, in nucleosides, at least in the solid state, the 2'- and 3'-hydroxy groups deviate from the true *cis*-conformation, which is a consequence (or the cause) of the bending of the ribose ring (see above), and the angle of twist φ_{00} is 43–54°.[23,45] Nevertheless the angle of twist φ_{00} is appreciably less for ribose and other sugar derivatives with the *cis*-glycol group than for sugars with the *trans*-disposition of the 2- and 3-hydroxy-groups, for which the minimum value of φ_{00} is 75° [38] (but not 180° as for the true *trans*-configuration). Thus, as a result of the deformation of the pentose ring, the difference between the values of φ_{00} for the *cis*- and *trans*-isomers is not as great as might have been expected, but it is sufficient to account for the fundamental differences in the reactivities of the compounds. It is known, that in contrast to *trans*-2,3-sugars, ribose derivatives readily react with formation of 2,3-cyclic compounds. A wide variety of 2',3'-alkylidene (isopropylidene, benzylidene, *p*-anisylidene, etc.) derivatives of nucleosides (see, for example, Refs. 1, 2, and 93–101), 2',3'-orthoformates[102] and orthocarbonates[103], 2,3'-carbonates and thiocarbonates[103–112], 2',3'-phenylboronates[113,114], 2',3'-cyclic phosphates (see, for example, Refs. 1, 2, and 114–119), and 2',3'-cyclic phosphites of nucleosides[120] and also of 2',3'-epoxynucleosides[1,121,122] have been described¶. The high rate of oxidation of ribonucleosides with lead tetra-acetate, osmium tetroxide, and periodate, is associated with the ease of formation of intermediate 2',3'-cyclic derivatives[38,123].

The lability of nucleoside 3'-phosphate esters in an alkaline medium is explained by the presence of an adjacent *cis*-hydroxy-group (see, for example, Refs. 1, 2, 93, and 124–126). The elucidation of this effect of the 2'-hydroxy-group assisted in the determination of the structure of RNA (see, for example, Refs. 1, 2, 93, 127 and 128).

There is a hypothesis that the presence of the *cis*-hydroxyl contributes to enhanced activity of the ester group in the *O*-aminoacyl derivatives of adenosine and *t*-RNA in consequence of the formation of a hydrogen bond between the 2'-hydroxy-group and the carbonyl oxygen of the aminoacyl residue[87–128]. In the majority of ribonucleosides and nucleotides in the crystalline state, the C_2,–O_2, and C_3,–O_3, bonds were found to have the *tg*-conformation, i.e. the O–H bond (O–P bond in 3'-phosphate) is oriented *trans* relative to the C_2,–C_3, bond and its orientation is *gauche* relative to the C_2,–C_1, bond or correspondingly the C_3,–C_4, bond (see Fig. 3).

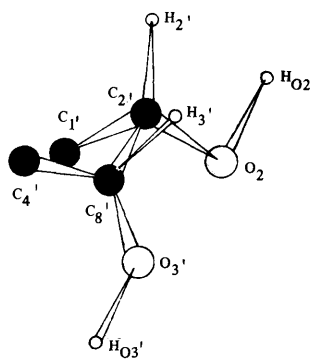


Figure 3. Conformation of the *cis*-glycol group (C_2,-*endo*-bending of the ribose ring).

6. CONFORMATION OF THE C_4,–C_5, BOND

For the exocyclic carbon–carbon C_4,–C_5, bond in the crystalline state, three types of conformation were observed (see Table 4 and Fig. 4): (a) *gg*—*gauche*-orientation of the C_5,–O_5, bond relative to the C_4,–O_1, bond and relative to the C_4,–C_3, bond; (b) *gt*—*gauche*-orientation of the C_5,–O_5, bond relative to the C_4,–O_1, bond and *trans*-orientation relative to the C_4,–C_3, bond; (c) *tg*—*trans*-orientation of the C_5,–O_5, bond relative to the C_4,–O_1, bond and *gauche*-orientation relative to the C_4,–C_3, bond.

Uridine residue	*gg*	62	57	

*See the footnote to Table 2.

As shown in Table 4, the *gg*-conformation is encountered most frequently, at least in the crystalline state. Probably this is because in this conformation the intramolecular interaction between the substituent at the C_5, atom, the base, and the sugar ring is a minimum[21].

7. STRUCTURE OF THE PHOSPHATE RESIDUE IN NUCLEOTIDES

It has been found for the crystals of all the nucleotides investigated that, when the 5'-hydroxy group is esterified by a phosphate residue (nucleoside 5'-phosphate), the O_5,–P bond occupies the *trans*-position relative to the C_4,–C_5, bond, thus ensuring the most extended form of the molecule.

¶Owing to the large number of studies in the field of 2',3'-cyclic derivatives of ribonucleosides, it is not claimed that the selection of literature on this problem presented here is exhaustive.

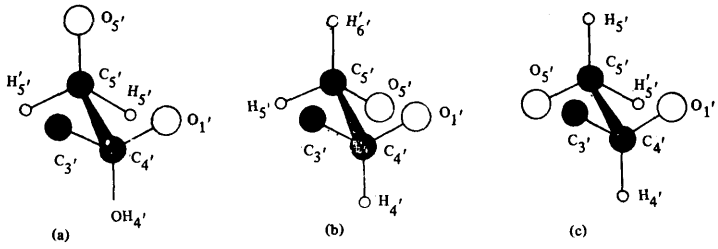

Figure 4. Conformation of the C_4,–C_5, bond: a) *gg*; b) *gt*; c) *tg*.

The phosphate residue in nucleotides in the crystalline form and in neutral solutions is present at the monoanion (this applies to both 3'- and 5'-phosphates). The P–O distance in nucleotides, as in other phosphoric acid esters[129–131], proved to be much shorter (by 0.24–0.09 Å[23, 36,38,43–45]) than the calculated value of 1.71 Å,[132] the bond length decreasing in the following sequence: P–OR > P–OH > P–O' > P=O. This confirms the presence in phosphoric acid esters of π-conjugation between the *d*-orbitals of phosphorus and the *p*-electrons of oxygen[133,134]. In other words, the phosphorus–oxygen bond in phosphoric acid esters has partial double bond character[133]. The decrease of the double bond character between the phosphorus and oxygen as a result of the breakdown of p_π–d_π conjugation results in a significant weakening of the phosphate ester bond. This happens, for example, in nucleoside cyclic phosphates.

8. NUCLEOSIDE CYCLIC PHOSPHATES

Nucleotides can form both five-membered 2',3'-cyclic phosphates and six-membered 3',5'-cyclic phosphates. The five-membered phosphate rings are strained[1,135], which is the main reason for their extremely great reactivity compared with non-cyclic-esters[1,93,135,136].

Probably in consequence of the strain of the five-membered phosphate ring, p_π–d_π conjugation between the oxygen and phosphorus breaks down, which is the reason for the lability of the P–O bond[134]. The much greater stability of the six-membered nucleoside 3',5'-cyclic phosphates is evidence of a lower strain of the ring. However, it follows from a comparison of the time required for 50% decomposition in 1 *N* sodium hydroxide at 100°C of thymidine 3',5'-cyclic phosphate, in which the six-membered phosphate ring is formed with participation of the *trans*-hydroxy-groups[137], 1,2-isopropylidenexylofuranose-3,5-cyclic phosphate, in which a phosphate ring of the same size is formed by *cis*-hydroxy-groups[136,138], and propane-1,3-diol cyclophosphate[136] (2,4, and 72 h respectively) that in nucleoside 3',5'-cyclic phosphates the phosphate ring is also strained, probably as a result of the *trans*-orientation of the C_4,–C_5, and C_3,–O_3, bonds relative to the pentose ring. Because of this configuration of the sugar, the only possible form of the six-membered phosphate ring is the chair conformation. For it to exist, the nature of the bending of the furanose ring must be altered and the C_3,-*endo*-C_4,-*exo*-conformation is the most probable[48,139]. Indeed, studies with the aid of X-ray diffraction showed that in the conversion of uridine 5'-phosphate into uridine 3',5'-cyclic phosphate the conformation of ribose changes from C_2,-*endo*-[36] to C_3,-*endo*-[37] and in the conversion of adenosine 5'-phosphate into adenosine 3',5'-cyclic phosphate the change is from C_3,-*endo*-[42,44] to C_4,-*exo*-[46] (Table 1). The change of the conformation of pentose probably entails the occurrence of some strain in the furanose ring. This is believed[136] to be the cause of the lowered stability of the glycoside bond in nucleoside 3',5'-cyclic phosphates compared with the corresponding nucleosides and nucleotides. On treatment with 1 *N* sodium hydroxide at 100°C, adenosine 3',5'-cyclic phosphate yields adenine, while under these conditions adenosine itself is stable[140]; thymidine 3',5'-cyclic phosphate splits off thymine completely on treatment with 0.1 *N* hydrochloric acid at 100°C for 5 min, while thymidine 5'-phosphate remains stable for more than 3 h under these conditions[136].

An interesting feature of the structure of nucleoside 3',5'-cyclic phosphates is the presence in the same crystal cell of two molecules with different conformations of the glycoside bond; in uridine 3',5'-cyclic phosphate both molecules have the *anti*-orientation of the base relative to the sugar[37], but in adenosine 3',5'-cyclic phosphate one molecule has the *anti*-orientation and the other the *syn*-orientation[46] (so far this is only the second, after deoxyguanosine, case of *syn*-orientation, see Table 3).

9. INTRAMOLECULAR INTERACTIONS IN NUCLEOTIDE ESTERS

When nucleotide esters other than cyclic phosphates are examined, the dependence of the properties of the phosphodiester group on the nature of the substituents in the sugar ring is striking. Thus it is known that *p*-nitrophenyl esters of various nucleotides are hydrolysed in different ways: *p*-nitrophenyl esters of thymidine 3'- and 5'-phosphates are hydrolysed with alkali via the intermediate formation of thymidine 3',5'-cyclic phosphate[141,142], while this behaviour was not observed for the *p*-nitrophenyl ester of uridine 5'-phosphate[142]. The different mechanisms of hydrolysis may be associated with the different conformations of the pentose ring, which may favour or hinder the mutual approach of the 3'-hydroxy-group and the 5'-phosphate group. In uridine 5'-phosphate and thymidine 5'-phosphate crystals different conformations of the carbohydrate ring have indeed been observed (see Table 1). Unfortunately the data are so far insufficient to confirm or reject this hypothesis.

The interaction of hydroxy- and phosphate-groups in *trans*-positions occurs also in other nucleotide derivatives. For example the formation of adenosine 3',5'-cyclic phosphate in the hydrolysis of ATP with barium hydroxide[140],

and the conversion of the methyl ester of thymidylyl-(3′–*N*)-phenylalanine into thymidine 3′,5′-cyclic phosphate on standing in dimethylformamide[143] have been described (for a more detailed treatment, see Section 12).

10. DINUCLEOSIDE PHOSPHATES AND OLIGONUCLEOTIDES

Dinucleoside phosphates constitute a special group of nucleotide esters. The study of adenylyl-(2′–5′)-uridine by X-ray diffraction revealed almost parallel disposition of the two bases and their partial overlapping[39] (Fig. 5). The study of solutions of dinucleoside phosphates and di-, tri- and oligo-nucleotides shows that the parallel orientation of the bases is most likely for these compounds also in solution.

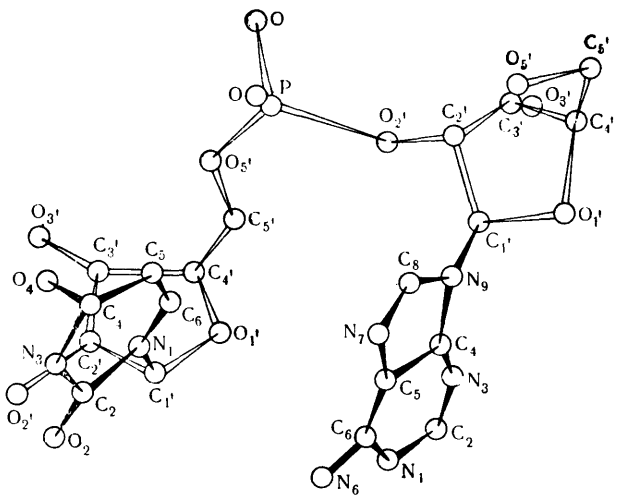

Figure 5. Model of the adenylyl-(2′–5′)-uridine molecule according to X-ray diffraction analysis[47].

Oligonucleotides have a number of specific properties: (1) on degradation of nucleotides, the intensity of ultraviolet absorption increases (hyperchromic effect) (see, for example, Refs. 1, 89, 144, and 145); (2) spectropolarimetry of oligonucleotides reveals a powerful cotton effect, which is not equal to the sum of the effects of the component mononucleotides, and the independence of the specific rotation of oligonucleotides of concentration[16,17,145–152]; (3) the circular dichroism of oligonucleotides does not agree with the sum of the effects associated with the circular dichroism of the component nucleotides[153,154]; (4) the fluorescence spectra of di- and poly-nucleotides and of the component monomers are qualitatively different[155,156]; (5) the NMR spectra of deoxyoligonucleotides reveal a shift of the proton signals from thymine relative to the mononucleotide[157].

The facts enumerated above indicate the occurrence of powerful interaction between the bases in oligonucleotides, which is shown even in dinucleotide phosphates. Several types of such interaction are possible, for example horizontal association via hydrogen bonds or vertical association as a result of π-electron interactions between the heterocyclic systems. Since dinucleoside phosphates which are derivatives of dimethylaminopurine exhibit a greater hyperchromism at all pH values than the adenine derivatives[158], it is unlikely that the interaction of the bases is determined by hydrogen bonds, particularly since it has been shown for diadenylic acid, for example, that the energy of interaction between the bases exceeds the energy of the hydrogen bond[157,159]. Furthermore, the disappearance of hyperchromism in dinucleotides such as adenylyl-(3′–5′)-uridine and adenylyl-(3′–5′)-cytidine 3′-phosphate on saturation of the 5,6-double bond by hydrogenation[160] or photolysis[161] demonstrates the important role of the π-electron systems of the bases in their interaction.

Finally, the study of aqueous solutions of mononucleotides, nucleosides, and purine and pyrimidine bases by NMR spectroscopy[162–165], osmometry[166,167], and ultracentrifugation[169] revealed a high degree of association of their molecules. It was then established that the interaction between the purine derivatives is favoured more than the interaction between purine and pyrimidine derivatives and the latter is in turn favoured more than the interaction between pyrimidine derivatives. On this basis, it was concluded that the mechanism of association consists in the arrangement of the bases in a pile, one on top of the other, as a result of the hydrophobic interactions between the π-electron systems of the bases. It is interesting that guanosine 3′- and 5′-phosphates and isoguanosine [6-amino-2-hydroxy-9-(β-D-ribofuranosyl)-purine] are believed to be arranged in a pile in the form of hydrogen-bonded tetramers with generation of a spiral ordered structure, which leads to the formation of a gel[169–175].

Association complexes of monomers in solution are not broken down by water molecules. This is explained by the presence of strong water–water hydrogen bonds. On the other hand, in dimethylformamide and in dimethyl sulphoxide such hydrogen bonds are not formed because of the absence of proton donors in the molecules of these solvents. However, since they are proton acceptors, they form hydrogen bonds with the molecules of the solute, breaking down its ordered structure[163].

The interaction between bases takes place, and actually to a greater extent than between monomers, in oligo- and poly-nucleotides. In these substances the interaction between the π-electrons of adjacent rings essentially gives rise to a new electronic system, which in fact determines the specific optical properties of the entire molecule[1,176,177].

The study of homogeneous oligo- and poly-nucleotides substituted in the heterocyclic ring (see, for example, Refs. 159 and 178–187) showed that the stability of the secondary structure of polymers increases somewhat on substitution, although at the same time the capacity for the formation of a double spiral with a complementary chain may be reduced. Probably hydrophobic interactions rather than hydrogen bonds play a decisive role in the stabilisation of the secondary structures of DNA and RNA (see, for example, Refs. 187 and 188 and also Tikhonenko's review[189])†.

†This review does not deal with the interactions between bases arising as a result of the formation of hydrogen bonds in accordance with the complementarity principle, since there is an extensive literature, including reviews, on this question, closely related to the study of the structure and functions of nucleic acids, which is outside this scope of the problem discussed here.

The significant role of hydrophobic forces and the stabilisation of the secondary structure of polynucleotides is also indicated by the observed association of purines with dinucleotides[190]: probably purine penetrates the dinucleotide molecule between the bases of the latter and, as a result of π-electron interaction with each of these, it, as it were, draws them together, forming a structure similar to a three-layer sandwich. In this connection there is an interesting hypothesis[191] that the possible cause of the biological activity of the notorious drug thalidomide is its similarity to nucleosides as regards capacity for hydrophobic interactions, as a result of which the thalidomide molecule may penetrate between the bases of DNA, altering its secondary structure.

11. DINUCLEOSIDE PYROPHOSPHATES AND NUCLEOTIDE COENZYMES

Evidently the interaction of the π-electron systems of the bases can also occur in P^1P^2-dinucleoside pyrophosphates. In addition, since the pyrophosphate link is more flexible than the phosphate link, it probably ensures a closer approach and maximum overlapping of the bases, which is reflected in larger hyperchromic effects of these compounds compared with dinucleotides[150,163].

An analogous phenomenon is observed also for other dinucleoside pyrophosphates, in particular the nucleotide coenzymes (flavine-adenine dinucleotide, nicotinamide-adenine dinucleotide). In the hydrolytic or enzymic dissociation of the pyrophosphate bond in FAD and NADH the ultraviolet absorption increases[192-197], which is evidence of interaction between the bases. This is confirmed also by fluoroscopic data. It has been found that nicotinamide forming part of reduced NAD fluoresces not only at 340 nm, as in the free state, but also at 260 nm,[198-201] the fluorescence being quenched by the addition of methanol to the solution of NADH.[202] On the other hand, the riboflavin forming part of FAD fluoresces more weakly than in the free state[203]. Furthermore the fluorescence of riboflavin is quenched on addition to its solution of purines[204-206], phenols[207], and chlorotetracycline[208]. By analogy with oligonucleotides, it was suggested that the interaction of the π-electron systems of adenine and the reduced nicotinamide or riboflavin is accompanied by an energy transfer[195,202,205] (see also Beinert's review[209]). The formation of such a complex is confirmed by spectropolarimetry[210,211] and NMR spectroscopy[212,213], and it has been shown at the same time that the π-complex form of NADH may be in equilibrium with an uncoiled form and that in certain enzymic reactions complete uncoiling of the coenzyme molecule takes place[213] (see Fig. 6).

The hypothesis of the π-electron nature of the interaction between the bases in nucleotide coenzymes is supported also by certain results of studies on their analogues: energy transfer, albeit much less effective than for NADH, has been observed for nicotinamide-uracil dinucleotide[214] and nicotinamide-phenol dinucleotide[215], while for nicotinamide-purine dinucleotide[216], nicotinamide-6-(β-hydroxyethylamino)purine dinucleotide[217], and nicotinamide-α-adenine dinucleotide[218] energy transfer almost as effective as for NADH has been observed. However, on the other hand, the absence of fluorescence in reduced nicotinamide-hypoxanthine dinucleotide[219] and the decrease of the fluorescence on alkylation of riboflavin in FAD at N_3 [220-222] may be regarded as evidence in favour of a considerable role of hydrogen bonds in the intramolecular association of the bases in nucleotide coenzymes.

It is most likely that intramolecular complexes in NADH and FAD are due to the interaction of the π-electron systems of the bases and are stabilised by hydrogen bonds.

An intramolecular complex, in the formation of which hydrogen bonds play the main role, is formed in nucleotide coenzymes of another type—nucleoside diphosphate sugars.

Examination of various natural NDPS [223,224] revealed a definite correspondence between the structure of the heterocyclic base and that of the residue of the nucleoside monosaccharide. Furthermore, there is a relation between the nature of the nucleotide residue in the NDPS and the type of biochemical reactions in which the NDPS is involved[223,224]. Since the NDPS react via the non-nucleoside monosaccharide residue, it was suggested that the specificity of the biochemical properties of NDPS is associated with the conformation of the monosaccharide, which in turn is determined by the structure of the nucleoside. The nucleoside residue may affect the structure of the monosaccharide residue as a result of the formation of intramolecular bonds with the latter, hydrogen bonds being the most likely. The equatorial orientation of the hydroxy-groups at the $C_{2''}$ and $C_{3''}$ atoms of the monosaccharide observed in all NDPS suggested that such bonds may arise between the –NH–CO–group in positions 3 and 4 of the base and the hydroxy-groups at the $C_{2''}$ and $C_{3''}$ atoms of the sugar (see, for example, Fig. 7). For uridine diphosphate sugars, there is also a possibility of a hydrogen bond between the 2-oxo group of the base and the 2′-hydroxy-group of ribose, as in other uracil ribonucleotides (see above).

The study of the activity of various synthetic analogues of uridine diphosphate glucose in enzymic reactions typical

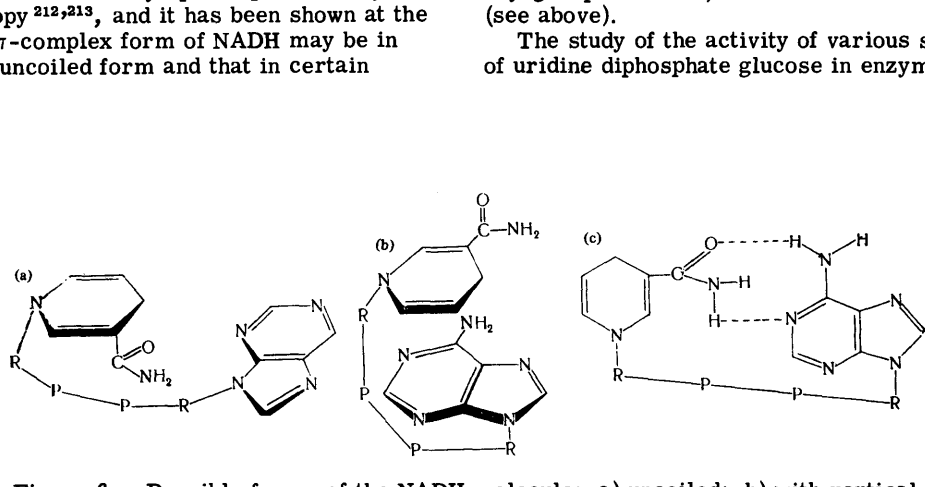

Figure 6. Possible forms of the NADH molecule: a) uncoiled; b) with vertical association of the bases; c) with hydrogen bonds[213].

for it[225-230] confirms the hypothesis that the specificity of biochemical reactions with participation of NDPS is determined by the steric structure of the NDPS molecule, since all the active analogues of UDPG contain the same grouping NH–C=O (or NH–C=S) in positions 3 and 4 of the heterocycle and consequently they can form similar intramolecular complexes.

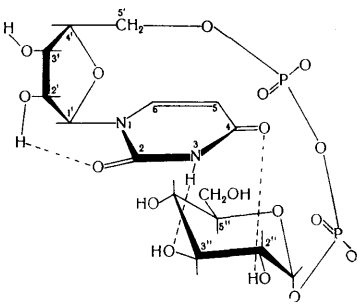

Figure 7. Schematic representation of the steric structure of the UDPG molecule[223].

The hypothesis of an intramolecular bond between the heterocycle and the sugar in NPDS was confirmed chemically by studying the rate of the catalytic hydrogenation (rhodium on alumina) of the carbon–carbon 5,6-double bond in UDPG and UMP-5'.[217] The considerable retardation of the reaction involving UDPG compared with UMP may be regarded as evidence for a significant difference in the steric accessibility of the double bonds in these compounds for the addition of hydrogen or for fixation on the surface of the catalyst, in consequence of their conformational differences. Similar results were obtained for 6-aza-UDPG and 6-aza-UMP, while *N*-methyl-UDPG, CDPG, and 2'-deoxy-UDPG are hydrogenated at the same rate as the corresponding nucleoside monophosphates[231]. The decrease of the differences in the rate of hydrogenation of UDPG and UMP in the presence of 7 M urea may be due to the breakdown of the hydrogen bond, which weakens the specific steric structure of the molecule[231].

The interaction of the base with the part of the molecule remote from it takes place in NDPS, as in FAD and NADH, because of the presence of the diphosphate unit which is fairly flexible due to the freedom of rotation characteristic of single bonds. A similar unit is present also in other nucleotide coenzymes, including nucleoside di- and triphosphates, among which adenosine 5'-diphosphate (ADP) and adenosine 5'-triphosphate (ATP) undoubtedly merit the greatest attention. Szent-Györgyi put forward the hypothesis[232] (see also later textbooks translated into Russian[233,234]) that the ADP molecule is "folded" in such a way that the terminal phosphate groups are in the immediate vicinity of the N_6 and N_7 atoms of adenine, forming with the latter a tetradentate chelate compound, using Mg^{2+} as a connecting link. A number of indirect infrared[235-237] and ultraviolet[238] spectroscopic and spectropolarimetric[239-240] data have been interpreted as favouring this hypothesis, so that it received wide recognition and the structure proposed by Szent-Györgyi for ATP may be found in many textbooks and reviews (see, for example, Refs. 241 and 242). Nevertheless the attempts to obtain direct proof of the interaction between Mg^{2+} and adenine were unsuccessful[243-252], although there is no doubt that a complex of Mg^{2+} with the phosphate group is really formed[243-255] (see also Bock's review[256]). In this connection it is suggested that in ADP and ATP the phosphate groups (via Mg^{2+}) and adenine form separate bonds with enzymes[244,256,257]. At the same time it should be noted that NMR spectroscopic data for ATP complexes with divalent zinc[245,247] and copper[245,246] ions are not inconsistent with the structure of the type proposed by Szent-Györgyi, i.e. a chelate complex of the metal ion with the nitrogen atoms of adenine and two phosphate groups, and it has been found that for the zinc complex the participation of the β- and γ-phosphate groups is more likely while for the copper complex the α- and β-phosphate groups are more likely to be involved. In addition, it has been established that Mn^{2+} may interact with adenine and with α-, β-, and γ-phosphate residues[245]. Probably Mn^{2+} can form complexes of different types. It is suggested that this capacity of the Mn^{2+} ion may explain why it can replace both Mg^{2+} and Zn^{2+} in enzymic reactions specific with respect to the ions of these metals[245]. The conformation of the possible complexes of ADP and ATP with metal ions is discussed in detail in other reviews[258,259].

12. INTRAMOLECULAR INTERACTIONS IN NUCLEOTIDOPEPTIDES

The amino-acid and peptide derivatives of nucleotides with a covalent bond between the fragments (nucleotidopeptides) play an important role in metabolic processes (see, for example, Refs. 260, 261). Unfortunately, from the chemical standpoint these compounds have been inadequately investigated. An exception are the nucleotidopeptides with a phosphoramidic nucleotidopeptide bond, for which the relation between the structure and chemical properties has been investigated systematically[262-268].

The polyfunctional nature of nucleotido-(P–N)-peptides and the large number of single bonds permitting a wide variety of relative positions of the individual parts of the molecule impart to the molecule a considerable capacity to assume the conformation suitable for intramolecular interactions between groups which are not directly linked. The effect of these interactions on the properties of the nucleotidopeptide bond may be very great because of the specific properties of both the phosphorus atom (capacity for p_π–d_π conjugation with atoms which are not directly linked to it) and the nitrogen atom (tendency to undergo protonation not only by the protons from the medium but also from the proton-donor groups of the same molecule).

The study of nucleotidyl-(5'–N)-amino-acids, in which the amino-acid residue does not contain additional functional groups, showed that the 5'-phosphoramidate bond in these compounds is readily hydrolysed in an acid medium and is stable in neutral and alkaline media[262-266] as in simple amides of phosphoric acid and its esters. However, in a weakly acid medium (pH 2.5–5) the hydrolytic stability of the phosphoramidate bond depends on the nature of the heterocyclic base of the nucleotide[262,263]. Examination of the structure of nucleotidyl-(5'–N)-amino-acids led to the hypothesis that the interaction of the base with the phosphoramino-acid residue takes place via hydrogen bonds, as shown in Fig. 8, for example. Although the *anti*-orientation of the base is typical for nucleotides, as shown on Russ. p. 227, it is possible that in this case (schemes a, b, and d) the energy required to overcome the barrier between the *anti*- and *syn*-regions is compensated by the formation of hydrogen bonds.

Some confirmation of the proposed structures was obtained by infrared and ultraviolet spectroscopy[262], but more detailed information about the intramolecular interactions in nucleotide-(P–N)-peptides was obtained by the study of their hydrolytic stability[262–268]. Fig. 8 shows that in the amino-acid derivative of guanosine 5′-phosphate (b) the phosphoramidate nitrogen is protonated even in a neutral medium, which probably accounts for the higher rate of its hydrolysis compared with the uridine 5′-phosphate derivative. On the other hand, adenylyl-(5′–N)-phenylalanine and uridylyl-(5′–N)-phenylalanine have similar stabilities, as was to be expected on the basis of the structures (a), (c), and (d) in Fig. 8. The decrease of the differences between the rates of hydrolysis of the phosphoramidate bond in phenylalanine derivatives of various nucleotides on raising the temperature[263] and on increasing the acidity of the medium[262,263] may be a consequence of the breakdown of specific hydrogen bonds.

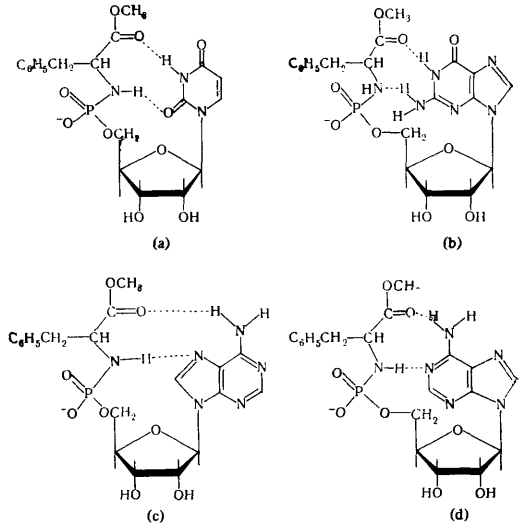

Figure 8. Schematic representation of the possible hydrogen bonds in methyl esters of uridylyl-(5′–N)-phenylalanine (a)[262], guanylyl-(5′–N)-phenylalanine (b)[263], and adenylyl-(5′–N)-phenylalanine (c)[264] or (d).

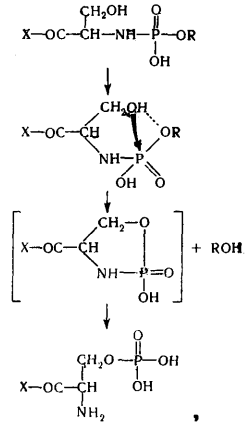
In the presence of the nucleotidopeptide molecule of other functional groups, the properties of the phosphoramidate bond can change. Thus the introduction into the 3′(2′)-position of the nucleotide fragment of an additional phosphate group leads to some stabilisation of the P–N bond, but only at a pH less than 2.5.[266] Probably under these conditions the 5′-phosphoramidate and the 3′(2′)-phosphate groups are close together, which may be favoured by the *gg*-conformation of the $C_{5'}$–$O_{5'}$ bond and the $C_{2'}$-*endo*-bending of the ribose ring. However, at higher pH this interaction breaks down as a result of the electrostatic repulsion between the dissociated phosphate groups.

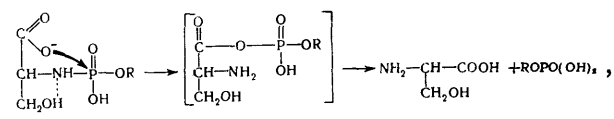
On going from amino-acid to peptide derivatives, the stability of the phosphoramidate bond also increases somewhat. The study of the rate of hydrolysis of a number of derivatives of guanosine 5′-phosphate at a pH less than 2.0 and at different temperatures led to the conclusion that the decisive factor in such increase of stability is the occurrence of steric hindrance in the protonation of the phosphoramidate nitrogen by the protons of the medium[263]. If, however, protonation takes place intramolecularly, for example with participation of the guaninine amino-group (see Fig. 8), an increase in the length of the peptide chain does not lead to any appreciable change in the stability of the phosphoramidate bond[263].

Examination of the hydrolytic stability of nucleotido-(5′–N)-peptides shows that the appreciable differences in the stability of the phosphoramidate bond are nevertheless only quantitative. However, when the peptide unit contains functional groups, there is a possibility of a fundamentally new type of dissociation of the nucleotidopeptide bond. Thus nucleotidyl-(5′–N)-amino-acids with a free carboxy-group[267] and esters of nucleotidyl-(5′–N)-serines with a free serine hydroxy-group[268] are hydrolysed on treatment with acid not only at the P–N bond with formation of the nucleotide and the amino-acid but also at the phosphoester bond with formation of the nucleoside and the phosphoramino-acid. One of the possible mechanisms of hydrolysis at the phosphoester bond includes intramolecular protonation of the phosphoramidate unit and the formation as an intermediate of a cyclic phosphoramino-acid derivative:



where ROH is the nucleoside and X is the peptide or OCH_3.

The intramolecular interaction between the hydroxy-group of serine and the phosphoramidate group is observed also in an alkaline medium, resulting in the dissociation of the phosphoramidate unit (simple phosphoramidates are stable in an alkaline medium)[268]. This dissociation takes place in different ways depending on which groups participate in the catalytic step. If this step involves the simultaneous participation of the hydroxy- and carboxy-groups, then the phosphoramidate bond dissociates (the carboxy-group may be either adjacent or remote, for example the terminal carboxy-group in the tri- and tetra-peptide derivative of the nucleotide where serine is the *N*-terminal amino-acid):

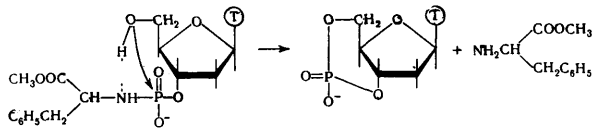


where ROH is the nucleoside.

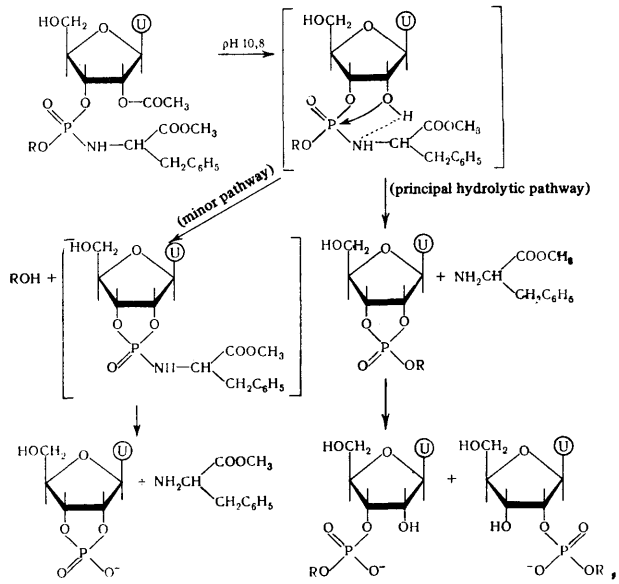
If only the hydroxy-group takes part in the catalytic step, then in alkaline degradation the phosphoester group dissociates by the acid hydrolytic mechanism described above, with formation of an intermediate five-membered cyclic phosphate, which dissociates in an alkaline medium to the *N*-phosphopeptide.

Thus a structure with a characteristic "loop" at the amino-acid end of the molecule is typical for nucleotidyl-(5′–N)-amino-acids with an additional functional group in the amino-acid fragment.

Electrophilic-nucleophilic intramolecular catalysis similar to that described above for serine derivatives of nucleoside 5′-phosphates is also observed for the thymidylyl-(3′–N)-phenylalanine ester, which on standing or brief heating in dimethylformamide is converted into thymidine 3′,5′-cyclic phosphate with simultaneous elimination of the amino-acid[143]:



In this case nucleophilic substitution at the phosphorus atom may be favoured by the conformation of the molecule in which the amide nitrogen is close to the 5′-hydroxy-group of deoxyribose (*gg*-conformation of the $C_{5'}$–$O_{5'}$ bond and $C_{3'}$-*endo*-bending of the pentose ring). An analogous intramolecular effect of the hydroxy-group favourably oriented in relation to the phosphoramidate group is most fully shown in ribonucleoside 3′-phosphoramino-acids, where the position of the hydroxyl near the P–N bond is fixed by the sugar ring. Indeed, while the amino-acid derivatives of thymidine 3′-phosphate and 5′-phosphate behave almost identically in aqueous solution regardless of the position of the phosphoramino-acid residue, being stable at pH > 3,[143] the amino-acid derivatives of ribonucleoside 3′-phosphates can exist under these conditions only if the 2′-hydroxy-group is blocked[262]. The role of the 2′-hydroxy-group in this phenomenon is confirmed by the formation of nucleoside 2′,3′-cyclic phosphate on elimination of the protective 2′-acetyl or 2′-tetrahydropyranyl groups under conditions where the isolated P–N bond is stable (pH 10.8 and 4.5 respectively)[262]. An analogous phenomenon was observed in the amino-acid derivatives of dinucleoside phosphates at the internucleotide phosphorus: while thymidylyl-(3′–5′)-thymidino-(P–N)-phenylalanine is quite stable in neutral aqueous solution, its ribo-analogue—2′-*O*-acetyluridylyl-(3′–5′)-uridino-(P–N)-phenylalanine—hydrolyses immediately after liberation of the 2′-hydroxyl:



where R = H for uridylyl-(3′–N)-phenylalanine and R is the nucleoside residue for uridylyl-(3′–5′)-uridino-(P–N)-phenylalanine.

The information obtained in the study of synthetic nucleotidopeptides suggests that, by virtue of numerous conformational possibilities, the individual fragments of the nucleotidopeptide can interact with one another. A consequence of this is extensive variability of the reactivity of nucleotidopeptides. This permits at least two conclusions. Firstly, in the determination of the types of covalent bonds in natural nucleotidopeptides one must use with great caution data obtained in the study of relatively simple structures. This is clearly shown for the phosphoramidate bond as an example, which, while stable in neutral and alkaline media in the case of simple compounds, becomes labile under the same conditions if the conformation of the molecule is such that proton-donor groups are adjacent to the phosphoramidate group. On the other hand, in the presence of functional groups capable of intramolecular catalysis of hydrolysis and sterically similar to the phosphoramidate group, anomalous dissociation of the phosphoramidate unit may occur also in an acid medium: instead of the dissociation of the phosphoramidate bond (as in simple nucleotide amides), the phosphate residue migrates from the nucleoside to the peptide. Thus, on the basis of the structure of the hydrolysis products of nucleotidopeptides, unambiguous conclusions concerning the nature of the bond in the natural compound cannot be arrived at. In the first place, the available information about the intramolecular interactions in nucleotido-(P–N)-peptides shows that even in a fairly simple molecule consisting of mononucleotide and peptide fragments there is considerable scope for self-regulation: the mutual approach of the phosphoramidic group and a proton donor or acceptor leads to an enhancement or correspondingly a decrease of its reactivity. This suggests the possibility of the existence of analogous mechanisms of the activation of the phosphate residue of mononucleotides in biosynthetic processes such as the formation of internucleotide bonds in the presence of specific enzymes. The enzyme–substrate complex of the phosphoramidate type with the appropriate conformation can effect the transfer of the mononucleotide residue to the 3′-hydroxy-group of the terminal nucleotide of the polynucleotide chain being formed. The ease of the regulation of such a process by the transfer of a proton to the phosphoramidic nitrogen or its removal makes this hypothesis very probable.

It may be expected that the study of the intramolecular interactions in more complex nucleotidopeptides, in particular in oligonucleotidopolypeptides with a specified structure (with a specified sequence of mononucleotides and amino-acids), can throw light on the most important problem of modern molecular biology—the problem of mutual "recognition" of specific nucleic acids and enzyme proteins.

Insect Sex Attractants

Yu.B.Pyatnova, L.L.Ivanov, and A.S.Kyskina

The review deals with the chemical study of natural attracting substances in insects. Insect attractants have been classified in accordance with structural factors: (1) unsaturated alcohols and their acetates; (2) aliphatic acids; (3) terpene-like substances. The methods of isolation of new attractants, biological tests, proof of individuality, determination of structure, and syntheses have been described in detail. The bibliography includes 140 references.

IV. Terpene-like compounds 136

I. INTRODUCTION

There are more than a million species of insects in nature. Among this wide variety similar species are encountered, which are almost indistinguishable in their external features. However, in the world of insects there is almost never any crossing of different species. The maintenance of "order" in nature is favoured by a number of refined phenomena involving sight, hearing, and especially smell, which is very highly developed in insects. This enables them to find food, sites for the deposition of eggs, and also individuals of the opposite sex.

The French naturalist Jean Henri Fabre was the first to note at the end of the XIXth century that the female of *Saturnia peri* (L) placed in a cage attracted a large number of males. He carried out experiments with other species of butterflies (moths) and concluded that the female executes vibrations which are propagated in air in the form of waves and are received by the antennae of the male. Later it was established that the information provided by the female is transmitted with the aid of a chemical substance. These substances have been called sex attractants†.

Sex attractants are extremely effective biologically active compounds and are distinguished by high specificity. These properties are of great value for the investigation of practical application of attractants for the purpose of attracting and destroying insects. The application of attractants in the fight against harmful insect species has developed in recent years and already considerable successes have been achieved. The practical importance of attracting substances stimulated the study of the chemical aspects of the problem. At the present time the structures of a number of natural attractants have been established.

The known compounds have definite structural features, which permit the classification of the sex attractants into three groups according to their structures: unsaturated alcohols and their esters, aliphatic acids, and terpene-like compounds. The first group contains the greatest number of the known attractants. It is noteworthy that the acetates of unsaturated aliphatic acids containing between 12 and 16 carbon atoms function as attractants for insects belonging mainly to the order Lepidoptera. No general conclusions concerning the other two groups are at the moment possible because of the insufficiency of factual data. In the present review the authors attempted to arrange the available data systematically in accordance with the structural features discovered.

A number of reviews dealing with sex attractants have been published[3-14], but these are of a descriptive type and the chemical aspects of the problem are touched upon only briefly. Nevertheless the chemical studies on sex attractants are very interesting because of their complexity and specificity. In the present review the authors' aim was to cover the literature data up to 1968 and to elucidate most fully the problems of the chemical nature and syntheses of attractants.

II. UNSATURATED ALCOHOLS AND THEIR ESTERS

1. Attractant of the Silkworm Moth [*Bombyx mori* (L.)]

In the 1940's Butenandt and coworkers began to study the attracting substance produced in the glands in the last two segments of the abdomen of the female silkworm moth. In 1959 they succeeded in isolating the sex attractant and in determining its structure[15,16]. The starting material consisted of the glands of 500 000 females. After a number of operations, shown in Scheme (I), fractions A, B, and C were obtained, which exhibited high activity. After three chromatographic purifications on Kieselguhr and then on silicic acid and repeated recrystallisation, 6 mg of the ester of 4'-nitroazobenzene-4-carboxylic acid was isolated from fraction B. After hydrolysis the substance yielded an alcohol with LE‡ = 10^{-10} μg, which was called bombykol. A further 6 mg of the bombykol ester was obtained from fractions A and C by analogous purification.

The general formula and the molecular weight of the bombykol ester were determined by elemental analysis and ultraviolet spectroscopy. The infrared spectrum showed absorption characteristic of the C–OH group in a primary alcohol, *cis-trans*-conjugated double bonds, and a methylene chain with not less than four carbon atoms. Catalytic

† The compounds secreted by one insect in order to influence another individual of the same species and to induce in the latter definite responses are frequently called "pheromones"[1]. Kirshenblat proposed a classification of such compounds and introduced the term "telergones"[2].

‡ *LE* is the unit of attraction defined as the weight of the substance in 1 ml of the attractant solution in petroleum ether which gives rise to a response in 50% of the males tested.

hydrogenation of bombykol yielded cetyl alcohol. The position of the double bonds in the molecule was established by oxidative degradation combined with paper chromatography of the ozonolysis products [17].

The combined data obtained led to the attribution of structure (I) to bombykol:

$$CH_3(CH_2)_2\underset{(I)}{CH{=}CH{-}CH{=}CH}(CH_2)_8CH_2OH\ .$$

The geometrical configuration of the compound was established by the synthesis of the four possible isomers of compound (I) and the comparison of their physicochemical and biological properties with those of the natural substance [18,19].

The *trans*-10-*cis*-12-isomer was obtained by the Wittig condensation of hex-2-ynylidenetriphenylphosphorane (II) with the aldehyde (III). This yields a mixture of the *cis*- and *trans*-isomers (IV) in approximately equal proportions. To separate the isomers and also in other syntheses [18,19], repeated crystallisation of the urea complexes was employed. After the hydrogenation of *trans*-(IV) using Lindlar's catalyst and after reduction with lithium aluminium hydride, *trans*-10-*cis*-12-(I) was obtained:

$$\underset{(II)}{CH_3(CH_2)_2C{\equiv}CCH{=}P(C_6H_5)_3} + \underset{(III)}{O{=}CH(CH_2)_8CO_2C_2H_5}$$

$$\downarrow$$

$$CH_3(CH_2)_2C{\equiv}C{-}\underset{\underset{(IV)}{}}{CH{=}CH}(CH_2)_8CO_2C_2H_5$$

$$\downarrow$$

$$CH_3(CH_2)_2C{\equiv}C{-}\underset{H}{\underset{|}{C}}{=}\underset{H}{\underset{|}{C}}(CH_2)_8CO_2C_2H_5$$

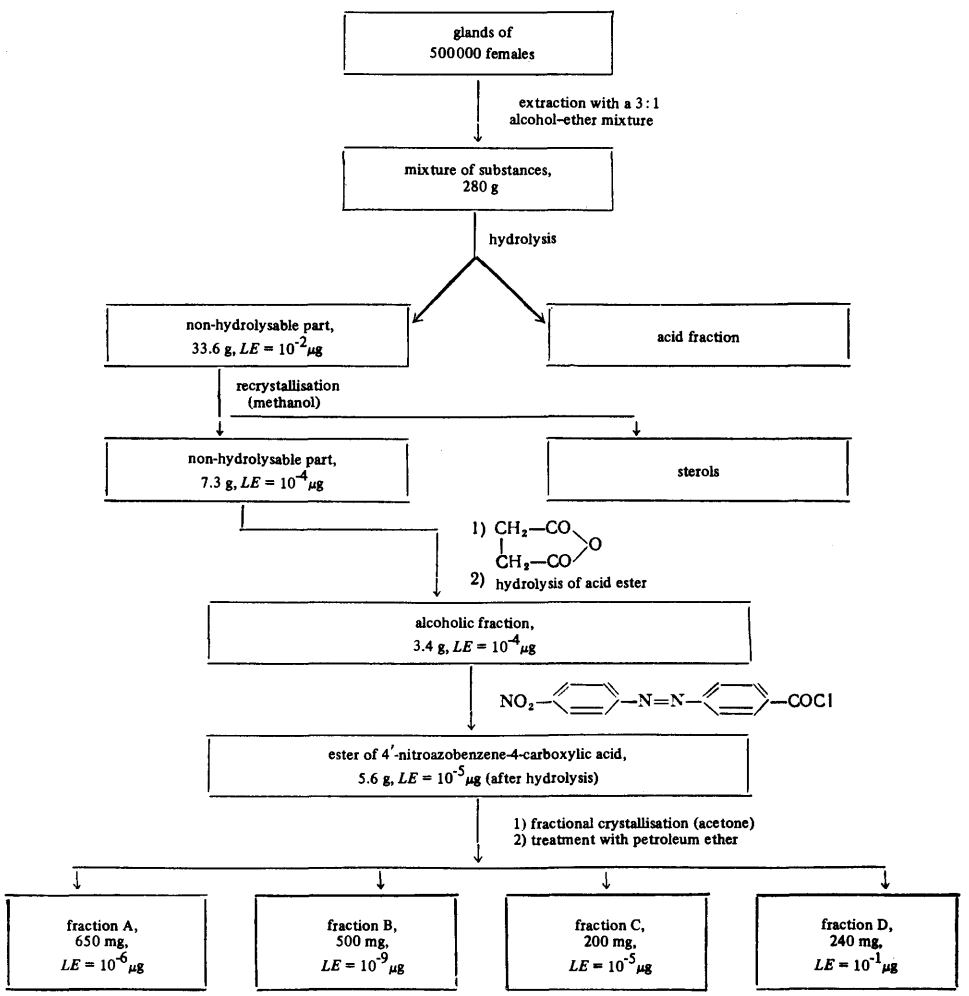
$$\downarrow\ 1)\ H_2,\ Pd/C;\quad 2)\ LiAlH_4$$

$$CH_3(CH_2)_2\overset{H}{\underset{|}{C}}{=}\overset{H}{\underset{|}{C}}{-}\overset{H}{\underset{|}{C}}{=}\underset{H}{\underset{|}{C}}(CH_2)_8CH_2OH\ .$$

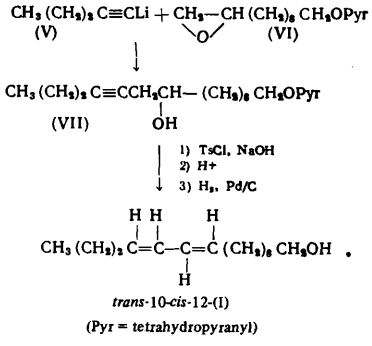
trans-10-*cis*-12-(I)

Scheme I

Isolation of the Natural Sex Attractant of the Silkworm Moth

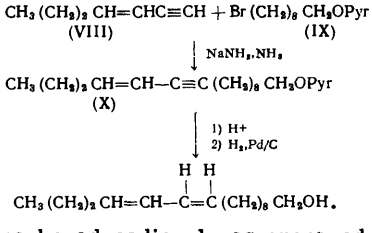


The same isomer was synthesised also by another method using the condensation of the lithium derivative of the pentyne (V) with the epoxide (VI):



After the dehydration of compound (VII), separation of the isomers, removal of the protective groups, and hydrogenation, the *trans*-10-*cis*-12-(I) isomer was obtained. The physicochemical properties of the latter were indistinguishable from those of the compound synthesised by the Wittig condensation.

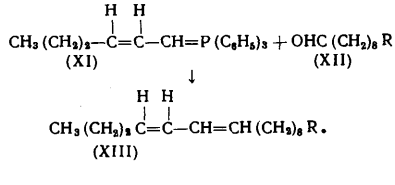
By the reaction of the sodium derivatives of *trans*- and *cis*-hept-3-enyne (VIII) with the tetrahydropyranyl ether of 9-bromononanol (IX), compound (X) was obtained, which after hydrolysis and hydrogenation by Lindlar's method gave respectively the *cis*-10-*trans*-12-(I) and the *cis*,*cis*-10,12-(I) isomers:



Trans,*trans*-hexadecadienol was prepared from *cis*-10-*trans*-12-(I) by photoisomerisation in the presence of iodine [19,9].

After comparing the melting points of the isomers and the natural bombykol, and also the melting points of the esters of 4'-nitroazobenzene-4-carboxylic acid and the ultraviolet and infrared spectroscopic data, the structure of *trans*-10-*cis*-12-hexadecadienol was attributed to bombykol. This was confirmed by comparing the activities of all the isomers in biological tests (Table 1).

Independently of these investigations, other workers [20] described the synthesis of all the isomers of compound (I). Like Butenandt, they employed the Wittig reaction, as one of the methods for the preparation of hexadecadienols:



In compounds (XII) and (XIII) R = $COOCH_3$, CH_2OCOCH_3, COOH, or CH_2OH.

Since it was shown that in the condensation process the configuration of the double bond in compound (XI) does not change, the reaction yields two isomers: *cis*-(XIII) and *trans*-(XIII). The problem of the separation of the isomers of compound (XIII) is greatly facilitated because the corresponding *cis*- and *trans*-acids differ fairly considerably in their solubility in petroleum ether and can be separated by recrystallisation [20]. This method makes it possible to obtain all four isomers.

The condensation of compounds (XIV) and (XV) was employed for the synthesis of the required *trans*-10-*cis*-12-(I), whereby it can be obtained with only a small admixture of the *trans*,*trans*-isomer:

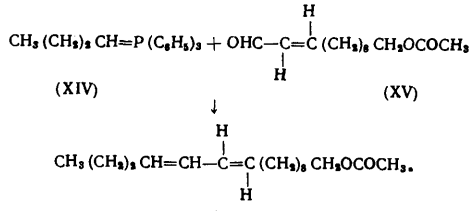


Table 1. Activity of bombykol and four geometrical isomers of a hexadeca-10,12-dienol.

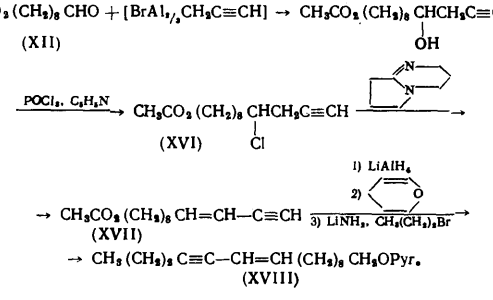
Compound	*LE*, μg ml^{-1}*	*LE*, μg ml^{-1}**
Bombykol	10^{-10}	—
cis,*cis*-Hexadeca-10,12-dienol	1	—
cis-10-*trans*-12-Hexadecadienol	10^{-8}	10^{-5}
trans-10-*cis*-12-Hexadecadienol	10^{-12}	10^{-13}
trans,*trans*-Hexadeca-10,12-dienol	10	10^{3}

* According to Butenandt [19].
** According to Eiter [20].

Furthermore the same isomer of compound (I) was obtained by the following mechanism starting with compound (XII):



Dehydrochlorination of compound (XVI) yields a mixture consisting of approximately 70% of *trans*-(XVII) and 30% of *cis*-(XVII). However, after the reduction of compound (XVII) to the alcohol, protection of the hydroxy-group, and condensation with propyl bromide, mainly *trans*-(XVIII) was obtained. The biological activities of the compounds synthesised [20] differed somewhat from the activities of the isomers described by Butenandt [19] (See Table 1).

2. Attractants of the Gypsy Moth (*Porthetria dispar*).

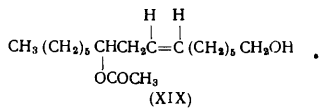
The gypsy moth causes serious damage to woods and fruit trees. After its accidental introduction in the past century into the USA, this insect multiplied rapidly and caused enormous damage in the forests of America. The gypsy moth is fairly widely distributed also in the USSR and periodically damages the forests in various regions.

It has long been known that the female of the gypsy moth attracts the male by means of "smell" and that the extract from the last two segments of the abdomen is a powerful attractant for males[21]. A benzene extract of the female abdomen is employed in the USA to control the numbers of the insects.

The first attempts to isolate the attractant were undertaken by Acree[22-24], who obtained an extract from the glands of 100 000 females and established that the non-hydrolysable fraction is active. By the chromatography of this fraction on magnesium carbonate and magnesium oxide, 12 mg of active but insufficiently pure substance was isolated, which the authors called "gyptol". Subsequently Jacobson et al.[25,26] isolated, using Acree's method[24], 75 mg of an active fraction from 500 000 females, which gave rise to five spots on paper. Only one of these was active. By extracting this spot, they obtained two substances: 3.4 mg of a solid fraction which was active at concentrations of 10^{-2} μg and 20 mg of a highly active liquid (10^{-7} μg in field tests) which fluoresced in ultraviolet light.

The reason for the existence of two natural active compounds has not been definitely established. It is suggested[26] that one of these serves to attract the male from a large distance and the other is necessary to cause it to mate.

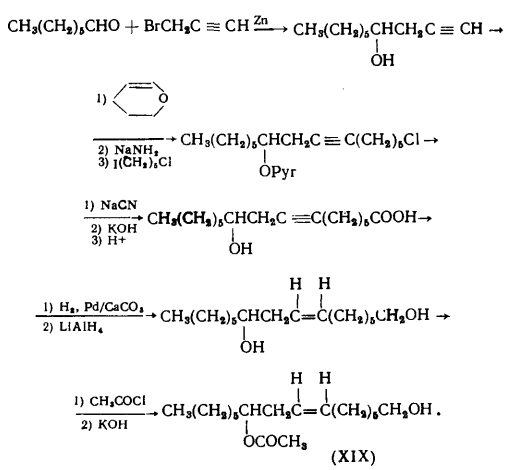
The chemical nature of the solid fraction has not been investigated. The liquid substance is optically active: $[\alpha]_D^{23} = +7.9°$. Its overall formula, $C_{17}H_{32}O_3$ or $C_{18}H_{34}O_3$, was established by elemental analysis. The infrared spectrum indicated the presence in the molecule of a primary hydroxyl, a secondary acetoxy-group, a *cis*-double bond, and a methylene chain with not less than four carbon atoms. Catalytic hydrogenation established the presence of only one double bond; its position and that of the acetoxy-group were demonstrated by oxidative degradation. As a result of these investigations, the attractant was identified as D-*cis*-10-acetoxyhexadec-7-enol (XIX):



(XIX)

Its structure was confirmed by the synthesis of the optically inactive form according to Scheme 2.

Scheme 2



DL-(XIX) was separated into the individual optical isomers[27]. The D- and L-isomers were identical in all respects, except for the sign of the angle of rotation. Nor did they differ in biological properties.

Gyptol analogues were obtained from the natural hydroxy-acids ricinoleic, (+)-14-hydroxy-*cis*-11-eicosenoic, and (+)-9-hydroxy-*cis*-12-octadecenoic by their reduction to the corresponding alcohols, acylation, and selective hydrolysis of the primary acetoxy-group[28-30] (Table 2).

Table 2. Activity of gyptol and its analogues.

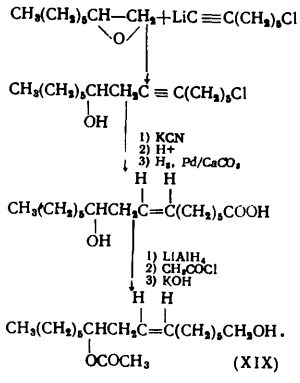
Compound	Activity, μg	
	laboratory	field
 (XIX)	10^{-12}	10^{-7}
 (XX)	10^{-12}	10^{-5}
trans-(XX)	10^{4}	$2.5 \cdot 10^{5}$
	inactive	
		
	10^{-2}	10
	inactive	

After studying the biological properties of compounds having structures similar to those of gyptol, the authors concluded that the presence of a *cis*-double bond and an acetoxy-group in β-position relative to the double bond is necessary for the activity of the molecule.

The most active analogue [compound (XX)] of the natural attractant was called "gyplure", and, because of the availability of the starting material for its manufacture, found practical application in the USA as a substitute for the benzene extract[31,32]. However, in industrial tests of the gyplure specimen the biological activity proved to be variable and in a number of cases the substance proved to be completely inactive. The authors explain this finding by the impurities produced in the preparation of gyplure under industrial conditions. In the study of this phenomenon it was found[33-35] that certain substances masked the effect of the attractant. For example, it is stated[34] that the presence of 20% of the *trans*-isomer in the highly active compound (XX) makes the latter completely inactive. An admixture of 7% of ricinoleyl alcohol also deactivates the attractant. Other workers[36,37] also note the absence of attracting capacity in gyplure specimens which they obtained by Jacobson's method[28,29]. The natural attractant (gyptol) synthesised[37] according to Scheme 3 also proved to be inactive.

The authors reject the hypothesis that in this case impurities may have masked the biological activity since the structure (XIX) of their compound was confirmed by infrared and NMR spectra. Furthermore, in tests by the electrophysiological method[38,39] of a mixture consisting of one part of the attractant obtained from Jacobson and nine parts of the synthetic substance[37], the mixture proved to be unexpectedly completely active. The reason for the loss of activity by attractants, in particular gyplure, is still not explained.

Scheme 3



(XIX)

Later a number of alcohols containing two conjugated double bonds[40] and also various unsaturated compounds incorporating a secondary acetoxy-group[41] were synthesised. Some of these alcohols, present at low concentrations, attracted insects of the order Lepidoptera. However, their activity was much lower than that of the natural attractant.

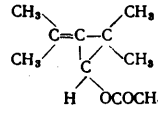
3. Attractant of the American Cockcroach [*Periplaneta americana* (L)]

Wharton and coworkers[42] isolated the active attracting substance from filter paper on which females of the black American cockcroach (*Periplaneta americana*) had been crawling and suggested that the substance was the sex attractant. The authors observed that the substance excites the male and gives rise to a characteristic behaviour of the latter. However, the amounts of attractant obtained (25 μg) were too small to establish fully its structure.

Subsequently Yamamoto[43] and Jacobson et al.[44] employed a method whereby it was possible to obtain the attracting mixture in much greater amounts and developed methods for its preparation. The methods which they proposed consist of the following steps: air was passed through a metal vessel containing about 1000 females of the American cockcroach for a period of nine months. The emerging gas stream was bubbled through a small amount of 0.1% hydrochloric acid and cooled with dry ice in a flask. The resulting condensate was extracted with hexane, the solvent was removed, and the residue was separated on a chromatographic column with silicic acid.

Thus 12.2 mg of pure attractant, consisting of a yellow liquid with a characteristic smell, was obtained from 10 000 females of the American cockcroach[44]. It gave rise to a response in the male even in an amount of 10^{-14} μg.

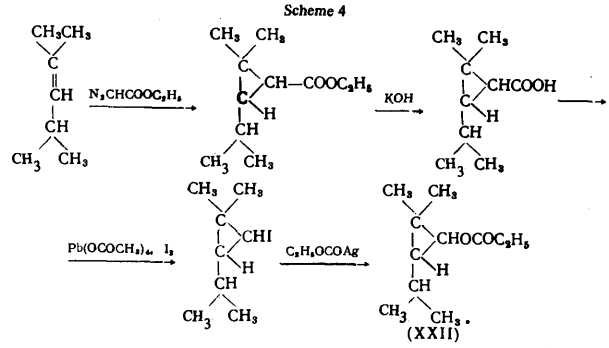
With the aid of elemental analysis, infrared and NMR spectroscopy, and chemical methods, the same authors established the structure of this substance (XXI):



(XXI)

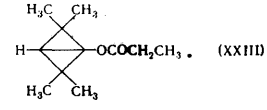
Catalytic hydrogenation of compound (XXI) yielded a substance which was identical with the dihydro-derivative (XXII), which was synthesised as indicated in Scheme 4.

Scheme 4



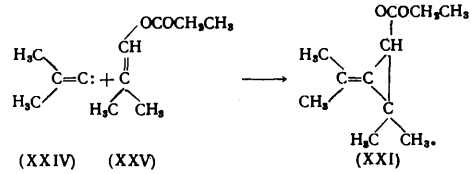
(XXII)

Jacobson's communication[44] attracted the interest of many chemists in different countries. Attempts were made to find methods of synthesis of compound (XXI) and its analogues[45-50]. Thus Day and coworkers[45] obtained compound (XXI) as one of the products of the reaction of 3-methylbuta-1,2-dienyl propionate with diazopropane followed by photolysis. The ester synthesised had the structure suggested by Jacobson for compound (XXI), but according to the NMR spectrum it differed appreciably from the natural attractant and was biologically inactive. On the basis of these data, Day and Whiting[45] suggested that the initially proposed structure for compound (XXI) is erroneous and that the bicyclobutane structure (XXIII) is more likely:



(XXIII)

Recently Wakabayashi[50] described a new synthesis of compound (XXI). The principal idea underlying the synthesis was the use of the reaction of the carbene (XXIV) with the enol ester (XXV):



(XXIV) (XXV) (XXI)

The carbene, formed in the reaction of dibromo-2-methylpropene with magnesium in tetrahydrofuran, was allowed to react with 2-methylpropenyl propionate (XXV) and gave the required product (XXI) in 18% yield. The latter had the same infrared and NMR spectra and the same gas–liquid chromatographic elution time as the substance obtained by Day and Whiting[45].

The absence of biological activity of the synthetic compound (XXI) confirms the earlier data[45] concerning its non-identity with the natural attractant.

Additional studies carried out by Jacobson and Beroza[51], who admitted that the initial structure (XXI) which they established for the sex attractant was erroneous, showed high instability of the natural compound. The crude attractant decomposes even in the cold in several days. However, in an atmosphere of nitrogen in a dilute hydrocarbon solution it can be stored at low temperatures for six months. The authors suggest[51] that compound (XXI) readily undergoes a complex rearrangement, the mechanism of which is still unknown. Thus the structure of the sex attractant of the American cockcroach requires revision.

4. The Sex Attractant of the Pink Bollworm Moth (*Pectinophora gossypiella*)

The pink bollworm moth causes considerable damage in the cotton industry. Its caterpillar, the pink bollworm, feeds on the seeds and seed filaments. All the countries in the world lose 20–25% of their cotton crop because of the pink bollworm. In the Soviet Union this variety of the insect is not widespread.

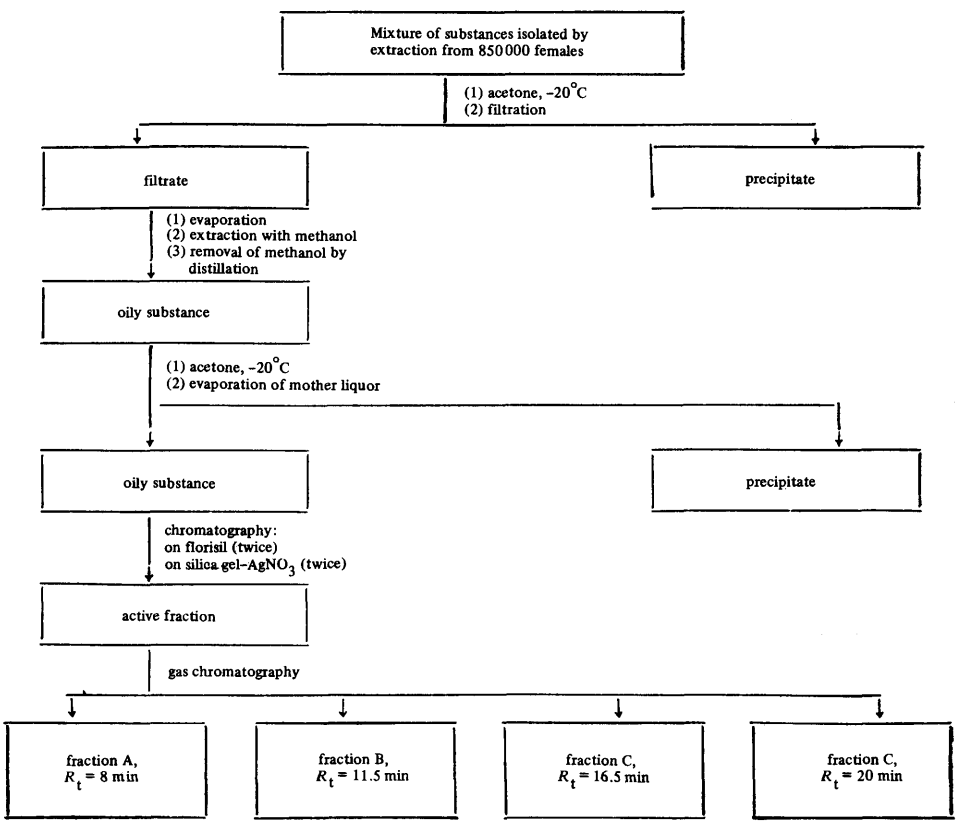
The first mention of the presence of an attractant in the females of the pink bollworm moth was made in 1957.[52] Then the characteristic behaviour of the male during mating was described[53]: excited flight, rapid wing vibration, and curving of the abdomen. A similar response was produced by an extract from the terminal segments of the female abdomen[53,54]. Such extracts were used to trap males under field conditions[54].

In 1966 the pure attractant of the pink bollworm moth was isolated and its structure was established[55]. The publication of this study is evidence of considerable progress in the chemistry of attractants. The authors, who had at their disposal 1.6 mg of the compound, established its complete structure, the investigation lasting only 2–3 years. The isolation of the sex attractant from the extract obtained from the whole bodies of 850 000 two days old females was carried out in accordance with Scheme 5.

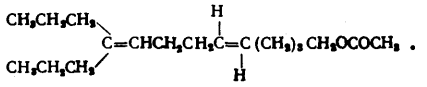
Only fraction B exhibited biological activity and was used to identify the attractant. The structure was established with the aid of physicochemical methods alone. The infrared spectrum demonstrated the presence in the molecule of a primary acetoxy-group, a *trans*-double bond, and a long methylene chain. The presence of a branched skeleton was demonstrated by means of the chromatography of the hydrogenation product[56]. The ultraviolet spectrum did not show the absorption characteristic of conjugated double bonds. Mass spectroscopy established the overall formula of the compound ($C_{18}H_{32}O_2$) and the molecular weight. These investigations suggested that the attractant is an acetate of a primary alcohol with 16 carbon atoms and has branched structure.

Scheme 5

Isolation of the Sex Attractant of Pectinophora gossypiella



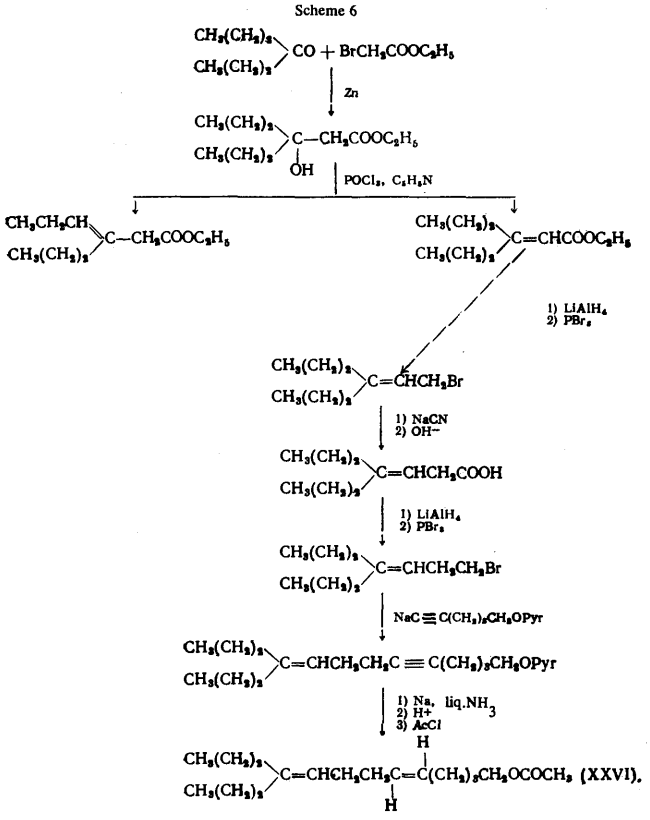
Additional NMR spectroscopic data showed that the sex attractant is *trans*-10-propyltrideca-5,9-dienyl acetate (XXVI):



(XXVI)

The structure of the attractant was confirmed by synthesis (Scheme 6) with a 0.2% yield of the final substance. The authors called compound (XXVI) "propylure" and stated that this is in fact the first natural substance with propyl branching.

Scheme 6

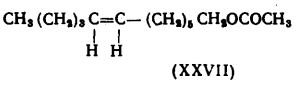


At the present time yet another method of synthesising "propylure", including a number of consecutive reactions in accordance with Scheme 7, is known.

Another cotton pest, the cotton leafworm moth [*Alabama argillacea* (Hübner)], secretes about 0.1 μg of the pheromone. A concentrate containing one tenth of this amount gives rise to a typical response in the males[57]. After the purification of the concentrate by thin-layer and gas chromatography, a substance was obtained with properties characteristic of a hydrocarbon with about 20 carbon atoms.

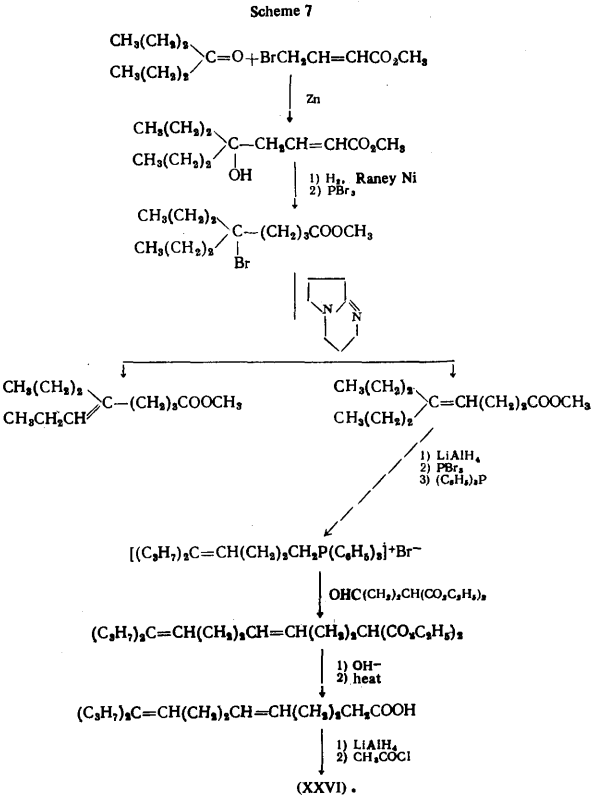
5. The Attractant of the Cabbage Looper (*Trichoplusia ni*)

The presence of a sex attractant in the females of the cabbage looper (*Trichoplusia ni*) became known thanks to the work of Ignoffo et al.[58] and Shorey[59]. In 1966 Berger[60] isolated by extraction with methylene chloride from 2500 females of the cabbage looper about 200 mg of a yellow oil containing the pheromone. The crude extract was separated from the major part of the lipids by chromatography on silicic acid, which yielded about 10 mg of a highly active substance; this, however, still contained impurities. Further purification by gas chromatography led to the isolation of the pure compound. Physicochemical methods and the chemical properties of the compound led to the determination of the structure of the attractant as *cis*-dodec-7-enyl acetate (XXVII).



(XXVII)

Scheme 7

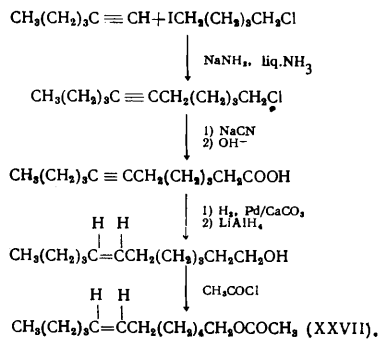


The proposed structure (XXVII) was confirmed by synthesis with an overall yield of product of 28%. The attractant was synthesised according to Scheme 8.

1-Chloroundec-6-yne (XXVII), obtained by the action of hex-1-yne and sodamide on 1-chloro-5-iodopentane in liquid ammonia, was converted into dodec-7-ynoic acid by treatment with sodium cyanide and subsequent hydrolysis. After the reduction of the triple bond in the presence of Lindlar's catalyst to a *cis*-double bond and of the carboxy-group with lithium aluminium hydride to an alcoholic group, a high yield of an unsaturated alcohol, *cis*-dodec-7-enol, was obtained. On acetylation of the hydroxy-group with acetyl chloride, the alcohol was converted into *cis*-dodec-7-enyl acetate (XXVII).

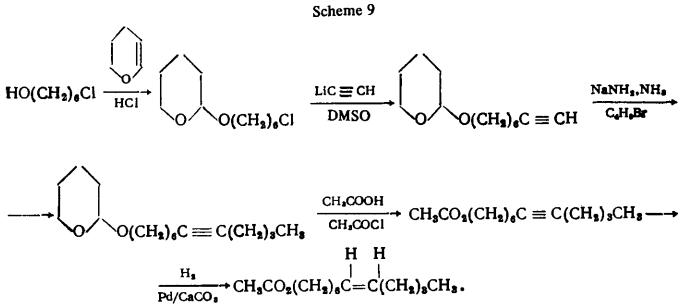
According to the infrared spectrum, the gas chromatographic elution time, and the physicochemical constants, the compound synthesised is identical with the natural attractant. The amounts of both the natural and the synthetic compounds showing the minimal biological activity are the same: 0.1 $\mu g\ ml^{-1}$.

Scheme 8



Green et al.[61] synthesised *cis*- and *trans*-dodec-7-enyl acetates by two different procedures. The method pf preparation of the *cis*-isomer (XXVII) is clear from Scheme 9 quoted below.

Scheme 9



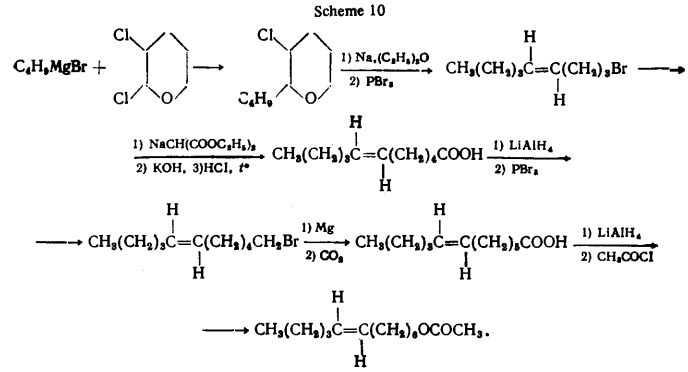
The synthesis of the *trans*-isomer according to Scheme 10 has the advantage that the final product is obtained without an admixture of the *cis*-form. The same workers and also Toba et al.[62] confirmed the high biological activity of the *cis*-acetate (XXVII) under both laboratory and field conditions. Synthetic analogues[61,63-65] of the natural attractant such as oct-7-ynyl, dodec-7-ynyl, *cis*-oct-7-enyl, *cis*-dec-7-enyl, *trans*-dodec-7-enyl, *cis*-dodec-5-enyl, *trans*-dodec-5-enyl, *cis*-dodec-9-enyl, dodecyl, and *cis*-tetradec-7-enyl acetates and the alcohols *cis*-dec-7-enol and dodecanol are weakly active or altogether inactive.

Thus the conditions necessary for the activity of the attractants of the cabbage looper are the presence of a straight twelve atom carbon chain, a *cis*-double bond in position 7, and an acetoxy-group in position 1. The failure of even one of these requirements leads to a sharp reduction or complete loss of the biological activity of the attractant.

6. Attractants of the Trinidad Butterfly (*Lycorea ceres ceres*)

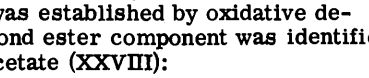
The males of the tropical butterfly of the subfamily Danainae have two organs, called androconia, which can be projected from the abdomen. During the "nuptial games" the male secretes the odorous substance through the androcones. The female attracted by the substance during the flight pursues the male.

Scheme 10



The data on the chemical nature of the substances secreted by the male moth are fewer than those of the attractants produced in the female organism. However, recently the chemical composition of the secretion of the male Trinidad butterfly (*Lycorea ceres ceres*) became known[66]. Extraction of the hairs removed from the androconia of several hundred males yielded a mixture which contained three substances according to gas–liquid chromatographic data. Adsorption chromatography of the extract from 100 males yielded two fractions: about 2.8 mg of the ester fraction and about 10 mg of the carbonyl fraction. The ester fraction was separated by preparative gas–liquid chromatography into two ester components. The infrared spectrum of one of these showed absorption characteristic of the acetate, which did not change on catalytic hydrogenation. On the basis of the mass spectra, the formula $C_{16}H_{33}OCOCH_3$ was proposed in the above investigations. The structure was confirmed by comparison with a cetyl acetate specimen.

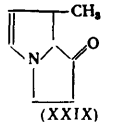
The second substance was investigated by infrared and mass spectroscopy. It was shown that it is the acetate derived from an alcohol with a molecular weight of 310, which corresponds to an unsaturated or monocyclic alcohol with 18 carbon atoms. Catalytic hydrogenation gave stearyl acetate. Comparison of the spectroscopic and chromatographic data for the compound isolated and oleyl acetate revealed a considerable similarity. The position of the double bond in the chain was established by oxidative degradation. Thus the second ester component was identified as *cis*-octadec-11-enyl acetate (XXVIII):



(XXVIII)

A synthetic specimen of compound (XXVIII) was obtained by the reduction of methyl *cis*-octadec-11-enoate with lithium aluminium hydride and acetylation of the resulting alcohol.

The unknown substance was isolated from the carbonyl fraction by vacuum sublimation. The study of the infrared, NMR, and mass spectra of this substance and a number of known compounds similar to the carbonyl component led to formula (XXIX) for the latter:



(XXIX)

The structure of the compound was confirmed by synthesis, which included the cyclisation of *N*-cyanoethyl-3-methylpyrrole[67]. The specimen obtained was identical with compound (XXIX) according to infrared, ultraviolet, NMR, and mass spectra, but it did not have the sweetish smell characteristic of the natural compound. Possibly this smell is due to traces of impurities[66]. The structure of compound (XXIX) differs sharply from that of the pheromones of the moth of this species and also from those of the attractant described earlier, but it is fairly similar to the structure of a number of plant alkaloids[68]. It is suggested[66] that compound (XXIX) is not produced in the insect organism but is introduced with the food or is derived from compounds obtained from the food.

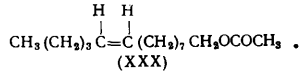
The males of another Danainae species, *Danaus gilippus berenice*, also produce an odorous secretion, which is exuded through androconia[69]. However, the chemical nature of their pheromones is still unknown.

7. Attractant of the Fall Armyworm Moth (*Spodoptera frugiperda*)

Various species of *Spodoptera frugiperda* secrete a substance which stimulates the male to mate. The substance is concentrated in the terminal segments of the abdomen. Each female produces approximately 0.01 μg of the odorous secretion[70,71].

The structure of the attractant secreted by *Spodoptera frugiperda* has now been established[72]. The terminal segments of 135 000 unmated females 3–5 days old were used for the isolation. The mixture (55 ml) obtained from the extract was separated by column and repeated thin-layer chromatography into a number of fractions. The active fractions were selected with the aid of a biological test. The final purification was achieved by preparative gas chromatography. In this way 900 mg of the pure attractant was obtained.

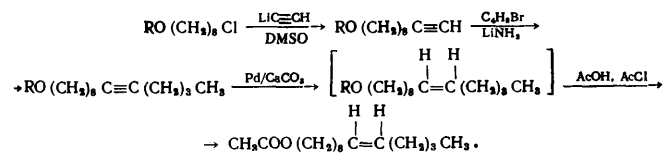
The infrared spectrum showed an absorption characteristic of the acetyl carbonyl group and a *cis*-double bond. The ultraviolet spectrum did not contain any absorption characteristic of conjugated bonds. The presence of an ester group was confirmed by alkaline hydrolysis, which resulted in complete disappearance of biological activity. On acetylating the hydrolysis product, the activity was restored. Catalytic hydrogenation yielded tetradecanol. The position of the double bond was established by ozonolysis. These investigations led to the identification of the attractant as *cis*-tetradec-9-enyl acetate (XXX)[72]:



(XXX)

Compound (XXX) was obtained from myristoleic (tetradecenoic) acid by reduction with lithium aluminium hydride and acetylation. The synthetic substance was active at a concentration of 3×10^{-12} g.

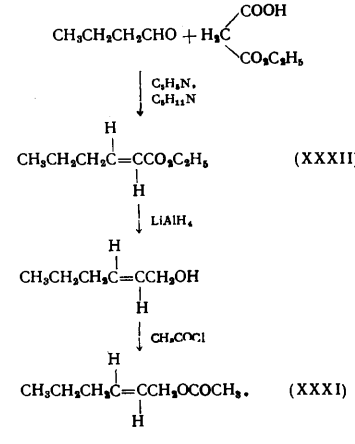
In addition, the complete synthesis of *cis*-tetradec-9-enyl acetate, based on the condensation dec-1-yn-10-ol with butyl bromide, has been described[73]:



Jacobson and Harding[74] suggested that *cis*-tetradec-9-enyl acetate be obtained using as the starting material the commercial preparation of dodec-7-enyl acetate—the attractant of *Trichoplusia ni*.

8. The Attractant of the Giant Water Beetle [*Belostoma indica vitalis* or *Lethocerus indicus* (Lep)]

The giant water beetle is a large insect approximately 7 cm long and 4 cm wide. It lives in ponds in South East Asia, Africa, and South America. The males have two tubes about 4 cm long on the abdomen. Through these the giant water beetles secrete approximately 0.02 ml of a transparent liquid with a cinnamon smell. In Southern Asia it is used as a spice in food. This liquid is probably the sex pheromone of the male[75]. Butenandt investigated the attractant of the giant water beetle[75]. To obtain the substance, he removed the glands from the male and squeezed the secretion from them. In this way he managed to secure 3 ml of the liquid. It was established by chemical reactions that the attractant is an acetate ester. The alcoholic component characterised as the 4′-nitroazobenzenecarboxylate ester[76], was found to be an unsaturated alcohol $C_6H_{11}OH$. The position of the double bond was determined by oxidative degradation. Thus it has been established that the main component of the secretion of the giant water beetle is *trans*-hex-2-enyl acetate (XXXI). This structure is confirmed by the synthesis of compound (XXXI) based on butyraldehyde and the half-ester of malonic acid. The ester (XXXII) formed on condensation was reduced to the alcohol with lithium aluminium hydride and acetylated:



(XXXII)

(XXXI)

III. ALIPHATIC ACIDS

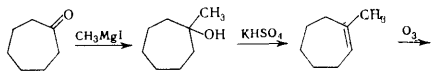
1. Attractants of the Honey Bee [*Apis mellifera* (L.)]

The complex life of the beehive is probably regulated and controlled by many pheromones having different purposes. At the present time at least several such compounds, produced by the queen and worker bees, are known. In 1959 Butler[77] showed that the secretions of the queen bee contain a pheromone which prevents the laying of eggs by the worker bees and the growth of new queens. This substance was isolated[78-81] and proved to be *trans*-9-oxodec-2-enoic acid. The studies carried out by Gary[82] provided the experimental proof of the existence of volatile sex attractants in the queen bee. The secretions of the mandibular glands of the queen enable the drones to find it during the nuptial fight. It was shown[81] that the scent attracting the drones is mainly due to 9-oxodecenoic acid. 9-Hydroxydecenoic acid accompanying it is only weakly active with respect to drones—it is responsible for the stabilisation of the swarm.

The practical and theoretical interest in the discovery of the pheromones of bees led over a short period of time to a number of independent investigations of the synthesis of *trans*-9-oxodec-2-enoic acid[79,86-92] (XXXIII), the biologically similar *cis*-isomer[93], and 9-hydroxydecenoic acid[80-91].

Among the methods described for the preparation of compound (XXXIII), the elegant synthesis from cycloheptanone[84,85] and the relatively simple synthesis, yielding compound (XXXIII) in large (of the order of 50–100 g) amounts, from glutaric aldehyde[90,91] are noteworthy.

When methylmagnesium iodide is allowed to act on cycloheptanone, 1-methylcycloheptanol is obtained, its dehydration over potassium hydrogen sulphate yielding 1-methylcycloheptene. Treatment with ozone with subsequent degradation of the ozonide yields 7-oxo-octanal, the condensation of which with malonic acid in pyridine gives after decarboxylation and purification 9-oxodecenoic acid in 20% yield:



$$\rightarrow CH_3C(CH_2)_5CHO \xrightarrow[C_5H_5N]{CH_2(COOH)_2} CH_3C(CH_2)_5CH{=}CHCOOH.$$

(XXXIII)

In another method glutaric aldehyde is converted by the Wittig reaction into the methyl ester of 2-formylhept-7-enoic acid (XXXIV):

$$OHC(CH_2)_3CHO + (C_6H_5)_3P{=}CHCOOCH_3 \rightarrow OHC(CH_2)_3CH{=}CHCOOCH_3.$$

(XXXIV)

The resulting ester (XXXIV) can be converted into the acid (XXXIII) in two ways:

(a) XXXIV $+ CH_3COCH_3 \xrightarrow{C_5H_{11}N\cdot CH_3COOH} CH_3COCH{=}CH(CH_2)_3CH{=}CHCOOCH_3 \rightarrow$

$$\xrightarrow[2)\ Na_2CO_3]{1)\ H_2;\ Pd/C} CH_3CO(CH_2)_5CH{=}CHCOOH.$$

(XXXIII)

(b) XXXIV $+ HC{\equiv}CCH_2Br \xrightarrow[Al]{Zn} HC{\equiv}CCH_2CH(OH)(CH_2)_3CH{=}CHCOOCH_3 \rightarrow$

$$\xrightarrow[HgSO_4,\ 2HgO]{1)\ H_2SO_4} CH_3COCH{=}CH(CH_2)_3CH{=}CHCOOCH_3 \rightarrow$$

$$\xrightarrow[2)\ Na_2CO_3]{1)\ H_2,Pd/C} CH_3CO(CH_2)_5CH{=}CHCOOH.$$

(XXXIII)

The *cis*- and *trans*-isomers are isolated by crystallisation from the mixture of 9-oxodecenoic acids. It is interesting that a considerable amount of 10-hydroxydec-2-enoic acid was detected in the food received by the queen[94]. The biochemical role of this acid is still not completely clear, but its bactericidal, fungicidal[95], and anti-tumour[96] properties are already known. The synthesis of this compound has also been worked out in detail[87,89,97-100].

In addition to *trans*-9-oxodecenoic and 9- and 10-hydroxydecenoic acids, a large number of carboxylic acids were also isolated from the queen bee extract and from the royal jelly. Thus nonanoic, decanoic, dec-2-enoic, *p*-methoxybenzoic, 9-oxodecanoic, 9-hydroxydecenoic, *p*-hydroxybenzoic, decane-1,10-dicarboxylic (sebacic), dec-2-ene-1,10-dicarboxylic, adipic, pimelic, and suberic acids in the form of their methyl esters and phenylacetic and phenylpropionic acids have been found and identified[80]. In addition there remain unidentified[80] a further 17 peaks, detected by the gas chromatography of the acid fraction of the royal jelly. Aromatic acids are frequently encountered in nature in many tissues and probably do not play a specific role in bees. On the other hand, the majority of the aliphatic acids isolated have a chain with ten carbon atoms. This situation is scarcely fortuitous. Members of this series of acids may be biogenetically related, constituting the units of a single series of reactions in the living organisms. However, their biochemical role and interrelations have not been adequately investigated.

2. The Attractant of the Black Carpet Beetle [*Attagenus megatoma* (Fabricius) or *Attagenus piceus* (Olivier)]

The attractant of the black carpet beetle was recently isolated and identified[101,102]. The active substance was found in the acid fraction of the extract from 30 000 females. After purification by adsorption and gas–liquid chromatography, the methyl ester of an unknown acid was isolated by three gas-chromatographic purifications.

The structure of the acid was established solely by physicochemical methods. The molecular weight and the general formula of the compound ($C_{15}O_{26}H_2$) were obtained with the aid of the mass spectrum. The infrared spectrum indicates the presence in the molecule of a carbonyl group, conjugated double bonds having the *cis*,*trans*-configuration, and a methylene chain. The ultraviolet spectrum confirmed the presence of a conjugated diene system.

The NMR spectrum confirmed the spectroscopic data. On the basis of these studies, the esterified attractant of the black carpet beetle could be identified as one of the two *cis*,*trans*-isomers of methyl tetradeca-3,5-dienoate (XXXV):

$$CH_3(CH_2)_7CH{=}CH{-}CH{=}CHCH_2COOCH_3.$$

(XXXV)

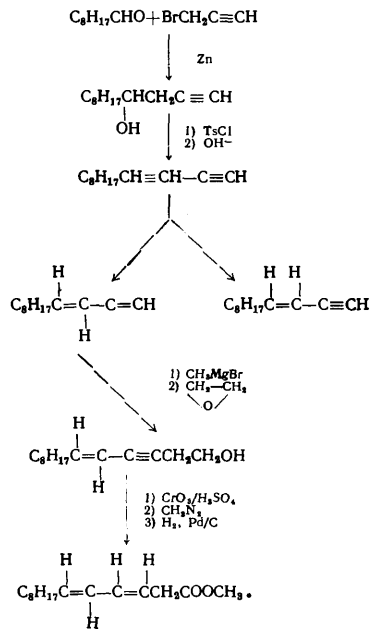
The geometrical configuration of the compound was established by synthesising the two isomers and comparing their physicochemical properties. Methyl *trans*-3-*cis*-5-tetradecadienoate was obtained by the method devised for the synthesis of methyl *trans*-3-*cis*-5-tridecanoate[103]. The *cis*-3-*trans*-5-isomer (XXXV) was synthesised according to Scheme 11.

The synthetic *trans*-3-*cis*-5-isomer (XXXV) had the same spectroscopic and chromatographic properties as the natural compound, while the *cis*-3-*trans*-5-isomer showed considerable differences in the infrared and NMR spectra. Therefore the structure of the *trans*-3-*cis*-5-tetradecadienoic acid was attributed to the compound. The response of the male to the synthetic substance was somewhat weaker than to the extract from the female. The authors suggest that[102] the extract might contain other active components, which were lost during isolation.

3. Attractant of the Sugar-beet Wireworm [*Limonius californicus* (Mann)]

The sugar-beet wireworm is a widespread pest on sugar-beet, potatoes, onions, and other crops. Its larvae live and develop in the soil on the roots of the plants, which makes the fight against them difficult. The adult insects crawl out on the surface of the earth in the spring for a brief period of mating. It was noted[104] that each female may attract a large number of males. Lilly[105] showed that this attraction is due to the sex pheromones produced by the female.

Scheme 11



In paper chromatographic experiments using a mixture of ethanol and ammonia (95 : 5) the alcoholic extract of the abdomens gave a spot with $R_f = 0.85$, which attracted the males under laboratory conditions.

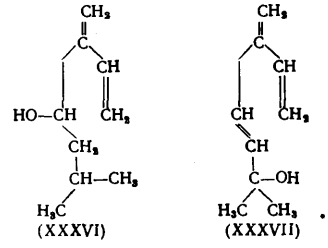
In his latest work Lilly[106] stated that he succeeded in isolating and identifying the sex attractant of the females. It proved to be n-valeric acid. The biological activities of synthetic n-valeric acid and the natural attractant were the same.

The female of the wireworm *Limonius canus* (Le Conte) also secretes a sex attractant[107] which gives rise to a response in the males when present in an amount equivalent to 0.005 of the total substance secreted by one female. According to preliminary data, the pheromone is a carboxylic acid.

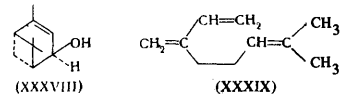
IV. TERPENE-LIKE COMPOUNDS

1. Attractant of the bark beetle (*Ips confusus*)

The males of the bark beetle bore passages in coniferous trees and produce a brown powder (a mixture of wood particles and excrement) which contains pheromones[108]. The powder attracts both sexes, especially females. A mass attack by the beetles due to the presence of these pheromones frequently results in the destruction of the tree. In biological tests an appreciable response of the female was obtained with the substance from the benzene extract corresponding to 3×10^{-8} g of the powder[108]. A highly active fraction[108] of pheromones was obtained in a yield of 0.0007% (relative to the weight of the initial powder) from 3 kg of the powder derived from 21 000 males by extraction, vacuum distillation, and gas chromatography. Nonanal, geranyl acetate, and two terpene alcohols, (XXXVI) and (XXXVII), hitherto not described in the literature were obtained from this fraction:



Apparently nonanal and geranyl acetate are impurities. It is not known whether the terpene alcohols (XXXVI) and (XXXVII) are of plant origin or metabolic products of the beetles. Subsequently (-)-2-methyl-6-methyleneoct-7-en-4-ol (XXXVI), detected previously, and two other terpene alcohols,



were isolated[109] from 4.5 kg of the powder produced by the males of *Ips confusus*. The structures of compounds (XXXVI), (XXXVIII), and (XXXIX) were established by physicochemical methods and confirmed by synthesis.

In laboratory biological tests compounds (XXXVI), (XXXVIII), and (XXXIX) were inactive[109] in amounts of 1000, 20, and 100 μg respectively. At the same time a mixture of 1 μg of compound (XXXVI) with 0.01 μg of compound (XXXVIII) and a mixture of 1 μg of compound (XXXVI) with 1 μg of compound (XXXIX) gave rise to a typical response by the beetles.

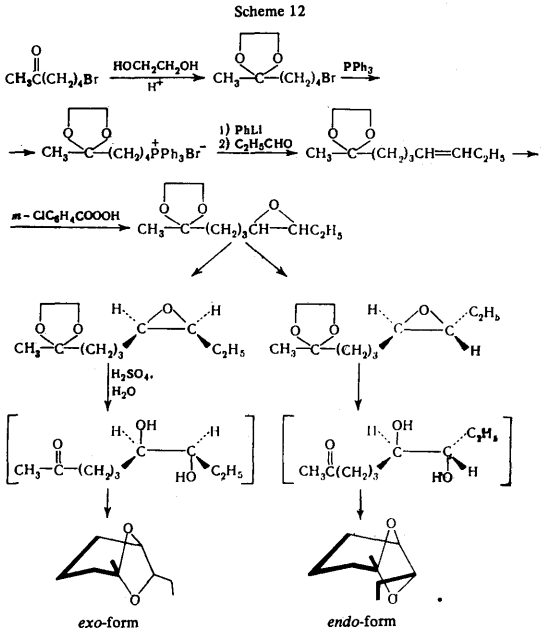
Tests under field conditions showed[110] that the most active is a mixture of compounds (XXXVI), (XXXVIII), and (XXXIX), which caused the appearance of 14 males and 18 females during 20 min (average per day). A mixture of compounds (XXXVI) and (XXXIX) attracted only the females. The individual compounds and their other combinations attracted only a few isolated insects.

An interesting and unexpected observation was made[110] that compound (XXXVI) and also its mixture with compound (XXXVIII) attracted *Ips latidens*. The addition of 0.1 μg of compound (XXXIX) to a mixture of 2 μg of compound (XXXVI) with 0.1 μg of compound (XXXVIII) greatly reduced the attraction of *Ips latidens*, but greatly enhanced the attraction of *Ips confusus*. The unusual synergistis system obtained by the addition of compound (XXXIX) to a mixture of compounds (XXXVI) and (XXXVIII) the attractive properties in relation to *Ips latidens* and enhances them in relation to *Ips confusus*.

Recently the structure of the sex attractant secreted by *Dendroctonus brevicomis* [western pine beetle (Ed. of Translation)] has become known[111]. The concentrate of the active substance was isolated from the brown powder. The pure

substance was obtained by column and gas–liquid chromatography. The study of the spectroscopic and chemical properties of the compound isolated established that it has the structure of a cyclic ketal. It was shown by the synthesis of *exo*- and *endo*-7-ethyl-5-methyl-6,8-dioxabicyclo[3,2,1]-octane (Scheme 12) and by comparison of the synthetic substances with the natural specimen that the attractant, which was called brevicomin, is the *exo*-form of the above compound. It is interesting that similar cyclic structures are rare among natural compounds.

Scheme 12



In the study of the biological activity it was shown that, as in the synergistic phenomenon observed for the attractants of *Ips confusus* [109], certain inactive natural fractions enhance the activity of brevicomin.

Another pest on conifers in which a sex attractant was detected, is the introduced pine sawfly [*Diprion similis* (Hartig)]. In 1960 Coppel et al.[112] noted that the unfertilised females of the introduced pine sawfly attract a large number of males under field conditions. Extraction of the filter paper on which the females of this species had been crawling followed by purification using preparative chromatography led to the isolation[113] of a concentrate containing as its main component the sex attractant of the female. This compound proved to be entirely stable. Thus it did not change at 100°C over a period of 5 h and lost its biological activity only at 180°C after 2 h. Recently Casida and coworkers[114] stated that, having modified Jamamoto's procedure[43] for the collection of the sex attractant of the American cockcroach (*Periplaneta americana*), they succeeded in isolating the fraction of the attractant of the introduced pine sawfly in greater amounts and contaminated to a smaller extent than in the isolation by earlier methods. Nevertheless the inadequate purity of the compound obtained precluded final conclusions concerning its structure.

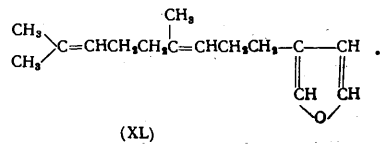
2. Pheromones Causing a Response of Fear or Defence

In social insects (ants, bees) a "chemical language" is fairly highly developed. Apart from the already known functions of attraction, these insects must have a means of communication with one another. There are a number of substances with the aid of which social insects communicate danger, indicate the direction to sources of food, mark their trail in order to return to the nest, etc.

A fairly large number of fear-inducing pheromones, secreted by various species of ants, are known at the present time. Frequently the response of ants to the same compounds is different depending on their concentration in air. Substances which when present in high concentrations give rise to a fear response, for example, at low concentrations attract the working individual.

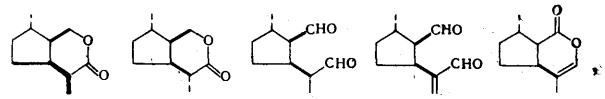
Most species of ants secrete formic and acetic acids which act as repellents. Some species secrete a mixture of acetic, propionic, and isovaleric acids[115]. The West African black ant *Crematogaster* (*Atopogyne*) *africana* (Mayr) emits a characteristic smell when alarmed. It was established[116] that the smell is due to hex-2-enal, which acts as a repellent. The same compound is secreted as a repellent by the cockcroach *Eurucotis floridana*[117].

The ant *Lasius fuliginosus* secretes a substance which causes the excitation of this species but is toxic to other ants. Its active component is dendrolasine[118] (XL):



(XL)

The pheromones of ants of various species of the genus *Iridomyrmex* and *Dolichoderus* have now been fairly well investigated. Thus it has been established[119–121] that the ants *Iridomyrmex detectus*, *I. humilis*, and *I. nitidus* secrete iridomyrmecin (XLI), isoiridomyrmecin (XLII), iridodial (XLIII), and isodihydronepetalactone:



(XLI) (XLII) (XLIII) (XLIV) (XLV)

Dolichodial (XLIV) was found in the secretion of the ant *Dolichoderus acanthoclinea* Clarki[122,123]. These compounds belong to the class of cyclopentanoid monoterpenes, since they are biogenetically related to terpenes[115]. 2-Methylhept-2-en-6-one, 2-methylheptan-4-one, 4-methylhexan-2-one, and 4-methylheptan-3-one, secreted by ants of various species, also have a terpene-like structure[115,124]. It is interesting that the structure of compounds (XLI) and (XLIV) closely resemble those of substances isolated from plant sources, in particular from *Nepeta cataria*[125], namely nepetalactone (XLV) and its analogues.

Together with completed investigations, studies have also been made where so far only the presence of attractants has been established in insects such as the moth of the tobacco hornworm [*Protoparce sexta* (Johannson)][126,127], the moth of the tobacco budworm [*Heliothis veriscens* (F.)][128], the moth of the lesser peach tree borer [*Synanthodon pictipes* (Grote and Robinson)][129], the beetles [*Rhopaea* (Ed. of Translation)] (Coleoptera: Scarabaeidae)[130], cockroaches (*Pycnoseelus suri* and *Nauphoeta cinerea*)[131,132], the apple fly (*Opius alloeus*)[133], the moth of the lesser apple worm[134], the moth of the sugarcane borer [*Diatraca saccharilis*

(F.)][135], the ambrosia beetle [*Trypodendron lineatum* (Oliv.)][136], the Angoumois grain moth *Sitotroga cerealella* (Oliv.)[137], the red cotton bug *Dysdercus cingulatus*[138], the California red scale *Aonidiella aurantii*[139], and the leaf roller *Argurotaenia velutinana*[140]. It is to be expected that further studies in the field of attractants will yield interesting and practically important results.

The Mechanism of Alkaline Catalytic Polymerisation of Hydrocarbon Monomers

A.A.Korotkov (deceased) and S.P.Mitsengendler

In contrast to free-radical polymerisation, there is no single theory of anionic polymerisation which could explain all the observed phenomena, these being treated usually from different standpoints. In the present review an attempt is made at a critical analysis of the existing hypotheses in this field. The bibliography includes 90 references.

The polymerisation of vinyl and divinyl compounds under the influence of alkali metals and their organic compounds is regarded by the majority of investigators as successive organometallic synthesis[1-5]. As a result of repeated stepwise addition of monomer molecules to the initial organometallic compound, a polymer with a high molecular weight is formed. If a fresh portion of monomer is added to such a polymeric organometallic compound, the former adds to the macromolecule and polymerisation is restarted. Szwarc very aptly called such growing polymer chains "living" polymers[6].

The growth of a "living" polymer occurs of course in the absence of impurities from the reaction medium (water, alcohol, aldehydes) and in the absence from the monomer of functional groups which could interact with the organometallic compounds.

In 1928 Ziegler[1,2] concluded, on the basis of his own experimental data and those of Schlenk[7] and other investigators, that the polymerisation of butadiene under the influence of sodium is a complex consecutive reaction in which the monomer adds to the organic disodium compound at each stage:

$$2\,Na + CH_2{=}CH{-}CH{=}CH_2 \rightarrow NaCH_2{-}CH{=}CH{-}CH_2Na \quad \text{or} \quad NaCH_2{-}\underset{\displaystyle CH{=}CH_2}{\underset{|}{CHNa}},$$

$$NaCH_2{-}CH{=}CH{-}CH_2Na + CH_2{=}CH{-}CH{=}CH_2 \rightarrow$$

$$\rightarrow NaCH_2{-}CH{=}CH{-}CH_2{-}CH_2{-}CH{=}CH{-}CH_2Na,$$

$$NaCH_2{-}CH{=}CH{-}CH_2{-}CH_2{-}CH{=}CH{-}CH_2Na + CH_2{=}CH{-}CH{=}CH_2 \rightarrow,$$

$$\rightarrow NaCH_2{-}CH{=}CH{-}CH_2{-}CH_2{-}CH{=}CH{-}CH_2{-}CH_2{-}CH{=}CH{-}CH_2Na,$$

etc.

If an organosodium compound is used instead of metallic sodium, the mechanism of the growth of the polymeric chains does not change, only the monomer now adds to the monosodium compound:

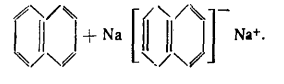
$$RNa + CH_2{=}CH{-}CH{=}CH_2 \rightarrow R{-}CH{-}CH{=}CH{-}CH_2Na\ .$$

Ziegler succeeded in isolating the intermediate products and in showing the stepwise occurrence of polymerisation. A characteristic feature of such stepwise reactions is the gradual growth of the molecular weight of the polymer with time. At low temperatures it is possible to terminate the chain growth at any stage. The degree of polymerisation is determined by the ratio of the amounts of monomer and catalyst consumed.

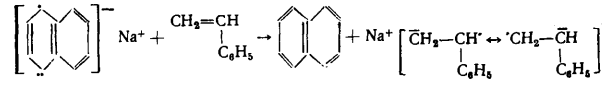
Ziegler[8,9], Medvedev[10], and Morton[11-13] pointed out the unusual form of the polymerisation reactions of vinyl monomers under the action of organic derivatives of alkali metals. For example, triphenylmethylsodium and diphenylethylpotassium polymerise butadiene and styrene with formation of polymers having relatively high molecular weights. Even in the presence of a large excess of the catalyst it is impossible to isolate the primary addition products of butadiene or styrene to the organometallic compound. When solutions of the monomer and the organometallic compound are mixed, the colour of the latter fades or disappears completely, but after the completion of polymerisation it is restored[10], i.e. the organometallic compound is hardly consumed and is regenerated. In contrast to the stepwise reactions, these processes were called catalytic. It was postulated that such catalytic polymerisation reactions must take place by a mechanism different from that of stepwise polymerisation. Contrary views were put forward on this subject: in his catalytic polymerisation Ziegler also isolated intermediate low-molecular products and thereby showed that the mechanism of the catalytic and stepwise polymerisation is the same[9].

Using an Alfin catalyst (typical) for catalytic polymerisation) and butyl-lithium (typical for stepwise polymerisation), Korotkov[14,15] obtained copolymers with the same composition. This confirmed that the reaction mechanism is the same in both cases. The observed differences in stepwise and catalytic polymerisation are related, according to Ziegler[9] and Korotkov[14], to the difference in the relative rates of initiation of polymerisation and of chain propagation and termination.

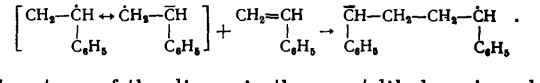
In recent years Szwarc and coworkers[3,16-18] put forward a new view concerning the mechanism of similar reactions. On dissolving in tetrahydrofuran in the presence of condensed aromatic compounds, metallic sodium forms a coloured complex[19,20]:



According to Szwarc, when a monomer is added to this compound, an electron is transferred from naphthalene-sodium to the monomer with formation of a radical-ion in which the unpaired electron is not localised, i.e. the compound formed is neither a true anion nor a true radical:



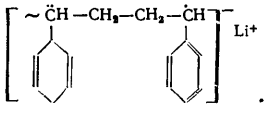
It was suggested that the radical-anion is formed only after the addition of a second styrene molecule without direct interaction between the three electrons:



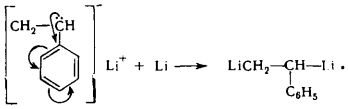
This structure of the dimer is the most likely, since both the anion and the radical are stabilised by the phenyl group. The dimeric radical-anion formed can, in principle, combine with styrene both by an anionic and a radical mechanism. As a rule, under the conditions of low-temperature

polymerisation, the radical ends of two dimeric radical-anion molecules recombine with formation of a tetrameric dianion, which becomes the sole active centre for polymerisation

Electron transfer from naphthalenesodium to the monomer takes place very rapidly in tetrahydrofuran but not at all in hydrocarbon media. Tobolsky's work [21-26] on the copolymerisation of styrene and methyl methacrylate in the presence of dispersed metallic lithium constitutes an experimental confirmation of Szwarc's hypothesis. The copolymers formed had in some cases an enchanced content of styrene units instead of being virtually pure poly(methyl methacrylate), which is obtained with other anionic catalysts, for example butyl-lithium. To account for the anomalous composition of the polymer, it was assumed that initiation with lithium is analogous to the reaction with naphthalenesodium, i.e. an electron is transferred from lithium to styrene with formation of a radical-anion with separated electrons:



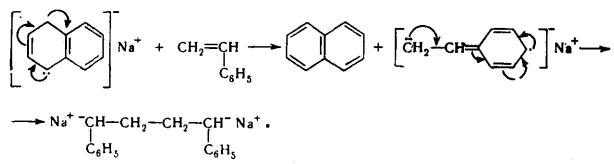
Such an active centre gives rise to further chain propagation by a radical mechanism at one end and by an anionic mechanism at the other. The enhanced styrene content in the resulting copolymer is due to polymerisation by a radical mechanism. In polar solvents the content of styrene units is sharply reduced. However, Korotkov and coworkers[27] obtained similar results in the polymerisation of styrene with methyl methacrylate in the presence of a typical anionic catalyst—solid methyl-lithium. It is suggested that the characteristic features of the reaction involving electron transfer from naphthalenesodium to styrene in solution should not apply to reactions with electron transfer from the surface of the metal, which occurs in the interaction of styrene with metallic lithium. Tobolsky's data are interpreted as follows: since, as a result of the primary initiation step, a radical-ion (styryllithium) is formed on the surface of the metal, its electron unsaturation must be immediately compensated by the electrons of the metal, which are highly mobile. As a result of the interaction between styrene and lithium, a dilithium compound should form:



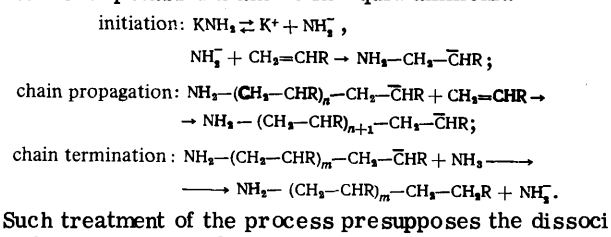
Because of the low solubility of the latter, chain propagation on the surface of the metal takes place preferentially with participation of the more readily adsorbed monomer. In this case styrene is evidently such a monomer.

After the polymeric chains reach a sufficiently large size and dissolve in the form of a dianion, the usual anionic polymerisation begins, in which virtually methyl methacrylate alone is incorporated in the polymeric chain. This leads to the formation of block polymers. On the other hand, in the copolymerisation of monomers with similar adsorption properties (for example, butadiene and styrene), the composition of the copolymer is independent of the heterogeneity of the catalyst or medium. Thus Tobolsky's results cannot serve as an unambiguous confirmation of Szwarc's hypothesis of the formation of a radical-anion with separated electrons.

On the basis of data on the copolymerisation of styrene and methyl methacrylate in the presence of anionic catalysts, Korotkov and coworkers[27] suggest that in polymerisation under homogeneous conditions the stage involving the formation of a radical-anion with separated electrons is absent. Dianions are formed by dimerisation in the initial initiation stage:

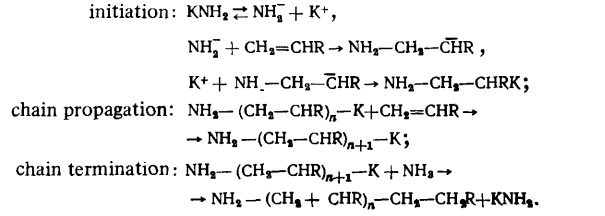


Price[28] was the first to suggest that alkaline polymerisation be regarded as an anionic process in which the active centre is trivalent negatively charged carbon (carbanion). Subsequently Sounderson and Hauser[29] and Higginson and Wooding[30] attempted to confirm experimentally the suggested mechanism. For example, the following mechanism was proposed for the polymerisation of styrene under the action of potassium amide in liquid ammonia[30]:



Such treatment of the process presupposes the dissociation of potassium amide into a free anion and cation. The attacking anion dissociates the double bond of the monomer with formation of a covalent bond at one end of the molecule and an active centre (carbanion) at the other. It is suggested that, within the limits of Coulombic attraction, the anion acts as an independent species, which is not bound to the counterion.

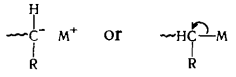
The mechanism quoted above was confirmed by kinetic studies on polymerisation carried out by Higginson, who showed that the rate of polymerisation is proportional to the concentration of the monomer and the amide ion, and that each polymer molecule contains the NH_2 group, while the molecular weight is independent of the concentration of the catalyst and is proportional to the concentration of the monomer. However, the results obtained can be explained with equal success on the basis of Ziegler's hypothesis by postulating the following mechanism for this reaction[31]:



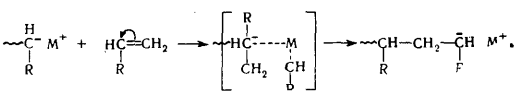
In this type of stepwise mechanism the equation for polymerisation kinetics and the dependence of the average molecular weight on the kinetic constants and the reactant concentrations are consistent with Higginson's relations obtained on the basis of an ionic mechanism of the reaction. Furthermore, Shatenshtein[32] showed that styrene polymerises on the surface of solid potassium amide, when the latter is not dissociated, and that this reaction cannot therefore be used as an unambiguous confirmation of Price's hypothesis.

Extensive experimental data confirm that the counterion always participates in the polymeric chain propagation steps. If the polymerisation centre were a free carbanion, the nature of the catalyst cation could affect only the rate of initiation of polymerisation centres but not the elementary chain propagation reaction. According to experimental data, the microstructure and properties of polymers, i.e. all the factors that are determined by the nature of the reaction, depend on the cation. For example, it is known that the content of 1,2- and 3,4-units in polydienes depends strongly on the nature of the cation[10,14,33,34] and that the stereoregularity of the polymer also depends on the latter[35,36]. Likewise the composition of the copolymers changes sharply on going from organolithium and organosodium compounds to organopotassium compounds[14,21,35,37]. The above differences in the structure of polymers and the composition of copolymers are sometimes explained by differences in the mechanism of the process. For example, it is believed that polymerisation in the presence of organolithium and organopotassium compounds takes place both by a radical and by an anionic mechanism, the relative contributions of which depend on the polymerisation conditions (the nature of the metal and medium)[5,34-42].

The experimental data on the effect of the catalyst metal on the rate and mode of polymerisation led the majority of investigators to the conclusion that in a hydrocarbon medium the active polymerisation centre is an ion pair or dipole[5,43-47]:



which is regenerated at the ends of the polymeric chains after the addition of each monomer molecule in the propagation step:



In polymerisation in the presence of catalysts which are readily ionised, for example, organosodium and organopotassium compounds in a strongly solvating or polar solvent, it is assumed that the degree of ionisation of the dipole is greatly enhanced and the active centre is regarded as a carbanion.

The hypotheses enumerated above have common features despite the apparent differences. The common features are that the polymerisation is regarded as a stepwise reaction involving consecutive addition of monomeric molecules to active centres, which may be anions or ion pairs, and therefore the nature of the active centres is analogous to that of the initial organometallic compounds.

Such treatment constitutes essentially a development of Ziegler's hypothesis with the sole difference that in the latter the C–M bond was regarded as covalent while in the new treatment it is regarded as ionic or of the ion–dipole type. A further difference is that, in the examination of actual reactions, account is now taken of the polarity of the bond in the terminal groups as a function of the structure of the monomer, the solvent, the nature of the metal, and other reaction conditions.

The experimental data which have accumulated in recent years cannot be accounted for from the standpoint of the stepwise polymerisation mechanism. To interpret the observed deviations, auxiliary hypotheses and assumptions are introduced. Some of the most typical cases are described below.

Thus regeneration of the catalyst after the completion of the polymerisation of butadiene or styrene in the presence of organic derivatives of alkali metals[8-10] (the reappearance of the initial colour of the solution) cannot be explained by regarding polymerisation as organometallic synthesis. For example, in the polymerisation of butadiene Ziegler[8,9] explained the reappearance of the colour of the initial catalyst (triphenylmethylsodium) by the metallation of traces of triphenylmethane. However, it is not clear why the metallation of the mobile hydrogen of triphenylmethane begins only after the completion of the polymerisation of butadiene. A similar case of regeneration of the catalyst in the polymerisation of butadiene in the presence of phenylisopropylpotassium in ethyl ether was accounted for by the possibility of the occurrence of a special case of "chain catalysis", but the mechanism of polymerisation and catalyst regeneration was not given[10].

In the polymerisation of isoprene[48], butadiene[49], and styrene[5,43] under the influence of butyl-lithium in a hydrocarbon medium and also of α-methylstyrene in the presence of naphthalenesodium in tetrahydrofuran[50] an anomalous variation of the reaction rate with the initial concentration of the organometallic compound was observed. The rate of reaction is independent of the initial concentration of the catalyst (n_0) when the latter is high and the resulting relation – $dm/dt = f(n_0)$ is represented by a curve exhibiting saturation.

This anomalous behaviour is explained by the specific properties of the organolithium compounds, namely the formation by the latter of association complexes in the hydrocarbon medium which are inactive in polymerisation[51-60]. For example, Welch[43] postulates the presence in the hydrocarbon medium of a dynamic equilibrium between the inactive associated molecules of the organolithium compounds and their monomeric active form:

$$(RLi)_n \overset{k}{\rightleftarrows} n\,RLi,$$

where R is butyl or polymeric radicals. In this case the rate of polymerisation reaction must be proportional to the sixth or seventh root of the initial concentration of butyllithium (for $n = 6$ or 7) and the variation of the rate of polymerisation of styrene with catalyst concentration will be represented by a curve exhibiting saturation. The hypothesis of the presence of association complexes combined with various assumptions makes it possible to explain for a number of cases the results of many investigations[53] and therefore it has found wide application and acceptance[5,52-64]. However, the proposed interpretation still requires a quantitative test. The adherents of the stepwise polymerisation mechanism, who assume that the nature of the active centres is the same as that of the initial organometallic compound, believe that the stability of the association complexes of the growing chains depends on the nature of the monomer, which explains the differences in the activity of monomers in polymerisation[68]. The higher activity of styrene compared with isoprene or butadiene when these are polymerised separately is attributed to the greater tendency of the growing polydiene chains towards association. However, the much lower activity of styrene compared with the above dienes in copolymerisation then becomes incomprehensible. Furthermore, it is known that the degree of association of organolithium compounds falls with increase in the size of the alkyl radical[46,65]. Therefore, on going from ethyllithium to polymeric lithium alkyls the anomaly in the dependence of the rate of polymerisation on the concentration of lithium alkyls should become less pronounced. However, this is not observed. For this reason, in the

formation of association complexes of mixed organolithium compounds (initial and high-molecular) the polymeric lithium alkyls should be present predominantly in the dissociated state. This must lead to the incomplete utilisation of the initial catalyst (for example butyl-lithium, even at relatively low concentrations of the latter), which should result in the formation of a polymer with a wide molecular weight distribution and a high number-average molecular weight. In anionic polymerisation the polymers obtained have as a rule a narrow molecular weight distribution and the degree of polymerisation is equal to the ratio of the concentrations of the monomer and the catalyst, i.e. all the initial organolithium compounds participate in the process. The evidence in favour of the presence of association complexes of "living" lithium polyalkyls, based on the observation that the viscosity of solutions of "living" polydienes falls on addition of butyl-lithium[66], tetrahydrofuran, or alcohol[67-69], cannot be regarded as unambiguous proof. The postulate that the anomalous relation $dm/dt = f(n_0)$ is due to the association of the organometallic compound in the hydrocarbon medium is inconsistent with the data of Podolsky and Korotkov[50] on the polymerisation of α-methylstyrene under the action of naphthylsodium in tetrahydrofuran. It was shown that in tetrahydrofuran, where organometallic compounds are not associated[43,57-67, 70,71], the rate of polymerisation is also independent of the initial concentrations of the catalyst when the latter are high. A similar anomalous relation was observed by Szwarc and coworkers and Schulz and coworkers[72-75] in the polymerisation of styrene in tetrahydrofuran under the influence of "living" polystyrene. They found that the polymerisation rate constant decreases with the initial concentration of the "living" polymer. The rate constant was calculated on the hypothesis that the reaction takes place without termination by a stepwise mechanism. Since it was assumed that the concentration of the active ends of the "living" polymer does not change during the reaction, the calculation was based on the equation for the kinetics of a pseudounimolecular reaction. To account for the anomalous relation, the authors put forward additional postulates, directly opposed to those discussed earlier, assuming that "living" polymers are dissociated in tetrahydrofuran:

$$\sim CH_2-\underset{\underset{C_6H_5}{|}}{CH}\sim Na^+ \rightleftharpoons \sim CH_2-\underset{\underset{C_6H_5}{|}}{\bar{C}H} + Na^+,$$

and that both the ion pair and the free carbanion behave as polymerisation centres but of course with different activities. This conclusion was based on the observed electrical conductivity of the "living" polystyrene in tetrahydrofuran[76] and also the finding that the addition of tetraphenylboronsodium led to a sharp reduction of the reaction rate constant, which depended little on the initial concentration of the "living" polystyrene[76-78]. The sharp decrease of the rate of polymerisation was regarded as evidence that at the ends of the growing chains there are free anions, whose concentration falls very appreciably on introduction of tetraphenylboronsodium, due to a sharp increase of the concentration of the counterions as a result of the dissociation reaction

$$[(C_6H_5)_4B]Na \rightleftarrows [(C_6H_5)_4B]^- + Na^+.$$

Fundamentally new hypotheses concerning the mechanism of homogeneous catalytic polymerisation in the presence of organometallic compounds were put forward by Korotkov[48,50,79-84]. On the basis of an analysis of the polymerisation kinetics and also by studying the dependence of the average molecular weight of the polymer and its molecular weight distribution on the concentrations of the initial reactants and the rate constants of the elementary reactions, he justified the hypothesis that anionic polymerisation is of a coordination type and that it takes place in a much more complex manner than would appear on the basis of the stepwise mechanism. In the suggested hypothesis the active polymerisation centres are regarded not as organometallic compounds but as more reactive complexes of the monomer and the organometallic compounds, formed using the π-electrons of the unsaturated compound and the p-electrons of the valence shell of the metal:

$$RNa + \underset{\underset{CHR}{\|}}{CH_2} \overset{k_1}{\rightleftarrows} R{:}Na{:}\ \underset{\underset{CHR}{|}}{CH_2}. \qquad (1)$$

In such complex compounds with a coordination number of two the disposition of ligands relative to the central atom (the metal) must be close to linearity, which ensures their relative stability. On the other hand, owing to the weakening and the polarisation of the C–M bond and also the coordination unsaturation of the central atom (alkali metal), the reactivity of these compounds increases and the addition of a second monomer molecule (chain propagation) should take place at a much higher rate:

$$\underset{\underset{CH_2}{\|}}{CHR} + R{:}\,Na{:}\ \underset{\underset{CH_2}{|}}{CHR} \xrightarrow{k_2'} RHC-CH_2 \xrightarrow{k_2'''} R-CH_2-CHR-Na{:}CH_2-CHR. \qquad (2)$$
$$\underset{\underset{CH_2}{|}}{CHR} \xleftarrow{k_2''} R{:}\,\ddot{N}a{:}CHR$$
$$\qquad\qquad\qquad

the addition of the first monomer molecule [Eqn. (2)] and the second, the catalytic coordination reaction, in which the initial organometallic compound retains its individuality in the propagation stage, i.e. participates in its entirety in the construction of the polymerisation active centre[81]:

$$RNa + M \xrightarrow{k_3} RNaM^*, \qquad (5)$$

$$RNaM_i^* \xrightarrow{k_3} RNaM_{i+1}^*,$$

but loses its individuality in the termination stage† [see mechanism(3)].

The organometallic compounds formed by reaction (3) (a, b, c) are capable of again initiating polymerisation, but now by the stepwise coordination mechanism.

On the basis of these postulates, Korotkov derived an equation for the kinetics of non-steady-state reactions and the degree of polymerisation using a new variable φ, which is called the effective time and which is related to the true time by the expression $d\varphi = mdt$, i.e. $\varphi = \int_0^t \bar{m}dt$, where m is the concentration of the monomer and t the reaction time.

The relations obtained explain the observed phenomena in the region of catalytic polymerisation. Thus it was shown that the complex relation between the rate of polymerisation and catalyst concentration described above, which is represented by a curve exhibiting saturation, is associated with the occurrence of kinetic chain termination [reaction (3)] and the complex form of the $x-\varphi$ kinetic curves is due to the nature of the termination [reaction (3) (a, b, c)]. While direct proportionality between the extent of polymerisation and x and φ is characteristic of the stepwise mechanism, i.e. $x = f(\varphi)$, in the coordination mechanism at a high degree of conversion the kinetic curves as a rule "bend" to the right in the presence of termination, in accordance with mechanisms (3a) and (3b) and to the left in termination by mechanism (3c). Since the propagation of the polymeric chain alternates with "rest periods" (kinetic termination), such a mechanism should result, in contrast to the stepwise mechanism, in the formation of polymers with a fairly narrow molecular weight distribution, approaching the Gaussian distribution, with a slow fall-off at high molecular weights. It has been shown for the polymerisation of φ-methylstyrene under the action of naphthylsodium in tetrahydrofuran at −78 °C as an example[50] that the experimental data for the kinetics $[x = F(t, \varphi)]$, the number-average molecular weight $[\bar{M} = F(n_0)]$, and the molecular weight distribution are in good agreement with the results calculated on the hypothesis that the polymerisation takes place consecutively by the catalytic coordination and stepwise coordination mechanisms. It is suggested[83] that the decrease of the polymerisation rate constants with increasing catalyst concentration observed by Szwarc and coworkers[77, 78] is not due to the fact that the polymerisation centres are both free ions and ion pairs but is caused by the kinetic termination of the growing chain, which becomes more pronounced in the presence of $[(C_6H_5)_4B]Na$.

According to the coordination mechanism, the effect of electron-donor additives (tetrahydrofuran, ethyl ether, amines) on the rate of polymerisation, the polymer structure, and also the composition of the copolymers[14,50,81-84] is not attributed to the dissociation of the organilithium compounds but to the capacity of these additives to form fairly stable complexes with the organometallic compounds, for example:

$$R^1:Li + 2(C_2H_5)_2O \rightleftharpoons R^1:Li\begin{matrix}:O(C_2H_5)_2\\:O(C_2H_5)_2\end{matrix}.$$

Esters and amines are more powerful bases than any unsaturated hydrocarbon capable of polymerisation. Therefore the formation of intermediate lithium (or sodium) complexes with a higher coordination number is postulated in the presence of such bases[82,84,85]:

$$R^1:Li\begin{matrix}:O(C_2H_5)_2\\:O(C_2H_5)_2\end{matrix} \rightleftharpoons R^1:Li\begin{matrix}:O(C_2H_5)_2\\:O(C_2H_5)_2\\H_2C{=}CHR\end{matrix}.$$

Nor can one exclude the possibility of the formation of mixed complexes resulting from the displacement of an ether molecule by the monomer:

$$R^1:Li\begin{matrix}:O(C_2H_5)_2\\:O(C_2H_5)_2\end{matrix} + \begin{matrix}CH_2\\\|\\CHR\end{matrix} \longrightarrow R^1:Li\begin{matrix}:O(C_2H_5)_2\\:CH_2\\CHR\end{matrix} + (C_2H_5)_2O.$$

In such compounds the R′–Li bond is more strongly polarised than in complex hydrocarbon compounds and the group R′ is more reactive. This is responsible for the low stability of the compound as a whole and therefore also for the higher rate of intramolecular isomerisation. We believe that all these factors are decisive in the acceleration of polymerisation according to the mechanism

$$\sim CH_2{-}\underset{R}{CH}:Li\begin{matrix}:O(C_2H_5)_2\\:O(C_2H_5)_2\end{matrix} + \begin{matrix}CH_2\\\|\\CHR\end{matrix} \longrightarrow \sim CH_2{-}\underset{R}{\overset{H_2C{-}CHR}{CH}}:Li\begin{matrix}:O(C_2H_5)_2\\:O(C_2H_5)_2\end{matrix} \longrightarrow$$

$$\longrightarrow \sim CH_2{-}\underset{R}{CH}{-}CH_2{-}\underset{R}{CH}:Li\begin{matrix}:O(C_2H_5)_2\\:O(C_2H_5)_2\end{matrix}.$$

The hypothesis that elementary reactions, in particular the chain propagation reaction, take place via relatively stable intermediate complexes, explains satisfactorily the observed change in the activity of two monomers on transition from separate polymerisation to copolymerisation[82,86-90]. For example, styrene, which is more reactive than butadiene in separate polymerisation, becomes relatively inactive in the copolymerisation of these monomers[87]. This is because butadiene forms relatively more stable intermediate complexes than styrene and the composition of these complexes in fact determines the composition of the copolymer. On the other hand, the isomerisation of the intermediate complex to an active centre affects only the overall rate but not the composition of the copolymer. In copolymerisation in a hydrocarbon medium butadiene is 400 times more reactive than styrene. In a strongly solvating medium, for example in tetrahydrofuran, the capacity for the formation of the butadiene complex decreases and its reactivity falls relative to styrene[84].

It follows from the above that in the field of catalytic "anionic" polymerisation of vinyl and diene monomers in the presence of organometallic compounds, two main hypotheses concerning the nature of the active centres exist so far. In one of these the active centres are regarded as ion pairs capable of dissociation in the limit into ions and it is supposed that the process takes place by a stepwise mechanism, i.e. via two elementary reactions. In the second hypothesis polymerisation is regarded as a coordination process proceeding via intermediate complexes of the monomers with the initial organometallic compounds. The polymerisation then consists of not less than three elementary reactions.

†The regeneration of the catalyst after the completion of polymerisation observed in the experiments of Ziegler, Medvedev, and Morton described above (see Russ. p. 277), can be explained from the standpoint of this hypothesis by a reaction according to the catalytic coordination mechanism.

The Mechanism of Light-induced Ageing and Light Stabilisation of Polymers

Yu.A.Ershov, S.I.Kuzina, and M.B.Neiman (deceased)

This review deals with processes accompanying the light-induced ageing of polymers which are subjected simultaneously to the action of oxygen and ultraviolet and visible light, and also with the distinctive features of these processes and possible pathways for the stabilisation of polymeric materials. Under natural conditions, solar radiation leads to rapid mechanical breakdown of unstabilised polymeric materials. The light stabilisation of polymers is one of the most important problems, because of the wide application of these materials[1] in space engineering, national economy, and ordinary life.
The authors' aim was not to give the maximum cover of the available literature on this problem, which has become fairly extensive during the last 5–6 years; attention is mainly concentrated on the mechanisms of the processes occurring in light-induced ageing and the methods available for their investigation. The bibliography includes 122 references.

1. CHANGE IN THE PRACTICAL PROPERTIES OF POLYMERS ON LIGHT-INDUCED AGEING

In most studies of light-induced ageing, the mechanical properties of polymers have been investigated as a function of the duration and conditions of irradiation[2-6]. This is quite reasonable, since the user is interested in the first place in the stability of such properties of the material as elasticity, strength, adhesion, constancy of dimensions, etc. However, most of the published work is of an unduly applied nature and reduces to simple statements of the magnitude of the changes occurring and the effect on these changes of various stabilisers against light.

Mechanical methods for testing polymers are most widely used. They are readily available and are highly sensitive. The changes in the ultimate strength and the relative elongation of polymer specimens as a function of the duration of irradiation are most frequently determined. The user obtains in this way virtually exhaustive data on the operational properties of the material, but, for a controlled increase of the stability of polymers with respect to light, it is necessary to know the internal mechanism of the observed changes.

Quantitative theory[7-9] relating the mechanical characteristics of the polymeric material to the chemical structure and the nature of the supermolecular structures is still in its development stage. A clear relation between the following changes in polymeric materials on light-induced ageing is by no means always clear: changes in chemical structure as a result of photochemical reactions, changes in supermolecular and hence crystalline structures as a result of the changes in chemical structure, and the changes in mechanical properties resulting from the changes in crystal structure. It is quite evident that, in studying the action of light on mechanical properties, it is necessary to follow the entire sequence of transformations. Only then can one hope to establish a quantitative relation between the first and last stages of the light-induced ageing process.

Instructive studies have been made by Baltenas[10,11] and by Ozawa and coworkers[5]. A number of polyethylene specimens differing in the number of local strains in the defects were investigated[10]: (1) a film (60μm) heat-treated in a vacuum above the melting point (this film is closest to equilibrium); (2) a film (60 μm) extruded under conditions of hot orientation and rapid cooling with high anisotropy of the mechanical properties, an irregular spherulitic structure, and local internal strains; (3) specimens obtained by cold drawing (neck) with breakdown into fibrils of the spherulitic structure and the maximum number of local strains. The specimens were irradiated with ultraviolet light from a PRK-2 lamp at 40°C in air over a period of 20 h.[13] On going from specimens (1) with a homogeneous spherulitic structure to specimens (2) and (3) with an increasingly defective structure, one observes an increase in the rate of accumulation of carbonyl groups (determined from infrared spectra), a more rapid decrease of mechanical strength, and an increase in the yellow colour of the specimens. These observations are consistent with the hypothesis[14] that the strength of the chemical bonds decreases with increasing mechanical strain in the specimen.

The study of the thermograms of the same specimens shows that, on light-induced ageing, the degree of crystallinity increases in all cases by 6–8%. Hence one may conclude that chemical bonds in the region of local strains are the first to dissociate in light-induced ageing, which may lead to the migration of units from the region of the defects to the crystal lattice. The so called destructive crystallisation takes place. The increase in the degree of crystallinity on ageing was noted also by other workers[5,15,16]. Thus the change in the properties of the polymeric material in light-induced ageing is determined mainly by the nature of the defects and not the structure of the crystal lattice[10].

The data quoted by Baltenas and Visciniene[12] are very instructive in this respect. The structure of the polyethylene coating of an aluminium foil is determined to a large extent by the method of its preparation. Fig. 1

presents the photomicrographs of sections of polyethylene coatings obtained by centrifugal deposition in a fluidised layer of polyethylene powder at 200°C. Slow cooling of the coating obtained in air results in a structure with large annular spherulites (Fig. 1*a*). On rapid cooling with water, smaller spherulites without visible rings are produced (Fig. 1*b*). Furthermore, in the latter case amorphous regions arise, particularly at the surface of the coating, without a visible spherulitic structure. It is found that the coating with a crystalline surface is more stable with respect to the action of ultraviolet light. Fig. 2 presents photomicrographs of the surface of the coating after irradiation for 30 h. On the coating with the crystalline surface (Fig. 2*a*), there are almost no cracks, while the coating with the amorphous surface (Fig. 2*b*) was virtually broken up as a result of the formation of a large number of cracks.

Figure 1. Spherulitic structure of a polyethylene coating in transverse section: *a*) obtained by centrifugal deposition with cooling in air; *b*) ditto with cooling in water.

The difference in the structures of the polymer is in turn determined by the chemical reactions occurring in the preparation of the coating. The formation of the structure with large spherulites on centrifugal deposition is probably caused by the thermal oxidation of polyethylene. In thermal oxidation in the melt, the macromolecules dissociate with formation of free radicals, whose reactions lead to the formation of oxygen-containing groups and to the cross-linking of the chains. It is suggested[17] that these chemical reactions appreciably alter the conditions for the formation of crystallisation nuclei (nucleation), as a result of which, the rate of their formation falls. There is a change in the relative rates of nucleation and crystallisation, which leads to the formation of large spherulites. The generation of amorphous regions on rapid cooling is due to the sharp decrease of the rate of nucleation. In the unoxidised polyethylene amorphous regions of this kind are absent. The increase of the rate of the light-induced ageing of the coating in the presence of amorphous regions may be caused by its higher permeability to oxygen.

The dependence of stability with respect to light on the dimensions of the crystalline regions and the degree of orientation of low-pressure polyethylene films has been investigated with irradiation, using a weatherometer, with light at a wavelength of 360–420 nm.[5]

The size of the crystallites and the molecular weight change little on irradiation. It is interesting to note that refusion of the specimens fully restores their mechanical properties. The authors' explanation is that amorphous regions of the polymel are the first to undergo polychemical oxidation, after which new crystalline regions appear, while large crystals break down under the action of high-energy quanta, giving rise to internal strains with weakened chemical bonds.

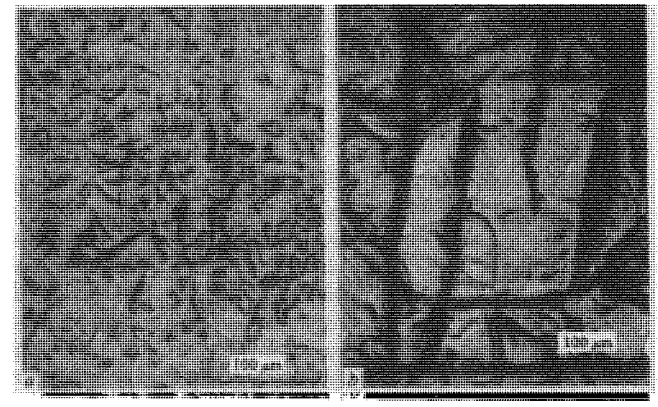

Figure 2. Photomicrographs of the surface of a polyethylene coating (viewed from above) after irradiation for 30 h with ultraviolet light: *a*) cooling in air; *b*) cooling with water.

The results obtained in the oxidation of polymers with different extents of branching provide an indirect indication of the relation between the light stability of the polymer and the structure of its macromolecules[18]. On irradiation with ultraviolet light (280 nm), polyolefins absorb oxygen at different rates depending on the degree of branching (Fig. 3).

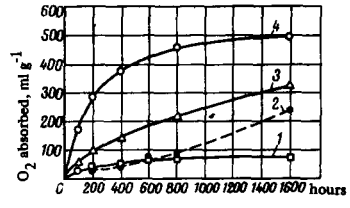

Figure 3. Variation of the extent of absorption of oxygen with the degree of branching of polyolefin specimens irradiated with ultraviolet light at a wavelength of 280 nm at 50°C: 1) linear polyethylene; 2) branched-polyethylene; 3) isotactic polypropylene; 4) poly-4-methylpent-1-ene.

Thus it is clear from the studies enumerated above that, although chemical reactions are important, they are by no means the sole factor determining the mechanical strength on light-induced ageing of polymeric materials and it is particularly important to take this into account in thermal processing of polymers.

The relation between the mechanical properties and chemical transformations in light-induced ageing of polymers has been investigated in greatest detail for the formation of cross-links on ultraviolet irradiation. The large number of studies on this problem has been stimulated by the cross-linking theory developed in detail for the ageing of polymers under the action of ionising radiation[19,20]. Although structure formation takes place under these conditions too, chemical reactions play a decisive role in this case, which makes it possible to establish certain quantitative relations between the number of cross-links and the mechanical properties.

2. KINETIC MECHANISM OF THE PHOTOCHEMICAL PROCESSES IN LIGHT-INDUCED AGEING

From the standpoint of the kinetics, the process of light-induced ageing of polymers can be divided into a number of stages, each of which is characterised by its own rate constant. These stages can occur both consecutively and simultaneously. In the latter case a number of competing reactions are observed, one of which may predominate, depending on the conditions.

Among the large number of studies dealing with the light-induced ageing of various polymers, there are only a few on the kinetic analysis of the results on the basis of a system of kinetic equations. This is fairly remarkable, because the studies on light-induced ageing are essentially kinetic, since the changes in a particular quantity are always investigated as a function of the duration of irradiation. The absence of kinetic analysis is due to the difficulties associated with the derivation and solution of an adequate system of kinetic equations and also with the complexity of the analysis of small amounts of products.

In this review an attempt is made to derive such a system and the solutions are analysed as far as possible.

1. Initation:

$$S + h\nu \xrightarrow{k_1} S^*, \qquad (1)$$

where S is a macromolecule containing an absorbing group in the ground singlet state and S^* the same macromolecule with the absorbing group in an excited singlet state.

2. Return to the initial state by light emission (fluorescence):

$$S^* \xrightarrow{k_2} S + h\nu'. \qquad (2)$$

3. Transition to an excited triplet state and a radiationless transition unaccompanied by dissociation:

$$S^* \xrightarrow{k_3} T; \quad S^* \xrightarrow{k_4} \tilde{S}, \qquad (3)$$

where $\tilde{S}$ is a molecule with excited vibrational states.

4. Return to the initial state by a singlet–singlet energy transfer (quenching of fluorescence):

$$S^* + A \xrightarrow{k_5} S + A^*, \qquad (4)$$

where A is an acceptor molecule.

5. Transformation of the triplet state:

$$T \xrightarrow{k_6}. \qquad (5)$$

6. Photodissociation:

$$S^* \xrightarrow{k_7} 2R. \qquad (6)$$

7. Formation of photolytic products:

$$M{-}M + R \xrightarrow{k_8} R + P_l, \qquad (7)$$

where M–M is a section of the macromolecule without an absorbing centre.

8. Cross-linking (chain termination) and diffusion of microradicals from the polymer matrix (linear termination):

$$2R \xrightarrow{k_9} C: \ R \ \text{(condensed phase)} \xrightarrow{k_9'} R \ \text{(gas)}. \qquad (8)$$

9. Oxidative processes:

$$R + O_2 \xrightarrow{k_{10}} P_0 + R, \qquad (9)$$

where P_0 are products obtained via a peroxy-radical; k_1–k_9 are the rate constants for the processes, ν is the frequency of the active light, and ν' the frequency of the light emitted in fluorescence (in the general case $\nu \neq \nu'$). The reversal of stage (4) results in sensitisation via impurities.

Despite the large number of stages quoted above, the mechanism is to a large extent simplified—in particular it is assumed that light-induced ageing takes place mainly via singlet states, the complex stages (7) and (9) are described by overall constants, quenching by oxygen is not taken into account, and it is assumed that various radicals have the same reactivity (the one-centre approximation). Stages (1)–(8) determine the kinetics of light-induced ageing in the absence of oxygen, i.e. in photolysis. The entire set of stages (1)–(9) describes oxidative ageing. Since all the photolytic processes can take place in oxidative light-induced ageing, the large number of studies dealing with the photolysis of various polymers is not surprising. The determination of the kinetic parameters for the photolytic breakdown of polymers is simpler than for oxidative ageing and yields important information about the initiation of photochemical processes. Usually[21–24] the first four stages of the mechanism, describing the physical photoactivation and deactivation processes, are not treated in detail and are combined in a single initiation stage. For example, the initiation stage in the photochemical oxidation of polyethylene[21,25] and polystyrene[26] is described as follows:

$$\ldots CH_2{-}CH_2{-}CH_2{-}CH_2\ldots \xrightarrow{h\nu,\ O_2} \ldots CH_2{-}CH_2{-}\underset{\displaystyle OOH}{CH}{-}CH_2\ldots,$$

$$\ldots CH_2{-}\underset{\displaystyle C_6H_5}{CH}{-}CH_2\ldots \xrightarrow{h\nu\ O_2} \ldots CH_2{-}\overset{\displaystyle OOH}{\underset{\displaystyle C_6H_5}{C}}{-}CH_2\ldots.$$

Undoubtedly mechanisms of this kind make it very difficult to understand the most important stage in light-induced ageing, namely initiation, and in photolysis by sunlight (λ = 290 nm) the nature of the light-absorption centres is completely obscure, since pure saturated hydrocarbons, for example, are transparent in this wavelength range.

3. THE MECHANISM OF INITIATION IN LIGHT-INDUCED AGEING. EXCITED STATES

The principal difference between photochemical and dark reactions is due to the nature of initiation of the process as a whole. In a dark reaction the energy required to overcome the activation barrier is drawn from the internal energy of the system and the rate and mechanism of the process under these conditions are determined by the temperature of the system. In a photochemical reaction the energy is provided from outside in the form of quanta of electromagnetic radiation and at a given temperature of the system the rate and mechanism of the process are determined by the intensity of the initiating radiation and its spectral distribution.

Usually[27,28] the primary photochemical step is regarded as the chemical reaction of the molecule excited by light absorption with formation of one or several primary photochemical products. However, the light absorption itself is essentially a chemical reaction of the molecule.

Indeed the chemical properties of the molecule are determined by the structure of its electron shell, which changes considerably on absorption of light; the chemical properties of the excited molecule, in particular its reactivity, may differ sharply from those of the molecule in the normal state[29,30].

Evidently, for a theoretical prediction of the nature of the excitation of the polymer molecule and hence of the entire light-induced ageing process as a function of the intensity of the incident radiation and its spectral distribution, it is necessary to have a clear idea about the nature of the absorbing groups and their electronic states.

The principal component of solar radiation at sea level consists of the long-wavelength region above 300 mn and only a small part of it is radiation at a wavelength less than 300 nm. The absorption spectra of the commonest polymers—poly(vinyl chloride) poly(methyl methacrylate), polystyrene, polyethylene, polypropylene, cellulose, polyamides, etc. —do not contain absorption bands in the region above 300 nm and therefore it would appear they should not undergo light-induced ageing. However, these polymers break down rapidly in sunlight. Hence it follows that it is precisely the small component of the short-wavelength solar radiation in the region of 300 nm that initiates the secondary photochemical processes leading to the light-induced ageing of polymers. The wings of the absorption bands attributed to carbonyl groups and polyene conjugated structures enter this region (the long-wavelength band of acetone is in the region of $\lambda_{max} = 280$ nm [31] and the band of $CH_3-(CH=CH)_4-CH_3$ is in the region of $\lambda_{max} = 290$ nm [32]). These groups and structures may be regarded as initiation centres for light-induced ageing in polymers whose monomer units do not contain absorbing groups†. The carbonyl group may form part of a monomer unit of the polymer, for example in polyamides, polymethacrylates, etc. In carbon chain polymers such as polyethylene, polypropylene, and polystyrene carbonyl groups and double bonds arise by thermal oxidation in the polymerisation and processing of the polymers.

An indirect demonstration of the role of C=O groups in light-induced ageing processes of polymers is provided by data on the photochemical degradation of poly(vinyl chloride) (with light at 300 nm). The photochemical degradation was appreciably accelerated on addition of acetone to the polymer[33,34].

The apparent absence of the corresponding bands in the absorption spectra of the polymers is due to the low concentration of the initiating groups and frequently the fact that such bands are masked by the intense bands associated with the chemical groups forming part of the monomer units of the polymer. For example, the spectrum of polystyrene is determined mainly by the absorption of the phenyl rings. Because of the difficulties of the direct spectroscopic determination of the absorbing groups of the above type, investigators resort to indirect methods (for example the measurement of the activation spectrum—the dependence of the quantum yields of the photochemical processes on the wavelength of the initiating radiation[35,36]) (Fig. 4).

It was also shown[37] that the maximum luminescence of polypropylene is observed on excitation with light at 280 nm, although in this region there is no detectable absorption maximum. Since the luminescence intensity is approximately proportional to the number of excited molecules, one may propose that, on irradiation with light at this wavelength, the most intense breakdown of the polymer will occur.

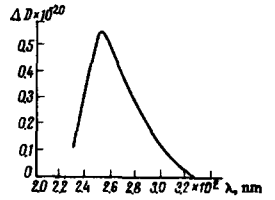

Figure 4. Variation of the optical density of poly(vinyl chloride) with the wavelength of ultraviolet radiation per incident quantum.

In view of the special role of carbonyl groups in light-induced ageing of various polymers, we shall consider in greater detail (as a model) the electronic structure of complex carbonyl-containing molecules[30,38]. It must be noted that the ultraviolet spectra and hence also the electronic structure of the carbonyl compounds of the polymers have been scarcely investigated and therefore the data quoted are suitable only for an approximate prediction of the course of photochemical processes in polymers.

The electronic structure of the carbonyl-containing compound in the region of the C=O group is determined by the presence of three groups of electrons:

(1) The non-bonding n electrons in the valence shell of the oxygen atom which do not enter into a chemical bond; (2) the bonding π electrons, the wave function of which is antisymmetric relative to the plane passing through the C=O bond; (3) the bonding σ electrons, the wave function of which is symmetrical relative to the axis of the C=O bond. The π electrons are usually delocalised in the region of the C=O group and the σ electrons are localised at the atoms which they bind together.

In a one-electron scheme these three groups of electrons correspond to three groups of levels (Fig. 5). The ground state of the molecule corresponds to the population of the one-electron states which ensures the minimum total energy of the molecule.

An excited state of the molecule arises as a result of the transition of one of the n, π, or σ electrons to an antibonding π^* or σ^* level. Depending on the nature of the transition, the excited states are denoted as follows: an $S_{n\pi^*}$ (singlet $n\pi^*$) state of the molecule arising by transition of a $2p$ electron from the n orbital to an antibonding π^* orbital, a $T_{n\pi^*}$ (triplet $n\pi^*$) state—a similar transition but with a change in the resultant spin of the system, etc.

The electronic absorption bands attributed to the carbonyl group are due to the corresponding transitions. The short-wavelength band with $\lambda_{max} = 150$ nm (8.3 eV) is due to the $\pi \rightarrow \pi^*$ transition, the middle band with $\lambda_{max} = 190$ nm (6.5 eV) corresponds to the $n \rightarrow \sigma^*$ transition, and the long-wavelength band with $\lambda_{max} = 280$ nm (4.4 eV), which is the most interesting from the standpoint of light-induced ageing, is caused by the $n \rightarrow \pi^*$ transition. In the region of the long-wavelength boundary of this band at

†The initiation can of course take place also via impurity molecules.

340 nm (3.6 eV) a vibrational structure is observed. In this transition both $S_{n\pi^*}$ and $T_{n\pi^*}$ excited states may be populated. Precisely these are the initial states in photochemical reactions undergone by various polymers with a carbonyl group in light-induced ageing and the concentration of these states must appear in the kinetic equations describing the light-induced ageing of a particular polymer.

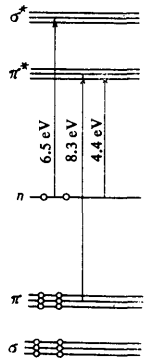

Figure 5. Schematic representation of one-electron levels in a molecule containing a carbonyl group.

Since under the usual experimental conditions absorption in the region of about 300 nm plays the main role, in the treatment below S^* must be understood as the $S_{n\pi^*}$ state. Eqns. (2)–(6) of the kinetic mechanism of light-induced ageing describe the processes involved in the degradation of the electronic excitation energy absorbed in the primary step (1). The relation between the rates of these processes ultimately determines the rate of light-induced ageing. Thus, for example, the number of breaks in the macromolecular chain (degradation), which has a destructive effect on the mechanical properties of the polymer, is determined (see below) by the relation $D = k_6 \int_0^t (S^*)dt = k_6(\bar{S}^*)t$, where $(\bar{S}^*)$ is the average concentration of excited states during the time of exposure t, i.e. with increasing (S^*), the rate of degradation of the polymer rises. However, if the rates of processes (2)–(5) are high, the concentration of excited states and hence also the rate of degradation are insignificant. The data for the constants k_2–k_5 may be obtained by spectroscopic luminescence techniques.

Many polymers in the solid state and in solution exhibit bright luminescence. Polymers with a wide variety of chemical structures, including biopolymers, have been investigated qualitatively[39]. The luminescence spectra‡ of all the polymers investigated extend as a continuum over the region 300–700 nm (when an ISP-51 glass spectrograph is used). This luminescence is not characteristic. It consists of maxima with fixed positions in the red part of the spectrum and the adjacent broad diffuse maximum in the blue-violet part. The latter maximum changes its position from compound to compound and with molecular weight in the same homologous series.

‡The observed glow has been referred to as fluorescence[39] without the appropriate evidence being adduced (see below).

Gachkovskii[39] did not explain the changes in the luminescence spectrum and their origin. It may be supposed that the observed glow is caused by the presence in the polymer of impurity groups, for example terminal groups, which consist of part of the initiator molecule. The relative content of these groups and therefore also the luminescence yield must fall with increasing molecular weight.

A more careful study of the luminescence of various polymers was carried out by Charlesby and Partridge[40,41]. The main aim of these investigations was to establish the nature of the centres responsible for the thermoluminescence observed when raising the temperature of the polymer specimens subjected to the action of γ-radiation or ultraviolet light at 77°K; the luminescence of the same polymers at room temperature, excited by ultraviolet light of different wavelengths, was studied simultaneously. The luminescence spectra of polyethylene, polypropylene, polystyrene, and polytetrafluoroethylene are produced by the superposition of the fluorescence spectra in the region of 300–400 nm and phosphorescence spectra in the region of 400–600 nm. The thermoluminescence spectra of these polymers are in the main analogous to their luminescence spectra.

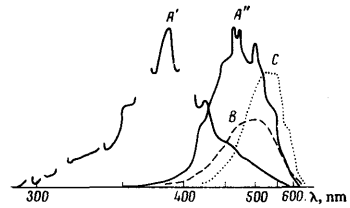

Figure 6. Luminescence spectrum of polyethylene: *A'*) and *A''*) complete luminescence spectrum; *B*) phosphorescence spectrum obtained on irradiation of polyethylene through a glass filter; *C*) phosphorescence spectrum obtained on irradiation of polyethylene through a filter transmitting light at wavelengths greater than 350 nm; the spectra are presented with different intensity scales.

Fig. 6 shows the luminescence spectrum of polyethylene resolved into the ultraviolet (*A'*) and visible (*A''*) components. The luminescence spectra of low- and high-density polyethylene are produced by the superposition of at least four spectra, which differ in structure and the limiting excitation wavelength. The complete phosphorescence spectrum (*A''*) of polyethylene consists of a series of sharp vibrational peaks against the background of a broad spectral band. Spectrum *B* is obtained when a glass filter, transmitting light at wavelengths greater than 300 nm, is interposed in the path of the exciting beam. Spectrum *C* is obtained with a filter transmitting light at a wavelength greater than 350 nm. The difference between spectrum *A''* and the sum of spectra *B* and *C* may be due to the presence of an undetected spectrum *D*. At a wavelength greater than 420 nm phosphorescence is not excited.

The phosphorescence spectrum of polystyrene is very similar to those of acetophenone and benzophenone, investigated by Kasha[42]. Kasha attributes the phosphorescence of benzophenone and acetophenone to the $n \rightarrow \pi^*$ transition of the carbonyl group. The distance between the distinct bands in the vibrational structure corresponding to the

stretching vibrations of the carbonyl group is 1665 cm^{-1} for benzophenone and 1690 cm^{-1} for acetophenone. In the phosphorescence spectrum of polystyrene this interval is 1600 ± 150 cm^{-1}. The great similarity of the phosphorescence spectrum of polystyrene to those of benzophenone and acetophenone can be hardly attributed to isolated admixtures of the latter. It is most likely that the phosphorescence of polystyrene is due to the presence of small amounts of carbonyl groups produced in the polymer during its preparation. Three types of carbonyl groups, two terminal and one distributed at random, are possible:

$$\underset{\underset{C_6H_5}{|}}{R-C=O}\ (I), \qquad \underset{\underset{H}{|}}{R-C=O}\ (II), \qquad \underset{\underset{O}{\|}}{R-C-R}\ (III).$$

The presence of these groups may explain the observed features of the phosphorescence spectra. Groups of type (I) give rise to a spectrum analogous to that of acetophenone but displaced towards the red region due to the presence of a heavy alkyl substituent—the polystyrene chain, as is observed for alkyl-substituted methyl ketones[43]. Spectra of groups (II) and (III) should be similar to those of aliphatic aldehydes and ketones and also polyethylene if the phosphorescence spectrum of the latter is due to carbonyl groups. These hypotheses are confirmed by experimental data. In particular, the fluorescence spectrum of polystyrene may be attributed to emission by carbonyl groups.

It is quite evident that the luminescence of polystyrene is not associated with the phosphorescence and fluorescence spectra of toluene (which should be the case if the isolated phenyl groups of the macrochain were responsible for the major part of the emission), since the 0,0 bands of toluene are in the region of 270 and 347 nm.[44] Nor can they be attributed to terminal groups, since the polystyrene was obtained by thermal polymerisation.

The luminescence of polyethylene cannot be due to the properties of the polyethylene chains, since saturated hydrocarbons do not luminesce. In this connection it is interesting to note that the entire luminescence spectrum is observed even in comparatively pure saturated hydrocarbons, such as, for example, pentatriacontane deposited in a thin layer on a quartz support.

It may be supposed that the luminescence of polyethylene is caused by the presence of double bonds in the chain. Evans[45] showed that the triplet 0,0 absorption bands of ethylenes lie in the region of 350 nm and Wilkinson and Mulliken[46] observed a singlet 0,0 band near 250 nm. Bearing in mind the presence of an "infinitely long" alkyl substituent in polyethylene, one may postulate the possibility of a corresponding shift of these bands towards the longest wavelengths observed in the phosphorescence spectra of polyethylene as 380 and 295 nm respectively. However, so far it has proved impossible to obtain reliable phosphorescence spectra of ethylene or its substituted derivatives. According to Potts[47], this may be caused by the capacity of the molecules of the ethylene type to rotate rapidly about the C=C bond after undergoing a transition to the triplet state. This entails an energy loss, the molecule reaches the point of intersection of the singlet and triplet terms and can undergo a radiationless transition to the ground state.

However, the majority of available facts are consistent with the hypothesis that carbonyl groups are the luminescence centres in polyethylene and polystyrene. This is suggested by the decrease of the luminescence yield on γ-radiolysis of the polymers (the number of double bonds then increases) and the increase of the luminescence yield on heating the polymer in air (the number of carbonyl groups increases).

Charlesby and coworkers[40,41] encountered considerable difficulties due to the inadequate sensitivity of the apparatus and the non-monochromatic nature of the exciting radiation. For example, the visual fluorescence observed for polytetrafluoroethylene could not be recorded with a spectrograph, which of course hinders a quantitative assessment of the observed phenomena.

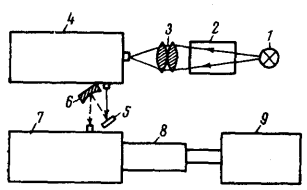

Figure 7. Diagram of apparatus for the recording of luminescence spectra: 1) DRL-500 mercury lamp; 2) water filter for the absorption of heat; 3) quartz condenser; 4) EMR-3 mirror monochromator; 5) specimen; 6) parabolic mirror; 7) SFD-2 monochromator; 8) FEU-19M photomultiplier; 9) U2-4 amplifier.

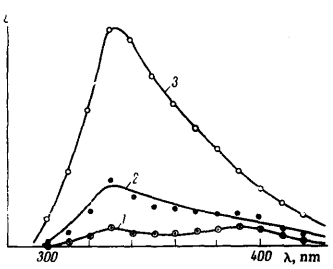

Figure 8. Effect of Tinuvine P (0.01 mole kg^{-1}) on the luminescence of polypropylene: 1) observed luminescence spectrum of the polymer with Tinuvine P; 2) luminescence spectrum of the polymer with Tinuvine P corrected for reabsorption and screening; 3) observed luminescence spectrum of the polymer without added Tinuvine P; L—luminescence intensity in relative units; the wavelength of the exciting light was 280.4 nm.

These difficulties were overcome after the construction from standard equipment of an apparatus (Fig. 7) for the investigation of low intensity luminescence with monochromatic excitation[37]. Fig. 8 shows a luminescence spectrum of atactic polypropylene obtained on this apparatus (Fig. 8, curve *3*). The spectrum of isotactic polypropylene is similar. These spectra make it possible to investigate quantitatively the form of the spectrum and the luminescence yield (see below).

It follows from the data quoted above that the fluorescence (reaction (2)] and phosphorescence [reactions (3) and (5)] processes may compete to a considerable degree with the photodissociation process (6), which is confirmed[40]

by the very low quantum yields of the radicals. We shall not consider here the role of the triplet states, because at room temperatures they are probably important only at very high light intensities (two-quantum processes[48]). The migration of energy [reaction (4)] will be examined below and now we shall consider the more important photodissociation reaction (6), which determines the nature of the radicals responsible for numerous secondary photochemical processes in light-induced ageing of polymers.

4. THE NATURE OF RADICALS FORMED ON ULTRAVIOLET IRRADIATION OF POLYMERS

The method most widely used at present to investigate the radicals formed on ultraviolet irradiation of polymers is electron spin resonance. As a rule these radicals are very reactive and they must be stabilised by a rigid polymeric matrix at low temperatures. Quantitative data concerning the accumulation of these radicals, their lifetimes, etc. at low temperatures cannot of course be used directly for kinetic calculations at room temperatures. However, these data are important for the understanding of the mechanism of light-induced ageing processes.

The processes involved in the formation of radicals in low-temperature photolysis (77°K) of polyethylene[41,49-51], polypropylene[49-54], poly(methyl methacrylate)[55], polystyrene, a number of polyolefins[49], and polyphenylmethylsiloxan[56] have been investigated in greatest detail.

When polyethylene was irradiated in air at room temperature, an ESR signal was not recorded[49]. At 77°K free radicals of two types were detected[51]: $\ldots CH_2-\dot{C}H-CH_2\ldots$, whose spectrum is the same as that of polyethylene subjected to ionising radiation and described in a number of studies[57-61], and the radical $\ldots CH_2-\dot{C}H_2$, arising on dissociation of the C–C bond of the polymer chain, which is not observed in the radiolysis of polyethylene. These two types of radicals are formed with approximately equal yields. Heating to 178°K transforms the initial ESR spectrum into a singlet, which has been tentatively attributed to a free radical of the allyl type produced from the radical $\ldots CH_2-\dot{C}H_2$ on dehydrogenation with the migration of the free valency along the polymer chain.

The results from the study of the ESR spectra of polypropylene irradiated with ultraviolet light differ from those obtained in the radiolysis of this polymer. The action of ionising radiation of polypropylene at a low temperature leads to the formation of the alkyl radical[62-69] $\ldots CH_2-\dot{C}(CH_3)-CH_2$. When the system is heated to room temperature, the eight-line spectrum of this radical is converted into a nine-line spectrum attributed to the allyl radical[64,66,67] $\ldots CH_2-\dot{C}(CH_3)-CH=C(CH)_3-CH_2\ldots$

γ-Irradiation of polypropylene at room temperature leads to the formation of a 17-line spectrum, attributed[66,67] to radicals of the allyl type. On the basis of new data, it is suggested that[70] this spectrum is due to an alkyl radical.

It follows from the results quoted above that, as a result of the action of ionising radiation on polypropylene, dissociation of C–H bonds predominates. The action of ultraviolet light on polypropylene at 77°K leads to the formation of a number of alkyl radicals.

Typical radical accumulation curves are presented in Fig. 9. The interpretation of the ESR spectra led to the discovery of the presence of the methyl radical[49,51,54] $\dot{C}H_3$ and the macroradicals $\ldots CH_2-\dot{C}H-CH_2\ldots$ and $\ldots CH(CH_3)-\dot{C}H-CH(CH_3)\ldots$ and also radicals with a free valence at the terminal CH_2 group, which are formed on dissociation of the C–C bond of the polymer chain: $\ldots CH_2-CH(CH_3)-\dot{C}H_2$.

The presence of the last named radical is most likely, since heating to 178°K converts the initial spectrum into a singlet, which, by analogy with polyethylene irradiation with ultraviolet light, was also attributed to an allylic radical arising on dehydrogenation of $\ldots CH_2-CH(CH_3)-\dot{C}H_2$.[51] The energy of ultraviolet light at a wavelength of 344.5 nm, consumed in the formation of a single free radical stable at 77°K, is 1.1×10^5 eV for polyethylene and 0.17×10^5 eV for polypropylene[51].

It is suggested[49,54,56] that the $\dot{C}H_3$ radicals can rotate rapidly in the polymer matrix even at liquid nitrogen temperature. This averages out the anisotropic broadening and yields the fairly well resolved ESR spectrum of polypropylene irradiated with ultraviolet light. The rotation frequency of $\dot{C}H_3$ in the polymer matrix is somewhat reduced (to about 30 MHz), and this accounts for the stabilisation of these radicals[51], which can exist for a week at 77°K.[49]

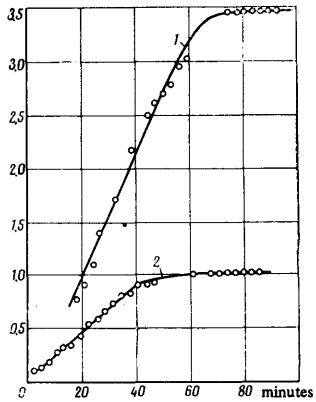

Figure 9. Curves for the accumulation of radicals in the photolysis of thermally oxidised atactic polypropylene: 1) irradiation in a quartz tube; 2) irradiation in a Pyrex tube (1 unit on the ordinate scale corresponds to 10^{16} particles).

When polypropylene was exposed to ionising radiation, the methyl radical was not detected. However, its intermediate existence is indicated by the presence of methane in the radiolysis products[71].

The irradiation of polyolefins containing short side chains results in the formation of free radicals of the corresponding side groups or methyl radicals if the side group contains a methyl[49]. Thus ethyl radicals $\dot{C}_2H_5$ and the macroradicals $\ldots CH_2-\dot{C}H-CH_2\ldots$ are formed in polybut-1-ene on irradiation with ultraviolet light; irradiation of poly-4-methylpent-1-ene leads to the formation of the same radicals as in polypropylene, while radicals similar to those in irradiated polyethylene are formed in polydodec-1-ene and polypent-1-ene.

In the low-temperature photolysis of poly(methyl methacrylate) (irradiation with the light of the DRSh-500 lamp) free radicals of two types were observed[55]: $\ldots CH_2-\dot{C}(CH_3)(COOCH_3)\ldots$, formed on dissociation of the main chain and long-lived only at the temperature of liquid nitrogen, and the radicals $\ldots CH_2-\underset{\displaystyle COOCH_3}{\overset{\displaystyle |}{\dot{C}}}H(CH_2)$, which persist at

room and higher (340°K) temperatures for several months. The authors believe that the radicals of the second type are produced from the radicals of the first type by the capture of a hydrogen atom from the methyl group by the free valence of the carbon atom in the polymer chain.

On ultraviolet irradiation of polystyrene, a broad singlet, tentatively attributed to phenyl radicals, was observed[49]. Free radicals of two types were identified by the ESR method in the low-temperature photolysis of polyphenylmethylsiloxan[56]: $\dot{C}H_3$ and $R-\dot{C}H_2$. The study of the kinetics of the accumulation of these radicals as a function of light intensity established that the relation between the rate of accumulation of the $\dot{C}H_3$ radicals and the intensity I_0 is $W_{CH_3} \propto I_0^2$ for low values of I_0 and $W_{CH_3} \propto I_0$ at high values of I_0, i.e. the relation becomes linear. For R = $\dot{C}H_2$, the rate of formation varies linearly with I_0 over the entire range of intensities investigated.

On the basis of these results, it was also concluded that the formation of the $\dot{C}H_3$ radical, requiring the dissociation of the Si–C bond, involves two quanta and the formation of $R-\dot{C}H_2$, requiring the dissociation of the C–H bond, involve one quantum. The authors assume that the absorption of the first quantum causes the transition of the molecule to an excited state in which the Si–C bond dissociates in such a way that the $\dot{C}H_3$ radical remains within the cage (one quantum at 300 nm is sufficient to dissociate the Si–C bond). This state of the radical in the cage presupposes a strong interaction with the residue of the molecule. Only the absorption of the second quantum enables the $\dot{C}H_3$ radical to leave the cage.

Strictly speaking a two-quantum process in photochemistry is thought to be one in which the absorption of the second quantum takes place from a photo-excited molecular level[48]. The quadratic relation between the rate of accumulation of radicals and light intensity can also be obtained when a molecule adsorbes two light quanta (a two-quantum mechanism), as in the case where the formation of radicals takes place via an intermediate compound (complex) produced under the action of the first light quantum followed by the absorption of a second quantum. In the latter case there is a two-stage mechanism. Therefore it is more correct to suppose that in the photolysis of polyphenylmethylsiloxan the generation of $\dot{C}H_3$ radicals involves a two-stage mechanism.

A two-quantum process is possible in photoinitiation via the CO group[32,41]. Thus thermoluminescence of polyethylene produced by ultraviolet light at 365 nm has been observed. This corresponds to a photon energy of 3.4 eV, which is insufficient for the ionisation of the carbonyl group. However, when the triplet state generated by the absorption of the first photon is long-lived (about 2 s), there is a possibility of absorption of a second photon before the molecule returns to the initial state by emitting a phosphorescence photon. The second photon raises the energy of the molecule above the ionisation limit and the CO group ionises.

As already mentioned above, in the group of polymers examined, the most probable centres absorbing ultraviolet light (at 300 nm) are impurity carbonyl groups in polyethylene, polypropylene, and other polyolefins, CO groups forming part of the monomer unit in poly(methyl methacrylate), and the phenyl rings in polymers such as polystyrene and polyphenylmethylsiloxan ($\lambda < 300$ nm).

Since the appropriate data are not available for the polymers, it is useful to employ data on the photodissociation of low-molecular compounds to elucidate the mechanism of the formation of radicals on ultraviolet irradiation of polymeric molecules in which the absorption centres consist of CO groups and benzene rings.

It may be assumed[30] that in the excited state the molecule has an additional valency compared with the ground state. In the $n\pi^*$ state (the $n \rightarrow \pi^*$ transition in the CO group) the molecule has an atomic valence and in the $\pi\pi^*$ state (the $\pi \rightarrow \pi^*$ transition in the benzene ring) the valence is delocalised over the entire molecule. The mechanisms of the reactions of molecules in these two states are different. In consequence of the delocalisation of the valence in the excited $\pi\pi^*$ state and in the absence of $\sigma-\pi$ conjugation, the utilisation of the valence is difficult and the molecules may break down simply due to the conversion of electronic energy into vibrational energy of a bond in the molecule. Then there may be two pathways for the conversion of the excitation energy into bond vibrational energy: the "direct" pathway when the electronic energy of the molecule is converted into the vibrational energy of the bond, the electron density of which changes at the instant of the transition (for example in the C–R bond of substituted benzene); the "indirect" pathway when the excitation energy is converted into the vibrational energy of the bond, but the electron density of the latter remains unchanged. The second pathway presupposes a pre-dissociation mechanism of the decomposition.

The mechanism of the photochemical decomposition of molecules in $n\pi^*$ states differs from the mechanism of the breakdown of molecules in $\pi\pi^*$ states. The presence of an atomic valence in the excited state leads to the possibility of intermolecular and intramolecular chemical reactions. In the intramolecular mechanism utilising the valence of the $n\pi^*$ state of the molecule the chemical bond linking atoms located in the same plane as the symmetry axis of the wave function of the n electron will dissociate. Thus in acetaldehyde in the $n\pi^*$ state the C–H bond will dissociate, in acetone the $C-CH_3$ bond, and in benzaldehyde the C–H or C–Ph bond.

Peters[38] calculated theoretically the electron densities of the bonds in formaldehyde for different electron transitions in the CO group. It follows from these data that the photolysis of low-molecular carbonyl compounds takes place via a stage involving the homolytic dissociation of one of the C–C or C–H σ bonds adjacent to the carbonyl group. Jellinek[23] points out that in the photolysis of low-molecular ketones caused by the absorption of light by the CO group two types of reactions may occur: (1) reactions with formation of free radicals with dissociation of the σ bond adjacent to the CO group:

$$R-CO-R_1 \xrightarrow{h\nu} \dot{R} + R_1\dot{C}O \rightarrow \dot{R} + \dot{R}_1 + CO;$$

(2) reactions accompanied by the dissociation of the C–C bond in the $\alpha-\beta$-position relative to the CO group; in this case radicals are not formed:

$$R-CH_2-CH_2-CH_2-CO-R_1 \xrightarrow{h\nu} RCH=CH_2+CH_3COR_1.$$

The formation of free radicals in the photolysis of monosubstituted benzenes and low-molecular carbonyl compounds has been confirmed experimentally by a tracer method[30]. Methyl radicals $\dot{C}H_3$ have been detected by the ESR method in the low-temperature photolysis of acetone and its aqueous solution[72]. However, the similarity to the photolysis of low-molecular compounds also fails to provide an unambiguous answer to the question of the site of bond dissociation in a polymer molecule on formation of free radicals. Among the polymers examined, polystyrene and polyphenylmethylsiloxan contain a benzene ring in the

monomer unit. According to the photodissociation mechanism of monosubstituted benzenes, it would appear that in the photolysis of polystyrene and polyphenylmethylsiloxan one might expect the photodissociation of the C–R bond of the benzene ring with formation of a phenyl radical and the counter-radical of the polymer molecule. The photolysis products should contain benzene or its derivatives. As already mentioned[49,50] the broad singlet in the ESR spectrum observed in the photolysis of polystyrene was tentatively assigned to the phenyl radical. The gaseous photolysis products at 77°K were not analysed.

However, in most studies on the photochemical degradation of polystyrene[26,73–75] it is suggested that the light-induced ageing of the polymer begins with the dissociation of a C–H bond at a tertiary carbon atom. As stated above, in the low-temperature photolysis of polyphenylmethylsiloxan the radicals $\dot{C}H_3$ and $R-\dot{C}H_2$ were detected, while the phenyl radical was not.

Possibly in the photolysis of polymers the excitation energy is transmitted from the benzene ring over larger distances than in monosubstituted benzenes causing the dissociation of remote bonds: C–H in polystyrene and $C-CH_3$ and CH_2-H in polyphenylmethylsiloxan.

In the photolysis of polymers with a C=O chromophoric group in the monomer unit one may expect, using the same analogy with the photolysis of low-molecular carbonyl compounds, the formation of radicals on dissociation of a bond adjacent to the CO group or in the $\alpha-\beta$-position relative to this group[23,30]. In the first case photolysis should be accompanied by the evolution of gaseous carbon monoxide.

In their study of the photolysis of polyamides at room temperature in a vacuum, Stephenson et al.[76] detected carbon monoxide among the gaseous photolysis products. In the photolysis of polyurethane, carbon monoxide was detected mass-spectrometrically[77]. Unfortunately the ESR spectra of the free radicals were not investigated in the first of these studies[76], while in the second[77] an ESR signal was observed but the radicals were not identified.

Evidently one may justifiably assume that in all these polymers the dissociation of the main chain takes place at bonds adjacent to the carbonyl group. In polyethylene, polypropylene, and other polyolefins the impurity carbonyl groups enter into the composition of the molecule, being located most probably in the main polymer chain: $\ldots CH_2-CO-CH_2-CH_2\ldots$ (polyethylene) and $\ldots CH_2-CH(CH_3)-CO-CH(CH_3)-CH_2\ldots$ and $\ldots CH_2-CO-CH_2-CH(CH_3)-CH_2\ldots$ (polypropylene).

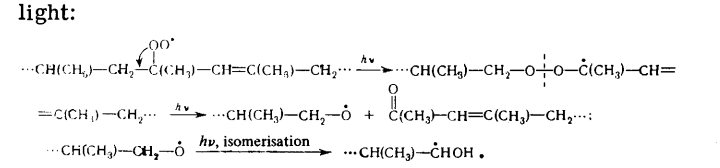
It has been suggested[51] that free radicals arising as a result of the dissociation of the main chain and with a free valence at the CH_2 group are produced in the photolysis of polyethylene and polypropylene: $\ldots CH_2-\dot{C}H_2$ for polyethylene and $\ldots CH(CH_3)-\dot{C}H_2$ for polypropylene. It may be supposed that in this case the C–C σ bond adjacent to the CO group dissociates. This photodissociation should be accompanied by the evolution of gaseous carbon monoxide. The gaseous products of the low-temperature photolysis of polyethylene and polypropylene were not analysed. At room temperature the photolysis of polyethylene in a vacuum and in a nitrogen atmosphere is accompanied by the evolution of hydrogen and methane[76]. Possibly, since the CO groups are present as impurities in the polymers investigated, carbon monoxide is difficult to detect experimentally because of its small amount.

However, the formation of the macroradicals $\ldots CH_2-\dot{C}H-CH_2\ldots$ in the photolysis of polyethylene and the radicals $\ldots CH_2-\dot{C}H-CH_2\ldots$ and $\ldots CH-(CH_3)-\dot{C}H-CH(CH_3)\ldots$ in the photolysis of polypropylene, and also data on the formation of radicals in polyolefins subjected to ultraviolet irradiation, when the side groups, or the methyls entering into the composition of the side group, mainly dissociate[49,50], suggest that in this case the photodissociation of polymers is not consistent with the mechanism of the photolysis of low-molecular carbonyl compounds. Possibly the excitation energy is transmitted over greater distances in the polymer molecule or the free valence migrates readily under the action of light.

Free radicals can change under the action of light and heat. In their study of the behaviour of radicals (generated by the γ-irradiation of a number of polymers at 77°K) under the action of the unfiltered light of a DRSh-250 lamp and heat, Milinchuk and Pshezhetskii[67,78,79] found that in many cases the radicals are destroyed and also that the ESR spectra of the radicals may change without a decrease in their concentration. In this case the destruction takes place at liquid nitrogen temperature where the possibility of mobility of different segments of the macromolecule may be virtually excluded.

The alkyl radical $\ldots CH_2-\dot{C}(CH_3)-CH_2\ldots$ formed initially in polypropylene at 77°K was converted on heating into the allyl type radical $\ldots CH_2-C(CH_3)-CH=C(CH_3)-CH_2\ldots$ and into the polyene radical $\ldots CH_2-\dot{C}(CH_3)-[CH=C(CH_3)]_n-CH_2\ldots$ The irradiation of allyl radicals with unfiltered light of a DRSh-250 lamp caused the reversion of the allyl radical to the alkyl radical. All the transformations of the radicals were deduced from changes in the hyperfine structure of the ESR spectra. The authors suggest that the mechanism of the formation of allyl and polyene radicals consists in the migration of the free valence of the alkyl radical along the polymer chain to a carbon atom adjacent to a double or conjugated bond. The migration is facilitated by the absorbed energy of the photon, which lowers the potential barrier to the migration of hydrogen atoms and the absorption is not necessarily associated solely with the chromophoric groups. Possibly the free radicals themselves absorb light. The mechanism of the migration of free valence in the macromolecule under the action of light and heat can explain the radical destruction processes at 77°K, the cross-linking and dissociation of the chain, the formation of double bonds, and the occurrence of conjugation.

Under the action of ultraviolet light, the peroxy-radicals derived from polypropylene are capable of isomerising to alkyl radicals[67]. The oxygen molecule is then incorporated in the polymer chain with formation of an –O–O– bond which is split by ultraviolet light with formation of a hydroxy-radical and a carbonyl group. Peroxy-radicals were accumulated by the oxidation of the alkyl radicals from polypropylene formed by γ-irradiation. The peroxy-radicals isomerised under the action of ultraviolet light with a maximum efficiency at 310–320 nm. The authors suggested that the peroxy-radical itself absorbs light:



Taking into account the possibility of the isomerisation of peroxy-radicals under the action of ultraviolet quanta from sunlight ($\lambda \simeq 300$ nm), one should note that the classical mechanism of oxidation via a stage involving the formation of hydroperoxide may not obtain in the photochemical oxidation of polypropylene, since the isomerisation is faster than the reaction $R\dot{O}_2 + RH \rightarrow$, which requires a favourable

encounter between the peroxy-radical and the hydrogen atom. Two mechanisms are possible for the reaction of $\dot{RO}_2$: isomerisation and the formation of hydroperoxide. This hypothesis requires experimental test.

Alkyl radicals obtained in the low-temperature photolysis or radiolysis of polymers are oxidised to peroxy-radicals on heating in an atmosphere of oxygen. The temperature of the oxidation of $\dot{R}$ to $\dot{RO}_2$ is 150° ± 10°K for polyethylene, natural rubber, and a number of saturated hydrocarbons, the recombination temperature being 210° ± 10°K.[80] The oxidation temperature of alkyl radicals was established on the basis of thermoluminescence data obtained on heating specimens irradiated with fast electrons. The thermoluminescence curves in the region of the phase transition temperatures show sharp rises, which are usually attributed to the lowering of the concentration of free radicals. The sharp rise ("flash") of thermoluminescence at temperatures 50–90 deg below the glass point, at which the concentration of radicals does not change, was attributed to the reaction of alkyl radicals with the oxygen dissolved in the specimen. Specimens subjected to preliminary evacuation did not show a rise of this kind in the thermoluminescence curve.

Since the temperature of the oxidation of alkyl radicals proved to be the same for polyethylene, natural rubber, and saturated hydrocarbons, it may be suggested that the reactivity of macroradicals is approximately the same and the temperature variation of the rate of oxidation of radicals is determined primarily by the increased mobility of segments of the chain and the penetration of oxygen to the site of the free valence.

5. KINETICS OF THE FORMATION OF THE PRODUCTS OF LIGHT-INDUCED AGEING

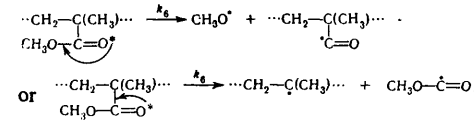
To obtain the theoretical relation between the accumulation of any one product and the duration of exposure to light, it is necessary to set up a system of kinetic equations in accordance with the mechanism. The variation of the concentrations of the reactants and products depends on the nature of the photoinitiation and destruction of radicals and therefore the kinetic equations will be different for different polymers.

Poly(methyl methacrylate) (PMMA) and polystyrene (PS) constitute a group of polymers in which the absorption of light (stage 1) can take place in any monomer unit and in early stages of the reaction the number of absorbing centres may be regarded as almost constant. The absorbing centres in PMMA are ester carbonyl groups and in polystyrene phenyl rings if the wave-length of the initiating radiation is less than 300 nm. The nature of these groups and their positions determine the mechanism of the degradation of the absorbed energy.

In view of the large number of studies dealing with the light-induced ageing of PMMA,[23,55,81-88] the mechanism of the reactions occurring in this polymer may be regarded as sufficiently well established. We shall consider initially the photolysis of PMMA at a wavelength of 254 nm. The absorption of a photon is accompanied by the transition of a p electron of the carbonyl group from the non-bonding orbital of the oxygen atom to the anti-bonding orbital ($n \rightarrow \pi^*$ transition, see Fig. 6).

In this particular case stage 1, $S + h\nu \rightarrow S^*$, has the form

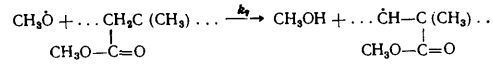
Then the excitation energy is transmitted by an intramolecular transition without emission to an ester C–O bond or a C–C bond, which leads to the photodissociation of the bond (stage 6 in the general mechanism, p. (149):



If each photon absorption step resulted in photodissociation the quantum yield φ of the photochemical reaction in light-induced ageing would be of the order of unity or even more than unity for a chain mechanism. However, at room temperature φ for a wide variety of polymers is of the order of 0.01 and frequently smaller by 2–3 powers of ten[23].

The mechanism which we propose for light-induced ageing clearly reveals the competing processes involving the degradation of electron excitation energy [reactions (2)–(6)] and permits a theoretical prediction of the quantum yield, provided that the corresponding rate constants are known.

The main products of the photolysis of PMMA are carbon monoxide, methanol, and methyl formate (see Fig. 10). Methanol is formed as a result of the secondary reaction



(stage 7 in the general mechanism, $P_f = CH_3OH$).

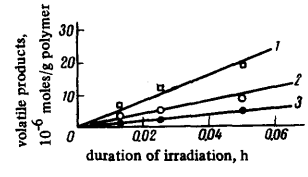


Figure 10. Amount of volatile products per gramme of PMMA as a function of the duration of irradiation at 30°C: 1) carbon monoxide; 2) methanol; 3) methyl formate.

The accumulation of methanol as a function of time is determined by the following set of equations

$$\frac{d(P_f)}{dt} = k_7(\text{M—M})(\text{R}), \tag{10}$$

$$\frac{d(\text{R})}{dt} = 2k_6(S^*) - k_8(\text{R})^2, \tag{11}$$

$$\frac{d(S^*)}{dt} = k_1 I_0(S) - [k_2 + k_3 + k_6](S^*). \tag{12}$$

Here round brackets denote the concentration of the corresponding reactant in cm^{-3}: (M–M), the concentration of hydrogen atoms combined with secondary carbon atoms, is almost constant and therefore $k_7(\text{M–M}) = \text{const.} = k'_7$; (S), the concentration of ester carbonyl groups is also almost constant, i.e. $k_1(S) = \text{const.} = k'_1$. Further, assuming that

the concentration of S^* corresponds to the steady state§, i.e. $d(S')/dt = 0$, we have from Eqn. (12)

$$(S^*)_{st} = \frac{k_1(S)I_0}{k_q}, \qquad (12a)$$

where $k_q = k_2 + k_3 + k_6$.

Similarly at the steady state¶ concentration (R), i.e. with $d(R)/dt = 0$, we have

$$(R)_{st} = \left(\frac{2k_6k_1}{k_qk_8}\right)^{\frac{1}{2}} I_0^{\frac{1}{2}} \sqrt{(S)}. \qquad (12b)$$

The accumulation of methanol is then determined from the equation

$$(P_f) = \int_0^t k_7(M-M)(R)\,dt = t\left(\frac{2k_6k_1}{k_qk_8}\right)^{\frac{1}{2}} k_7(M-M)I_0^{\frac{1}{2}}\sqrt{(S)}, \qquad (13)$$

i.e. the amount of methanol is proportional to the duration of exposure t, in agreement with Fig. 10.

The quantum yield of methanol is

$$\varphi_{CH_3OH} = \frac{(P_f)}{\Delta N}, \qquad (14)$$

where ΔN is the number of photons absorbed during time t. Assuming that radiation is only slightly absorbed in a layer ΔX, we have

$$\Delta N = I_0 t \cdot \kappa_1(S)\Delta X. \qquad (15)$$

Consequently

$$\varphi_{CH_3OH} = \left(\frac{2k_6k_1}{k_qk_8}\right)^{\frac{1}{2}} \cdot \frac{k_7\sqrt{(S)}}{I_0^{\frac{1}{2}}\,D}(M-M), \qquad (16)$$

where $D = k_1(S)\Delta X$ is the optical density of this layer.

It follows from the expressions obtained that, for a theoretical calculation of the rate of accumulation of the product and of the quantum yield with respect to this product, it is necessary to know a number of constants, which are not as a rule available. The data on the quenching constant k_q are particularly scarce and therefore it is difficult to assess the validity of the hypotheses concerning the mechanism of photolysis in this and other cases. However, the relations obtained make it possible to assess the nature of the process as a function of the given conditions. In particular, when account is taken of the quenching processes (2)–(6), the correct value of φ can be obtained with the aid of the constant k_q on substituting reasonable values of the constants. Unless k_q is taken into account, the discrepancy can amount to ten powers of ten.

It follows from Eqns. (13) and (16) that very important data on the mechanism of light-induced ageing can be secured by studying the kinetics of light-induced ageing at various intensities I_0 of the incident light.

In the case considered, the rate of accumulation of the photolysis products is directly proportional and the quantum yield inversely proportional to the square root of the intensity of the incident light. Experimental confirmation of this relation implies that the destruction of radicals takes place when two radicals meet (quadratic termination). However, such a mechanism of destruction in light-induced ageing of polymers is not the only one possible.

In the light-induced ageing of polystyrene, investigated in detail by Grassie[73,75] and other workers[26,74,89,90], a linear relation between the rate of formation of volatile and other products and the intensity I_0 of the incident light is observed both in photolysis and in photochemical oxidation. Precisely this fact is reflected in stage (8) of the general mechanism. Usually the destruction of radicals without collision with another radical (linear termination) in the condensed phase is disregarded. However, if account is taken of the fact that photochemical processes take place in a very thin surface layer, then, in view of the high mobility of hydrogen atoms and light $\dot{C}H_3$ radicals and the considerable inertia of macroradicals, it is quite possible that the light radical diffuses to the gas phase and therefore escapes from the reaction. The data quoted by Pudov and Taitarenko[91] indicate the occurrence of processes of this type.

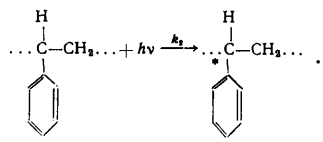
Grassie and Weir[75] investigated the photochemical oxidation of polystyrene films under the action of ultraviolet light (at 254 nm) at oxygen pressures up to 600 mmHg and temperatures of 28–57°C. Only water and carbon dioxide are formed in appreciable amounts from the gaseous products. At an oxygen pressure below 20 mmHg the rate measured from the absorption of oxygen is independent of the intensity I_0 of the incident light and at higher pressures it is proportional to I_0.

In accordance with the general mechanism of light-induced ageing the absorption of oxygen takes place in stage (9):

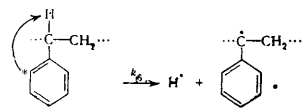
$$\frac{d(O_2)}{dt} = -k_9(O_2)(R), \qquad (17)$$

$$\frac{d(R)}{dt} = k_6(S)^* - k_8'(R), \qquad (18)$$

where (S^*) represents, as for PMMA, the steady-state concentration of excited states, with the difference that in polystyrene the absorbing centres are benzene rings:



As pointed out above, the electronic excitation energy during its dissipation is transmitted to the C–H bond of a tertiary carbon atom, which leads to the elimination of a hydrogen atom:



It is interesting that in the photochemical oxidation of polystyrene hydrogen is absent from the gaseous products, which is probably due to the rapid reaction $\dot{H} + O_2 \rightarrow H\dot{O}_2$.

As in PMMA, the steady-state concentration $(S^*)_{st}$ is determined from Eqn. (12):

$$(S^*)_{st} = \frac{k_1(S)I_0}{k_q}.$$

The steady-state concentration of the radicals $[d(R)/dt = 0]$ is determined from Eqn. (18):

$$(R)_{st} = \frac{k_6k_1(S)}{k_8'k_q} \cdot I_0.$$

Then, in accordance with Eqn. (17), the consumption of oxygen is determined by the equation

$$-\Delta(O_2) = \int_0^t k_9(O_2)(R)\,dt = \frac{k_9k_6k_1(S)}{k_8'k_q} \cdot (O_2)\;I_0t,$$

---

§The exact solution is $(S^*) = k_1(S)I_0(1-e^{-k_2t})/k_q$, i.e. $k \simeq 10^8\ s^{-1}$. To a high degree of accuracy after only one 1 s, $(S^*) = k_1(S)I_0/k_q$, i.e. (S^*) depends only on (S).

¶The exact solution is $(R) = (R)_{st}\tanh bt$.

i.e. in agreement with the experimental data at high pressures, the amount of oxygen absorbed is proportional to the concentration of O_2 and the light intensity I_0. In reality the situation is more complex and radical diffusion and gas diffusion processes play a considerable role. In particular, the solubility of oxygen in the polymer is low and proportional to its pressure[92]. Therefore at oxygen pressures below 20 mmHg the rate of absorption of O_2 is fully determined by the rate of diffusion and is independent of the light intensity. It is noteworthy that, depending on the conditions and the properties of the polymer, both linear and quadratic termination can occur in the system simultaneously and the variation of the rate of the process with intensity may be, generally speaking, of any kind.

Kinetic analysis of light-induced ageing is more complex for polymers where initiation takes place via absorbing groups of impurities, for example carbonyl groups. As already mentioned, polyethylene, polypropylene, and poly(vinyl chloride) belong to polymers of this type. In a number of studies[93-98] dealing with the light-induced ageing of polyethylene and polypropylene it has been shown that ultraviolet irradiation of such polymers is accompanied by the absorption of oxygen and the accumulation of oxygen-containing groups: carbonyl groups, hydroxy-groups, and others. The rate of absorption of O_2 by polyethylene is proportional to the square root of the intensity, i.e. quadratic chain termination takes place.

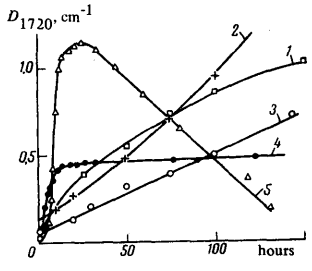


Figure 11. Kinetics of the accumulation of CO groups in the light-induced ageing of various polymers: 1) low-pressure polyethylene; 2) high-pressure polyethylene; 3) high-pressure polyethylene with a stabiliser (phenyl-α-naphthylamine + diphenylphenylenediamine + carbon black); 4) poly(vinyl chloride); 5) polyvinylbutyraldehyde.

The accumulation of CO groups is a complex function of time (Fig. 11, curves *1* and *2* for polyethylene) and depends on the properties of the polymer. In high-pressure polyethylene the number of CO groups rapidly increases with acceleration, while in low-pressure polyethylene the rate of accumulation of CO groups falls and after a certain time their accumulation is strongly retarded[96].

The difference between the nature of the ageing of high- and low-pressure polyethylene may be accounted for by their different degrees of crystallinity. It has been shown[18] that the rate of photochemical oxidation, determined from the absorption of O_2, is higher for crystalline polyethylene than for the pressed material, which is to a large extent amorphous. There is no doubt that this finding is related to the change in the rate of diffusion and solubility of oxygen on increasing the crystallinity of the polymer[92].

The amount of oxygen absorbed varies with time as a function of the crystallinity as well as the number of carbonyl groups.

The experimental data presented here are satisfactorily consistent with the general mechanism of light-induced ageing proposed above. Since the number of carbonyl groups is proportional to the amount of oxygen absorbed, it follows that $d(O_2)/dt = (P_0)/dt$, where (P_0) denotes in this case the concentration of initiating carbonyl groups. Since the carbonyl groups formed here behave at the same time as absorption centres, it follows that $(S) = (S_0) + (P_0)$, where (S_0) is the concentration of S at the initial instant of illumination at $t = 0$. Consequently $d(P_0)/dt = d(S)/dt$, i.e. the accumulation of P_0 is determined by the accumulation of S. In accordance with the general mechanism,

$$\frac{d(S)}{dt} = -k_1 I_0 (S) + k_2 (S^*_{st}) + k_9 (O_2)(R). \qquad (19)$$

As for PMMA, the steady-state concentrations $(S^*)_{st}$ and $(R)_{st}$ are determined by Eqns. (12a) and (12b) respectively. After substitution of $(S^*)_{st}$ and $(R)_{st}$ in Eqn. (19), we obtain

$$\frac{d(S)}{dt} = -k_1 I_0 \left(1 - \frac{k_2}{k_q}\right)(S) + k_9 \left(\frac{2k_6 \cdot k_1}{k_q\, k_8}\right)^{1/2} I_0^{1/2} (S)^{1/2}.$$

The differential equation obtained is a Bernoulli equation and can be solved analytically:

$$(S) = e^{-2p' I_0 t}\left[(S_\infty)^{1/2} e^{p' I_0 t} + (S_0)^{1/2} - (S_\infty)^{1/2}\right]^2, \qquad (20)$$

where $p' = (k_1/2)\,(1 - k_2/k_q)$ and (S_∞) is the limiting concentration of carbonyl groups at irradiation time $t \to \infty$:

$$S_\infty = \frac{2k_9^2\, k_6\, k_q}{k_1 (k_q - k_2)} \cdot \frac{(O_2)^2}{I_0}. \qquad (21)$$

According to solution (20), the concentration of CO groups increases steadily with time if $(S_0) < (S_\infty)$ and reaches a constant value (S_∞), which is in fact observed experimentally[96]. The time required for the attainment of the limiting concentration falls very rapidly (exponentially) with increasing intensity and strongly depends on the absorption (k_1) and quenching (k_2 and k_q) constants. The limiting concentration (S_∞) increases in direct proportion to the square of the concentration of oxygen and in inverse proportion to the intensity I_0.

The variation of (S_∞) with I_0 is particularly interesting It follows from Eqn. (20) that, when $(S_0) > (S_\infty)$, the concentration of CO groups must decrease with time during the initial period of the reaction until the limiting value (S_∞) is attained. Consequently if I_0 is small and (S_∞) large, carbonyl and other oxygen-containing groups will accumulate in light-induced ageing. Conversely, if I_0 is large, then S_∞ is small, and in the initial period the concentration of oxygen-containing groups should fall. This behaviour was confirmed experimentally in a number of studies[98,99] for the carbonyl groups of oxidised polyethylene (by infrared spectroscopy) and the hydroperoxy-groups of oxidised polypropylene (iodometrically). It is also interesting to note that, according to Eqn. (20), the rate of decomposition of oxygen-containing groups decreases with increasing oxygen pressure.

The conclusions based on the kinetic analysis of light-induced ageing of polyolefins are in general valid also for poly(vinyl chloride). It must be pointed out that a fairly large number of studies[100-106] dealing with this polymer are frequently contradictory, particularly as regards the composition of gaseous photochemical degradation products.

The paper by Reinisch[36], in which a general account is given of preceding studies and the experimental part was

carried out very carefully, must be regarded as the most reliable. Not even traces of water, carbon monoxide, and carbon dioxide, the formation of which was indicated, for example by Wilson[100] and others, were observed in the photolysis of poly(vinyl chloride). These products, together with hydrogen chloride, are characteristic of the photochemical oxidation of poly(vinyl chloride). The initiating centres are impurity CO groups both in the photochemical oxidation and in the photolysis of oxidised poly(vinyl chloride) (this in fact accounts for the evolution of the products enumerated above). In extensive oxidation and in the photolysis of non-oxidised poly(vinyl chloride) the absorbing centres are polyene structures.

6. THE MECHANISM OF THE SENSITISATION AND STABILISATION OF POLYMERS AGAINST LIGHT

Most of the studies on the light-induced ageing of polymers involve the search for effective additives, called light stabilisers, which inhibit the light-induced ageing and protect the polymer from the destructive effect of sunlight. However, so far there is no single point of view on the mechanism of light stabilisation, which hinders to a great extent the search for substances with protective activity and also the selection of light stabilisers for new polymers.

The most widely held is the view that the mechanism of light stabilisation reduces to the screening effect of the additive[4,85,107-109], i.e. it is suggested that the light stabiliser acts as a filter weakening the flux of ultraviolet radiation incident on the polymer. Attempts are then made[110] to establish a correlation between the absorption spectrum and the efficiency of the light stabiliser. If the absorption spectrum of the light stabiliser is known, it is not difficult to determine, in accordance with the Beer–Lambert law, the energy absorbed by a planar polymer specimen without an additive:

$$\Delta\epsilon_0 = Ft\sum_{\lambda_1}^{\lambda_2} I_{0\lambda}(1-e^{-\epsilon_{p\lambda}c_p d}), \qquad (21a)$$

and the energy absorbed by the same specimen with added light stabiliser (on the assumption that the absorbing centres are independent):

$$\Delta\epsilon_s = Ft\sum_{\lambda_1}^{\lambda_2} I_{0\lambda}(1-e^{-(\epsilon_{p\lambda}c_p+\epsilon_{s\lambda}C_s)d})\frac{\epsilon_{p\lambda}C_p}{\epsilon_{p\lambda}C_p+\epsilon_{s\lambda}C_s}. \qquad (21b)$$

Then the protective effect of the light stabiliser may be determined from the relation[111]

$$PE = \frac{\Delta\epsilon_0}{\Delta\epsilon_s} = \frac{\sum_{\lambda_1}^{\lambda_2} I_{0\lambda}(1-e^{-\epsilon_{p\lambda}C_p d})}{\sum_{\lambda_1}^{\lambda_2} I_{0\lambda}(1-e^{-(\epsilon_{p\lambda}C_p+\epsilon_{c\lambda}C_s)d})\frac{\epsilon_{p\lambda}C_p}{\epsilon_{p\lambda}C_p+\epsilon_{s\lambda}C_s}}. \qquad (21c)$$

Here $I_{0\lambda}$ is the intensity of incident light at a given wavelength λ, $\epsilon_{p\lambda}$ the molar extinction coefficient of the initiating groups of the polymer† (cm^2), C_p the concentration of these groups (cm^3), $\epsilon_{s\lambda}$ and C_s the corresponding values for the light stabiliser, F the surface area of the specimen, d its thickness, and t the duration of irradiation. Each term of the sums in the numerator and denominator represents the energy absorbed by the polymer at a given wavelength and the sums themselves define the energy absorbed in the wavelength range from λ_1 to λ_2. The functions $\epsilon_{p\lambda}C_p d = D_p$ and $\epsilon_{s\lambda}C_s d = D_s$ represent the optical densities of the polymer and the light stabiliser and may be determined experimentally by spectrophotometric measurements. The summation can be performed graphically.

It follows from Eqn. (21c) that, since $\Delta\epsilon_s$ is always less than $\Delta\epsilon_0$, PE is always greater than unity, i.e. almost any substance absorbing ultraviolet light at a given wavelength λ should exhibit a stabilising effect in irradiation with light having this wavelength.

Experimental tests[105,110] showed that this is not so. In general there is no correlation between the ultraviolet spectra of light stabilisers and their stabilising effect. For example, Schlimper[105] points out that, despite the broad and intense absorption band in the region of 300–400 nm, azo-compounds exhibit poor stabilising properties in relation to poly(vinyl chloride) and polyamides.

Direct comparison of the calculated value of the protective effect PE with experimental data on the light-induced ageing of different polymers shows[95,111] that the effect of additives cannot be explained merely by screening. Furthermore, benzophenone, which absorbs in the ultraviolet region, not only does not stabilise polyethylene film but actually accelerates its light-induced ageing[112], i.e. behaves as a sensitiser.

The attempt to eliminate completely the observed inconsistency between the absorbance of the light stabiliser and its protective effect on the hypothesis of photochemical reactions of the additive and its chemical interaction with the polymer[107-109,112] was also unsuccessful[95].

Recently a mechanism has been developed[37], according to which the protective effect or, conversely, the sensitising effect of the additive depends not only on the absorbance or photochemical reactions but also on the capacity of the given additive to participate in non-radiative transfer of electron energy as an acceptor or a donor. The derivation of Eqn. (21c) itself contains the assumption of the independence of the absorption by different centres, i.e. the possibility of the interaction of these centres is thereby assumed in principle.

The postulate of non-radiative energy transfer between molecules and photochemical processes is itself not new and has been elucidated in detail both theoretically and experimentally. In particular the work of the school of Vavilov and Terenin in this field should be mentioned[113-115].

The hypothesis of the occurrence of such processes in the light-induced ageing of polymers has been put forward by various workers, in particular by Schmitt and Hirt[111], but these questions have not been adequately elucidated in respect of light stabilisers. Probably this is due not only to the experimental difficulties but also to the deep-rooted concept of the screening mechanism for the effect of light stabilisers.

It has been suggested[37] that the protective effect of the light stabiliser, caused by the non-radiative energy transfer from the excited centre of the polymer molecule to the light stabiliser molecule, can be estimated from the efficiency of the quenching of the luminescence of the polymer by the given light stabiliser (in this case the additive behaves as an energy acceptor, denoted in the general kinetic mechanism by A). Indeed, since the luminescence intensity is proportional to the number of excited polymer molecules, the decrease of the intensity can characterise in principle the decrease in the number of molecules tending to decompose (stage 6), and therefore also the efficiency of the light stabiliser. Quenching may of course not be due solely to energy transfer and therefore the proposed characterisation of the protective effect may

†It is assumed that the absorption by other groups is low.

prove to be incomplete, like the characterisation based solely on the screening effect. The above hypotheses have been tested for common light stabilisers added to polypropylene[37].

Curve 3 in Fig. 8 represents the luminescence spectrum of polypropylene without additive excited by light at 280.4 nm. On addition of 0.01 mole kg^{-1} of 2-hydroxy-5-methylphenylbenzotriazole (Tinuvine P), an effective light stabiliser for polypropylene, the luminescence intensity L falls sharply (curve 1). It has been shown experimentally that L is proportional to the amount of light absorbed by the polymer.

It would appear that the decrease of luminescence intensity may be explained by the fact that, in consequence of the absorption of the initiating radiation by the light stabiliser, the energy absorbed by the polymer decreases by an amount

$$\Delta\epsilon = \Delta\epsilon_0 - \Delta\epsilon_s \qquad \text{[see Eqns.(21a) and (21b).]}$$

The additional decrease of L takes place as a result of reabsorption—the absorption of the light due to the luminescence by the light stabiliser. Consequently, when appropriate corrections are made for screening and reabsorption, curve *1* should coincide with curev *3*. However, these corrections yield only curve *2*, which lies much below curve 3. Hence it follows that in the presence of the light stabiliser some kind of quenching mechanism operates. In particular, such a mechanism may be energy transfer from polymeric molecules to light stabiliser molecules.

Thus in the study of light-induced ageing it is necessary to take into account both the screening effect of the light stabiliser and its protective acceptor effect. In the general mechanism of light-induced ageing the possibility of of the inhibiting effect of acceptor additives was taken into account in stage 4. Allowance for this effect is reflected in the appearance of yet another term, $k_4(A)$, in the denominator of the expression for the steady-state concentration of excited centres $(S^*)_{st}$ and the steady-state concentration of the radicals $(R)_{st}$, since the quenching constant is now defined by the equation $k_q' = k_2 + k_3 + k_6 + k_4(A)$. Since this quantity enters with a plus sign into the denominator, in the presence of a light stabiliser (acceptor A), $(S^*)_{st}$ and $(R)_{st}$ are smaller than in the polymer without additives. Correspondingly the rate of accumulation of oxygen-containing products will be lower, in agreement with experiment (Fig. 8, cf. curves *2* and *3*).

The screening effect of additives in the polymer was not taken into account the general mechanism, because in the preceding sections we did not deal with the problem of the effect of additives and in fact we assumed that the process takes place in a thin layer under the action of monochromatic light. Assuming that the incident light is *monochromatic* to simplify the treatment, we shall now introduce a correction for screening. In the presence of a light stabiliser of the acceptor type at a concentration (A) in a flat specimen of thickness d and with a surface area F, the number of excited states initiated during a time dt is, according to Eqn. (21b),

$$dS^* = I_0 F\, dt\,(1 - e^{-[\epsilon_S(S)+\epsilon_A(A)]d})\,\frac{\epsilon_S(S)}{\epsilon_S(S)+\epsilon_A(A)},$$

and the rate of initiation of excited states, expressed in $cm^3\ s^{-1}$, is defined by the following equation in the presence of A:

$$\Delta I_s = \frac{dS^*}{dF\,dt} = \frac{d(S^*)}{dt} = k_1' I_0(S), \qquad (22)$$

where

$$k_1' = \frac{\epsilon_S}{d[\epsilon_S(S)+\epsilon_A(A)]}\cdot(1 - e^{-[\epsilon_S(S)+\epsilon_A(A)]d}).$$

Here (S) and (A) are the concentrations of the absorbing centres of the polymer and acceptor respectively and ϵ_S and ϵ_A are their molar extinction coefficients, i.e. in the modification of Eqn. (21b) it was assumed that

$$C_p = (S),\ C_s = (A),\ \epsilon_{p\lambda} = \epsilon_S,\ \epsilon_{s\lambda} = \epsilon_A.$$

When $d \ll 1$, we obtain the following expression from Eqn. (22) on expanding the exponential term in series:

$$\Delta I_s = \epsilon_S\ I_0(S). \qquad (22a)$$

As was to be expected, for an infinitely thin specimen, we obtain the expression used earlier for the rate of initiation. To show that, it is sufficient to put $\epsilon_S = k_1$. The significance of the constant k_1 now becomes clear.

The general form of the kinetic equations does not change after the introduction of corrections for quenching and screening, but the constants have different values. For example, the accumulation of oxygen-containing products in initiation via impurity CO groups in the presence of a light stabiliser is defined by a relation analogous to Eqn. (20):

$$S = e^{-2p''I_0 t}\,(S_\infty^{1/2} e^{p''I_0 t} + S_0^{1/2} - S_\infty^{1/2})^2,$$

where the constants are

$$p'' = \frac{k_1'}{2}\left(1 - \frac{k_2'}{k_q'}\right) = \frac{1}{2}\frac{\epsilon_S}{[\epsilon_S(S)+\epsilon_A(A)]}(1 - e^{-[\epsilon_S(S)+\epsilon_A(A)]d})\left(1 - \frac{k_2 + K_4(A)}{k_q + k_4(A)}\right);$$

$$S_\infty' = \frac{2k_9^2\ k_6\ k_q'}{k_1'(k_q - k_2)}.$$

It is evident from the above expressions that, on introduction of additives into the polymer, the accumulation of products depends in a very complex manner on the concentration of the light stabiliser and the initiating centres and on the thickness of the specimen. Analysis of these relations may be greatly simplified for short time intervals.

This assumption is quite acceptable for the analysis of slow light-induced ageing processes. The relations obtained lead to the interesting finding that in very thin specimens the light stabiliser has no influence whatever if it exhibits only a screening effect. This conclusion is quite clear also on the basis of physical considerations; in a very thin layer the molecules of the light stabiliser cannot "eclipse" the absorbing centres of the polymer.

Furthermore, the additive may have a sensitising effect, i.e. may accelerate photochemical processes by the transfer of the energy absorbed by the additive to the polymer and can at the same time retard the light-induced ageing of thick specimens. A phenomenon of this kind was observed by Grassie[75] for the stabilisation of polystyrene by the widely known light stabiliser 2-hydroxy-4-methoxybenzophenone. In thin layers this light stabiliser accelerates the oxidation. In thick specimens the surface layer breaks down more rapidly on addition of the light stabiliser, but the main bulk of the polymer is protected from the action of light by the screening effect of the additive.

Thus, as a result of the interaction of two effects (screening and energy transfer) the same substance can exhibit stabilising and sensitising activity depending on the conditions. This has been clearly shown by Fox and Price[116]. It has been found that the characteristic features of the photolysis ($\lambda = 254$ nm) of PMMA and poly-α-methylstyrene dissolved in methylene chloride with

various additives can be accounted for by postulating the possibility of energy transfer between the additive and the polymer. The energy transfer can take place via both triplet and singlet levels. It has been observed that most additives, in particular the familiar light stabiliser 2,4-dihydroxybenzophenone, sensitise the photolysis of PMMA. The sensitisation, as for polystyrene films[75], is usually masked by the filtering effect of the additive. On the other hand, benzophenone has a stabilising effect because of the energy transfer from the PMMA molecule to the triplet level of benzophenone.

Two principles, on the basis of which light stabilisers can be selected for polymers, follow from the above findings. In the first place the light stabiliser must have an electron level which corresponds to a maximum in the absorption spectrum in the same region as the maximum in the luminescence spectrum of the polymer. This will ensure the greatest overlapping of the maxima and hence will give rise to the greatest possibility of energy transfer[113]. In the second place the light stabiliser must have an electron level which corresponds to a maximum in the absorption spectrum in the same region as the maximum in the absorption spectrum of the polymer.

In conclusion we may note that the laws governing the effect of light stabilisers are in the main valid also for the effect of dyes[5,6] on light-induced ageing of polymers.

7. METHODS FOR THE ACCELERATION OF LIGHT-INDUCED AGEING

In connection with the low rate of the light-induced ageing process under natural conditions (duration of tests up to 7.5 years[117]), methods of accelerated ageing have found wide application. For this purpose, a number of industrial and laboratory devices have been constructed.

In the development of apparatus for the artifical light-induced ageing the principal problem is of course the possibility of creating conditions resembling natural conditions to the maximum extent. In view of what has been said above, the difficulty of constructing such apparatus is quite evident. It consists in the fact that the requirements for rapid tests and for the maximum similarity to natural conditions are mutually exclusive. The point is that the creation of a source with a spectrum analogous to that of the sun does not by itself ensure that the data on light-induced ageing obtained with the aid of such a source can be applied under natural conditions, since the variation of the rates of various photochemical processes with intensity and hence the variation of the rate of the overall light-induced ageing process is frequently complex (see above).

For example, it has been shown by X-ray diffraction[18,119] that on ultraviolet irradiation the crystallinity of cellulose (cotton fibre) decreases steadily. It is then found that the decrease under the action of sunlight is smaller by a factor of only 3–5 than the decrease obtained by irradiation with the unfiltered light of a mercury lamp (200–800 nm), although the intensity in the latter case is higher by a factor of about 50 and a considerable part of the energy in the spectrum corresponds to the short-wavelength region.

If it is remembered that the emission intensity of artifical sources is frequently higher by a factor of hundreds and even thousands than that of solar radiation, it is quite evident that, for extrapolation to natural conditions, it is essential to have data on artificial light-induced ageing at different intensities and hence in the design of apparatus for accelerated ageing, provision must be made for the regulation of light intensity over a fairly wide range.

Another no less important requirement which must be taken into account in the design of apparatus for artificial light-induced ageing is the creation of a source with a spectral energy distribution resembling sunlight with sufficient precision particularly in the short-wavelength region. Only then can one transfer with adequate justification the results of artificial light-induced ageing to natural conditions. The presence of bands in the absorption spectra of polymers[73,77] by itself shows that the sensitivity of the polymer to radiation of different wavelengths (activation spectrum) will vary.

A particularly striking illustration of the dependence of the rate of light-induced ageing on the wavelength of ultraviolet radiation is provided by the data[36] in Fig. 4. The rate of change of the optical density (D) of poly(vinyl chloride), which is proportional to the amount of hydrogen chloride evolved, increases with increasing wavelength, passes through a maximum at 260 nm, and then falls to zero at 332 nm. The maximum is then found to coincide with the absorption maximum of polyene structures, which behave as activation centres for the light-induced ageing of poly(vinyl chloride).

It would appear that the problem of obtaining the required spectral distribution in the light source might be solved by studying the light-induced ageing under the action of monochromatic radiation at different wavelengths. The resulting rates of light-induced ageing might be adjusted to the solar spectrum by summing the rates of ageing at different wavelengths taking into account the intensity. However, in the general case such summation is not valid because of a kind of "synergism" of different wavelengths. For example, in the photolysis of poly(vinyl chloride) the number of photons required to obtain the same amount of hydrogen chloride with monochromatic irradiation is approximately 100 times greater than with polychromatic irradiation[35].

Apart from the conditions which must be satisfied by the emission, apparatus for artificial light-induced ageing must also make provision for the control of temperature and moisture content, which must correspond to the natural conditions. The available apparatus for artificial light-induced ageing as a rule only partially satisfies the conditions formulated above[77,98,118–122].

The Electron Paramagnetic Resonance Method in the Study of Electron Phototransfer Reactions and Sensitised Photoreactions

V.E.Kholmogorov

This review examines critically almost all available results of studies of electron phototransfer reactions and sensitised photochemical reactions. The unique possibilities provided by the electron paramagnetic resonance method in the study of photochemical processes are demonstrated. New work on two-quantum photochemical reactions is examined in particular detail. The important part played by electron phototransfer reactions in photochemistry is also emphasised. The bibliography contains 161 references

III. The study of photosensitised reactions of organic compounds by the electron paramagnetic resonance method 171

I. INTRODUCTION

The possibilities provided by the fruitful utilisation of the electron paramagnetic resonance method (EPR method) for the study of elementary photoprocesses in photochemically active systems, namely the detection and study of intermediate products of the free radical and radical-ion type, were demonstrated fairly convincingly in several hundred papers published in the period 1954–1966 in the Soviet Union and other countries. In a review[1] devoted to the application of the EPR method to the study of photodecomposition reactions (photodissociation and photoionisation), we examined the chief results and conclusions reached by various workers in the study of the mechanisms and types of phototransformations undergone by various compounds with the formation of free radicals as intermediate products. In most instances the EPR method was used as a supplementary method to confirm various conclusions regarding a photoprocess which had previously been detected or discovered by other methods.

The most interesting results have been obtained by using the EPR method to study electron phototransfer reactions (photo-oxidation, photoreduction, and photodissociative electron attachment) and the photosenitisation of chemical transformations of a substance under the influence of near ultraviolet and visible light. Terenin devoted considerable attention to this aspect, in connection with the investigation of methods for the utilisation of light energy in the model systems of a photosynthesising apparatus, particularly in connection with the study of the primary photophysical and photochemical transformations undergone by pigments, dyes, and related compounds[2]. The EPR method can undoubtedly give important information even for such complex photosensitive systems as photosynthesising organisms. The possibilities provided by the EPR method are illustrated in the present review for the example of many original studies of electron phototransfer reactions and photosensitised chemical transformations of substances.

II. THE EPR METHOD IN THE STUDY OF ELECTRON PHOTOTRANSFER REACTIONS

1. Photo-oxidation

The result of the reaction of a photoexcited substance with electron donors or acceptors may be elementary photoreduction or photo-oxidation, that is the acceptance of an electron by one component and its simultaneous loss by another component of the photosensitive system, that is electron phototransfer. In some instances the elementary photo-oxidation process, carried out in solid matrices at low temperature under the influence of ultraviolet light, is accompanied by the formation of free radicals. An example of a photoreaction of this kind is provided by the photo-oxidation of ions of the iron group or halide ions in acid medium in the presence of water[3–6]:

$$[Fe^{2+} + H_2O\,(H_3O^+)]_{H_2SO_4} \xrightarrow{h\nu} [Fe^{3+} + OH^-\,(H_2O) + H^\cdot]_{H_2SO_4}$$

$$[I^- + H_2O\,(H_3O^+)]_{H_2SO_4} \xrightarrow{h\nu} [I^\cdot + OH^-\,(H_2O) + H^\cdot]_{H_2SO_4}$$

The EPR method provides a direct and convenient means of detecting the hydrogen atoms formed in this reaction, since they have a characteristic spectrum consisting of two narrow lines at a distance of 508 Oe from one another. Under ordinary conditions, however, as a result of the high mobility and high reactivity of the hydrogen atoms, they cannot be obtained in sufficient quantities for detection. Published data show that in solid matrices, including ice, hydrogen atoms diffuse readily even at 77°K, and to detect them it is necessary to carry out the studies at 4.2°K and 20°K.[7] In frozen aqueous and concentrated sulphuric, phosphoric, and perchloric acids, however, the hydrogen atoms do not recombine at 77°K.[8] This property of acid solutions was used by Bubnov and coworkers[9,10] to detect the hydrogen atoms produced during electron phototransfer

from metal ions with variable valency (V^{2+}, Cr^{2+}, Fe^{2+}, Mn^{2+}, Co^{2+}, etc.) and various anions (I^-, N_3^-, SH^-, SO_3^{2-}, etc.) in aqueous medium.

For example, when solutions of $FeSO_4$ in sulphuric and phosphoric acids, frozen at 77°K, were illuminated, an EPR signal consisting of a doublet with splitting 507 Oe was detected. This indicated unambiguously that hydrogen atoms are formed in the electron phototransfer reaction. To confirm this conclusion, experiments were carried out with solutions containing heavy water. The triplet signal of atomic deuterium was then detected in the EPR spectrum.

In another experiment, these workers showed that not only ions, but also the neutral molecules of aromatic compounds, can take part in photoreactions of this type. When solutions of benzene in aqueous sulphuric and phosphoric acids, frozen at 77°K, were illuminated, they observed the EPR lines of hydrogen atoms and the EPR spectra of various radicals formed from benzene derivatives ($\dot{C}_6H_6^+$, $\dot{C}_6H_7$, $\dot{C}_6H_5$), produced according to the scheme:

$$[C_6H_6 + H_2O]_{H_2SO_4} \xrightarrow{h\nu} [\dot{C}_6H_6^+ + OH^- + H^\cdot]_{H_2SO_4}$$

$$\dot{C}_6H_6^+ + OH^- \rightarrow \dot{C}_6H_5 + H_2O; \quad \dot{H} + C_6H_6 \rightarrow \dot{C}_6H_7$$

The positive benzene radical-ion $\dot{C}_6H_6^+$ was identified by Carter and Vincow[11] in solutions of benzene in H_2SO_4 at 77°K, irradiated with ultraviolet light. The EPR signal with $g \simeq 2.0$ also consisted of the superposition of the EPR spectra of several radicals. The seven-component spectrum of the $\dot{C}_6H_6^+$ radical-ion was resolved when the irradiated solution was heated. It was found that the $\dot{C}_6H_6^+$ radical-ion is relatively stable in the range 85–170°K, whereas the other radicals disappear in this temperature range. The authors cited confirmed the identification of the EPR spectrum using deuterated benzene (C_6H_5D and C_6D_6). They also obtained the EPR spectra of hexamethylbenzene and hexaethylbenzene, photoionised under the same conditions, and measured the hyperfine interaction constants and g-factor for these radical-ions.

We also detected hydrogen atoms by the EPR method in an electron phototransfer reaction when diphenylamine in aqueous sulphuric acid was illuminated with ultraviolet light[12]. The hydrogen atoms were produced according to the scheme:

$$[Ph_2\dot{N}H + H_2O]_{H_2SO_4} \xrightarrow{h\nu} [Ph_2\overset{+}{N}H + OH^- + H^\cdot]_{H_2SO_4}$$

The formation of the positive diphenylamine molecular ion in this photoreaction was confirmed by the production of a coloured product with absorption maximum at 680 nm[13].

The formation of alkyl radicals during electron phototransfer was observed by Bubnov and coworkers[14] when solutions of oxalic, acetic, and chloroacetic acids in various alcohols (methanol, ethanol, propanol, and butanol), frozen at 77°K, were illuminated with ultraviolet light. To explain the results obtained, the authors cited made allowance for the fact that in the system studied, partial protonation of the alcohol may take place in the presence of acids. In fact, if a certain amount of ROH_2^+ and X^- ions are formed in a system of the type ROH + HX (where ROH is a molecule of alcohol, and HX a molecule of acid), irradiation of the system with ultraviolet light will lead to electron phototransfer from the X^- anion to the ROH_2^+ cation, with the formation of an alkyl radical $\dot{R}$ according to the scheme:

$$ROHH^+ + X^- \xrightarrow{h\nu} \dot{R} + H_2O + X$$

In all instances the concentration of alkyl radicals $\dot{C}H_3$, $\dot{C}_2H_5$, $\dot{C}_3H_7$, and $\dot{C}_4H_9$ amounted to 0.01–0.03 times the concentration of acid.

Intracomplex electron phototransfer, leading finally to the production of free radicals, was studied by the EPR method by Shagisultanova and coworkers[15]. They give the results obtained by measuring the EPR spectra of solutions of complexes of the type $K_3[M(C_2O_4)_3]$, where M = Co, Fe, Cr, and Mn, and also $[Co(NH_3)_6]_2(C_2O_4)_3$, in dilute sulphuric acid (0.5–20%) or in aqueous alcohol at 77°K, irradiated with ultraviolet light (PRK-7). The concentration of the salts was varied in the range 2.5×10^{-3}–10^{-1} M. The doublet EPR signal of hydrogen atoms was detected in the irradiated solutions. It was found that the nature of the coordinated ligand and complex-forming metal has a marked influence on the production of hydrogen atoms: the intensity of the hydrogen doublet is maximal for the axalato-complex of Fe^{3+}, and minimal for the oxalato-complex of Cr^{3+}. In addition to the hydrogen doublet, the central section of the EPR spectrum at $g = 2.0036$ showed a slightly asymmetric line, with weak lines on both sides of it, belonging to the formyl radical $H\dot{C}O$. The authors cited consider that the primary step in the action of quanta of ultraviolet light on these coordination compounds is electron phototransfer between the ligand and metal, leading to the production of doubly-charged metal ions M^{2+} (Fe^{2+}, Co^{2+}, etc.). The formation of hydrogen atoms takes place by the reduction of the water molecules present in the hydration sheath of the complex, as a result of the charge in charge $M^{2+} \rightarrow M^{3+}$. It is possible, however, that under the influence of ultraviolet light the coordination complex undergoes photodissociation with the liberation of oxalate ions, which then reduce the water: $C_2O_4^{2-} + HOH \rightarrow C_2O_4^{-} + \dot{H} + OH^-$, as takes place in $K_2C_2O_4$ and $[Co(NH_3)_6]_2(C_2O_4)_3$.

Tollin and Green[16] used the EPR method to study a reaction which is very important for the solution of the problem of photosynthesis, namely electron phototransfer from chlorophyll A to various quinones (9,10-phenanthrenequinone, p-benzoquinone, coenzyme Q_6, *p*-chloranil, and *o*-chloranil) in solution (EPA mixture 8 : 3 : 5) at 268–100°K in a vacuum. Irradiation of the solution with light absorbed only by chlorophyll ($\lambda \geq 550$ nm) produced an intense EPR signal (10^{15}–10^{17} unpaired electrons per ml) of the corresponding quinone radical-anion, that is the semiquinone ion, in accordance with the photoreaction scheme:

$$Chl + Q \xrightarrow{h\nu} Chl^* + Q \rightarrow \underset{\downarrow\uparrow \quad \downarrow\uparrow}{(Chl^+ \ldots Q^-)^*} \\ Chl + QChl^+ + Q^-$$

or:

$$Chl + Q \rightarrow (Chl \ldots Q) \xrightarrow{h\nu} \underset{\downarrow\uparrow \quad \downarrow\uparrow}{(Chl^+ \ldots Q^-)^*} \\ Chl + Q\,Chl^+ + Q^-$$

Tollin and Green[16] postulated as intermediate product of the photoreaction an excited charge-transfer complex (CTC), capable of dissociating to form the positive chlorophyll radical-ion (Chl^+) and the quinone radical-anion (Q^-). It was found that the degree of dissociation is determined by the electron affinity of the quinone, temperature, and the polarity and viscosity of the solvent. Only the signals of the quinone radical-anion were detected by the EPR method. The positive chlorophyll radical-ions could not be detected. This is not a specific feature of this photochemical system: the EPR spectra of chlorophyll radical-cations in solutions has not yet been obtained, even at low temperatures.

2. Photodissociative Electron Attachment

Allen and Ingram [17] and Azizova [18-21] showed that ultraviolet irradiation of aqueous solutions of aromatic aminoacids at 77°K leads to their photoionisation with the production of the EPR singlet signals of the aminoacid radical-cations and hydrated electrons. In the presence of aliphatic aminoacids (glycine, alanine, valine, lysine, glyclyglycine, and alanylalanine), which do not absorb ultraviolet radiation directly in the range 240–290 nm, the action of ultraviolet light ($\lambda > 240$ nm) produced the multicomponent EPR signals of the corresponding aliphatic aminoacids. Ultraviolet irradiation of aqueous solutions of aliphatic aminoacids in the absence of aromatic aminoacids does not produce EPR signals. To investigate the mechanism of the free radical formation, the EPR method was used to study aqueous solutions of a mixture of aromatic and aliphatic aminoacids, irradiated with ultraviolet light, at 77°K and various pH values. It was found that at pH 12, when the aliphatic aminoacids are present in the form $RCH(NH_2)COO^-$, irradiation with ultraviolet light does not lead to the formation of free radicals. The formation of radicals of the aliphatic aminoacids takes place in acid medium (pH 0.5) when the aminoacids are present in the form $RCH(NH_3^+)COO^-$. This fact, and the decrease in the quantity of hydrated electrons in the specimen with increase in the concentration of aliphatic aminoacids, suggest that the free radicals are produced as a result of electron phototransfer according to the scheme:

$$\text{tryptophan}^+\,(\text{tyrosine}^+) + R{-}\underset{\displaystyle NH_3^+}{\underset{|}{CH}}{-}COO^- \xrightarrow{h\nu} \text{tryptophan}^+\,(\text{tyrosine}^+) + R{-}\dot{C}H{-}COO^- + NH_3$$

Thus the deamination of the aliphatic aminoacids, detected from the SPR spectra, takes place as a result of an electron phototransfer reaction.

The study of the deamination of aliphatic aminoacids by means of coloured compounds which absorb visible light, for example riboflavine or dyestuffs (trypaflavine, Acridine Orange, eosin), is of considerable interest. The irradiation of aqueous solutions of Acridine Orange (10^{-3} M) in the presence of alanine (10^{-1} M) produces the quintet EPR spectrum of the alanine free radical [22,23].

A large variety of aminoacids, peptides, and di- and tripeptides containing free amine groups in different parts of the molecule (gly-ala, ala-gly, ala-gly-gly, gly-met, gly-ser, leu-gly, etc.) have been studied. In the presence of readily ionisable additives, deamination takes place as a result of the transfer of an electron to the NH_3^+ group of the molecule.

The formation of free radicals from alkyl halides by electron phototransfer from a readily ionisable additive to the alkyl halide ($RX + e^- \rightarrow \dot{R} + X^-$) was demonstrated by Claridge and Willard [24] for the tetramethyl-*p*-phenylenediamine + alkyl halide system (methyl, ethyl, propyl, and butyl halides) in 3-methylpentane at 77°K. Alkyl radicals were detected by the EPR method. The alkyl halides, which exhibit diffuse absorption bands in the region of 250 nm, readily undergo photodecomposition in 3-methylpentane at 77°K with rupture of the C–I (Cl, Br) bond under the influence of ultraviolet light of $\lambda \leq 254$ nm. Tetramethyl-*p*-phenylenediamine in organic glasses at 77°K has an absorption maximum at 320 nm [25] with molar absorptivity 3×10^3, and on irradiation in this range it readily undergoes photoionisation, as indicated by the production of the characteristic colour of its radical-cation [26] and the corresponding EPR spectrum [27-30]. In the presence of alkyl halides, the action of light of $\lambda > 300$ nm produces not only the EPR spectrum of the tetramethyl-*p*-phenylenediamine radical-cation but also the distinct EPR spectra of the alkyl radicals $\dot{C}H_3$, $\dot{C}_2H_5$, n-$\dot{C}_3H_7$, i-$\dot{C}_3H_7$, n-$\dot{C}_4H_9$, and i-$\dot{C}_4H_9$; these authors assume that the latter are produced by the dissociative attachment of electrons, removed by photoreactions from tetramethyl-*p*-phenylenediamine, to the molecules of the corresponding alkyl halides, which have a positive electron affinity. The relative yields of the radicals for equal integral exposures ($\lambda > 300$ nm) are as follows: CH_3Cl 100%, CH_3Br 30 %, CH_3I 10%, C_2H_5Cl 40%, C_2H_5Br 25%, C_2H_5I 5%, i-C_3J_7Cl 20%, n-C_3H_7Cl 10%, i-C_4H_9Cl 20%, and n-C_4H_9Cl 10%.

3. Photoreduction

Ketones act as photosensitisers for the oxidation of various alcohols [31,32]. Although the mechanism of the sensitisation of this photoreaction is not completely clear [33,34], it has been established that unstable sensitiser semiquinones and solvent radicals are formed. [35] The overall scheme for the chemical transformations is:

$$AQ + h\nu \rightarrow AQ^*; \quad AQ^* + RH \rightarrow A\dot{Q}H + \dot{R};$$

$$A\dot{Q}H \xrightarrow{pH>8} A\dot{Q}^- + H^+; \quad 2A\dot{Q}H \rightarrow AQH_2 + AQ$$

where **AQ** is the quinone, and **RH** the solvent.

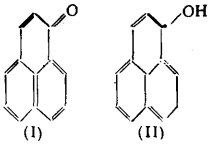
The production of semiquinones and radical-anions in this photoreaction was recorded from their optical absorption spectra by flash spectroscopy [33,36]. Their detection by the EPR method was of considerable interest.

Elschner and coworkers [37] used the EPR method to study the photoreduction of anthraquinone and its derivatives sodium anthraquinone-2,6-disulphonate, sodium anthraquinone-2-sulphonate, and 2,6-dichloroanthraquinone, at room temperature in alcohol. The structure of the EPR spectra of the semiquinones corresponds, as expected, to the interaction of an unpaired electron with two groups of equivalent protons. Solvent radicals were not detected, because of their low stability at room temperature.

The photochemical reduction of benzophenone in alcohols also involves an intermediate state [38]. Irradiation of a solution of benzophenone in propan-2-ol at −150° produced a structureless EPR signal, which disappeared when the temperature of the solutions was raised to −100°. Since the EPR signals in these experiments did not have a resolved hyperfine structure, their exact interpretation was difficult. Moreover, the experiment was carried out at −150°, and alcohol radicals were not detected.

Sharp and coworkers [39] used the EPR method to study the photoreduction of anthraquinone and benzophenone in methanol and propan-2-ol at room temperature and at low temperatures. EPR signals were not obtained when anthraquinone in methanol was irradiated at room temperature. When the temperature of the solution was lowered to −190°, however, a broad singlet without hyperfine structure was produced. The EPR signal disappeared with increase in temperature to −150°.

Under the influence of ultraviolet light, in degassed solvents such as methanol, ethanol, propanol, ethyl acetate, and acetone, which act as hydrogen donors, perinaphthenone (I) (absorption maximum at 359 nm)



(I) (II)

rapidly acquires a green colour ($\lambda = 650$ nm), which slowly

disappears in the dark[40]. It might be expected that this corresponds to the hydroxyperinaphthenyl radical (II), produced as a result of dehydrogenation of a solvent molecule by the photoexcited ketone. In fact, in degassed solutions of perinaphthenone irradiated with ultraviolet light (GEH-100 or Osram HBO-500 high-pressure mercury lamp) at 300°K, an intense EPR signal with hyperfine structure was obtained[41]. The hyperfine structure of the EPR spectrum of the radical formed is due to the interaction of the unpaired electron with the five protons of the equivalent hydrogen atoms in positions 3, 4, 6, 7, and 9, and with the three protons of the other equivalent hydrogen atoms in positions 2, 5, and 8. The same EPR signal was also obtained in solutions of perinaphthenone in dimethylformamide, irradiated with ultraviolet light, but the solution was not coloured. The green colour is apparently not due to the hydroperinaphthenyl radical.

Ayscough and Wilson, in a detailed study of the structure of aromatic ketyls[42-44] and radical-anions of aromatic nitro-compounds[45], used photoreduction of the starting materials (ketones and nitrobenzene derivatives) in concentrated alcoholic solutions of sodium methoxide or ethoxide at 20° in a vacuum as one method for obtaining negatively charged mono-ions.

The mechanisms by which these radical-anions are formed was investigated by Porter and Wilkinson[46]. On ultraviolet irradiation ($\lambda = 330$ nm), benzophenone is excited into a singlet state, from which it undergoes non-radiative transfer into a chemically active triplet state $Ph_2CO \xrightarrow{h\nu} Ph_2CO^* \rightarrow Ph_2CO_{T_0}$. Benzophenone in the triplet state removes a hydrogen atom from a suitable solvent, leading to the formation of the ketyl radical $Ph_2\dot{C}O_{T_0}$ + $RH \rightarrow Ph_2\dot{C}OH + \dot{R}$. In alkaline solutions, the radical-anion of the ketone (ketyl), familiar from its blue colour, is stabilised: $Ph_2\dot{C}OH + OH^- \rightarrow Ph_2\dot{C}O + H_2O$.

In Ayscough and Wilson's experiments, the source of ultraviolet light was a medium-pressure 250 W mercury lamp; the light from this lamp passed through a water filter to remove infrared radiation and was focussed by means of quartz lenses on the specimen situated in the resonator of the spectrometer. The photoreduction of benzophenone, 4,4-dichlorobenzophenone, and fluorenone, like electrolytic and chemical (by means of Na and K) reduction, led to the production of intensely coloured blue (benzophenones) or red (fluorenone) products. These coloured products gave well resolved spectra. These are the EPR spectra of the corresponding ketyls: Ph_2CO^-, Ar_2CO^-, and $C_{13}H_8O^-$. The maximal intensity of the EPR spectrum of the benzophenone ketyl is reached several seconds after the start of illumination. The ketyls of 4,4-dichlorobenzophenone and fluoroenone reached their maximal concentration 5–10 min after the start of illumination. The rates of disappearance of the ketyls in the dark correspond to the rates of their appearance. These spectra contain a larger number of components than the EPR spectra of the ketyls obtained by electrolytic reduction in acetonitrile. This is not due to better resolution of the spectrum as a result of narrowing of the individual components, however, but is due to a slight distortion of the distribution of the density of the unpaired electron in the ketyl as a result of a solvation effect. It is possible that an increase in the electron density of the unpaired electron in the aromatic ring is brought about by hydrogen bonding between the carbon–oxygen group of the ketyl and an alcohol molecule. Thus the ketyls in these systems should be regarded as Ph_2CO^-(solvated), Ar_2CO^-(solvated), and $C_{13}H_8O^-$(solvated).

The ketyls of benzaldehyde and acetophenone were obtained similarly. Their EPR spectra were observed several seconds after the start of ultraviolet irradiation. The short delay period is possibly due to the presence in the solution of uncontrolled impurities, which react with the radicals. For these ketyls, a solvation effect influencing the distribution of the density of the unpaired electron was also observed. It is revealed particularly clearly by comparing the splitting constants in alkaline methanol or ethanol solutions with the splitting constants in acetonitrile: all the splitting constants of the protons are decreased in acetonitrile. The stability of the ketyls also decreases in acetonitrile, due to the absence of a solvation sheath.

On ultraviolet irradiation of solutions of duroquinone in methanol, ethanol, or propan-2-ol in the presence of alkoxide ions, Cough and Symons[47] detected the EPR spectrum of durosemiquinone. Irradiation of solutions which did not contain alkoxide ions produced the EPR spectrum of the monoprotonated form of durosemiquinone[48]. Bridge and Porter[33] established that the mechanism of the formation of the radical-anions of quinones in alkaline solutions is the same as that in alkaline solutions of aromatic ketones. When strongly polar alcohols are replaced by less polar alcohols (quaternary pentanol), in which there is association of the radical-anion of the quinone (the semiquinone ion) with the alkali metal cation (Li, Na, or K) of the added alkoxide, the EPR spectrum of the semiquinone ion shows an additional structure, produced by the interaction of the unpaired electron with the nucleus of the alkali metal[49,50]. This indicates the formation of ion pairs. The magnitude of the hyperfine splitting is proportional to the effective density of the unpaired electron, which has 0.1–1% *s* character. By changing the polarity of the solvent, Cough and Symons altered the degree of association of the anion–cation pairs, and measured the rate constants for reactions of the type $M^+A^- \rightleftharpoons M^+ + A^-$ and $M^+A^- \rightleftharpoons A^-M^+$. Thus the EPR spectra of photoreduced aromatic ketones and diketones have been used to study not only solvation effects, but also the nature of ion association.

Ayscough and Wilson[44] detected solvation effects for the anions of aromatic nitro-compounds, obtained by photo-reduction in alcoholic solution in the presence of sodium methoxide or ethoxide. 16 para-substituted nitrobenzenes (*p*-alkoxynitrobenzenes, *p*-alkyl- and *p*-phenylnitrobenzenes, *p*-nitrobenzene alcohols, methyl *p*-nitrobenzoate, *p*-nitrobenzaldehyde, *p*-dinitrobenzene, and *p*-halogeno(Cl, Br, F)nitrobenzenes), *ortho*- and *meta*-fluoronitrobenzenes, and 2,6-dimethylnitrobenzene were subjected to photoreduction. The ease with which the aromatic nitro-compounds add an electron, and the stability of the resulting radical-anions, which give the solution a yellow-brown colour, permitted a detailed analysis of the EPR spectra and a comparison with the EPR spectra of the radical-anions of the corresponding nitrobenzenes, obtained chemically by reduction with glucose in alcoholic (ethanol or methanol) or aqueous-alcoholic medium in the presence of sodium ethoxide. The comparison showed that the spectra are identical. Most of the EPR spectra consist of three well resolved groups of lines, corresponding to the interaction of an unpaired electron with the nucleus of the nitrogen atom ($a_N = 7.9–14.8$ Oe), with the protons of the ring ($a_{H_o} = 3.1–3.5$ Oe; $a_{H_m} = 0.78–1.2$ Oe), and with the magnetic nuclei of substituents in the *para*-position ($a_p = 0.26–8$ Oe). Comparison of the EPR spectra of these radical-anions with the spectra of the same radical-anions obtained in an aromatic solvent shows that a proton-

donating solvent influences the distribution of the unpaired electron around the nitrogen atom, possibly as a result of the formation of a hydrogen bond with a solvent molecule.

Winkler and coworkers[51] showed by the EPR method that the radical-anions of various aromatic hydrocarbons can be obtained by photoreduction in the presence of phenyl-lithium. The action of ultraviolet light from a PL = 313 (70 W) high-pressure mercury lamp on solutions of biphenyl, terphenylene, naphthalene, phenanthrene, chrysene, pyrene anthracene, perylene, pentacene, and acenaphthene in diethyl ether at 20° gave coloured solutions, whose EPR spectra indicated the formation of radical-anions of the corresponding aromatic compounds. An additional hyperfine structure, due to the interaction of the unpaired electron with the lithium nucleus (^{7}Li, $I = 3/2$), was detected, indicating the existence of polyacene$^-$–Li$^+$ ion pairs under these conditions[52,53]. For example, the EPR spectrum of the anthracene radical-anion had the following characteristics: $a_\gamma = 5.35$ Oe, $a_\alpha = 2.45$ Oe, $a_\beta = 1.58$ Oe, and $a_{Li} = 1.70$ Oe. The mechanism of this photoreaction is being studied.

Charge transfer in molecular complexes, leading to the production of radical-anions, has been demonstrated by the EPR method for many charge-transfer complexes in the solid state. Lagercrantz and Yhland[54] showed that charge transfer can be induced by light in solutions of various organic charge-transfer complexes. An electron acceptor (chloranil, sym-trinitrobenzene, picryl chloride, or *m*-dinitrobenzene) was dissolved in an electron donor (tetrahydrofuran, *p*-dioxan, xylene, mesitylene, dimethoxyethane, or *o*-chlorophenol) and irradiated with ultraviolet light. Electron phototransfer was detected from the appearance of the EPR signals of the radical-anions of the corresponding electron acceptors. The maximal concentration of radical-anions amounts to 0.1% of the concentration of neutral molecules. The chloranil + tetrahydrofuran pair produces a single structureless EPR line, which disappears in the dark indicating that the phototransformations in the system are reversible. The EPR spectrum obtained on irradiation of the sym-trinitrobenzene + tetrahydrofuran pair has the hyperfine structure characteristic of the radical-anion of the electron acceptor.

Ward[55] observed the production of paramagnetism when a solution of nitrobenzene in tetrahydrofuran was illuminated, but the EPR spectrum of the paramagnetic centre contained a larger number of components than might have been expected for the nitrobenzene radical-anion. He was able to establish by means of deuterotetrahydrofuran that the additional splitting ($a_H = 0.38 \pm 0.04$ Oe) is due to the proton of the α-hydrogen of the tetrahydrofuran molecule. It may thus be assumed that under the influence of ultraviolet light, photoexcited nitrobenzene removes the α-hydrogen of the tetrahydrofuran molecule, and not the electron. The dehydrogenated tetrahydrofuran radical repidly dimerises or disproportionates, producing a non-paramagnetic compound. The conclusion that an uncharged nitrobenzene radical is produced on illumination of its tetrahydrofuran solution is confirmed by the absence of photoconductivity[56].

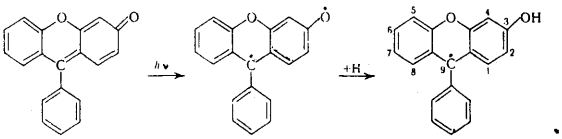
Tetracyanoethylene dissolves in most organic solvents to give solutions with an intense colour[57,58], due to the formation of a weak intermolecular complex with charge transfer[59-62] between the solvent molecule (the donor) and tetracyanoethylene (the acceptor). The production of a weak complex with charge transfer between tetracyanoethylene and tetrahydrofuran leads to the appearance of an absorption band at 318 nm[58]. The absorption band of the pyromellitic dianhydride + tetrahydrofuran complex lies in the range 330–385 nm[63]. Ward[56] showed that on illumination of their solutions the absorption band of the charge-transfer complex shows the EPR signals of the corresponding radical-anions: the eleven-component spectrum of the tetracyanoethylene radical-anion[64] and the three-component spectrum of the pyromellitic dianhydride radical-anion. The photogeneration of anion-radicals in these systems was confirmed by the production of photoconductivity. Analogous results were obtained on ultraviolet irradiation of solutions of tetracyanoethylene in methyltetrahydrofuran and *NN'*dimethylformamide. The photoreaction can be represented by the following scheme:

$$D + A \rightarrow D^{\delta+}A^{\delta-};\quad D^{\delta+}A^{\delta-} \xrightarrow{h\nu} D^+ + A^-\ .$$

As in the previous examples, proof of the existence of the positive tetrahydrofuran ion was not obtained.

Analogous results were obtained by Ilten and Calvin[65], who studied the photoinduced EPR signals and photoconductivity of solutions of tetracyanoethylene in tetrahydrofuran.

Bubnov and coworkers[66,67] used the EPR method to study the photoreduction of eosin. The photoreduction of eosin in the presence of a reducing agent involves the transformation of the dye into the leuco-compound. The mechanism of this reaction was previously studied by potentiometric and spectroscopic methods[68,69], and it was established that the reaction takes place in stages with the formation of intermediate product—the semiquinone of the dye. The lifetime of this intermediate product at room temperature amounts to several seconds. Illumination of eosin in pyridine in the presence of ascorbic acid (reducing agent) in fact leads to the production of the EPR signal of the corresponding semiquinone. The formation of the semiquinone in the photoreduction of eosin can be completely explained by Schenck's scheme[70].



eosin biradical semiquinone

The reversible photochemical reduction of chlorophyll by ascorbic acid is a model system for the photochemical stage of photosynthesis, in which light energy is stored in the photoproducts. Spectroscopic and electrometric measurements[71-73] have shown that the photoreduction involves the following elementary stages (Krasnovskii's reaction):

$$X + AH \xrightarrow{h\nu} X^* + AH \rightarrow X^{\cdot-} + \dot{A}H^+ \rightarrow \dot{X}H + \dot{A}$$

where X represents chlorophyll, and AH ascorbic acid.

The EPR method has been used to detect and study radical intermediate products formed on illumination of this model system[74,75]. Experiments on the photoreduction of chlorophyll and its analogues (pheophytin, haematoporphyrin, and magnesium phthalocyanine) were carried out in pyridine solutions in air and in a vacuum. The EPR signal produced in the illuminated solutions was found to be the same for all the pigments studied, and consisted of a doublet with a plitting equal to 1.8 Oe and $g = 2.004$. The spectra obtained belonged to the radical semi-oxidised form of ascorbic acid (monodehydroascorbic acid). In the system studied, the final stage involves the formation of a non-paramagnetic reduced form of the pigment and an

oxidised form of ascorbic acid. The EPR spectrum of the radical forms of the pigments could not be detected in any of the experiments, apparently because of their extremely high activity and correspondingly short lifetime in the system studied.

The semireduced semiquinone forms of the synthetic analogues of chlorophyll—the phthalocyanines—were detected by the EPR method during the dark reduction and photoreduction of these dyes in solutions in the presence of aliphatic amines or alkali metals[76,77]. Eigenmann[76] studied the photoreduction of copper phthalocyanine and phthalocyanine without metal in aqueous solutions in the presence of triethylamine and ethylenediamine. In the photoreduction of copper phthalocyanine, Cu^{2+} was converted into Cu^{+}, accompanied by a change in the intensity of the EPR signal. In the photoreduction of phthalocyanine without metal, which is a diamagnetic compound, a free radical whose EPR spectrum consisted of a narrow singlet was produced as intermediate product.

We showed[77] that the semi-reduced radical-ion form of Mg phthalocyanine and phthalocyanine without metal, produced by the reaction of the dye molecule with metallic sodium in tetrahydrofuran, is characterised by a structureless singlet EPR line with $g = 2.003$ and $\Delta H = 7$ Oe. These results show that the photoreduction of phthalocyanines takes place in an elementrary act involving the acceptance of one electron by the dye molecule.

Fujimori and Tavla[78] detected the formation of paramagnetic intermediate products in the photoreduction of chlorophylls *a* and *b* by hydroquinone in methanol under the influence of red light. Degassed solutions of $(4.5–4.9) \times 10^{-4}$ M chlorophyll and 10^{-2} M hydroquinone in methanol give two types of EPR signal on illumination. One has the hyperfine structure characteristic of the *p*-benzosemiquinone free radical, whereas the other is broad and is possibly due to the reduced form of chlorophyll. Measurements of the photovoltaic effect in these systems confirm the photoreduction of chlorophyll. The action of light apparently leads to electron phototransfer from hydroquinone to chlorophyll. Tollin and Banerjee[79] used the EPR method to study the reversible photoreduction of chlorophyll and pheophytin (*A* and *B*) by hydroquinone in alcohol solution in a vacuum (10^{-6} torr). They showed that the well resolved five-component EPR spectrum of benzosemiquinone is produced when a degassed solution of chlorophyll or pheophytin (7.3×10^{-5} M) and hydroquinone (2.2×10^{-2} M) in ethanol is illuminated with red light (duration of illumination from 30 min to 3 h). This photoinduced signal disappears very rapidly (< 1 s) on interruption of the illumination of the specimen, placed in the resonator of the spectrograph. Measurement of the optical absorption spectra of the solution before and after illumination showed that the electron transfer from the hydroquinone molecule to the photoexcited pigment is completely reversible. It was also found that oxygen effectively inhibits the oxidation of hydroquinone by reacting with the photoexcited pigment molecule[80,81].

It was found, however, that the addition of 0.1% pyridine (1.25×10^{-2} M) to this system increases the efficiency of the photoformation of the benzosemiquinone. Tollin and Banerjee suggest that this is due to the initial formation in solution of more readily oxidised non-paramagnetic complexes by the pyridinium ion and the hydroquinone anion, of the form $PyH^{+}...Q^{-}$. It is not excluded, however, that the addition of an organic base such as pyridine to the solution alters the pH of the medium and displaces the equilibrium for the reversible electron transfer towards the formation of the semiquonone.

The temperature dependence of electron transfer between hydroquinone and the photoexcited pigment molecule (chlorophyll or pheophytin) in the presence of pyridine was studied, and it was shown that electron transfer takes place even at −100°.

These results, and those given earlier, show that the photoexcited chlorophyll molecule, depending on the medium and its partners, may either take up or give up an electron with high efficiency, and this apparently determines its role in photosynthesis.

Rikhireva and coworkers[82,83] used the EPR method to detect chlorophyll molecules in the photoexcited triplet state, and also to study the free-radical forms of the pigment in ethanol solutions (5% HCl) at 77°K under the influence of visible light. Under these conditions a singlet EPR signal ($g \simeq 2$, $\Delta H = 9–11$ Oe) is produced in solutions of chlorophyll[83] and also of porphin and a number of prophyrins[84]. Similar singlet EPR signals were detected when solutions of chlorophyll in ethanol containing 20% water were illuminated with visible light at 77°K. The presence of reducing agents (ascorbic acid or phenylhydrazine) or oxidising agents (oxygen) in the solutions did not lead to intensification of the photoreaction at 77°K. Illumination of solutions of chlorophyll and pheophytin in ethanol, pyridine, piperidine, and 1 : 3 pyridine–ethanol mixtures at 300°K followed by rapid freezing ("fixation") of the solutions with liquid nitrogen leads to an increase in the intensity of the photoinduced EPR signals[85]. Under these conditions the concentration of paramagnetic photoproducts increases when oxygen, water, or a reducing agent are introduced into the solution. The authors cited[85] reached the following conclusion regarding the nature of the singlet EPR signal: the photoinduced EPR signal is due either to a charge-transfer complex formed by the photoexcited pigment molecule and the solvent molecule (with the participation of molecules of water and oxygen) or to a radical (radical-ion) form of the pigment.

Mauzerall and Feher[86] detected the EPR signals of the semireduced forms of various porphyrins, produced on illumination ($600 \leqslant \lambda \leqslant 700$ nm) of their degassed solutions in water, and also in aqueous glycerol at 25° in the presence of reducing agents. Three isomers of uroporphyrin and α,β-dihydroxyethyldeuteroporphyrin were studied. Ethylenediaminetetra-acetic acid, thiazolidine-4-carboxylic acid, NADH, and sparteine were used as reducing agents. The integral light intensity in the range 606–625 nm, corresponding to the long-wave absorption bands of the porphyrins, reached 10^{17} quanta $cm^{-2}s^{-1}$. Illumination produced singlet EPR lines of Gaussian form with $g = 2.0021 \pm 0.0001$ and $\Delta H = 5.4 \pm 0.2$ Oe. The EPR signal disappeared rapidly in the dark. Study of the kinetics of the disappearance of the EPR signal showed that the process involved in the disappearance of the paramagnetic centres is a second-order reaction. The processes taking place in these solutions can be described by the following scheme:

$$P + h\nu \xrightarrow{k_1} P^*$$

$$P^* \xrightarrow{k_2} P + h\nu_{fl.}\ (\text{heat})$$

$$P^* + R \xrightarrow{k_3} P^{\cdot} + R^{\cdot}$$

$$P^{\cdot} + P^{\cdot} \xrightarrow{k_4} P + \text{phlorin (dihydroporphyrin)}$$

$$R^{\cdot} + R^{\cdot} \xrightarrow{k_5} \text{product}$$

A possible reason for the absence of EPR signals from the radicals of the reducing agent ($\dot{R}$) may be that the rate constant $k_5 > k_4$, so that the steady-state concentration of $\dot{R}$ is too small for detection.

The formation of semireduced free-radical forms of various porphyrins on irradiation of their alcoholic solutions at 77°K by unfiltered light from a DRSh-1000 mercury lamp was detected by Gribova[87-91], who showed that the observed EPR spectrum of the free radicals consists of the singlet line of the free radical or porphyrin superimposed on the spectrum of the free-radical products of the decomposition of ethanol. It was also found that photoexcitation of porphyrins only in the long-wave absorption band (578 nm and 542 nm) leads to transfer of the chromophore molecule into the ground triplet state, but does not lead to the formation of free radicals. Comparison of the absorption spectra of a frozen solution of Mg etioporphyrin at 77°K before and after illumination with unfiltered light from a mercury lamp showed that in place of the characteristic absorption bands of porphyrin at 578 nm and 542 nm, an intense absorption band is produced at 686 nm, with a small maximum at 606 nm. Parallel qualitative comparison of the change in the concentration of the chromophore radical (singlet EPR line) and the absorption spectrum of the specimen with increase in temperature at 150°K showed that the decrease in the intensity of the absorption band at 686 nm corresponds to the decrease in the intensity of the EPR singlet line. According to these results, the absorption band at 686 nm can be assigned to the porphyrin free radical. As Gribova suggests, the porphyrin free radical may be produced as a result of the photoreduction of the chromophore molecule, existing in a high excited triplet state, by the solvent molecule.

4. Secondary Processes

The irradiation of salts of tervalent iron in alcoholic solutions with near ultraviolet or violet light leads to their reduction, with simultaneous oxidation of the solvent[92,93]. The basic elementary step in the photochemical reduction of tervalent iron in alcohols involves electron transfer within the complex:

$$Fe^{3+}Cl^- \xrightarrow{h\nu} Fe^{2+} + Cl^{\cdot}.$$

The chlorine atoms cannot be detected by the EPR method, but their formation is readily recorded from secondary processes—the chlorine atoms readily react with the alcohol, leading to the formation of free radicals:

$$RCH_2OH + Cl^{\cdot} \rightarrow R\dot{C}HOH + HCl.$$

Kryukov and coworkers[94] used the EPR method to detect and identify these radicals. To stabilise the alcohol radicals, the irradiation and the recording to the EPR spectra were carried out in methanol, ethanol, propan-1-ol, and propan-2-ol at 77°K. In all experiments a clearly defined EPR spectrum with hyperfine splitting was observed, indicating the presence of the free radical of the dehydrogenated alcohol in the system. The nature of the radicals is determined by the nature of the alcohol, and is independent of the nature of the iron complex.

Bazhin and coworkers[95], in a study of photoprocesses in an $H_2O + H_2SO_4 + FeSO_4$ mixture at 77°K in a vacuum, found that if the previously irradiated ($\lambda = 254$ nm) mixture is kept at 120°K and then cooled again to 77°K, the spectrum of the hydrogen atoms produced as a result of electron phototransfer disappears. This cannot be regarded as the result of recombination of the hydrogen atoms at 120°K, however. If the specimen is then subjected to irradiation again with visible light ($\lambda > 480$ nm), the doublet EPR signal of the hydrogen atoms is produced almost immediately on illumination. The formation of the "secondary" hydrogen atoms is observed if the second irradiation is carried out using red light ($\lambda > 600$ nm). These results show that the $H_2O + H_2SO_4 + FeSO_4$ photochemical system contains unique hydrogen atom traps, in which they are stabilised at 120°K. It is most probable that the hydrogen atoms at 120°K react with Fe^{2+} to form complexes of the type $(Fe^{2+}...H)$[96], which decompose under the influence of light with long wavelength ($\lambda > 260$ nm).

The use of the hydrogen atoms obtained in this way to study chemical reactions with various compounds at low temperatures is of considerable interest. Bazhin and coworkers[97] studied the reaction of hydrogen atoms with acetylene, ethylene, propene, allyl alcohol, and carbon monoxide at 90°K and 120°K. It was shown that at these temperatures the hydrogen atoms are capable of addition to these compounds with the formation of the corresponding radicals. Thus the reaction of hydrogen atoms with acetylene gives the vinyl radical $(H_2C=\dot{C}H$ (eight-component EPR spectrum with $a_\alpha = 16$ Oe, $a_\beta = 63$ Oe, and $a_{\beta_2} = 3.8$ Oe). The reaction of a hydrogen atom with ethylene gives the ethyl radical $\dot{C}_2H_5$. The reaction of a $\dot{H}$ atom with propene gives the isopropyl radical $CH_3\dot{C}HCH_3$. The reaction of a $\dot{H}$ atom with allyl alcohol $CH_2=CH-CH_2OH$ gives the radical $\dot{C}H_2-CH_2-CH_2OH$ (or $\dot{C}H_2-CH_2-CH_2OH_2^+$). The reaction of an $\dot{H}$ atom with CO gives the radical $H\dot{C}O$. Thus atomic hydrogen at 90–120°K can react with unsaturated compounds by addition to a double or triple bond or to a pair of unshared electrons (CO).

Whereas atomic hydrogen undergoes addition to unsaturated hydrocarbons at 90–120°K, in its reactions with saturated organic compounds in the same temperature range it removes a labile hydrogen atom. This was shown by Bazhin and coworkers[98], in a study of the reactions of atomic hydrogen with methanol, ethanol, propan-2-ol, ethylene glycol, isobutyric acid, malonic acid, and acetone. Bazhin and coworkers results[98] indicate that a "cold" $\dot{H}$ atom at 90°K is able to remove a labile hydrogen atom from the molecules of aliphatic alcohols, organic acids, and ketones.

Bazhin and coworkers[99] recently described the low-temperature reactions of hydrogen atoms with various aromatic compounds. They studied the reaction of atomic hydrogen in the $FeSO_4 + H_2O + H_2SO_4$ system irradiated with ultraviolet light ($\lambda = 254$ nm) with molecules of the following compounds: benzene, phenol, resorcinol, phloroglucinol, pyrocatechol, hydroquinone, guaiacol, 1,4-dimethoxybenzene, anisole, benzenesulphonic acid, benzyl alcohol, aniline, diphenylamine, and toluene. All the reactions at 90°K or 120°K produced radicals formed by the "attachment" of a hydrogen atom to the molecules of the aromatic compounds, characterised by an EPR triplet spectrum with a splitting of ~40–50 Oe for the protons of the $\diagdown CH_2$ group[100]. The additional splitting of the components of the triplet dependended on the position of the attached hydrogen atom relative to the substituent, and on the nature of the substituents. The EPR spectra of the radicals formed by the "attachment" of hydrogen atoms to the molecules of phenol, anisole, and benzenesulphonic acid show that 60–80% of the hydrogen atoms are attached in the ortho- or para-positions relative to the substituents. With resorcinol, the attachment of the hydrogen atom takes place chiefly in the ortho- or para-position relative to the OH groups. For pyrocatechol, hydroquinone, 1,4-dimethoxybenzene, and guaiacol, the EPR spectrum of the radicals formed by the "attachment" of a hydrogen atom consisted of a triplet of triplets, since in these radicals

the form of the EPR spectrum is independent of the position of attachment of the hydrogen atom. The observed EPR spectra for the radicals produced by the attachment of hydrogen atoms to the molecules of aniline, diphenylamine, and benzyl alcohol correspond to radicals with an H atom in the meta-position relative to the substituent.

Theoretical calculation[101] shows that the hydrogen atom should be attached chiefly in the ortho- or para-positions relative to the substituent, irrespective of the nature of the latter.

III. THE STUDY OF PHOTOSENSITISED REACTIONS OF ORGANIC COMPOUNDS BY THE EPR METHOD

1. Sensitised Photo-oxidation

The photo-oxidation and photoreduction of organic compounds, which require large quanta of energy, can be sensitised to the visible range of the spectrum by means of various dyes and pigments. A typical example of a photoreaction of this type is the photosensitised autoxidation of various aromatic compounds, studied by Ashkinazi and coworkers[102-104] by the EPR method.

When an ethanol solution of diphenylamine (10^{-2} M) at 293–295°K in the presence of chlorophyll *A* (10^{-5} M) and oxygen is irradiated with red light ($\lambda > 600$ nm), the colour of the reaction mixture changes in 10–15 min: the green solution first becomes reddish-brown, and then brown[102,103]. This is accompanied by a marked increase in the absorption in the range 400–560 nm. The same result is obtained when pheophytin *A* is used as senitiser. Prolonged irradiation of diphenylamine solutions freed from molecular oxygen does not change the absorption spectrum. The coloured product of the photoreaction was isolated in pure form. Its absorption spectrum is characterised by two maxima at 460 nm and 260 nm. The addition of a reducing agent (ascorbic acid, hydrazine, or hydroquinone) to a solution of this product instantaneously regenerates diphenylamine. This indicates that the autoxidation of diphenylamine sensitised by pigments gives a product which is not extensively oxidised. The authors cited[102,103] suggest that this product may be the diphenylnitrogen free radical $(C_6H_5)_2\dot{N}$. As confirmation of their suggestion, they give the EPR spectrum of the photoreaction product responsible for the colour; this spectrum consists of a triplet with component intensity ratio 1 : 1 : 1 and a splitting of 10–11 Oe. Ashkinazi and coworkers[103] suggest the following photoreaction scheme. A triplet molecule of the sensitiser reacts with the oxidation substrate (diphenylamine), removing an electron from it. This gives the diphenylamine radical-cation $[(C_6H_5)_2NH]^+$, which readily gives up a proton H^+ and is converted into the diphenylnitrogen radical $(C_6H_5)_2N$, which accumulates during the photoreaction. This scheme, however, ignores completely the part played by molecular oxygen in this photosensitised autoxidation. According to the above scheme, the photoreaction would take place with even greater efficiency under vacuum conditions, because of the quenching action of molecular oxygen on the triplet molecules of the sensitiser. Moreover, it is known that the diphenylnitrogen radical is extremely unstable in the presence of molecular oxygen and is rapidly converted in the dark into the diphenylnitroxide radical $(C_6H_5)_2\dot{N}O$, the EPR spectrum of which is extremely similar to the EPR spectrum of the diphenylnitrogen radical, showing only slight differences in the hyperfine interaction constants[105]. It may therefore be assumed that the accumulating free-radical product of the oxidation of diphenylamine, photosensitised by pigments (chlorophyll *A* or pheophytin *A*) is diphenylnitroxide. The diphenylnitrogen radical may be produced as a labile intermediate product of this photoreaction, as in the oxidation of diphenylamine by peroxo-compounds in the dark[106-108].

The formation of free-radical products was also detected by Ashkinazi and coworkers[103] in the autoxidation of *p*-phenylenediammonium chloride, photosensitised by pheophytin *A*, in alcoholic solution in the presence of molecular oxygen under the influence of red light. The photoreaction produced a reddish-yellow product (absorption maxima at 462 nm and 480 nm) with a singlet EPR signal and $\Delta H = 14$ Oe. The authors suggest that this product is the *p*-phenylenediamine radical-cation. The mechanism of the photoreaction is not discussed.

Ashkinazi and Dolidze[104] observed the autoxidation of α-naphthylamine, photosensitised by chlorophyll *A* and pheophytin *A*. In these experiments they observed a characteristic photo-after-effect: after the illumination of the system with red light was interrupted, the formation of an intensely coloured product (absorption maxima at 440 nm and 465 nm) continued for some time. The photoreaction does not take place in the presence of a reducing agent (ascorbic acid). EPR measurements showed that the photosensitised autoxidation of α-naphthylamine gives a free radical, the EPR spectrum of which consists of a singlet line with $\Delta H = 9$ Oe. The EPR signal disappears after several hours in the dark. Parallel measurement of the intensity of the absorption spectrum of the same specimen showed that the absorption increases so long as the EPR signal exists. This indicates that the free radical formed in the photoreaction takes part in a secondary reaction, leading to the production of a coloured product. The mechanism and nature of the intermediate product of the photoreaction have not yet been established.

The photo-oxidation of *NN*-diphenylamine, sensitised to visible light by eosin, in solution at room temperature was studied by Lagercrantz and Yhland[109] by the EPR method. They dissolved *NN*-diphenylamine in ethanol or pyridine (10^{-2} M), to which eosin was added (10^{-4} M). Illumination of the system with the visible part of the light from a xenon lamp (with a filter consisting of 5 cm of a 10% solution of $CuSO_4$ in H_2O) led to the immediate formation of a paramagnetic product, which disappeared under the influence of light in 5 min. This paramagnetic product is stable, however, in the dark in a vacuum. The EPR spectrum, recorded in the dark immediately after the attainment of the maximal concentration of the paramagnetic product, consisted of 37 components, situated in three main groups. It may be assumed that the photoexcited sensitiser (eosin) removes the hydrogen atom attached to the nitrogen atom of diphenylamine, leading to the production of the free radical $(C_6H_5)_2\dot{N}$, which is observed in the photoreaction. Unfortunately, the authors[109] did not study the optical absorption spectra of the photosensitive system before and after illumination. Precise identification of the paramagnetic product is therefore impossible.

Lagercrantz and Yhland[109] also detected the formation of a paramagnetic product in the photo-oxidation of phenothiazine, sensitised by eosin. Since the paramagnetic product is unstable in the dark, they were unable to obtain a complete well-resolved EPR spectrum. It was established, however, that the spectrum consists of three groups of lines, with a splitting of 9.5 Oe, due to the interaction of the unpaired electron with the nucleus of the nitrogen atom of phenothiazine. Each group contains a large number of

components. Although this EPR spectrum does not give complete information, it may be assumed that the phenothiazine free radical is produced as a result of the removal, sensitised by eosin, of a hydrogen atom from the bridging nitrogen atom.

The characteristic five-component EPR spectrum of *p*-benzosemiquinone was produced when alcoholic solutions of hydroquinone and *p*-benzoquinone (10^{-2} M) to which eosin had been added (10^{-3} M) were irradiated with visible light. The semiquinone appeared and disappeared as the light was switched on and off. Radicals were not detected when *p*-dimethoxybenzene was used as substrate. The reaction mechanism was not discussed. In these instances we undoubtedly have an example of oxidation or reduction of the substrate, photosensitised by the dye.

The EPR method has found application not only in sensitised photo-oxidation–photoreduction, but also in the polymerisation of a substrate, sensitised by dyes. Schenck and coworkers [110,111] showed that the cyclodimerisation of acenaphthalene (7×10^{-2} M), photosensitised by Bengal Rose (10^{-2} M), in methanol at room temperature gives as intermediate product a short-lived complex (adduct–product) of the photoexcited sensitiser molecule (Sens*) and acenaphthalene (Ace):

$$\text{Sens} \xrightarrow{h\nu} \text{Sens}^* \xrightarrow{+\text{Ace}} \text{Sens}^* \,\text{Ace} \xrightarrow{+\text{Ace}} \text{AceAce} + \text{Sens}$$

This complex is paramagnetic, and gives a three-component EPR signal, which differs from the EPR signal of the semiquinone of the sensitiser [66]. The authors cited point out that the photosensitised cyclodimerisation of acenaphthalene is an example of the photochemical transfer of energy from a sensitiser to the molecules of a substrate through a biradical complex [112].

2. The Photosensitised Decomposition of Organic Compounds

A unique position among photoreactions, sensitised to light of long wavelength, which have been studied by the EPR method, is occupied by the sensitised photodecomposition of saturated hydrocarbons, aliphatic alcohols, their esters, and various alkyl halides. These photoreactions provide examples of the chemical utilisation of light energy, transferred from a photoexcited sensitiser to substrate molecules (molecules of solvent or added substrate), in which is used in fairly high yield for the rupture of the weakest bond. There is now convincing proof that these photoreactions take place by a two-quantum mechanism with the participation of triplet molecules of the sensitiser (aromatic hydrocarbons, ketones, amines, dyes, and pigments).

Shelimov and coworkers [113-116] were the first to detect the sensitised formation of free radicals under the influence of ultraviolet light in transparent solutions of benzene in aliphatic hydrocarbons, frozen at 77°K. On ultraviolet irradiation ($\lambda = 254$ nm) in hydrocarbon media at 77°K, benzene is decomposed with rupture of a C–C bond of the benzene ring. Ultraviolet spectroscopy and gas chromatography showed that the product of the photochemical decomposition of benzene at 77°K is a substituted hexatriene.

Shelimov and coworkers [113-115] found by the EPR method that the reaction at 77°K gives not only hexatriene but also alkyl radicals (R̊), the formation of which did not fit into any of the schemes proposed to explain the formation of the substituted hexatriene. In their experiments, transparent solid solutions of benzene (1.8×10^{-3}–2.1×10^{-1} M) in methycyclohexane and 3-methylpentane were subjected to the action of light (PRK-7) at 77°K in a vacuum. Irradiation of these solutions with ultraviolet light ($\lambda > 230$ nm) produced free radicals, identified from the EPR spectra as methylcyclohexyl and 3-methylpentyl respectively. Alkyl radicals were also obtained by ultraviolet irradiation of hydrocarbon solutions of hexadeuterobenzene, toluene, ethylbenzene, isopropylbenzene, *o*-, *m*-, and *p*-xylenes, diphenylmethane, triphenylmethane [117], and naphthalene [118].

The fact that molecular hydrogen is formed on irradiation is extremely significant. The process leading to the simultaneous formation of alkyl radicals and hydrogen can only be the dehydrogenation of the aliphatic hydrocarbons, photosensitised by the aromatic hydrocarbons.

Shelimov recently † studied the dependence of the rates of formation of hydrogen (H_2) and alkyl radicals in solutions of benzene, toluene [117], and naphthalene [118] in 3-methylpentane on the intensity of the light. The quadratic dependence which he observed indicates that the photosensitisation is a two-quantum process. It should be noted that the rate of formation of the substiuted hexatriene is linearly dependent on the light intensity [121], that is this reaction is a one-quantum process. Shelimov and coworkers suggested [116] and demonstrated [117,122] that the intermediate state in the sensitisation is the triplet state of the aromatic hydrocarbon; in this state the hydrocarbon absorbs a second quantum of light with $\lambda < 370$ nm.

The ability of aromatic amines to bring about the photosensitisation of the dehydrogenation of aliphatic alcohols was observed by us in 1960 during an EPR study, carried out at the suggestion of A. N. Terenin, of the photoionisation of aromatic amines in an alcohol–ether mixture at 77°K. The publication of the results of this study [123] was stimulated by a paper published by Smaller [124] towards the end of 1962, on a study of the photodehydrogenating power of indole with respect to methanol at 77°K. In our experiments we studied solutions of the following amines: aniline, diphenylamine, triphenylamine, *p*-phenylenediamine, and tetramethyl-*p*-phenylenediamine; and the following heterocyclic compounds containing amine nitrogen: indole, carbazole, and 9,10-dihdroacridan. The solvents, which were purified by distillation, were methanol, ethanol, propan-2-ol, n-butanol, and 2-methylpropanol, and also diethyl, dipropyl, and dibutyl ethers. Control experiments showed that the solvents themselves do not decompose even on prolonged (3 h) irradiation with ultraviolet light ($\lambda \geq 300$ nm). Illumination of solutions of the aromatic amines and N-heterocycles (10^{-4}–10^{-1} M), frozen at 77°K, however, produced considerable concentrations of the free radicals of the solvent (alcohol or ether), formed by the removal of the labile α-hydrogen [123]. We made a detailed study of the dependence of this photoreaction on the duration and intensity of the ultraviolet irradiation, the spectral composition of the light source (DRSh-500), the temperature of the solution, and the presence of selective extinguishing agents for the triplet state of the sensitiser.

The inhibiting action of added naphthalene on the yield of the photoreaction in an ethanol solution of triphenylamine (carbazole) at 77°K provided convincing proof of the participation of triplet molecules of the amines in the photoprocess [123]. On the other hand, by means of the intermittent illumination method, we were able, like

† This study was undertaken by Shelimov and coworkers after the publication of papers by Bagdasar'yan and coworkers [119] and Terenin and coworkers [120], demonstrating the two-photon mechanism of the sensitised decomposition of aliphatic compounds.

Smaller for indole[124], to show that aromatic amines and N-heterocycles in the ground triplet state are not capable of dehydrogenating aliphatic alcohols at 77°K. The formation of free radicals took place only on irradiation and in the presence of triplet molecules of the sensitiser. We therefore suggested that the sensitisation photoprocess is a two-photon process[120]. An analogous suggestion that the sensitisation of the rupture of the C_α–H bond in methanol by photoexcited indole is a two-photon process was first put forward by Smaller[124]. In this instance the rate of formation of the radicals (dR/dt) should have shown a quadratic dependence on the intensity (I) of the light exciting the sensitiser, that is $dR/dt \sim I^2$. In fact, as shown by the measurements of Bagdasar'yan and coworkers[119,125,126] and results which we obtained[120], this relationship is observed fairly satisfactorily in experiments on the sensitisation by triphenylamine and diphenylamine of the dehydrogenation of methanol and ethanol at 77°K. It should be noted, however, that a quadratic dependence of dR/dt on I may be obtained both as a result of the absorption of two quanta of light by the sensitiser molecule (a two-photon mechanism) and also if the formation of free radicals of the solvent takes place through a photoactive intermediate compound (complex), which is produced under the influence of the first quantum of light and then absorbs a second quantum (a two-stage mechanism)[127-131].

To prove that the photoreaction is a two-photon process, it was necessary not only to obtain a quadratic dependence on the intensity of the light exciting the sensitiser, but also to prove that the absorption of the second quantum takes place in the photoexcited triplet-level of the sensitiser molecule (triplet–triplet absorption).

Bagdasar'yan and coworkers[125,126] studied the mechanism of this photoreaction by the method involving interrupted illumination of the specimens; by measuring the rates of the photoreaction with interrupted illumination ($t_{light} = t_{dark}$ = 0.5, 1.875, 3.75, and 7.5 s, duration of illumination 6–9 min) and continuous illumination (2 min) by light with λ = 313 nm, they estimated the characteristic lifetime of the intermediate state responsible for the absorption of the second photon in the diphenylamine + ethanol (5×10^{-4} M) and triphenylamine + ethanol (5×10^{-4} M) systems at 77°K. The agreement between this quantity (1.95–2.14 s for diphenylamine and 0.56–0.81 s for triphenylamine) and the lifetime of the sensitisers used in the triplet state (τ_{phosph} for diphenylamine = 1.9 s and τ_{phosph} for triphenylamine = 0.7 s[132]) must be regarded as providing quantitative confirmation of the earlier suggestion that the formation of alcohol radicals in these systems takes place as a result of an optical triplet–triplet transition of the amine molecule. Unfortunately, the positions of the short-wave and ultraviolet bands of the triplet–triplet absorption have not been established for aromatic amines and N-heterocycles. According to our data, they should lie in the range 260–340 nm, since it is this light which is photochemically active as the second quantum in the photoreactions involved in the dehydrogenation of primary and secondary alcohols at 77°K, sensitised by aromatic amines and N-heterocycles.

We obtained definite proof that the two-photon excitation of the sensitiser to high triplet states is a necessary stage in the sensitisation photoprocess in a study of the sensitised photodecomposition of t-butyl alcohol. t-Butyl alcohol $(CH_3)_3COH$ is an example of an alcohol which does not contain α-hydrogens. We showed[133] that by its sensitised photodecomposition it is possible, in the primary act of the photoreaction, to bring about rupture of a C–C bond with the formation of methyl radicals and the free radicals of the alcohol. When a solution of diphenylamine, triphenylamine, or indole (10^{-2}–10^{-3} M) in t-butyl alcohol at 77°K is irradiated with ultraviolet light ($\lambda \geqslant 320$ nm) corresponding to the long-wave edges of the absorption bands of the amines, the system after 5 min gives the EPR spectrum characteristic of the $\dot{C}H_3$ radical, and also an EPR spectrum identical to the spectrum of the radical of dehydrogenated propan-2-ol $(\dot{C}H_3)_2COH$. Similar spectra were observed on illumination ($\lambda \geqslant 300$ nm) of the solutions of naphthalene, phenanthrene, and biphenyl in t-butyl alcohol at 77°K, used as sensitisers. Of considerable interest in the rupture of the C–C bond in t-butyl alcohol, sensitised by dissolved naphthalene, for which the positions of the triplet–triplet bands, including the ultraviolet bands, are well known[134]. By illumination of specimens with monochromatic light from two sources, one of which (λ = 313 nm) was used to obtain high concentration of triplet molecules of naphthalene, whereas the light from the other corresponded to a given band of the triplet–triplet absorption of naphthalene, it was established that photochemically active conditions correspond to simultaneous subsidiary illumination of the solution by light with $\lambda > 365$ nm (the $T_0 \rightarrow T^*$ transition is brought about under the influence of light with λ = 415, 391, and 375 nm)[135].

Rupture of the C–CH_3 bond in t-butyl alcohol can be sensitised by means of various dyes. Acridine Yellow, Rhoduline Orange, and fluorescein (H^+ cation) were found to be extremely effective. The rate of production of free radicals shows a quadratic dependence on the intensity of the light exciting the dye[135,136]. By irradiation of solutions of the dyes by two light sources with different spectral compositions ($\lambda_1 > 400$ nm, $\lambda_2 < 400$ nm) it was established that the second photon is absorbed by a triplet molecule of the dye with its subsequent excitation to a high triplet state ($T_0 \rightarrow T_4^* - T_5^*$ -transition)[137,138].

Various biologically important compounds such as aromatic aminoacids (tryptophan, tyrosine, and phenylalanine) and nucleic acid bases (purine, adenosine, and guanosine), were found to have sensitising properties very similar to those of aromatic amines and N-heterocycles. Gribova and coworkers[87,89] studied the EPR of the triplet state of porphyrins and aromatic aminoacids (transition $\Delta m = \pm 2$) and found that during the ultraviolet irradiation of alcoholic solutions of aromatic aminoacids at 77°K the concentration of the latter in the triplet state decreases, with the simultaneous formation of free radicals of the dehydrogenated alcohol. The concentration of free radicals produced is proportional to the concentration of aromatic aminoacid molecules excited to the triplet state. A similar observation was made by Douzou and Ptak[139]. Azizova[18,20] found that brief (5 s) ultraviolet irradiation (unfiltered light from a DRSh-1000 mercury lamp) of a solution of tryptophan (2.5×10^{-3} M) in water in the presence of 2% ethanol at 77°K produces an EPR signal consisting of the superposition of the spectra of three paramagnetic products—the free radical $CH_3\dot{C}HOH$ (five-component spectrum), the positive tryptophan radical-ion, and an electron trapped in the matrix (singlet line). Subsequent prolonged irradiation of the solution by light with $\lambda \geqslant 320$ nm leads to a decrease in the intensity of the singlet EPR signal and to the appearance of components of the $\dot{C}H_3$ radical, produced as a result of photodecomposition of ethanol free radicals. The photosensitised decomposition of ethanol molecules also takes place in aqueous-alcoholic solutions of tyrosine and phenylalanine. The participation of the ground triplet state of aromatic amino-

acids in the photoreaction was confirmed by Gribova[87-91] in a study of the yield of free radicals obtained by interrupted and continuous irradiation of the specimens (tryptophan in ethanol, concentration 5×10^{-4} M) by light with the same intensity for the same total period of illumination. It was found that the yield of free radicals is smaller by a factor of 20 for interrupted irradiation (irradiation intervals 0.45 s, dark period 7 s). The participation of the excited triplet state of the aromatic aminoacids in the photoreaction was proved by the dependence of the yield of free radicals on the intensity of the incident light, which was found to be close to quadratic[89,91].

Helene and coworkers[140] found that purine, adenosine, and guanosine have a similar ability to sensitise the photodehydrogenation of aliphatic alcohols at 77°K. Ultraviolet irradiation ($\lambda > 250$ nm) of aqueous solutions of purine and adenosine (10^{-2} M) with 2% ethanol (0.35 M) at 77°K produced the five-component EPR spectrum of the $CH_3\dot{C}HOH$ radical, superimposed on a singlet EPR line‡. Subsequent irradiation of these solutions with visible light ($\lambda > 450$ nm) decreases the singlet signal, as a result of which the signal of the ethanol radical becomes more clearly defined. In aqueous solution containing 20% ethanol (3.5 M) or in pure ethanol solution, ultraviolet irradiation produced only the EPR signal of the ethanol radical $CH_3\dot{C}HOH$. At low intensities of the ultraviolet light, the rate of formation of the ethanol radicals remains unchanged with time and is proportional to I^2_{eff}, where I_{eff} is the intensity of the light absorbed by the molecules of the added sensitisers. At any moment of time, the rate of formation of the radicals is proportional to the concentration of triplet molecules of the sensitisers. The photosensitisation of the dehydrogenation of ethanol molecules by purine, adenosine, and guanosine evidently proceeds through an excited triplet state, produced by the two-photon photoexcitation of the sensitiser.

Irradiation of an ethanol solution of Mg etioporphyrin at 77°K by light from a superhigh-pressure mercury lamp (DRSh-1000) produces a large number of free radicals of the chromophore and ethanol $CH_3\dot{C}HOH$[87]. Gribova[88] showed by the EPR method that the irradiation of an ethanol solution of Mg etioporphyrin at 77°K by light with $\lambda =$ 578 nm, corresponding to the long-wave absorption band, produces only the EPR absorption due to molecules of the chromophore excited to the ground triplet state. The irradiation of frozen solutions by light with wavelength 248–365 nm for 5–10 min does not lead to the formation of free radicals, or produces them in very low yield. On simultaneous irradiation of solutions of Mg etioporphyrin in ethanol at 77°K by light from two sources (two DRSh-1000 lamps) with different spectral compositions, the yield of free radicals increases sharply (by a factor of 5–20) when the first source contains light of wavelength $\lambda = 578$ nm, leading to the formation of triplet molecules of the chromophore, and the second source has $\lambda < 322$ nm. Increase in the energy quantum from the second source increases the rate of formation of the free radicals. The EPR spectrum in this instance consists of the superposition of a single line due to the chromophore radical and a low concentration of free radicals of the alcohol $CH_3\dot{C}HOH$. From these results obtained by Gribova, it follows that the energy of a quantum of light of $\lambda = 578$ nm, absorbed by Mg etioporphyrin, is sufficient only for the excitation of its molecules to the ground triplet state, but is insufficient for the formation of free radicals; in the ground triplet state the chromophore is photochemically inactive in an ethanol matrix at 77°K. A high-energy quantum of light ($\lambda =$ 248–365 nm), however, is also insufficient for the dehydrogenation of ethanol in the absence of chromophore molecules excited to the ground triplet state. Free radicals of the chromophore and matrix are formed only on simultaneous irradiation by two quanta of light of $\lambda = 578$ nm and $\lambda < 322$ nm. The addition of glutathione, which was found to be a selective extinguishing agent for the triplet state of the chromophore, to an ethanol solution of Mg etioporphyrin led to a sharp decrease in the yield of radicals[89,91]. The participation of the ground triplet state as an intermediate state in the photochemical dehydrogenation of ethanol was proved by the dependence of the yield of free radicals on the intensity of the incident light; this dependence was found to be close to quadratic[89,91]. Direct proof of the participation of the ground triplet state of Mg etioporphyrin as an intermediate state in the photodehydrogenation of ethanol at 77°K was obtained by determining the influence of interrupted illumination on the yield of free radicals[90]. The solution was illuminated by unfiltered light from a DRSh-500 mercury lamp. The experiment was carried out at low light intensities. The periods of illumination were 1.8×10^{-2}, 9.0×10^{-3}, and 6.0×10^{-3} s, that is much less than τ_{phosph} for Mg etioporphyrin ($\tau_{phosph} = 1.83 \times 10^{-1}$ s [141]). The dark periods amounted to 1–2 s. Comparison of the yields of radicals for continuous and interrupted illumination for the same total periods of illumination showed that the concentration of radicals for continuous illumination is greater by a factor of 16 than for interrupted illumination with illumination intervals of 1.8×10^{-2} s, and greater by a factor of 25–30 than that for interrupted illumination with illumination periods of 9×10^{-3} s; this agrees with theoretical calculation and shows that a short-wave light quantum is absorbed by the chromophore molecule in the ground triplet state.

We noted in our first paper[123] that naphthalene, acting as sensitiser, can bring about the dehydrogenating of primary aliphatic alcohols at 77°K, but the yield of the photoreaction is lower by two orders of magnitide than that observed when aromatic amines and heterocycles with an amine group are used as sensitisers. Siegel and coworkers[142,143] made a detailed EPR study of the photodehydrogenation of ethanol, diethyl ether, and methylcyclohexane at 77°K, sensitised by naphthalene. They found that the rate of dehydrogenation also shows a quadratic dependence on the intensity of the light exciting the naphthalene. They also established that radiation with wavelength 270–300 nm is effective for the excitation of naphthalene molecules to the ground triplet state. Photochemical activity was observed, however, when the specimens were irradiated simultaneously with this radiation and by light of wavelength 250–260 nm. The naphthalene acting as sensitiser was not used up to a significant extent in the photoprocess. The observed decrease in the intensity of the EPR signal of the triplet molecules of naphthalene (transition $\Delta m = \pm 2$) was related to the decrease, by a factor of more than 100, in the lifetime of naphthalene in the triplet state as a result of the extinguishing action of the free radicals of the dehydrogenated solvent, produced on illumination. The formation of radicals of the solvent was not observed on illumination of non-degassed solutions of naphthalene at 100°K, that is under conditions where the

‡ In aqueous solutions of purine, adenosine, and guanosine, ultraviolet irradiation ionises the molecules $Pu \xrightarrow{h\nu} Pu^+ + e$. The singlet EPR signals actually consists of the signal of the Pu^+ radical-cation and the signal of electrons trapped by the matrix at 77°K.

steady-state concentration of the triplet molecules of naphthalene is low as a result of extinction by diffusing molecules of oxygen. The rate of appearance of free radicals of the dehydrogenated solvent increases significantly at 77°K when naphthalene is replaced by completely deuterated naphthalene, since the lifetime of the latter in the triplet state is greater by a factor of 5. [144] These results show that the groud triplet state of the naphthalene molecules is an intermediate state in the photosensitisation. The quadratic relationship shown by the rate of formation of the free radicals, and the fact that the range of photochemically active wavelengths coincide with the short-wave band of the triplet–triplet absorption of the naphthalene molecule ($\lambda \simeq 260$ nm)[134], enabled Siegel and Eisenthal to postulate that the sensitisation is a two-photon process, in which the final stage is the excitation of the molecule of the sensitiser (naphthalene) to a high triplet state.

West and coworkers [145,146] made a detailed optical study of the decomposition of alkyl iodides in hexane and ethanol at 300°K, photosensitised by naphthalene. We used the EPR method to study the primary processes taking place during the ultraviolet irradiation of solutions of alkyl iodides (methyl iodide and ethyl iodide) containing various sensitisers (diphenylamine, triphenylamine, naphthalene, biphenyl, phenanthrene, and benzophenone) at 77°K, and found that the sensitisation of the rupture of the C–I bond of the alkyl iodides is a two-photon process [147–150]. The spectral dependence of this photoreaction was studied for specimens containing naphthalene as sensitiser. The specimens were irradiated by two light sources. The light from one of these sources (a DRSh-500 superhigh-pressure mercury lamp) was filtered through a filter which picked out the 313 nm mercury line, necessary for the excitation of naphthalene to the triplet state. The light from the other source (DRSh-250), which was combined with an SZS-22 filter, contained the 365, 404, and 408 nm mercury lines, falling in the known range of the triplet–triplet absorption of naphthalene [134]. It was established beforehand that each source taken separately did not bring about the photodecomposition of the alkyl iodides at 77°K. Photodecomposition took place, however, under the simultaneous influence of both sources.

Similar experiments were carried out with specimens containing the dyes Acridine Yellow, Rhoduline Orange, fluorescein, and porphyrins as sensitisers. The only difference was that visible light ($\lambda > 400$ nm) was used to excite the dyes to the triplet state, and the triplet–triplet transitions were brought about under the influence of ultraviolet light with $\lambda < 400$ nm. The absorption spectrum of the triplet molecules of the dyes contains diffuse bands in the near ultraviolet range [137,138].

Siegel and Judeikes [151] used the EPR method to detect the decomposition of polydimethylsiloxane $[-O-Si(CH_3)_2-O-]_n$, photosensitised by naphthalene at 77°K. Methylsiloxanes are very stable to near ultraviolet light ($\lambda > 240$ nm) since neither the O–Si–O group not the $Si-CH_3$ group have absorption bands in this spectral range. In the presence of naphthalene, however, polydimethylsiloxane is decomposed at 77°K by light of $\lambda > 240$ nm, and the EPR spectrum shows two types of radical $\dot{C}H_3$ and $[-O(\dot{C}H_2)Si(CH_3)-O-]$. The quadratic dependence of the yield of $\dot{C}H_3$ radicals on the intensity of the incident light indicates that the sensitisation is a two-photon process. The naphthalene molecule is transferred to the ground triplet state under the influence of protons with $\lambda \leqslant 313$ nm. The simultaneous action of protons with $\lambda \simeq 250$–260 nm converts the naphthalene molecule into a high triplet state.

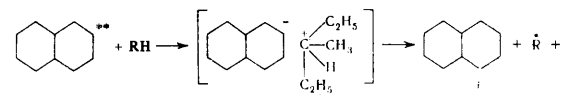
These results of the study of the photosensitised decomposition of substances to form free radicals at 77°K prove convincingly that the sensitisation of these processes takes place by a two-photon mechanism. It has been shown that the second quantum is absorbed by a triplet molecule of the aromatic compound, which acts as sensitiser. The least well-established feature is the final stage of the photoprocess—the mechanism of the interaction of the photoexcited sensitiser with the molecules undergoing photolysis. Three suggestions have been put forward regarding the type of interaction and the mechanism of the decomposition of the molecule undergoing photolysis to free radicals, recorded by the EPR method.

1. The formation of a complex of the charge-transfer type between a molecule of the sensitiser, photoexcited to a high triplet state, and a molecule of the dissociating substrate, followed by removal of a hydrogen atom [23,88,89,91] or decomposition with the formation of free-radical products [152].

2. Two-photon ionisation of the sensitiser molecule with subsequent dissociative attachment of an electron (solvated electron) to a molecule of the substrate [153,154].

3. Non-radiative transfer of energy from the photoexcited sensitiser to a molecule of the dissociating substrate with excitation of the latter to the decomposition state [120,135,136,140,142,155,156].

The first view is held by Bagdasar'yan [152], who suggested that photoexcited molecules of the sensitisers at 77°K can form complexes with the surrounding solvent molecules (substrate). These complexes, which are of the charge-transfer type but are formed only from excited molecules, have a short lifetime. Dissociation (predissociation) of this complex (reverse transfer of an electron to the substrate RH) may lead to decomposition of the solvent molecule (substrate) to free radicals. For example:



Gribova [23,88,89,91] proposed the following scheme for the two-photon dehydrogenation of ethanol by Mg etioporphyrin at 77°K. The chromophore molecule is converted into a lower triplet state under the influence of the first photon ($\lambda = 578$ nm). The second light quantum ($\lambda < 320$ nm), absorbed by the triplet molecules of the chromophore, transfers an electron of the triplet molecule of the chromophore to a state with higher energy. The strong coupling between the electrons forming the state of the chromophore with spin equal to 1 is weakened to such an extent that a labile biradical is produced (spin equal to 1/2). The chromophore molecule in this state is very active and adds on a hydrogen atom from neighbouring molecules of the matrix (ethanol), leading to the production of free radicals of dehydrogenated ethanol. Simultaneously, the Mg etieporphyrin molecule becomes a semi-reduced free radical. Study of the optical absorption spectrum of an irradiated frozen solution of Mg etioporphyrin in ethanol confirmed the formation of a free-radical form of the chromophore in this photochemical system.

Alfimov and coworkers [153] put forward yet another possible mechanism for the photosensitised dehydrogenation of alcohols by aromatic amines (diphenylamine or carbazole), involving two-photon ionisation of the amine molecules and interaction of the electrons produced with molecules of the alcohol. During the photodecolourisation of methanol solutions of diphenylamine and carbazole irradiated with ultraviolet light at 77°K, Alfimov and coworkers

found that the disappearance of the absorption band of the solvated electrons with λ_{max} = 600 nm is accompanied by a simultaneous increase in the concentration of alcohol radicals $\dot{C}H_2OH$. They therefore suggested that the formation of the $\dot{C}H_2OH$ radicals is associated with the disappearance of the centres absorbing light of λ = 600 nm, that is solvated electrons.

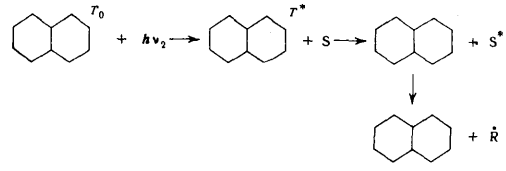
Shelimov and coworkers [154] tried to attribute the photosensitising action of aromatic hydrocarbons to the participation of ionic states formed by the action of ultraviolet light with short wavelength (λ < 300 nm) on their solutions in aliphatic hydrocarbons and alcohols at 77°K. For this purpose, they studied the decomposition of compounds with clearly defined electron-donating and electron-accepting properties in alcohol and hydrocarbons matrices, sensitised by aromatic hydrocarbons [154]. They carried out the photolysis of alcoholic solutions of naphthalene and phenanthrene in the presence of added compounds of the type R–Cl (n-propyl chloride, isopropyl chloride, benzyl chloride, methylene chloride, and carbon tetrachloride). In all instances with the exception of CCl_4, the formation of alkyl radicals $\dot{R}$ was observed. The rate of their formation was proportional to the square of the light intensity. If two-quantum photoionisation of naphthalene and phenanthrene [157] under the influence of ultraviolet light with λ = 254 nm is assumed, the formation of $\dot{R}$ radicals can be attributed to the dissociative attachment of an electron: $e + RCl \rightarrow \dot{R} + Cl^-$. The fact that the optical absorption spectra and the EPR spectra do not show the signals of the sensitiser radical-cations (A^+), which according to the photoreaction scheme should accumulate, was attributed by Shelimov to the disappearance of the greater part of these radical-cations by a "discharge" reaction: $A^+ + Cl^- \rightarrow A^* + \dot{C}l$. In the opinion of Shelimov and coworkers [154], the two-quantum formation of alcohol radicals during the illumination of solutions of aromatic compounds in ethanol at 77°K can also be explained by assuming photoionisation of the aromatic sensitisers followed by reaction of an electron with the oxonium ion ($CH_3CH_2OH_2^+$) or molecule of the alcohol ($CH_3–CH_2O^-H^+$). As confirmation of this suggestion, they give data on the observed increase in the rate of formation of alcohol radicals with decrease in the pH of the medium (increase in the concentration of $CH_3CH_2^+$ ions).

According to the suggestions which we put forward [120, 135,136,155], the final stage in the two-photon sensitisation of the rupture of the C_α–H and C–CH_3 bonds in alcohols and ethers and the C–I(Br, Cl) bonds in alkyl halides at 77°K involves the non-radiative transfer of energy from the photoexcited sensitiser in a high triplet state (aromatic amine, N-heterocycle, aromatic hydrocarbon, dye) to a molecule of the substrate (alcohol, ether, alkyl halide). We turned our attention [135,143,150] to the energetics of the photophysical stage of the two-photon sensitisation of the rupture of the C–I bond in alkyl iodides and the C–CH_3 bond in t-butyl alcohol at 77°K in the presence of aromatic compounds. It was found that the total energy of photoexcitation of the added sensitiser $E_{T_0} + h\nu_2$, where E_{T_0} is the energy height of the triplet level T_0 of the sensitiser, and $h\nu_2$ the photon absorbed by the sensitiser molecule in the triplet state, is always equal to or slightly greater than the energy of the photon $h\nu_{diss}$ bringing about the direct photodecomposition of the substrate molecules.

This energy relationship is a necessary condition for the non-radiative transfer of energy [158]. As a result of this resonance transfer of energy, the substrate molecule either is transferred directly to the repulsion potential curve of the bond being broken (C–H, C–CH_3, or C–I), which corresponds to excitation of a σ – or n-electron to a non-bonding orbital (σ–σ^* or n–σ^* transition) or decomposes by a predissociation mechanism. The efficiency of the transfer of energy to the substrate from the sensitiser photoexcited to a high triplet state is determined by the multiplicity of the electronic state of the substrate to which the energy is transferred [158–163]. The probability of energy transfer from an excited triplet level of the sensitiser (energy donor) to a triplet level of the substrate molecule (energy acceptor) should evidently be significantly greater than that for transfer to a singlet level, in accordance with the principle of preservation of the total spin of the system.

Since these intermolecular interactions have a limited sphere of influence [160–163], the dependence of the yield of radicals of the substrate on its concentration in a photochemically neutral matrix at 77°K at constant sensitiser concentration and constant experimental conditions, or, in principle, the magnitude of the radius of the sphere of influence of energy transfer, can be used to determine precisely the type of resonance energy transfer (triplet–triplet or triplet–singlet). We carried out these measurements [135,155] for two systems: naphthalene + t-butyl alcohol in ethanol and naphthalene + methyl iodide in ethanol at 77°K. The sphere of influence of the intramolecular energy transfer was taken as the averaged distance between the molecules of the energy donor and the energy acceptor, for which the probability of energy transfer from a molecule of the sensitiser (donor), excited to a high triplet state, to a molecule of the substrate (acceptor) was equal to the probability of intramolecular deactivation of the photoexcited sensitiser ($T^* \rightarrow T_0$ transition). The results showed that the characteristic radius of the sphere of interaction between the photoexcited sensitiser and the substrate is limited and is equal to 10–12 Å; this is characteristic of exchange-resonance interaction leading to triplet–triplet energy transfer [163].

Siegel and coworkers [142,143] reached a similar conclusion regarding the final stage of the mechanism of the two-photon sensitisation of the dehydrogenation of ethanol, diethyl ether, and methylcyclohexane, and also polydimethylsiloxane, by means of naphthalene. On the basis of their results they suggested that there is non-radiative resonance transfer of energy from a naphthalene molecule, photoexcited to a high triplet state, to a molecule of the solvent (ethanol, diethyl, or methylcyclohexane), followed by dissociation (rupture of the C–H bond). The proposed scheme for the two-photon sensitisation of the dehydrogenation of the solvent is as follows:



Douzou and coworkers [140] hold the same view regarding the mechanism of the two-photon sensitisation of the dehydrogenation of alcohols by aminoacids and nucleic acid bases.

Porter and coworkers [156] recently reproduced the experiments of Shelimov and coworkers on the two-photon sensitisation of dehydrogenation of unsaturated hydrocarbons by benzene derivatibes and various polycyclic compounds, and they also suggest that the final stage in

the sensitisation mechanism is the transfer of energy from the sensitiser, photoexcited to a high triplet state, to a molecule of the solvent (hydrocarbon), which is thus excited to a triplet decomposition state.

Since there is at present insufficient information for final resolution of the problem of the mechanism of the recently discovered two-quantum reactions of sensitised decomposition, it is necessary to carry out new and comprehensive studies in this direction by a combination of various physical methods of study (spectroscopy, EPR, mass spectroscopy, photoconductivity, etc.).

Shpol'skii's Method in the Spectroscopy of Polyatomic Molecules

R.N.Nurmukhametov

This review examines various general historical aspects of Shpol'skii's method, together with the results obtained for various classes of organic compound; problems of the relationship between the form of the vibronic spectrum and molecular structure are considered, and various analytical applications of the procedure of quasi-line spectra are described briefly. The bibliography contains 161 references.

1. SHPOL'SKII'S SPECTRA. FUTURE PROSPECTS IN RESEARCH AND ITS APPLICATIONS

A molecule is a quantum system with a discrete set of characteristic energy states, but the electronic spectra of molecules usually have the form of broad bands with little structure.

In practice we study the spectra not of a single isolated molecule, but of a large number of molecules undergoing greater or lesser external perturbation. It might seem that the spectra of vapours should be closest to the spectrum of an individual molecule, but the spectra of vapours of polyatomic molecules are generally extremely unsharp. Without going into all the reasons for the lack of sharpness in the structure of the electronic bands of vapours, we would merely mention as an obvious factor the "spreading" of the vibrational sublevels of the quasi-continuous system of rotational sublevels (due to the small magnitude of $\Delta E_{rot} \simeq 1\ cm^{-1}$). As a result of this and other factors, the unsharp structure cannot be resolved, irrespective of the resolving power of the instrument. It should also be mentioned that many compounds are unstable in the vapour state.

Aromatic polyatomic molecules are usually studied in the condensed phase, in the form of liquid and solid solutions, or pure and mixed crystals. The best spectral resolution in the condensed phase is obtained at low temperatures for crystals and solid solutions. Molecular rotation is restricted at low temperature. Moreover, nonradiative processes are suppressed at low temperatures, leading to an intensification of fluorescence and the appearance of the intercombinationally forbidden $T-S_0$ emission—phosphorescence. For a long time it was assumed that the intramolecular factors leading to loss of sharpness in the structure were the principal factors, so that it was assumed to be impossible to improve the resolution of the structure by altering the molecular environment.

In 1952, Shpol'skii and coworkers[1] obtained the quasi-line spectra of a number of complex aromatic molecules in frozen crystalline solutions. The discovery of the quasi-line spectra of polyatomic molecules stimulated a large number of new studies in the field of the electronic spectroscopy of complex organic compounds. The investigation of the origin of the electronic spectrum of a molecule involves two types of problem: 1) the determination of the frequency of the electronic transition, and its interpretation; and 2) the determination of the mechanism of formation of the band contours, that is the interpretation of its vibrational structure. Problems of the first type were solved with some approximation from spectra with broad bands, but the solution of problems of the second type could be solved only by resolving the structure of the bands. Quasi-line spectra are very characteristic, and they can be used to determine with high accuracy the frequency and intensity of the purely electronic band and the vibrational frequencies combining with the given electronic transition. These spectra reflect more deeply the characteristic features of the electronic and spatial structures of a molecule (this is examined in detail in section 3). Examination of the dependence of the vibronic spectra on structure can be used to find possible answers to the following questions: why is the observed system of electronic bands characteristic of the molecule, what is the mechanism of formation of the bands (the vibrational structure), and what contribution do the various atomic groups constituting the molecule make to its electronic state? The form of the vibrational structure and its degree of resolution are closely related to the nature of the electronic transition, so that the structure can give definite information on the nature of the transition responsible for the electronic band being considered. On the other hand, if we know the relationship between the nature of a transition and the structure of the band, it is possible to predict beforehand the expected form of the vibrational structure and the changes which it undergoes with change in the nature of the electronic transition, which in turn may be changed by definite changes in the structure of the molecule.

The manifestation of the frequency ranges representing a combination or overtone of the normal vibrations makes it possible to examine the problems of the interaction of vibrations and the form of the potential surface. In particular, the decrease in the frequency range in the overtones relative to the additive sum establishes the degree of anharmonicity of the potential curve. The interpretation of the vibrational structure makes it possible to determine which vibrations are involved in the most effective conversion of the electronic excitation energy into vibrational energy. Quasi-line absorption spectra reveal the frequencies of the vibrations of molecules in electronically excited states. Thus the examination of these spectra provides a simple method for determining the vibrational frequencies of excited molecules.

At first, the range of molecules studied was restricted to aromatic polycyclic condensed hydrocarbons. These molecules have a rigid planar structure, and this facilitates

resolution of the vibrational structure of the bands, which, moreover, are determined in the near ultraviolet and visible ranges by the same type of $\pi-\pi^*$ transition. It was not clear whether it was possible to obtain a quasi-line spectrum for molecules containing heteroatoms. In 1958, Shigorin and coworkers[2] reported the quasi-line luminescence spectrum of anthraquinone and its derivatives. Subsequently, Shpol'skii's method was successfuly extended to the molecules of compounds of various classes. A quasi-line structure was not always obtained, particularly for molecules with a non-rigid structure, but a sufficiently clearly resolved vibrational structure, suitable for analysis, was often attained. From the degree of resolution, in turn, it was possible to obtain information on the intramolecular factors leading to loss of sharpness of the bands, and on the spatial structure of the molecules. The stabilisation of certain radicals in solid matrices at low temperatures makes it possible to obtain Shpol'skii's quasi-line spectra not only for molecules, but also for radicals (see R.p. 355).

A large number of studies have been devoted to the vibronic spectra of aromatic molecules, with a chain structure, widely used as scintillating additives (polyphenyls, diphenylpolyenes, arylethylenes, aryloxadiazoles, diarildivinylbenzenes, arylnaphthoxazoles, benzoxazoles, etc.). Shpol'skii's method has been used to study the spectra of aromatic aldehydes, ketones, diketones, various dyes and related compounds (xanthone, acridones, phthalimides, thioindigoids, and indigoids), and *N*-heteroaromatic molecules (the aza-heteroanalogues of triphenylene, quinoline, and bipyridyls). Finally, a quasi-line structure has been obtained for the spectra of the complex molecules of phthalocyanines and porphyrins.

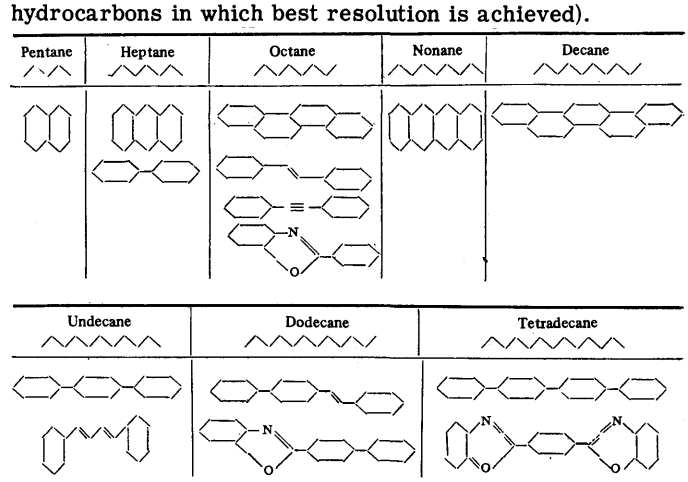
To obtain quasi-line spectra, Shpol'skii and coworkers used a comparatively simple procedure, which can be described briefly as follows: 1) highly dilute solutions with concentrations of $10^{-4}-10^{-5}$ M are used, so that there is almost no interaction between the dissolved molecules; 2) inert neutral solvents—saturated n-hydrocarbons—are used as media; 3) the solutions are cooled to low temperature (77, 20, and 4 °K) and are frozen to form a crystalline mass; and 4) the spectra of these frozen solutions are studied.

By the use of mixed solvents, Shpol'skii's method was extended to compounds which do not dissolve directly in n-hydrocarbons. Thus the spectra of phthalocyanines was obtained with a solution in acetone[3], which was then diluted with n-hydrocarbons. When a benzene solution of perylene was diluted with hexane, the spectrum obtained did not differ from the spectrum of the pure hexane solution[4]. Indigo and indigoids were dissolved in hexane by means of a dioxan solution[5]. A similar technique was used to obtain the spectra of *N*-substituted acridones[6,7].

The range of matrices in which a quasi-line structure can be obtained has been extended. Sponer, Kanda, and coworkers[8-10] showed that these spectra are also obtained in a cyclohexane matrix. Sheremet'ev and Val'dman[11] obtained the quasi-line spectrum of perylene in dibenzylaminoethanol. We showed for the example of pyrene in poly-2-methylpropene[12,13] that it is possible to resolve a quasi-line structure in a polymeric matrix. It has been reported[4] that the spectra of pyrene show a quasi-line structure in hexanol at 77 °K.

A remarkable characteristic feature of quasi-line spectra is the frequently observed multiplet structure of the vibronic bands, so that the spectrum consists of the superposition of several identical molecular spectra, displaced relative to one another. The degree of resolution and the multiplet structure of the bands are found to be very characteristic of the solute–solvent system. Analysis of the characteristic features of quasi-line spectra established one important reason for the loss of sharpness in the spectra of solid solutions—non-uniform perturbation of the electronic levels of the dissolved molecules by the field of the environment (as a result of non-uniformity of the matrix) leading to dispersion of the energies (frequencies) of the electronic transitions in the set of molecules. Experiment shows that it is possible to eliminate this dispersion by choice of a suitable solvent. Although there is no general rule for the selection of a solvent in which we can expect the best resolution of the structure for a given compound, in some instances it is possible to use a relationship established by Bolotnikova[14-16], who showed that the best resolution of the spectra of polyacenes is observed in those hydrocarbons whose molecular dimensions are close to those of the polyacene. Thus the best resolution was obtained in pentane for naphthalene, in heptane for anthracene, and in nonane for naphthacene (Table 1). A similar result was obtained for the angular hydrocarbons chrysene[17], picene[18], and benzanthracene[19]. Gobov[20,21] showed that this rule is applicable for the biphenyl–terphenyl–quaterphenyl series, for the diphenylpolyenes stilbene and diphenylbutadiene, and for various benzoxazoles[22] (see Table 1). It is not a universal rule, however. As

Table 1. The role of correspondence in the dimensions of the molecules of the solvent and the luminophor in improving the resolution of the vibrational structure of electronic bands. The upper row gives the carbon frameworks of the n-hydrocarbon molecules, and the lower row gives the frameworks of the luminophor molecules (under the n-hydrocarbons in which best resolution is achieved).



an illustration, we would point out that the spectrum of 1,4-distyrylbenzene, whose molecule is longer, by the length of the styryl group, than that of stilbene, is most clearly defined in hexane[23], and not in n-hydrocarbons with a longer chain. The high sensitivity of the structure to the solvent, concentration, and method of freezing, and in some instances to the presence of impurities, provides an effective indicator for the study of the fine effects of intermolecular interaction.

We shall not consider in detail experimental data on the investigation of the nature of the multiplet structure[24-26]; these are discussed in detail in reviews by Shpol'skii[4,27-30]. The aim of the present review is to examine the progress made in the study and interpretation of the vibronic spectra of molecules of various classes, and the new information which has been obtained on the relationship between electronic spectra and structure (the manifestation, in the spectra, of the characteristic features of the electronic transition and the electronic and spatial structures of the molecules, particularly in the excited state). A quasi-line structure cannot be obtained for all molecules. In the present review an attempt is made to determine which factors of the intramolecular structure influence the resolution (or lack of resolution) of the structure.

The high sensitivity and characteristic nature of quasi-line spectra have provided a basis for a number of spectroscopic-analytical methods for the qualitative and quantitative determination of substances in various products. These problems will be examined in section 4.

2. THE QUASI-LINE SPECTRA OF VARIOUS CLASSES OF COMPOUND

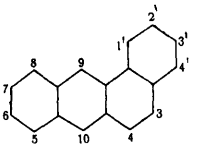
Aromatic polycyclic condensed hydrocarbons. The compounds of this class which have been studied by Shpol'skii's method are given in Table 2; for all of these, a quasi-line structure has been obtained in a suitable solvent. A general characteristic feature of the vibrational structure of the electronic bands for compounds of this class is that the frequencies of the normal vibrations of the carbon framework predominate. The vibrational frequencies active in the luminescence spectra correspond to the vibrations of the molecule in the ground electronic state and are equal to or very close to the frequencies active in the Raman spectrum of the same compound. Another characteristic feature of the structure of the electronic bands of aromatic hydrocarbons is the appearance of common frequencies with very similar values. An analogous picture of very similar frequencies is observed in the infrared spectra of various aromatic hydrocarbons, so that the spectra are not characteristic, and are unsuitable for analytical purposes. We shall not deal in detail with the problems of the relationship between the vibronic spectra and the structure of molecules of this class, since this has already been done[62].

Table 2. Aromatic condensed hydrocarbons with quasi-line spectra which have been studied.

Compound	References	Compound	References
Benzene	8,31,32	1,2,4,5-Dibenzpyrene	48
Naphthalene	15,33-35	3,4-Naphtho-6,7-benzpyrene	47
Anthracene	14,16,36,37	3,4,8,9-Dibenzpyrene	48
Naphthacene	14,16,37	1,12-Benzperylene	49,50
Phenanthrene	38-41	Perylene	51-53
Benzanthracene	19	Triphenylene	54,55
Chrysene	17	Fluoranthene	56
Dibenzanthracene	14	Fluorene	8,57,58
Pyrene	14,42,43	Acenaphthene	58,59
1,2-Benzpyrene	44	Rubicene	60
3,4-Benzpyrene	45	Azulene	61
Picene	18,46	Pentacene	46
Penthaphene	46	Benznaphthalene	46

Aromatic hydrocarbon radicals. Grajcar and Leach[63] obtained absorption spectra ($\nu_{0-0} = 21\,580\,cm^{-1}$) and fluorescence spectra ($\nu_{0-0} = 21\,630\,cm^{-1}$) showing considerable structure for the benzyl radical at 77°K in a methylcyclohexane + 3-methylpentane (2:3) matrix. The fluorescence spectra showed vibrational frequencies of 570, 965, 1050, 1295, and 1460 cm^{-1}, some of which are close to the vibrational frequencies of benzene. Ripoche[64] studied the fluorescence spectra at 88°K for benzyl radicals, again produced by the photolysis of toluene, in new matrices—cyclopentane, methylcyclopentane, and methylcyclohexane. Under these conditions he obtained quasi-line spectra with a large number of quasi-lines; he made a detailed vibrational analysis and assigned the frequencies to definite types of normal vibration. Vibrational frequencies were distinguished at 363, 532, 820, 872, 982, 1017, 1087, 1145, 1376, 1439, 1475, 1540, and 1593 cm^{-1} (in cyclopentane). Mileshina and coworkers[65] obtained the quasi-line fluorescence spectrum of the diphenylmethylene biradical in a hexane matrix at 77°K. This spectrum is due to a $T^* \rightarrow T_0$ transition (the ground state of diphenylmethylene is a triplet state) and is interpreted by means of the frequencies 630, 800, 1012, 1170, and 1600 cm^{-1}, which are close to the vibrational frequencies of the benzene ring, active in the fluorescence spectra of the benzyl and triphenylmethyl radicals.

Substituted aromatic hydrocarbons. The introduction of substituents influences the electronic structure, electronic transitions, symmetry, and spatial configuration of the molecule, and alters its dimensions and the nature of its interaction with solvent molecules. All this is reflected not only in the position and intensity of the electronic bands, but also in the nature of the vibrational structure and its degree of resolution. Let us consider first the spectra of alkyl, halogeno, and vinyl derivatives of aromatic hydrocarbons. Kharitonova[66] studied the quasi-line spectra of α- and β-methylnaphthalenes in hexane at 20°K. Dikun[67,68] obtained the quasi-line spectra of ~ 40 derivatives of 1,2-benzanthracene with alkyl and halogeno substituents.



Fenina[19,69] carried out a more detailed study and interpretation of the vibrational structure of the fluorescence spectra of 1,2-benzanthracene and all its monomethyl derivatives, and from the quasi-line spectra determined the frequencies of the long-wave ^1L_b–$^1A_1$ transition. The maximal long-wave displacement (450 cm^{-1}) was observed when the CH_3 group was introduced into position 9 or 10, a marked displacement was observed for the 3-methyl derivative (300 cm^{-1}), approximately equal medium displacements of 100 cm^{-1} were observed for substitution in the 1'-, 2'-, 4'-, and 7-positions, a small displacement was observed for the 3'-, 5-, 8-, and 4-CH_3 derivatives, and 6-CH_3-benzanthracene even showed a slight short-wave displacement. The values of the displacements only in a few instances agree with the predictions of the theory of the influence of alkyl substituents on the energy of the electronic transitions of benzanthracene. On the basis of an analysis of the quasi-line absorption spectra it was concluded that the frequency of the ^1L_a–$^1A_1$ transition in benzanthracene is 1600–1700 cm^{-1} higher than the frequency of the ^1L_b–$^1A_1$ transition. The spectra of all the derivatives

except the 3-methyl derivative were sharper in octane. The spectra of the 3-methyl derivative are equally sharp in hexane and heptane, and less sharp in octane.. The sterically hindered substituents in positions 9 and 1′ produce a marked decrease in the sharpness of the structure. Utkina [70-72] made a systematic study of anthracene derivatives, and showed that the introduction of alkyl substituents (methyl, ethyl, and propyl) lowers the frequency of the electronic transition by about 700–750 cm^{-1}, and the introduction of two alkyl substituents produces a displacement which is approximately twice this value. The attachment of an allyl radical with the $-CH=CH_2$ double bond isolated from the π system of the anthracene nucleus produces the same displacement of the spectra as alkyl radicals. When the double bond is conjugated (in 9-vinylanthracene), however, the long-wave displacement of the band amounts to about 2000 cm^{-1}, that is by an amount characteristic of an increase in the π system by a double bond in the direction of the electronic transition being considered. The structure of the fluorescence spectrum is less sharp, the greater the steric hindrance in the molecule. A particularly marked decrease in sharpness is observed as a result of the introduction of vinyl groups. The phenanthrene derivative retene gave a quasi-line structure very similar to the structure of the spectra of the unsubstituted molecule. A quasi-line structure was also obtained for halogenopyrenes. The introduction of halogens improves the resolution of the structure considerably. Val'dman [11] obtained a quasi-line fluorescence spectrum for a complex derivative of perylene—di-isobutyl perylene-3,9-dicarboxylate. Hydrocarbon derivatives containing the electron-donating groups NR_2, NR, OR, and SR (aromatic amines, ethers, and thioethers) will be examined below.

N-Heteroanalogues of aromatic hydrocarbons have been studied by Shpol'skii's method to a much smaller extent, apparently due to the difficulties encountered in the resolution of their structure. In the first place, many of these compounds either do not show fluorescence, or show only weak fluorescence in non-polar solvents, because of strong deactivation due to singlet–triplet conversion with the participation of excited $n-\pi^*$ states [73-76]. Secondly, thanks to the presence of the n electrons of the N atom, these molecules readily undergo association with polar molecules, traces of which are almost always present in hydrocarbon solvents.

Mamedov described the quasi-line phosphorescence spectra of quinoline in hexane [77] and pentane [78] and of 5,6-benzquinoline in hexane [78]. Ruziewicz [79,80] resolved the structure of the phosphorescence bands of 1,4-diazotriphenylene and 1-azotriphenylene. El-Sayed [81] reported the quasi-line structure of the luminescence band of pyridazine in hexane.

Polyphenyls and diphenylpolyenes. Gobov [20,21,82-84] described the structure of the luminescence spectra of biphenyl, terphenyl, and quaterphenyl at 77 °K, and showed that the best resolution of the structure for the longer polyphenyl molecules is obtained in the hydrocarbons with longer chains: in hexane and heptane for biphenyl, in undecane for terphenyl, and in cetane ($C_{15}H_{30}$) for quaterphenyl. The fluorescence band of the O–O transition has a frequency of 33 355 cm^{-1} in biphenyl, and lower values of 30 715 cm^{-1} in terphenyl and 28 080 cm^{-1} in quaterphenyl, that is the frequency is reduced by about 2600 cm^{-1} with increase in the size of the molecule by one phenyl unit. A common characteristic of the structures of the fluorescence spectra of polyphenyls is the predominance of the frequency of the antisymmetric pulsating vibration of the benzene ring at 1600 cm^{-1}. In the spectra of terphenyl and quaterphenyl it forms intense progressions, determining the periodic form of the structure. The range of their fluorescence bands is determined by the overtones 4×1600 cm^{-1}. Biphenyl gives a structured phosphorescence band with $\nu_{0-0} = 22\,905$ cm^{-1}; visible phosphorescence is not observed for terphenyl and quaterphenyl.

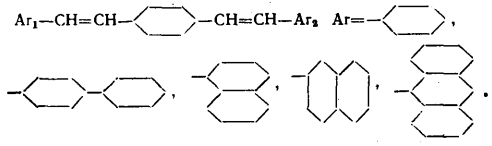
As early as 1935, Hausser and coworkers [85] made a systematic study of the absorption and luminescence spectra of a series of diphenylpolyenes with $n = 1-7$. They observed a regular displacement of the spectra towards longer wavelengths with increase in the number of polyene groups in the molecule. The structures of the fluorescence spectra of diphenylpolyenes are very similar and are described by a series formula $\nu = \nu_0 - 1550\,n_1 - 1660\,n_2$, where $n_1 = 0.1$, $n_2 = 2.3$, and ν_0 has values 29 730 cm^{-1} for stilbene ($n = 1$), 27 250 cm^{-1} for diphenylbutadiene ($n = 2$), 24 900 cm^{-1} for diphenylhexatriene ($n = 3$), 22 135 cm^{-1} for $n = 4$, and 19 870 cm^{-1} for $n = 5$. The vibrational structure of the spectra of stilbene was subsequently studied many times. Gobov [83] and Levshin and Mamedov [86] resolved the vibrational structure of the fluorescence band and the long-wave absorption at 77 °K in octane. Malykhina and Shpak [87] studied the quasi-line spectra in polarised light for an octane–stilbene single crystal, and Dyck and McClure [88] made a similar study of a bibenzyl–stilbene single crystal. The frequency of the $S_1^*-S_0$ transition for stilbene is 30 034 cm^{-1} in octane and 29 903 cm^{-1} in bibenzyl. All the authors cited showed that the form of the spectrum is determined chiefly by the progressions of the frequency of the stretching vibration of the ethylene group ($\nu_{C=C}$ = 1640–1659 cm^{-1} in fluorescence, and 1600 cm^{-1} in absorption). The spectrum also shows another seven frequencies, observed independently and in combination with the above frequency; most of these seven frequencies are assigned to the skeletal vibrations of the benzene rings.

The structured fluorescence spectra of stilbene, diphenylbutadiene, and diphenylhexatriene show considerable resemblances to the spectra of polyphenyls. Their structure has a similar periodic form, determined by the progressions of the frequency of the stretching vibration of the ethylene and polyene groups. This frequency lies at 1640 cm^{-1} in stilbene, 1616 cm^{-1} in diphenylbutadiene, and 1600 cm^{-1} in diphenylhexatriene (for the latter, only a coarse vibrational structure is observed; the spectrum [89] consists of broad bands with $\Delta\nu \simeq 400$ cm^{-1}). The band for the O–O transition in stilbene (30 034 cm^{-1}) is very close to the band for terphenyl (30 715 cm^{-1}), and the band for diphenylbutadiene (27 948 cm^{-1}) is very close to the band for quaterphenyl (28 080 cm^{-1}), so that the replacement of the internal phenyl units in the polyphenyl chain by an ethylenic bond does not alter significantly the position of the absorption and fluorescence bands of this chain π system. This is true, however, only for the initial members of the polyphenyl series; with further increase in the length of the polyphenyl chain, the decrease in the frequency of the long-wave transition is much smaller than that for increase in the length of the polyene chain in diphenylpolyenes [90].

Arylethylenes. Fluorescence spectra of arylethylenes in n-hydrocarbons at 77 °K, with the most clearly defined structures, were obtained [89,91] for phenylstilbene in undecane and dodecane, and for di-α-naphthylethylene, di-β-naphthylethylene, α-naphthyl-β-naphthylethylene, and β-naphthylphenylethylene in hexane. The fluorescence

spectrum of diphenylstilbene in all n-hydrocarbons can be resolved only into broad bands ($\Delta\nu \simeq 300$ cm^{-1}). Decrease in temperature to 20°K did not lead to additional resolution of the structure of the spectrum of phenylstilbene; only a slight decrease in the width of the bands was observed[89]. A characteristic common feature of the vibronic spectra of arylethylenes is the periodic form of the structure. The period interval is a frequency in the range 1600–1640 cm^{-1}, assigned to the stretching vibration of the ethylenic bond. The frequency decreases with increase in the weight of the aryl radicals and with increase in the efficiency of the conjugation (estimated from the decrease in the frequency of the electronic transition). In the fluorescence spectra it has the value 1640 cm^{-1} for stilbene, 1635 cm^{-1} for β-naphthylphenylethylene, 1620 cm^{-1} for phenylstilbene, 1610 cm^{-1} for α-naphthyl-β-naphthylethylene, and 1600 cm^{-1} for di-α-naphthylethylene. The width of the fluorescence band for these molecules is determined by the range 4×1600 cm^{-1}, and the maxima in the fluorescence spectrum at room temperature are separated from one another by about 1600 cm^{-1}.

Diaryldivinylbenzenes



The fluorescence spectra have been studied[23] at 77°K in hexane, heptane, octane, nonane, undecane, and heptadecane solutions. A well resolved vibrational structure was obtained for most compounds. The narrowest bands were obtained for solutions of distyrylbenzene and di-β-naphthyldivinylbenzene in hexane. The bands in the fluorescence spectra of bis(biphenyl)-, di-β-naphthyl, β-naphthylphenyl-, α-naphthylphenyl-, and biphenylphenyldivinylbenzenes were found to be more diffuse, but the fluorescence spectrum of dianthryldivinylbenzene has very narrow bands. The poor resolution of the structure for the latter compounds is due to the appreciably non-planar structure of the molecule, resulting from considerable steric hindrance. A common characteristic feature of the structured spectra of diaryldivinylbenzenes is the periodic form of the structure, in which the frequencies of the range 1550–1520 cm^{-1}, corresponding to the stretching vibrations of the divinylbenzene group and its overtones, predominate.

Arylacetylenes. Gobov[83] described the structure of the luminescence and absorption spectra of tolane in n-octane. The fluorescence spectrum was interpreted by means of the frequencies 260, 524, 700, 1000, 1150, 1493, 1600, and 2232 cm^{-1}; the same frequencies, with the exception of 524 cm^{-1} and 1493 cm^{-1}, were distinguished in phosphorescence. The 2232 cm^{-1} frequency, which is the most characteristic of the spectrum and combines with the other frequencies, shows appreciable anharmonicity and is assigned to the stretching vibration of the acetylenic group. In the absorption spectrum the frequency is lowered to 2150 cm^{-1}. The 1000 cm^{-1} and 1600 cm^{-1} frequencies were interpreted as characteristic frequencies of the benzene rings.

The structures of the long-wave absorption, fluorescence, and phosphorescence spectra of phenylacetylene have been described[92]. The triple bond vibrational frequency, whose value is lowered to 2100 cm^{-1} as a result of kinematic factors, is also active in the luminescence spectra. This frequency, however, does not predominate in the spectrum, and the frequencies of the benzene ring, particularly the 1600 cm^{-1} and 1000 cm^{-1} frequencies, are equally active. In agreement with the low intensity of the long-wave absorption band, a relatively low intensity is observed for the O–O band, indicating an electronic transition partly forbidden by symmetry. The superposition of the incompletely symmetrical vibration at 600 cm^{-1} partly removes the forbidden character. This is characteristic of benzene derivatives such as phenylacetylene, styrene, biphenyl, and naphthalene. The transition is not forbidden in phosphorescence. Phenylacetylene and tolane are characterised by a difference in the $S_1^* - T$ splitting of 10 000 cm^{-1}, which is the same as that in the polyacene series. Bagratishvili and coworkers[93] obtained the quasi-line fluorescence and phosphorescence spectra of bi-β-naphthyl, whose molecule is appreciably non-planar due to steric hindrance. The band structure contains many "naphthalene" frequencies.

Benzoxazoles and naphthoxazoles. The quasi-line fluorescence spectra of 2-phenylbenzoxazole, 2-biphenylylbenzoxazole, 2-styrylbenzoxazole, 1,4-di-(2′-benzoxazolyl)-benzene, and 1,4-di-(2′-benzoxazolyl)-ethylene in n-hydrocarbon solutions at 77°K have been described and interpreted[22]. It was shown that the fluorescence spectrum is determined by the $\pi-\pi^*$ transition, and that the π system of these molecules is isoelectric with the π system of the corresponding arylethylenes, for example the phenylbenzoxazole and stilbene molecules are π isoelectronic. The interaction of the unshared pairs of electrons of the O and N heteroatoms appears to lead to mutual exclusion of their influence on the π electronic system. The similarity in the π electronic structures leads not only to similar electronic bands and identical luminescence and scintillation properties, but also to an identical mechanism of formation of the vibrational structure of the bands. The structure of the spectra is characterised by a periodicity. The period corresponds to the stretching vibrations of the internal connecting group. In the phenylbenzoxazole molecule this is the C–N bond of the oxazole ring, and the predominant frequencies in the structure are those at 920, 1550, and 1610 cm^{-1}, which, according to the interpretation of the vibrational spectra[94] are the characteristic vibrations of the oxazole ring. In the molecules of 2-biphenylylbenzoxazole and 1,4-di-(2′benzoxazolyl)-benzene, the internal connecting group consists of a C=N bond and a phenyl ring; in the structure of the spectrum, the 1600 cm^{-1} vibrational frequency of the phenyl ring is correspondingly more active. In the molecules of 2-styrylbenzoxazole and 1,4-di-(2′-benzoxazolyl)-ethylene, this frequency is replaced by the vibrational frequency of the ethylenic group at 1640 cm^{-1}. The structures of the absorption spectra of these compounds have been obtained and analysed[95]. Very clearly defined structures were observed for the vibronic fluorescence and absorption spectra[96] of phenylnaphthoxazoles; the biphenylylnaphthoxazoles showed a less clearly defined structure. Their electronic bands were found to be similar to the bands of the corresponding naphthylphenylethylenes and biphenylnaphthylethylenes.

Aromatic amines, alcohols, and ethers. The electronic long-wave absorption and luminescence bands of amino- and *N*-dialkylamino-derivatives of aromatic hydrocarbons in solution at room temperature have the form of broad structureless bands. In vitreous solutions at low temperature, these are resolved into a number of comparatively broad bands. Ermolaev[97] described fluorescence and phosphorescence spectra of this type, with a

coarse vibrational structure, for a number of aromatic amines in EPA solutions (petroleum ether + ethanol + 3-methylbutane) at 77°K. For those compounds in which the amino-group is not included in the rigid framework and is capable of rotating relative to the C–N axis (for example in aniline, dimethylaniline, diphenylamine, and triphenylamine), it is not possible to observe greater resolution of the structure in n-hydrocarbon solutions compared with vitreous solutions. When the amino-group is rigidly fixed in the molecule, however, a quasi-line structure can be obtained. The spectra of carbazole in hexane and heptane have been obtained[98], and the quasi-line spectra of acridan have been described[7]. The fluorescence and phosphorescence spectra of these molecules show purely electronic bands of high intensity, indicating that the transitions are allowed. The skeletal vibrations, particularly that of the benzene ring at 1600 cm^{-1}, are active in the structure. Attempts to obtain an effectively resolved structure for the electronic bands of aromatic alcohols and ethers, such as phenol, naphthols, anisole, methoxynaphthalenes, etc. in n-hydrocarbon solutions did not give positive results. When the –O– or –S– bridge is part of a rigidly fixed structure, quasi-line spectra can be obtained (diphenylene oxide and diphenylene sulphide)[98]. The quasi-line fluorescence and phosphorescence spectra of diphenylene oxide have been described[100]. The quasi-line spectra of diphenylene oxide and carbazole have been studied[99,100].

Aldehydes and ketones. The luminescence spectra of aliphatic aldehydes—formaldehyde, acetaldehyde, propionaldehyde, and butyraldehyde—and ketones—acetone, diethyl ketone, methyl ethyl ketone, cyclohexanone, cyclopentanone, and cycloheptanone—in the vapour state and in n-hydrocarbon solutions frozen at 77°K have been studied[101]. Emission bands with little structure were observed in the vapours and solutions; slight improvement in the structure in solutions was observed for the aldehydes on going from butyraldehyde to acetaldehyde. The emission was attributed to the $T_{n-\pi^*}-S_0$ transition. The $n-\pi^*$ phosphorescence and long-wave $n-\pi^*$ absorption spectra of aromatic aldehydes and ketones (benzaldehyde, acetophenone, benzophenone, and their derivatives) are resolved in n-hydrocarbons at 77°K to give a few broad bands, as in the vitreous solutions[102,103]. The only frequencies which can be clearly distinguished in their structure are those of the stretching vibration of the C=O group, which form an intense progression. In the phosphorescence bands this frequency has the value 1680–1660 cm^{-1}, corresponding to the vibration in the ground electronic state, but in the absorption bands it is lowered to 1200 cm^{-1}, indicating a considerable decrease in the strength of the C=O bond in the excited $n-\pi^*$ state. In this state there is also a significant increase in the equilibrium distance in the C=O group, and this determines the nature of the distribution of the band intensities. When the keto-group forms part of a rigid structure, a quasi-line structure can be observed for the $n-\pi^*$ phosphorescence. Shigorin and Shcheglova[104] reported the quasi-line phosphorescence spectrum of anthrone, and we reported that of anthraquinone[2,25]. A detailed analysis of the quasi-line structure of the $n-\pi^*$ phosphorescence spectrum of anthraquinone was carried out[25]. It was shown that the $\nu_{C=O}$ frequency forms predominant progressions and combines with all other vibrational frequencies active in the spectrum. In aromatic aldehydes and ketones with $\pi-\pi^*$ phosphorescence, it is possible to obtain a quasi-line structure for its band, as shown for the example of biphenylaldehyde and α- and β-naphthaldehydes[105].

Derivatives of anthraquinone and other quinones. Shigorin and coworkers[106-111] studied the influence of the intramolecular interaction of various atomic groups in these compounds on the quasi-line luminescence and long-wave absorption spectra. It was shown that the introduction of various β-substituents (β-halogeno[2,25], β-carboxy, β-carbalkoxy[106], and β-alkyl[107]) into the anthraquinone molecule does not alter the nature of the luminescence band. The luminescence spectra of β-substituted anthraquinones are determined by the $n-\pi^*$ phosphorescence and exhibit a vibrational structure similar to that of the spectrum of anthraquinone, in which a progression of the vibrational frequency of the CO group of the anthraquinone ring predominates. The β-substituents produce only a slight change in the position of the spectrum and the multiplicity of its bands. The introduction of α-substituents (α-alkyl, α-aryl[107], and α-halogeno[108]) leads to a marked long-wave displacement of the absorption bands and to the appearance of a fluorescence band, often with an indistinct structure. Particularly marked changes are produced by α-hydroxy substituents and their ethers[111]. For the former, this can be attributed to the production of a stable intramolecular hydrogen bond with the formation of a quasi-aromatic ring. The formation of a ring of this kind has been assumed to be responsible for the production of a quasi-line structure in the absorption and fluorescence spectra of 1,4-dihydroxyanthraquinone and 1,2,5,8- and 1,4,5,8-tetrahydroxyanthraquinones, which are displaced considerably towards longer wavelengths compared with the spectra of anthraquinone. The influence of the nature and position of the substituent on the structure of the spectra for a series of naphthoquinone derivatives has been studied[110], and the dependence of the spectra of quinones on the number and relative arrangement of the keto-groups in the aromatic ring (anthrone, phenanthrenequinone, and anthraquinone) has been investigated[104].

Esters of dicarboxylic acids. Ivanova[111] recorded the structure of the fluorescence spectra of two diethyl esters of ω,ω′-dicarboxylic acids. Distinct resolution of the structure of the spectrum of $C_2H_5OOC.(CH=CH)_6COOC_2H_5$ was observed in n-octadecanol (half-width of the bands about 30–50 cm^{-1}), with initial ν_{0-0} band at 20023 cm^{-1}. The fluorescence bands of the ester $C_2H_5COO(CH=CH)COOC_2H_5$ were found to be more diffuse ($\Delta\nu \simeq 150$ cm^{-1}) and approximately the same in dodecane, cetane, and octadecanol. The most characteristic frequencies in the structure of the spectra were 1550 cm^{-1} and 1140 cm^{-1}, assigned to the stretching vibrations of the polyene chain. The long-wave absorption and fluorescence bands are determined in these esters by a $\pi-\pi^*$ transition, so that the characteristic frequencies of the carboxyl group do not appear distinctly in the structure.

Xanthone and acridones. The xanthone molecule contains two oxygen atoms joined in different ways to the π system, and the interaction of these atoms is responsible for a number of remarkable characteristic features. Under the influence of the electron-donating –O– bridge, the energies of the $n-\pi^*$ transitions are increased, and the energies of the $\pi-\pi^*$ transitions are decreased, so that the $n-\pi^*$ absorption band is partly overlapped by the $\pi-\pi^*$ band, although it remains a long-wave band, and the $T_{n-\pi^*}$ and $T_{\pi-\pi^*}$ levels have very similar energies, so that inversion of the positions of the $T_{n-\pi^*}$ and $T_{\pi-\pi^*}$ levels is observed[112] under the influence of solvent. In n-hydrocarbon solutions, xanthone exhibits short-lived $n-\pi^*$ phosphorescence, and in alcohol it exhibits long-lived $\pi-\pi^*$

phosphorescence. In hexane and heptance solutions at 77°K a quasi-line structure was obtained for the $n-\pi^*$ phosphorescence bands and two absorption bands, associated with the $\pi-\pi^*$ transitions ($\nu_{S_2^*-S_0}$ = 29 575 cm^{-1} and $\nu_{S_3^*-S_0}$ = 35 370 cm^{-1}). Under the same conditions, however, the $n-\pi^*$ absorption band remains diffuse. This makes it possible to define more precisely one of Kasha's distinguishing criteria for $n-\pi^*$ and $\pi-\pi^*$ bands, which says that in a condensed phase the $n-\pi^*$ bands are diffuse, whereas the $\pi-\pi^*$ bands have more structure. The example of xanthone shows that this is true only for the $n-\pi^*$ absorption bands, but not for $n-\pi^*$ phosphorescence.

The vibrational structure of the phosphorescence spectrum of xanthone has a very characteristic periodic form, determined by the fact that the $\nu_{C=O}$ frequency forms intense progressions and combines with all other vibrational frequencies. The values of the frequencies decrease in the overtones, indicating anharmonicity of the vibration of the C=O group. In the $\pi-\pi^*$ absorption bands, this predominance of one of the frequencies, which would be close to the frequency of vibration of the C=O group, is not observed.

In the acridone molecule the –NH– bridge is a stronger electron-donating substituent, so that the lower excited S_1^* and T levels are $\pi-\pi^*$ levels. Acridone itself does not dissolve in n-hydrocarbons, but its N-substituted derivatives can be studied in hexane by diluting the latter with a dioxan solution[7]. For the N-methyl, N-ethyl, and N-phenyl derivatives of acridone it has been possible to obtain a quasi-line structure for the $\pi-\pi^*$ phosphorescence band, in which the frequencies of the skeletal vibrations are active. Although the vibrational frequency of the C=O group appears in the spectrum, it is not the predominant frequency.

Phthalimides and naphthalimides. Although the absorption and phosphorescence spectra of phthalimide and its N-substituted derivatives in solid glasses at 77°K show a coarse vibrational structure[113-115], the first attempts to obtain the quasi-line structure of the absorption bands in n-hydrocarbons were unsuccessful[114,115]. This was due chiefly to the low solubility of the phthalimides in n-hydrocarbons. Phthalimide itself is almost insoluble, and its N-substituted derivatives readily precipitate from solution on cooling to 77°K, so that the concentration is insufficient for observation of the absorption spectrum of the solution, We were able[116] to obtain the quasi-line structure of the phosphorescence spectrum of N-methylphthalimide in hexane at 77°K; the spectrum consisted of a large number (more than 30) of closely situated quasi-lines. There are no predominant frequencies in the structure, and intervals close to the frequency of the stretching vibration of the C=O group do not appear distinctly. This characteristic feature of the structure is an important additional argument for assigning the phosphorescence of phthalimide to the $\pi-\pi^*$ transition.

The molecule of naphthalimide differs from that of phthalimide in its more extensive π system, and this leads to a different arrangement of the singlet and triplet $n-\pi^*$ and $\pi-\pi^*$ levels and the production of fluorescence in naphthalimide. In hexane at 77°K the fluorescence spectrum consists of a broad diffuse band, on which a number of narrow intense bands are superimposed. Better resolution of the structure could not be obtained in n-hydrocarbons, however.

Thioindigoids and indigoids. Nurmukhametov and coworkers[5,117,118] studied the vibronic spectra of thioindigoid and indigoid dyes, to investigate the nature of the electronic transition determining their colours. The fluorescence spectrum of thioindigo[118,119] is resolved in hexane and heptane into 12 narrow bands, which are less distinct in other n-hydrocarbons, beginning at octane. These bands were interpreted from the initial resonance O–O band at 18 308 cm^{-1} (in hexane) by means of the frequencies 220, 480, and 1540 cm^{-1}. The last frequency is the most characteristic in the spectrum, and it combines with the other frequencies, and this determines the two-fold repeated form of the structure of the emission band. The nature of the distribution of intensity in the spectrum indicates that the transition is allowed by symmetry and the Franck–Condon principle. The 1540 cm^{-1} frequency is assigned to the stretching vibration of the central ethylenic group. A similar structure is observed in absorption, interpreted by means of the frequencies 220, 480, and 1500 cm^{-1}. Although the molecule contains two carbonyl groups, their characteristic frequencies, which according to the infrared spectra of thioindigo should have the value 1650 cm^{-1}, do not appear in the structure. A possible explanation is that the long-wave transition of the thioindigo molecule is a $\pi-\pi^*$ transition, in which the excitation energy is concentrated to a large extent on the C=C group, and not on the C=O groups, as in an $n-\pi^*$ transition. This interpretation of the spectrum of thioindigo agrees with its ready cis-trans photoisomerisation, established by Rogers, Margerum, and Wyman. Photoisomerisation requires concentration of the excitation energy in the C=C bond.

The structure of the spectra of various derivatives of thioindigo and related molecules[13], whose formulae are given in Table 3, have also been studied. Their spectra preserve the general characteristic features of the thioindigoid spectrum.

Table 3. Vibronic spectra (at 77°K) of arytoxadiazoles, arylbenzoxazoles, thioindigoids, and indigoids (absorption and fluorescence).

Although the indigo molecule differs from that of thioindigo only in the replacement of S atoms by NH groups, the colours differ significantly: crystals of the former are deep blue, whereas those of the latter are red. For isolated indigo and thioindigo molecules, the differences in absorption are much smaller. Study of the structure of the vibronic spectra of these molecules has made possible

a more valid explanation of their common and individual properties. Indigo does not dissolve directly in n-hydrocarbons. The structure of the fluorescence and absorption spectra were obtained at 77 °K by diluting the dioxan solution with hexane in the ratio 1 : 15.[5,117] The form of the structure is similar to that for thioindigo, but the range of the spectrum is shorter, the number of bands is smaller (6), and the intensity of the O–O band with frequency 16 440 cm^{-1} relative to the other vibronic bands is much higher. The definite similarity in the quasi-line spectra of thioindigo and indigo indicates that their colours are determined by electronic transitions of the same character, and the main contribution to the excited state is made by the C=C group, whose vibrational frequency is most characteristic for the structure of the band due to this transition. The –NH– bridges in indigo are stronger auxochromes than the –S– bridges in thioindigo, leading to a more marked (by 1900 cm^{-1}) bathochromic shift in the band and a higher intensity for the O–O band.

Study of indigo derivatives (see Table 3)[5,117] showed that halogeno substituents have little influence on the structure and position of the fluorescence spectrum, showing their greatest influence on the relative intensity of the O–O band and leading in some instances to a more diffuse structure. Methylation of the NH group leads to a marked bathochromic shift and a decrease in the sharpness of the structure of the electronic bands. The low solubility of the indigoids is due to their marked association, and this is due chiefly to strong intermolecular hydrogen bonds, as shown by Shigorin and coworkers for the example of indigo molecules, which are associated by means of hydrogen bonds. This association is also responsible for the significant difference in the colours of indigo and thioindigo (the molecules of the latter cannot form hydrogen bonds with one another).

Porphyrins and phthalocyanines. Personov and Litvin[120,121] were the first to apply Shpol'skii's method successfully to compounds of these classes, which are of considerable biological importance. The three broad fluorescence bands observed under ordinary conditions for phthalocyanine without metal are resolved in octane at 77 °K into more than 30 bands, lying in the range 6840–7775 Å, with characteristic doublet splitting ($\Delta\nu$ between doublets 60 cm^{-1}). The 6939/6910 Å doublet has absorption bands which coincide by resonance. The spectrum of the long-wave absorption band is approximately the mirror image of the fluorescence spectrum and extends from 6939 Å to 6248 Å. Quasi-line long-wave absorption and fluorescence spectra have also been obtained for magnesium phthalocyanine; each is resolved into more than 30 bands, and there is a complex multiplet structure. The fluorescence spectrum of protoporphyrin in octane consists of a large number of doublets with $\Delta\nu = 20$ cm^{-1}, and can be interpreted satisfactorily by means of the vibrational frequencies 240, 740, 790, 985, 1135, 1225, 1345, 1550, and 1585 cm^{-1}.

Personov[121] made a detailed study of the quasi-line spectra of phthalocyanine in octane, nonane, and decane at 77 °K, and gave a detailed vibrational analysis. He pointed out the change in the distance between the doublets in different solvents, and on the basis of the fine details of the structure he concluded that in the range of the long-wave absorption, the fine structure of the overlapping bands of two electronic transitions with λ_{0-0} (I) = 6907/6917 Å (in decane) and λ_{0-0} (II) = 6506/6530 Å (in decane) is observed.

Shkirman and Solov'ev[122] obtained the quasi-line absorption and fluorescence spectra of tetrabenzoporphin and tetrazaporphin in octane at 77 °K. Because of their low solubilities, the former was dissolved first in chlorobenzene, and the latter in a pyridine–acetone mixture. The tetrazaporphin bands consist of complex multiplets, in which two components are the most intense. The intense doublet of the O–O band is observed at 6115/6134 Å with $\Delta\nu = 51$ cm^{-1}. The fluorescence and absorption spectra are almost mirror images and were interpreted by means of 17 vibrational frequencies. The quasi-line spectra of tetrabenzoporphin consist of characteristic doublets with intense resonance lines at 6580/6594 Å, with an interval $\Delta\nu = 32$ cm^{-1} between them. The fluorescence and absorption spectra are not mirror images. The quasi-line spectra of porphin and dihydroporphin (chlorin) in octane and decane at 77 °K have been described[123]. These compounds were dissolved in n-hydrocarbons through a buffer benzene solution. The fluorescence and absorption spectra of porphin consist of series of triplets with a resonance triplet of the O–O transition at 6127/6134/6149 Å (in octane). The structure of the fluorescence spectrum was interpreted by means of the frequencies 155, 310, 720, 786, 955, 974, 1014, 1057, 1176, 1222, 1263, 1319, 1361, 1389, 1409, 1456, 1497, 1539, 1605, and 1615 cm^{-1}. The spectrum of chlorin contains approximately the same frequencies, with the exception of the frequencies 786, 1176, 1319, 1456, and 1605 cm^{-1}. These frequencies of porphin are assigned to the symmetry species b_{1g}. Since in porphin the O–O transition is assumed to be forbidden by symmetry, these frequencies remove the forbidden character. The symmetry of the chlorin molecule is lower, and the transition is allowed by symmetry, so that only the completely symmetrical vibrations are active in its spectrum.

The absorption and luminescence spectra of azo-compounds and azomethine compounds have been studied in n-hydrocarbons and other solvents[124–127]. It was established that arylazo-compounds with general formula Ar-N=N-Ar′ become fluorescent only when an *o*-hydroxy substituent is introduced into the aryl ring; intramolecular hydrogen bonding then leads to the formation of a six-membered ring containing the –N=N– azo-group. The luminescence spectra of hydroxyazo-compounds are resolved only into a few broad bands. A similar picture is observed for the spectra of hydroxyazomethine compounds, in which the hydroxyl group is introduced into the aldehyde ring and forms a stable intramolecular hydrogen bond. Azomethines also become fluorescent when the $-N(CH_3)_2$ substituent is introduced into the *p*-position of the phenyl rings. From the example of α-hydroxyanthraquinones, hydroxyazo-compounds, and hydroxyazomethine compounds, it may be concluded that when an intramolecular hydrogen bond is formed, the electronic bands usually have a diffuse structure, but the increase in symmetry in the dihydroxy- and tetrahydroxyanthraquinones is accompanied by improved resolution of the structure. A less sharp structure compared with the spectra of benzophenones is also observed for *o*-hydroxybenzophenones.

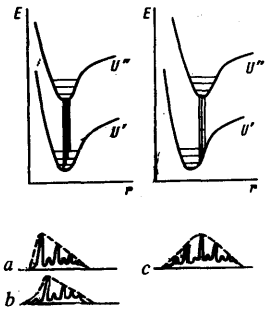
Shpol'skii's method has been used chiefly to resolve the structures of the electronic bands of luminescent molecules. In principle, however, it can also be used to obtain the quasi-line absorption spectra of non-fluorescent molecules. This can be illustrated by azobenzene, which does not exhibit luminescence. Dyck and McClure studied the absorption spectrum of an azobenzene–bibenzyl mixed crystal at 77 °K and 4 °K and found that whereas the long-wave $n-\pi^*$ absorption band does not show a resolved structure, the position and vibrational structure of the $\pi-\pi^*$ absorption band are similar to those of the absorption band of stilbene. Finally, triplet–triplet absorption bands have been observed under the conditions of Shpol'skii's method[128,129].

3. THE VIBRONIC SPECTRUM AND THE STRUCTURE OF MOLECULES

Electronic transitions in molecules differ in the type of excited state ($n-\pi^*$ or $\pi-\pi^*$) realised in the transition; in whether the transition is allowed or forbidden by symmetry or the Franck–Condon principle; and in whether the transition can take place between states with the same multiplicity—singlet–singlet or triplet–triplet—or different multiplicities—singlet–triplet. All these features determine the nature of the electronic transition, which has a significant influence on the form of the vibrational structure.

When the transition is allowed by symmetry, the band due to the purely electronic transition in the system of vibronic bands is clearly distinguished in the spectrum and has a comparatively high intensity (if it is forbidden by other reasons, for example by the Franck–Condon principle). The frequencies of the completely symmetrical vibrations, chiefly those of the framework containing the electronic system excited in the transition, predominate in the structure of the band. In the case of hydrocarbons these are the vibrational frequencies of the carbon framework of the π system. The values of the frequencies in the fluorescence and phosphorescence spectra (in which the vibrations of the ground electronic state appear) coincide with or are very close to the values of the frequencies found in the Raman spectrum of the same compound. In the absorption spectra, however, the same vibrations may have slightly altered frequency values, and this makes the identification of the type of the vibrations difficult. Thanks to the mirror symmetry rule, however, identification is often possible, so that the change in the vibrational frequencies in different electronic states can be estimated. The structure may reveal not only the completely symmetrical vibrations, but also a certain type of incompletely symmetrical vibration, namely those in which the transition is still allowed by symmetry but in which the direction of its polarisation changes. This was shown in a series of papers by Zimmerman and Yoop[130-135] on the study of the polarisation absorption and fluorescence spectra at −180°C for alcoholic solutions of naphthalene, phenanthrene, anthracene, tetracene, tetraphene, chrysene, pyrene, perylene, and azulene. Dörr and coworkers[136-138] showed that the incompletely symmetrical vibrations which rotate the plane of polarisation of the vibronic oscillator through 90° appear in the phosphorescence spectra of a number of aromatic hydrocarbons. Shpak and Malykhina established that the fluorescence spectrum of stilbene contains two mutually perpendicular polarised band series. Naphthalene, phenanthrene, and pyrene provide examples of molecules in whose quasi-line spectra it has been possible to observe incompletely symmetrical vibrations. Bolotnikova found that the fluorescence spectrum of naphthalene in pentane at 77°K shows the 495 cm^{-1} frequency of the vibration with symmetry b_{1g}; the frequencies of the completely symmetrical vibrations combine with it to form a second series of bands which are polarised, in agreement with McClure's studies, in a direction perpendicular to that for the first series of bands, beginning from the initial purely electronic O–O band. Analysis of the quasi-line fluorescence and phosphorescence spectra of phenanthrene enabled Pesteil and Rabaud[40] to distinguish in the spectrum the frequencies of the normal vibrations, the number of which is greater than the total number of completely symmetrical vibrations. On this basis, using data from the vibrational spectra, these authors assigned some of the frequencies to definite incompletely symmetrical vibrations. Klimova[43] established that the spectra of pyrene show the frequencies of incompletely symmetrical vibrations.

When the transition is forbidden by symmetry, the purely electronic band either is not observed or has a low intensity. The forbidden character resulting from symmetry is removed in this instance by the superposition of a definite type of incompletely symmetrical vibration on the electronic transition. The corresponding vibronic band is more intense than the purely electronic band and serves as the origin for progressions of the frequencies of the completely symmetrical vibrations. These electronic bands are characterised by example *b* (see Figure) of the distribution of band intensity along the spectrum, if in the excited state the equilibrium interatomic distances are close to the distances in the ground state. This type of vibrational structure (low intensity of the purely electronic band, removal of the forbidden character by a quantum of the incompletely symmetrical vibration, and distribution of the band intensity along the spectrum according to example *b*) is observed in the spectra of the molecules of benzene, coronene, and triphenylene, which have an O,O transition forbidden by symmetry. A similar picture is observed in the spectra of biphenyl and naphthalene, where the purely electronic transition is partly forbidden.



Different examples of the distribution of intensity in the vibronic bands: *a*) for an electronic transition allowed by symmetry and $r_0' = r_0''$; *b*) for a transition forbidden by symmetry and $r_0' = r_0''$; *c*) for a transition between states with $r_0'' > r_0'$; u' and u'' are the potential curves of the ground and excited states, and r_0' and r_0'' the equilibrium distances in these states.

If however the electronic transition takes place into a state with significantly altered equilibrium distances, the purely electronic transition is forbidden or greatly weakened as a consequence of the Franck–Condon principle, and the system of bands for this transition is characterised by example *c* of the distribution of intensity within this system (see Figure). This is observed for the $n-\pi^*$ transitions of carbonyl-containing molecules, as shown for a number of aromatic aldehydes and ketones, anthraquinone, etc.

Thus from the relative intensity of the purely electronic band it is possible to obtain information on the degree of allowed character (or forbidden character) of the electronic transition, and from the form of the intensity distribution it is possible to obtain information on the forbidden character of the transition.

The form and degree of resolution of the structure are closely related to the nature (type) of the electronic transition, and this is reflected in one of the distinguishing criteria for $n-\pi^*$ and $\pi-\pi^*$ bands. Kasha [73] pointed out that the structure of $n-\pi^*$ bands is usually exceptionally sharp for vapours, but is much less sharp in the condensed phase (liquid and solid solutions), whereas the structure of the $\pi-\pi^*$ bands is more diffuse in vapours, and improvement in the resolution of the structure is observed in solutions, particularly at low temperatures. It should be noted that these differences do not always emerge clearly. For example, for molecules with a non-rigid and non-planar structure, both the $n-\pi^*$ and $\pi-\pi^*$ bands are often structureless (the influence of spatial configuration on structure will be examined below). In those instances, however, where structural factors do not lead to a decrease in the sharpness of the bands, the formulated criterion for bands due to $n-\pi^*$ transitions is applicable only for singlet–singlet transitions, that is for the $n-\pi^*$ absorption bands and for $n-\pi^*$ fluorescence, when this takes place.

Resolution of the quasi-line structure is possible for the $n-\pi^*$ fluorescence bands, as demonstrated for the molecules of anthraquinone, anthrone, xanthone, etc. Under those conditions favouring the resolution of the vibrational structure, the $n-\pi^*$ absorption band remains structureless or shows little structure, whereas resolution of the structure is observed for the absorption bands of the higher $\pi-\pi^*$ transitions. If in a molecule the $n-\pi^*$ levels lie above the $\pi-\pi^*$ levels for a definite change in the structure of the molecule, the $\pi-\pi^*$ absorption, fluorescence, and phosphorescence bands may show a quasi-line vibrational structure (α- and β-naphthaldehydes, N-methylphthalimide, and N-substituted derivatives of acridone provide examples of molecules with $\pi-\pi^*$ phosphorescence and a resolved structure). The close relationship between the form of the vibrational structure and the nature of the electronic transition provides new possibilities for obtaining information on this transition from the characteristic features of the structure of the band.

Dependence of the vibrational structure of the electronic bands on the three-dimensional structure. For molecules of aromatic hydrocarbons (with the same type of $\pi-\pi^*$ transitions) with a rigid structure it is possible in most instances to select conditions for distinct resolution of the structure. The introduction into these molecules of alkyl and halogeno substituents, which have little influence on the energy and nature of the $\pi-\pi^*$ transitions, may influence the form of the structure and its degree of resolution in different ways. Various examples of the spectra of halogeno-derivatives (halogenonaphthalenes, halogenoanthracenes, and halogenopyrenes) show that despite the strongly polar character of the C–halogen bond, which should lead to intensification of the interaction between the dissolved molecule and the solvent, the introduction of halogen usually is not accompanied by a marked decrease in the sharpness of the structure. Moreover, the change from pyrene to halogenopyrenes is accompanied by the same decrease in the width of the quasi-lines at 77°K as is observed for the spectra of pyrene on going from 77°K to 4°K.

The spectra of aromatic hydrocarbons (polyphenyls, diphenylpolyenes, and arylethylenes) usually consist of more diffuse bands, particularly for molecules with sterically hindered groups. For example, the electronic bands of biphenyl show a clearly defined structure, which becomes less distinct when α-alkyl substituents are introduced. The absorption and fluorescence bands of trans-stilbene have a clearly defined structure, whereas the absorption bands of cis-stilbene are structureless, and fluorescence is not observed.

Although a non-planar structure leads to significant weakening of the π-conjugation, so that the aryl fragments of the molecule are chiefly responsible for the electronic bands, these bands nevertheless show a clearly defined structure, which is similar to that of the bands for the hydrocarbons corresponding to this fragment. A bridge with extensively weakened conjugation begins to play the part of a substituent. This picture was observed for β-binaphthyl and the cis-isomer of di-(9-anthryl)ethylene.

The introduction of bridges which fix the planar structure but do not alter the π system leads to more distinct resolution of the structure.

In substituted aromatic compounds with an electron-donating group $-NR_2$, $-NR-$, $-OR$, $-O-$, $-SR$, or $-S-$, the unshared pair of electrons of the heteroatoms X = N, O, or S is conjugated with the π electrons, and their electronic bands are determined by the excitation of the complete π ($2p_z$) system of electrons. These π,π^* ($2p_z$) bands have certain characteristic features, some of which are due to the incomplete conjugation of the $2p_z$ electrons of the heteroatom with the π electrons. Kasha [139] pointed out that because of the nature of the hybridisation, the orbitals of the unshared pairs of these heteroatoms are not strictly parallel to the p orbitals of the π electrons, but may lie at an angle to them, leading to incomplete π conjugation. To this he attributed the slightly lower values of the absorptivities ϵ of the absorption bands due to the $\pi-\pi^*$ ($2p_z$) transitions compared with those for the bands of the resolved $\pi-\pi^*$ transitions, and also the decrease in the lifetime of the phosphorescence (that is the increase in the probability of triplet–singlet conversion resulting from the fact that the $2p_z$ orbital of the heteroatom, lying at an angle to the p orbitals of the π system, as it were occupies an intermediate position between the p orbitals and the n orbitals which are perpendicular to the p orbitals). Since these electron-donating groups can rotate relative to the C–X bond, the angle of slope of this orbital will generally be different in different electronic states. This is apparently one of the chief reasons for the lack of sharpness of the structure in the spectra of aromatic amines, alcohols, ethers, and thioethers to the extent that their bands show only a coarse structure, and not a quasi-line structure. Convincing evidence in support of this is provided by the fact that the electronic bands show a quasi-line structure when the $-NR-$, $-O-$, or $-S-$ bridges are included in a rigid ring. Nurmukhametov and Gobov [98] demonstrated this for molecules with general formula  where X = NH (carbazole), O (diphenylene oxide or dibenzofuran), or S (diphenylene sulphide). Nurmukhametov and coworkers [7] obtained the same result for the molecules of acridan (9,10-dihydroacridine), xanthone, and N-substituted derivatives of acridone.

Another factor leading to a decrease in the sharpness of the spectra of compounds of this type is the high sensitivity of their electronic bands to the nature of the solvent. A marked displacement of the bands is usually observed for these compounds on going from a non-polar solvent to a polar solvent. The presence of small quantities of polar impurities in n-hydrocarbon solvents is therefore sufficient for the formation, in the solution, of molecular centres with appreciable dispersion of the frequencies of the electronic transitions. A unique example of the departure from a planar structure as a result of interaction of the electrons of an unshared pair with π electrons is provided

by benzylideneaniline, in which the N-phenyl ring is turned out of the plane by 60°, so that the molecule acquires the energetically most favourable spatial configuration. The introduction of an –O– bridge (the phenylbenzoxazole molecule) leads to a planar structure for the molecule, in which the n electrons are now not conjugated with the π electrons of the N-phenyl ring. Benzylideneaniline shows broad absorption bands and no fluorescence, whereas the absorption and fluorescence bands of 2-phenylbenzoxazole show a clearly defined quasi-line structure.

4. SPECTROSCOPIC-ANALYTICAL APPLICATIONS

The highly characteristic nature of quasi-line electronic spectra has found extensive application as a basis for the development of spectroscopic-analytical methods for the detection and quantitative determination of small quantities of organic substances. On the basis of the quasi-line luminescence spectra it has been possible to achieve the high sensitivity in the determination of traces of organic compounds (down to 10^{-12} M) which was previously attained only for inorganic compounds. The fact that the luminescence light in these spectra is collected into narrow quasi-line bands makes it possible to carry out an analysis at "noise level", that is when the luminescence of other trace materials in the same range has an intensity comparable with that of the compound being determined. The high sensitivity, the speed of the analysis, the unlimited reproducibility in a given specimen, and the fact that the specimens to be analysed do not have to satisfy special requirements make analytical methods based on Shpol'skii's spectra very effective and promising. The analytical applications have been developed chiefly for substances which exhibit fluorescence in the visible range. Shpol'skii's spectra have proved very effective for the detection and determination of carcinogenic aromatic compounds. Carcinogenic substances have been detected and their concentrations determined in atmospheric air [140,141], tobacco smoke [142], industrial products [143], and in various smoked products [144]. Work on the detection and identification of individual aromatic compounds in bitumens and petroleums has been carried out by Il'ina and coworkers [145-147], who unambiguously identified perylene, 1,12-benzperylene, coronene, and pyrene in the naphthenic–aromatic fractions of bituminous substances. Utkina [148], without preliminary chromatography, determined a number of aromatic hydrocarbons of the anthracene–phenanthrene fraction of coal tar.

A series of papers by Teplitskaya and coworkers [149-154] described the use of Shpol'skii's spectra in the analytical determination of organic substances in rocks of different origin, meteorites, and minerals. The organic substances are present in rocks in small quantities (10^{-4}–10^{-1}% [154]) and the concentration of aromatic hydrocarbons to be determined often amounts to only 10^{-7}%. The authors cited [149-154] were able to determine organic substances in rocks even when this was impossible by other analytical methods. Teplitskaya [149] was the first to detect a number of polycyclic aromatic hydrocarbons in igneous rocks, using Shpol'skii spectra. The individual composition of the carbonaceous material in igneous rocks has been studied [151] and it has been established that calcite from the Darasun deposit contains 1,12-benzperylene, 3,4-benzpyrene, and various other unidentified aromatic compounds.

By means of Shpol'skii's spectra, it has been possible for the first time to identify the individual organic substances present in meteorites; before this, it was considered an achievement to determine even the group composition of the organic material in meteorites. Teplitskaya and coworkers [152] identified a number of individual compounds—anthracene, 3,4-benzpyrene, 1,12-benzperylene, and coronene—in extracts obtained from meteorites—carbonaceous chondrites. The authors cited [152] also observed a similarity in the compositions of the polycyclic aromatic hydrocarbons in the organic material from carbonaceous chondrites, rocks, and minerals of endogenic origin.

Interesting results were obtained by Teplitskaya and coworkers [153] in a study of the spectra of the mineral hackmanite, which exhibits phototropic properties. Some specimens of hackmanite show a pink-red colour, which becomes paler under the influence of daylight. This colour is restored in the dark or under the influence of ultraviolet light. The luminescence spectrum associated with the red colour centres of hackmanite shows a structure at 77°K similar to the structure of the spectra of thioindigoids. On this basis, these authors [153] put forward the new suggestion that the colour centres in this instance are organic sulphur-containing compounds. The presence of aromatic compounds was established from the quasi-line spectra in extracts of organic substances from hackmanite.

Shpol'skii's method has also been used as a basis for the development of quantitative methods of spectrochemical analysis. Personov and Teplitskaya [155] developed a method for the quantitative determination of small quantities of perylene and 1,12-benzperylene from their quasi-line fluorescence spectra, and achieved a high sensitivity (down to 10^{-11} g ml^{-1}) with an accuracy of 10–20%. Quantitative methods for the determination of the strongly carcinogenic 3,4-benzpyrene from the quasi-line spectra were described by Muel and Lacroix [156], Dikun [157], Personov [158], and Khesina [159]. Photoelectric recording [156,158,159] or photographic recording [157] were used. Muel and Lacroix determined the concentration by the method of additions, and Personov used the method of internal standards; the latter achieved a sensitivity of 10^{-9} M with an accuracy of 7–15%.

---o0o---

Extensive possibilities are provided by Shpol'skii's spectra in photochemical studies. Personov [52] observed the photochemical transformation of perylene in chloroform under the influence of daylight. The product of the photoreaction, tentatively regarded as a chloro-substituted perylene, gave a quasi-line fluorescence spectrum in hexane solution at 77°K, displaced towards lower frequencies by ~ 400 cm^{-1}.

Gobov and coworkers [89] showed that ultraviolet irradiation of a solution of di-α-naphthylethylene produces a photoproduct for which the quasi-line structure of the fluorescence and phosphorescence spectra indicated the presence of naphthyl nuclei in the molecular structure. Later, Nurmukhametov and Grishina [160] proved unambiguously that these spectra are due to the hydrocarbon picene, produced by the photocyclohydrogenation of di-α-naphthylethylene.

Intensive studies are now being made of the widely encountered reaction of photochemical cyclisation (photocyclodehydrogenation), by means of which polycyclic condensed hydrocarbons are formed from arylethylenes (for example phenanthrene from stilbene), the corresponding substituted polycyclic hydrocarbons are obtained from substituted arylethylenes, N-heteroaromatic polycyclic compounds are obtained from the N-heteroanalogues of arylethylenes, etc. The photocyclisation products are characterised by a more rigid molecular structure, and

hence by electronic bands with a clearly defined vibrational structure. The use of Shpol'skii's spectra to study these reactions opens up the possibility of ready, rapid, and unambiguous identification of the photocyclisation products and the possibility of studying the kinetics of the reaction by spectroscopic methods. Nurmukhametov and Grishina[161] unambiguously established from the quasi-line spectra the formation of chrysene from α-naphthylphenylethylene, 3,4-benzphenanthrene from β-naphthylphenylethylene, and 1,12-benzperylene from di-β-naphthylethylene.

The application of Shpol'skii's method to the detection and identification of aromatic radicals appears attractive. Grajcar and Leach[63] used the characteristic structure of the fluorescence spectrum in the region of 4600 Å to establish the formation of the benzyl radical when a solution of toluene in methylcyclohexane + 3-methylbutane (2 : 3), frozen at 77°K, was irradiated by light with wavelength 2537 Å (λ_{Hg}). Mileshina and coworkers[65] observed the production of green luminescence during the photolysis of diphenylketen in hexane at 77°K. On the basis of an analysis of the quasi-line spectrum of this luminescence, together with electron paramagnetic resonance data, it was shown that the biradical of diphenylmethylene is formed from diphenylketen.

The Development of Russian Chemistry and the Mendeleev Society† (The Centenary of the All-Union D.I.Mendeleev Chemical Society)

S.I.Vol'fkovich

A hundred years ago chemistry in Russia was represented by several score scientists, chiefly teachers, whose research interests were mostly concerned with the analysis of naturally occurring substances and their technological application. Only a few Russian scientists were engaged in theoretical studies on the borderlines between chemistry and physics, and investigations of organic syntheses only began in the middle of the last century.

M. V. Lomonosov's genius introduced fundamental concepts into many aspects of theoretical and practical chemistry, and foresaw the lines of development of chemistry for centuries to come; Lomonosov left a scientific legacy which exercised an immense influence over the subsequent advances of Russian chemistry.

Two scientists are regarded by science historians as the founders of the first large schools of chemistry in Russia: firstly, A. A. Voskresenskii, Professor at the Chief Pedagogical Institute, St. Petersburg, and at the University of St. Petersburg, who trained a number of generations of chemists including D. I. Mendeleev, N. A. Menshutkin, P. A. Il'enkov and others, justifying his reputation as the "grandfather of Russian chemists"; and secondly, N. N. Zinin, Professor at Kazan University and later at the Medical and Surgical Academy at St. Petersburg, whose students included, among others, A. M. Butlerov and A. N. Engelgardt.

Voskresenskii's and Zinin's outstanding activities reached their peak during the Forties and Fifties of the last century.

In 1854–1857, in St. Petersburg, P.A.Il'enkov, N.N.Sokolov, A. N. Engelgardt and several other chemists organised two small groups who used to meet at their houses to exchange the results of their work, help one another and engage in lively discussions of the ways to advance chemical industry and chemical education. Sokolov and Engelgardt equipped a private laboratory at home for the members of their group, offering facilities for those who wanted to experiment or to try out experimental techniques. The laboratory proved to be a great success. However, after only 3 years it had to be abandoned because of a lack of funds, and all the equipment was donated to St. Petersburg University, where Sokolov went in 1860 to deputise for D. I. Mendeleev, who was abroad. At that time, the chemical laboratory for the University students consisted of a single room, and the chemical laboratories of the Academy of Sciences numbered 4 rooms. This brief reference shows that the organisers of the abovementioned groups were active, forward-looking and public spirited men. Their biographical backgrounds are also interesting. Sokolov was a Law graduate of St. Petersburg University, who then joined the Natural Philosophy Faculty, graduating as Candidate of Philosophy. He worked for several years in various chemical and physical laboratories in Germany and France; then he studied the natural deposits of the Urals; eventually he became interested in organic chemistry, obtained his Doctorate, and embarked on courses of lectures in general and organic chemistry, which were brilliantly presented and greatly appreciated by students. Engelgardt graduated from the Artillery Academy, became interested in chemistry, retired, and began teaching chemistry at the Institute of Forestry. He was awarded a doctorate by St. Petersburg University, without defending a thesis, for his work on the

† An augmented paper given on 24th October 1968, at the Palace of Congresses in Moscow, at the plenary meeting to celebrate the Centenary of the All-Union D. I. Mendeleev Chemical Society, by the Society's President, S. I. Vol'fkovich.

Kursk phosphorites and on the development of the methods of alkali treatment of bones, among other topics. In 1870 he was arrested for being a member of the "Land and Liberty" party, and after serving a term of imprisonment at the Petropavlovsk fortress he was exiled from St. Petersburg and deprived of the right to live in University towns. He settled at the Batishchevo estate in the Smolensk region, where he lived for many years, working on agricultural problems, especially experiments on the use of phosphorites and the development of agricultural technology. It was not until 1880 that Engelgardt regained his right to free movement, through the good offices of the Russian Chemical Society. Lenin is known to have read Engelgardt's articles "Letters from the Country" with interest, noting their educational and populist bias.

Mendeleev took an active part in these groups, showing from the very start of his scientific and teaching career great social initiative, putting forward bold and original ideas. He never undertook any work or proposed any hypotheses without public discussion, at the same time taking an interest in the work of others and assessing it critically; also he always maintained close contact with Russian industry and with foreign scientists. Other members of these groups were also socially aware and progressive men.

They soon came to feel the need for attracting wider circles of chemists in order to enhance the scope of the work in various areas of chemistry. A proposal was made to organise an officially functioning Society.

Until 1868 a number of chemists were members of the oldest Russian scientific Society, whose membership was made up of widely varying specialists—the Free Economic Society (founded in 1765) and of the Russian Technical Society (founded in 1866), whose members were mostly connected with industry. Advances in chemistry and increasing specialisation created a need for more profound and many-sided contact between people working in chemistry, at that time still not a very popular science, and largely unfamiliar to many engineers, technologists, biologists, economists and other specialists.

THE FIRST FIFTY YEARS

The Eighteen-Sixties in Russia were a period of important social developments. The abolition of serfdom, the beginnings of capitalism and the first steps towards the exploitation of native natural resources had a great influence on the Russian intelligentsia.

The first congress of Russian natural scientists, called together on the initiative of the Chemical section, took place in St. Petersburg from 28th December 1867 to 4th January 1868 and adopted a resolution stating that it was desirable to organise a Chemical Society which would "have members in all Russian cities" and whose publications would include "the work of all Russian chemists". A special commission worked out the constitution of the Russian Chemical Society, and on 1st October 1868 the first organisational meeting of the Society took place under the chairmanship of G. G. Gustavson, at which Mendeleev reported on the views of the Scientific Committee of the Ministry of Public Education concerning the projected constitution of the Society. The constitution was approved by the Ministry on 6th November. At the first meeting of the Russian Chemical Society, with a membership of 35, on 18th November 1868 N. N. Zinin was elected President and N. A. Menshutkin—Secretary. The latter was Editor of the Society's Journal, which first appeared in 1869, for thirty years.

The Physical Society, which was organised in 1872 at St. Petersburg University, amalgamated with the Chemical Society in 1878 to form the Russian Physico-Chemical Society which soon acquired great authority and international popularity. This was especially due to the fact that the Society's Journal and the Society's members' meetings became a focal point and forum for many outstanding communications, investigations and discoveries.

In 1878 A. M. Butlerov was unanimously elected President of the Society.

It is possible to state, without "jubilee exaggerations", that no serious chemical investigation went without a report to the Society or publication in Zhurnal Russkogo Fiziko-Khimicheskogo Obshchestva, which over a period of 62 years (1869–1931) published about six thousand papers; the Journal was taken by all chemical libraries and laboratories abroad. Mendeleev presented his work to the Society and published 135 of his papers in its Journal, where A. M. Butlerov published 58.

Russian chemists considered it an honour to give a paper at the Society's meetings or have a paper published by the Journal. In fact, the epoch-making report of Mendeleev's discovery of the Periodic Law of the chemical elements was made at the Society's meeting by N. A. Menshutkin, on the author's behalf since Mendeleev himself was ill, on 18th March 1869; the paper was entitled "The Relation of Properties to the Atomic Weight of the Elements".

A. M. Butlerov first presented his theory of the chemical structure of organic compounds to the Society.

The first report on the invention of radio was made by A. S. Popov in 1895 at a meeting of the Russian Physico-Chemical Society. D. N. Chernov, who created the science of metallography, also presented a paper at the Society.

From the first days of its inception the Society was interested in science and industry, and tried to promote the development of productive potential and the creation of a Russian chemical industry.

To encourage original work and to attract younger scientists to research, the Society established a series of commemorative prizes for the best research projects.

Apart from the discoveries by Mendeleev and Butlerov mentioned above, a number of other outstanding investigations were carried out by Russian chemists in the last century.

In 1842 N. N. Zinin discovered the reaction for the preparation of aniline which formed the basis of the aniline dyestuffs industry all over the world. His work on primary aromatic amines initiated the synthesis of a number of intermediate products, pharmaceutical preparations, nitroglycerine, etc. The important dye, fuchsine, was discovered by Ya. Natanson in 1855.

In 1840 Hess discovered one of the basic laws of thermochemistry—the law stating that the sum of the heats is constant‡. His text-book "The Fundamentals of Pure Chemistry" saw seven editions during the author's lifetime.

In 1838–1841 A. A. Voskresenskii obtained a new alkaloid —theobromine, which found extensive application in medicine—and quinone, whose derivatives became intermediates in dyestuffs synthesis.

Professor K. K. Klaus of Kazan University discovered a new element—ruthenium, in 1844 and studied a number of other platinum metals.

---

‡ Hess formulated his law 2 years before the appearance of Meyer's publication and 7 years before Helmholtz indicated the general significance of the principle of the conservation of energy.

During the Eighteen-Forties B.S. Yakobi invented galvanoplasty, without applying for a patent so as to make the method available for universal use.

In 1868 A.N. Engelgardt first established the effectiveness of using phosphorites as fertilisers in acid soils; I.A. Il'enkov proposed in 1865 an alkali method for making bone fertilisers.

N.N. Beketov first isolated metals from their solutions by means of hydrogen under pressure (1862–1865) and developed the alumothermal method of obtaining pure metals by reducing their oxides with aluminium.

In September 1883 K.E. Tsiolkovskii sent a number of papers, among them "The Work of Gravity" and "The Mechanics of a Congruently Changing Organism" to the Journal, whose editors, P.I. Borgman and I.M. Sechenov, noted the author's ability. In 1897 Tsiolkovskii asked for his projected experiments on the dirigible to be considered, and, should they be found to be promising, for a grant of 200 roubles to be made from the Society's funds. The Society found the proposed experiments to be most important and much larger scale investigations to be essential. In 1900 on the recommendation of the Society, Tsiolkovskii was given a grant by the Academy of Sciences, for experiments with large models.

A series of original papers on periodic systems, on the "Evolution of the Worlds from a Modern Astrophysical and Geophysical Point of View", and others, was presented to the Society by the former inmate of the Schliesselburg Fortress, the Populist N.A. Morozov. It is remarkable that Morozov, despite 29 years of solitary confinement in Tsarist prisons, must have been the first to postulate a hypothesis of a radioactive origin of the planets and stars.

At the First Mendeleev Congress, D.N. Pryanishnikov reported the results of his investigations of root secretions and his original work on the nitrogen feeding of plants.

In the Seventies and Eighties V.V. Markovnikov studied in depth the composition of Caucasian oil and discovered a new type of hydrocarbon compounds—the polymethylenes.

In our time it is superfluous to talk of the world-wide importance of Mendeleev's Periodic Law, discovered in 1869 and of Butlerov's theory of the chemical structure of organic compounds; these are now familiar not only to chemists but also to all educated people. It is fitting, however, to mention here that Mendeleev and Butlerov made great contributions to other areas of chemical science, industry and agriculture, as well as to public life.

Mendeleev, Butlerov, Zinin, Menshutkin, Beketov and their colleagues can, like their contemporaries in music, be justly called the "mighty bunch" in chemistry. They were indeed giants in chemical science. Engels wrote in his "The Dialectics of Nature": "Mendeleev made an immensely important scientific achievement in unconsciously applying the Hegelian law of the transformation of quantity into quality..."

Several other chemists who carried out outstanding investigations at the end of the last century should be mentioned.

A.P. Borodin, Professor of Organic Chemistry, physician and composer, reported in 1869 to the Society his studies of the products of acetaldehyde condensation and the discovery of a new aldol compound.

I.G. Kucherov discovered and elaborated (1881) a method for preparing acetaldehyde by catalytic hydration of acetylene, which became widely used for the production of acetic acid.

In the Eighties, N.A. Menshutkin became one of the pioneers in the study of the kinetics of a number of important reactions and the relation between the reactivity and the composition and structure of organic compounds.

A.E. Favorskii discovered and studied the interconversions of acetylene hydrocarbons, thus laying the foundations of an extensive range of industrial processes.

In the Eighties and Nineties D.P. Konovalov discovered the laws determining the evaporation and boiling of binary liquid systems.

I.A. Kablukov first discovered in 1889–1891 anomalous electrical conductivity in solutions of electrolytes in non-aqueous organic solvents.

In the Nineties, A.N. Bakh formulated the peroxide theory of slow oxidation, which explained the action of oxidising enzymes, the mechanism of respiration and a number of other fundamental questions.

N.A. Shilov, in 1904, studied the nature of conjugated reactions and developed the methodological basis for anti-gas protection.

In 1905 L.A. Chugaev discovered the rule of cycles in the chemistry of complex compounds, prepared for the first time a series of organic platinum compounds, and pioneered the use of organic reagents in analytical chemistry.

A.E. Arbuzov published in 1905 the first paper in an extensive and important cycle of investigations of the structure, synthesis and properties of organo-phosphorus compounds.

At the beginning of the twentieth century A.V. Kistyakovskii developed a detailed oxide theory of the appearance of reticulate films which passivate metals, this was of practical importance in connection with anti-corrosion measures.

N.S. Kurnakov undertook, in the Nineties, a systematic study in depth of the relationship between the composition and the properties of metal alloys, salts and other systems, developing his studies over half a century and founding a large school of physico-chemical analysis.

V.N. Ipat'ev published in 1901 his catalytic methods of preparation of a series of organic compounds, at high pressures and temperatures (hydrogenation, decomposition and other reactions), which found application in the petroleum industry and the technology of other hydrocarbons.

In 1897 L.V. Pisarzhevskii and P.E. Melikashvili (Malikov) published in the Society's Journal their work on the structure and properties of the peroxide compounds of a number of metals and peracids.

At the beginning of this century M.S. Tsvet created a new adsorption method of analysis—chromatography, which now enjoys the widest application and further development not only in analysis but also in technology, for the separation of complex mixtures of substances.

V.I. Vernadskii deserves special mention for creating the new branches of science which combined chemistry with geology and biology—geochemistry and biogeochemistry—and for laying the foundations of extensive radiochemical investigations and a systematic study of Russia's productive potential.

N.D. Zelinskii is gratefully remembered for developing in 1915 a carbon gas-mask which saved the lives of many thousands of soldiers during the First World War; he also pioneered much work on catalytic transformations of hydrocarbons, petrochemistry, and the chemistry of proteins and other substances.

The list of outstanding research of the last century and the beginning of the present one could, naturally, be very much extended, but even the above selection suffices to illustrate the high level of originality and the fundamental significance of the investigations undertaken in the unfav-

ourable climate of pre-revolutionary Russia. All the research work mentioned above was either reported to the Society or published in its Journal.

In his speech at the annual meeting in 1924 the President of the Chemical Society in England, Wynne, stressed the great importance of the work of Russian chemists and advised young English chemists to study the Russian language in order to be able to read Russian publications in Zhurnal Russkogo Fiziko-Khimicheskogo Obshchestva in the original. Similar views were expressed by scientists in other countries.

It is worth mentioning that strong materialistic, progressive and democratic tendencies were characteristic of the Russian Chemical, and subsequently the Russian Physico-Chemical, Society. Many of its leading members repeatedly attacked the reactionary Tsarist regime and social oppression.

N. N. Zinin, N. N. Sokolov and others often spoke against idealistic philosophy, pointing out that it ignored the achievements of materialistic natural science.

Leading Russian chemists were sharply critical of Wilhelm Ostwald from the time of the appearance of his energetic teachings; in 1895 he read a paper entitled "The Untenable Nature of Scientific Materialism", rejecting atomic and molecular concepts. Mendeleev, Beketov, Vernadskii, Kablukov, Kurnakov, Kurbatov and many others were among the many chemists and physicists who defended materialistic concepts and the atomic-molecular theory. These discussions often appeared in the pages of the Journal. Mendeleev had this to say about Ostwald's views: "There are scientists who deny matter, since, they say, we know only energy .... matter is only energy .... such concepts ... cannot be entertained in any sane mind"[1]. Lenin is known to have considered Ostwald's views critically and in detail in his work "Materialism and Empiric Criticism", in which he called Ostwald "a very great chemist and a very confused philosopher"[2]. As the result of discussions and a series of experimental verifications, Ostwald was forced to admit, in 1908, that he had been mistaken.

In another guise, the pre-eminence of energy, and in particular, of electricity and electrification in relation to chemistry and its application formed the subject of numerous discussions[3-8]. G. M. Krzhizhanovskii wrote: "Chemistry is becoming a section of the general subject of electricity". The resolution of the Plenary Session of the Central Committee of the Communist Party of the Soviet Union dated 13th December 1963 states: "We can now say, with full justification, that Communism is Soviet power plus electrification of the whole country plus the application of chemistry to the national economy".

The Society has often discussed the economic problems of the chemical industry, including metallurgy, the production of building materials, the food, textile and other industries, as well as the production and use of mineral and organic fertilisers.

The Society's members have often expressed anti-Malthusian views. Mendeleev called the "theory" and proposals put forward by Malthus—"ravings", and D. N. Pryanishnikov, who gave a lecture on "Malthus and Russia"[9], said that "... for another 150 years Russia need not worry about the supplies of food, even if it doubled its population every 50 years".

Despite his dualism in some of his social and political views, Mendeleev was a true revolutionary not only in science and technology, but also in many state and public undertakings. He not only urged the industrialisation of the country and help for agriculture by industry, but also actively assisted this by his fundamental economic studies, his frequent visits to mines, industries, factories, agricultural and forestry concerns. He did much to promote higher education for women, encouraged cooperation, and despite the approaches of capitalist oil-producers and others, refused on principle any participation as a member or shareholder of their concerns.

Both Mendeleev himself and his closest friends were both great patriots and convinced internationalists who maintained friendly scientific contacts with chemists abroad.

In 1870, when the German chemists Kolbe and Volhard put forward nationalistic views, chauvinistically designed to debase the importance of French chemical research and elevate German work, Zinin, Butlerov, Mendeleev and Engelgardt published a protest against nationalism and chauvinism in science.

An excerpt from the telegram sent by the Russian Physico-Chemical Society in April 1906 to the French Physical Society on the death of Pierre Curie is interesting for ideological insight. It said: "Curie should be dear to all nationalities. He belonged to that part of the French people who work for the benefit of all humanity and do not serve the base interests of finance or reactionary governments".

Mendeleev was not only a man of the highest principles and progressive concern for social advancement, but also a bold and courageous citizen who never put personal interests before those of the community. One example of this was when he left the University as a protest during student unrest.

He took the refusal to elect him as an active member of the Academy of Sciences as a public affront, since almost all the Universities and learned societies in Russia and a number in other countries had elected him as an honorary member, and expressed their angry indignation at this rebuff.

It is instructive to recall that, despite the deep friendship between Mendeleev and Butlerov, when they were involved in their well-known controversy about the existence of spiritualism Mendeleev spent much effort and time in attempting to refute Butlerov's errors and misconceptions by experimental and strictly scientific means—with objectivity, loyalty to principles and love of truth which never deserted them.

The Society reacted vigorously more than once to the reactionary actions of the Tsarist government. Below is a characteristic excerpt from the minutes of the meeting of the Chemical Section of the Russian Physico-Chemical Society, four days after the infamous mass shooting of the workers in the Palace Square on 9th January 1905. The minutes, signed by N. S. Kurnakov, say: "In view of the terrible events of recent days and the impossibility of finding the peace of mind needed for the discussion of scientific reports, the Chemical Section, on the suggestion of the Council, resolved to close the meeting... The memory of those who fell was honoured by standing". Several subsequent meetings of the Society were also overshadowed by the political events of those times.

On 9th January, Mendeleev, troubled by the atrocities in the streets, went to see S. Yu. Vitte, in an attempt to persuade him to stop the massacre, but returned extremely depressed, since it was all to no avail[10].

The Society not infrequently approached the Tsarist government with requests and proposals concerning improvement of higher chemical education, greater autonomy for the Universities, admission of women to Universities, financial aid for research and other questions, but these were almost always rejected.

During the First World War, when the whole Russian industry, including the chemical, stood revealed in all its enormous backwardness, being unable to meet the needs of

defence and the production of essential medical supplies, the chemical community showed great initiative and persistence, and obtained permission to extend the scope of the most nationally-important scientific investigations.

Russian chemists throughout the last century devoted much time and effort to the popularisation of chemistry. Popular scientific lectures were often given by Hess, Butlerov, Il'enkov, Kittary, Khodnev, Sokolov, Markovnikov, Lesgaft, Shugaev, Shilov and Kablukov; these lectures were a great success. The Society took part in several exhibitions, where new synthetic compounds and apparatus, created with the Society's help, were demonstrated.

The Moscow Polytechnical Museum was founded in 1872, chiefly through the efforts of Professors Bogdanov and Arkhipov of Moscow University, and the Moscow Society of the Friends of Natural Sciences, Anthropology and Ethnography§. A number of exhibits was given to the Museum by members of the Russian Physico-Chemical Society, who gave popular lectures at the Museum.

It is clear from the above that the pre-revolutionary development of the Society was often chequered. It may be interesting to recall that among those professors and lecturers who left Moscow University as a sign of protest against the actions of the Tsarist Minister Kasso were such prominent members of the Chemistry Department as V. I. Vernadskii, N. D. Zelinskii, A. V. Rakovskii, N. A. Shilov, A. E. Chichibabin, S. S. Nametkin, A. K. Reformatskii and many others. The Chemistry Department noted in its records the enormous loss suffered by the University as the result of this action and in appreciating the immense sacrifice made by the people concerned, it expressed to them its deep sympathy and certainty that "in any case their gifts would not be lost to science, which is close to us all". Vengeful Tsarist officials stooped so low as to forbid the Russian Physico-Chemical Society twice to make a collection towards a monument to A. M. Butlerov in Kazan.

Mendeleev and Menshutkin died in January 1907. These grievous losses naturally led to an even stronger wish to consolidate the "chemical fraternity" (Mendeleev's expression), and the special meeting of the Russian Physico-Chemical Society dedicated to Mendeleev's memory and held in March 1907 adopted the resolution to organise periodically Mendeleev Congresses of Pure and Applied Chemistry¶. The First Mendeleev Congress took place in December 1907 in St. Petersburg; it united not only chemists but also physicists, engineers, technologists and a number of biologists. For this reason, the Chairman of the Congress was the eminent chemist N. N. Beketov; the Praesidium of the Congress included, as Vice-Chairman, P. N. Lebedev, the physicist; N. E. Zhukovskii, the mechanical engineer; I. A. Kablukov, S. N. Reformatskii, F. M. Flavitskii and P. I. Valden, the chemists; D. N. Pryanishnikov, the chemist and agricultural chemist; the Swedish chemist Arrhenius, and as Secretaries—L. A. Chugaev and K. P. Kasterin.

The First Mendeleev Congress was very representative and fruitful. Over a thousand delegates from 80 cities took part in it. All the most eminent Russian chemists, physicists, and technologists played an active part in the work of the Congress.

The Second Mendeleev Congress took place in St. Petersburg in December 1911. It was concerned not only with questions of general chemistry and physics, but also with chemico-technological, metallurgical, silicate, pharmaceutical and food problems. N. A. Umov was Chairman of the Congress, N. D. Zelinskii, T. A. Tamman, D. A. Goldgammer and A. G. Gruzintsev were Vice-Chairmen, and L. V. Pisarzhevskii and A. F. Kolli—Secretaries.

Foreign scientists attended the Congresses. During the Second Congress the Mendeleev Museum, situated in part of his University flat, was opened at St. Petersburg University. This is not merely a commemorative institution, but also a scientific one, since it contains Mendeleev's collected manuscripts and published works, which are still being studied and republished†.

The fact that no funds were made available to establish a Chair of Physical Chemistry at St. Petersburg University was lampooned in a specially written satirical play by B. B. Byzov and colleagues "A Tragedy of Physical Chemistry or the Fatal Hole in the University Stocking", which was performed at the Second Congress.

Further Mendeleev Congresses took place after the October Revolution.

THE SECOND FIFTY YEARS

The October Socialist Revolution, which turned the history of mankind in a new enlightened direction, naturally also had a revivifying effect on the chemical community. Scientific life, like the life of any organism which is bound up with its environment—climate, sources of nutrition and other vital conditions—is bound up with the social structure, the ideological interests of the society, its economic possibilities and aims, its cultural level, etc.

Thus the second fifty years of the Society's activities are characterised not only by an approximately 300-fold growth of its membership, but also a sharp change in the content and form of its work. Whereas formerly most of the members were science teachers predominantly from capital and large cities, after the Revolution there has been an ever growing influx into the Society's membership of specialists in chemical and allied industries, as well as industrial innovators and students, working in all the chemical centres of the Soviet Union.

At present the Mendeleev Society consists of 1949 primary organisations, 81 Republican, area and regional associations and a total of 171,000 members. The membership of the Russian Physico-Chemical Society in 1917 totalled 565.

In addition to the many specialised sections, the Society has under its aegis many teams working on special projects, and various commissions, institutes, laboratories, courses, schools, groups—with numerous annual cycles of lectures and practical courses for raising scientific and technical qualifications, excursions to leading industrial concerns and research Institutes both in the Soviet Union and in other countries, predominantly the Socialist ones. Participation of students and pupils from the higher forms of high schools has recently increased considerably—the "Young Chemist" section of the Society, organised 3 years ago, now has a

§ In response to public requests, the Government together with industrialists assigned 500,000 roubles towards the establishment of the Museum. A special building was built for the Museum in 1877; it now belongs to the All-Union Society "Nauka" (Science).

¶ These Congresses are now known as the Mendeleev Congresses of General and Applied Chemistry.

† In connection with the forthcoming centenary (in 1969) of the discovery of the Periodic Law, the Government has decided to place the whole of Mendeleev's flat at the disposal of the Museum and to refurbish it. The Leningrad section of the All-Union Chemical Society organises annual Mendeleev readings, devoted to present day chemical problems.

membership of 75 thousand. The All-Union Chemical Society, together with the "Nauka" Society, organises chemical contests and exhibitions and publishes popular scientific literature. The Mendeleev Society organises hundreds of scientific and technological meetings and conferences in various towns and factories every year.

The Mendeleev Congresses of Pure and Applied Chemistry enjoy great popularity in the Soviet Union and abroad; they are milestones in chemical circles, attracting thousands of active participants in recent years. Each Congress has been carefully prepared and has served not only as a review of achievements, but also as a gateway to new and fruitful lines of research and progress.

The Third Congress, convened in 1922 in Moscow (the first after the October Revolution) paid particular attention to the development of the chemical industry, which at that time was going through a difficult period of recovery.

The Fourth Congress took place in 1925, in Moscow; a number of fundamental theoretical studies in chemistry, physics and biology were reported, as well as communications concerning new chemical technological investigations.

The Fifth Congress took place in 1928, in Kazan—"the Russian chemical Mecca"‡; it was dedicated to the memory of A. M. Butlerov and his scientific legacy. In addition to the theoretical papers, the Congress approved unanimously a note on the application of chemistry to the national economy submitted not long previously to the Government, and adopted a number of resolutions aimed at the construction of chemical plants and the application of chemistry to agriculture on a new scientific and technological basis. This Congress initiated the All-Union Bureau of Higher Chemical Education, the Commission for the Chemical Nomenclature of Inorganic Compounds, and expressed a wish to establish a chemical research Institute in Kazan, which was created under the directorship of A. E. Arbuzov and has been for many years now active in much original work.

The Sixth Mendeleev Congress was held in 1932 in Kharkov, during the final period of the First Five-Year Plan; it was planned to coincide with the fifteenth anniversary of the October Revolution. At this Congress it was possible to summarise the significant achievements of Soviet Chemistry during the early years of the First Five-Year Plan and to outline new perspectives for the Second Five-Year Plan. The Congress looked particularly closely at the problems of further development of the main branches of the chemical industry—the production of sulphuric acid, synthetic ammonia, phosphorus and potassium fertilisers, the development of electrochemical industries, the production of artificial fibres, plastics, and synthetic rubber, as well as the training of chemists and the various aims of applying chemistry to the national economy. This Congress adopted the resolution concerning the need for uniting the chemists working in different areas of science and technology within the single Mendeleev All-Union Chemical Society.

The Seventh Congress took place in 1934 in Leningrad and celebrated the centenary of Mendeleev's birth. Many foreign scientists attended this Congress. The main papers dealt with the modern status of the Periodic Law and Mendeleev's other fundamental work in various spheres of science and technology, and the current problems in these directions.

The Eighth Congress was held in Moscow in 1939 and was the best attended and most representative of all the others. Hundreds of the most diverse papers were given in plenary and specialised sessions, which reflected the considerable achievements in theoretical and industrial research; the main goals of chemistry within the National Seven-Year Economic Plan were also considered. Foreign scientists contributed many papers at this Congress§.

The war which broke out in 1941 delayed the Ninth Congress by many years, in fact until 1965. This Congress, unlike its predecessors, dealt with narrower, more current problems linking chemistry with biology and the corresponding areas of technology: the application of chemistry to agriculture, medicine and the production of food. It took place in Kiev. The Congress discussed fertilisers, animal feedstuffs and sanitary preparations, chemicals for the protection of plants, pharmaceutical preparations, perspectives in synthetic foodstuffs, and many other problems.

The Tenth Mendeleev Congress will take place in the autumn of 1969 in Leningrad, and will celebrate the centenary of the Periodic Law, and deal with its status, applications and perspectives.

The connections between the Society and various Ministries and scientific and economic organisations are growing closer every year.

Many books[12,13] and articles[14-38] dealing with the achievements of Soviet chemistry during the last half-century were published in connection with the Jubilee of the October Revolution in 1967. We shall be dealing later with the Society's work at various periods of Socialist progress. Together with the development of well-established schools, many new schools of chemistry and many new lines of research appeared in the Soviet Union, some of which have gained world recognition, and are developing vigorously not only in the direction of chemical science and industry, but also in close contact with physics, biology, geology and other natural and technological sciences. The new Soviet schools of chemical kinetics and catalysis, photochemistry, electrochemistry, polymer chemistry, fundamental organic synthesis and organo-elemental chemistry, naturally occurring compounds, radiochemistry and isotopes, physicochemical mechanics, and others, are well known.

"Hybrid" sciences have appeared and are rapidly developing: among them chemical physics, biochemistry and agricultural chemistry, bio-organic chemistry, molecular biology, polymer chemistry, radiochemistry, geochemistry and biogeochemistry, photochemistry, chemotherapy, chemical microbiology, astrochemistry and cosmochemistry, chemical materials science, chemical cybernetics.

Schools of chemistry and research have been developing, since the Revolution, in all Soviet Republics and regions, in industry, farming, clinics, expeditions on land, sea and in space.

It is relevant to recall that before the Revolution there were no national organisations coordinating and directing the development of chemistry; there were only small groups of qualified chemists working in the Academy of Sciences, colleges and factories. There was not a single Chemical Research Institute. Therefore the Russian Physico-Chemical Society, whose active members included practically all the leading and most highly qualified chemists in the country, rapidly became the most authoritative scientific association of chemists not only in Russia, but also abroad. Mendeleev, in his remarkable note, only published in 1966, "What kind of Academy is needed in Russia?"[39] stressed the need for the integration of science

‡ A. E. Favorskii's expression.

§ Detailed information about the work of all the Mendeleev Congresses is available in the Transactions; that of the first eight is described in V. V. Kozlov's monumental work[11].

and technology and the importance of the Academy of Sciences as a social factor. He said:

"The monastery, the academy and the university—these are the successive stages of the development of science, characteristic of past centuries... It could be said that the rôle of the monastery in science was first progressive and then conservative. In the most recent times.... science made a further step, directly into life itself. Almost every Ministry needs a scientific committee...where possible mutual contacts have been established, and scientific societies formed....

The history of the development of Russian scientific societies is short, but it is already very instructive.... by summation of resources achieving a more significant resultant... Without taking into account the development of scientific Societies in our country it seems to me impossible to achieve any further understanding of the rôle of the Academy of Sciences. Science is absolutely free. That is how it has come to be in scientific societies... The Academy will have dual responsibilities: firstly, as a central scientific society... secondly as a central scientific council, which should also deal with undertakings of practical national importance.

....Science is pre-eminently not a private and detached concern, but a social and public one....

...The Academy should have the funds not only for its own research programmes but also for helping other societies in this respect..."

Much of what Mendeleev was urging only came to be realised after the Revolution.

The qualitative and quantitative growth of chemical science and technology in the USSR has, undoubtedly, been determined to a great extent by the industrialisation of the country and the genuine cultural revolution which has been, and is being, promulgated by the Communist Party since the first days of the October Revolution. In fifty years Soviet chemistry has grown into a mighty power, which at present produces about fifteen thousand various products in amounts several hundred-fold greater than before the revolution. As early as December 1917 a chemical section was established within the Supreme National Economic Council, in which highly qualified chemists with a social awareness played the most active role, under the direction of L.A.Karpov. Lenin, in his article "Current Aims of the Soviet Government" put the development of the chemical industry among the top-priority aims, and in his "Outline Plan for Scientific and Technical Developments" he said: "The Academy of Sciences, having started a systematic investigation and survey of the productive potential of Russia, should be commissioned forthwith by the Supreme National Economic Council to form a series of specialist commissions to expedite as rapidly as possible a plan for the reorganisation of industry and the economic progress of Russia"[40].

The Russian chemical community, represented by the most outstanding scientists such as L. Ya. Karpov, A. N. Bakh, V. N. Ipat'ev, E. V. Britske, P. M. Luk'yanov, Ya. V. Samoilov, D. N. Pryanishnikov, N. S. Kurnakov, N. D. Zelinskii, N. F. Yushkevich, V. P. Kamzolkin, V. S. Kiselev, M. N. Gurvich, I. A. Tishchenko, B. S. Shvetsov, P. P. Budnikov and others, came out on the side of the Soviet government at once, without vacillation.

The enthusiasm and deep sense of responsibility to their country felt by Soviet chemists is well illustrated by the now historical note, sent by a considerable group of scientists to the Soviet Government in March 1928, offering their services to the development of chemical science and technology, and the use of their achievements in other areas of the national economy and culture. These proposals were discussed with a delegation of scientists¶ and considered by a specially appointed Government Commission, made up by Ya. E. Rudzutak, G. K. Ordzhonikidze, A. I. Mikoyan, G. M. Krzhizhanovskii and N. P. Gorbunov; as the result of this, the Council of the People's Commissars of the USSR issued an edict on 28th April 1928 "Measures for the Application of Chemistry to the National Economy", which was followed by the formation of a very representative Committee of highly qualified specialists and Government officials, and the organisation of a chemical section in the State Planning Organisation of the USSR. The Committee was chaired by Ya. E. Rudzutak, and then by V. V. Kuibyshev.

The remarkable note mentioned above, which even now makes most interesting reading, said:

"..... The profound changes which have recently occurred in the concepts of the elementary nature of matter mark an epoch in the history of science. In the field of chemistry the past decade has seen attempts at penetrating the structure of matter, which open up limitless future possibilities of its technological exploitation (catalysis, radioactivity, intra-atomic energy, etc.). The achievements of theoretical chemists have created such an integrated picture of the interaction of atoms that it has become possible to elaborate systematically and rationally an experimental elucidation of, among others, the chemical processes in the soil and in plants. Chemistry is now at the point of transition to the most extensive and profound development of all its technology.

The new chemistry has created a large number of materials until recently completely unknown, such as synthetic fibres, oil, leather, rubber, plastics, tanning substances, light alloys, etc., and its further development is bound to create a revolution in the industrial economy. Even greater economic achievements are foreshadowed by the use of all wastes, i.e. raw materials present in the wrong place which have so far not found their application.

A general plan of economic development must take into account all the prospective developments of modern science, which clearly show the ever growing influence of chemistry on the replacement of many mechanical processes in industry, agriculture, defence and daily life by chemico-technological ones.

A great advantage for the creation of future new technology in the Soviet Union is likely to be, paradoxically enough, its very poverty at this time, i.e. the absence of large investments in the form of capital and equipment, since experience has shown that the application of advanced scientific ideas is often hampered in capitalist countries by the need to run the equipment down to complete depreciation.

These measures designed to advance chemistry can effect the most radical changes both in the technological aspect and the economic structure of industry, be it metallurgy, mechanical engineering, mining, transport, textiles and other branches of the national economy, considerably lowering the costs of production and raising the efficiency of capital investment.

The solution of the above economic problems is particularly bound up with the development of chemical science in the USSR.

¶ The delegation was led by A. N. Bakh, who later became the first President of the Mendeleev All-Union Chemical Society.

The Soviet Union, as a country which has taken giant steps in the rearrangement of the social and economic conditions must first of all direct the full might of chemical thought towards the fullest development of chemical technology. This will give a firm basis for economic development and at the same time ensure the country's invulnerability and independence in the event of possible hostile actions.

History has shown that the rapid flowering of chemistry in the nineteenth century, which created all the brilliance of chemical science seen now, was initiated and determined by theoretical scientists: Lavoisier, Brane, Dalton, Faraday, Dumas, Le Chatelier, Frankland, Hoffmann, Bayer, Clapeyron, Zinin, Mendeleev, Butlerov, and others. Lavoisier, Faraday, Lomonosov and Mendeleev examplify the fact that the greater the scientist as a theorist, the clearer his view of the requirements conditioned by life and by technology.

In order to utilise rationally the country's immense and varied natural resources it will be inevitably essential to solve a series of new problems on the basis of our own, original, creative and purely scientific work. It is not sufficient to make use of Western discoveries—we must ourselves be at the forefront of chemical research.

It follows from this that our country's urgent aim should be the widest development of scientific research, regardless of cost, and not only in applied but also in theoretical chemistry.

In addition to extensive planned research related to current industrial needs, generous funds should be allocated to theoretical research outside such a plan, which would provide starting points for radical changes in chemical technology.

It is essential to extend and reinforce mutual contact between our scientists and industrial organisations and the leading countries of the world, making these contacts more constantly systematic and easy, by increasing the number of visits to foreign countries, by inviting foreign consultants to the USSR, and by other means.

Scientists should be involved in the development of a general plan for the chemical industry and agriculture, and play a bigger part in the work of factory laboratories and industrial workshops.

Great care must be given to the organisation and equipment of factory laboratories, and to improving the working conditions of factory technical personnel, always providing opportunities for improving their qualifications.

The call to organised work embracing such wide horizons will, naturally, bring to life the potential creative forces and enthusiasm in both the mature and the young chemists, physicists and technologists.

The undersigned appeal to the Government to organise within the Soviet People's Committee a special Commission on the application of chemistry to the national economy, to discover and apply all the measures necessary for achieving this goal"[41].

The Soviet People's Committee defined the main aims of the Commission as follows:

"The Commission must give top priority to a detailed scientific, technological and economic study of the following problems: the rational utilisation and extension of native natural resources; the application of modern chemical developments to individual branches of industry and social needs—building, transport, public health, and others; the production of agricultural fertilisers and insecticides and fungicides; the establishment of a potash industry; the further development of the organic dye-stuffs industry; the radical reconstruction of the coke and petroleum industry; the industrialisation of modern forest chemistry; the investigation and maximal development of the rare elements industry; the basic problems of modern synthetic chemistry (synthetic rubber, petrol and liquid fuels, synthetic esters, etc.); and the increased production of chemically pure reagents and laboratory equipment in the USSR"†.

The penetration of chemistry, its methods and products, into the different areas of the national economy became so important and widespread that a special term "chemisation" was coined for it in the Soviet Union, later used also in other countries; it has come into common usage in much the same way as "mechanisation" and "electrification".

During the First Five-Year Plan vast deposits of Khibinsk apatites, and Solikamsk potassium salts were discovered and developed; the first synthetic ammonia plants were built and a series of other basic mineral and organic chemical concerns established. Large teams began working within a single plan, in a coordinated tackling of research, design, construction, equipment and production. The chemists and engineers showed great creative enthusiasm in those years, helping in a variety of ways to solve the difficult problems of prospecting for and utilising mineral deposits, and to apply scientific discoveries to practical needs.

Members of the Society initiated the establishment of a series of Institutes, both in central and remote regions. They now number over 150.

A group of organic chemists led by I. P. Losev prepared the first comprehensive report on the paths for the development of basic organic chemical industry, which was approved by the planning bodies.

During the Second World War the Society carried out diverse research and production projects for defence. Many leading specialists offered their help to the Government in the very first days of the war; as the result of this, the State Committee for Defence appointed an executive to deal with chemical matters, with a staff of specialists who helped to mobilise those working in colleges, research, and industrial organisations for development work required to meet the needs both of the frontline and the rear. Much was achieved in mobilising natural resources and raw materials, organising the production of sanitary and medicinal preparations, and in matters of chemical defence.

Whereas the role of chemists in the early Five-Year Plans was primarily consultative, on their own initiative, and concerned with individual proposals, after the war the All-Union Chemical Society has been organically and systematically included within the general State economic planning; this has occurred in accordance with Party and Government resolutions. The Society now not only puts forward its proposals and criticisms but also makes practical contributions towards the realisation of plans, the improvement of the quality and tempo of research, of design and construction projects and of building and industrial undertakings. This activity of the Society is continually growing and gaining in variety, especially on sites.

In recent years much work has been done by the Society's sections dealing with higher education, polymers, silicates, and the application of chemistry to agriculture (chiefly in the South-Western regions).

Evaluation commissions, reviewing and recording many hundreds of research and industrial papers, have been

† Detailed data on this are in the Transactions of the Commission's plenary sessions and also in the Journal published by the Commission "Khimiya isotsialisticheskoe Khozyaistvo" (Chemistry and Socialist Economy) (Gosudarstvennoe Nauchno-Tekhnicheskoe Izdatelstvo).

working hard both at headquarters and in some of the branches. The Society acts as scientific and technical consultants in many industrial concerns. The State Committee of Science and Technology at the Council of Ministers of the USSR, the Academy of Sciences of the USSR, and the Trade Unions maintain regular contact with the Society, to mutual advantage. The Society aims not only at responding creatively to various Party and Government resolutions, but also at initiating and promoting progressive ideas, techniques, and theoretical and practical achievements.

Special mention should be made of the Society's work over many years in organising systematic courses, conferences and reference publications on the chemistry and technology of polymers, which are very popular among chemists for bringing them up to date. Some sections of the Society have done similar work on new analytical techniques and production control. The Society also has considerable consultative functions in connection with the current economic reforms. However, these progressive functions are concerned more with chemico-technological and industrial matters, than with theoretical and scientific ones. Therefore the Society is now assisting with the development of fundamental research both in Institutes and in industrial laboratories.

Among the most active leading members of long standing in the Society during the Soviet era have been: N. S. Kurnakov, N. D. Zelinskii, V. M. Rodionov, V. S. Kiselev, I. P. Losev, P. P. Budnikov, P. M. Luk'yanov, A. I. Lazarev, V. V. Kozlov, Z. A. Rogovin, S. N. Danilov, S. A. Shchukarev, A. I. Brodskii, M. M. Dubinin, A. E. Porai-Koshits, L. K. Lepin, E. A. Shilov, I. I. Chernyaev, S. S. Nametkin, N. M. Zhavoronkov, O. E. Songina, V. M. Kakabadze, O. S. Stepanova, N. M. Karavaev, S. V. Gorbachev, and other chemists.

We shall now mention some achievements in those spheres of modern Soviet chemistry where the main contributions have been made by active members of the Society.

---o0o---

The variety of chemical elements and natural raw materials used by chemical industries increases annually. Petroleum, industrial and natural gases, coal, wood pulp, sand, limestone, clay, aluminosilicates and many other widely distributed natural raw materials are extensively utilised. The scope of synthetic chemistry has grown tremendously.

The advances of atomic physics and chemistry have made it possible to synthesise and to degrade elements, thus laying the foundation of revolutionary transformations in chemistry and in chemical technology. The remarkable words of A. M. Butlerov, written about ninety years ago, are relevant to the immense and rapidly expanding advances in organic synthesis. He wrote: "... it is certain that every organic substance can be synthetically produced"[42].

These words have become the slogan of modern chemistry, whose aim it is to synthesize the most varied and complex substances with tailor-made properties, utilizing for this purpose common and preferably cheap raw materials. At the same time there has been a great increase in the utilization of mineral raw materials containing rare and transition elements, coloured and noble metals, etc. Chemists are paying more and more attention to complex processing methods and to the elimination of industrial waste.

The problem facing contemporary science is extremely important and difficult: the relationship between the properties of numerous and varied materials and substances and their composition and structure. Many of these substances are novel and important, including semi-conductors, thermostable materials, quantum-generating and biologically active substances.

The deep penetration of organic chemistry into biology has led to the most refined and complicated syntheses of analogues of natural products—e.g. sex hormones, vitamins, enzymes, antibiotics, etc.—and to the discovery of substances carrying genetic information and of mutagens, thus demonstrating the great achievements of science. Similarly, the collaboration of physicists and chemists has resulted in the discovery of twelve elements of the periodic system (eleven transuranium elements) and over 1800 radioactive and stable isotopes. Many of these have proved useful in various spheres of industry, public health and scientific investigations. The achievements of inorganic chemistry have been enormous in the last twenty-five years, especially in radiochemistry, the chemistry of rare and transition elements, extra pure semiconductors, ultra hard and chemically stable substances, etc., as well as in studies in depth of the structure, properties and transformations of inorganic matter. Many of the rare and transition elements have remarkable properties and play an important part in the production of special steels and metal alloys, endowing them with hardness, thermostability, resistance to corrosion and many other valuable properties. Certain rare elements are widely used in electronics, in radio engineering, photographic technology, production of ignition compounds, in medicine and in agriculture. Compounds of some chemical elements are used as microfertilizers and in food supplements in animal husbandry, etc.

As a result of notable achievements in organic syntheses, various classes and groups of organic compounds previosuly regarded as strictly individual have become interconvertible, and some considered inactive ("chemical corpses" in the acute words of M. I. Konovalov) are now easily converted into other compounds. These successes have opened up possibilities of using less valuable, extensively occurring raw materials instead of more valuable and scarce ones. The raw material resources of chemical industry are thus constantly expanding.

On the basis of extensive creative efforts of Soviet chemists the petroleum and gas industries have created numerous new processes which form a solid foundation for basic and heavy industrial organic synthesis.

The production of high molecular weight compounds has developed extensively and fruitfully, particularly since the plenary session of the Central Committee of the Communist Party of the USSR in May, 1958. Soviet industry produces many scores of various types of rubber, plastics, fibres, films, etc. Many synthetic high-molecular weight compounds have remarkable properties superior to those of natural products. The achievements in this area have resulted in a peculiar competition between the synthetic and natural materials.

The notable work of S. V. Lebedev and other chemists has resulted in the Soviet industry's being the first in the world to produce synthetic rubber from alcohol. The method of Lebedev has found wide application in several countries abroad. Synthetic rubber is also made in the USSR from other raw materials, e.g. gases from petroleum processing, acetylene, etc.

Work on the synthesis of organosilicates has acquired great interest and increasing importance since their use in the production of rubber-like plastics results in great sta-

bility to temperature variations, and in electrical insulation, hydrophobic and other properties. They are also used in making special high quality resins, lacquers, etc.

Soviet workers have synthesised and studied in detail a series of new and modified synthetic fibres of high quality, used in many branches of technology.

Considerable advances have also been made in recent years in the production of inorganic polymers of high thermostability, particularly among polyphosphates and polysilicates.

High molecular weight ion exchange resins capable of removing various ions from solutions are widely used in many technological processes which require the isolation of rare, valuable or radioactive elements from very dilute solutions. The resins are also used in the high purification of water, in analysis and in other spheres. Soviet chemists have synthesized scores of divers highly efficient ion exchange agents.

Among the outstanding achievements of Soviet organic chemists over the last 20–30 years the following should be mentioned as having theoretical and practical significance: dehydrocyclization of paraffins to cyclopentane hydrocarbons; the development of the cumene process of phenol synthesis and the synthesis of acetone from isopropylbenzene; the development of the synthesis of benzene homologues; the discovery of the disproportionation reaction of cyclopentane in the presence of vanadium oxide; the discovery of the opening of three-membered rings through the action of mercury acetate; the development of processes for the production of alcohols and fatty acids through the continuous oxidation of paraffins, etc.

Of great future significance are the numerous studies in various spheres of organo-elemental chemistry. Among these especially noteworthy are the development of the diazo methods of synthesis, the investigations of ferrocene, and the study of the reactions of radicals in solution.

A series of new methods of preparation of aromatic compounds has been developed. A method for the production of anthraquinone sulphonic acid has been worked out; interesting studies of the chemistry of heterocyclic compounds have been carried out. A new area of organic chemistry—fluoro-organic compounds—has been developed. V. M. Rodionov has worked out original methods of synthesizing beta-amino acids. V. E. Tishchenko has studied in depth pinene and camphene, whilst A. E. Arbuzov has investigated terpenes.

A. E. Favorskii and his school have produced extensive and very fruitful work in the field of organic syntheses based on acetylene, including the production of synthetic rubbers, glues and other high-polymer materials.

One of the most important problems facing chemical industries is the substitution of synthetic raw materials for edible plant raw materials currently used for technological purposes.

Considerable successes have been achieved in the syntheses of new and of more effective medicinal, disinfectant and analgesic compounds. Soviet medicine is indebted to I. N. Nazarov for the discovery of promedol and of other very effective analgesics. Substances enhancing the maturation of blood corpuscles, organic fluoro-compounds and other polymers are used successfully in surgery in replacements of blood vessels, and of bone and other tissues.

A. E. Chichibabin, V. M. Rodionov, their students and collaborators and other investigators have carried out detailed investigations into drugs and into series of analogues of natural products. Recent years have seen successful collaboration between chemists and biologists and doctors on the synthesis of powerful agents against tuberculosis, pneumonia, encephalitis, dysentery, poliomyelitis, leukemia and various infectious diseases.

Numerous chemicals have been developed which are active against plant pests and diseases and against weeds; defoliating and desiccating agents for the pre-harvest removal of leaves from cotton plants, potatoes and other vegetables; stimulants and regulators of plant growth and many other physiologically active substances. Herbicides and scores of pesticides as well as defoliants (particularly in cotton cultivation) are widely used in agriculture.

A. E. and B. A. Arbuzov, in Kazan', have carried out basic research into the synthesis of organo-phosphorus compounds and of medicinal substances. It is noteworthy that these studies which have great practical importance resulted from purely theoretical investigations by A. E. Arbuzov into the various aspects of a new class of compounds, viz. esters of phosphoric acids. Many agricultural toxic chemicals which have found extensive application were synthesized by workers of the Institutes of the Academy of Sciences, at the Scientific Fertiliser and Insectofungicide Institute (NIUIF), the All-Union Institute for the Chemical Protection of Plants (VNIIKhZR) and others. Institutes in Moscow, Kazan', Kiev and other towns have produced extremely valuable work on the synthesis of organo-phosphorus insecticides and other producs.

Important original work on the synthesis of dye-stuffs, photoreagents for colour cine-film and various fine chemicals has been done by M. A. Il'inskii, A. E. and B. A. Porai-Koshits, N. M. Kizhner, A. I. Kiprianov, N. N. Vorozhtsov and others. The remarkable theoretical work of A. N. Terenin in photochemistry should be mentioned. The study and synthesis of organo-elemental compounds has greatly expanded in the Soviet Union. Among these compounds many are effective agricultural agents, intermediates in the production of polymers, etc. The Institute of Organo-elemental Compounds of the Academy of Sciences of the USSR was established for the extensive development of studies of these compounds because of their theoretical and practical significance.

Considerable achievements in inorganic chemistry have resulted in recent years from the work of I. I. Chernyaev, A. A. Grinberg, A. F. Kapustinskii, S. A. Shchukarev, V. G. Khlopin, E. V. Britske, N. F. Yushkevich, G. G. Urazov, B. A. Nikitin and others.

Outstanding achievements must be noted in inorganic materials science, which have ensured the production of various compounds for atomic, nuclear and electronic technology. These achievements were preceded by an enormous amount of original work on the isolation of rare and radioactive elements and their isotopes. Many of these are isolated in the so-called spectroscopically pure state (this degree of purity allows the presence of one atom of admixture to 10^8–10^{12} atoms of substance).

Numerous new metal alloys, glass, ceramic and other materials have been created, possessing previously unattainable stability, hardness, thermostability and resistance to radiation and various chemical actions (e.g. corrosion). Soviet industry is now producing a whole series of valuable types of glass, glass fibres, thermo- and electro-insulating materials. The development of silicate chemistry owes much to the work of I. V. Grebenshchikov, P. P. Budnikov, I. I. Kitaigorodskii, N. A. Toropov and many workers in the building materials industry.

The achievements of Soviet chemistry have also been great in the theory of complex compounds and in the development of new methods of production and refining of the platinum group of metals, viz. rhodium, iridium, osmium, ruthenium, etc.

The chemistry of rare and radioactive elements has been widely studied, entailing the development of many novel, refined methods of investigation, of isolation, separation and profound purification of substances. Whilst in the years immediately following the October Revolution main efforts were directed to the development of methods of isolation of radium from ores and to the utilization of certain rare metals in metallurgy, in recent years the creation of atomic technology has resulted in extensive original work on the chemistry and technology of uranium, thorium and other transuranium radioactive elements, as well as beryllium, zirconium and others.

The rapid development of the production of semiconductors has led to divers studies and investigations in depth of substances possessing electronic conductivity whose magnitude places them midway between metals and insulators. With this aim in view, various sources of raw materials have been investigated as well as methods for obtaining such elements as germanium, silicon, indium, tellurium and others in a pure state, and for preparing a whole series of their chemical compounds.

Contemporary aircraft equipped with jet engines and other new technological developments require the creation of novel types of metal construction, stable to high temperatures, pressures, corrosion and other influences. Chemists and metallurgists have succeeded in solving numerous difficult problems in utilizing for these purposes metals new to the industry—viz. magnesium, titanium, and various alloys containing rare elements.

Great contributions to radio- and isotope chemistry have been made by V. G. Khlopin, I. D. Bashilov, I. V. Kurchatov, G. N. Flerov, A. P. Vinogradov, I. E. Starik, A. I. Brodskii, V. I. Spitsin and others.

The successes of Soviet chemistry have resulted from profound theoretical studies, based to a considerable degree on the use of refined physical methods of investigation, i.e. spectroscopy, X-ray analysis, radioactive isotopes, mass-spectrometry, chromatography, polarography and many others. Much original theoretical and practical work in analytical chemistry has been done by Soviet chemists.

Thanks to the high precision and rapidity of the new analytical methods automatic control and regulation of continuous industrial processes has become possible. Modern achievements in the production of ultra pure substances, in nuclear and electronic technology, in many areas of biology, medicine and other branches of science and technology would be impossible without the new analytical methods incorporating chemical and physical methods with high standards of instrument technology.

Penetrating and varied studies of divers important chemical reactions have been carried out, as well as of methods of their acceleration by means of catalysts, high temperatures, high pressures and other "levers" influencing the course of reactions. Significant contributions to this sphere have been made by the eminent Soviet scientists N. D. Zelinskii, N. N. Semenov, A. A. Balandin, V. N. Ipat'ev, E. V. Britske, P. P. Fedot'ev and others. Studies on reaction rates have resulted in the intensification of some industrial processes and the development of new technological procedures. N. N. Semenov was awarded the Nobel prize for his outstanding contributions to chemical kinetics and chain reactions (the Nobel prize was simultaneously awarded to the eminent British chemist Cyril Hinshelwood for his studies of chemical reaction mechanisms). This sphere of science originated in the Soviet Union and has developed fruitfully there for over a quarter of a century: the leading centre for these studies is the Chemico-physical Institute of the Academy of Sciences of the USSR. Outstanding theoretical studies on the structure, reactivity and energetics of chemical reactions have been carried out during the period of Soviet rule.

In recent years penetrating and extensive studies have been initiated into the mechanisms of surface phenomena which play a large part in the accomplishment of many technological processes, e.g. gas absorption, flotational enrichment of ores, resistance of metals to corrosion, etc. This sphere has been well served by A. N. Frumkin, V. A. Kistyakovskii, P. A. Rebinder, N. A. Izgaryshev, G. V. Akimov and others.

The most difficult problem of mastering atomic and nuclear processes has been solved in a short period of time by collaborative efforts of physicists, chemists and technologists.

Soviet chemical engineers have achieved considerable successes in utilizing native mineral resources, including many types of raw materials containing coloured metals and rare elements, phosphorus, boron and various other ores (work of geologists and chemists including A. E. Fersman, I. M. Gubkin, Ya. V. Samoilov and others, as well as E. V. Britske, N. F. Yushkevich, I. P. Bardin and others); before the Revolution most of the mineral raw materials were imported into Russian from abroad.

The discovery 40 years ago by the Academy of Sciences expedition and the exploration by NIUIF beyond the Polar circle of the world-scale deposits of Khibin apatite-nephelite ores as well as the discovery before World War II of large deposits of phosphorite in Karatau (Southern Kazakhstan) and of other deposits, have led to the establishment of extensive phosphate fertiliser industries producing at present about 450 times more fertilisers than before the Revolution. Utilization of novel types of raw materials (volcanic apatites, nephelites, etc.) previously not used, demanded much original work by chemists, which has enabled Soviet chemical and metallurgical industries to produce from these materials scores of valuable products—phosphate fertilizers and salts, phosphorus, fluorine salts, aluminium, soda, potash, cement, glass, etc.

The discovery and exploration in 1926 of the largest in the world deposits of potassium salts in northern Urals (in the Solikamsk district), and then of further potassium deposits in various areas of the USSR, laid the foundation for an extensive industry producing potassium fertilizers, magnesium, bromine, rubidium and various salts. It is relevant to mention here the extensive studies of other natural salts, based on their chemico-physical analysis (marine and lake sulphates, soda, borates, etc.), carried out by N. S. Kurnakov, G. G. Urazov, V. P. Il'inskii, E. V. Burkser, N. N. Efremov and many others.

Abundance of food stuffs and of raw materials for light industry is ensured in the USSR by the organisation of extensive, advanced and rapidly growing industry based on fixed nitrogen, together with developments in the production of phosphorus and potassium fertilizers and of chemical agents for the protection of useful plants and animals and of feed-preserving and sanitary substances used in animal husbandry.

The so-called combustible minerals, viz. petroleum, coal, natural gases, turf, etc., as well as wood pulp, are more and more widely used not only as fuel but also as valuable chemical raw materials. Their processing is complex, using energo-chemical methods. Chemico-technological methods of processing underground mineral deposits in situ are being studied, including the possibilities of dissolving, melting or gasifying a series of salts and ores ("geotechnological" processes).

Technologists have worked out complex methods of processing natural raw materials which eliminate enormous losses of valuable components in the solid, liquid and gaseous industrial wastes. In recent years much work has been devoted to the acute and important problem of air and water polution—a growing problem related to the expansion of industry.

Since the Revolution the science and methods of chemical technology, i.e. the mass conversion of raw materials into useful products, have been transformed. The enormous problems of Socialist construction have revivified it. Before the Revolution this science was largely empirical, it developed in a chaotic manner in the rapacious interests of profit-making concerns. In the Soviet Union the development of chemical technology proceeds according to plan and expediently, based on the theory and progress of all branches of physico-chemical and technical sciences, in the interests of maximal satisfaction of the needs of society as a whole.

New sectors of chemical technology are growing rapidly in the USSR, e.g. studies of processes and of apparatus, physico-chemical bases of industrial processes, their optimization and programming, as well as the science of chemical materials and machine construction.

Valuable results have been obtained from theoretical studies of chemico-technological processes by Soviet chemical engineers, especially in the field of contact processes and apparatus, intensification of production and separation and purification of products.

Valuable forward-looking work has been done on the production of oxygen and its application in various areas of chemical and metallurgical industries, resulting in considerable intensification of some important production processes (I. P. Bardin, P. L. Kapitsa et al.).

The growth of research and planning in new chemical industries has been considerably influenced by developments of theories of similarities and by model processes and apparatus, and in recent years by mathematical and physical methods of planning experiments related to the problems of chemical cybernetics. The study of processes and apparatus are much indebted to I. A. Tishchenko, L. F. Fokin, K. F. Pavlov, A. G. Kasatkin and others.

Recent decades have seen a particularly deep penetration of chemical methods not only into physics but into biology including its applied branches, viz. medicine, horticulture, animal husbandry, microbiology both bacterial and viral, and into the food industry. The cross-fertilization of natural and technological sciences has so great an influence on the direction of chemical efforts penetrating all spheres of life, that there is already talk of the coming of the "age of biology" in which the main roles will be played presumably by biochemistry, physiology, bioorganic chemistry, molecular biology, chemical cytology and other hybrid sciences coupled with the widest possible application of the latest physical and mathematical methods of research. After all, the knowledge of life processes, of metabolism, growth, fertility, transmission of heredetary characteristics, the functioning of the nervous system, variation of micro- and macro-organisms, is still modest. Significant results have been obtained in certain intermittently advancing areas of experimental physiology and biochemistry. It is obvious that problems involved in the life sciences require the most sophisticated and complex chemical and physical research methods. Until comparatively recently chemists and biologists collaborated in expeditions, in descriptive, analytical and synthetic methods of investigating natural products (this must have given rise to the conventional and imprecise term "chemistry of natural products"; strictly speaking, mineral substances forming the earth's crust, water and air also form natural products). Chemists and biologists are faced with the need to study in depth the processes occurring in living organisms. Whilst quite recently research was directed towards the composition, structure and properties of protein ("bricks"—amino-acids, hydrocarbons, lipids, terpenes and other components of natural and technical products, in the last decades research has concentrated on vitamins, enzymes, hormones, antibiotics and other physiologically active substances including medicinal and agricultural products as well as other regulators of life processes, possessing genetic, mutagenic and toxicogenic functions. Industrial production of certain vitamins and medicinal substances has been established in the USSR on the basis of experience at home and abroad (including the work of A. E. Chichibabin, V. M. Rodionov, A. E. Arbuzov, M. M. Shemyakin, A. P. Orekhov, Kh. U. Usmanov and others).

In recent years Soviet chemists have achieved successes in the synthesis of a series of important protein-peptide substances, in the studies of muscular contraction mechanisms, of the conditions of enzyme action in amino-acid metabolism, of the basis of the bioactivity of the main types of proteins and peptides. Of great significance are the studies to clarify the mechanisms of the transmission of hereditary characteristics by means of investigating the structure of deoxyribonucleic acids, as well as of one of the most important messenger ribonucleic acids involved in the synthesis of the protein chain from amino-acids. Valuable pioneer work has been carried out in the USSR on the use of numerous chemical compounds selectively altering hereditary characteristics (mutagens). Methods have been worked out for obtaining male and female sex hormones from available raw materials and for the synthesis of other steroid hormones. Significant results have come from investigations by Soviet biochemists into the synthesis of vitamins produced industrially (at the present time vitamins A, B_1, B_2, B_6, C and others are being produced). Developments are taking place in studies of blood, and blood substitutes have been developed. Considerable achievements have been made in the synthesis of physiologically important carbohydrates and lipids. Chemists, biologists and doctors are collaborating in the search for effective preparations against malignant tumours, carcinomata, sarcomata, etc.

Research work is becoming more and more team-work and increasingly complex. The clear demarcation previously existing between inorganic and organic or inorganic and physical chemistry is becoming blurred in many areas. Theoretical, methodological and prospecting investigations are increasingly done by the combined forces of the Academies of Science, graduate schools, professional institutes and plant laboratories according to a common, agreed plan. Much of this work is stimulated by the competitions and discussions initiated by the Mendeleev Society.

PROSPECTS IN CHEMISTRY

Soviet chemists are faced with tremendous and exciting problems. Developments in the study of the theory of structure and of reactivity of chemical compounds, of kinetics and chemical reaction rates, of the course of nuclear processes are opening more and more prospects of directed synthesis and transformation of elements and of their compounds and of enhancing the possibility of regulating life processes of creating new materially valuable products.

In the coming decades energetics will presumably cease to be the limiting factor in the development of electrochemical, electrothermal and other energy requiring industrial processes. This view is based on the long experience of the construction and exploitation of large thermo- and hydroelectric power stations and on the considerable advances in recent years in the building and use of atomic power stations. It is therefore to be expected that the production and use of oxygen, hydrogen, nitrogen, chlorine, caustic alkali, light metals, silicon, phosphorus and other elements and their compounds will expand, making these substances more easily available and cheaper. Because of new resources and of new forms of energy new technological processes will come into being, and many of the existing ones will be radically changed. Processes taking place at high or super-high temperatures will be increasingly important not only in the chemical and metallurgical industries but in many other branches of technology (mining, building construction etc.). Processes at extremely low temperatures will also be developed. The use of medium and of high vacuum will be extended. Electromagnetic and electrostatic action, ionizing radiation, radiolysis, photolysis and other physical "levers" will speed up processes in the desired directions.

These developments will lead to numerous new processes, apparatus, chemical products and construction materials. Even now the world chemical industry produces tens of thousands of compounds, and their number is constantly and rapidly increasing. The number and variety of chemical products is limitless.

Soviet research laboratories produce annually many thousands of new chemical compounds, hundreds of which are then produced industrially. This progress may be likened to an avalanche; it is directed to the satisfaction of requirements in the national economy, public health, defence, culture and everyday life.

Chemical technology has up to the present studied and achieved syntheses, degradations and other transformation on the "molecular level"; in the future these processes will also be developed on the "atomic-nuclear level". Radioactive processes of transforming one element into another, already realizable, will in the future extend the raw material sources of elements deficient in the earth's crust. The chemistry of organo-elemental compounds is expanding rapidly.

Significant progress is to be expected in the biochemical and especially the microbiological industry, solving important problems in the sphere of food production, of medicine, etc.

Thanks to new sources of energy, and to chemical and mechanical advances, it will be possible to investigate and to extract mineral raw materials from great depths of our planet—tens of kilometres, or even deeper, down. These problems are only beginning to be studied (at present the deepest bores are 7–8 kilometres deep, the average diameter of the earth being 6510 kilometres). At the same time the problems of the extraction and processing of mineral raw material underground (by dissolving, melting out, gasification) will be tackled, similarly to the underground extraction of solutions of rock salt which are distributed to soda-producing plants, and to the melting of underground deposits of sulphur by means of steam (a method long used in Louisiana). In the first instance such methods of extraction could apply to water soluble salts, e.g. potassium (as has been done in recent years in Canada), magnesium and others, as well as to low-melting minerals or those decomposable at comparatively low temperatures.

Electrochemical sources of power will introduce radical changes into land, air and cosmic transport. In the USSR as well as in other countries vigorous research is being pursued which should provide in the near future powerful, economic and portable chemical sources of power, replacing in many processes the heavy accumulators and the usual fuels, e.g. kerosene, gasoline, compressed and liquefied gases, etc., and possibly competing in certain applications with atomic power generators.

There is no doubt of the importance of research into the processes of photosynthesis, which play so tremendous a part in life processes on Earth.

The number of chemical elements known at the present time is 104 (element 104 of the periodic system was discovered by I. V. Kurchatov and named "Kurchatovium" in his honour); approximately 1800 radioactive and stable isotopes are also known. The heavy elements series of the periodic system is expected to be considerably extended in the future.

Concurrently with the studies of physical, chemical, biological and technological properties of the elements, their use and novel application are being developed. Obviously the widest and most varied application will be found for those elements which are most abundant in the earth's crust, in water and in air. To this type of raw material belong sand, clay, limestone, gypsum, salts and other common mineral raw materials. Petroleum and natural gas are of especial interest in many parts of the world. The enormous deposits of coal have to be used on the largest possible scale in conjunction with the production of a wide assortment of chemicals, similarly to the petrochemical industry. This also applies to peat deposits. Much more attention should be paid to the chemical technology and diversified use of wood pulp—the most widely available and self-replacing natural raw material.

The chemistry of high-molecular weight compounds will be developed on the widest possible scale.

The threatening shortage of pure fresh water in certain areas will be eliminated by desalination and purification of sea water and of underground water by chemical, mechanical and physico-chemical means, including the utilisation of heat from atomic reactors and of helio-technology.

Industrial waste waters present an acute and complex problem which will require complex methods and means of elimination to be worked out by joint efforts of science and technology (as has been done in recent years in the USSR in connection with some important problems in this sphere).

There are large areas in the USSR where the soil is acid, saline or eroded—and these defects will have to be remedied to ensure effective agricultural development. A solution of these problems is liming of acid soils, and treatment with gypsum of solonetz and solonchak soils. These measures are to be extended. The struggle against wind and water erosion—present on a very large scale in places—will have to involve the collaboration of chemists, physicists and soil scientists. A number of polymers, latex-like substances, silicates, etc. capable of binding and strengthening soil particles has already been investigated. But the economic aspects of this problem are not yet solved: they have attracted insufficient efforts and expenditure so far.

In the coming decades the plant foodstuffs will not be basically replaced, but will be enriched and supplemented by synthetic products (protein concentrates, amino-acids, carbamide, phosphates, microelements, vitamins, etc.).

Some food and feed production problems have, however, already been solved by synthetic chemistry, by-passing

crop raising, and this process will undoubtedly develop further.

The three sources of plant nutrition—nitrogen, phosphorus and potassium—are found in nature in widely differing situations. The supply of nitrogen from the air is limitless, as well as the content of oxygen. Soviet deposits of water-soluble potassium salts are also enormous, ensuring sufficient amounts for agriculture for millenia. The case of phosphorus is different: the deposits of reasonably rich sources of phosphorites and apatites so far explored can ensure large-scale development of the fertilizer industry for several decades only.

The process of binding nitrogen as synthetic ammonia—used in many countries—is complicated and cumbersome. The electric arc process of binding atmospheric nitrogen and oxygen to form nitric acid and its salts, used at the beginning of the twentieth century in some foreign plant proved uneconomical because of the enormous expenditure of energy and of extremely low efficiency. This problem is being tackled from different directions by various research and pilot-plant establishments in the USSR and abroad. Plasmas, radiolysis, new types of furnaces with high efficiency coefficients, have been studied, as well as the mechanism of the biological utilization of atmospheric nitrogen as its oxides and ammonia in the hope of replicating it technologically. It is to be hoped that all these conjoint efforts will succeed in the next few decades in synthesising economically nitrogen compounds from atmospheric nitrogen.

The research, begun before World War II by the All-Union Institute of Halurgy, into the underground extraction and processing of soluble potassium salts should develop further.

Because of the comparatively limited natural deposits in the USSR of phosphates, geological exploration in Siberia, Central Asia and the Caucasus should be developed; at the same time all possible measures should be taken to work out economic methods of enrichment and chemical processing of low-content, contaminated with undesirable admixtures, phosphorites. The rapid and extensive construction of power stations and the consequently cheaper supplies of energy will result in the more economical electrothermal processing of poor phosphate ores into phosphorus and phosphoric acids. It may become possible to obtain phosphorus anhydride directly through thermal dissociation of calcium phosphates, by-passing the reduction of elementary phosphorus and its oxidation. Similar processes may be of interest in the future in the production of other acid anhydrides.

The contention put forward by Soviet scientists over half a century ago regarding the necessity of developing complex (multiple and mixed) fertilizers including liquid ones, has become universally accepted. Up to the present the widespread use of the considerably cheaper liquid fertilizers has been limited by administrative and technical difficulties, viz. the need to mass-produce machines for introducing them into the soil, to build special storage containers and to ensure transport facilities.

Hydroponics will be developed in northern areas, unsuitable for ordinary agriculture, with conditioned and automated supply of liquid complex fertilizers to the plants.

Chemical industry faces the great and acute problem of satisfying, in the shortest possible time, the qualitative and quantitative needs of animal husbandry for feed-stuffs, preservatives and sanitary agents. Chemical industry has entered the sphere of animal husbandry later than that of horticulture. The economic effect of using feed-stuffs is considerably greater than that of using mineral fertilizers. We shall not dwell here on the numerous problems facing the chemical, petrochemical, silicate and other branches of industry covered by the plans for the immediate future, as these are dealt with in other publications[45].

In view of the rapidly expanding use of pesticides there will be considerable expansion of investigations by chemists, biologists, agriculturists, doctors, veterinary surgeons and other experts to ensure the safety of applying these agents; at the same time steps will be taken to enlighten the users of the agricultural agents. In recent times research organisations and ministries have worked out measures to expand biological and agro-technical means of protecting plants, and to integrate their use with that of chemical agents which are the most quick-acting and most widely-available.

Future researches of chemists and biologist will undoubtedly succeed in combatting various human and animal infectious diseases, malignant tumours, sclerosis, mental and other serious illnesses. Collaboration between chemical and medical establishments and between relevant learned societies could prove very effective in these researches.

FUNDAMENTAL PROBLEMS OF THE SOCIETY

The significance of the activities of learned societies is constantly increasing in view of the rapidly growing rôle of science in industrial progress, penetrating as it does all spheres of life, and in view of the collaboration among various specialists. Naturally, under conditions of socialism and at the time of a scientific-industrial revolution when on the one hand there is growing specialization and division of labour and on the other hand cooperation and integration of effort, the content, form and effect of the work of the Chemical Society must be given special attention and must be perfected. The significance of the resolution of the Soviet Peoples' Committee signed in 1921 by Lenin has not decreased but grown, viz. "...the creation of scientific and technical societies is to be encouraged"[43]. In this document it was submitted that "....engineering and technical societies, in the interests of optimal development and elucidation of technical and economic and administrative problems, (are) to be given all facilities for holding meetings and conferences, for publishing their reports and results of work, and for liason with scientific and technical organizations abroad".

Other government and party resolutions have been of great significance in promoting the effectiveness of scientific and technical societies, especially the resolution of the Council of Ministers of the USSR of 17th October, 1962: "On improvements of the utilization in the national economy of the recommendations of scientific and technical societies".

The Chemical Society has gone a long and honourable way in the last hundred years. The number of members has grown in the past ten years over 50-fold; the activities of the Society have become more diversified and concerned closer with problems posed by life; it takes an active and creative part in socialist construction.

It should be remembered that the Mendeleev Society had initiated the publication of several journals: "Khimiya v Shkole" (Chemistry in the School), "Uspekhi Khimii", Referativnyi Khimicheskii Zhurnal (Journal of Chemical Abstracts), of the popular scientific journal "Khimiya i thizn" (Chemistry and Life), the Journal of the All-Union D. I. Mendeleev Chemical Society, every issue of which publishes a diversified account of a given branch of the science and of technology, its state and problems, thus acting as a live, constantly expanding encyclopaedia of chemistry and

its relationship with the disciplines bordering on it. After the October Revolution the Journal of the Russian Physico-chemical Society split into the Journal of General Chemistry (Zhurnal Obshchei Khimii) and the Journal of Applied Chemistry (Zhurnal Prikladnoi Khimii). In 1920, on the initiative of chemists, was created the Chemico-technological publishing house (now the publishers "Khimiya"[44]).

The annual competitions organized by the Society for the best research work in a given subject attract several thousand scientists each year. A great stimulus is also provided by the annual review of the adoption of new techniques in industry and in institutes; this review is undertaken jointly by the Society and by the trade unions of the petroleum processing industry and of chemical industry and by the ministries concerned.

On the initiative of the All-Union Chemical Society the Government inaugurated in 1965 the award of a Mendeleev Gold Medal for outstanding chemical work of significance to the national economy. The award is made jointly by the Praesidium of the All-Union Chemical Society and the Academy of Sciences of the USSR.

Apart from Mendeleev congresses and numerous conferences and symposia, the Society organizes seminars and schools dealing with chemical achievements and experience; conjointly with the society "Knowledge" lectures and publications are used to disseminate chemical information. Consultations and expert advice services are expanding—especially to industry, to novel undertakings, to workers and young people, to inventors and innovators. A great deal of attention is devoted to everyday problems in chemistry and to local industries.

The most important problem facing the Society in the immediate future is the improvement of the quality of its activities: effectiveness, creative initiative, the involvement in scientific and industrial work of all its members. In the course of recent congresses and plenary sessions of the Society its members were exhorted to take all possible measures to develop independent creative work in divers chemical spheres and to strengthen the contacts and expand the cooperation with physicists, biologists, technologists and other specialists. At the present time the Mendeleev Society is endeavouring to enhance the interest in, and the quality of, theoretical and research studies, attracting a wider circle of young scientists and especially of students.

The current economic reforms necessitate further efforts by economists and engineers to perfect the planning and stimulation of industry, the prognosis of the directions in which chemistry will benefit the national economy, the optimal geographical placing of industrial plant, the methodology of technical economic estimates in industry and in science.

It must be noted with great satisfaction that many retired chemists continue with extremely useful activities, viz. as consultants, experts, organizers; giving guidance to young scientists working for higher qualifications and solving scientific and technical problems.

The complexity of many problems to be solved demands increasingly efficient organization, and the selection and education of gifted, erudite, highly educated organizers and leaders with a great deal of initiative; their numbers are still deficient in the USSR.

Problems arising from the progress of science and technology necessitate continuing searches along the limitless routes of chemical synthesis and continuing expansion of the assortment and properties of the countless products; the physico-chemical mechanisms of chemical reactions have to be studied in depth; technological processes have to be intensified and improved; methods and agents for harmless and safe chemical industrial processes have to be developed, and nature and people have to be safeguarded; research has to be speeded up and the tempo of assimilation of novel techniques by industry has to be accelerated.

This acceleration and a decrease in the cost of experimental work is aided by the efforts of members of the Society who are intensifying the study and application of powerful new means, viz. mathematics, computer techniques, automation and cybernetics, of pilot-plant work and of developing optimal conditions for chemical processes.

The Society has to respond to the pulse of life, to recognize as quickly as possible "growing points" and to ensure their development.

Chemical propaganda at the present time is carried on on a higher plane: it reaches deeper and is directed not only to dissemination of basic information to a wide public but aims at the raising of qualifications of chemists who are specialists in borderline topics of chemistry and technology. The spasmodic lectures and discussions, on the most popular level, are increasingly giving way to systematic cycles of lectures, schools, seminars, laboratory sessions and excursions. Because of the wide range and many-sidedness of the Society's activities the Praesidium is entertaining hopes of creating "Houses of Chemistry".

---o0o---

Modern chemistry in a socialist state is a powerful and noble force, increasing productivity and helping to raise the level of well-being and culture of the people.

In celebrating the centenary of the "chemical troop" we are not only surveying with legitimate pride the Society's record of successes whilst analysing the mistakes and shortcomings, but we also look to the future, and hope to inspire and direct our members to new creative efforts "for the common harvest", to accelerate the achievement of a happy, thriving human society.

Halogen Derivatives of Alkyl(or aryl)halogenosilanes and Tetrasubstituted Silanes

K.A.Andrianov and A.I.Petrashko

In recent years there have been many investigations in the field of organosilicon compounds containing halogen-substituted organic groups. These investigations offer prospects of the use of these compounds in the synthesis of polyorganosiloxanes. The extensive data on methods of synthesis of halogen derivatives of alkyl(or aryl)halogenosilanes and tetrasubstituted silanes, their properties, and use are scattered in many periodicals. Monographs and review articles have so far examined only isolated aspects of the chemistry of organosilicon compounds[1-4]. This has stimulated us to survey the accumulated experimental results, the analysis of which even now allows definite regularities to be found in the occurrence of certain reactions and processes in the synthesis and conversions of halogen derivatives of organosilicon compounds. There is a bibliography of 677 references.

III. Applications 225

I. METHODS OF SYNTHESIS

1. Halogenation of Alkyl(or aryl)halogenosilanes and Tetrasubstituted Silanes

When halogens act on organosilicon compounds two reactions are possible: (1) detachment of an alkyl or aryl group from a silicon atom, for example, in the bromination of tetraphenylsilane[5,6]:

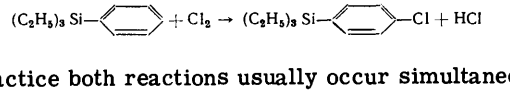
$$(C_6H_5)_4Si + Br_2 \rightarrow (C_6H_5)_3SiBr + C_6H_5Br,$$

or in the halogenation of a trialkylhalogenosilane[7]:

$$R_3SiX + X'_2 \rightarrow R_2SiXX' + RX',$$

where R = alkyl, and X and X' are halogens.

Depending on the halogen attached to the silicon in the alkylhalogenosilane(X), the rate of this reaction increases in the order Br < Cl < F < I. (2) Halogenation of the alkyl and aryl groups of the organosilicon compound, for example, in the chlorination of triethylphenylsilane[8]:



In practice both reactions usually occur simultaneously. The predominating direction of the reaction depends on the conditions under which the process is carried out, and also the catalyst type.

a. Halogenation of alkylhalogenosilanes and tetra-alkylsilanes. The first studies of the chlorination of alkylchlorosilanes and tetrasubstituted alkylsilanes date back to 1945[9].

The chlorination of alkylchlorosilanes and tetra-alkylsilanes can be brought about by the action of chlorine in the liquid or the gaseous phase or by the action of sulphuryl chloride. The photochemical chlorination of methylchlorosilanes, depending on their structure, takes place at different rates, and leads to the formation of chloro(chloromethyl)silanes with different degrees of substitution[10-12].

In liquid-phase chlorination of chlorotrimethylsilane in the presence of azobisisobutyronitrile the composition of the reaction products depends mainly on the ratio of $(CH_3)_3SiCl$ to Cl_2. With increase in this ratio the proportion of polychloro-substituted derivatives diminishes and the yield of $CH_2ClSi(CH_3)_2Cl$ increases[13]. When $(CH_3)_3SiCl : Cl_2 = 1 : 4.15$ the chlorination proceeds with the formation of appreciable quantities of $CH_3.SiCl.(CH_2Cl)_2$ [14] and also of tri- and tetra-substituted derivatives[15]. Further chlorination in CCl_4 leads to the formation of chlorotris(trichloromethyl)silane in 50% yield.

Dichlorodimethylsilane and trichloro(methyl)silane are chlorinated with greater difficulty than chlorotrimethylsilane. It was found[14-19] that the replacement of one methyl radical in chlorotrimethylsilane by a chlorine atom reduces the rate of chlorination by a factor of nine. Unlike chlorotrimethylsilane, in the chlorination of dichlorodimethylsilane by chlorine the hydrogen atoms of a single methyl group are replaced successively[14,16]. Increasing the reaction temperature from 0° to 24.4°C increases the rate of the process three times, but the ratio between the rates of chlorination of $CH_2ClSiCl_3$ and CH_3SiCl_3 is retained. In chlorination by gaseous chlorine at 60°C in the presence of azobisisobutyronitrile, dichlorobis(trichloromethyl)silane is formed in 40–50% yield[17]. The reaction is accompanied by the formation of CCl_4 and CCl_3SiCl_3 as side-products[18]. The chlorination of $CH_3(CCl_3)SiCl_2$ under analogous conditions leads to the formation of $(CCl_3)_2SiCl_2$ in ~ 60% yield. In the liquid-phase photochemical chlorination of trichloro(methyl)silane CCl_3SiCl_3 is formed predominantly[20-23].

The considerable difference in the rates of chlorination of the methyl and chloromethyl groups connected with a silicon atom hinders the production of trichloro(chloromethyl)silane, which is usually obtained by carrying out the reaction with a great excess of trichloro(methyl)silane[24] or by continuously removing the trichloro(chloromethyl)-silane from the reaction zone[25-33]. The chlorination by this method of trichloro(methyl)silane, dichlorodimethylsilane, chlorotrimethylsilane, and tetramethylsilane gives the corresponding monochloro-derivatives in good yields[16,28,34,35].

The use of azobisisobutyronitrile as initiator in the chlorination of chlorotrimethylsilane, unlike the initiation by ultraviolet light, allows $CH_2ClSiCl_3$ to be obtained even in conditions which do not provide for the removal of the chlorination product from the reaction zone[36], which shows

that the nature of the initiator has a significant effect on the chlorination.

In the liquid-phase chlorination of trichloro(methyl)silane and of dichlorodimethylsilane, acetylcyclohexylsulphonyl peroxide is a better initiator for the process than azobisisobutyronitrile[37] but the use of the former helps to increase the yield of polychloro-derivatives.

Tetramethylsilane is readily chlorinated in liquid-phase chlorination[38], just as is neopentane[7]. Here, as for chlorotrimethylsilane, the introduction of a second chlorine atom into the molecule leads to the formation of $(CH_3)_2Si(CH_2Cl)_2$.[39] In the photochemical chlorination of trichloro(methoxy)silane[40,41], a mixture of $CH_2ClOSiCl_3$ and CCl_3OSiCl_3 is formed[42].

With fluorine as the initiator, the chlorination of chloro(methyl)silanes takes place in the dark[43,44]. $CH_2Cl.SiCl_2.CH_3$ was obtained in 50.2% yield from dichlorodimethylsilane by this method, and $(CH_3)_2SiCl.CH_2Cl$ (40.9%) and $(CH_3)_2SiCl.CHCl_2$ (3.8%) from the chlorination of chlorotrimethylsilane. The chlorination of trichloro(methyl)silane under the action of γ-radiation takes place at a high rate[45,46]. The chlorination of poly(dimethylsiloxane) rubber at 0°C under the action of γ-radiation (^{60}Co source) proceeds readily up to the introduction of an average of two chlorine atoms in the polymer unit, after which the rate of the process drops sharply[47]. The chlorination of poly(dimethylsiloxane) rubber by elemental chlorine in CCl_4 in the presence of azobisisobutyronitrile is slow and accompanied by decomposition with formation of difficultly soluble polymers[48].

$(CH_3)_3Si.SiCl.(CH_3)_2$ (25%) and $[CH_2Cl(CH_3)_2Si]_2$ (5.0%) are obtained in the chlorination of hexamethyldisilane[49].

Under the action of chlorine, especially on prolonged chlorination, methylsiloxanes decompose with rupture of the siloxane bond[30,50-55], owing to the hydrogen chloride which is formed.

When the reaction is carried out under mild conditions and the chlorination products are removed continuously from the sphere of the reaction, breaking of the Si–O–Si bonds can be avoided. For example, in the chlorination of octamethylcyclotetrasiloxane[30,56-58] chloromethylheptamethylcyclotetrasiloxane is obtained; more extensive chlorination in the presence of azobisisobutyronitrile leads to the formation of a difficultly separable mixture of chloro-substituted derivatives[59].

On initiation with ultraviolet light tetraethylsilane is chlorinated with the formation of monochloro- and dichloro-derivatives; the reaction is accelerated by phosphorus(V) chloride[60-62].

The photochemical chlorination of chloro(ethyl)silanes with removal of the chlorination products from the reaction zone allows the trichloro-(1-chloroethyl)- and trichloro-(2)-chloroethyl)-silanes to be obtained in 1 : 1.6 ratio[63-68]. The vapour-phase chlorination of trichloro(ethyl)silane at 350°C leads to the formation of 1- and 2-chloroethyl derivatives[69] in the ratio 1 : 1.08. In the chlorination of dichloro(ethyl)methylsilane under ultraviolet irradiation dichloro(chloromethyl)ethylsilane is formed predominantly[70]. When the reaction is carried out with illumination from a 150 W electric lamp (16–21°C) dichloro-(1-chloroethyl) methylsilane can be obtained in 38% yield on the dichloro(ethyl)methylsilane which has reacted. $CF_2HCF_2SiCl_3$ is chlorinated at 150–200°C with the formation of $CF_2ClCF_2SiCl_3$.[71]

The chlorination of trichloro(propyl)silane leads to the formation of α-, β-, and γ-chloro-derivatives in the ratio 0.7 : 1 : 1.[31] Trichloro-(isopropyl)silane is chlorinated with preferential formation of trichloro-(2-chloro-1-methylethyl)silane[72]. A necessary condition for obtaining the monochloro-derivatives in the chlorination of the trichloro-(propyl)silanes is the removal of the chlorination products from the reaction zone[73-76].

In the chlorination of $CF_3CH_2CH_2SiCl_3$ under the action of ultraviolet radiation[77] the C–H bond in the α-position is 6.2 times more susceptible to attack by chlorine than that in β-position. At the ratio $Cl_2 : CF_3CH_2CH_2SiCl_3 = 1.5$ and 25–100°C, 80% $CF_3CH_2CHClSiCl_3$ and 20% $CF_3CHClCH_2SiCl_3$; $CF_3CH_2CCl_2SiCl_3$ is formed as an impurity. The predominant formation of the α-chloro-derivatives also occurs in the chlorination of $CF_3CH_2CH_2Si(CH_3)Cl_2$.[78] Consequently the CF_3 group acts more strongly than the dichloro(methyl)-silyl and trichlorosilyl groups as β-orienting agents.

Trichloro(vinyl)silane is chlorinated differently depending on the temperature: at 200–350°C substitution occurs with the formation of $CH_2=CClSiCl_3$; at 160–200°C chlorine adds at the double bond with the formation of $CH_2ClCHClSiCl_3$.[79] Trichloro(methylallyl)silane is chlorinated with replacement of hydrogen in the methyl group even at room temperature[80,81]:

$$Cl_3SiCH_2C(CH_3)=CH_2 \xrightarrow{Cl_2} Cl_3SiCH_2C(CH_2Cl)=CH_2 .$$

Substitutional chlorination also takes place with trichloro(isocrotyl)silane[82]; however, the addition of chlorine in the chlorination of alkenyl- and (alkenyl)alkylchlorosilanes is the main reaction[21,23,74,79,83-86].

A series of studies was devoted to the chlorination of hexachlorodisilylmethane[31,37], hexachlorodisilylethane[31,88], and other compounds of this type[39,89,90]. In the photochlorination of 1,1,3,3,5,5,7,7-octachloro-1,3,5,7-tetrasilacyclo-octane[91] 1,1,2,2,3,3,4,5,5,6,7,7,8-tridecachloro-1,3,5,7-tetrasilacyclo-octane is formed.

Chlorocyanoalkyl-substituted silanes of the general formula

$$[NC(CH_{2-a}Cl_a)_b]_n SiR_mX_{4-m-n}$$

where $a = 1$ or 2, $b = 2$–12, $n = 1$–3, $m = 0$–2, and X = Cl or F, are obtained by chlorination with elemental chlorine at 20–80°C and ultraviolet irradiation of the corresponding cyanoalkyl-substituted halogenosilanes[92].

Chlorination of alkylchlorosilanes and alkyl-substituted esters of orthosilicic acid by sulphuryl chloride takes place on heating in the presence of benzoyl peroxide[93-95].

Sulphuryl chloride is a less active chlorinating agent, therefore it is recommended for the chlorination of chloro(methyl)silanes when the formation of polychloro-derivatives must be avoided[96].

In the chlorination by sulphuryl chloride of chlorotrimethylsilane in the presence of peroxide in chlorobenzene as medium chloro(chloromethyl)dimethylsilane is formed[97,98]. Trichloro(methyl)silane in a medium of *o*-dichlorobenzene at 80°C is chlorinated by sulphuryl chloride to trichloro-(chloromethyl)silane, but its yield is only ~ 2.6%[23].

Under ultraviolet irradiation dichlorodimethylsilane reacts with sulphuryl chloride with great difficulty, giving a small quantity of dichloro(chloromethyl)methylsilane[99].

Owing to their higher boiling points chloro(ethyl)silanes are readily chlorinated by sulphuryl chloride in the absence of solvents; 1- and 2-chloroethylchlorosilanes are formed as a result[21,93,100]. The ethyl group is chlorinated more easily than the methyl group. Thus in the chlorination by sulphuryl chloride of dichloro(ethyl)methyl silane the main products are dichloro-(1-chloroethyl)methylsilane and dichloro-(2-chloroethyl)methylsilane[101]. Tetraethylsilane forms 1-chloroethyl derivatives[28,63,102,103]; in the chlorination of trichloro(ethyl)silane, dichlorodiethylsilane, and

chlorotriethylsilane, mixtures of chloro-(1- and 2-chloroethyl)silanes are formed [93,100,104]. The yield of the 2-isomers increases with the increase in the number of chlorine atoms at the silicon [64].

Chlorination of trichloro(propyl)silane by sulphuryl chloride leads to the formation of the 1-, 2-, and 3-isomers [108] in the ratio 1 : 3.5 : 3.1; trichloro(isopropyl)silanes give a mixture of the 1- and 2- isomers [106] in the ratio 1 : 3.5. Trichloro-(t-butyl)silane forms $CH_2Cl(CH_3)_2C.SiCl_3$ on chlorination [107]. Hexamethyldisilane is chlorinated by sulphuryl chloride to chloromethylpentamethyldisilane [108].

Organosilicon alcohols, can be easily converted into the corresponding halogen derivatives with hydrogen halides [109-111,113], thionyl chloride [112-115], phosphorus(III) bromide [116-119], etc.

Sulphuryl chloride readily chlorinates bis(trichlorosilyl)-methane and bistrichlorosilylethane [31] and also cyclocarbosilanes containing chlorine atoms [120,121] and methyl groups [122] at the silicon.

t-Butyl hypochlorite is also used as a chlorinating agent in the chlorination of alkyl-substituted organosilicon compounds [123,124].

Tetrasubstituted silanes are brominated directly by bromine [125-127] and by bromosuccinimide [128-130]. In the bromination of tetraethylsilane $(C_2H_5)_3SiCHBrCH_3$ and $(C_2H_5)_3SiCBr_2CH_3$ [25,28-33] are formed [134]. Chloro(methyl)-silanes and tetramethylsilanes have been brominated by ultraviolet irradiation and the simultaneous passage of bromine and chlorine [135]. Bromination of chloro(ethyl)silanes in this way gives a mixture of 1- and 2-bromoethylsilanes [136,137]. Under these conditions hexamethyldisiloxane forms bromomethylpentamethyldisiloxane [138]. Trichloro-(2-cyanoethyl)silane is brominated with formation of bromocyanoethyltrichlorosilane [139]. The bromination of 1,1,2-triphenyl-1-silacyclobutane with *N*-bromosuccinimide leads to the formation of 2-bromo-1,1,2-triphenyl-1-silacyclobutane [140].

When bromine acts on unsaturated alkenylchlorosilanes and alkenylalkylsilanes addition of bromine at a multiple bond takes place [71,141-143].

b. Halogenation of arylhalogenosilanes, arylalkylhalogenosilanes, and tetra-aryl (or arylalkyl)-substituted silanes. Ladenburg carried out the direct chlorination of triethoxy(phenyl)-silane [144] but an intensive study of this process began in the 1940's after the appearance of a patent [145] on the chlorination of dichlorodiphenylsilane and dichloro(methyl)phenylsilane.

The chlorination of the aromatic nuclei of organosilicon compounds takes place in the presence of catalysts: metallic iron, iodine, phosphorus(V) chloride, antimony(III) chloride, or aluminium chloride, and is initiated by ultraviolet light [146].

There have been many studies of the chlorination of trichloro(phenyl)silane [147-159]; in these investigations the production of trichlorochlorophenylsilanes of all degrees of substitution of chlorine for hydrogen in the phenyl group under various conditions was investigated using radical catalysts.

The chlorination of chloro(phenyl)silanes in the presence of iodine and phosphorus(V) chloride takes place at 110-140°C without splitting of the chlorination products, but the catalytic activity of these substances is low. They can therefore be used for obtaining monochloro-derivatives of trichloro(phenyl)silane and dichlorodiphenylsilane. ICl and ICl_3 react with trichloro(phenyl)silane at low temperature (-40°C) with the formation of $C_6H_5 - nCl_nSiCl_3$ ($n = 1$ or 2), the main reaction product being trichloro-(*m*-chlorophenyl)silane [160]. The reaction of $Cl_2C_6H_3SiCl_3$ with ICl_3 at 20°C leads to $Cl_3C_6H_2SiCl_3$. Photochemical chlorination of trichloro(phenyl)silane in the presence of iodine at 20°C leads to the formation of a product of incompletely additive chlorination [161] $C_6H_5Cl_4SiCl_3$.

The splitting of the Si-C bond in the presence of catalysts increases with the chlorination temperature; it can be reduced to a minimum by carrying out the reaction under milder conditions (for example, at 20-30°C in a medium of carbon tetrachloride or some other solvent which is inert in relation to chlorine). When aluminium chloride or iron(III) chloride is used as catalyst splitting of the reaction products takes place even at 30°C—at the very start of chlorination. In the presence of antimony(III) chloride this process is observed in more extensive chlorination and at higher temperatures [162].

In the chlorination of dichlorodiphenylsilane at 70-80°C in the presence of antimony(V) chloride the process takes place with considerable evolution of heat; the main product of the reaction is dichlorobistrichlorophenylsilane. Dichlorobispentachlorophenylsilane can be obtained by further chlorination at 120°C but then the splitting of the Si-C bond can be considerably intensified.

Chlorination at 100°C and over without catalysts or chlorination with irradiation of the reaction mixture with ultraviolet light at 70°C does not bring about splitting of the Si-C bond in trichloro(phenyl)silane or dichlorodiphenylsilane.

Temperature has a considerable influence on the nature of the chlorination of trichloro(phenyl)silane in light (there is no reaction in the dark) and in ultraviolet radiation [158,161,163]. At 0-2°C addition of chlorine occurs, at 95-100°C as well as the addition there is replacement of hydrogen atoms of the phenyl group by chlorine; at 125-150°C the reaction is more vigorous than in the presence of azobisisobutyronitrile.

Depending on the chlorination conditions, the $SiCl_3$ group exhibits a different orienting effect. In chlorinating trichloro(phenyl)silane in the presence of iron a mixture of *m*-, *p*-, and *o*-chlorophenyltrichlorosilanes in the ratio 74 : 2 : 24 is formed [150], but in the chlorination of trifluoro-(phenyl)silane the ratio is 82 : 0 : 18 [164]. This shows that the trichlorosilyl and trifluorosilyl groups orient the replacement of hydrogen of the benzene nucleus by chlorine, mainly in the *meta*-position. Chlorination of trimethyl-(phenyl)silane gives a mixture of the *o*-, *p*-, and *m*-chlorophenyltrimethylsilanes in the ratio 24 : 25 : 51 [164].

In the electrophilic chlorination of trichloro(phenyl)-silane in the presence of $FeCl_3$ and $AlCl_3$ and $SiCl_3$ group is also a *meta*-orientant; 28% of the *ortho*-isomer is formed [159].

In the photochemical chlorination of trichloro(phenyl)-silane at 120-150°C in the presence of azobisisobutyronitrile 43% *o*-$ClC_6H_4SiCl_3$ is formed. When iodine is used as catalyst (whether with illumination or in the dark) at 20°C 67% trichloro-*o*-chlorophenylsilane and $C_6H_5Cl_4SiCl_3$ is formed.

The polymers which contain phenyl groups at silicon atoms are converted during chlorination into the corresponding polymers with chlorophenyl groups [165].

It should be noted that the distribution of chlorine between the phenyl groups in the fractions is irregular: the degree of chlorination increases with decrease in the molecular weight of the fraction.

The chlorination of *p*-chlorophenyltrichlorosilane, trifluoro(phenyl)silane [164] and tetraphenylsilane [166] is effected

in the presence of $FeCl_3$ and $SbCl_5$ as catalysts in CCl_4 medium to decrease cleavage of the Si–C bond.

When there are alkyl substituents at the phenyl group they are the first to be chlorinated. In the chlorination of trichloro-*p*-tolylsilane, trichloro-*p*-trichloromethylphenylsilane is obtained[167,168]; when the process is carried out with ultraviolet irradiation trichloro-*p*-trichloromethylphenylsilane can be obtained in 92% yield. Trichloro-*o*-tolylsilane under these conditions is not chlorinated, owing to steric hindrance by the $SiCl_3$ group[168], whereas trifluoro-*o*-tolylsilane is chlorinated readily.

The chlorination of trichloro(ethyl)phenylsilanes lead to the production of $C_2H_5 - {}_nCl_nC_6H_4SiCl_3$ [169] and p-$CH_2ClCH_2 . C_6H_5SiCl_3$ [170,171]. Trichloro(*p*-ethylphenyl)silane is readily chlorinated on illumination with two luminescent lamps; the p-$C_2H_4ClC_6H_4SiCl_3$ which is formed is used to obtain p-$CH_2{=}CHC_6H_4SiCl_3$.[170,172–174].

Compounds in which the phenyl groups are connected with silicon by methylene links are readily chlorinated by sulphuryl chloride[175]:

$$C_6H_5CH_2SiCl_3 \xrightarrow{SOCl_2} C_6H_5CH_{2-n}Cl_nSiCl_3.$$

A series of compounds of this type was obtained by this reaction, for example, $C_6H_5CHClSi(CH_3)_3$, and $(C_6H_5)_2 . CClSi(CH_3)_3$ [93,176–178] and also chloro-substituted benzyltrichlorosilane and trichloro-(-*p*-xylenyl)silane[176].

The direction of the chlorination of dichloro(methyl)phenylsilane is determined by the conditions. The use as catalysts of $FeCl_3$ and $SbCl_5$,[180] $SbCl_3$ at 10–15 °C, and also iodine (the reaction being carried out in CCl_4 or without a solvent)[181] leads to substitution of chlorine for hydrogen atoms in the phenyl groups; chlorination of the methyl groups does not take place under these conditions, but the reaction is accompanied by splitting of the $Si-C_{aryl}$ bond, the splitting proceeding more readily than with dichlorodiphenylsilane. The CH_3SiCl_2 group, like the $SiCl_3$ group, orients the replacement of hydrogen in the benzene nucleus by chlorine mainly into the *meta*-position.

In the presence of azobisisobutyronitrile the chlorination of dichloro(methyl)phenylsilane takes place with the chlorine replacing hydrogen atoms in the methyl group; the product of exhaustive chlorination at 110–115 °C is $C_6H_5(CCl_3)SiCl_2$.[182,183]

In the photochemical chlorination of dichloro(methyl)phenylsilane at 20–25 °C in addition to the substitution of chlorine for the hydrogen atoms in the methyl groups[163] addition of chlorine to the phenyl group takes place[184].

The chlorination of dichloro(methyl)phenylsilane in diffuse daylight proceeds in different directions depending on the temperature of the reaction. At 0–5 °C the only reaction is addition of chlorine to the phenyl group with the formation of dichloro(methyl)(hexachlorocyclohexyl)silane in 78.4% yield[185]; raising the temperature of the reaction to 20–25 °C leads to a decrease in the yield of $C_6H_5Cl_6(CH_3) . SiCl_2$ to 46% owing to the formation of dichloro(dichlorophenyl)methylsilane (19.6%)[163,186]. With a further rise in the chlorination temperature the substitution reaction rate increases and at 50–55 °C replacement of hydrogen by chlorine in the phenyl group takes place exclusively[187], with the formation of $C_6H_5 - {}_nCl_n(CH_3)SiCl_2$ (n = 2 or 3); the CH_3SiCl_2 group is a *meta*-orientant here.

Unlike dichloro(methyl)phenylsilane, dichloro(phenyl)(trichloromethyl)silane does not react with chlorine in diffuse daylight at 110–115 °C in the absence of initiating and catalysing additions[188]. On raising the temperature to 150 °C the $Si-C_{aryl}$ bond is broken. In the presence of $SbCl_3$ or iodine, $C_6H_5 - {}_nCl_n(CCl_3)SiCl_2$ is formed (n = 1–3). Like $SiCl_3$, the CCl_3SiCl_2 group directs the chlorine atom entering the phenyl nucleus mainly into the *meta*-position.

$C_6H_4Cl_6(CCl_3)SiCl_2$ is formed in the photochemical chlorination of $C_6H_5(CCl_3)SiCl_2$ at 20–25 °C. Analogous results are given by azobisisobutyronitrile as initiator. The increased stability of $C_6H_5(CCl_3)SiCl_2$ in comparison with $C_6H_5(CH_3)SiCl_2$ in electrophilic and radical chlorinations is explained by the increaee in the electrophilic nature of the silicon atom in $C_6H_5(CCl_3)SiCl_2$ owing to replacement of the electron-donating methyl group by the electron-accepting trichloromethyl group.

In the chlorination of $(p$-$CH_3C_6H_4)CH_3SiCl_2$ in the presence of azobisisobutyronitrile at 110–115 °C by chlorine the hydrogen in the methyl group of the aromatic nucleus is replaced first[189]. Trichloromethyltriphenylsilane is formed in the chlorination of methyltriphenylsilane[190].

The chlorination of dichloro(methyl)phenylsilane with the aid of sulphuryl chloride in the presence of radical catalysts takes place with substitution of chlorine for the hydrogen atoms in the methyl groups[191]; the main product of the reaction when the process is carried out in the presence of azobisisobutyronitrile is $C_6H_5(CHCl_2)SiCl_2$.

The chlorination of dichloro(methyl)phenylsilane under the action of radiation (^{60}Co) leads to the formation of $C_6H_2Cl_3(CCl_3)SiCl_2$.[47] In the chlorination of polyphenylmethylsiloxanes under these conditions, in addition to substitution additive chlorination in the phenyl nucleus also takes place under these conditions[47,192].

The production of bromoarylchlorosilanes by the direct bromination of aryltrichlorosilanes and diaryldichlorosilanes is accompanied by cleavage of the Si–C bond. This reaction is especially prominent in the synthesis of the polybromophenylchlorosilanes.

Bromophenyltrichlorosilane was obtained in 40% yield by the simultaneous action of bromine and chlorine on trichloro(phenyl)silane with irradiation by ultraviolet light[135,193]. The bromination of trifluoro(phenyl)silane in the presence of iron gives pronounced splitting of the Si–C bond; the yield of bromophenyltrifluorosilane is only 3.5%.

Of the other aromatic chlorosilanes there have been studies of the bromination of benzyltrichlorosilane[194], trichloro-(*p*-tolyl)silane[195], and tetra-(*p*-tolyl)silane[196]. It was found that the $-(CH_2)_nSiCl_mR_{3-n-m}$ groups are strong *ortho*- and *para*-orienting agents and activate the benzene ring in electrophilic substitutions[197].

Benzyltrimethylsilane is brominated more readily than benzyltrichlorosilane[198]; on boiling a solution of it in CCl_4 with *N*-bromosuccinimide $C_6H_5CHBrSi(CH_3)_3$ and $C_6H_5CBr_2Si(CH_3)_3$ are formed[177]. In the bromination of $R_3SiCH(C_6H_5)_2$, $R_3SiC(C_6H_5)_2Br$ is obtained in yields up to 96%.[199] p-$CH_2BrC_6H_4Si(C_6H_5)_3$ is obtained by an analogous method[128]. o-$CH_2BrC_6H_4Si(C_6H_5)_2Br$ was obtained by the action of *N*-bromosuccinimide on o-$CH_3C_6H_4Si(C_6H_5)_2H$.[200] *N*-Bromosuccinimide readily brominates 2:3-benz-1-silacycloalkanes[201] to form 4-bromo-substituted derivatives.

The formation of p-bromobenzyltrifluorosilane in the bromination of benzyltrifluorosilane takes place without cleavage of the Si–C bond[164].

The bromination of dichloro(methyl)phenylsilane in the absence of a catalyst at 0°–25 °C leads to the production of $C_6H_5 - {}_nBr_n(CH_3)SiCl_2$ and is not accompanied by Si–C bond cleavage[202]. With catalysts (iodine, $SbCl_3$) at 10–15 °C the formation of these products is accompanied by $Si-C_{aryl}$ bond cleavage. In both instances the CH_3SiCl_2 group is a *meta*-orientant.

In the bromination of $BrC_6H_4Si(CH_3)_3$ 92.5% trimethylbromosilane and 92.7% dibromobenzene are formed.

The bromination of arylsilanes containing acetamido-[203], dimethylamino-[204], and hydroxyl[205] groups in the phenyl

group and of 9-fluorenyltrimethylsilane[206] has also been studied.

2. Addition of a Triorgano(halogeno)silyl Group to Unsaturated Halogenohydrocarbons

The addition of a triorgano(halogeno)silyl group to unsaturated halogenohydrocarbons was first effected at the start of the 1950's[207,208].

The addition of silanes to halogeno-substituted ethylenes takes place with greater difficulty than to ethylene. Depending on the type and number of halogen atoms in the molecule, the halogen-substituted ethylenes can be arranged in the following series of decreasing reactivity in the presence of platinum catalysts[209-213]: $CH_2=CH_2 > CH_2=CF_2 > CF_2=CFCl > CF_2=CF_2$.

Dichloro(alkyl)silanes add with difficulty to tetrafluoroethylene in the presence of platinum or palladium on carriers[211,214,215], $H_2PtCl_6.6H_2O$,[211,213] and under the action of γ-radiation[216]. Better results are obtained on initiation with ozone[217-219]; the maximal yield of addition products occurs on initiation of the reaction with ultraviolet light[220-223]. Under these conditions SiH_4 adds to $CF_2=CF_2$ with the formation of tetrafluoroethylsilanes of all degrees of substitution[224].

Trichlorosilane adds more readily to halogenoethylenes, the initiation of the reaction with ultraviolet light also being most effective[225,226].

Radiochemical synthesis with γ-radiation can be effected only when the rate of polymerisation of the halogenoalkene is lower than that for the addition. The maximal yield of addition products occurs when the initial mixture of reagents contains 1 mole alkene per hydrogen atom of silane[216].

Alkenes of the general formula $RR'C=CR''R'''$ add silanes of the formula $SiH_{4-m-n}X_nZ_m$ (where X is halogen, Z alkyl, $n = 2$ or 3, $m = 0$ or 1, and R, R', R'', and R''' are H, alkyl or aryl, at least one group being electronegative) in the presence of catalytic amounts of tertiary amines[227]. The reaction takes place at 25–130°C and pressures of 3.5–17.5 atm.

The order of addition depends on the nature of the compounds reacting and the type of catalyst. In the presence of platinum catalysts silanes add to 1,1-difluoroethylene in such a way that the silyl group will be at the carbon atom of the methyl group:

$$CF_2=CH_2 + HSi\lessgtr \rightarrow CF_2H-CH_2Si\lessgtr .$$

The addition of trichlorosilane to chloroethylene in the presence of benzoyl peroxide proceeds in two directions[224]:

$$CH_2=CHCl + HSiCl_3 \xrightarrow{(C_6H_5COO)_2} \begin{cases} \rightarrow ClCH_2CH_2SiCl_3 \\ \rightarrow CH_3CHClSiCl_3. \end{cases}$$

The order of addition of trichlorosilane to chlorotrifluoroethylene has not been established: some investigators[214,215,228] think that the silyl group adds to the CFCl group; others[225,226], to the CF_2 group.

Silanes react more difficultly with perfluoropropene than with perfluoroethylene[226]. When the double bond is not screened by fluorine atoms the addition proceeds much more readily, although with somewhat greater difficulty than with propene. For example, silanes add to trifluoropropene under the influence of ultraviolet radiation[226,229-231], peroxides[226], platinum on carbon[228,232,233], and $H_2PtCl_6.6H_2O$.[234-236].

In the presence of hydrogen hexachloroplatinate(IV) $HSiCl_3$ adds to $(CF_3)_2C=CH_2$:[237]

$$(CF_3)_2C=CH_2 + HSiCl_3 \rightarrow (CF_3)_2CHCH_2SiCl_3.$$

In the presence of radical initiators dichlorosilane adds to fluorinated alkenes with the formation of compounds of the general formula:

$$(RCF_2CHR'CH_2)_2SiCl_2,$$

where R = H, F or a perfluoroalkyl group, R' = H, CH_3, CF_3, C_2H_5, or C_3F_7.[238]

Difluoropropene $CHF_2CH=CH_2$ adds to organohydrochlorosilanes more readily than $CF_3CH=CH_2$.[239]

$CF_3CF_2CH=CH_2$ [230,240-242] and $CF_3CF_2CF_2CH=CH_2$ [228,229,232,240] react readily with silanes; $CF_3CF_2CF=CH_2$ [226] reacts with greater difficulty. In the presence of hydrogen hexachloroplatinate(IV) compounds of the formulae $HSiCl_3$, $RSiHCl_2$, and R_3SiH add to 3,4-dichlorobut-1-ene exclusively according to Farmer's rule; addition to 1,4-dichlorobut-2-ene is accompanied by the formation of anomalous reaction products[243].

The addition of silanes to allyl chloride proceeds readily under the action of ultraviolet light and peroxides[244], platinum on carriers[245], and complexes of $PtCl_2$.[246] As well as the additions, reduction of the allyl chloride by the silane occurs[247]:

$$CH_2=CHCH_2Cl + HSi\lessgtr \rightarrow \gtrless SiCl + CH_3=CHCH_3.$$

Dichloro(methyl)silane reacts with allyl bromide in the presence of hydrogen hexachloroplatinate(VI) to form $BrCH_2CH_2CH_2Si(CH_3)Cl_2$;[248,249] the reaction is more difficult than that with allyl chloride.

The addition of silanes to methylallylchloride in the presence of platinum on carriers[214,250,251] or $H_2PtCl_6.6H_2O$ [248-252] proceeds with higher yields than for allyl chloride.

The removal of electronegative groups or atoms from the double bond favours an increase in the reactivity of halogenoalkenes in additions[214].

Trichlorosilane adds to *m*- and *p*-$ClC_6H_4CH_2CH_2CH=CH_2$ with the formation of $ClC_6H_4[CH_2]_4SiCl_3$ with $ClC_6H_4CH.(SiCl_3)[CH_2]_3CH_3$ as impurity; the *o*-chloro-substituted addition of trichlorosilane with the formation of only $ClC_6H_4[CH_2]_4SiCl_3$.[253]

The addition of trichlorosilane and dichloro(methyl)-silane to the chlorobutenes in the presence of platinum is accompanied by allyl rearrangement, loss of chlorine in the allyl position, and migration of a double bond[254].

Compounds with a triple bond react with silanes to form alkenylhalogenosilanes. Trichloro-(1,2-dichlorovinyl)silane was obtained in this way[255,256]:

$$ClC \equiv CCl + HSiCl_3 \rightarrow CHCl = CClSiCl_3.$$

This reaction is accelerated in the presence of peroxides, on irradiation with ultraviolet light, or on heating to a temperature close to the decomposition temperature of dichloroacetylene.

In the presence of $H_2PtCl_6.6H_2O$, $RSiHCl_2$ (R = Cl or CH_3) adds vigorously to $CH_2ClC\equiv CH$ with the formation of various amounts of $RCl_2SiCH=CHCH_2Cl$ and $RCl_2SiC(=CH_2)CH_2.Cl$.[257] The reaction with $HC\equiv CCH_2Br$ takes place in a similar manner[258]. 1,4-Dichlorobutyne reacts with $HSiR_xCl_{3-x}$ according to the scheme[243]:

$$CH_2ClC\equiv CCH_2Cl + HSi\lessgtr \rightarrow \gtrless SiC(CH_2Cl)=CHCH_2Cl.$$

Triorganosilanes add to $CX_3CH(OH)OC(CH_3)(CR_2)C{\equiv}CH$ according to the Farmer rule with the formation of

$$CX_3CH(OH)OC(CH_3)(CR_2)CH{=}CHSiR'_3,$$

where R = H or CH_3, X = Cl or Br, R = CH_3, C_2H_5, or C_3H_7.[259]

In reaction with 1,1,2,2-tetrafluoroethylallyl ether[210, 212, 260-262] in the presence of platinum catalysts the alkylhalogenosilanes can be arranged in order of decreasing activity:

$$R_3SiH > R_2SiHCl > RSiHCl_2 > HSiCl_3.$$

Aryldichlorosilanes add most easily to this ether[263].

The addition of R_nSiHX_{3-n} (R = CH_3, C_2H_5; $n \neq 0, 1, 3$; X = halogen) to vinyl ethers of the $R'OCH{=}CH_2$ type (R' = p-ClC_6H_4, 2,4-$Cl_2C_6H_3$), leading to the formation of $R'OCH_2CH_2SiR_nX_{3-n}$, which is accompanied by β-decomposition, which leads to the production of $R'OSiR_nX_{3-n}$.[264]

The direction of the addition of silanes to unsaturated halogenohydrins depends on the position of the double bond relative to the halogen-bound carbon atom[265,266].

In the presence of hydrogen hexachloroplatinate(IV), $HSiCl_3$, CH_3SiHCl_2, and $HSi(OC_2H_5)_3$ adds to 2-chloromethylbicyclo[2,2,1]hept-5-ene,[267]

3. Addition of Halogens to Multiple Bonds of Alkenylsilanes

The addition of halogens proceeds readily to almost any organosilicon compound containing a multiple bond. When the organosilicon compound has at the silicon atom a vinyl group or another group with a double bond in the α-position, then $\alpha\beta$-alkyldihalogenosilanes are formed, which are rather stable thermally:

$$R_3SiCH{=}CH_2 + X_2 \rightarrow R_3SiCHXCH_2X,$$

where X = halogen. When the double bond is in the β-position to the silicon atom then $\beta\gamma$-dihalogenoalkylsilanes are formed in the reaction with the halogens; these are thermally unstable and undergo the so-called β-decomposition[268]:

$$R_3SiCH_2CH{=}CH_2 + X_2 \rightarrow R_3SiCH_2CHXCH_2X \rightarrow R_3SiX + CH_2XCH{=}CH_2.$$

$\beta\beta$-Difluoroalkyl-substituted organosilicon compounds readily decompose at low temperatures, as do $\alpha\alpha\beta\beta$-tetrafluoroethyl-substituted compounds[269]. Compounds with γ- and more distant positions of the double bond relative to the silicon atom readily add on halogens to form stable dihalogenoalkylsilanes. For example, the pyrolysis of trifluoropropyl-substituted organosilicon compounds is observed only at temperatures above 550°C.[269] The thermal stability of the dihalogenoalkylsilanes depends considerably on the nature of the remaining substituents at the silicon atom. The presence of a trichlorosilyl group sharply increases the thermal stability of even $\beta\gamma$-dichloroalkylsilanes.

There have been many studies of the addition of halogens to various alkenosilanes[81,143,268,270-279]. These papers describe the synthesis and properties of a large number of halogenoalkylsilanes. There have been several recent studies of this problem[280-282]. It was found that the replacement of three hydrogen atoms by fluorine considerably decreases the activity of a double bond in the addition of halogens, hydrogen halides, and polyhalogenomethanes[280].

Organosilicon compounds containing silacycloalkenic structures readily add halogens. For example, 1,1-dichlorosilacyclopent-2-ene adds bromine in CCl_4 at 0°C with the formation of 1,1-dichloro-2,3-dibromosilacyclopentene[283]. The reaction of 1,1,3,3-tetramethyl-1,3-disilacyclopentene with bromine and chlorine takes place analogously[284].

In a gas chromatographic investigation of the pyrolysis products of $Si(CH_3)_4$, $(CH_3)_2Si{=}CHSi(CH_3)_3$ was isolated, which vigorously reacts with bromine[285]:

$$(CH_3)_3Si{=}CHSi(CH_3)_3 + Br_2 \rightarrow (CH_3)_3BrSiCHBrSi(CH_3)_3.$$

$(CH_3)_3SiCH{=}C{=}O$, which is formed in the thermal (120-130°C) decomposition of $(CH_3)_3SiC{=}COC_2H_5$, adds on bromine with the formation of $(CH_3)_3SiCHBrCOBr$.[286]

The reaction of 1,1-bis(trimethylsilyl)ethylene with chlorine and bromine leads to the loss of one trimethylsilyl group[287]:

$$[(CH_3)_3Si]_2C{=}CH_2 + X_2 \rightarrow (CH_3)_3SiX + (CH_3)_3SiCX{=}CH_2.$$

The addition of bromine to silyl-substituted acetylenes leads to the formation of vinyl derivatives[141,288-290].

Hydrogen halides add to alkenylsilanes less vigorously than halogens. The presence of chlorine atoms at the silicon atom strongly retards and the presence of three alkyl groups accelerates the addition of hydrogen halides. On transferring the multiple bond from the α and β position the rate of addition increases, but further in the γ position, it falls. The rate of addition of hydrogen halides to alkenylsilanes increases in the order: HCl < HBr < HI. The addition of hydrogen halides, with the exception of hydrogen bromide, to allyl- and methylallyl-alkylsilanes takes place according to Markovnikov's rule independently of the nature of the alkyl groups connected to the silicon[291-295].

The reaction of vinyl-containing organosilicon compounds with hydrogen halides was first effected by the scheme[296]:

$$(CH_3)_3SiCH{=}CH_2 + HI \rightarrow (CH_3)_3SiCH_2CH_2I.$$

Subsequent investigations[275,292,297-300] showed that the addition of hydrogen halides to vinylsilanes takes place contrary to the Markovnikov rule. Just as for halogens, $CF_2{=}CFSi(C_2H_5)_3$ adds hydrogen halides worse then $CH_2{=}CHSi(C_2H_5)_3$.[280] HBr can add to $(CH_3)_3SiCH_2CH_2CH{=}CH_2$ both according to and contrary to the Markovnikov rule[116,204].

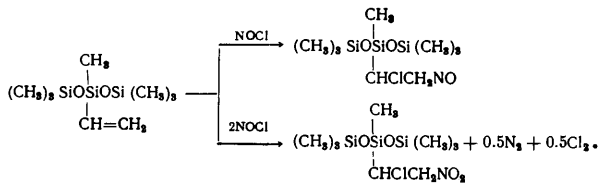
The addition of HBr and HCl to isopropenyltrimethylsilane[82,275,301] and isocrotyltrimethylsilane[82,300,302] obeys the Markovnikov rule, whereas HBr adds to $\alpha\beta$-dimethylvinyltrimethylsilane and $\gamma\gamma$-dimethylallyltrimethylsilane contrary to the Markovnikov rule[82].

Hydrogen halides add to silacyclopentenes with the formation of the corresponding halogeno-substituted silacyclopentanes[283,284].

As already noted, the β-halogenosilanes formed on addition of hydrogen halides to $\alpha\beta$-unsaturated silanes are extremely unstable compounds, which readily undergo β-decomposition with various reagents[173,303] or on raising the temperature[304-306]. The kinetics of the thermal decomposition of trichloro-2-chloroethylsilane[305] and 2,2-difluoroethyltrifluorosilane[307] in the gas phase follow a first-order equation.

Depending on the type of trimethylsilylalka-1,5-diyne, the addition to it of halogens and hydrogen halides proceeds differently[308]: (a) bromine adds to trimethylsilyldipropargyl at both triple bonds; (b) it adds to 1-trimethylsilylocta-1,5-diyne predominantly at the triple bond unsubstituted by silicon. HBr adds to 1-trimethylsilylhexa-1,5-diyne at the disubstituted triple bond with partial splitting of the adduct along the C–Si bond.

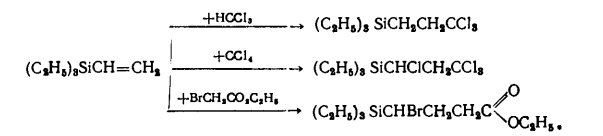
The nitrosochlorination of the vinyl-containing organosilicon compounds takes place in two directions[309]:



$ClNO_3$ adds to vinyltrichlorosilane according to the reaction[310]:

$$Cl_3SiCH{=}CH_2 + ClNO_3 \rightarrow Cl_3SiCHClCH_2NO_3.$$

The addition of polyhalogenomethanes and other halogenated hydrocarbons to vinylsilanes takes place with high yields, according to the reactions[280,311-316]:

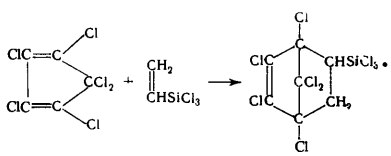


Polyhalogenohydrocarbons containing fluorine also add to vinyl-containing compounds[313,314,316,318].

When $CHCl_3$ and t-C_4H_9OK react with vinyl- and allyl-containing organosilicon compounds, products with dichlorocyclopropane groups are formed[319-322]:

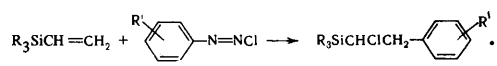
$$\equiv Si[CH_2]_nCH{=}CH_2 + CCl_2 \rightarrow \equiv Si[CH_2]_n\overline{CHCH_2CCl_2}.$$

Trichloro(vinyl)silane readily undergoes a diene condensation with cyclopentadiene and hexachlorocyclopentadiene[323-327]:

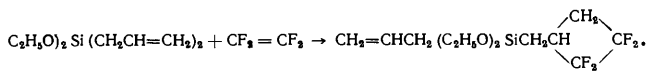


Allyldichloro(methyl)silane and 5,5-difluorotetrachlorocyclopentadiene[328,329] also undergo an analogous reaction[328,329], the latter reacting more readily than hexachlorocyclopentadiene. Alkenylsilanes containing hydrogen at the silicon undergo diene condensation with these compounds particularly readily.

Vinyl-containing organosilicon compounds undergo a Meerwein condensation with aryldiazonium halides[315]:



The reaction of alkenylsilanes with halogenoalkenes is also used for the preparation of halogeno-derivatives of organosilicon compounds[317,330]:



Organosilicon compounds with halogenated sulphur-containing organic groups are obtained by the reaction[331]:

$$p\text{-}ClC_6H_4SH + CH_2{=}CHSi(CH_3)(OC_2H_5)_2 \rightarrow p\text{-}ClC_6H_4SCH_2CH_2Si(CH_3)(OC_2H_5)_2.$$

The reaction takes place at 60°C under ultraviolet irradiation.

4. Organometallic Synthesis

Organometallic synthesis is widely used as a preparative method for obtaining various halogen-substituted organosilicon compounds with the halogen in a known position in the organic group bound to silicon.

The reaction of *p*-chlorophenylmagnesium bromide with silicon tetrachloride gives trichloro-*p*-chlorophenylsilane[332]. The reaction of *p*-chlorophenylmagnesium iodide with trichloro(methyl)silane gives dichloro-(*p*-chlorophenyl)methylsilane[333], that with chlorotrimethylsilane, *p*-chlorophenyltrimethylsilane[334]; that with trichlorosilane, dichloro-*p*-chlorophenylsilane[335]; that with trichloro(vinyl)-silane, dichloro-*p*-chlorophenylvinylsilane; and that with allyltrichlorosilane, allyldichloro-*p*-chlorophenylsilane[336]. *p*-Chlorophenylmagnesium bromide reacts analogously[154,333,336,337-341], but *o*-chlorophenylmagnesium bromide does not undergo these reactions[153]. A phenyl group with halogen in the *ortho*-position can be introduced in the reaction of *o*-halogenophenylmagnesium iodide with organohalogenosilanes[342]:

$$o\text{-}XC_6H_4MgI + (CH_3)_3SiCl \rightarrow o\text{-}XC_6H_4Si(CH_3)_3 + MgClI,$$

where X = Cl or F.

3-(*o*-Chlorophenyl)propylmagnesium bromide reacts with chlorotriphenylsilane by the reaction[343]:

$$o\text{-}ClC_6H_4[CH_2]_3MgBr + (C_6H_5)_3SiCl \rightarrow o\text{-}ClC_6H_4[CH_2]_3Si(C_6H_5)_3 + MgClBr.$$

Chlorobenzyl-substituted compounds are obtained in the reaction of organochlorosilanes with *o*- and *p*-chlorobenzylmagnesium chloride and *m*-chlorobenzylmagnesium bromide[344,345].

Polychlorophenylalkylchlorosilanes $C_6H_5 - {}_nCl_n(C_2H_5).SiCl_2$ [154,155] are obtained with the aid of an organomagnesium synthesis. Hexachlorobenzene, magnesium, and the corresponding halogenosilanes in tetrahydrofuran solution yielded perchlorophenyltrichlorosilane and alkylperchlorophenyldichlorosilanes[346].

p-Chlorophenylmagnesium bromide reacts with diethoxydiphenylsilane according to the reaction[347]

$$p\text{-}ClC_6H_4MgBr + (C_6H_5)_2Si(OC_2H_5)_2 \rightarrow p\text{-}ClC_6H_4(C_6H_5)_2SiOC_2H_5 + Mg(OC_2H_5)Br.$$

Fluorophenylmagnesium bromide reacts with silicon tetrachloride and alkylchlorosilanes to form trichloro-(fluorophenyl)silane[348] and alkyldichloro(fluorophenyl)silanes[349]. *p*-Fluorophenylmagnesium bromide reacts with trichloro(methyl)silane slowly, dichloro-(*p*-fluorophenyl)-methylsilane being formed. The reaction with difluorophenylmagnesium bromide is still more difficult, and as a result 2,4- and 3,5-$F_2C_6H_3(CH_3)SiCl_2$ are obtained. The reaction with dichlorodimethylsilane takes place more readily than that with trichloro(methyl)silane; triethoxy-(methyl)silane reacts even better with fluorophenylmagnesium bromides[350].

The production of fluoroaryl-substituted silanes by Grignard reaction has also been described[338,351,352]. Perfluorophenyl-substituted silanes[353], tetrakis-*m*-fluorobenzylsilane[354], and *m*-trifluoromethylphenyl-substituted silanes[328,348,354-358] were also obtained by this method.

Bromo-derivatives of aromatic and aliphatic-aromatic compounds with a known position of the bromine in the nucleus were obtained in an analogous manner[332,337,338,351,359-370].

Using organomagnesium compounds *p*-chlorophenyl- and *p*-bromophenylpentamethyldisilanes were obtained from pentamethyldisilane[49]. Mono- and di-substituted trifluoropropylchlorosilanes were obtained from $CF_3CH_2CH_2MgCl$ and $HSiCl_3$;[234] $(CF_3CH_2CH_2)_3SiH$ was obtained by the reaction of $HSiCl_3$ and $CF_3CH_2CH_2MgI$.[235]

Fully and partly fluorinated silanes[371-376], ω-chloroalkylsilanes[377,378] and halogen-containing acetylenic silanes[379] are obtained in an analogous manner.

Organolithium compounds are also widely used for obtaining halogenoaryl-substituted organosilicon compounds[190,380-382]. This method is especially effective for obtaining compounds containing rather large groups at the silicon atom. The reaction of *p*-bromophenyl-lithium with chlorotriphenylsilane gives *p*-bromophenyltriphenylsilane in 75% yield[383]. 3,5-Dibromophenyl-lithium reacts with silicon tetrachloride, trichloro(methyl)silane, and dichlorodimethylsilane[384] to form the corresponding dibromodiphenyl derivatives. Pentafluorophenyl-lithium and silicon tetrachloride gave tetrakisperfluorophenylsilane[385]; *m*-fluorophenyl-lithium and chloro(phenyl)silanes gave compounds of the formula $(m\text{-}FC_6H_4)_nSi(C_6H_5)_{4-n}$, where $n = 1-4$.[386]

Trimethyltribromomethylsilane was obtained from tribromomethyl-lithium and trimethylsilane[387]. *p*-Bromo and *p*-chloro-phenylethynyl-lithium react with silicon tetrachloride to form $(p\text{-}XC_6H_4C{\equiv}C)_4Si$, where X = Cl or Br.[388]

Organosodium synthesis was used for the introduction of chlorophenyl groups into bis(organochlorosilyl)-substituted benzenes[389]: the reaction of bromochlorobenzene with bis(phenyldichlorosilyl)benzene in the presence of sodium gave

$$[(ClC_6H_4)_2(C_6H_5)Si]_2C_6H_4;$$

$[(ClC_6H_4)_3Si]_2C_6H_4$ was obtained analogously from $(Cl_3Si)_2C_6H_4$.

5. Other Methods of Synthesis

Of the other methods for obtaining halogeno-derivatives of alkyl(or aryl)halogenosilanes and tetrasubstituted silanes, that of high-temperature condensation of alkyl and aryl halides with chlorosilanes is interesting. This reaction was first described in 1949[390,391] as applicable to the synthesis of alkyl- and alkenyl-silanes:

$$RX + HSiR'_3 \rightarrow RSiR'_3 + HX,$$

where R = alkyl or alkenyl group, and X = halogen. Subsequently it was used successfully for the synthesis of halogenoaryl substituted silanes.

The reaction can be effected in the liquid phase under pressure or in the gas phase at atmospheric pressure and 300–700°C. The reaction temperature can be greatly reduced by use of catalysts and initiators. These include halides of aluminium and of boron[392-394], aluminium oxide[390,395], palladium[396], benzoyl peroxide and ultraviolet light[226,397].

The reaction of dichlorobenzene and trichlorobenzene with trichlorosilane and dichloro(methyl)silane at 525°C in the vapour phase over palladium leads to the synthesis of the corresponding chloro- and dichloro-phenylchlorosilanes[396,398]. *p*-Dichlorobenzene reacts with chloro(methyl)phenylsilane[399] to form *p*-chlorophenylmethylphenylchlorosilane, and with chlorodimethylsilane[400] to form *p*-chlorophenyldimethylchlorosilane.

Hexafluorobenzene reacts with trichlorosilane to form dichlorofluoropentafluorophenylsilane and a mixture of isomers of bis(dichlorofluorosilyl)benzene[401].

The chloro-derivatives of thiophen (like thiophen itself) exhibit a much greater reactivity than benzene and its chloro-derivatives in condensation with silanes[402]. The condensation of silanes with 2,5-dichlorothiophen in the vapour phase at 570–580°C yielded 2-chloro-5-trichlorosilylthiophen and 2-chloro-5-dichloro(methyl)silylthiophen.

This method allowed the corresponding chloro(chlorovinyl)silanes to be obtained easily from dichloroethylene[85,210,400,403,404], trichloroethylene[85,210,398,405], and trichlorosilane, methyl- and ethyl-dichlorosilanes, chlorodimethylsilane, dichlorosilane, and chloro(methyl)silane.

The condensation of 1,3-dichlorobut-2-ene with dichlorosilane and trichlorosilane[406] gave respectively:

$$CH_3CCl{=}CHCH_2SiHCl_2 \text{ and } CH_3CCl{=}CHCH_2SiCl_3.$$

The reaction of silicon difluoride with hexafluorobenzene[407] gave trifluoro(pentafluorophenyl)silane $C_6F_5SiF_3$ and a mixture of the isomers of bis(trifluorosilyl)benzene.

The chloromethylation of benzylchlorodimethylsilane with CH_2O in fuming hydrochloric acid without a catalyst leads to the production of $ClCH_2C_6H_4CH_2Si(CH_3)_2Cl$; in the presence of $ZnCl_2$ chloromethylation is accompanied by side-processes[408]. The chloromethylation of the trialkyl(benzyl)silanes $R_3SiCH_2C_6H_5$ with 37% aqueous formalin solution and also with paraformaldehyde in CCl_4 and CH_3COOH leads to the formation of $CH_2ClC_6H_4CH_2SiR_3$.[409,410] With increase in the size of R the reaction becomes more difficult. Depending on the reaction conditions, different quantities of *p*-chloromethyl derivatives are formed; chloromethylation in water leads to the formation of > 90% of the *para*-isomer.

α-Methyltrimethylene oxide reacts with the chloroorganosilanes to form chloroalkoxy-derivatives[411]. The reaction of ethylene oxide with chloro(chloromethyl)methylphenylsilane, trichlorochlorophenylsilane, and chlorodichloromethyldimethylsilane gave the corresponding 2-chloroethoxysilanes[412].

The reaction of phosphorus(V) chloride with allyltrimethylsilane is interesting[413]:

$$(CH_3)_3SiCH_2CH{=}CH_2 + \overset{+}{P}Cl_4 \cdot \bar{P}Cl_6 \rightarrow (CH_3)_3SiCH_2CHClCH_2\overset{+}{P}Cl_3 \cdot \bar{P}Cl_6 \rightarrow \xrightarrow{SO_2} (CH_3)_3SiCH_2CHClCH_2P(O)Cl_2.$$

Tetrakis-(2,4,6-trichlorophenoxy)silane and tetrakis-(pentachlorophenoxy)silane are obtained from the corresponding phenoxides and silicon tetrachloride[414]. The reaction of chlorotriorganosilanes with $CH_2FCOONa$ and of triorganoethoxysilanes with $CH_2FCOONa$ gave halogen-substituted derivatives of the general formula $R_3SiOCOCH_2X$ (X = F or Br)[415].

On treating the carbinols $R_3SiC{\equiv}CR'R''OH$ with concentrated hydrochloric acid or sulphuryl chloride[416-418] the corresponding compounds with a chlorine atom in the organic group $R_3SiC{\equiv}CR'R''Cl$ are obtained.

An analogous reaction occurs between *p*-(2-hydroxyethyl)phenyltrimethylsilane and sulphuryl chloride in the presence of $CaCO_3$.[112]

On reacting with sulphuryl chloride, silicon-containing carboxylic acids are converted into the corresponding acid chlorides[419].

Chloromethyl-substituted organosilicon compounds can be obtained by the reaction[420]:

$$(C_2H_5OCH_2)_2Si(CH_3)R + 2 \cdot CH_3COCl \rightarrow (ClCH_2)_2Si(CH_3)R + 2 \cdot CH_3COOC_2H_5,$$

where R = CH_3 or C_3H_7.

Trichloro(phenyl)silane reacts with diazomethane[421] to form dichloro(chloromethyl)phenylsilane. Compounds of the general formula $(C_6H_5)_nSiCl_{4-n}$, where $n > 1$, do not undergo this reaction.

Triphenylsilyl-lithium reacts with halogenomethanes thus[422]:

$$(C_6H_5)_3SiLi + CH_nX_{4-n} \rightarrow CH_nX_{3-n}Si(C_6H_5)_3 + LiX,$$

where X = Cl, Br, or I, and $n = 0$, 1, or 2.

II. PROPERTIES

1. Reactions with Participation of the Halogen in the Organic Group

A halogen atom in the organic groups of organosilicon compounds is capable of taking part in nucleophilic substitutions [423-427].

α-Halogenoalkyl-substituted organosilanes are exceptionally inert towards electrophilic agents, but are considerably more reactive towards nucleophiles than the corresponding halogenohydrocarbons.

α-Chloro-derivatives are more reactive than γ-derivatives in most reactions. The reactivity of chlorine in compounds of the type $R_n(CH_3)_{3-n}SiCH_2Cl$ (R = C_6H_5, *p*-ClC_6H_4, $n = 1-3$) is considerably affected by the number of phenyl groups at the silicon atom; with increase in their number there is a sharp drop in the rate of substitution, owing to the steric effect of the phenyl groups [428].

Trialkyl-α-halogenosilanes are readily converted into the corresponding nitriles. Compounds of the general formula $R_nSi([CH_2]_xBr)_{4-n}$ react quantitatively in alcohol with NaCN and KCN to form $R_nSi([CH_2]_xCN)_{4-n}$; [429,430] with chloromethyl derivatives side reactions are observed (splitting). Cyanoalkyl-substituted organofluorosilanes are obtained by the same method [431]. By replacing bromine by the nitrile group in bromophenyl-substituted organoalkoxysilanes, cyanophenylorganoalkoxysilanes are obtained [432,433]. The replacement of bromine in the alkyl substituent in the aromatic ring takes place analogously [112]:

$$p\text{-}BrCH_2C_6H_4Si(CH_3)_3 + NaCN \rightarrow p\text{-}NCCH_2C_6H_4Si(CH_3)_3.$$

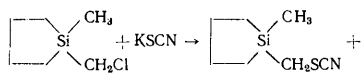
p-Bromophenyltrimethylsilane reacts with CuCn in the presence of pyridine [434]:

$$(CH_3)_3SiC_6H_4Br\text{-}p + CuCN \xrightarrow{C_5H_5N} (CH_3)_3SiC_6H_4CN\text{-}p.$$

$(NC)_2CHCH_2Si(CH_3)(OC_2H_5)_2$ was made from $CH_2I(CH_3)Si(OC_2H_5)_2$ and $NaCH(CN)_2$. [435] $CH_3(NC)_2CCH_2Si(CH_3)(OC_2H_5)_2$, which is more stable, was obtained in an analogous manner.

The nitriles obtained in this way can be easily converted into the corresponding amines, alcohols, and acids.

The halogen in an alkyl group can also be substituted by a thiocyanato-group, for example [436]:

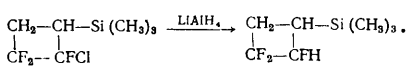


The chlorine atom in organic groups can be readily replaced by iodine [436-440]:

$$(CH_3)_3SiCH_2Cl + NaI \rightarrow (CH_3)_3SiCH_2I + NaCl.$$

In the reaction with KI the steric factor of the groups connected with the silicon plays an important part: $C_6H_5(CH_3)_2SiCH_2Cl$ and $(CH_3)_3SiOSi(CH_3)_2CH_2Cl$ react at only half the rate for $(CH_3)_3SiCH_2Cl$, [118,437] whereas $(C_6H_5)_3SiCH_2Cl$ does not react at all. [119] α-Halogenoalkylsilanes react with KI 3-5 times more rapidly than γ-halogenoalkyl-substituted silanes [423]. In the reaction with alkali metal halides chloroalkyl-substituted disilanes can be used successfully, for example, $ClCH_2(CH_3)_2SiSi(CH_3)_2CH_2Cl$ and $(CH_3)_3SiSi(CH_3)_2CH_2Cl$. [108]

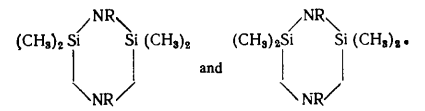
Under the action of $LiAlH_4$ halogen derivatives of tetrasubstituted silanes are hydrided [317]:



On treating halogenoalkylsilanes with $AgNO_2$ nitroso-derivatives are obtained, but on treatment with $NaNO_2$ nitro-derivatives—for γ-iodopropyltriethoxysilane $ONOCH_2CH_2CH_2Si(OC_2H_5)_3$ and $O_2NCH_2CH_2CH_2Si(OC_2H_5)_3$ respectively [441].

On heating $R_3SiCH_2C_6H_4CH_2Cl$ with $CaCO_3$ a chlorine atom is replaced by a hydroxyl group with the formation of $R_3SiCH_2C_6H_4CH_2OH$. [410]

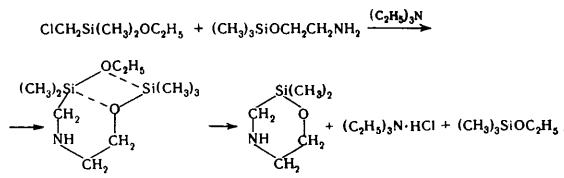
The reaction of compounds of the type $R_3Si[CH_2]_nCl$ (n = 1 or 3) with ammonia or amines, organosilicon amines are formed [32,176,440,442-446]. A mixture of 2,6- and 2,5-disilapiperazines is formed in the reaction of bromomethylchlorodimethylsilane with primary amines or NH_3: [447]



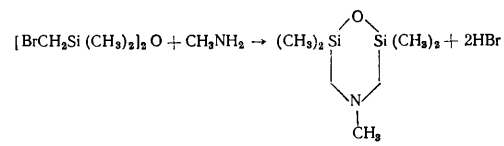
γ-Bromopropyl- and δ-bromobutyldimethyl(bromomethyl)silanes react with primary amines to form 3-sila-1-azacycloalkanes [448,449]:

where x = 3 or 4.

α-Chloroalkylalkoxysilanes react with 2-(trimethylsiloxy)ethylamine [450]:



The reaction of 1,3-di(chloromethyl)-1,1,3,3-tetramethyldisiloxane with 2-aminoethoxytrimethylsilane yields 2,2,6,6-tetramethyl-4-(2-trimethylsiloxyethyl)-1-oxa-2,5-disila-4-azacyclohexane [451,452]. 1,3-Di(bromomethyl)-tetramethyldisiloxane reacts with methylamine to form 2,2,4,6,6-pentamethyl-2,6-disilamorpholine [447]:



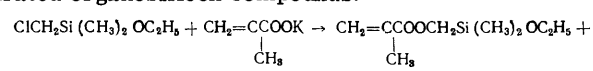
where X = halogen, R = alkyl.

Silylamines are obtained by treating halogenoalkyltrialkylsilanes with sodium acylamides [453,454]:

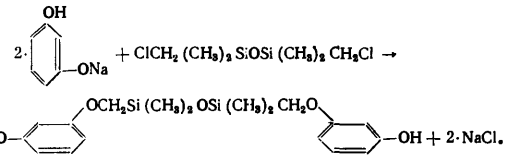
$$CH_3(R_2)SiCH_2X + CH_3CON(Na)C_2H_5 \rightarrow CH_3(R_2)SiCH_2N(C_2H_5)COCH_3 + NaX,$$

where X = halogen, R = alkyl.

In the reactions described above a halogen in the α-position to the silicon atom is more active than one in the γ-position. The reverse occurs in reactions with potassium acetate: greater activity is then exhibited by a halogen in the γ-position [455]. The synthesis of silicon-containing esters by this method has been studied often [420,436,456-459]. There is special interest in the reaction of halogenoalkyl-substituted silanes with salts of unsaturated acids, in particular methylacrylic acid, as a synthetic method for unsaturated organosilicon compounds:



In connection with this reaction mention must also be made of the reaction of chloromethylsiloxanes with monosodium and disodium salts of dihydric phenols[460]:



Silicon-containing esters are also obtained in the reaction of halogenoalkyl-substituted silanes with sodiomalonic and sodioacetoacetic esters[461-468] and also of chloromethylmethylalkoxysilanes with various acids in the presence of triethylamine[469].

Silicon-containing esters are used for obtaining organosilicon alcohols[57]:

$$R_3Si[CH_2)_nOCOCH_3 \xrightarrow[H_2SO_4]{CH_3OH} R_3Si[CH_2]_nOH.$$

γ-Chloroalkyltrialkylsilanes are more reactive than α-derivatives of also in reactions with the exchange of chlorine for an alkoxy-group under the action of sodium alkoxides on chloroalkyltrialkoxysilanes[470] and chloroalkyltrialkylsilanes[471]. Cellulose ethers are also obtained by this reaction—triethylsilylmethyl cellulose and trimethylsilyl methyl cellulose

$$[C_6H_7O_2(OH)_{3-x}(OCH_2SiR_3)_x]_n,$$

where R = CH_3 or C_2H_5.[472]

In these reactions, in addition to the replacement of chlorine by an ester group there is splitting of the Si–C bond[9,10], which increases with increase in the length of the radical in the sodium alkoxide[473].

A study of the reaction of halogenoalkylchlorosilanes with aromatic hydrocarbons in the presence of Friedel–Crafts catalysts[31,474-479] showed that β- and γ-chloroalkylchlorosilanes are more reactive than α-chloro-substituted ones. The reactivity increases with replacement of chlorine at a silicon atom by alkyl groups. These reactions are used for obtaining various aliphatic-aromatic chlorosilanes. The mechanism of this reaction for the α-chloroalkyl-substituted silanes can be represented as follows[475]:

$$Cl_2(C_2H_5)SiCHClCH_3 \xrightarrow{AlCl_3} Cl_2(C_2H_5)\overset{+}{S}iCHCH_3 + [AlCl_4]^- \rightarrow$$

$$\rightarrow Cl_2(C_2H_5)SiCH_2\overset{+}{C}H_2 + [AlCl_4]^- \xrightarrow{-C_6H_6} Cl_2(C_2H_5)SiCH_2CH_2C_6H_5 + AlCl_3 + HCl.$$

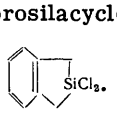
γ-Chloroalkyl-substituted derivatives react according to the scheme[478]:

$$Cl_3SiCH_2CH_2CH_2Cl \xrightarrow[C_6H_6]{AlCl_3} Cl_3SiCH_2\underset{CH_3}{CHC_6H_5} + Cl_3Si(CH_2)_3C_6H_5.$$

Compounds with halogenoacyl group can be used as acylating agents[480]:

$$(CH_3)_3SiC_6H_5COCl + C_6H_5CH_3 \rightarrow (CH_3)_3SiC_6H_5COC_6H_5CH_3\text{-}p + HCl.$$

The action of $AlCl_3$ on chloromethylbenzyldichlorosilane gives 3 : 4 benz-1,1-dichlorosilacyclopentane[481]:



The silylalkylation of aromatic hydrocarbons by dichloromethylchlorosilanes proceeds normally, but for $\alpha\alpha$-, $\beta\beta$-, and $\alpha\beta$-dichloroalkyl-substituted compounds is complicated by the reduction of one C–Cl bond by hydrogen.

Attention has recently been attracted to the high-temperature condensation of (chloroaryl)chlorosilanes with organochlorosilanes, leading to the formation of bis(organochlorosilyl)-substituted benzenes[399,482-484]:

$$Cl_{3-n}R_nSiC_6H_4Cl + HSiR'_mCl_{3-m} \rightarrow Cl_{3-n}R_nSiC_6H_4SiR'_mCl_{3-m}.$$

The condensation can proceed both in the liquid and in the vapour phase and is accompanied by several side-reactions. For example, in the reaction of chlorophenylalkylchlorosilanes with alkylchlorohydrosilanes the main reaction is accompanied by the following reactions[485]:

$$Cl_{3-n}R_nSiC_6H_4Cl + HSiR_mCl_{3-m} \rightarrow Cl_{3-n}R_nSiC_6H_5 + SiR_mCl_{4-m},$$

$$HSiR_mCl_{3-m} + HCl \rightarrow SiR_mCl_{4-m} + H_2,$$

$$Cl_{3-n}R_nSiC_6H_4SiR_mCl_{3-m} + HCl \rightarrow Cl_{3-n}R_nSiC_6H_5 + SiR_mCl_{4-m}.$$

Halogenosilanes other than chlorosilanes are also used in condensation, for example, chlorophenyltrifluorosilane[486].

In the gas-phase condensation of trichlorosilane and dichloro(methyl)silane with $ClC_{10}H_8SiCl_3$ (mixture of isomers), bis(organochlorosilyl)naphthalenes are formed[487].

In the action of nucleophilic and electrophilic reagents on halogenoalkylchlorosilanes, as well as cleavage of the Si–C bond, loss of hydrogen halide also takes place leading to the formation of halogenosilanes with alkenyl radicals.

A systematic study of this reaction[61,82,83,86,101,102,170,171,248,274,298,488-508] led to the finding and formulation of the principal regularities[509] and to the determination of the boundary of applicability of the various dehydrohalogenating agents in this reaction.

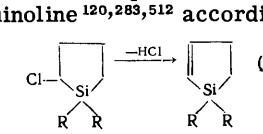
The ease of loss of HCl from the monochloroalkylchlorosilanes depends on the position of chlorine relative to the silyl group and decrease in the order $\beta > \alpha > \gamma$. The HCl is removed from secondary α- and β-chloroalkyl groups more readily than from primary groups. HBr is lost more readily than HCl. In the stepwise replacement of alkyl groups for chlorine the β-decomposition of the compounds of the type $R_3SiCH_2CH_2Cl$ gives way to dehydrochlorination.

Quinoline, isoquinoline, and piperidine dehydrochlorinate compounds with any silyl groups, but with quinoline the removal of HCl takes place successfully only from β-chloroalkyl groups, whereas catalytic amounts of piperidine are capable of bringing about the loss of HCl also from γ-chloroalkyl and chloroacyl groups. In the dehydrochlorination of $\beta\gamma$-dichloropropyltrichlorosilane under the action of $AlCl_3$ γ-chloroallyltrichlorosilane is formed; in the dehydrochlorination by quinoline $Cl_3SiCH{=}CHCH_2Cl$ and $Cl_3SiCH_2CH{=}CHCl$ are formed in approximately equal amounts[510].

In the dehydrochlorination of 1-phenyl-2-trichlorosilyl-1,2-dichloroethane and 1-phenyl-1-trichlorosilyl-1,2-dichloroethane in the presence of $AlCl_3$, 1-phenyl-2-chlorovinyltrichlorosilane is formed[511].

Chloropolychloroalkylsilanes are dehydrochlorinated by quinoline much more readily than the monochloro-derivatives.

Silacycloalkanes are dehydrochlorinated on heating and also in the presence of quinoline and *N*-methyl-1,2,3,4-tetrahydroquinoline[120,283,512] according to the reaction:



Unlike the 2-chloro-substituted, 1,1,3-trichlorosilacyclopentane is converted under analogous conditions into 3-butenyltrichlorosilane. The dehydrobromination of 2-bromo-1,1,2-triphenyl-1-silacyclobutane leads to the formation of 1,1,2-triphenyl-1-silacyclobut-2-ene[140].

The dehydrobromination of 2-cyanobromoethyltrichlorosilane by quinoline gives β-cyanovinyltrichlorosilane [139]. The dehydrochlorination of $R_3SiCH_2SCHClCH_3$ gives $R_3SiCH_2SCH{=}CH_2$. [513]

A reaction very similar to the dehydrohalogenation considered above is dehalogenation, leading to the formation of silyl-substituted compounds of the ethylene and acetylene type [514]. For example:

$$(Cl_3SiCCl_2)_2 \xrightarrow{-Cl_2} Cl_3SiCCl{=}CClSiCl_3.$$

On further dehalogenation, $Cl_3SiC{\equiv}CSiCl_3$ is formed. The reaction occurs at a temperature above 100°C in the presence of copper.

Metallic zinc can also be used as a dehydrochlorinating and dehalogenating agent. The ease of removal of halogens then decreases in the order: I > Cl > Br [229,317,515]; fluorine is not lost. For example [229]:

$$CF_2ClCFClCH_2CHISi(CH_3)_3 \xrightarrow[(C_4H_9)_2O]{Zn} CF_2{=}CFCH{=}CHSi(CH_3)_3.$$

Di-(iodomethyl)dimethylsilane is reduced to tetramethylsilane [38]:

$$(CH_3)_2Si(CH_2I)_2 \xrightarrow[C_3H_6OH]{Zn} (CH_3)_4Si.$$

$AlCl_3$ can be used for the dehydrochlorination only of compounds with trichlorosilyl groups; in other instances there is either decomposition or rearrangement of the organosilicon compounds. The rearrangement consists of the migration of an alkyl group from a silicon to a carbon atom [265]. For example [516]:

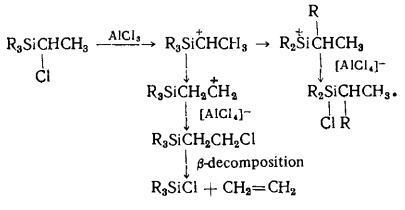
$$(CH_3)_3SiCH_2Cl \xrightarrow{AlCl_3} C_2H_5(CH_3)_2SiCl.$$

The mechanism of this reaction can be represented as follows:

$$(CH_3)_3SiCH_2Cl \xrightarrow{AlCl_3} (CH_3)_3\overset{+}{S}iCH_2 + [AlCl_4]^- \rightarrow$$

$$\rightarrow (CH_3)_2\overset{+}{S}iCH_2CH_3 + [AlCl_4]^- \rightarrow C_2H_5(CH_3)_2SiCl + AlCl_3.$$

For α-chloroethyltriorganosilane the reaction proceeds in two directions [103]:



For dichloromethyltrimethylsilane α-chloroethyldimethylchlorosilane is formed in the first stage, and then rearranges according to the scheme given above:

$$(CH_3)_3SiCHCl_2 \xrightarrow{AlCl_3} (CH_3)_2\underset{Cl\ Cl}{SiCHCH_3} \rightarrow (CH_3)_2SiCl_2 + CH_2{=}CH_2.$$

$AlCl_3$ also catalyses the migration of trimethylsilyl and dimethylchlorosilyl groups [87,517]:

$$\begin{matrix}(CH_3)_nSiCl_{3-n}\\ |\\ (CH_3)_2SiCH_2Cl\end{matrix} \xrightarrow{AlCl_3} (CH_3)_2\overset{Cl}{\underset{|}{Si}}CH_2Si(CH_3)_nCl_{3-n}.$$

Chloromethylpentamethyldisilane undergoes an analogous rearrangement in the presence of sodium ethoxide [108] with the formation of $(CH_3)_3SiCH_2Si(CH_3)_2OC_2H_5$.

Di(chloromethyl)tetramethyldisilane rearranges under the action of $AlCl_3$ into $(CH_3)_3SiCHClSi(CH_3)_2Cl$ or $\{Cl(CH_3)_2Si\}_2CHCH_3$, depending on the conditions [108].

1-Chloromethyl-1-methylsilacyclopentane rearranges into 1-chloromethyl-1-methylsilacyclohexane under the action of $AlCl_3$. [436]

Chloro- and bromo-alkyltriorganosilanes (with the exception of β-halogeno-derivatives) readily form the corresponding organo-magnesium and -lithium compounds, which are capable of all the reactions peculiar to Grignard reagents [205,518,519]. There is a report [520] of the preparation of organomagnesium compounds of the type $R_3SiO[CH_2]_nMgCl$ (where R is alkyl or phenyl; $n = 4$ or 5). Organomagnesium compounds can also be obtained from halogenomethyl-substituted organocyclosiloxanes [521] and disilanes [108].

Organosilicon compounds which contain a halogen in the aromatic nucleus directly connected with silicon directly or through alkyl groups form organo-magnesium and -lithium compounds in high yields [351,368,382,387,410,480,522-528].

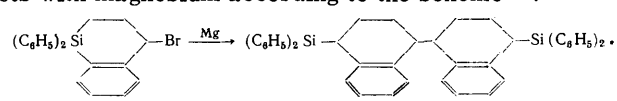
The formation of organolithium compounds is greatly influenced by the steric effect of organic groups bound to the silicon atom. Chloromethyltrimethylsilane readily forms trimethylsilylmethyl-lithium [529,530]:

$$ClCH_2Si(CH_3)_3 + 2Li \rightarrow LiCH_2Si(CH_3)_3 + LiCl.$$

However, organolithium compounds could not be obtained from chloromethyldimethylphenylsilane [531]. γ-(*o*-chlorophenylpropyltriphenylsilane also does not react with lithium. However, all these compounds readily form organomagnesium derivatives.

p-Chlorophenyldimethylsilane forms organo-lithium and -magnesium compounds [532]; $p\text{-}LiC_6H_4Si(CH_3)_2H$ readily condenses with the formation of oligomers with phenylenesilyl units.

4-Bromo-2,3-benz-1,1-diphenyl-1-silacyclobutane reacts with magnesium according to the scheme [201]:



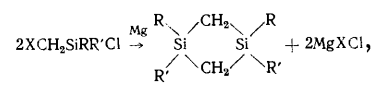
With mercury(II) chloride, organomagnesium compounds can be readily converted into organomercury compounds [92,108,471,531,533]:

$$ClMgCH_2Si(CH_3)_2R + HgCl_2 \rightarrow (CH_3)_2Si(R)CH_2HgCl.$$

Halogenoalkyl(or aryl)silanes which contain reactive atoms or groups (halogen, OR) do not form Grignard reagents. Reactions between γ-chloroalkylchlorosilanes and magnesium lead to the formation of silacyclobutanes [214,534,535]:

$$ClCH_2CH_2CH_2SiRCl_2 \xrightarrow{Mg} \overline{CH_2CH_2CH_2SiRCl}$$

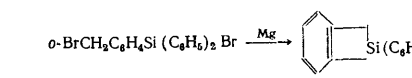
Halogenomethyldialkylchlorosilanes react with magnesium in ether or tetrahydrofuran with the formation of disilacyclobutanes [536-540]:



where X = Cl or Br; R and R′ = CH_3 or C_6H_5.

Under the same conditions $BrR_2SiCH_2SiR_2CH_2SiR_2CH_2Cl$ is converted into 1,3,5-trisilacyclohexane [541].

o-Bromomethylphenyldiphenylbromosilane reacts under the same conditions with magnesium with the formation of 2:3-benz-1,1-diphenyl-1-silacyclobut-2-ene [200]:



Halogenomethyltriorganosilanes react with sodium to form 1,2-triorganosilyl-substituted ethanes[542,543]:

$$2\cdot(CH_3)_3SiCH_2Br \xrightarrow{Na} (CH_3)_3SiCH_2CH_2Si(CH_3)_3.$$

When there is common condensation of halogenoalkyl-substituted silanes and triorganohalogenosilanes with sodium the reaction is[544]:

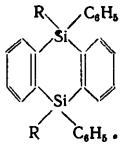
$$(CH_3)_3SiCCl{=}CH_2 + ClSi(CH_3)_3 \xrightarrow{Na} [(CH_3)_3Si]_2C{=}CH_2.$$

Several disila-alkenes were obtained by this method[545]. The use of bifunctional compounds in this reaction leads to the formation of silacycloalkanes. For example, $Br(CH_3)_2SiCH_2Si(CH_3)_2CH_2Si(CH_3)_2Br$ and $(CH_3)_2Si(CH_2Cl)_2$ react with sodium to form a ring of composition $[Si(CH_3)_2CH_2]_4$.[531]

Silacyclopropane, which is formed in the reaction of $RR'Si(CH_2Cl)_2$ with sodium–potassium alloy (at 260–280°C in a stream of helium) is unstable and readily rearranges into $R'RSiH(CH{=}CH_2)$.[548] When chloro(chloromethyl)dimethylsilane and dichlorodimethylsilane react with magnesium, zinc or alkali metals, ωω′-dichloropoly(dimethylmethylenes) are formed[519]; *m*- and *p*-halogenophenyldiorganochlorosilanes react with finely divided sodium or magnesium to form silylphenylene polymers of linear structure[547].

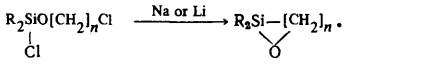
Condensation with sodium can be used for the replacement of halogens in an organic group, for example, by arsenic[337]:

Reaction of ω-(*o*-chlorophenyl)alkyldiorganosilanes with sodium leads to the formation of 2:3-benz-1-silacycloalkanes[548]. $o\text{-}ClC_6H_4Si(R)(C_6H_5)H$ reacts with sodium[549] with the formation of *cis*- and *trans*-isomers:



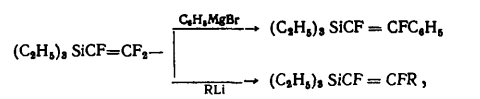
γ-(*o*-Chlorophenyl)propyltriphenylsilane reacts with sodium with loss of a phenyl group and formation of 2:3-benz-1,1-diphenylsilacyclohex-2-ene[343]. This reaction does not take place with lithium, but the same results can be obtained by the reaction of γ-(*o*-chlorophenyl)propyldiphenylsilane with lithium.

Halogenoalkoxy-substituted organochlorosilanes are converted into cyclic compounds under the action of sodium or lithium, according to the reaction[550]:



α- and β-chloroalkyltrichlorosilanes react with organomagnesium compounds differently: $CH_3CHClSiCl_3$ and CH_3MgBr form the corresponding trimethyl derivative, but $ClCH_2CH_2SiCl_3$ undergoes β-decomposition with formation of tetramethylsilane and ethylene only[173]. There are no side reactions in alkylation by Grignard reagents of α-, γ-, and δ-chloroalkylchlorosilanes. It was subsequently established[551] that the reaction of $ClCH_2CH_2SiCl_3$ with a Grignard reagent takes place through trialkylchlorosilanes which are formed as a result of β-decomposition; the latter, by reacting with the Grignard reagent, form the tetraalkylsilanes. There is simultaneous reaction at the C–Cl bond, hence the β-halogenoalkyltrichlorosilanes are capable of undergoing the usual Grignard–Wurtz reaction[292,293], the yield of products thus obtained depends on the nature of both reagents. This reaction enabled the chlorine in the trichlorosilyl group to be partially replaced by organic groups[552].

Perfluorovinyltriorganosilanes react readily with organo-magnesium and -lithium compounds with replacement of the fluorine in the β-position by organic groups[553]:

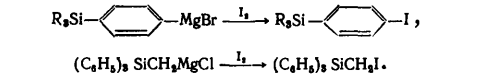


where R = C_6H_5, $CH_2{=}CH$, $CH_2{=}CH{-}CH_2$, or C_4H_9.

Halogenomethyl-substituted organohalogenosilanes react with organomagnesium compounds with replacement of the halogen in the methyl group[119,554]:

$$CH_3Si(Cl_3)\,CH_2Cl + 2RMgI \rightarrow R_2(CH_3)\,SiCH_2I + MgCl_2 + MgClI,$$

Similar results are obtained in the reaction with organomagnesium halides of compounds obtained on the basis of halogenoalkyl(or aryl)-substituted silanes[555]:



$$(C_6H_5)_3SiCH_2MgCl \xrightarrow{I_2} (C_6H_5)_3SiCH_2I.$$

The introduction of a halogen into an ethynyl group is based on the same method[556]:

$$R_3SiC{\equiv}CH \xrightarrow{R'MgBr} R_3SiC{\equiv}CMgBr \xrightarrow{Br_2} R_3SiC{\equiv}CBr.$$

The reaction of trichloromethyltrimethylsilane with methylmagnesium bromide proceeds with loss of the trichloromethyl group[557].

Chloro-substituted silacyclopentanes react with CH_3MgI differently depending on the position of the chlorine in the ring[283]: 1,1,2-trichlorosilacyclopentane reacts with replacement of the chlorine atoms at the silicon atom by methyl groups with the formation of 1,1-dimethyl-2-chlorosilacyclopentane, whereas 1,1,3-trichlorosilacyclopentane undergoes rearrangement under the action of CH_3MgI with the formation of 3-butenyltrichlorosilane, which is methylated by methylmagnesium iodide, being converted into $CH_2{=}CHCH_2CH_2Si(CH_3)_3$.

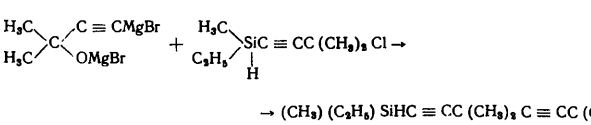
In the reaction of halogen derivatives of organohalogenosilanes with Iotsich reagent, first there is replacement of halogen connected with silicon atoms[558]; for example, $(CH_3)_2(CH_2Cl)SiCl$ and $HOC(R)(R')C{\equiv}CMgX$ give:

$$HOC(R)(R')C{\equiv}CSi(CH_3)_2CH_2Cl.$$

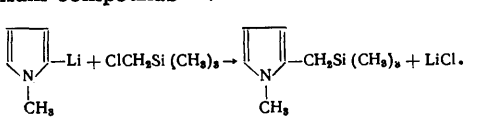
Halogen derivatives of tetrasubstituted silanes react at the halogen atom with entry into the organic group[418]:

$$R_3SiC{\equiv}CC(CH_3)_2Cl + XMgC{\equiv}CC(CH_3)_2OH \rightarrow$$
$$\rightarrow R_3SiC{\equiv}CC(CH_3)_2C{\equiv}CC(CH_3)_2OH + MgClX.$$

This reaction is widely used for obtaining organosilicon alcohols of the diacetylene series[559–562]. For example,



Silylmethylpyrroles have been obtained with the aid of organolithium compounds[563]:

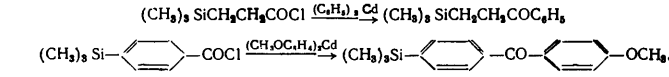


It has been reported[564] that in the reaction of chloromethyltrimethylsilane with butyl-lithium trimethylsilylcarbene $(CH_3)_3SiCH$ is formed, which on recombination gives

$$(CH_3)_2SiCH = CHSi(CH_3)_3.$$

Organosilicon acyl halides react with organocadmium compounds to form the corresponding ketones[110,480]:

$$(CH_3)_3SiCH_2CH_2COCl \xrightarrow{(C_6H_5)_2Cd} (CH_3)_3SiCH_2CH_2COC_6H_5$$



Halogenoalkyl-substituted silanes react with organic derivatives of phosphoric and phosphinic acids.

The Arbuzov rearrangement of $P(OC_2H_5)_3$ [565] and $C_6H_5P(OC_2H_5)_2$ [566] with $R_n(R'O)_{3-n}Si[CH_2]_XCl$ was used to synthesise compounds of the general formula

$$R_n(R'O)_{3-n}Si[CH_2]_xP\cdot(O)(R'')OC_2H_5.$$

where R and R′ are alkyl groups and R″ is C_6H_5 or OC_2H_5.

Chloromethyltrialkylsilanes react with R_3P [567,568] to form phosphonium salts:

$$R'_3SiCH_2Cl + R_3P \longrightarrow (R'_3SiCH_2PR_3)^+Cl^-$$

which on pyrolysis are converted into $R'_3SiCH{=}PR_3$.

Trialkylsilyl-substituted alkylphosphinic acids are obtained by the reactions[569,570]:

$$R_3Si[CH_2]_nCl + (R'O)_3P \xrightarrow{(t\text{-}C_4H_9O)_2} R_3Si[CH_2]_nP(O)(OR')_2 + R'Cl,$$

where R and R′ are alkyl groups and $n = 1$ or 3. The reaction with $(C_6H_5)_2POC_2H_5$ takes place analogously[570,571].

Dialkyl(triorganosilylmethoxymethyl) phosphinates are obtained in the reaction of dialkyl(sodioxymethyl) phosphinates with chloromethyltriorganosilanes[572,573]:

$$R_2P(O)CH_2ONa + ClCH_2SiR'_3 \longrightarrow R_2P(O)CH_2OCH_2SiR'_3 + NaCl.$$

Compounds of the formula $(RO)_2P(O)CH_2ONa$, [574] phosphine oxides, and their alkali metal salts[575] can be used in this reaction.

The chlorine in the chloromethyl group can also be replaced by residues of dialkyl(or aryl)dithiophosphonic (or dithiophosphinic) acids[576]. Chloropropylmethyldiethoxysilane is used for the production of γ-mercaptopropylmethyldiethoxysilane[577].

Bromomethyl-γ-bromopropyldimethylsilane reacts with Na_2S to form 3-sila-1-thiocyclohexane[448]:

$$BrCH_2Si(CH_3)_2CH_2CH_2CH_2Br + Na_2S \rightarrow (CH_3)_2\overline{SiCH_2CH_2CH_2SCH_2} + 2\,NaBr.$$

3-Sila-1-thiocycloheptane is obtained analogously from the δ-bromobutyl-derivative of silane[449].

Heterocycles containing silicon and sulphur are also obtained by the reaction[578]:

$$[ClCH_2(CH_3)_2Si]_2NH + 2H_2S \xrightarrow{(C_2H_5)_3N}$$

$$\rightarrow (CH_3)_2\overline{SiSSi(CH_3)_2CH_2SCH_2} + NH_4Cl + (C_2H_5)_3N\cdot HCl.$$

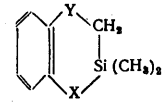
1,3-Bis(chloromethyl)tetramethyldisiloxane reacts with KSH to form 2,2,6,6-tetramethyl-1-oxa-4-thio-2,6-disilacyclohexane[579].

Chloromethyldimethylchlorosilane reacts with thiols[580]:

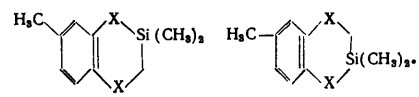
$$ClCH_2(CH_3)_2SiCl + HS[CH_2]_nSH \rightarrow (CH_3)_2\overline{SiS[CH_2]_nSCH_2} + 2HCl,$$

where $n = 2$ or 3.

Chloro(chloromethyl)dimethylsilane in the presence of triethylamine reacts with compounds of the general formula $o\text{-}HXC_6H_4YH$ (where X = O or NH and Y = O, NH, or S)[581] to form



The reaction of chloro(chloromethyl)dimethylsilane with $3,4\text{-}(HX)_2C_6H_3CH_3$ (where X = O or S)[582] in an analogous manner to form a mixture of compounds corresponding to the formulae:



Chloromethyl-containing organosilicon alcohols undergo intramolecular condensation on heating[448,449]:

$$ClCH_2(CH_3)_2Si[CH_2]_nOH \rightarrow (CH_3)_2\overline{Si[CH_2]_nOCH_2} + HCl,$$

where $n = 3$ or 4.

2. Reactions which Do Not Involve a Halogen in an Organic Group

Halogen-substituted organohalogenosilanes, according to the reactivity of the halogens connected with silicon, in reactions with nucleophilic reagents surpass the analogous compounds which do not contain a halogen in an organic group. The Si–Cl bond is more reactive than the C–Cl bond, therefore the action of nucleophilic reagents is directed towards it first[583]. The reactivity of the halogen connected with silicon is also greatly affected by the type and number of the organic groups at the silicon. Chloro(chloromethyl)methylsilanes can be arranged in the following series according to reactivity[584]:

$$CHCl_2Si(CH_3)_2Cl < CH_2ClSi(CH_3)_2Cl < CH_2ClSi(CH_3)Cl_2.$$

In the esterification of halogenoalkyl(or aryl)halogenosilanes the corresponding halogenoalkyl(or aryl)alkoxyderivatives are formed, for example, halogenoalkylethoxysilanes[17,18,184,377], halogenoarylethoxysilanes[180,187], and halogenocycloalkylethoxysilanes[184,186]. In partial esterification under mild conditions (in the presence of hydrogen chloride at reduced temperature) halogenoalkylalkoxychlorosilanes can be isolated, for example, chloromethylmethylethoxychlorosilane[539], γγγ-trifluoropropylmethylethylethoxychlorosilane[585]. The basicity of trimethylethoxysilane decreases regularly as the methyl groups are replaced by γγγ-trifluoropropyl groups[586,587].

In the hydrolysis of trifluoropropylchlorosilanes $(CF_3CH_2CH_2)_nSiCl_{4-n}$ the products obtained[231,235] are $(R_3Si)_2O$ ($n = 3$), $(R_2SiO)_X$ ($n = 2$), and $(RSiO_{1.5})_X$ ($n = 1$), where $R = CF_3CH_2CH_2$. The hydrolysis of γγγ-trifluoro-α-chloropropylmethyldichlorosilane and γγγ-trifluoro-β-chloropropylmethyldichlorosilane leads to the formation of linear and cyclic siloxanes of composition[77]:

$$[CF_3CH_2CHClSi(CH_3)O]_n \text{ and } [CF_3CHClCH_2Si(CH_3)O]_n.$$

Disiloxanes are obtained by hydrolysis of bromophenylmethylvinylchlorosilane[588] and trifluoropropylmethylchlorosilanes of formula[585]:

$$(CF_3CH_2CH_2)_n(CH_3)_{3-n}SiCl,$$

and also acyloxy-derivatives[589,590] of formula

$$(p\text{-}XC_6H_4)_3SiOCOR,$$

where X = halogen.

In the hydrolysis of γγγ-trifluoropropylmethyldichlorosilane and the subsequent catalytic destruction of the moist hydrolysate in a vacuum in the presence of catalytic amounts of alkali[580,591,592], two stereoisomers of 1,3,5-tris-(γγγ-trifluoropropyl)-1,3,5-trimethylcyclotrisiloxane are isolated.

Under the same conditions, cyclic trimer and cyclic tetramer were isolated[239] from a hydrolysate of general formula

$$[CHF_2CH_2CH_2(CH_3)_n \times SiO_{\frac{3-n}{2}}]_x$$

and cyclic tri-, tetra-, and penta-siloxanes were isolated from a mixture of $(CH_3)_2SiCl_2$ and $CF_3CH_2CH_2(CH_3)SiCl_2$.[593] On heating bis-(γγγ-trifluoropropyl)diethoxysilane with dilute HCl, $[(CF_3CH_2CH_2)_2SiO]_4$ was obtained, which on heating in the presence of a little KOH rearranges into a cyclic trimer[594].

Chloromethylmethylcyclosiloxanes with three and four siloxane units were obtained by the hydrolysis of ωω′-dichloro(chloromethyl)methylpolysiloxanes ($n = 1-5$).[595]

On treatment of $ClCH_2(CH_3)SiCl_2$ and $BrCH_2(CH_3)SiCl_2$ with a mixture of ether, acetone, aniline, and water, chloro- and bromo-methylethyldihydroxysilanes are obtained[596]; chloromethyldimethylhydroxysilane is obtained by hydrolysis of 1,3-dichloromethyltetramethyldisilazane[597]. In the hydrolysis of an ethereal solution of $C_6H_3Cl_2Si(OCOCH_3)_3$ with water[598] the monomer $C_6H_3Cl_2Si(OH)_3$ is isolated. Under analogous conditions $(p\text{-}ClC_6H_4)_2Si(OH)_2$ and $(p\text{-}BrC_6H_4)_2Si(OH)_2$[599,600] are obtained, and also a compound of the formula

$$R_{n-3}(p\text{-}XC_6H_4)Si(OH)_n,$$

where R = CH_3 or C_6H_5; X = Cl or Br and $n = 1$ or 2[601].

In the hydrolysis of m- and p-$XC_6H_4Si(CH_3)_2Y_2$ (where X = Cl or Br and Y = Cl or OCH_3)[602] the corresponding m- and p-$XC_6H_4Si(CH_3)(OH)_2$ are obtained.

$(p\text{-}XC_6H_4)_2Si(OH)_2$, where X = Cl or F, were obtained by hydrolysis of the corresponding organochlorosilanes in the presence of $(NH_4)_2CO_3$ at 0°C.[603,604]

ωω-Dihydroxy(chloromethyl)methylpolysiloxane oligomers with two, three, and four siloxane units were obtained by the hydrolysis of the corresponding ωω-dichloro-containing compounds[595].

The nature of the substituent at the silicon atom has a considerable effect on the acid properties of organohydroxysilanes: the introduction of halogen into alkyl[605] and aryl[604] groups increases the acidity.

The rate of polycondensation of halogenomethylmethyldihydroxysilanes is considerably less than that for dimethylhydroxysilane[606]; in particular, chloromethylmethyldihydroxysilane is condensed at less than one-thirtieth the rate of dimethyldihydroxysilane[607].

Chloromethyldimethylhydroxysilane reacts with dimethyldichlorosilane in the presence of triethylamine to form 1,5-bis(chloromethyl)hexamethyltrisiloxane[608].

In the reactions of halogenated organohalogenosilanes with organometallic compounds, first of all the halogen at the silicon atom is replaced by organic groups[77,202,485,609]. Halogenoaryl silanes react with organolithium compounds with replacement of a hydrogen atom by an organic group[343]:

$$o\text{-}ClC_6H_4[CH_2]_3Si(C_6H_5)_2H + C_6H_5Li \rightarrow o\text{-}ClC_6H_4[CH_2]_3Si(C_6H_5)_3 + LiH.$$

Chloromethylorganodichlorosilanes react with organomagnesium compounds from ωω-dibromoalkanes, forming silacycloalkanes[438,610]:

$$CH_2Cl(CH_3)SiCl_2 + BrMg[CH_2]_4MgBr \rightarrow \square Si\begin{matrix}CH_3\\CH_2Cl\end{matrix} + 2MgClBr.$$

In the hydrogenation of chloromethylchlorosilanes of the type

$$CH_{3-n}Cl_nSiCl_3[611] \quad \text{or} \quad CH_2ClSiR_{3-n}Cl_n[448],$$

the corresponding silicon hydrides are formed. In the hydrogenation of organochlorosilanes with trifluoropropyl groups[235,237], compounds of the formula $(CF_3CH_2CH_2)_n.SiH_{4-n}$ are obtained. The action of $LiAlH_4$, on $Cl_3SiCCl_2.SiCl_3$ yielded $H_3SiCCl_2SiH_3$,[87] which explodes when heated in a vacuum.

Chloromethyldimethylchlorosilane reacts with ammonia to form a silazane[578]:

$$ClCH_2(CH_3)_2SiCl + NH_3 \rightarrow [ClCH_2(CH_3)_2Si]_2NH + HCl.$$

The main products of the ammonolysis of $CF_3CHFCH_2Si.(CH_3)Cl_2$ are

$$[CF_3CHFCF_2(CH_3)(NH_2)Si]_2NH$$

and cyclosilazanes[612].

In the reaction of chloroalkylorganochlorosilanes with KHF_2 fluorine replaces chlorine attached to silicon[245]:

$$ClCH_2CH_2CH_2Si(C_2H_5)Cl_2 + KHF_2 \rightarrow ClCH_2CH_2CH_2Si(C_2H_5)F_2.$$

Halogeno-organochlorosilanes react with anhydrides and salts of organic acids[613,614] and with salts of difluorophosphoric acid[615] according to the reactions:

$$R_3SiCl + (R'CO)_2O \rightarrow R_3SiOCOR' + R'COCl,$$

$$R_3SiCl + HCOONa \rightarrow R_3SiOCOH,$$

$$RR'_2SiCl + NH_4OP(O)F_2 \rightarrow RR'_2SiOP(O)F_2 + NH_4Cl,$$

where R = p-XC_6H_4 (X = Cl, Br, F), R′ = H, CH_2, C_2H_5, $CH_{3-n}Cl_n$.

Halogenoalkyl(or aryl)silanes react with alcohols in the presence of sodium alkoxides[616,617] or H_2PtCl_6[249] with the formation of alkoxysilanes; they are readily halogenated at the Si–H bond by the action of halides[613,614,617-620] or phosphorus(V) chloride[200].

The presence of electrophilic halogenoalkyl substituents in silane is responsible for the considerable retardation of the halogenation (in comparison with organosilanes, which do not contain halogen atoms in the organic groups)[620]. The reactivity of $ClC_6H_4SiH_3$ in reactions with RCOOH is greater than that of $C_6H_5SiH_3$.[621] The condensation of tri-p-chlorophenylsilane with alkyl chlorides, alkenyl chlorides, chlorobenzene, and p-dichlorobenzene proceeds with higher yields than for triphenylsilane[367,622].

The introduction of chloroalkyl groups into organosilicon compounds sharply activates them in telomerisation with hexamethylcyclotrisiloxane[623]; the activity depends on the position of chlorine in the alkyl group relative to the silicon atom and decreases in the order: $\beta > \alpha > \gamma$.

Halogenoalkyl-substituted hydrido- and alkenyl-silanes can be used in additions. γ-Trifluoropropylalkenylchlorosilanes add to methylhydrochlorosilanes with the formation of

$$CF_3CH_2CH_2Si(Cl_2)(CH_2)_nSi(R)(CH_3)Cl$$

where R = Cl or CH_3 and $n = 2$ or 3.[624] Chloromethyldimethylsilane adds to

$$CH_2{=}CHCH(R)OSi(CH_3)_3$$

in the presence of Pt/C with the formation[488] of:

$$ClCH_2Si(CH_3)_2CH_2CH_2CH(R)OSi(CH_3)_3.$$

As the methyl groups in hexamethyldisiloxane are replaced by $\gamma\gamma\gamma$-trifluoropropyl groups the splitting of the siloxane bond by nucleophilic reagents is facilitated, but electrophilic reagents are hindered[586,587,625]. Silicon halides break the siloxane bond in $[R(CH_3)_2Si]_2O$, where R is $CF_3C(CH_3)_2$ or $Cl_2C_6H_3$, with formation of the corresponding halogenoalkyl(or aryl)dimethylhalogenosilanes[626].

Halogenoalkyl(or aryl)-containing organoacetoxysilanes undergo condensation with metal alkoxides. Compounds of the general formula $R_nR'_{3-n}SiOAl(OPr^{iso})_2$, where R = $CF_3CH_2CH_2$ or m-$CF_3C_6H_4$ and n = 1–3 have been obtained by the reaction of $R_nR'_{3-n}SiOCOCH_3$ with $Al(OPr^{iso})_3$.[627]

3. Reactions Accompanied by the Loss of a Halogen-Containing Group from Silicon

When aqueous NaOH acts on hexachlorocyclohexylmethyldichlorosilane the loss of $C_6H_6Cl_6$ is accompanied by dehydrochlorination and by the formation of 1,2,4-trichlorobenzene with 86.6% yield; hexachlorocyclohexylchloromethyldichlorosilane decomposes with the formation of chloromethane in addition to trichlorobenzene[184,186]. In the reaction of NaOH with chlorinated dimethyldichlorosilane and bis(trichloromethyl)diethoxysilane[18] the yields of $CHCl_3$ are 94.3 and 89.6% respectively. In 1-chloromethyl-1-methylsilacyclopentane the chloromethyl group is lost even on boiling with quinoline[512]; on boiling in the presence of water *sym*-dimethylbis(cyclotetramethylene)disiloxane is formed. In chloromethyl trichlorosilanes the mono- and di-chloro-substituted groups are completely stable even on boiling with anhydrous $FeCl_3$, and trichloromethyltrichlorosilane decomposes even in the absence of a catalyst with the formation of $SiCl_4$ and C_2H_4.[628]

In polyorganosiloxanes the stability of the halogenoalkyl groups is just the same as for the monomeric compounds, depends on the position of the halogen relative to the silicon atom. In $(CHF_2CF_2SiO_{1.5})_n$ and $(CHF_2CH_2SiO_{1.5})_n$ the Si–C bond is broken on shaking with 10% NaOH solution at 20°C; under these conditions $(CF_3CH_2CH_2SiO_{1.5})_n$ is completely stable[629].

The breaking of the Si–C bond also occurs with sodium, for example, on chloromethyltrimethylsilane[630] and also in the reaction of tetrakis(pentafluorophenyl)silane with lithium[385]:

$$(C_6F_5)_4Si + 2Li \rightarrow (C_6F_5)_3SiLi + C_6F_5Li\ .$$

The pentafluorophenyl group is lost under the action of bromine[385]:

$$(C_6F_5)_4Si + Br_2 \rightarrow (C_6F_5)_3SiBr + C_6H_5Br\ .$$

The presence of a halogenomethyl substituent greatly accelerates the solvolysis of organosilanes in alcohol–water medium[631,632], which here proceeds in two directions:

$$CH_2ClSi(CH_3)_2H + H_2O + OH^- \rightarrow CH_2ClSi(CH_3)_2OH + H_2 + OH^-\ , \quad (1)$$

$$CH_2ClSi(CH_3)_2H + H_2O + OH^- \rightarrow (CH_3)_3SiOH + H_2O + Cl^-\ . \quad (2)$$

The relative contribution of reaction (2) in this process depends on the nature of the halogenoalkyl radical and increases in the order: $CHCl_2 < CH_2Cl < CH_2I < CH_2Br$.

The hydrolysis of $(CH_3)_3SiSi(CH_3)_2CH_2Cl$ gives $[(CH_3)_3SiSi(CH_3)_2]_2O$.[49]

4. Physical Properties

There have been comparatively few studies of the physical properties of the halogenoalkyl(or aryl)-substituted organosilicon compounds.

The infrared[48,78,104,165,201,242,308,361,422,436,596,618,633–637], ultraviolet[253,635,638], Raman[49,267,350,637], electron absorption[281], NMR[77,78,120,140,201,253,308,639], nuclear quadrupole resonance[640–643], and proton magnetic resonance[644] spectra, polarographic behaviour[645], and electron microscopic examination of polyorganosiloxanes[646] have been described.

III. APPLICATIONS

Organosilicon compounds containing halogenated alkyl and aryl groups find application in various fields of technology[647,648].

For example, the use of organochlorosilanes with $\gamma\gamma\gamma$-trifluoropropyl[239] and α-(trichloromethyl)propyl[649] groups for the hydrophobisation of ceramic and other materials is known; halogenoalkyl-containing compounds are converted into nitro- and nitrito-derivatives for use in the pharmaceutical industry[446]. The replacement of alkyl and aryl groups in molecules of polyorganosiloxane liquids by halogenoalkyl and halogenoaryl groups markedly changes their properties, in particular, it increases the activation energy for viscous flow[634], increases chemical stability, and leads to a deterioration in their lubricating properties[650].

One of the most widely used types of liquid for these purposes are the $\gamma\gamma\gamma$-trifluoropropylmethylsiloxanes. They exhibit good lubricating properties on all metals[651]. In distinction from other organosilicon liquids polytrifluoropropylmethylsiloxanes are used successfully as lubricants for steel–steel couples[652].

Consistent lubricants based on these liquids[653,654] exhibit high stability to the action of water and solvents.

Liquids with other halogenoalkyl groups are used under the same designation, for example, $\alpha\alpha\gamma$-tribromopropyl, $\gamma\gamma\gamma$-trichloropropyl[316], β-(perfluoroalkyl)ethyl[655], ω-chloroalkyl[377], trifluorovinyl[419], and also bromophenyl[656], chlorophenyl[657], and chlorocyanoalkyl[92,658] groups. Liquid polyorganosiloxanes with molecules of formula p-$ClC_6H_4SCH_2CH_2Si(CH_3)O$ as elementary units of the chain exhibit good lubricating properties[331].

Linear polidimethylsiloxanes with $-[CH_2]_nCOOR$ terminal groups, where $R = CH_xF_{3-x}[CH_yF_{2-y}]_nCH_2-$ (x = 0–2, y = 0–2, n = 0–10),[659] $CHF_2[CF_2]_nCH_2-$ or $CClF_2.[CF_2CFCl]_nCH_2-$[660] are synthetic liquids which combine the best properties of organosilicon, fluorohydrocarbon, and ester oils. These liquids exhibit good viscosity characteristics over a wide range of temperatures, and a low freezing point; they are suitable for work under conditions of high temperature (205–260°C) and pressure. Analogous properties are exhibited by liquids with elementary unit of the chain molecule $OSi(CH_3)[CH_2]_4COOR$, where R = $C_3H_7CH_2$, $H[CF_2]_4CH_2$, or hexachlorobicycloheptenylmethyl[661].

Liquids which contain fluorinated organic groups are of great interest as dielectrics[239,644,662]. For example, a liquid of composition $[CF_3C_6H_4Si(CH_3)O]_n$ has ϵ = 6.5–9.5 in the range of temperatures from –20° to +100°C and frequencies of 100–100 000 Hz and is used as insulating impregnants of condensers.

Liquids containing hexafluoroisobutyl groups and active hydrogen are used for conferring oil-resistance on articles made of glass, metal, wood, leather, textiles, etc.[237]. Liquids with fluoroalkyl groups are used as fire-extinguishing materials[663], hydraulic liquids, and plasticisers[654].

Rubbers with β-(perfluoroalkyl)ethyl groups [664], in particular with trifluoropropylsiloxane units [238,654,665] and β-trifluoromethylpropyl [649] units are stable in air to 200°C and in a vacuum to 250°C. Polytrifluoropropylmethylsiloxane rubbers exhibit reduced residual deformation [666] and better technological properties [667] in comparison with polydimethylsiloxanes.

Unfilled arylenesiloxane vulcanisates with trifluoropropyl groups [663] have a tensile strength of 30 kgf cm^{-2} and when reinforced 90–105 kgf cm^{-2} at a relative elongation of 300–400%. Resins based on these rubbers retain their elasticity after radiation doses which considerably (more then 15 times) exceed that critical for polydimethylsiloxanes.

Rubbers with chloromethyl groups at silicon atoms are used [669,670]. The use of polyorganosiloxanes with halogenated alkyl groups in the composition with polytetrafluoroethylene is well known [671].

To obtain polymers with halogenophenyl groups, the method of catalytic polymerisation is widely employed. The introduction of halogenophenyl groups instead of phenyl groups greatly retards polymerisation [672,673]; depending on the number of chlorine atoms in the phenyl groups their effect on the retardation of the polymerisation process increases in the order [674]:

$$C_6H_5<ClC_6H_4<Cl_3C_6H_2<Cl_2C_6H_3<Cl_4C_6H.$$

The thermal stability of the polymers decreases with increase in the number of chlorine atoms in the phenyl group [675]. Polymers with halogenophenyl groups are used as non-inflammable adhesives for plastics, enamels, and glues in electrical insulating technology [676,677]. They also modify organic resins and lakes for conferring fire-resistance.

Polymers with halogenoalkyl ($CF_3CH_2CH_2$, [239] $Cl[CH_2]_n$, [377] $CHFClCF_2$, and $CHCl_2CCl_2$ [227]) and chlorocyanoalkyl [92] groups are used for obtaining plastics, decorative coatings, and other purposes.

Progress in Organic Synthesis Based on 1-Alkoxydienes and 1-Alkoxypolyenes

S.M.Makin

This review covers the methods of preparation and chemical properties of 1-alkoxydienes and 1-alkoxypolyenes. The interest in 1-alkoxydienes arises because they form a basis for the easy production of various classes of organic compounds: aliphatic, carbocyclic, and heterocyclic. 1-Alkoxydienes have acquired the greatest importance in the synthesis of polyenes, including natural compounds of the vitamin A and β-carotene type. The higher cyanine dyes have become accessible on the basis of the 1-alkoxydienes.
The review deals with both theoretical and practical aspects of the chemistry of the 1-alkoxydienes and 1-alkoxypolyenes. The review surveys all the information available in world literature on the chemistry of the alkoxydienes and is intended for a wide circle of organic chemists, students, and research students. There is a bibliography of 86 references.

CONTENTS

I. Introduction 237
II. Synthesis of 1-alkoxy-1,3-dienes 237
III. Synthesis of 1-alkoxypolyenes 239
IV. Synthesis on the basis of 1-alkoxy-1,3-dienes 240

I. INTRODUCTION

The extremely reactive 1-alkoxydienes, which possess a conjugated diene system and a labile alkoxy-group, are of great interest for synthetic organic chemistry. Studies in recent years have shown that these compounds can be used successfully to obtain aliphatic, carbocyclic, and heterocyclic compounds. However, 1-alkoxydienes are most frequently used for the synthesis of various types of unsaturated compounds, including polyenes belonging to the vitamin A series and carotenoids. The higher cyanines used as dyes also became accessible through the 1-alkoxydienes.

Progress in the field of synthesis and the use of 1-alkoxydienes has still not been surveyed in the chemical literature and the present review has the aim of filling this lacuna. Furthermore this review gives the information, still extremely scanty, about the 1-alkoxypolyenes.

II. SYNTHESIS OF 1-ALKOXY-1,3-DIENES

1. From Acetals of 3-Chlorobutyraldehyde

1-Alkoxy-1,3-dienes were first obtained by Wichterle[1] by heating dialkylacetals of 3-chlorobutyraldehyde with powdered potassium hydroxide; dehydrochlorination occurred with the simultaneous loss of alcohol:

$$CH_3-\underset{\displaystyle Cl}{\underset{|}{CH}}-CH_2CH(OR)_2 \xrightarrow{KOH} CH_2=CH-CH=CHOR + ROH + HCl$$

where R = C_2H_5, n-C_3H_7, n-C_4H_9, iso-C_4H_9.

However, in this method of synthesis the yields of 1-alkoxydienes are very low (~10%) and poorly reproducible. Acetals of crotonaldehyde are usually formed exclusively instead of dienes[2]. Since alkoxydienes could not be obtained by this method in much later investigation[3] it must generally be taken as unsatisfactory.

2. From Ethynyl Vinyl Ethers

Shostakovskii and coworkers[4,5] proposed a method for obtaining 1-alkoxydienes by the partial hydrogenation of ethynyl vinyl ethers over a palladium catalyst. The initial ethers were obtained by the addition of alcohols to diacetylene:

$$CH\equiv C-C\equiv CH + ROH \rightarrow CH\equiv C-CH=CHOR \xrightarrow[Pd]{H_2} CH_2=CH-CH=CHOR,$$

where R = C_4H_9, C_6H_{11}, $C_{10}H_{17}$.

This method was also used for the synthesis of 4-substituted 1-alkoxydiene[6]:

$$C_3H_7-C\equiv C-CH=CHOC_2H_5 \xrightarrow[Pd]{H_2} C_3H_7CH=CH-CH=CHOC_2H_5.$$

3. From Vinylacetylene

Wichterle and Prochazka[7] obtained 1-ethoxybuta-1,3-diene by heating vinylacetylene and alcohol with alkali in an autoclave:

$$CH_2=CH-C\equiv CH + ROH \rightarrow CH_2=CH-CH=CH-OR.$$

According to Treibs[8,9], 1-alkoxybutadiene can be obtained by the addition of aliphatic or cycloaliphatic alcohols to vinylacetylene in the presence of alkali metal alkoxides.

In the production of diacetylene from 1,4-dichlorobutyne and potassium hydroxide solution in methanol Shostakovskii and Khomenko[10] observed the formation of a little 3-chloro-1-methoxybuta-1,3-diene together with other compounds:

$$ClCH_2-C\equiv C-CH_2Cl \rightarrow \left[CH_2=\underset{\displaystyle Cl}{\underset{|}{C}}-\underset{\displaystyle Cl}{\underset{|}{C}}=CH_2\right] \rightarrow CH_2=\underset{\displaystyle Cl}{\underset{|}{C}}-C\equiv CH \xrightarrow[KOH]{CH_3OH} CH_2=\underset{\displaystyle Cl}{\underset{|}{C}}-CH=CHOCH_3.$$

4. From Acetals of αβ-Unsaturated Aldehydes

Flaig[11] showed that 1-methoxy- and 1-ethoxy-butadiene are readily formed on passing the vapour of the corresponding acetals of crotonaldehyde over contact catalysts

such as NaH_2PO_4, $Al_2(SO_4)_3$, $MgSO_4$, or B_2O_3, at 300–350°C and reduced pressure.

In this way Nazarov and coworkers[12] succeeded in obtaining 1-methoxy- and 1-ethoxy-3-methylbutadiene from acetals of dimethylacrylaldehyde. 1-Butoxy- and 1-hexoxy-butadienes were obtained analogously[13] using Al_2O_3 as catalyst.

Nazarov and coworkers[14] developed a method for obtaining 1-alkoxydienes by the liquid-phase pyrolysis of acetals of $\alpha\beta$-unsaturated aldehydes, for example:

$$CH_3-\underset{\displaystyle R^1}{\underset{|}{C}}=CH-CH(OR)_2 \rightarrow CH_2=\underset{\displaystyle R^1}{\underset{|}{C}}-CH=CHOR,$$

where $R^1 = H$, CH_3.

This method consisted in heating acetals of $\alpha\beta$-unsaturated aldehydes at 165–220°C in the presence of catalysts of the acid type. The process goes in such a manner that the low-boiling alcohols and 1-alkoxydiene formed during the pyrolysis are continuously removed from the reaction zone.

5. From Acetals of Vinylacetaldehyde

A convenient method for obtaining 1-alkoxybutadienes is the pyrolysis of acetals of vinylacetaldehyde[15,16], which can be obtained readily by the condensation of alkyl vinyl ethers in the presence of the complex catalysts $BF_3.O(C_2H_5)_2$ + $Hg(OCOCH_3)_2$ or $BF_3.O(C_2H_5)_2$ + HgO:[15,17]

$$2CH_2=CHOR \xrightarrow[Hg(OCOCH_3)_2]{BF_3\cdot O(C_2H_5)_2} CH_2=CH-CH_2CH(OR)_2 \rightarrow CH_2=CH-CH=CHOR,$$

where R = C_2H_5, n-C_4H_9, iso-C_5H_{11}.

The alcohol is removed at 330–350°C in the presence of the catalysts $MgHPO_4.Na_2SiO_3$ [15] or $BaO.SiO_2$,[16] the yield of the dienes being > 70%.

6. From 1,1,3-Trialkoxyalkanes

The most general and convenient method for obtaining 1-alkoxydienes is the pyrolysis of 1,1,3-trialkoxyalkanes:

$$R^1CH_2-\underset{\displaystyle OR}{\underset{|}{CR^2}}-CHR^3-CH(OR)_2 \rightarrow \underset{\displaystyle R^1}{\underset{|}{CH}}=\underset{\displaystyle R^2}{\underset{|}{C}}-\underset{\displaystyle R^3}{\underset{|}{C}}=CHOR + 2ROH.$$

This method allows 1-alkoxydienes with various substituents, both in the diene part and in the alkoxy-residue, to be synthesised in high yield[11,12,14,18–24] (see Table 1).

The initial 1,1,3-trialkoxyalkanes are readily obtained by the condensation of acetals and ketals with alkyl vinyl ethers in the presence of aprotic acids[25,26]:

$$R^1CH_2-CR^2(OR)_2 + R^3-CH=CHOR \xrightarrow{BF_3\cdot O(C_2H_5)_2} R^1CH_2-\underset{\displaystyle OR}{\underset{|}{CR^2}}-CHR^3-CH(OR)_2.$$

This method of synthesis of the 1,1,3-trialkoxyalkanes acquired real practical importance in connection with the development of a practicable method of obtaining ketals and acetals with the aid of tetra-alkoxysilanes[28]. Of the other methods of synthesis of the initial compounds mention must be made of a convenient way of obtaining 1,1,3-trialkoxybutanes from crotonaldehyde and an alcohol[17]:

$$CH_3CH=CH-CHO + ROH \xrightarrow{HCl} CH_3-\underset{\displaystyle OR}{\underset{|}{CH}}-CH_2-CH(OR)_2.$$

The exchange of the alkoxy-groups of 1,1,3-trimethoxy- and 1,1,3-triethoxy-alkanes with higher alcohols allows trialkoxy-compounds with other alkoxy-residues to be obtained easily. Such trialkoxy-derivatives are the starting substances for the synthesis of 1-alkoxydienes with heavy alkoxy-groups[27]:

$$CH_3CR^1(OR)-CHR^2-CH(OR)_2 \xrightarrow[-2ROH]{+2R^1OH} CH_3CR^1(OR^1)-CHR^2-CH(OR^1)_2.$$

The production of 1-alkoxydienes by the pyrolysis of 1,1,3-trialkoxyalkanes is carried out in two ways: vapour-phase and liquid-phase.

In the vapour-phase method for the production of 1-alkoxydienes the vapour of trialkoxyalkanes is passed at reduced pressure over a catalyst at 300–350°C. The catalysts which are used include: $BaO.4SiO_2$ or $BaO.5SiO_2$; $Al_2(SO_4)_3$, $MgSO_4$, NaH_2PO_4, B_2O_3, SiO_2, $MgHPO_4$, and $AlPO_4$.[11,12,14,15,22,27]

It has been shown[12,14,22,29] that the best yields of 1-alkoxydienes are obtained by using $MgHPO_4$ and this catalyst lasts longest.

Table 1. Yields of 1-alkoxydienes in the pyrolysis of 1,1,3-trialkoxyalkanes.

1-Alkoxydiene	Yield, %		Reference
	vapour-phase process	liquid-phase process	
$CH_2=CH-CH=CHOCH_3$	64.0	—	11,12
$CH_2=CH-CH=CHOC_2H_5$	72.0	77.5	11,12,13
$CH_2=CH-CH=CHOC_4H_9$-n	42.0	—	27
$CH_2=CH-CH=CHOC_5H_{11}$-iso	37.0	—	27
$CH_2=CH-CH=CHOC_6H_{13}$-n	43.0	—	27
$CH_3CH=CH-CH=CHOC_2H_5$	71.5	65.0	14,24
$CH_2=C(CH_3)-CH=CH-OCH_3$	71.0	—	12
$CH_2=C(CH_3)-CH=CH-OC_2H_5$	77.0	64.0	12,14,23–24
$CH_2=C(CH_3)-CH=CH-OC_4H_9$-n	51.5	52.0	14,27
$CH_2=C(CH_3)-CH=CH-OC_5H_{11}$-iso	—	43.5	27
$CH_2=CH-(CH_3)C=CHOC_2H_5$	62.0	68.3	14,24
$CH_2=CH-(CH_3)C=CHOC_5H_{11}$-iso	41.0	—	27
$C_2H_5CH=CH-CH=CHOC_2H_5$	—	68.6	14
$(CH_3)_2C=CH-CH=CHOC_2H_5$	—	77.8	14
$CH_2=C(CH_3)-C(CH_3)=CHOC_2H_5$	—	65.0	14,24
$CH_3-CH=CH-C(CH_3)=CHOC_2H_5$	—	59.0	14,24
	75.4	82.0	14
	—	83.2	14

The liquid-phase pyrolysis of 1,1,3-trialkoxyalkanes is carried out just as for the acetals of $\alpha\beta$-unsaturated aldehydes (see above). NaH_2PO_4, $NH_4H_2PO_4$, *p*-toluenesulphonic acid[29], and *p*-toluenesulphonic acid–quinoline mixture[23,24] have been used as catalysts[14,21], the best being $NH_4H_2PO_4$ and *p*-$CH_3C_6H_4SO_3H$–quinoline.

It should be noted that when a mixture of *p*-toluenesulphonic acid and quinoline is used as catalyst the pyrolysis of alkoxyalkanes with a terminal isoprenyl group $CH_2=C(CH_3)-$, rearrangement is observed, with the formation of 1-alkoxydienes with an n-propenyl structure $CH_3-CH=CH-$, the content of which in the reaction products reaches 10–20%:[30]

$$CH_2=\underset{\displaystyle CH_3}{\underset{|}{C}}-\underset{\displaystyle R}{\underset{|}{C}}=CH-OC_2H_5 \rightarrow CH_3CH=CH-\underset{\displaystyle R}{\underset{|}{C}}=CHOC_2H_5$$

where R = H, CH_3.

7. From Phosphonates of γ-Vinyl Ethers and Carbonyl Compounds (According to Khorner)

In this method the phosphonates of γ-vinyl ethers, which can be obtained by the pyrolysis of the acetals of γ-carbonylphosphonates, react with carbonyl compounds in the presence of a base (sodium hydride) in a medium of hexamethylphosphotriamide[31]. As a result 1-alkoxydienes are formed:

$$(RO)_2\overset{\displaystyle O}{\underset{|}{P}}-CH_2CH_2-\underset{\displaystyle R^1}{\underset{|}{C}}(OC_2H_5)_2 \rightarrow (RO)_2\overset{\displaystyle O}{\underset{|}{P}}-CH_2-CH=\underset{\displaystyle R^1}{\underset{|}{C}}-OC_2H_5$$

$$\xrightarrow{O=CR^2R^3} R^2R^3C=CH-CH=CR^1-OC_2H_5.$$

This method is extremely laborious and the initial compounds are not readily available; however, it allowed 1-ethoxydienes with structures which could not be made by other methods to be obtained. Table 2 gives the yields of the 1-ethoxydienes obtained by this method[31].

Table 2. Yields of 1-alkoxydienes after Sturtz and Lavielle[31].

Ethoxydiene	Yield %	Ethoxydiene	Yield %
$(C_6H_5)_2C{=}CH{-}CH{=}CHOC_2H_5$	68	cyclo-$C_6H_{10}{=}CH{-}CH{=}CHOC_2H_5$	37
$C_6H_5CH{=}CH{-}CH{=}CHOC_2H_5$	48	$(C_6H_5)_2C{=}CH{-}CH{=}C(CH_3){-}OC_2H_5$	40
p-$CH_3OC_6H_4{-}CH{=}CH{-}CH{=}CHOC_2H_5$	47	p-$CH_3OC_6H_4CH{=}CHCH{=}C{-}OC_2H_5$	40
p-$(CH_3)_2NC_6H_4CH{=}CH{-}CH{=}CHOC_2H_5$	48	CH_3	
$(CH_3)_2CH{-}CH{=}CH{-}CH{=}CHOC_2H_5$	57		
$C_2H_5{-}C(CH_3){=}CH{-}CH{=}CHOC_2H_5$	33	cyclo-$C_6H_{10}{=}CH{-}CH{=}C(CH_3){-}OC_2H_5$	40

8. Geometrical Isomerism of 1-Alkoxydienes

The problem of the geometric isomerism of 1-alkoxydienes has been repeatedly mentioned in the literature but a conclusive solution has not yet been obtained.

In 1950 Farmilo and Nichols[20] reported that in the pyrolysis of 1,1,3-trimethoxybutane isomeric *cis*- and *trans*-1-methoxybutadienes are formed, the proportion of the *cis*-isomer being ~ 60%. Their conclusion that *cis*–*trans* isomerism existed in the reaction products was based on the fact that in the reaction with maleic anhydride an addition product corresponding to the *trans*-isomer is readily formed, whereas under these conditions the *cis*-isomer evidently does not give an adduct with maleic anhydride, but polymerises.

In 1964 Štěpek[32] studied the problem of the existence of geometric isomers of 1-methoxybutadiene, but despite extreme care could not isolate *cis*- and *trans*-isomers. On the other hand, kinetic investigations of the reaction of 1-methoxybutadiene with maleic anhydride showed that this reaction actually proceeds in two directions—diene synthesis and copolymerisation—however, this is explained not by the existence of stable *cis*- and *trans*-isomers, as has been suggested[20], but signifies that two parallel reactions with different mechanisms occur. Copolymerisation proceeds by a radical mechanism, whereas the diene addition is not affected by either radical initiators or inhibitors. In this connection Štěpek assumes that Farmilo and Nichols[20] erroneously took to be the *cis*-isomer of 1-methoxybutadiene a certain amount of the dimethylacetal of crotonaldehyde, which is obtained in the synthesis of 1-methoxybutadiene.

In 1967 it was shown[33], with the aid of infrared spectroscopy and gas-liquid chromatography that the 1-methoxybutadiene obtained by the loss of alcohol from 1,1,3-trimethoxybutane in the presence of phosphoric acid as catalyst[34] is the pure *trans*-isomer.

However, Martin and coworkers[35], who employed semi-preparative gas–liquid chromatography succeeded in isolating small quantities of a strongly enriched mixture and in some instances, the pure *cis*- and *trans*-isomers of 1-ethoxy-1,3-dienes

$$R{-}CH{=}C(R^1){-}C(R^2){=}CHOC_2H_5,$$

(where R, R^1, and R^2 = H, CH_3) and of identifying them by the NMR method. Furthermore, the NMR method was used to study the relative stability of compounds unsubstituted at the end of the chain (R = H) and to determine the equilibrium constants of the *cis*–*trans* isomerisation. On the basis of the results obtained it was concluded that the *trans*-1,2-isomer is always more stable than the *cis*-1,2-isomer and substitution at the double bond increases the stability of the *cis*-1,2-configuration.

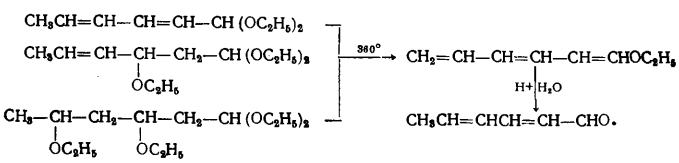
The ultraviolet and infrared spectra of the 1-alkoxydienes, both unsubstituted and with various substituents in the chain, have been investigated[27]. All the 1-alkoxydienes have an absorption band in the 235–247 nm range (in heptane), displaced considerably to longer wavelengths in comparison with the absorption band of butadiene (~ 217 nm [36]).

In the infrared spectra the frequency of the stretching vibrations of the C–C bond of the 1-alkoxydienes lies in the same range as for the alkyl derivatives of butadiene (~ 1650 cm^{-1}); splitting of the lines of the C–C bond is sometimes observed.

III. SYNTHESIS OF 1-ALKOXYPOLYENES

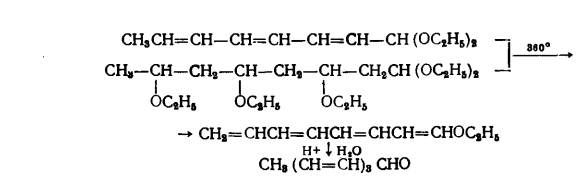
1-Alkoxypolyenes, like 1-alkoxydienes, are vinylogues of the simple vinyl ethers. Makin and Sudakova[37] showed that the pyrolysis of acetals and alkoxyacetals is universal and can be used with success not only for the synthesis of simple vinyl and diene ethers but also for the synthesis of 1-alkoxypolyenes.

In the vapour-phase pyrolysis of the acetal of 2,4-hexadienaldehyde and also of 1,1,3-triethoxyhex-4-ene over $MgHPO_4$, Na_2SiO_3 as catalyst at 360°C and reduced pressure, 1-ethoxyhexa-1,3,5-triene is formed in > 70% yield:



The structure of 1-ethoxyhexa-1,3,5-triene was confirmed by the presence in the ultraviolet spectrum of an absorption maximum at 272 nm (in heptane), which is characteristic for three conjugated bonds. In the hydrolysis of 1-ethoxyhexatriene by a dilute solution of sulphuric acid, hexa-2,4-dienaldehyde is formed. 1-Ethoxyhexa-1,3,5-triene is readily polymerised in air but in nitrogen at 0°C it can be kept for several months.

Similarly, 1-ethoxyocta-1,3,5,7-tetraene was obtained in 49–54% yield by the pyrolysis of either octatrienal acetal or 1,1,3,5,7-pentaethoxyoctane over acid phosphates[37]:



1-Ethoxytetraene is unstable and is converted into octa-2,4,6-trienal on hydrolysis in acid.

IV. SYNTHESIS ON THE BASIS OF 1-ALKOXY-1,3-DIENES

1. Hydrogenation

The exhaustive hydrogenation of 1-alkoxydienes in the presence of platinum black, $Pd/CaCO_3$, or nickel catalysts leads to ethers[33,38]. Thus butyl methyl, ethyl isopentyl, and butyl isopentyl ethers were obtained from 1-methoxybuta-1,3-diene, 1-ethoxy-3-methylbuta-1,3-diene, and 1-butoxy-3-methylbuta-1,3-diene respectively. The partial hydrogenation of 1-alkoxydienes does not take place selectively, but with the formation of a mixture of isomeric compounds[33,39], as is shown in the scheme. The addition of 1 mole hydrogen to *trans*-1-methoxybuta-1,3-diene gives a mixture of all possible hydrogenation products[33]:

$$CH_2{=}CHCH{=}CHOCH_3 + H_2 \rightarrow \underset{\text{1,2- addition}}{CH_2{=}CHCH_2CH_2OCH_3} +$$
$$+ \underset{\text{1,4- addition}}{CH_3CH{=}CHCH_2OCH_3} + \underset{\text{3,4- addition}}{CH_3CH_2CH{=}CHOCH_3} + \underset{\text{complete hydrogenation}}{C_4H_9OCH_3}$$
cis- and *trans*- *cis* and *trans*-

In the presence of platinum black and especially palladium catalyst the main product is *trans*-1-methoxybut-1-ene (3,4-addition). Partial hydrogenation in the presence of Raney nickel catalyst gives almost equal amounts of the products of 1,2-, 3,4-, and 1,4-addition.

2. Hydrolysis

The hydrolysis of 1-alkoxydienes under the action of 2% sulphuric acid leads $\alpha\beta$-unsaturated aldehydes[38]:

$$R{-}CH{=}\overset{R^1}{\overset{|}{C}}{-}CH{=}CHOC_2H_5 \xrightarrow[H^+]{H_2O} RCH_2{-}\overset{R^1}{\overset{|}{C}}{=}CH{-}CHO$$

where R, R^1 = H, CH_3.

In this way crotonaldehyde, 3-methylcrotonaldehyde, and 4-methylcrotonaldehyde were obtained in good yield from 1-ethoxybuta-1,3-diene, 1-ethoxy-3-methylbuta-1,3-diene, and 1-ethoxypenta-1,3-diene respectively. Probably the addition of water to 1-alkoxydienes occurs in the 1,4-position of the diene system, although it is difficult to draw definite conclusions since $\beta\gamma$-unsaturated aldehydes (obtained when there is 1,2-addition) readily rearrange in acid medium into $\alpha\beta$-unsaturated aldehydes.

3. Addition of [Substituted] Silanes

It was shown recently that 1-alkoxydienes are capable of adding silane derivatives[40]. The addition of fluoromethylpropylsilanes to a diene ether takes place in the presence of hydrogen hexachloroplatinate(IV) with the formation of 1-butoxy-4-(fluoromethylpropylsilyl)but-1-ene with yields of up to 91%; an addition product with two molecules of the silane is liberated in small amounts:

$$C_4H_9OCH{=}CH{-}CH{=}CH_2 + HSiRR'F \begin{cases} \rightarrow C_4H_9OCH{=}CHCH_2CH_2SiRR'F \\ \rightarrow C_4H_9OCH_2CH(SiRR'F){-}CH_2CH_2SiRR'F. \end{cases}$$

Here we encounter a rare instance of addition to 1-alkoxydienes in the 1,2- and 3,4-positions.

The reaction of methyldichlorosilane with 1-butoxybuta-1,3-diene is accompanied by resinification of the ether and the addition product could be isolated only in 1.2% yield.

4. Addition of Alchols

1-Alkoxy-1,3-dienes add alcohols even in the cold or at room temperature in the presence of catalytic amounts of hydrochloric acid, acetals of $\alpha\beta$-unsaturated aldehydes being obtained in good yield[14,38,41]:

$$CH_2{=}\overset{R^1}{\overset{|}{C}}{-}CH{=}CHOR + ROH \xrightarrow{H^+} CH_2{=}\overset{R^1}{\overset{|}{C}}{-}CH{-}CH(OR)_2$$

where R^1 = H, CH_3; R = CH_3, C_2H_5, n-C_4H_9, iso-C_5H_{11}.

The structure of the reaction products was shown by countersyntheses and infrared spectroscopy[38].

The diethyl-, dibutyl-, and di-isopentyl-acetals of crotonaldehyde were obtained in this way from 1-ethoxy-, 1-butoxy-, and 1-isopentyloxy-butadiene respectively[38,41] and the diethyl- and dibutyl-acetals of 3-methylcrotonaldehyde were obtained from ethoxy- and butoxy-isoprene[14,38].

Kubler[42], having studied the addition of methanol to 1-methoxybutadiene and of ethanol to 1-ethoxybutadiene in the presence of sulphuric acid, states that this reaction is accompanied by the formation of 1,1,5-trialkoxyocta-2,6-dienes by the scheme:

$$CH_2{=}CH{-}CH{=}CHOCH_3 + H^+ \rightarrow CH_3CH{=}CH{-}\overset{+}{C}HOCH_3 \rightarrow$$
$$\xrightarrow{CH_2=CH-CH=CHOCH_3} CH_3CH{=}CHCH(OCH_3)CH_2CH{=}\overset{+}{C}HOCH_3 \rightarrow$$
$$\xrightarrow{CH_3OH} CH_3CH{=}CH{-}CH(OCH_3)CH_2CH{=}CHCH(OCH_3)_2 + H^+.$$

It should be noted that the addition of alcohols to 1-alkoxydienes can serve as a preparative method for obtaining difficultly accessible acetals from $\alpha\beta$-unsaturated aldehydes.

5. Bromination and Bromoalkoxylation

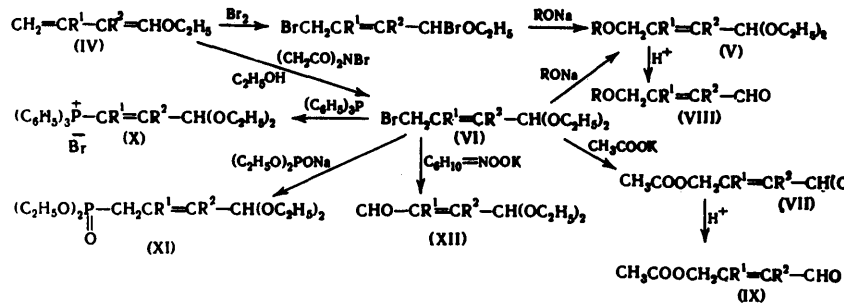
1-Ethoxybutadiene adds the first bromine molecule in the 1,4-position of the diene system. In further bromination a second bromine molecule is added with the formation of a crystalline tetrabromide[11]:

$$CH_2{=}CH{-}CH{=}CHOC_2H_5 \xrightarrow{Br_2} CH_2{-}\underset{Br}{CH}{=}CH{-}\underset{Br}{CHOC_2H_5} \xrightarrow{Br_2}$$
$$\rightarrow \underset{(I)}{CH_2{-}\underset{Br}{CH}{-}\underset{Br}{CH}{-}CHOC_2H_5}.$$
$$\underset{Br\ \ Br\ \ Br\ \ Br}{\ }$$

Both the dibromide (I) and, in particular, the tetrabromide are very unstable compounds. On treating dibromide (I) with sodium ethoxide it is converted into an acetal of 4-ethoxycrotonaldehyde (II) and the loss of alcohol from (II) yielded 1,4-diethoxybuta-1,3-diene (III):[11]

$$(I) \xrightarrow{2C_2H_5ONa} \underset{(II)}{C_2H_5OCH_2CH{=}CHCH(OC_2H_5)_2} \xrightarrow[Al_2O_3]{350^\circ} \underset{(III)}{C_2H_5OCH{=}CHCH{=}CHOC_2H_5}.$$

The bromination of substituted 1-alkoxydienes (IV) has been studied[38], and the direction of the reaction and structure of the bromides obtained was established from the products of their reaction with alkoxides. The formation of acetals of $\alpha\beta$-unsaturated γ-alkoxyaldehydes (V) shows that the addition of bromine occurs in the 1,4-position.



where R = CH_3, C_2H_5; R^1 and R^2 = H, CH_3.

The bromoalkoxylation of 1-alkoxydienes (IV) is extremely interesting and promising. This reaction, which takes place on the treatment of 1-alkoxydienes with bromosuccinimide in alcoholic medium leads to acetals of $\alpha\beta$-unsaturated 4-bromoaldehydes (VI).[11,38] Using the high reactivity of allyl bromide, various difficultly accessible bifunctional derivatives of $\alpha\beta$-unsaturated aldehydes[38] were readily obtained, a route of wide use in organic synthesis. The bromoalkoxylation of 1-ethoxybuta-1,3-diene[11,38], 1-ethoxy-2-methylbuta-1,3-diene[38], and 1-ethoxy-3-methylbuta-1,3-diene[38] was investigated.

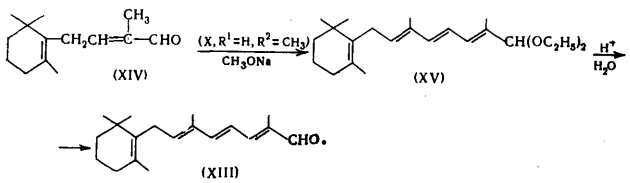
The reaction of 4-bromoacetals (VI) with alkoxides or potassium acetate gave in good yield the acetals of γ-alkoxy- (V) and γ-acetoxy- (VII) derivatives of $\alpha\beta$-unsaturated aldehydes respectively. In the hydrolysis by dilute phosphoric acid, (V) and (VII) are readily converted into the corresponding γ-alkoxy- (VIII) and γ-acetoxy- (IX) substituted $\alpha\beta$-unsaturated aldehydes[38].

γ-Bromoacetals (VI) react readily with triphenylphosphine with the formation of phosphonium salts[29,43-45] (X), and on reaction with sodium diethyl phosphite they are converted into phosphonates (XI).[29]

The bromomethyl group in 4-bromoacetals (VI) can be oxidised to an aldehyde group by reaction with the potassium salt of nitrocyclohexane[38,46,47]. This provides a possible route to the previously difficultly accessible monoacetals of fumaraldehyde and its alkylsubstituted derivatives (XII).

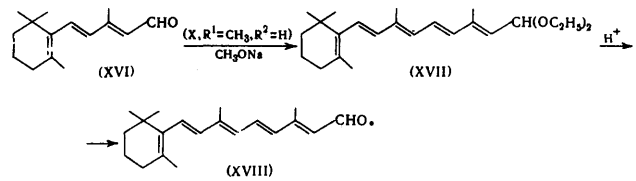
The bifunctional derivatives of $\alpha\beta$-unsaturated aldehydes obtained on the basis of 1-alkoxydienes were used for the synthesis of polyene compounds of various types and principally for the synthesis of derivatives of vitamin A and carotenoid precursors.

Thus, 1-ethoxy-2-methylbutadiene was used for obtaining β-C_{19}-aldehyde (XIII)[44], which is a key product in the synthesis of β-carotene:

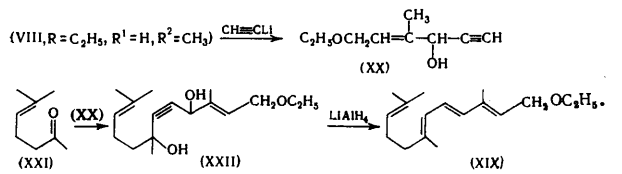


Here the reaction of the phosphonium salt (X; R^1 = H, R^2 = CH_3) with β-C_{14} aldehyde (XIV) in the presence of sodium methoxide gave an acetal of β-C_{19} aldehyde (XV), hydrolysis of which by dilute phosphoric acid gave quantitatively a mixture of the *cis–trans*-isomers of β-C_{19} aldehyde (XIII).

Similarly, reaction of β-ionolydeneacetaldehyde (XVI) with a phosphonium salt (X; R^1 = CH_3, R^2 = H) obtained from 1-ethoxy-3-methylbutadiene, gave the acetal of the aldehyde of vitamin A (XVII), which forms on acid hydrolysis the aldehyde of vitamin A (XVIII)[45]:

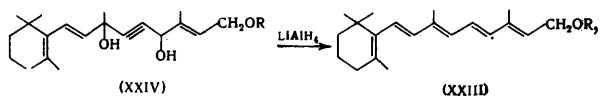


Several synthetic routes to the polyene ethers of isoprenoid structure (including ethers of vitamin A) have been proposed on the basis of 1-alkoxydienes. The scheme given below shows the synthesis of the ethyl ether of dehydrofarnesol (XIX)[48]:



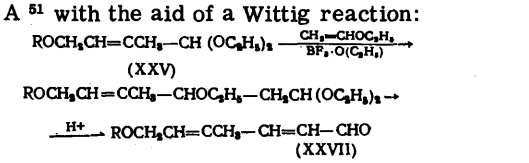
In this synthesis the condensation of 1-ethoxy-3-methylhex-2-en-5-yn-4-ol (XX) with methylheptenone (XXI) gave the acetylenic glycol (XXII), which on reaction with lithium tetrahydroaluminate was converted into the ethyl ether of dehydrofarnesol (XIX) (the Nayler–Whiting reaction[49]).

This reaction was subsequently used to obtain the ethyl ether of vitamin A (XXIII):[50]



where R = C_2H_5. The initial acetylenic glycol (XXIV) was obtained by two paths: (1) by condensation of β-ionone with the Iotsich complex obtained from (XX), and (2) from ethynyl-β-ionol and γ-ethoxytiglinaldehyde (VIII; R = C_2H_5, R^1 = H, R^2 = CH_3).

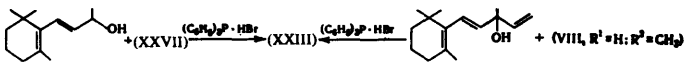
γ-Alkoxy- and γ-acetoxy-tiglinaldehydes and their acetals obtained from the corresponding 1-alkoxydienes open yet another synthetic route to the esters and ethers of vitamin A[51] with the aid of a Wittig reaction:



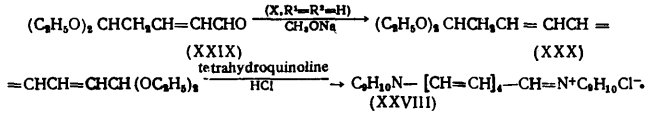
where R = CH_3, $COCH_3$.

The acetals of γ-methoxy- and γ-acetoxytiglinaldehyde (XXV) readily condense with ethyl vinyl ether with the formation of the corresponding 1,1,3-trialkoxy-compounds (XXVI), which on heating with acetic acid are converted

into ω-substituted hexadienals (XXVII). Ethers of vitamin A (XXIII; R = CH_3, $COCH_3$) were synthesised[51] subsequently, as is shown by the scheme:



The reactions of 1-alkoxydienes considered above can be used successfully for the synthesis of cyanines. Thus the acetal of γ-bromocrotonaldehyde, obtained from 1-ethoxybutadiene, was used for making the cyanine (XXVIII)—an intermediate in the synthesis of pentacarbocyanine sensitisers[29,52]:

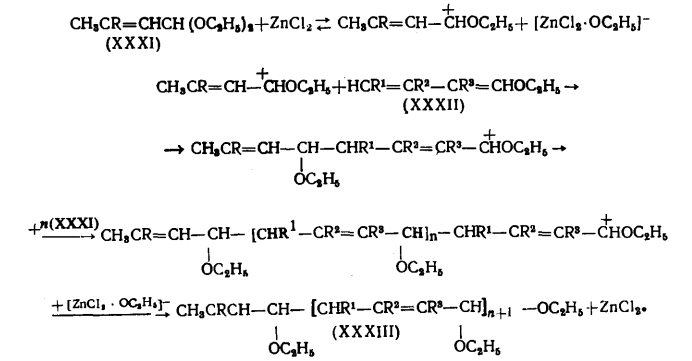


Here the condensation of 5,5-diethoxypent-2-enal[52,53] (XXIX) with 4-(1,1-diethoxybut-2-enyl)triphenylphosphonium bromide (X; $R^1 = R^2 = H$) in the presence of sodium methoxide gives nonatriendial tetraethyl acetal (XXX), which on treatment with tetrahydroquinoline in hydrochloric acid is readily converted into (XXVIII).

6. Condensation with Acetals of $\alpha\beta$-Unsaturated Aldehydes

Nazarov and Krasnaya showed[54,55] that 1-alkoxydienes, like alkyl vinyl ethers, readily condense with the acetals of $\alpha\beta$-unsaturated aldehydes in the presence of aprotic acids —$ZnCl_2$, $BF_3.O(C_2H_5)_2$, etc. For example, it was shown that in the condensation of the acetals of crotonaldehyde and β-methylcrotonaldehyde with 1-ethoxybuta-1,3-diene, 1-ethoxy-3-methylbuta-1,3-diene[54,55], 1-ethoxy-2-methylbuta-1,3-diene[56], 1-ethoxypenta-1,3-diene[57], and 1-ethoxy-2,3-dimethylbuta-1,3-diene[56], the addition of acetals to 1-alkoxydienes, whether substituted or unsubstituted, takes place in the 1,4-position of the diene system of the 1-alkoxydiene.

The addition of acetals (XXXI) to 1-alkoxydienes (XXXII) yields new acetals of $\alpha\beta$-unsaturated aldehydes, which in their turn are also capable of addition to 1-alkoxydienes so that a mixture of the first, second, third, and other successive addition products (XXXIII) is obtained, readily separable by fractional distillation. The mechanism of this condensation is as follows[56]:



Hence the addition of acetals to 1-alkoxydienes has the character of telomerisation, the extent of which depends on the ratio of the acetal and alkoxydiene taken in the reaction.

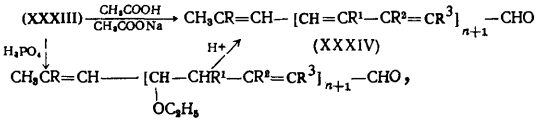
The example of the condensation of crotonaldehyde acetal with 1-ethoxypenta-1,3-diene was used[57] to investigate the dependence of the composition of the telomeric products on the ratio of the acetal to 1-alkoxydiene; the results are given in Table 3.

Table 3 shows that a change in the alkoxydiene : acetal ratio allows the course of the reaction to be regulated to some extent, by directing it to the side of the preferential formation of the desired product. A similar picture is also observed for other 1-alkoxydienes and acetals. The reaction examined is a comparatively simple method of growing a chain of 4, 8, 12, or 16 carbon atoms at one stroke.

Table 3. Telomerisation[57] of acetals of crotonaldehyde with 1-ethoxypenta-1,3-dienes.

Alkoxydiene : acetal ratio	Yield of telomer (XXXIII $R' = CH_3$, $R = R^2 = R^3 = H$)				
	$n=0$	$n=1$	$n=2$	$n=3$	total
1:2	48	30	12	3	93
2:3	28	41	16.5	5	90.5
1:1	27	12	37	8.5	84.5
2:1	9.5	6	26	26.5	68

A remarkable property of alkoxyacetals (XXXIII) was that on heating with 90% acetic acid they are converted in high yield into polyene aldehydes (XXXIV) and on heating with dilute phosphoric acid are hydrolysed with quantitative formation of alkoxyaldehydes (XXXV) which under the action of *p*-toluenesulphonic acid in toluene are also readily converted into polyenals (XXXIV)[54-57].

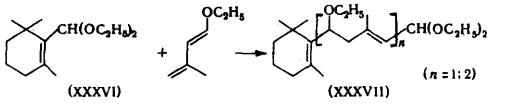


where R, R^1, R^2, R^3 = H, CH_3; n = 0, 1, 2.

The condensation of acetals of $\alpha\beta$-unsaturated aldehydes with 1-alkoxydienes has made the natural polyenes of the isoprenoid structure extremely accessible.

The conversions considered above were used for the synthesis of β-ionolideneacetaldehyde, the aldehyde of vitamin A, and vitamin A (alcohol).

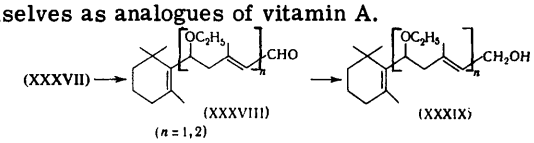
The condensation of β-cyclocitral acetal (XXXVI) with 1-ethoxyisoprene in the presence of zinc chloride as catalyst yielded[58] a mixture of the ethoxyacetals of C_{15} aldehyde (XXXVII; n = 1) and the C_{20} aldehyde (XXXVII; n = 2) with yields of 44.6 and 25% respectively:



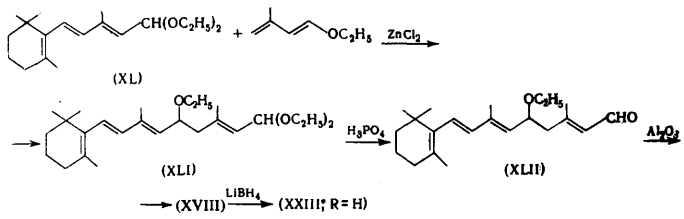
Under the action of orthophosphoric acid in dioxan, (XXXVII; n = 1) is converted into β-ionolideneacetaldehyde (XVI) and on hydrolysis with dilute phosphoric acid,

into ethoxydihydro-β-ionolideneacetaldehyde (XXXVIII, $n = 1$) in good yield. Reduction of (XXXVIII; $n = 1$) with sodium tetrahydroborate gives ethoxydihydro-β-ionolideneethanol (XXXIX; $n = 1$).

In a similar manner, the diethoxybisdihydroaldehyde of vitamin A (XXXVIII; $n = 2$) and diethoxybisdihydrovitamin A (XXXIX; $n = 2$) were obtained in good yield from (XXXVII; $n = 2$). These compounds can be used for the synthesis of vitamin A and in addition they are of interest themselves as analogues of vitamin A.

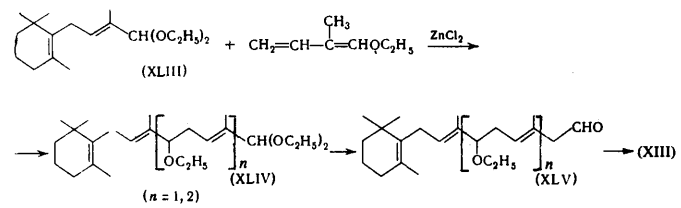


Vitamin A was synthesised by the condensation of β-ionolideneacetaldehyde (XL) with 1-ethoxyisoprene [59,60]. The ethoxyacetal (XLI) thus obtained in 62% yield hydrolyses quantitatively into dihydrovitamin A ethoxyaldehyde (XLII), which on chromatography on aluminium oxide gives the vitamin A aldehyde (XVIII):



On reduction of (XVIII) with lithium tetrahydroborate vitamin A (XXIII, R = H) is obtained.

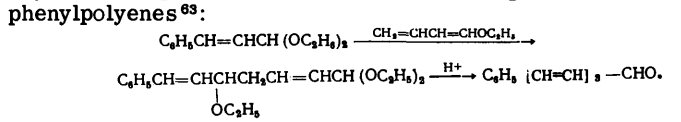
The method described above for growing a polyene chain was used for the synthesis of β-C_{19} aldehyde (XIII) [61].



With this aim the β-C_{19} ethoxyacetal (XLIV; $n = 1$) and β-C_{24}-diethoxyacetal (XLIV; $n = 2$) were obtained by the addition of β-C_{14} aldehyde acetal to 1-ethoxy-2-methylbutadiene. The hydrolysis of these ethoxyacetals with dilute phosphoric acid gives, in quantitative yield, β-C_{19}-ethoxyaldehyde (XLV; $n = 1$) and β-C_{24}-diethoxyaldehyde (XLV; $n = 2$) respectively. Removal of alcohol from (XLV; $n = 1$) led to the fully *trans*-β-C_{19}-aldehyde (XIII).

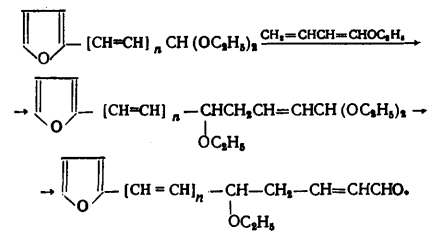
It has been shown [62] that citral acetal is also capable of being condensed with 1-ethoxyisoprene, to form a mixture of telomers of isoprenoid structure.

The condensation of cinnamaldehyde acetal with 1-ethoxybutadiene provided a new method for the production of phenylpolyenes [63]:



In this way the acetals of αβ-unsaturated aldehydes are readily condensed with 1-alkoxydienes. However, there is almost no information about a similar condensation for ketals. The reaction of acetophenone ketal with 1-ethoxybutadiene has been described [64], it being noted that the yield of the condensation product was very low.

Furfural acetal and β-(2-furyl)acrolein acetal readily add to 1-ethoxybutadiene to form normal condensation products [63]:

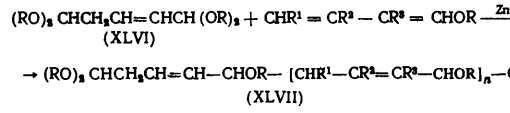


($n = 0$ or 1; yield 40%).

The condensation of 1-alkoxydienes with diacetals of glutaconaldehyde (XLVI) is very interesting, since it allowed previously inaccessible cyanines—the derivatives of higher polyene dialdehydes—to be synthesised simply [29,65-67].

Glutaconaldehyde acetals have two acetal groups, one of which is αβ-unsaturated, the other βγ-unsaturated. It was found experimentally that the condensation of glutaconaldehyde acetal takes place selectively, solely at the αβ-unsaturated acetal group, and the βγ-unsaturated group does not participate in the reaction. This course for the reaction agrees with the theoretical ideas about the mechanism of addition of acetals to alkyl vinyl ethers [68,69].

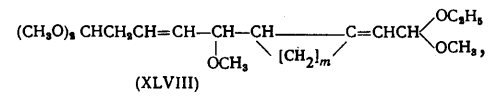
The condensation of glutaconaldehyde acetals [70,71] with 1-methoxybuta-1,3-diene, 1-ethoxypenta-1,3-diene, 1-ethoxy-2-methylbuta-1,3-diene, and 1-ethoxy-3-methylbuta-1,3-diene [29,66] has been studied. In every instance a mixture of telomeric compounds (XLVII), readily separable by fractional distillation, was obtained:



where $n = 1, 2, 3$; R = CH_3, C_2H_5; R^1, R^2, R^3 = H, CH_3.

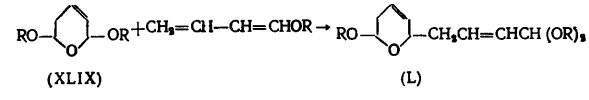
Alkoxyacetals of dialdehydes with 9, 13, and 17 carbon atoms in the chain were obtained according to this scheme.

Derivatives of a dialdehyde with six-membered ($m = 4$) and five-membered ($m = 3$) rings in the chain were obtained in the condensation of glutaconaldehyde acetals with 1-β-(ethoxyvinyl)cyclohexene and 1-β-(ethoxyvinyl)cyclopentene [66]:



where $m = 3$ or 4.

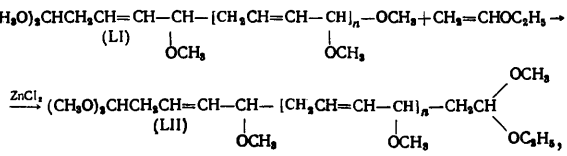
Although 1-alkoxydienes are capable of condensing with 2,6-dialkoxy-Δ^3-dihydropyranes (VLIX) [72] the yield of the condensation product (L) is low (17%) [65]:



where R = CH_3.

In their turn C_9- and C_{13}-alkoxydiacetals (LI; $n = 1$ and 2, respectively), obtained by the condensation of glutaconaldehyde acetal with 1-methoxybutadiene, are capable of reacting with ethyl vinyl ether to form alkoxyacetals

(LII), containing respectively 11 and 15 carbon atoms in the chain. The yield of (LII) is 41–43%:

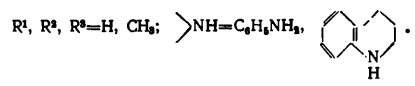


where $n = 1$ or 2.

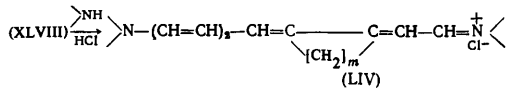
The condensation examined is a simple general method for the synthesis of alkoxyacetals of unsaturated dialdehydes with 9, 11, 13, 15, or 17 carbon atoms in the chain.

In the acid hydrolysis of the condensation products of glutaconaldehyde with 1-alkoxydienes (XLII; $n = 1$) in the presence of primary or secondary amines a δ-alkoxy-group is lost extremely readily, and cyanines (LIII) are formed in very good yield (up to 80%) [29,67]:

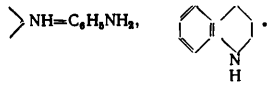
where



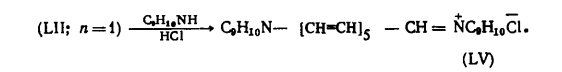
Cyanines (LIV) with six- and five-membered rings respectively in a conjugated chain [29] were obtained from alkoxydiacetals (XLVIII; $m = 4$ and 3)



where $m = 3$ or 4;



This method for obtaining cyanines was used for the synthesis of undecamethine compounds. Thus in the treatment of 1,3,7,11,11-pentamethoxy-1-ethoxyundeca-4,8-diene (LII; $n = 1$) with tetrahydroquinoline in dilute hydrochloric acid, bistetrahydroquinolide undecatetraenedial chloride [quinolinylundecapentaeneylidene quinolinium chloride] (LV) is formed in good yield [66]:

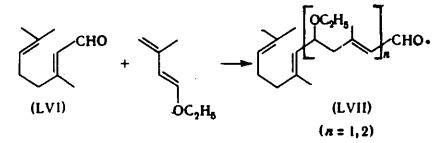


7. Condensation with αβ-Unsaturated Aldehydes

In the presence of catalysts such as BF_3, $ZnCl_2$, and $H_3BO_3 + (COOH)_2$, 1-alkoxydienes are capable of reacting readily also with αβ-unsaturated aldehydes [73]. It was found that alkoxyaldehydes (XXXV) are formed in this condensation:

which are readily converted into polyenals (XXXIV) on heating with phosphoric acid. 5-Ethoxycitral, 5,9-diethoxyfarnesal, octa-2,4,6-trienal, 3-methylocta-2,4,6-trienal, dodeca-2,4,6,8,10-pentaenal, and dehydrocitral were obtained in this way [73].

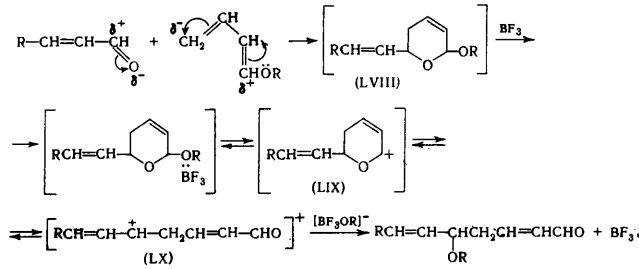
Citral (LVI) is also capable of undergoing this condensation, with the formation of terpene compounds [73] (LVII):



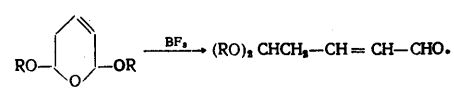
Furfural condenses rather readily with 1-ethoxybutadiene in the presence of the catalysts mentioned above. Here, as in other instances, a mixture of telomeric alkoxyaldehydes is obtained, which are then easily converted into furylpolyenals [73]. Unlike furfural, benzaldehyde condenses with 1-ethoxybutadiene with great difficulty, the yield of condensation product (5-ethoxy-5-phenylpent-2-enal) being ~ 10%.

β-Cyclocitral, 2,3-dihydro-2-methylbenzaldehyde, and also aliphatic aldehydes (butyraldehyde, isovaleraldehyde) seemed to be incapable of undergoing this condensation [73].

From our standpoint it seems most probable that the condensation of unsaturated aldehydes with 1-alkoxydienes is accompanied by the intermediate formation of dihydropyran (LVIII) as a result of a reaction of the diene synthesis type. Furthermore, the action of an acid catalyst, for example, BF_3, on (LVIII) produces an unstable carbonium ion (LIX), which then rearranges into the more stable αβ-unsaturated cation (LX). The reaction of (LX) with $[BF_3OR]^-$ leads to δ-alkoxyaldehydes of the (XXXV) type:



An indirect confirmation of this mechanism is the recent observation [53] of the rearrangement of 2,6-dialkoxy-Δ³-dihydropyrans into glutaconaldehyde monoacetal:



8. Reaction with Formylating Agents

In the reaction of 1-alkoxybutadienes with (chloromethylene)dimethylammonium chloride, obtained from dimethylformamide and carbonyl chloride (the Wilsmeier–Hagg reaction), Arnold [74] observed the formation of derivatives of glutaconaldehyde, which are cyclised in the reaction mixture under the action of ammonium salts into compounds of the pyridine series. It is interesting to note that such compounds are also formed by the acetals of crotonaldehyde and even by 1,1,3-trialkoxybutanes under the action of a formylating agent. This fact can evidently be explained only by the reaction of crotonaldehyde and

CHEMICAL SOCIETY REFERENCE LIBRARY BURLINGTON HOUSE, W.1

1,1,3-trialkoxybutane acetals with the strongly electrophilic formylating agent producing intermediate 1-alkoxydienes, which also undergo formylation[74]:

$$CH_2=CH-CH=CHOR \xrightarrow{[(CH_3)_2N=CHCl]^+Cl^-} \rightarrow [(CH_3)_2N=CHCH=CHCH=CHOR]^+Cl^- \xrightarrow{OH^-} \rightarrow (CH_3)_2NCH=CH-CH=CH-CHO \xrightarrow{NH_4Cl}$$

Normant and Martin[24] made a detailed study of the formylation of some substituted 1-alkoxydienes with the aid of formylating agent from dimethylformamide and phosphoryl(V) chloride. This reaction gave a series of substituted unsaturated aminoaldehydes (LXI):

$$RCH=CR^1-CR^2=CHOC_2H_5 + [(CH_3)_2N=CHCl]^+[OPOCl_2] \rightarrow \rightarrow [(CH_3)_2NCHCl-CHR-CR^1=CR^2-CHOC_2H_5][OPOCl_2]^- \xrightarrow{-HCl} \rightarrow [(CH_3)_2NCH=CR-CR^1=CR^2-\overset{+}{C}HOC_2H_5 \longleftrightarrow (CH_3)_2\overset{+}{N}=CH-CR= =CR^1-CR^2=CHOC_2H_5][OPOCl_2]^- \xrightarrow{OH^-} (CH_3)_2N-CH=CR-CR^1=CR^2-CHO, \quad (LXI)$$

where R, R^1, R^2 = H or CH_3.

Normant and Martin[24] note certain features in the formylation of substituted 1-alkoxydienes. Thus with 1-ethoxy-3-methylbuta-1,3-diene the corresponding amino-aldehyde

$$(CH_3)_2N-CH=CH-CCH_3=CHCHO$$

could not be obtained. This is explained by the steric hindrance to electrophilic attack of the formylating agent by the terminal $CH_2=CCH_3$-group of the diene.

In the reaction of a formylating agent with 1-ethoxypenta-1,3-diene instead of the expected amino-aldehyde

$$(CH_3)_2NCH=CCH_3-CH=CHCHO \quad (LXII)$$

the amino-aldehyde

$$(CH_3)_2NCH=CHCH=CCH_3-CHO \quad (LXIII)$$

the structure of which was proved by the NMR method, was obtained. Normant and Martin[24] think that in the action of the formylating agent on 1-ethoxypenta-1,3-diene a carbonium ion normal for this diene salt is formed:

$$[(CH_3)_2N-CH=CCH_3-CH=\overset{+}{C}HOC_2H_5 \longleftrightarrow (CH_3)_2\overset{+}{N}=CH-CCH_3=CH-CH=CHOC_2H_5]$$

In the decomposition of this salt in alkaline medium initially the aminoaldehyde (LXII) is formed and also the dialdehyde

$$CHO-CCH_3=CHCH_2CHO \quad (LXIV)$$

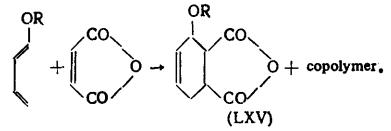
and dimethylamine (as a result of the hydrolysis of the excess of formylating agent). The dimethylamine liberated immediately reacts with the amino-aldehyde (LXII) and dialdehyde (LXIV) to form the isomeric cation

$$[(CH_3)_2NCH=CCH_3-CH=CHCH=\overset{+}{N}(CH_3)_2],$$

hydrolysis of which gives the more stable (LXIII).

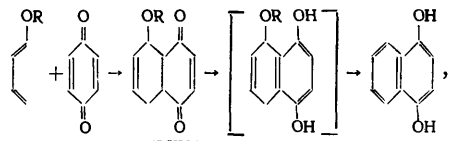
9. Diene Synthesis

The diene condensation of 1-alkoxybutadienes with maleic anhydride has been frequently studied[5,11,15,19,20,32,75,76]. Most authors[5,11,32,75] report that this reaction takes place very vigorously and leads to the formation of a normal addition product—the anhydride of 2-alkoxy-2,5,6-tetrahydrophthalic acid (LXV). Furthermore, the reaction is accompanied by the copolymerisation of 1-alkoxydiene with maleic anhydride:



(LXV)

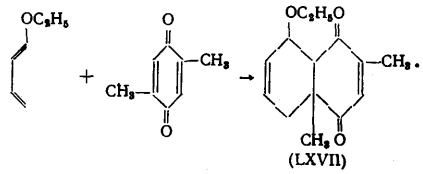
The reaction of 1-alkoxybutadienes with various quinones has been studied best. In the reaction of 1-methoxy- and 1-ethoxy-butadiene with *p*-benzoquinone addition products (LXVI) are formed, which lose alcohol under the influence of acetic acid and hydrogen bromide and are converted into 1,4-dihydroxynaphthalene[77]:



(LXVI)

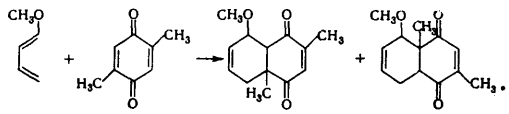
where R = CH_3, C_2H_5.

The reaction of 1-ethoxybutadiene with xyloquinone[78] gave only one isomer of the addition product, which was ascribed structure (LXVII) without proof:



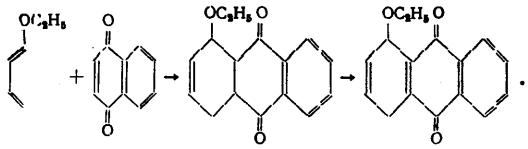
(LXVII)

The condensation of 1-methoxybutadiene with the same dienophile leads to a mixture of two structural isomers, the ratio of the amounts of *"ortho"* (LVIII) and *"meta"* (LXIX) isomers being 10 : 1:



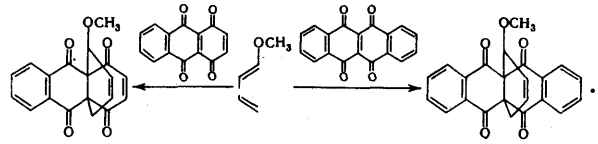
(LXIX) (LXVIII)

1-Ethoxybutadiene reacts readily with 1,4-naphthaquinone to form compound (LXX) which is readily oxidised by atmospheric oxygen to a dihydroanthraquinone derivative (LXXI)[11]:



(LXX) (LXXI)

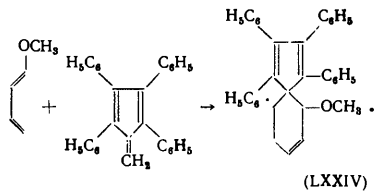
The condensation of 1-methoxybutadiene with quinizarin-quinone gives compound (LXXII) and that with tetracene-quinone gives compound (LXXIII)[79]:



(LXXII) (LXXIII)

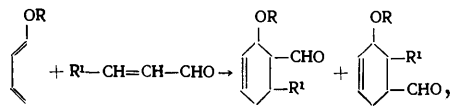
The condensation of 1-methoxybutadiene with tetraphenylfulvene gives an addition product (LXXIV) and in

condensation with tetraphenylpentadiene a substance whose structure has still not been explained is produced[80]:



(LXXIV)

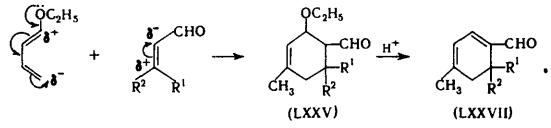
The diene condensation of 1-alkoxydienes with unsymmetrical dienophiles has been studied in a series of papers. Wichterle[1] was the first to condense unsaturated 1-alkoxybutadienes with acrylaldehyde and crotonaldehyde. He suggested that the addition products obtained contain both of the theoretically possible isomers:



where R^1 = H or CH_3. However, the structure of the addition products obtained was not proved.

The condensation of 1-cyclohexyloxybutadiene with crotonaldehyde was effected recently[5]. The authors, without giving any proof, consider that the addition product obtained is 3-cyclohexyloxy-2-methyl-1,2,3,6-tetrahydrobenzaldehyde (a *"meta"* adduct).

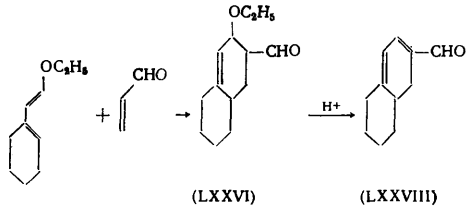
A special study[76] of the structural selectivity of the diene synthesis of 1-alkoxydienes with $\alpha\beta$-unsaturated aldehydes, revealed that the condensation of 1-ethoxy-3-methylbutadiene with acrylaldehyde, crotonaldehyde, and β-methylcrotonaldehyde leads to the formation exclusively of *"ortho"* addition products (LXXV) in accordance with the polarisation of the diene and dienophile:



(LXXV) (LXXVII)

The structure of the products (LXXV) was established chemically and by ultraviolet spectroscopy.

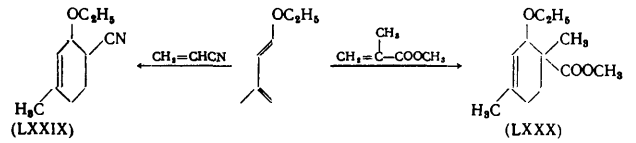
There is also structural selectivity in the reaction between 1-(β-ethoxyvinyl)cyclohexene and acrylaldehyde[76] with the formation of compound (LXXVI):



(LXXVI) (LXXVIII)

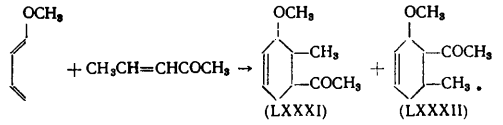
These reactions make accessible the cyclodialkenic aldehydes (LXXVII) and (LXXVIII) which are obtained by other methods in a much more complex manner.

1-Ethoxy-3-methylbutadiene readily undergoes a diene synthesis with acrylonitrile and methyl methacrylate to form 2-ethoxy-1,2,5,6-tetrahydro-4-methylbenzonitrile (LXXIX) and methyl 2-ethoxy-1,4-dimethylcyclohexene-3-carboxylate (LXXX). The reaction here is also structurally directed[76]:



(LXXIX) (LXXX)

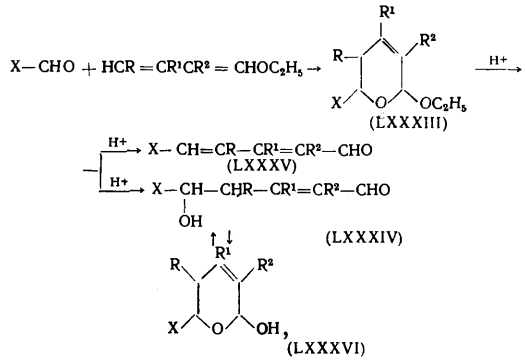
However, the condensation of methoxybutadiene with methyl propenyl ketone leads to a mixture of the two possible isomers (LXXXI) and (LXXXII)[81]:



(LXXXI) (LXXXII)

These isomers were separated by fractional distillation or (less successfully) chemically on the basis of the difference in activity of the carbonyl groups in the compounds (LXXXI) and (LXXXII) in the production of some of their derivatives.

The condensation of the 1-alkoxydienes with heterodienophiles has still been little studied. It was shown that 1-alkoxydienes are capable of undergoing a diene synthesis with paraform[82,83] and with aldehydes having electron-acceptor groups in the α-position—chloral and esters of glyoxylic acid[83]. In every instance the reaction leads to substituted 2-alkoxy-Δ^3-dihydropyrans (LXXXIII):

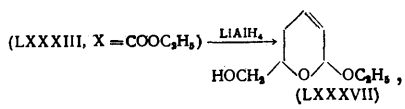


(LXXXIII) (LXXXV) (LXXXIV) (LXXXVI)

where X = H, $CCl_3COOC_2H_5$; R, R^1, R^2 = H, CH_3.

The hydrolysis of the dihydropyrans (LXXXIII) in acid medium allows either $\alpha\beta$-unsaturated δ-hydroxyaldehydes (LXXXIV) or ω-functionally substituted polyene aldehydes (LXXXV) to be obtained, depending on the reaction conditions. The compounds (LXXXIV) are in tautomeric equilibrium with their cyclic forms (LXXXVI).

6-Carboethoxy-2-ethoxy-Δ^3-dihydropyran (LXXXIII; X = $COOC_2H_5$) is readily reduced by lithium tetrahydroaluminate to give 2-ethoxy-6-hydroxymethyl-Δ^3-dihydropyran (LXXXVII) which is of interest as a starting material for the production of desoxysugars[83]:

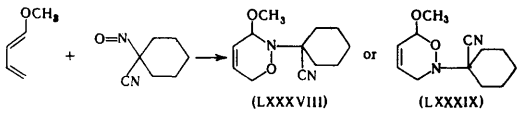


(LXXXVII)

where R^1 = R^2 = R^3 = H.

Finally, the condensation of 1-methoxybutadiene with 1-nitrosocyclohexanecarbonitrile has been described[84].

An addition product of structure (LXXXVIII) or (LXXXIX) is obtained in good yield:



(LXXXVIII) (LXXXIX)

10. Polymerisation of 1-Alkoxydienes

Due to the presence of an alkoxy-group, 1-alkoxydienes are rather strongly polarised and therefore tend mainly to ionic polymerisation. According to a patent[85] the polymerisation of 1-methoxybutadiene can be satisfactorily carried out in a reactor packed with kaolin. Clay, kaolin, hydrosilicates, etc. are used as catalysts, either pure or carried on silica gel or activated carbon. The solvents employed are petroleum ether, benzene, CCl_4, $CHCl_3$, etc. Liquid, viscous, and solid polymers were obtained in this way. Other authors[86] polymerised 1-methoxybutadiene using Ziegler catalysts: a polymer of crystalline structure was obtained, the infrared spectrum of which showed that it has a completely *trans*-structure.

Catalysis and Coordination Interaction

M.I.Siling and A.I.Gel'bshtein

The following topics are reviewed: catalyst activity and co-ordination power; influence of co-ordination on ligand reactivity; influence of ligands on the catalytic activity of metal ions; co-ordination interaction and characteristics of the transition state of the catalytic reaction. Because interactions of the co-ordination type occur frequently in catalysis, the experimental results and the theoretical concepts of co-ordination chemistry can be fruitfully applied to problems in catalysis: various approaches of this type are discussed. The important role of mixed complexes and of dative interaction in the mechanism of many catalytic reactions is stressed. 210 references.

I. INTRODUCTION

The mechanism of catalysis is determined primarily by the nature of the intermediate chemical interaction between the reagent (R) and the catalyst (C). The following are the two cases most frequently met: the R–C interaction is covalent in character, i.e. σ-electrons are directly involved; the R–C interaction is of the coordination type, i.e. with the direct participation of unshared electron pairs or of π-electrons in vacant orbitals. This subdivision is similar to the classification proposed by Roginskii[1], according to which catalytic processes can be divided into two large classes: oxidation–reduction and acid–base, i.e. with or without the fission of an electron pair (homolytic and heterolytic processes respectively).

The assignment of the R–C interaction to the covalent or the coordination type is fairly arbitrary. Often, and particularly in complicated reactions, interactions of both types occur simultaneously. Yet, each of these two types of interaction shows some characteristic features, and it is therefore convenient to discuss them separately.

The specific features of the coordination type interaction (CTI) are favourable to catalysis. Thus, a good catalyst should interact rapidly with the reagents, it should thereby influence their reactivity profoundly, and it should be easily regenerated. The electrons involved in CTI are the least firmly bound (n- or π-electrons), their energy levels lying above the level of the bonding σ-electrons. Hence, the activation energy of the complex-formation reaction is usually small, leading to fast interaction. Furthermore, coordination can have a marked effect on the reactivity of the ligand. Thus, it has been shown[2] that molecules bound to the catalyst surface by a hydrogen bond or by a stable covalent bond do not undergo alcohol dehydration and ethylene oxide polymerisation reactions. The most favourable bond energy in this case is that of molecules bound by coordination forces to a surface metal atom.

It does not follow, of course, that the R–C interaction is of the coordination type in all cases of catalysis. First of all, the participating molecules do not always have n- or π-electrons, and catalysts (e.g., metals) sometimes lack the requisite electron-acceptor properties. Furthermore, CTI does not always effectively weaken the "required" bonds in the reactant molecules (i.e., those which must be broken during the reaction). Thus, although alcohol and amine molecules can undergo CTI, the stability of the C–H bond is not appreciably affected. These compounds are usually dehydrogenated on metallic catalysts. In this case the R–C interaction which is responsible for catalysis is probably of the covalent rather than the coordination type. Thus, CTI can be the predominant type of interaction in those cases of catalysis where the electronic structure of both the reactant molecules and the catalyst is conducive to it (by weakening the bonds to be broken in the reaction or by assisting the formation of new bonds). Many heterolytic reactions belong to this type of chemical process.

Homolytic reactions also involve, on occasions, a significant amount of CTI, particularly when individual atoms or ions act as the catalytically active centre. However, the specific surface effect arising from the presence of free electrons in the solid catalyst, which is of fundamental importance in many cases of heterogeneous catalysis, is obviously not a case of CTI.

Because of the frequency with which CTI occurs in catalytic processes[3–12], there is a need to apply the experimental results and the theoretical ideas of coordination chemistry to problems in catalysis. The important advances in coordination chemistry made during the last two decades give reason to expect a deep penetration into the science of catalysis of the theories and ideas developed for complexes.

II. CATALYTIC ACTIVITY AND COMPLEX-FORMATION FUNCTION

The relationship between complex-formation and catalytic properties of a substance is determined by two basic factors: the tendency to undergo CTI with the reactants and the influence of this interaction on the reactivity of the species involved in the catalytic reaction. To illustrate this statement, we consider the simple catalytic reaction

$$R_1 + C \overset{K}{\rightleftharpoons} R_1C$$

$$R_1C + R_2 \overset{K}{\rightleftharpoons} R_1R_2 + C$$

where K is the equilibrium constant of the first step, and k is the rate constant of the second (rate-limiting) step. If $K \ll 1$ the observed rate constant is

$$k_{obs} = Kk.$$

In this equation K expresses the affinity of the catalyst for R_1, and k depends on the reactivity of this reagent in the intermediate complex. In general:

$$k_{obs} = f(K_1,\ldots,K_n,k),$$

where $K_1, \ldots, K_n$ are constants which characterise the equilibria preceding the limiting step. The expressions for k_{obs} are in keeping with the well known principle that the catalytic activity of a substance cannot in general be defined by thermodynamic quantities only. The properties of the reactants in the intermediate complexes must also be considered. We shall examine each of these factors separately in the following subsections.

1. Catalyst Activity and Coordination Power

Catalytic processes consisting of a single elementary step have a low probability. A multi-stage reaction implies some affinity between the catalyst and at least one of the reactants. Hence, and in view of the frequent occurrence of CTI in catalysis, we may conclude that the catalytic activity of a substance should be related to its ability to coordinate to the reactants. Correlations of this type have frequently been reported: one example is shown in Fig. 1.

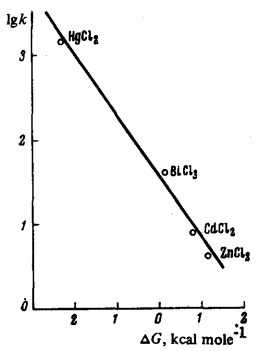

Figure 1. Catalytic activity of salts in the hydrochlorination of acetylene as a function of the stability of the catalyst–acetylene complex[46,47,167]: k is the rate constant for the reaction, ΔG is the free energy of formation of the $MCl_n.C_2H_2$ complex.

Information on the ability of the reactants to form complexes with various substances must obviously be of value in the selection of catalysts. The necessary data can be obtained, in the first place, from the accumulated fund of experimental material on the chemistry of complexes[13-19]. This approach to the problem of catalyst selection is subject to the following limitations: 1) existing data on the ability of reactants to form complexes with all the potentially useful catalysts are not sufficiently comprehensive; 2) the affinity of the catalyst for the reactant could be so low as to make an experimental study of the system excessively difficult; 3) the affinity could manifest itself only under conditions unfavourable to the study of complex formation.

The first of these limitations can be overcome to some extent by using published data on complex formation between the catalyst and some other compound, similar to the reactant in chemical structure. Strictly speaking, the molecules of the reactant and of the other compound should coordinate through the same functional group. The second and the third limitation should become less significant as more refined experimental techniques are developed. Lastly, all the limitations can be circumvented in principle by using theoretical ideas to evaluate the coordination power of a compound. Modern theories of the chemical bond in complexes (such as the valence bond theory, the crystal field and ligand field theories) allow useful though essentially qualitative predictions to be made of the possibility of coordination and of the stability of the coordinate bond. This problem has been discussed in a number of monographs and review articles[18-26,205]. Various semi-empirical relationships between the stability of the complex and characteristics of the central ion and of the ligand such as charge, ionisation potential, electronegativity, electron affinity, and polarisability can also be used[16,18,27-31].

Direct interaction between the catalyst and each of the reactants must, of course, be conducive to effective catalysis in multimolecular reactions, since it weakens the appropriate bonds of all the reacting molecules. Furthermore, the fixation of two or more reactant molecules close to an atom (or ion) of the catalyst can give rise to conditions which are sterically more favourable to interaction. In their discussion of the mechanism of enzyme action Braunshtein and coworkers[32] show that the formation of an intermediate complex (involving oriented contact of the reactants) produces a drastic increase in rate because low-probability, high-order reactions are replaced by first-order reactions. According to Bender[33], complex formation between the catalyst and both reactants can favour a bimolecular reaction by increasing the entropy of activation. Bender[33] and Eichorn[34] also point out that electrostatic repulsion should be minimised in the complex formed by a positively charged catalyst with nucleophilic reactants.

The above considerations justify the assumption that interaction between the catalyst and each of the reactants is involved in the mechanism of many catalytic reactions. In the case of CTI, mixed complexes may be formed. We shall consider a number of results which confirm the importance of mixed complexes in catalysis.

If the ability of the catalyst to coordinate to both reactants is important in many types of bimolecular catalystic reaction, compounds of metals able to form complexes with a wide variety of ligands should be the most effective catalysts. Grinberg[19] characterised the tendency of an element to form complexes in terms of the number of ligand types with which complexes are formed. In this sense, the Group VIII elements and the Cu, Zn, and Cr subgroup show the highest tendency to form complexes. These same elements, and their compounds, are found to catalyse many types of reaction.

There is experimental evidence that the mechanism of various enzyme processes involves the formation of mixed complexes between the enzyme and both reactants[35,36].

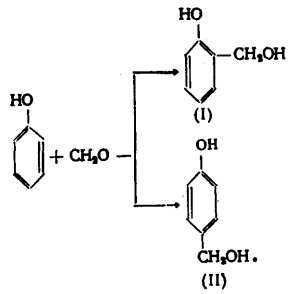
Flid and coworkers[37-43,53,54], and Gel'bshtein and coworkers[12,44-52], have studied in detail the addition of HX molecules to acetylene (where X = OH, Cl, CH_3COO). The reactions were catalysed by salts of metals of the Zn and Cu subgroups. It was found that these reactions involve, as an intermediate step, the formation and the transformation of a mixed complex (C_2H_2.catalyst.HX). The most convincing argument in favour of this mechanism is the experimentally established fact that the catalyst forms complexes both with C_2H_2 and with HX under the conditions of the reaction[12,43,45,46,51-54].

The retardation of various reactions by one of the reactants and the relationship between the coordination number of the metal atom or ion and its activity can be explained in the light of the role of mixed complexes in the mechanism of catalysis. Formation of the mixed complex is hindered when the catalyst shows too great a tendency to coordinate to one of the reactants, because all the free sites in the coordination sphere are occupied by one of the participants in the reaction. In this case the rate of the reaction can decrease as the concentration of this reactant increases. (This phenomenon, known as substrate retardation, is typical of many enzyme reactions[36].) A study of the kinetics of the vapour-phase synthesis of vinyl acetate from acetylene and acetic acid[48,51,55] has shown that the reaction is retarded by an excess of acetylene when catalysed by mercuric acetate, and by acetic acid when cadmium or zinc acetate are used as the catalyst. It has been suggested that the retardation arises from the formation of a complex between the catalytic salt and two molecules of one of the reactants, which prevents the formation of the mixed complex. This hypothesis was confirmed by adsorption measurements[12,50], according to which mercuric acetate can form a complex with two molecules of C_2H_2 under the conditions of the reaction, whereas zinc and cadmium acetates form complexes with two molecules of CH_3COOH. Order-of-magnitude agreement was obtained between the complex-formation constants of the catalytic salts with acetic acid calculated from the kinetic data by assuming the above mechanism[48,55] and the values determined from adsorption measurements[12,50].

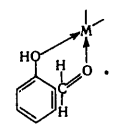
The smaller the number of free sites in the coordination sphere of a metal ion playing the part of the catalytically active centre, the lower will be its power to coordinate reactants, and in particular its power to form mixed complexes. This explains the known fact that the activity of an ion decreases, as a rule, as its coordination number increases. The effect is observed in a variety of catalytic reactions, for example in the decomposition of hydrogen peroxide catalysed by various catalase models[56], in the cracking and dehydration reactions of isopropanol on naturally occurring aluminosilicates[57], and in the solvolysis of fluorophosphates catalysed by various metal chelates[58].

The reactant molecules in the mixed complex take up well defined relative orientations: this effect can often lead to high catalytic specificity. According to Thompson and Busch[59], the coordination sphere of the metal ion can act as a matrix for the reaction, by imposing strictly defined positions on the reacting groups and thus controlling highly selective multistage reactions. The importance of the matrix function of the catalyst has been stressed by Roginskii[60].

The reaction between phenol and formaldehyde, giving saligenin (I) and *p*-hydroxybenzyl alcohol (II) as primary products, is a good illustration of the influence of mixed complex formation on the selectivity of the reaction:



When the reaction is catalysed by a proton acid (pH 1–2) the two phenolic alcohols are formed in approximately equal amounts[61,62]. On the other hand, catalysis by some metallic salts (such as zinc acetate) leads almost exclusively to the formation of saligenin[63,64]. This effect can be easily explained by postulating an intermediate mixed complex (III) whose spatial configuration favours reaction in the *ortho*-position:



(III)

The synthesis of phenolic alcohols belongs to the large group of heterolytic reactions which are accelerated both by proton acids and by aprotic (Lewis) acids. The observed differences in the catalytic action of the two types of acid can be ascribed to various causes, intimately related to the complex-formation properties of the catalyst. The proton is catalytically more active than aprotic acids in a number of reactions[9,58], but the opposite can also be true. Thus, the esters and amides of α-aminoacids are hydrolysed much more rapidly in the presence of Cu^{2+} ions than in the presence of hydrogen ions[65]. The catalytic activity of Hg^{2+}, Cd, Zn, and Bi chlorides supported on active carbon towards the hydrochlorination of acetylene in the vapour phase is much greater than that of HCl adsorbed on the carbon surface[47]. The liquid-phase hydration of acetylene proceeds quite rapidly in the presence of mercuric chloride, but it not catalysed to any extent by proton acids[37-40]. Many examples of this type could be quoted.

The very high activity of proton acids towards many reactions is evidently associated with the extremely small radius of the proton (10^{-13} cm), which is smaller than the typical radius of metal ions by 5 orders of magnitude. As a result, the proton is characterised by a high polarising effect as well as negligible steric hindrance.

The higher activity of aprotic catalysts in a number of cases is more difficult to explain. Many workers stress the greater positive charge of the metal ion[34,66], but this factor does not seem to be the essential one to the present writers. The electron-acceptor and the polarising power of a cation are determined by the parameters z/r and z/r^2, which involve the radius as well as the charge of the ion. It is obvious that the value of these parameters must be higher for the proton than for any metal ion, even

multiply charged. Furthermore, it now appears unlikely[67] that the metal ion in a catalyst structure carries a high positive charge.

Many workers[7,33,68,69] ascribe the high activity of Lewis acids (as compared with the proton) to the ability of a metal ion to coordinate to several reactants (or two groups in the molecule of a single reactant) at the same time. This view is consistent with the suggested importance of mixed complexes in catalysis.

Another possible explanation of the high catalytic activity of aprotic acids towards certain reactions should be mentioned. A large group of metal ions can exhibit electron-donating as well as electron-accepting properties in CTI, a function of which the proton is quite incapable. When activation of the reactant is mainly by dative C–R interaction we can expect metal cations liable to this type of interaction to show significantly higher catalytic activity than the proton. The acetylene addition reactions considered above are an example of this type of system.

2. Influence of Coordination on Ligand Reactivity†

In this section we shall discuss the influence of CTI between catalyst and reactant on the ability of the latter to undergo chemical change. Data on the reactivity of coordinated ligands should be relevant to this problem, whether an intermediate complex is formed during the catalytic reaction or whether CTI is confined to the transition state.

Coordination causes redistribution of the electron density in the ligand molecule, alters the interatomic distances and the bond angles, and therefore affects the polarity and the stability of the bonds. In general, therefore, coordination cannot fail to influence the reactivity of the ligand. Usually (but not invariably), the bonds nearest to the coordination bond are weakened. Coordination due to interaction between non-bonding electrons of the ligand and vacant orbitals of the metal atom shifts the electron density within the ligand molecule towards the central atom of the complex. As a result, the coordinated molecule becomes more electrophilic than the free ligand.

The situation becomes more complicated when dative interaction (leading to transfer of negative charge in the opposite sense, from the central atom towards the ligand) contributes significantly to the formation of the coordination bond. However, it does not follow that formation of a dative π-bond must weaken the influence of coordination on the reactivity of the ligand. When a double bond is formed between the metal and the ligand the disturbance caused by coordination extends over a greater number of electrons. Under these conditions the antibonding orbitals of the ligand become involved, and substantial weakening of some of the bonds within the coordinated molecule can ensue. Orgel[24] states that "the combined effect of two bond-formation mechanisms is much greater than the sum of the separate effects, because each mechanism removes the unfavourable charge accumulation due to the other".

The following are some of the most important sources of information on the reactivity of ligands in complexes: 1) data on the chemical reactions of coordinated molecules. (Unfortunately, very few data of this type are as yet available.) 2) infrared spectral data on the complexes. (The decrease in the force constant or the lowering of the stretching vibration frequency for a particular bond in the ligand molecule resulting from coordination can be taken as an approximate measure of the relative weakening of that bond.) 3) the effect of coordination on the E–H bond (where E = O, N, S, Cl, etc.) can be assessed by using relative data on the acid ionisation constant of the complex and of the free ligands. (The acid–base properties of complexes have been discussed in detail by Grinberg[19].) 4) indirect evidence on the influence of CTI on ligand reactivity can be obtained by comparing the catalytic activities of various substances in reactions involving the ligand in question.

We shall discuss the influence of coordination on the tendency of ligands to undergo chemical change by considering groups of ligands of a given type. This approach should be fruitful because it allows us to apply existing data to the problems of catalysis, and in particular to catalyst selection and the mechanism of catalysis.

Amines

Amines coordinated through the lone pair of electrons on the nitrogen atom show a weakening of the N–H bond, which manifests itself in an enhancement of the acidic properties of coordinated amines[19]. For example, the ionisation constants of complexes with imidazole derivatives are higher than those of the free ligands by 3–4 orders of magnitude[70–72]. The large drop in the N–H stretching vibration frequency observed[73–77] in the infrared spectra of the complexes (as compared with the uncoordinated amines) is consistent with these results. In complexes with different metals this frequency decreases as the stability of the complex increases. Thus, a study of the infrared spectra of aminoacid complexes with various bivalent metals[77] has shown that ν_{N-H} for the complexes is consistently lower than for the sodium salts of the aminoacids. The authors ascribe this frequency shift to an increased positive charge on the nitrogen on formation of the M–N bond, resulting in a decrease of the N–H force constant in proportion to the strength of the M–N bond, i.e. to the stability of the complex. According to Filimonov and Bystrov[76], the strength of the N–H bond in the coordinated amine is influenced not only by the lower electron density on the nitrogen atom, but also by the change in hybridisation of the nitrogen valency orbitals resulting from coordination. It has been pointed out[74,75] that hydrogen bond formation between a coordinated amine and an anion in the outer sphere of the complex can also weaken the N–H bond and shift its absorption band towards lower frequencies.

Several workers have studied the reactions of ammines. Chugaev[78] showed that HCl is eliminated from chloropentammineplatinum(IV) chloride under the influence of alkali:

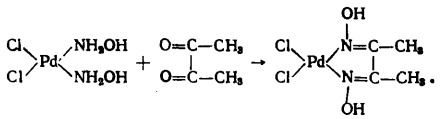
$$[Pt(NH_3)_5Cl]Cl_3 + NaOH \rightarrow [Pt(NH_3)_4NH_2Cl]Cl_2 + NaCl + H_2O.$$

Grinberg and Gil'dengershel' found[79] that ethylamine molecules in the inner sphere of a Pt^{4+} complex can be hydrolysed to ethanol and ammonia, the latter remaining coordinated to the platinum. Very drastic conditions are needed to hydrolyse free aliphatic amines, and hence we may conclude that coordination weakens not only the nitrogen–hydrogen but also the nitrogen–alkyl bond. Kukushkin[80–84] has made a detailed study of the chlorination of ammonia bound in various Pt^{4+} complexes, and found that the rate constant for coordinated ammonia can be higher or

†For a review of the early work, mainly up to 1940, the reader is referred to Ref. 3.

lower than for the ammonium ion, depending on the charge of the complex ion and on the nature of the ligands.

It has been reported[85] that coordinated hydroxylamine can be condensed with α-diketones with formation of dioximes;



Activation of the N–H bond as a result of CTI should evidently be noticeable in the catalysis of specific amine reactions by Lewis acids. Reactions of this type include the interaction of amines with ketones (catalysed by Zn and Cd salts[4]), the synthesis of mono-, di-, and trimethylamines from ammonia and methanol over alumina, the synthesis of flavanthrone by condensation of 2-aminoanthraquinone in the presence of $SbCl_3$, used in the production of dyestuffs, etc.

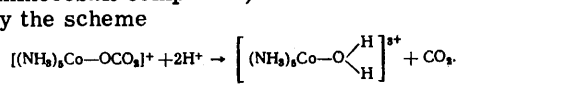
Oxygen-containing ligands. The coordination of ligands through an oxygen atom usually weakens the bonds adjacent to M–O. It is well known that complex formation increases the acidity of oxygen-containing molecules[19,86–88]: for example, the acidic ionisation constant of the aquo-ions of various metals is several orders of magnitude higher than the value for water. This is consistent with the observation[74] that the stretching vibration frequency of water is drastically decreased by coordination.

The spectra of the complexes of ligands containing carbonyl groups, such as ketones, esters, salicylaldehyde, tropolone, etc., have been studied intensively[73–75]. As a rule, coordination lowers the frequency of the C=O stretching vibration, obviously because the multiplicity of the bond is lowered by the shift of the π-electron cloud towards the oxygen atom[74]. The parallelism between this lowering of frequency and the stability of the complex has been repeatedly stressed.

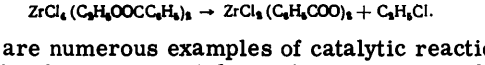
Nakamoto's analysis[75], of the infrared spectra of metal acetylacetonates leads to the conclusion that coordination of acetylacetone causes a weakening of the C–C as well as the C–O bond. It has been stated[73–75] that coordination of the carboxylate anion $(R-C\overset{O}{\underset{O}{<}})^-$ produces a lowering of the stretching vibration frequency for one of the C–O bonds, whilst at the same time increasing the frequency for the other C–O bond. Thus, the coordinated carboxyl group approximates to the structure $-C\overset{O}{\underset{O^-}{<}}$, characteristic of esters.

The weakening of the bonds adjacent to the coordination bond produced by complex formation is made evident by the reactions of oxygen-containing ligands. Meerwein and Hinz[89] had found, as long ago as in 1930, that butyl methyl ether is formed when diazomethane is passed through solutions of some salts ($ZnCl_2$, $FeCl_3$, etc.) in butanol. Free butanol does not undergo this reaction. Meerwein therefore suggested that dissolution of these salts in the alcohol involves the formation of complexes of the $\begin{matrix}R\\H\end{matrix}\!\!>\!O\ldots MX_n$ type.

Hunt and coworkers[90] showed, using ^{18}O, that the Co–O bond is not broken during acid hydrolysis of carbonatopentaamminecobalt complexes, and that the reaction occurs by the scheme



Phenyl esters complexed with $AlBr_3$ split off alkyl bromide when heated in benzene, and are subsequently hydrolysed to phenol by water[91]. Benzoate esters complexed with Hf or Fe chlorides undergo thermal decomposition with evolution of alkyl chloride[92,93]. For example,



There are numerous examples of catalytic reactions in which CTI between a metal ion of the catalyst and an oxygen atom of the reactant plays a mechanistically important role. There is little doubt that the weakening effect of this interaction on the O=C, O–C, O–H bonds and also on their neighbouring bonds is one of the key factors in many catalytic reactions. Typical of these are the decarboxylation of keto-acids, catalysed by various metal ions[94,95], the dehydration of acids and alcohols[2,96] over Al_2O_3, the Friedel–Crafts alkylation and acylation of aromatic compounds, the synthesis of phenol–formaldehyde resins of the *ortho*-Novolak type[63,64,97], the hydrochlorination of methanol on metal chlorides[98] (Cd, Zn, and Bi), and others.

Alkenes and alkynes. A considerable amount of work has been done on the coordination of olefins and acetylenes, and several review articles have been published[99–104]. Dewar[105,106] has suggested that coordination of unsaturated compounds involves the interaction of π-electrons from the ligand with vacant orbitals of the metal ion, as well as dative interaction between *d*-electrons from the metal and antibonding π-orbitals of the ligand. Experimental confirmation of Dewar's views has recently been obtained (see Ref. 104), and these views are now generally accepted. Thus, the metal ion in general shows both acceptor and donor properties in the coordination of unsaturated ligands. Because of the acceptor and donor behaviour of the central ion of the complex, the electron population of the bonding π-orbitals of the ligand decreases, and the population of the antibonding orbitals increases. Hence, the coordination of unsaturated compounds at a carbon–carbon multiple bond should cause weakening of this bond. Many workers have in fact reported a significant lowering of the stretching vibration frequency of a multiple bond as a result of complex formation: for example, in studies of the Ag^+ complexes with alkenes and alkynes[107,108], of compounds of the Zeisse's salt type[109–111], of the acetylene complexes of copper and platinum[112,113], and others (see Refs. 73–75).

In some systems, coordination also weakens the =C–H and ≡C–H bonds. The acidic properties of acetylene and vinylacetylene are enhanced by complex formation with Cu(I) salts[114,115]. Temkin[43] made an analysis of the published data on the excited states of acetylene, and concluded that dative interaction has a profound effect on the weakening of the C–H and C≡C bonds.

The activation of olefins on coordination is reflected in the reactions of many platinum complexes[103]. Thus, bromine reacts with olefin complexes to form bromosubstituted olefins. The ethylene complex is rapidly and quantitatively reduced by hydrogen at room temperature with formation of ethane. Zeises's salt is decomposed by hot water according to the equation

A similar reaction occurs also with the ethylene complexes of platinum[116,129].

CTI plays an important part in determining the mechanism of the catalytic reactions of alkenes and alkynes. We

need mention only the reactions of olefin polymerisation[117-126], oxidation of ethylene to acetaldehyde[127-134], and acetylene addition reactions[37-55]. Many workers[12,40-43,47-52,135] have stressed the importance of dative interaction in the catalysis of the reactions of unsaturated compounds.

Aromatic compounds. Coordination interaction between aromatic hydrocarbons and metal cations can arise through the π-electron system of the hydrocarbon. The possible role of the resulting π-complexes in electrophilic substitution reactions has been exhaustively discussed in the literature (see, for example, Refs. 136 and 137). A great deal of work[138,139] has been done on the ArH–HX–MX system, where X = halogen.

Recent work[140-144] has led to the hypothesis that the π-complexes of aromatic hydrocarbons with metallic or oxidic catalysts can play the role of intermediates in catalytic reactions. Thus, Völter[143] suggests that the hydrogenation of alkylbenzenes on Ni–MgO catalysts involves the formation of π-complexes between the hydrocarbon and the catalyst, which are then hydrogenated by adsorbed hydrogen atoms.

Existing data are not sufficient to justify a definite conclusion on the role of CTI in determining the reactivity of aromatic hydrocarbons. We may assume that the effect does occur, and results in a slight decrease in reactivity towards electrophilic reagents. Data on the chemical reactivity of complexes of the ferrocene and dibenzene-chromium type are of little help, because we still lack general rules as to the behaviour of these compounds[145-147]. Thus, ferrocene is more reactive than benzene towards electrophilic substitution, a behaviour diametrically opposite to that of the dicyclopentadienyl complexes of other metals.

Jones and coworkers[148-153] studied the effect of coordination on the reactivity of aromatic ligands containing nitrogen or oxygen atoms. The reaction rate was significantly affected by complex formation in only a few cases. Thus, a study of the rate of nitrogen coupling of 8-quinolinol-5-sulphonic acid and of its Zn^{2+} complex showed[151] that the free phenate ion reacts 10^4 times faster that the same ion coordinated to the zinc ion, but the latter is significantly more reactive than the undissociated ligand. Inner complexes of 8-quinolinol with Fe^{3+}, Cr^{3+}, and Co^{3+} are brominated 35 times faster than the free ligand[153]. On the other hand, it is stated[148] that the activity of aniline and pyridine towards electrophilic reagents is the same whether the bases are free or coordinated to Cr^{3+}. Jones' general conclusion is that coordination of simple aromatic ligands has a relatively minor effect on their reactivity towards electrophilic agents. Two papers[154,155] are quoted in support of this conclusion. In the former, the π–π^* transition in the electronic spectrum of pyridine is shown to be relatively insensitive to coordination. In the latter, the π-electron density on the atoms of the porphin ring was calculated and shown to be little influenced by complex formation with Fe(II)

Jones also concluded[152] that the direction of electrophilic substitution reactions of aromatic compounds is not affected, as a rule, by coordination. The present writers consider, however, that coordination can influence the isomeric composition of the products of electrophilic substitution when both species involved in the reaction can undergo CTI with the catalyst. The reaction between phenol and formaldehyde discussed above (p. 484 of Russian; p. 11 of translation) is an example of this type of behaviour.

Hydrogen halides. Coordination increases the polarity of the bond in the hydrogen halide (HX) molecule. The cations of many metals, and in particular those of the platinum group and of the copper and zinc subgroups, can coordinate to HX with formation of $H_n[MX_m]$ acidocomplexes, in which the hydrogen is located in the outer sphere of the complex as a proton[15-17,19,156,157]. Complexes of this type are formed not only in solution, but also in molten salts[158,159], and on surfaces[12,46].

Ahrland[160] suggested the formation of a dative π-bond between M and X, by the interaction between the d-electrons of the metal and the free d-orbitals of the halogen, in order to explain many experimental observations on the stability of halogeno-complexes[16,18]. This hypothesis is consistent with the report[157] that the cations of certain metals (alkali, alkaline-earth, tervalent rare-earth, and some others) which have no mobile d-electrons cannot readily form negatively charged complexes with the chloride anion. On the other hand, cations prone to dative interaction (e.g. Pt, Pd, Hg, Ag) form complexes of this type over the whole of the HCl concentration range.

The polarising and weakening effect of CTI on HX molecules is relevant to the catalysis of many reactions involving hydrogen halides. We may mention, as an example, the hydrochlorination reactions of acetylene[47,49,51] and methanol[98], catalysed by Hg^{2+}, Cd, Zn, and Bi chlorides.

Carbon monoxide. The drastic change in reactivity resulting from the coordination of carbon monoxide was first observed by Hieber and coworkers[161,162] in the early 1930's. The ease of oxidation in particular, of CO is very much increased by coordination. The following are typical reactions:

$$PtCl_2CO + H_2O \rightarrow Pt + CO_2 + HCl$$
$$Fe(CO)_5 + 2NH_3 + H_2O \rightarrow H_2NCOONH_4 + H_2.$$

According to currently-held views, CO takes place in CTI not only as a donor but also as an acceptor of electrons[24,163,164]. Dative interaction, made possible by the free antibonding π-orbitals of the ligand, contributes very significantly to the stability of the resulting carbonyl complexes. This is confirmed by the fact that carbon monoxide forms complexes with many transition metals but not with the usual acceptors of unshared pairs such as BF_3.

Coordination of carbon monoxide decreases the stability of the C–O bond. Thus the C–O stretching vibration frequency is significantly lowered on going from free carbon monoxide to carbonyl complexes[75,164]. The dative component contributes significantly to the loosening effect of CTI on the C–O bond. Markov and Fasman[165] studied the mechanism of the catalytic activation of CO in solutions, and concluded that dative interaction between the metal and carbon monoxide is one of the necessary conditions for activation.

The influence of CTI on the reactivity of carbon monoxide is shown by the many catalytic reactions involving metal carbonyls (e.g., oxo-synthesis reactions).

Nitrogen. The activation of molecular nitrogen due to CTI is discussed at length in a recent review article by Vol'pin and Shur[166].

Oxygen. The possibility of CTI between metal ions or atoms and the O_2 molecule has been considered by many authors[9,11,68,163]. According to Jones[11], activation of molecular oxygen by coordination should be widespread in inorganic and in biological systems. He suggests that

the cations which are most active in this respect are characterised by a tendency to form π-bonds and to transfer an electron to the oxygen. These properties are found in Fe^{2+}, Mn^{2+}, Co^{2+}, and Cu^{+}.

A coordinate bond involving a dative component can be realised in the ions FeO_2^{2+} and CuO_2^{+}, which play an important role as oxygen carriers in the activity of some enzymes[168]. Orgel[24] mentions oxyhemoglobin, oxymyoglobin, and other biologically important compounds of iron, copper, and cobalt as examples of oxygen-containing complexes. Griffith[169] considers the bond between O_2 and iron in the hemoglobin complex to be similar to the Pt–ethylene bond in the Zeise salt (see Refs. 74 and 104).

It can be assumed that an oxygen molecule is held by a coordinate bond in the molecule $[IrCl(CO)O_2(PPh_3)_2]$, where $Ph = C_6H_5$. The structure of this product, prepared by Vaska[170] by treating the complex $[IrCl(CO)(PPh_3)_2]$ with molecular oxygen, has been investigated[171]. The oxygen atoms were found to lie at the same distance from the iridium atom, the length of the O–O bond (1.30 Å) being close to the distance between oxygen atoms in the O_2^- ion (1.28 Å).

Hydrogen. The activation of molecular hydrogen by metal ions has been discussed in a number of papers[172-176]. Interaction between an H_2 molecule and a metal ion or atom may involve attraction of the electrons from the hydrogen towards the free orbitals of the metal, and dative interaction between the *d*-electrons of the metal and the antibonding orbital of the hydrogen[163,177]. Strictly speaking, only the latter should be termed CTI, since the σ-electrons of the H_2 molecules are involved in the former.

Bykhovskii and Temkin[177] consider dative interaction to be an essential part of the mechanism of molecular hydrogen activation in homogeneous catalysis. Arguing against Halpern's suggestion[172] that the activation of H_2 is determined primarily by the electron-acceptor properties of the metal, these workers point out that the bond order in the H_2 molecule and the H_3^+ and H_3^- ions is consistent with a considerable loosening of the H–H bond, resulting from the transfer of an electron to the antibonding orbital of the hydrogen molecule. Gupta's[178] quantum-mechanical calculation for the H_2^- ion lends support to this view.

Hydrido-complexes, such as $[IrH_2Cl(CO)(Ph_3P)_2]$ [179] and $\{PtHCl[P(C_2H_5)_3]_2\}$,[180] have recently been prepared. The nature of the metal–hydrogen bond in these compounds is evidently the same as in covalent metal hydrides[179]. According to Halpern[174], the mechanism of the catalytic activation of hydrogen often involves the formation of intermediate hydride complexes in which the hydrogen can be treated as an anionic ligand.

III. INFLUENCE OF LIGANDS ON THE CATALYTIC ACTIVITY OF METAL IONS

The catalytic properties of a metal ion are often substantially influenced by the nature of the ligands. Halpern[173] has obtained data which characterise the relative influence of various complexing agents on the activity of the Cu^{2+} ion in homogeneous hydrogenation reactions (see Table).

It is reported[181] that the reactivity of platinum complexes towards the CO oxidation reaction decreases along the following series of ligands:

$$I > Br > CNS > Cl > NO_2 > OH > NH_3 > CN.$$

Replacement of the chloride by the citrate anion in the coordination sphere of the Ru^{3+} complex causes a significant increase in the catalytic activity of the complex towards the oxidation of ethylene and acetaldehyde[182].

Terent'ev and Mogilyanskii found[183-185] that aromatic amines in a pyridine solution in the presence of Cu_2Cl_2 are oxidised by atmospheric oxygen to diazo compounds. The catalyst in this case is a pyridine complex of the copper salt. On replacing the pyridine by 2-methylpyridine the reaction proceeds much more slowly, and if quinoline, dioxan, or alcohol are used as solvents no oxidation is observed.

Influence of complexing agents on the catalytic activity of the Cu^{2+} ion.

Agent	Relative catalytic activity	Agent	Relative catalytic activity
Perchlorate	1	Sulphate	6.5
Butyrate	150	Chloride	2.5
Propionate	150	Glycine	0.5
Acetate		Ethylenediamine	0.1

The nature of the ligands has a particularly strong influence in the case of enzymes and their models. The catalase activity of lead ions complexed with various Schiff's bases is almost 300 times higher than the activity of the simple lead ion[186]. The activity increases by several orders on going from the hydrated iron ion to an albumin–porphyrin complex of iron[187]. Many examples of this type are quoted by Langenbeck[188] and Nikolaev[189,190].

Often the nature of the ligand affects the direction of the reaction as well as the activity of the metal-containing catalyst. The emulsion polymerisation of butadiene in the presence of K_2PdCl_6 gives mainly a 1,2-polybutadiene structure, whereas the 1,4- polymer is the main yield when PdI_2 is used as catalyst[191]. Depending on the coordination sphere of the nickel complexes used as catalysts the polymerisation of acetylene can yield benzene or cyclooctatetrene[192].

To explain the influence of ligands on the catalytic properties of complexes, several factors must be considered. The tendency of catalysts to form complexes with ligands, and the influence of CTI on their reactivity, are determined first and foremost by the acceptor and donor properties of the metal ion. Hence, these properties must also to a large extent determine the catalytic activity of the complex. The nature of the metal–ligand bond has a profound effect on the donor–acceptor properties of the central atom. As the ionicity of this bond increases, the acceptor tendency of the metal ion increases and the donor tendency decreases. Formation of dative bonds increases the positive charge on the central atom and thus enhances its acceptor properties.

In mixed complexes, the ability of some of the ligands to undergo dative interaction results in a loosening of the dative bonds between the metal and the other ligands. In this case, the ligands are competing for the *d*-electrons of the metal. If dative interaction is needed to activate the reagents, a good catalyst will not include ligands capable of forming dative bonds.

These considerations can be used to analyse the effect of the carrier on the activity of the catalyst when CTI between the metal ion (or atom) and the carrier can be assumed. We have used this approach[12,49,51,52] in our work on vapour-phase addition reactions to acetylene to explain the fact that salts are more active when deposited on carbon than on other carriers. We were able to conclude that carbon, as a ligand, can enter into donor–acceptor interaction with a metal ion, playing the part of an electron donor. As a result, the donor properties of the cation and its tendency to undergo dative interaction are enhanced: this is a very significant factor in determining the activation of acetylene.

The crystal field theory can be used to discuss the role of the carrier. Erofeev and coworkers[193] have suggested an interaction between the atoms or ions of the deposited metal and the crystal lattice of the carrier, resulting in penetration of the metal ions into the surface layer of the carrier. On this assumption, they were able to explain why γ-Al_2O_3 is the best carrier for nickel hydrogenation and dehydrogenation catalysts and for chromium oxide dehydrocyclisation catalysts. The structure of γ-alumina is such that the Cr^{3+} and Ni^{2+} ions find themselves in an octahedral field, which offers a higher stabilisation energy than fields of different symmetry.

Unusual oxidation states for particular metals can often be stabilised by complex formation. Thus, complexes of Cu^{3+}, Ag^{2+} and Ag^{3+}, Ni^{+}, Cr^{5+}, Pt^{3+}, Pt^{5+}, Pt^{6+}, Pt^{8+}, have been shown[194-196] to exist with certain ligands. In these complexes, the donor–acceptor properties of the metal atom can differ very substantially from those of the same atom in its usual valency states. Several instances of catalytic activity have been reported for metals in unusual oxidation states. Rich and Taube[197] showed that a number of isotope exchange reactions are catalysed by Pt^{2+} and Au^{2+} compounds. It has been pointed out[198] that Cr^{5+} ions are the active centres of chromium oxide polymerisation catalysts.

Once it is established that a particular oxidation state of a metal shows maximum catalytic activity, the factors which contribute to the stabilisation of this state can be evaluated. Ligands tending to form dative π-bonds stabilise the lower oxidation states[24]. The effect of the nature of the ligands on the stability of the states of a metal ion with a different number of d-electrons can easily be evaluated in the crystal field theory approximation. For example, the Cr^{5+} state, in which the ion has one d-electron, is stabilised by the ligand field. Cr^{6+}, on the other hand, has no d-electrons, and the stabilisation energy for this state is zero. Hence, the stability of the Cr^{5+} state increases with the strength of the ligand field.

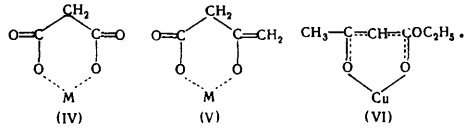
In all probability, the ligands themselves often participate directly in the catalytic process. Taube[199-201] believes electron transfer through a ligand bridge to be a possibility in oxidation–reduction reactions, and Stranks[195] considers this to be the most likely mechanism for the Cr^{2+}–Cr^{3+} system. Matveev and coworkers[133] believe that the oxidation of the Pd^0 complex by the Cu^{2+} ion during the catalytic oxidation of ethylene to acetaldehyde occurs through a bridging complex, and that electron transfer from ion to ion is accompanied by the transfer of a ligand. They point out that the oxidation is fastest when the ligand being transferred has an unshared electron pair.

Coordinated ligands can form hydrogen bonds with other molecules[74]. This effect can be important in controlling the orientation of reacting molecules, particularly in enzyme catalysis[32].

IV. COORDINATION INTERACTION AND CHARACTERISTICS OF THE TRANSITION STATE OF CATALYTIC REACTIONS

Several attempts have been made to use complexes as models of the transition state. Hammond[202] formulated the following postulate: if the transition state and the intermediate complex are formed consecutively during the reaction and have similar energies, their molecular structures can be expected to be similar. Since complex formation is an exothermic process, the postulate implies that the transition state and the intermediate complex can have similar structures only when the activation energy of the reaction is low.

The parallelism between the reaction rate and the stability of complexes is often interpreted as evidence for a similarity in structure between the complex and the transition state. Prue and Hoppe[95,203] suggested that the catalytic activity of metal cations towards the decarboxylation of acetonedicarboxylic acid and the hydrolysis of dicarboxylic acid and aminoacid esters depends on the mode of chelation of the activated complex in these reactions. They based this conclusion on the good correlation between the activity of various metal cations and the stability constant of the complexes of these metals with malonic acid. The structure of these complexes and the proposed configuration of the transition state for the decarboxylation of acetonedicarboxylic acid is shown by formulae (IV) and (V):



(IV) (V) (VI)

According to Bell[204], the transition state during the bromination of ethyl acetoacetate in the presence of copper ions is stabilised by a metal cation in a form similar to that of the chelate complex (VI).

The crystal field theory has made possible a new approach to the characterisation of the transition state. Several papers[7,18,23,24,205,206] have dealt with the activation energy of ligand replacement reactions in complexes. The transition state was treated as a complex in which the number of ligands per reacting unit is smaller (S_N1 mechanism) or greater (S_N2 mechanism) than in the starting complex. By assuming a specific steric configuration for the activated complex it is possible to estimate the change in the crystal field stabilisation energy attending the change from the starting complex to the activated complex. The result is one of the terms which make up the activation energy. tion energy.

The same approach can be applied to catalytic reactions. Dowden and Wells[207] applied the crystal field theory in their analysis of the catalytic activity of various metals, oxides, and sulphides. Unsaturated valencies on the surface of the catalyst were treated as empty sites in the coordination sphere of a complex having one of the surface cations as its central ion. A change in the coordination of the surface complex takes place during formation of the transition state of the limiting step, which includes adsorption. For example, a square pyramid changes to an octahedron, and a tetrahedron changes to a square pyramid. Under these conditions, the stabilisation energy due to the crystal field of the transition state will differ for the various catalysts according to the number of d-electrons in the metal. In this way, the authors were able to explain why the minimum activity in H_2–D_2 exchange reactions and in some

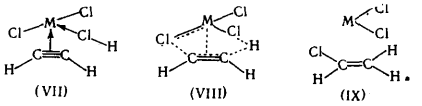
oxidation–reduction reactions is found with catalysts containing cations with d^0, d^5, and d^{10} electronic configurations, for which the stabilisation energy is zero. At the same time, the d^3 and d^7 systems (in which the stabilisation energy attending the formation of the activated complex is greatest) showed the maximum catalytic activity.

Krylov[208] points out that the opposite relationship should be observed when formation of the transition state involves a decrease rather than an increase in the coordination number. In this case the stabilisation energy due to the crystal field will decrease, as a rule, on formation of the transition state, and the highest catalytic activity will be found in d^0, d^5, and d^{10} systems. Catalysts of this type have been shown to be the most active in the polymerisation of ethylene oxide on metal oxides and hydroxides, in the dehydration of formic acid, etc.

Glasstone, Laidler, and Eyring[209] state that the transition state of many reactions can be expected to be similar to the final state. Hence, and in view of the important role of mixed complexes in catalysis discussed above, we may conclude that the transition state of many bimolecular reactions of the type

$$A + B \xrightarrow{K} \text{reaction products}$$

has a configuration intermediate between the final state and the mixed complex AKB. For example, the hydrochlorination of acetylene on MCl_2 salts[47] has been described by the following formulae for the mixed complex (VII), the proposed activated complex (VIII), and the final state (IX):



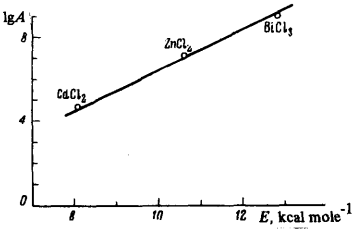


Figure 2. Compensation effect in the catalytic hydrochlorination of acetylene.

Structures (VII) and (VIII) can serve as an illustration of the present writers' suggestion[12,51] that the interaction between the catalyst and the reagent in the transition state can be similar to the interaction between the metal and the ligand in the corresponding complex. This hypothesis allows us to characterise the transition state in terms of data on the influence of CTI on the ligands, and to establish a relationship between the parameters of the metal ion which are important in coordination and the characteristics of the transition state of a reaction catalysed by the same ion. For the reaction

$$MCl_n \cdot C_2H_2 + HCl \rightarrow CH_2{=}CHCl + MCl_n \cdot$$

we had previously determined[47] the pre-exponential factor (A) and the activation energy (E). We found that both A and E increase along the series of catalytic salts $HgCl_2$–$CdCl_2$–$ZnCl_2$–$BiCl_3$, in which the acceptor properties of the cation increase and the donor properties decrease[12,49,51]. The relationship between lg A and E is accurately linear for the chlorides of Cd, Zn, and Bi (Fig. 2). Similar results were obtained for the catalytic synthesis of vinyl acetate from acetylene and acetic acid[48], and for the hydrochlorination of methanol[98]. Thus, at least some reactions show a definite relationship between the Arrhenius parameters and the donor–acceptor properties of the catalyst. This dependence may sometimes give rise to a compensation effect, since an increase in acceptor properties along a series of similar catalysts is usually accompanied by a decrease in donor properties. The decrease in activation energy accompanying an increase in the donor tendency of a catalyst can be explained by the drastic loosening effect of dative interaction on the reactant molecule[12,41–43,49,51,177,210].

The Chemistry and Physicochemical Features of the Microbiological Oxidation of Petroleum Hydrocarbons

V.I.Karban, R.V.Kucher, and N.I.Mironenko

The review examines Soviet and foreign literature on the microbiological synthesis of proteins from petroleum hydrocarbons. The general characteristics of the process and the conditions for its occurrence are described together with the chemical mechanism of the microbiological oxidation of aliphatic, aromatic, and heterocyclic hydrocarbons. Particular attention has been devoted to the physicochemical and topochemical features of the process. It has been shown that the process is similar from the physicochemical standpoint to the oxidation of hydrocarbons in emulsions. The bibliography includes 241 references.

CONTENTS

I. Introduction 261
II. General characteristics of the microbiological synthesis of proteins from hydrocarbons 261
III. The chemical mechanism of the microbiological oxidation of hydrocarbons 263
IV. Physicochemical and topochemical features of the process 265

I. INTRODUCTION

The enzymic synthesis of proteins and vitamins in the yeast cell has been attracting recently an increasing amount of attention from workers in many fields. A new branch of industry, dealing with the microbiological manufacture of amino-acids, vitamins, and other valuable products, has arisen and has been developing vigorously. Certain micro-organisms are known to be capable of utilising pure hydrocarbons[1-5], alcohols, and acids[6-9], and also petroleum and petroleum products[10-16] as sources of carbon and energy. The possibility of the oxidation of petroleum hydrocarbons by micro-organisms was pointed out as early as the 1920's–1930's by the leading Soviet microbiologist Tauson[17]. Certain species of micro-organisms develop very successfully in stagnant waters in petroleum-processing factories[18], in subsurface waters in petroleum deposits, in soils impregnated with petroleum[19], and also under bituminous road surfaces[20,21]. These micro-organisms are mainly aerobic and they metabolise saturated hydrocarbons, mainly with straight-chain structures[22,23]. Since the microbes are living organisms, they have a fairly rich protein store. Thus petroleum can become a source of proteins, which are an essential and the most deficient component in the food of man and animals.

According to McFerson's data[24], to make good this deficit, which is acute as far as the bulk of the world population is concerned, it will be necessary to produce in 1980 an additional amount of about 18 million tons of fats, 9.9 million tons of animal protein, and 11.4 million tons of amino-acids per year. The most convenient and cheapest of the principal raw materials for the synthesis of food products is petroleum and atmospheric nitrogen fixed in the form of ammonia.

The microbiological synthesis of food products is very convenient because of the high rate of multiplication of micro-organisms, their high biochemical activity, the possibility of using relatively cheap starting materials, and also the independence of the manufacture of climatic and weather conditions. Thanks to the progress in the technology of the growing of micro-organisms, favourable conditions have been created for the control of their development under industrial conditions.

At the present time there exists a fairly extensive Soviet and foreign scientific literature on the development of micro-organisms on separate fractions of petroleum and on pure hydrocarbons[25-32]. In particular, one should mention the work of French investigators led by Champagnat[33-37]. By growing micro-organisms (mainly yeasts) on various petroleum fractions, they obtained proteins and valuable water-soluble vitamins. The product was called the protein-vitamin concentrate (PVC). At the same time the removal of paraffins improved the quality of the petroleum, since the solidification temperatures of the fuels and oils obtained from it are thereby reduced[38]. The work of Senez and coworkers[39-42] is of great interest in this respect. Recently extensive studies are being carried out in the USSR on the isolation and selection of micro-organisms assimilating petroleum hydrocarbons, experimental industrial apparatus for the manufacture of PVC has been set up, and tests are being made on the nutritional value and the possible harmful effects of the product[43-54].

The microbiological synthesis of proteins and vitamins from petroleum is based on the enzymic oxidation of hydrocarbons and their derivatives. Little is known at present about the conditions of the occurrence, mechanism, and products of microbiological oxidation, which differs appreciably from the chemical oxidation of these hydrocarbons, and the available information is not systematic and requires revision. Chemists, in close collaboration with microbiologists, biochemists, and workers in other fields, should play the main part in the creation of a theory of the enzymic oxidation of hydrocarbons.

II. GENERAL CHARACTERISTICS OF THE MICROBIOLOGICAL SYNTHESIS OF PROTEINS FROM HYDROCARBONS

The principal raw material for the manufacture of the protein–vitamin concentrate are liquid saturated petroleum hydrocarbons with a straight-chain structure obtained in the process of elimination of paraffins from Diesel fuels with subsequent purification by adsorption. Saturated hydrocarbons obtained in the low-temperature elimination of paraffins and purified with sulphuric acid are also suitable. As a result of such purification, the saturated hydrocarbons contain not more than 0.5% of aromatic

hydrocarbons. Certain species of micro-organisms can be grown on individual fractions of Diesel fuels without preliminary isolation of straight-chain saturated hydrocarbons from the latter. Then the paraffin-free part of the fuel must be separated from the crude protein mass.

In petroleum from different deposits the content of alkanes with different carbon chain lengths varies within wide limits. Different micro-organisms assimulate mainly saturated hydrocarbons with 10–24 (C_{10}–C_{24}) [1-5] and also 1–4 (C_1–C_4) [25-32,49] carbon atoms. Thus in most cases yeasts assimilate hydrocarbons ranging from n-nonane to n-octadecane (C_9–C_{18}) and also unsaturated hydrocarbons with the same carbon chain length[50].

Experiments show that micro-organisms exhibit definite selectivity in their capacity to assimilate a particular substrate[51-65]. Isoalkanes are utilised by micro-organism less satisfactorily than straight-chain alkanes[66]. Aromatic compounds are not very suitable as sources of carbon for micro-organisms of the genus Candida[56,67,68]. An even narrower substrate specificity has also been observed. Micro-organisms can grow on one hydrocarbon but not on another with a similar structure[69].

At the present time search is going on for highly active micro-organism cultures (mainly yeasts) ensuring rapid accumulation of biological material. Most investigators have devoted particular attention to yeasts of the genus Candida, since these are the most active[3,29,70].

Yeasts are rich in B vitamins, the content of which depends on the yeast culture, the nutritional medium, and the method of cultivation (Table 2), [47,48,89,90]. Yeasts grown on petroleum hydrocarbons contain vitamins combined with other growth factors of unknown composition.

Table 2. Content (mg) of water-soluble vitamins and their importance[30].

	Thiamine B_1	Riboflavine B_2	Nicotinic acid PP	Pantothenic acid	Pyridoxine B_6
Daily requirement in man	2	3	15	3	2
Content of vitamins in various products:					
Meat (beef)	1—3	2	40—100	7—21	1—4
Liver	5—10	16	75—275	30—60	5
Milk	0.3—0.7	1—3	1—5	1—4	1—3
Grain	0.5—7.0	1—1.5	10—30	5—20	3—6
Dry yeast	2—20	30—60	200—500	30—200	40—50
Protein-vitamin concentrate	3—16	75	130—200	150—192	23
Functions	carbohydrate metabolism	dehydrogenation, oxidation	carbon transport	acetylation. synthesis of aliphatic acids	transamination
Consequences of vitamin deficiency	nervous disorder, beri-beri	arrest of development	pellagra	arrest of development	dermatitis

Table 1. Content of certain amino-acids in yeast, meat, and wheat grain[30].

Amino-acid	Daily requirement in man, g	Amino-acid content, g/100g		
		in yeast	in animal tissues	in wheat grain
Arginine	3.5	4.3	7.1	3.0
Histidine	2.0	2.8	2.2	1.2
Lysine	5.2	6.4	8.1	2.7
Tyrosine	3.9	4.2	3.1	—
Tryptophan	1.1	1.4	1.2	1.0
Phenylalanine	4.4	4.1	4.5	9.3
Cystine + Methionine	3.8	1.3 traces	1.1 + 3.3	with tyrosine 4.3
Leucine	9.1	13.2	12.1	13.0
Isoleucine	3.3	3.4	3.4	4.0
Valine	3.8	4.4	3.4	3.5
Threonine	3.5	5.0	5.2	3.3

The nutritional value of yeast was first pointed out by Dellbrook in 1875; this hypothesis was developed in later studies by other workers[71-78]. The nutritional value of protein is determined in the first place by the relative amounts of its constituent amino-acids[79]. The amino-acid composition of yeast protein depends on the yeast species, the nutritional medium, and the method of cultivating the yeast[80,81]. However, different yeast species do not show sharp differences in their amino-acid content[82] and this is the reason for the high biological value of yeast protein[83,84] (Table 1).

Yeast proteins are assimilated by [animal] organisms to the extent of 85–88%; in this respect they occupy an intermediate position between proteins of plant (65–75%) and animal (90–95%) origin[85-87]. Because of their high lysine and valine content, yeasts are a useful additive to cereal proteins and improves their nutritional value[88].

Like any other living organism, yeasts can exist only in the presence of water. Their nutrient must contain carbon, nitrogen, phosphorus, potassium, magnesium, and many micro-elements. Petroleum hydrocarbons are the exclusive source of carbon and energy. Nitrogen, phosphorus, potassium, and magnesium form part of the nutrient medium in the form of a solution of mineral salts in water. Thus microbiological oxidation takes place in an emulsion of the hydrocarbon in the aqueous phase. The elements essential for the growth and development of yeast include in the first place iron, zinc, and manganese[91,92]. Iron enters into the composition of many enzymes and is necessary for the growth of yeasts and the accumulation of biological material[93,94]. Zinc also enters into the composition of carboxyoxidase, cytochrome, cytochrome oxidase, and certain other enzymes[95]. Manganese influences the catalytic activity of many oxidative enzymes. One may assume that other elements, required in smaller doses, such as copper, molybdenum, cobalt, iodine, boron, and others, are present in sufficient amount in tap water and in the mineral salts usually employed in the cultivation of yeasts.

The principal parameter of process development is temperature. For each micro-organism there exists an optimum temperature at which the time required for cell division is a minimum. All these temperatures lie in the range 25–40°C [42,96,97] and therefore the microbiological oxidation of petroleum hydrocarbons is energetically more favourable than chemical oxidation, which occurs at an adequate rate only at elevated temperatures.

An important factor in the cultivation of micro-organisms on hydrocarbon substrates under aerobic conditions is the supply of oxygen. Oxygen is required not only to synthesise the biological material itself, but also to oxidise the hydrocarbon and to satisfy the energy requirements of the metabolism of yeast cells. The overall

requirement of oxygen in the growing of yeasts on hydrocarbons is higher by a factor of 2–4 than on carbohydrate substrates, since in the latter case oxygen is required only to make good the energy expended on the growth and is not fixed by the cell[30]. The oxygen needed by the micro-organisms must be dissolved in the aqueous medium. The limiting cell growth is determined by the diffusion of atmospheric oxygen into the medium.

At the present time the efforts of scientists and engineers are directed towards the development of a theory and the improvement of apparatus for continuous microbiological oxidation of petroleum hydrocarbons[98-102]. The microbiological oxidation of petroleum hydrocarbons may be carried out in two ways: by growing micro-organisms to be used as such in the form of protein-vitamin concentrates or by extracting from the aqeuous medium the valuable products synthesised by the micro-organisms. The industrial methods for the microbiological synthesis of amino-acids and vitamins used in many countries are based on these properties of micro-organisms[103-110]. The micro-organism species which, after metabolising the carbon-containing substances secrete into the reaction medium predominantly one or other amino-acid, are of particular interest. Glutamic acid and lysine are at present manufactured in this way on an industrial scale from carbohydrates and plant raw material. Scientists in the laboratories of Japan, the USA, the Soviet Union, and other countries are working intensively on the development of methods for the biological synthesis of other amino-acids[111-120].

III. THE CHEMICAL MECHANISM OF THE MICROBIOLOGICAL OXIDATION OF HYDROCARBONS

Numerous experiments have shown that the mechanism of the oxidation of hydrocarbons by micro-organisms differs from that of chemical oxidation. It has been firmly established that in the liquid-phase oxidation of hydrocarbons the primary oxidation product is a hydroperoxide, subsequently responsible for the degenerate branching of the complex chain oxidation process. The main radical propagating the reaction chains is the peroxy-radical $ROO^{\cdot}$.

The chemical oxidation of hydrocarbons has been investigated in detail by Emanuel' and coworkers[121,122], who elucidated a number of its kinetic features and proposed the following oxidation mechanism:

$$RH + O_2 \rightarrow R^{\cdot} + HO_2$$
$$R^{\cdot} + O_2 \rightarrow RO_2^{\cdot}$$
$$RO_2^{\cdot} + RH \rightarrow ROOH + R^{\cdot}$$
$$ROOH \rightarrow RO^{\cdot} + O^{\cdot}H$$
$$2RO_2^{\cdot} \searrow$$
$$R^{\cdot} + RO_2^{\cdot} \rightarrow \text{chain termination.}$$
$$2R^{\cdot} \nearrow$$

The mechanism of the microbiological oxidation of hydrocarbons differs from that given above and has been much less studied.

The assimilation of hydrocarbons by micro-organisms depends on the following conditions: the penetration of the hydrocarbons into the cell, the capacity of micro-organisms to become adapted to the hydrocarbons, and finally the presence of enzymes necessary for the primary oxidation of the hydrocarbons[123,124]. The penetration of hydrocarbons into the cells of the micro-organisms, which largely determines the topochemistry of the reaction, is to a considerable extent associated with the physicochemical features of the process, which will be examined below.

The adaptation phenomenon, which probably takes place at the level of enzymic systems, is now attracting the attention of many investigators[125-135]. Micro-organisms assimilating hydrocarbons must be adapted to the nutrient medium, which under natural conditions undergoes considerable changes. Some micro-organisms, die, having failed to adapt to the new conditions. Others gradually become adapted, and begin to assimilate the new substrates[136].

The intrinsic oxidation process takes place with the aid of enzymes which lower the activation energy by 16–18 kcal $mole^{-1}$, while non-biological catalysts result in a lowering of activation energy by only 4–8 kcal $mole^{-1}$.[137] Both the prosthetic group and certain groups of the protein carrier forming part of the active centre of the enzyme take a direct part in catalysis[138]. It has been shown[139,140] that the configuration of molecules in certain enzymes changes appreciably in the course of interaction with the substrates. Evidently the catalytic groups are then arranged in the order necessary for enzyme action on the substrate[141-143].

In the formation of the enzyme–substrate complex bonds are polarised and this is the cause of the "strained configuration" of the complex. In a complex of this kind the bonds are stretched and weakened[140]. The binding of the substrate by the enzyme induces a change in the conformation of the protein base of the enzyme, and, conversely, under the influence of the enzyme the substrate molecules are distroted and activated. The coordinated action of two of several groups of the active enzyme centre involving the polarisation of definite bonds in the substrate constitutes the basis of the catalytic action of the enzyme[144,145]. The kinetics of enzyme action are described by the Michaelis equation or more complex equations, depending on the number of components in the active centres[146,147].

The data on the role and mechanism of the action of enzymes in the microbiological oxidation of hydrocarbons are inadequate. Only recently interesting studies on the participation of enzymes in these processes have begun to be published[129,132,133,135,148].

The primary step in microbiological oxidation is attack by oxygen on the hydrocarbon molecule. Unfortunately, so far there is no unanimous view in the literature concerning the site of the attack. Many investigators believe that the most likely pathway in the microbiological oxidation of straight-chain paraffins involves the oxidation of one of the terminal methyl groups to a carboxy-group via the intermediate formation of an alcohol and an aldehyde[149-154].

Using the tracer atom method, Stewart and coworkers[155] showed that molecular oxygen is incorporated in the hydrocarbon molecule, the primary oxidation product being a hydroperoxide:

$$R{-}CH_3 \xrightarrow{+{}^{18}O_2} R{-}CH_2{}^{18}O{}^{18}O \rightarrow R{-}CH_2{}^{18}O\,H \rightarrow R{-}C^{18}O\,OH.$$

The presence of a hydroperoxide in the metabolic products is indicated also by other workers[40,156,157]. The possibility of the formation of a hydroperoxide as an oxidation intermediate is confirmed by the fact that synthetic alkyl 1-hydroperoxides are oxidised by micrococci grown on hydrocarbon substrates[136].

The process mechanism described above is not as yet reliably established. Apart from the oxidation of the terminal atom in the straight-chain hydrocarbon, it is believed that the carbon atom in the α-position may be oxidised[158]. Then the formation of aliphatic acids takes place via secondary alcohols and alkyl methyl ketones:

$$R{-}CH_2{-}CH_3 \rightarrow R{-}CHOH{-}CH_3 \rightarrow R{-}CO{-}CH_3.$$

Foster explains the oxidation of the carbon atom in the α-position on the hypothesis that the free radicals within

the chain of the straight-chain hydrocarbon are in equilibrium[165]. Primary activation consists in the formation of a free n-alkyl radical at the terminal carbon atom. However, the hydrogen atom can migrate within the molecule and activate the adjacent carbon atom, i.e. the primary radical isomerises to a radical with the corresponding iso-structure. The initial stable products formed by this mechanism are ketones. These compounds are detected only in certain cultures, grown on saturated hydrocarbons[158-161], but the relative ease with which methyl ketones are assimilated by micro-organisms oxidising hydrocarbons suggests that these substances may behave as intermediates in the oxidation of straight-chain alkanes, particularly those with a short chain[158-162].

In the cultivation of various bacteria (*Pseudomonas aeruginosa*, *Achromobacter* sp., *Nocardia* sp., *Mycobacterium* sp.) on purified hydrocarbons with an even and odd number of carbon atoms (C_6 and C_7), Treccani et al. noted the formation of saturated aliphatic acids with unbranched chains[163-165]. Lower alkanes with an even and odd number of carbon atoms yield various oxidation products[69]. When n-hexane is used as a substrate, caproic, butyric, and acetic acids are formed, while with n-heptane the products are all the [straight-chain] aliphatic acids containing between 1 and 7 carbon atoms in the molecule. This investigation requires additional experimental confirmation. The assimilation of alkanes with an even number of carbon atoms is hindered by the presence in the reaction mass of acids with an odd number of carbon atoms. If, on the other hand, the cells assimilate a hydrocarbon with an odd number of carbon atoms the presence of any aliphatic acids in the reaction medium does not interfere with the reaction[165].

It has been established that *Pseudomonas methanica* converts gaseous hydrocarbons into oxidation products with the same number of carbon atoms as the initial hydrocarbons[166-169]. When ethane, propane, and n-butane were added, the products detected were respectively acetic acid and acetaldehyde, propionic acid and acetone, and butyric acid and 2-butanone. In the microbiological oxidation of methane the extracellular products formed are methanol, formaldehyde, formic acid, carbon dioxide, hydrogen, and polysaccharides[170].

In the oxidation of n-hexadecane the final product is cetyl palmitate[165-171]. The cetyl alcohol which esterifies palmitic acid is formed from n-hexadecyl hydroperoxide, which is probably the first intermediate in the oxidation of n-hexadecane. Micro-organisms grown on hexadecane readily oxidised this hydroperoxide. An ester is also formed when micro-organisms are grown on octa- and tetra-decane[172]. The alcoholic component of the ester has the same hydrocarbon skeleton as the alkane in the substrate. On this basis, one may say that the alcoholic component of the ester obtained from the hydrocarbon is formed directly from the alkane by the oxidation of the terminal carbon atom.

On the other hand, according to Treccani[69], the acid component of esters in all cases of bacterial oxidation of alkanes probably contains 16 carbon atoms regardless of the chain length of the straight-chain hydrocarbon used as the substrate.

Gololobov believes[136] that palmitic acid is not always the acid component of the esters. This is also the view of Kallio and Finnerty[173,174], who isolated two esters from the medium in which micrococci were grown with octadecane: octadecyl palmitate $CH_3(CH)_{14}COOCH_2(CH_2)_{16}CH_3$ and octadecyl stearate $CH_3(CH_2)_{16}COOCH_2(CH_2)_{16}CH_3$.

The acid component of octadecyl stearate is formed as a result of the oxidation of the terminal carbon atom in octadecane:

$$CH_3-(CH_2)_{15}-CH_2-CH_3 \rightarrow CH_3-(CH_2)_{15}-CH_2-CH_2OH \rightarrow CH_3-(CH_2)_{15}-CH_2-COOH.$$

In octadecyl palmitate the acid component contains 2 carbon atoms less than the hydrocarbon. The formation of palmitic acid may be explained by assuming the oxidation of the α-carbon atom in octadecane with formation of a secondary alcohol and then an alkyl methyl ketone, the latter being subsequently split by the following mechanism:

$$CH_3-(CH_2)_{15}-\overset{\alpha}{C}H_2-CH_3 \longrightarrow CH_3-(CH_2)_{15}-\underset{OH}{\overset{\alpha}{C}H}-CH_3 \longrightarrow$$

$$\rightarrow CH_3-(CH_2)_{14}-\overset{H}{\underset{2O}{CH}}-\overset{\alpha}{\underset{O}{C}}-CH_3 \longrightarrow CH_3-(CH_2)_{14}-COOH + CH_3COOH.$$

As stated above, in the microbiological oxidation of hydrocarbons direct binding of oxygen is observed[175,176]. Many investigators suggest that primary enzyme action on the hydrocarbon molecules is possible with direct participation of oxygen. This hypothesis has been proved[169] by the incorporation of oxygen-18 into cetyl palmitate.

The possibility of the microbiological decomposition of hydrocarbons under anaerobic conditions appears to be less likely[177,178], but recent communications describe the development of specific hydrocarbon-oxidising bacteria of the genus *Pseudomonas* on a mineral medium with petroleum under anaerobic conditions[179].

Thus the conversion of aliphatic hydrocarbons consist in the formation during the initial reaction period of saturated aliphatic acids with unbranched chains. Different workers have obtained not entirely consistent results concerning the further breakdown of the aliphatic acids. In the view of the majority[156,159], acids with an even number of carbon atoms break down by a mechanism involving β-oxidation to acetic acid. When the number of carbon atoms is odd, the acids can also undergo α-oxidation and be converted into acids with an even number of carbon atoms, which subsequently undergo only β-oxidation to propionic and acetic acids. Thus, according to Stadman[23], *Methanobacterium suboxydans* converts valeric acid by β-oxidation into propionic and acetic acids, while butyric and caproic acids are converted into acetic acid.

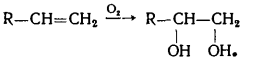
Certain bacterial species are capable of oxidising straight-chain alkane molecules from both ends, forming both mono- and di-carboxylic acids[180]. ω-Oxidation to dicarboxylic acids is evidently a secondary pathway and constitutes the first stages of the subsequent β-oxidation.

The oxidation of metabolic intermediates may be artificially retarded by adding to the reaction medium inhibitors such as sodium azide, sodium cyanide, $\alpha\alpha'$-dipyridyl, heavy metal ions, and others[23,181]. Possibly the use of inhibitors will prove useful in the investigation of the mechanism of the formation and accumulation of valuable products and also for the determination of the role of the enzymes involved in the process.

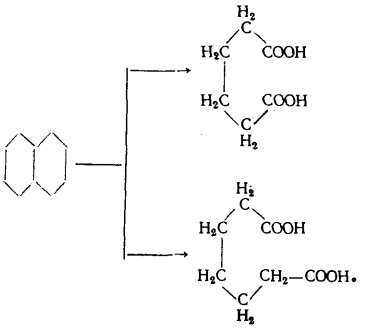
The mechanism of the bacterial oxidation of unsaturated compounds has been little investigated. It is known that micro-organisms are capable of assimilating olefins as sources of carbon and energy. According to Shturm's paper[182], unsaturated hydrocarbons are assimilated by micro-organisms more readily than the corresponding alkanes. Both saturated and double bonds in olefins are attacked. Thus van der Linden and coworkers established that in the decomposition of oct-1-ene by cells of *Pseudomonas aeruginosa* the principal changes take place at the

saturated end of the molecular chain of the olefin, while the double bond is not affected[183].

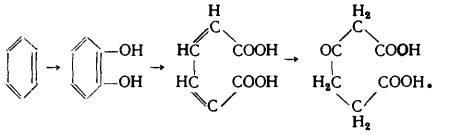
The finding that the oxidation of hexadec-1-ene by the yeast *Candida lipolytica* results in the accumulation of hexadecane-1,2-diol as an intermediate[184] is interesting. This indicates the possibility of the simultaneous oxidation in the olefin at the two carbon atoms linked by a double bond[185]:



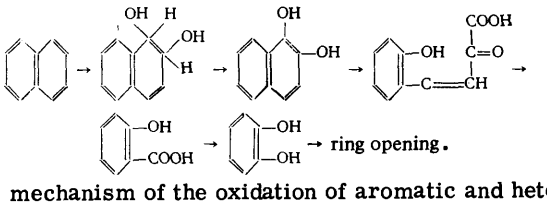
Little is known about the mechanism of the microbiological oxidation of cyclic saturated compounds such as cyclohexane, decalin, perhydrophenanthrene, and perhydroanthracene[186,187]. The formation of a peroxide formaldehyde, and valeric and formic acids when *Pseudomonas fluorescens* is grown on cyclohexane has been demonstrated. When *Flavobacterium* is grown on decalin, adipic acid is an intermediate[189]:



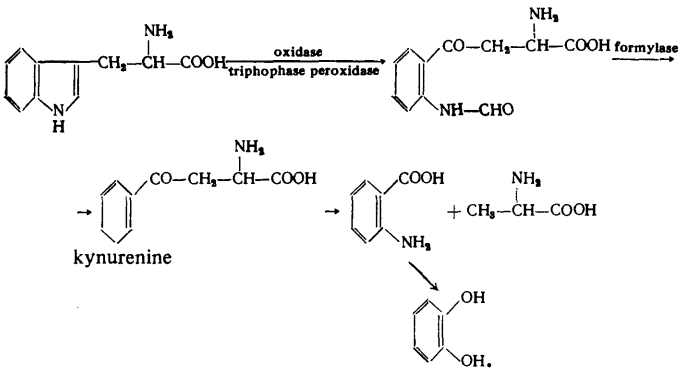
Micro-organisms assimilate aromatic compounds by converting them into *o*- or *p*-dihydroxy phenolic derivatives and then splitting the ring to aliphatic acids[190,191]. In the oxidation of benzene[192,193] catechol is formed as an intermediate; phenol and *cis,cis*-muconic acid also accumulate[194]. Benzene oxidase, which converts benzene into 3-oxoadipic acid, has been isolated from cells grown on benzene[195,196]. The enzymic extract does not contain phenol oxidase and only whole cells grown on phenol (but not adapted to benzene) immediately bind oxygen in the presence of phenol. The oxidation of benzene can be represented by the following mechanism:



Walker and Wiltshire showed in their investigation of the pathways for the decomposition of naphthalene during the growth of five different microorganisms that in all cases the intermediates are naphthalenediol, salicyclic acid, and catechol. The same mechanism has been confirmed by the work of Azoulay and coworkers[198,199]:



The mechanism of the oxidation of aromatic and heterocyclic hydrocarbons has been described in detail in Treccani's review[69]. For example, the decomposition of tryptophan takes place by the following mechanism:



Indole reacts similarly. The microbiological oxidation of indolylacetic and nicotinic acids, nicotine, aromatic nitrocompounds, and compounds of the lignin group have also been studied.

IV. PHYSICOCHEMICAL AND TOPOCHEMICAL FEATURES OF THE PROCESS

Brief examination of the chemistry of the oxidation of petroleum hydrocarbons convincingly demonstrates that only the first steps have been taken in its investigation. The available data are far from adequate.

At present no papers have been published on the physical chemistry of microbiological oxidation and the kinetics of its individual stages. However, in view of the current importance of this process and its application in industry such information is very necessary, since without the knowledge of the physical chemistry and kinetics of the process it is difficult to consider the possibility of its rational control.

It is stated in papers published recently that during the growth of yeast cells free radicals are observed[200,201]. This is confirmed by the presence of ESR signals in the yeast *Saccharomyces cervisiae* and also in the oxidation of NADH by the cells of *Mycobacterium phlei*. In the latter case it is suggested that the ESR signals may be due to radicals similar in structure to semiquinone. The possible participation of free radicals in microbiological oxidation may be established by studying the chemiluminescence arising when free radicals act upon yeast cells[202]. The considerable role of free radicals in enzymic oxidation processes has been confirmed by the work of Emanuel' and coworkers on enzymic oxidation involving succinate dehydrogenase and other enzymes[203-206]. Free radical reactions in enzymic oxidation may be inhibited by inhibitors of chain oxidation processes, such as phenolic compounds and others. All these findings show that one cannot exclude the possibility that individual stages in the microbiological oxidation of petroleum hydrocarbons take place with participation of free radicals.

The microbiological oxidation of petroleum hydrocarbons takes place in a complex system consisting of several phases. The hydrocarbon in a dispersed state and the cells of the micro-organisms are present in the aqueous medium. As a result of the growth of the micro-organisms, surface-active substances responsible for the additional emulsification of the hydrocarbon are produced[36,37]. All this suggests that the system is extremely

complicated. Factors associated with the vital activity of micro-organisms and also with the colloidal-chemical nature of the system are superimposed on the purely chemical processes. From this point of view, it is desirable to examine the mechanism of the penetration of the hydrocarbon into the cells present in the aqueous phases, since the process is impossible without the two component parts of the system coming into contact. There exist various theories explaining the mechanism of the entry of nutrient materials into the cell. Thus Johnson suggests[66] that the penetration of the hydrocarbon into the cell takes place with participation of the lipids in the cell membrane the long alkane chain becoming part of the phospholipid micelle of the cell membrane. This explanation is very general and it leaves many facts obscure. It has been suggested that the initial oxidation of the alkane takes place outside the cell[207]. Then it would be necessary for certain enzymes to be secreted by the cell into the medium[208], but many workers disagree with this postulate[136]. An interesting amount of evidence shows that the enzyme must be incorporated in definite structural formations within the cell in an unchanged form in order to exhibit its activity[209-217].

The intracellular activity of enzymes may be increased by surface-active emulsifying agents, as happens when such agents act upon the yeast *Candida albicans*[218]. In this case the catalase activity of *Candida albicans* increases by virtue of the increase in the permeability of the cell wall under the action of ionic surface-active substances. The interaction of surface-active emulsifying agents with *Saccharomyces ellipsoideus* leads to the formation of complexes with the lipids, lipoproteins, or proteins of the cell surface, whereby metabolic processes are distorted[219].

The complexity of the reaction system suggests that, in order to formulate the general laws governing the process, it is necessary to examine its topochemistry. Since virtually no such investigations of microbiological oxidation have been made, we believe it interesting to consider briefly the oxidation in emulsion of petroleum hydrocarbon, which resembles microbiological oxidation from the physicochemical standpoint. Probably later it will be possible to draw a number of analogies between the two reactions. The kinetics of the oxidation of hydrocarbons in emulsions have been thoroughly studied by Kucner and coworkers, who put forward a hypothesis concerning the topochemistry of the process[220-222].

In the first place they showed that surface-active emulsifying agents constitute an important kinetic factor; they alter the rate of the process (usually increase it) as a result of the stabilisation of the hydrocarbon droplets and also the droplets of the reaction products in the aqueous medium.

When hydrocarbons are oxidised in emulsions, it is quite possible that individual stages of the process take place in the aqueous phase[222]. By postulating the existence of micelles of the emulsifying agents, the nucleus of which consists of the organic part of the molecule and is oleophilic, one may assume that water-insoluble substances will dissolve fairly readily in the nucleus of the micelle. As a result, the loose micellar structure, which is constantly in contact with water, contains a high local concentration of the reactants which are subject to the polarising action of water. Here it is quite reasonable to assume an enhanced reactivity of the solubilised substances.

In this case the hydrocarbon phase is a source of the reactants which undergo solubilisation. Furthermore, the reaction products formed in the aqueous phase diffuse into the hydrocarbon phase. It is quite reasonable that all these processes should be coupled with the diffusion of the reactants from one phase to the other. A somewhat simplified topochemical mechanism of the reaction is presented in Fig. 1.

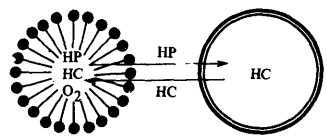


Figure 1. Topochemical mechanism of the oxidation of hydrocarbons in emulsions in the presence of an emulsifying agent. [HP (hydroperoxide) and HC (hydrocarbon) are the tentative interpretation of the Russian abbreviations GP and UVC (Ed. of Translation).]

However, this mechanism is not universal. It postulates the presence of surface-active emulsifying agents in the system and completely disregards the oxidation of hydrocarbons in emulsions not stabilised by such agents.

A number of experiments[223] convincingly demonstrate that the pressure of oxidising oxygen plays a significant role in the oxidation of hydrocarbons in emulsions. Thus in the oxidation of isopropylbenzene in a stainless steel autoclave an increase of pressure up to 10 atm leads to an increase of the reaction rate, which, however, scarcely changes any more when the pressure is raised above 15 atm. All these findings suggest that the oxidation of hydrocarbons in emulsions at atmospheric pressure is diffusion-dependent and is not determined by the kinetics. Then the rate of the process is limited by the solubility of oxygen in the emulsion and particularly in the aqueous phase. It has also been established[224] that the solubility of oxygen in the aqueous phase increases appreciably in the presence of dissolved surface-active emulsifying agents. Fig. 2 shows that the solubility and particularly the rate of dissolution of oxygen are higher in solutions of emulsifying agents than in pure water.

Finally, it has been established by a number of kinetic experiments on the oxidation of hydrocarbons in emulsions that the individual stages of the reaction (in this case it is the initiation reaction, taking place in the decomposition of a hydroperoxide) occur at the interface[225]. In particular, this applies to reactions in which surface-active agents (for example hydroperoxides), which are adsorbed on the surface of hydrocarbon droplets, take part. Here different media act upon different parts of the reactant molecule. The organic (hydrophobic) part of the molecule is drawn into the hydrocarbon medium, while the hydrophilic part is solvated by water molecules.

Thus the difference between the chemical potentials of the substance, different parts of the molecule of which are in different phases, gives rise to an additional polarising effect, which leads to an enhanced reactivity of the reactant. This is particularly evident in the decomposition of the hydroperoxide, the rate of which increases appreciably in the presence of the aqueous phase (Fig. 3).

Turning back now to the consideration of the microbiological oxidation of hydrocarbons, we may note the similarity of a number of its features with the oxidation of hydrocarbons in emulsions. In the first place the individual stages of the reaction take place in different phases or at the interface. The cell membrane consists of diphilic protein molecules, the structure of which resembles the diphilic structure of the molecules of surface-active emulsifying agents[226]. In this case the incorporation of the hydrocarbon between the organic chains of the hydrophobic "tails" of the protein molecules, similar to that occurring in the solubilisation of oleophilic substances in the so called "lamellar" micelles, is quite likely[227].

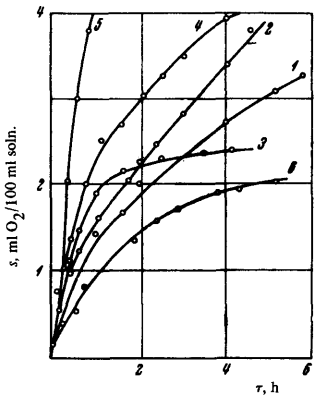

Figure 2. Kinetics of the dissolution of oxygen: 1) in 5% solution of Nekal; 2) in 5% solution of Leukanol; 3) in 0.1 *N* solution of potassium palmitate in 0.1 *N* solution of sodium carbonate; 4) ditto with solubilised isopropylbenzene; 5) in isopropylbenzene at 80°C; 6) in 0.1 *N* solution of sodium carbonate at 25°C.

Probably exceptionally favourable conditions are achieved at the interface, and in the first place on the surface of the cell, for the formation of the enzyme–substrate complex, since in this case a very high local concentration of these species is set up. The rate and kinetics of microbiological oxidation should also be influenced by the degree of dispersion of the reactants. This applies both to the degree of dispersion of the hydrocarbons droplets and the bubbles of the oxidising gas. These questions require systematic investigation. In their solution it is necessary to carry out experiments showing to what extent the rate of the process changes during the mechanical stirring of the reaction mixture. The study of the effect of the mechanical stirring of the oxidising emulsion of the hydrocarbon should make it easier to elucidate the role of diffusion factors in the kinetics of the microbiological oxidation of hydrocarbons, since an increase in the stirring rate produces an increased rate of diffusion of the individual components.

It is quite likely that, when the reaction is carried out at atmospheric pressure, the topochemical mechanism quoted above (Fig. 1) may be used for its explanation to some extent. In this connection it is also interesting to elucidate the effect of the solubilisation of the individual components in the aqueous phase on the process kinetics. We believe that such studies should be performed under conditions of a continually decreasing amount of the hydrocarbon phase until the complete disappearance of the hydrocarbon–aqueous solution interface.

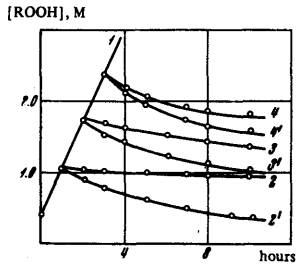

Figure 3. Kinetic curves for the oxidation of isopropylbenzene in emulsion (curve *1*) and for the breakdown of the hydroperoxide in the separated hydrocarbon phase (curves *2*–*4*) and in the emulsion (curves *2′*–*4′*) at 110°C.

Finally, the last process requiring solution at the present time is the effect of the increasing pressure of the oxidising gas containing oxygen. At an elevated pressure the solubility of oxygen increases. Thus, when the concentration of oxygen in the aqueous phase is raised, the rate of its diffusion into the hydrocarbon droplets or cells saturated by the hydrocarbon also rises. Then the process may be accelerated, as is observed in the oxidation of hydrocarbons in emulsions, but in microbiological oxidation account must be taken of the effect of pressure on the metabolism of the micro-organisms[228]. It is known from the literature that high pressures (up to 200 atm) are destructive to yeast organisms[70]. At a pressure in excess of atmospheric, oxygen may suppress and limit the growth of micro-organisms capable of developing in various nutrient media. Further studies should be directed towards the search for cultures stable under conditions of increased oxygen pressure.

From the kinetic standpoint, microbiological synthesis of proteins (more correctly its individual stages) takes place in an open system, since there is material exchange between the reaction site and the external medium[229]. A change in the amount of substance in an open system results not only from chemical processes but also from material exchange with the surrounding medium, which must be taken into account in the determination of the reaction rate.

---o0o---

The aim of the present review was to examine the present state of our knowledge of the mechanism of the microbiological oxidation of petroleum hydrocarbons. The importance of this problem is evident. The interest which it has aroused has led to what is actually a new branch of natural science, at the boundary between chemistry and microbiology, which deals with the problems of the preparation of various substances with the aid of micro-organisms. Although microbiological synthesis itself has been known and used industrially for a long time, insufficient

attention has been devoted so far to the processing by this procedure of petroleum hydrocarbons, despite its importance. This applies to the physicochemical features of the process, since its microbiological and biochemical aspects have been vigorously investigated. To avoid overloading the review, many important purely biochemical and microbiological problems, which have been dealt with in other reviews, are omitted.

Much attention was devoted to the biosynthesis of proteins and vitamins at the Eighth and Ninth International Microbiological Congresses held in recent years (Moscow, 1962 and 1966), the Conference on Applied Microbiology, (Stockholm, 1963), the Symposium on Petroleum Microbiology (Czechoslovakia, 1964), and other scientific meetings[230-233]. At the present time most of the work in the field of microbiological synthesis concerns the accumulation of experimental data on the selection of the raw material and the micro-organism cultures, the study and isolation of the oxidation products, the development of methods for the control and investigation of the process, and also the relevant apparatus. Process conditions are selected and the nutritional value of the oxidation product is studied. Some advances have been made in the establishment of the mechanism of the enzymic oxidation of hydrocarbons and the role of trace elements in this process, and the mechanism of the interaction of the living cell with the hydrocarbon is being studied.

However, we believe that the time has come for a more detailed investigation of the chemical (particularly physicochemical) aspect of the microbiological oxidation of hydrocarbons. As in all developing branches of science, there are a number of factors here concerning which there exist only reasonable guesses or the data are contradictory. There has been hardly any work on the physicochemical aspect of the process, although such studies are of primary importance for the improvement of the technology. The chemists studying this process should employ the available literature data on similar processes (liquid-phase oxidation of hydrocarbons, reactions in emulsions, etc.).

The main difficulty in the investigation of the enzymic oxidation of hydrocarbons is in the first place the complexity of the reaction system, which requires the combined efforts of investigators in many fields, including many branches of chemistry. The weak development of our knowledge concerning the purely chemical aspect of enzymic processes, particularly as regards the microbiological oxidation of hydrocarbons, also hinders studies in this field. The development of such investigations promises to create a new technology of the preparation of food products and animal feed and also the synthesis of valuable organic substances (amino-acids, vitamins, etc). There is reason to believe that the development of the theory, the elucidation of the general laws governing the microbiological oxidation of hydrocarbons, and in particular the chemical mechanism of the process, will advance significantly in the next few years. It is quite clear that the extension and deepening of knowledge concerning the mechanism of the enzymic oxidation of petroleum hydrocarbons will lead to a real improvement of the existing technological processes for the synthesis of proteins from petroleum and also the organisation of new processes involving the selective conversion of petroleum hydrocarbons into important products and intermediates in industrial organic synthesis.

During the preparation of this review for the press, new papers on the enzymic oxidation of solid straight chain alkanes by different groups of micro-organisms were published[234,235]. The unsatisfactory growth of certain hydrocarbon-oxidising micro-organisms on solid alkanes can be explained in many cases by the instability of the dispersions of these hydrocarbons. Even in the presence of emulsifying agents, comminuted solid alkanes form large particles in an aqueous medium, which hinders the growth of micro-organisms. Miller and Johnson[234] suggest that solid alkanes be dissolved in liquid hydrocarbons which are not themselves assimilated by a given micro-organisms (or are assimilated to only a slight extent) and can serve as solvents. These workers grew *Candida intermedia* and *Candida lipolytica* on eicosane (C_{20}) and hexadecane (C_{16}) dissolved in pristane (2,6,10,14-tetramethylpentadecane) and noted a high yield of cells. However, the number of alkanes which can be investigated under these conditions is limited by their solubility in pristane.

Recently papers have also been published on the action of surface-active substances on micro-organisms and the study of the relation between the structure and functions of surface-active substances[236,237]. These investigations show that surface-active materials react with the cell wall, altering its permeability and giving rise to a loss of metabolically important components of protoplasm (various amino-acids and nucleic acid derivatives) as a result of the breakdown of osmotic equilibrium. Surface-active substances also influence the localisation of enzymes within the organism and the interaction between the enzymes. Depending on the pH of the medium, there is either an increase in the activity of enzymes in the presence of surface-active materials or their catalytic effect is suppressed.

As before, much attention is devoted to problems of the microbiological conversion of aromatic hydrocarbons[238,239] and also the growth of micro-organisms on gaseous hydrocarbons[240,241].

Homogeneous Hydrogenation

M.E.Vol'pin and I.S.Kolomnikov

The present review examines catalytic systems which activate molecular hydrogen. Particular attention is paid to catalysis by compounds of transition metals. These systems are discussed in the following order: catalysis by salts of transition metals; catalysis by salts of transition metals in the presence of reducing agents (complex-forming reagents); and catalysis by individual complexes. General problems relating to the activation of hydrogen and the mechanism of the hydrogenation of organic compounds are also discussed. A separate section is devoted to the activation of molecular hydrogen by enzymatic systems. The bibliography contains 282 references.

III.	Hydrogenation	275
IV.	General systematic features and mechanism of the activation of hydrogen and homogeneous hydrogenation	280
V.	Enzymatic catalysis of hydrogenation and the isotopic exchange and conversion of hydrogen	284

I. INTRODUCTION

Increasing attention is now being paid to homogeneous reactions involving complexes of transition metals: hydrogenation, hydroformylation, the polymerisation and oxidation of alkenes, the fixation of nitrogen, etc. A number of factors, for example the mode of activation of the substrate, the nature of the active species, etc., are common to these processes. Many hydroformylation catalysts are also effective hydrogenation catalysts; various Ziegler–Natta polymerisation catalysts are also active catalysts for hydrogenation and the fixation of nitrogen, etc. The investigation of the systematic features of these processes is therefore of general importance.

The problem of homogeneous hydrogenation is also of practical interest. For example, the use of molecular hydrogen in the polymerisation of alkenes by means of Ziegler–Natta catalysts makes it possible to control the molecular weight of the polymers formed[1], and homogeneous hydrogenation catalysts are used in fuel cells[2].

Research workers have long recognised the advantages of homogeneous over heterogeneous catalytic hydrogenation; the most important advantages are the ease of regeneration of the catalyst and the milder conditions of the process, combined with high efficiency, selectivity, and stereospecificity, and convenience for kinetic studies. In the last ten years the number of known homogeneous hydrogenation catalysts has increased considerably, and this has made possible a deeper and more complete study of a number of problems relating to the mechanism of hydrogenation.

In general, homogeneous hydrogenation with the participation of molecular hydrogen involves two inter-related stages: 1) the activation of molecular hydrogen; and 2) the actual hydrogenation, including activation of the substrate and the transfer of activated hydrogen to the substrate.

In the activation stage, molecular hydrogen reacts with the active compound with rupture of the H–H bond and the eventual formation of a hydrido complex, which may undergo further reactions (isotopic exchange, hydrogenation, etc.). Proof of the intermediate formation of these hydrides is an important task in the study of the mechanism of hydrogenation.

The activation of hydrogen has been the subject of an extensive review by Halpern[3], various papers[4–10], and individual chapters in other reviews[11–13]. The amount of work in this field has increased considerably since then, and the number of known homogeneous hydrogenation catalysts has increased significantly.

The present review covers data published up to 1967 and part of the data published in 1968; particular attention has been paid to the latest developments in the study of the mechanism of the activation of molecular hydrogen and homogeneous hydrogenation. Catalytic systems are classified as follows: a) systems without transition metal compounds; b) systems with transition metal derivatives; and c) biological systems.

It seemed convenient to consider isotopic exchange and the ortho-para conversion of hydrogen separately from hydrogenation.

II. ISOTOPIC EXCHANGE AND CONVERSION OF HYDROGEN

The isotopic exchange of molecular hydrogen and the conversion of ortho-hydrogen into para-hydrogen, which unavoidably involve rupture of the H–H bond, can be used successfully to study the activation of hydrogen. A significant advantage of these reactions compared with hydrogenation is their convenience for kinetic studies and their relative simplicity, since there is no need for the activation of a substrate, and the chemical changes in the system are minimal. Comparison of the results of studies of the exchange and conversion of hydrogen with data on hydrogenation for the same catalytic system provides an extremely fruitful method for investigating the mechanism of the activation of hydrogen and hydrogenation.

1. ACID–BASE SYSTEMS

Available data indicate the possibility of heterolysis of the H–H bond, primarily under the influence of various bases.

As early as 1936, Witz and Bonhoeffer[14] established that a 1 *N* aqueous solution of alkali at 100°C catalyses the exchange of molecular hydrogen with D_2O. The catalysis of the exchange and conversion of hydrogen by bases in aqueous solutions was subsequently studied by various groups of workers[15–19].

The kinetic studies of Wilmarth and coworkers[16] and Shindewolf[19] showed that the rate-determining stage of the reaction is the activation of H_2O by one hydroxide ion. In alcoholic solutions, the RO^- anion may act as hydrogen activator[19,20].

The activation energy for rupture of the H–H bond depends to a marked extent on the basic nature of the catalyst. Thus for the KNH_2–NH_3 catalytic system[19,21–25] this energy is 15 kcal mole^{-1} lower, and for the sodium acetate–acetic acid system 10 kcal mole^{-1} higher, than that for the reaction in aqueous alkali solutions[19]. The lowest activation energy for rupture of the H–H bond was observed when C_2H_5NHK–$C_2H_5NH_2$, that is the least basic catalytic system, was used[20]. Dilute and concentrated acids[16,17], and the BF_3–HF system[6], do not catalyse the exchange and conversion of hydrogen.

2. SYSTEMS CONTAINING SALTS OF TRANSITION METALS

The homogeneous isotopic exchange and ortho-para conversion of hydrogen in the presence of salts of transition metals was first observed by Calvin[26]. To explain these results he assumed a scheme involving the intermediate formation of the transition metal hydride:

$$n\,Cu^{I} + H_2 \rightleftarrows Cu^{I}_n \cdot H_2$$
$$Cu^{I}_n \cdot H_2 + 2\,Cu^{II} \rightleftarrows (n+2)\,Cu^{I} + 2\,H^+$$

It was found that in the presence of Cu^{II} acetate, neither conversion nor isotopic exchange of hydrogen takes place, and the molecular hydrogen is used up only in the reduction of the bivalent copper acetate; it is only when this reaction is complete that the Cu^{I} acetate formed begins to catalyse the exchange and conversion of H_2. It has also been reported[27], however, that the competing reactions of reduction and the isotopic exchange (or conversion) of hydrogen take place simultaneously under these conditions.

The rate of the ortho-para conversion is greater than the rate of the isotopic exchange of hydrogen. This is due to the fact that the conversion of hydrogen generally involves the recombination of two hydrogen atoms on a single metallic centre, whereas the exchange of hydrogen also requires interaction between the metal–hydrogen bond and the solvent. The isotopic exchange and ortho-para conversion of hydrogen are catalysed not only by copper salts but also by salts of silver, ruthenium, cobalt, etc. Both heterolytic and homolytic rupture of the H–H bond may take place. Thus homolytic rupture of the bond in the hydrogen molecule apparently takes place when the $CoCl_2$–KCN catalytic system is used[19,28,29], and also in the presence of copper acetate in quinoline[30]. On the other hand, detailed study of the kinetics of the exchange and conversion of hydrogen in the presence of $RuCl_3$–HCl–H_2O [19,31,32] showed that the hydrogen in this system undergoes heterolytic splitting according to the scheme:

$$Ru^{III}Cl^- + D_2 \rightarrow Ru^{III}D^- + D^+ + Cl^-$$
$$Ru^{III}D^- \xrightarrow{HCl} Ru^{III}Cl^- + HD$$
$$Ru^{III}D^- \xrightarrow{H_2O} Ru^{III}H^- + HOD$$
$$Ru^{III}H^- \xrightarrow{HCl} Ru^{III}Cl^- + H_2$$

where $Ru^{III}Cl^-$ represents the active chloro-complex of ruthenium.

According to this scheme, the exchange and conversion of hydrogen are accompanied by the intermediate formation of hydride (and deuteride) complexes of ruthenium. Of particular interest in this connection are the recently prepared iridium complexes $IrHD(CO)(PPh_3)_3$, which contain H and D attached simultaneously to the same metal atom, and which are active in hydrogenation[33]. It may be assumed that the study of the properties of these mixed hydrides will make it possible not only to reach a deeper understanding of the individual stages in the exchange, but also to reach definite conclusions regarding the structures of the intermediate hydride complexes.

III. HYDROGENATION

1. SYSTEMS WITHOUT COMPOUNDS OF TRANSITION METALS

a. Hydrogenation Under Conditions of Acid-base Catalysis

Systems of basic character, capable of catalysing the isotopic exchange and ortho-para conversion of hydrogen, can be regarded as potential hydrogenation catalysts. Basic systems of this kind were first used for hydrogenation by Walling and Bolliki[34,35], who showed that in the presence of potassium t-butoxide in butanol, benzene, or diglyme under fairly severe conditions (170–200°C, H_2 pressure 90–140 atm), benzophenone is hydrogenated with the formation of benzhydrol. The authors cited consider that in this instance the hydrogen undergoes heterolytic splitting with the formation of a hydride ion, which takes part in the first stage of the hydrogenation:

$$RO^- + H_2 \rightleftarrows ROH + H^-$$
$$H^- + R_2C{=}O \rightleftarrows R_2CH{-}O^-$$
$$R_2CH{-}O^- + ROH \rightleftarrows R_2CHOH + RO^- .$$

Aniline could be obtained from nitrobenzene under the same conditions; an attempt to hydrogenate cyclohexene was unsuccessful, and an attempt to hydrogenate acetone led to an aldol condensation.

The same authors also studied the possibility of acid-catalysed hydrogenation with activation of the hydrogen by means of a carbonium ion:

$$R^+ + H_2 \rightleftarrows RH + H^+ .$$

Thus when Lewis acids were used to obtain the carbonium ion (16% solution of $AlBr_3$ in cyclohexane at 150°C and 82 atm H_2), appreciable absorption of hydrogen was observed. A small quantity of hydrogen was also absorbed by benzene in the presence of $AlBr_3$, but neither cyclohexane nor methylcyclopentane were detected in the reaction products. In the hydrogenation of 2-methylpropene and cyclohexene in the presence of $AlCl_3$ in $CHCl_3$ at 140°C and 120 atm H_2, traces of saturated hydrocarbons were detected.

Thus even if acid catalysis of hydrogenation is possible, it takes place with much greater difficulty than base catalysis.

b. Hydrogenation Catalysed by Systems Based on Compounds of Boron and Aluminium

Köster and coworkers[36,37] showed that homogeneous hydrogenation of alkenes takes place in the presence of alkylboranes at temperatures greater than 200°C and a hydrogen pressure of 70 atm. DeWitt and coworkers[38,39], using boranes as catalysts, hydrogenated cyclohexene, oct-1-ene, polymers of butadiene, etc. With the trialkyl derivatives of boron, the first stage of the reaction gives a hydride, which subsequently reacts with the substrate:

$$BR_3 + H_2 \rightleftarrows R_2BH + RH$$
$$R_2BH + RCH{=}CH_2 \rightleftarrows RCH_2CH_2BR_2$$
$$RCH_2CH_2BR_2 + 2H_2 \rightarrow RCH_2CH_3 + RH + RBH_2 .$$

The same authors also made a detailed study of the influence of added Lewis acids on the hydrogenating power of alkylboranes. Lewis acids catalyse the addition of boron hydrides to alkenes, but in the present instance it was found that Lewis acids do not lower the hydrogenation temperature. In the opinion of the authors cited, this shows that the rate-determining stage of the reaction is the hydrogenolysis of the B–C bond.

The use of aluminium hydrides as catalysts for homogeneous hydrogenation was described in the patent literature[40]. Recently, Slaugh[41] showed that $LiAlH_4$ may act as a selective catalyst for the homogeneous hydrogenation of conjugated dienes (cyclo-octa-1,3-diene, cyclopentadiene) and dialkylacetylenes (pent-2-yne) to monoalkenes (hydrogenation takes place above 150°C in an atmosphere of H_2). A reaction scheme involving the formation and subsequent hydrogenolysis of an Al–C bond was proposed:

$$CH_3{-}CH{=}CH{-}CH{=}CHCH_3 + LiAlH_4 \rightarrow LiAlH_3(n\text{-}C_5H_9) \xrightarrow{n\text{-}(C_5H_9)} LiAlH_3(n\text{-}C_5H_9)_2 \text{ etc.}$$
$$LiAlH_3(n\text{-}C_5H_9) \xrightarrow{H_2} n\text{-}C_5H_{10} + LiAlH_4$$

Tracer studies showed that the hydrogenation of a conjugated diene involves one hydrogen atom from the hydride and another from the gaseous phase.

2. SYSTEMS CONTAINING COMPOUNDS OF THE TRANSITION METALS

Calvin's work[26,42] laid the foundation for the study of an extensive branch of homogeneous catalysis—the activation of molecular hydrogen by salts of transition metals. These systems, of which the great majority have been studied by Halpern and his school, can activate hydrogen under mild conditions, and their study has played an important part in the development of the theory of the activation of hydrogen and homogeneous hydrogenation.

The activation of hydrogen by transition metal complexes has been the subject of recent successful studies. It is difficult to make a sharp distinction between these two types of catalyst. For example, a polarographic study[43] of solutions of univalent copper salts in pyridine showed that the solution contains the ionic complexes $CuPy_2^+$, $CuPy_3^+$, $CuPy_4^+$, and $CuPy_6^+$. The ligands may be negative ions (Cl^-, CH_3COO^-, etc.) or uncharged molecules (amines, water, etc.). For convenience in the subsequent discussion, however, we shall divide catalysts of homogeneous hydrogenation involving transition metal compounds into three classes: a) salts of transition metals (in this instance the reaction of the salts with the solvent leads to the formation of a complicated system of ionic complexes); b) two-component systems (in this instance the transition metal salt reacts with organometallic compounds or with complex-forming reagents); and c) individual transition metal complexes with known composition.

a. Salts of Transition Metals

The catalytic activity of solutions of transition metal salts in water and in ammonia has been most widely studied. Reactions of three types have been studied: 1) the exchange and conversion of hydrogen, examined above; 2) the reduction of inorganic ions ($Cr_2O_7^{2-}$, IO_3^-, etc.) by hydrogen; and 3) the hydrogenation of organic compounds.

Of the salts studied, those of copper[2,44–54], silver[55–64], and mercury[65–67], and compounds of manganese (MnO_4^-),[68] molybdenum (MoO_4^{2-}),[69] and metals of the platinum group[70–73] were found to be active in aqueous solutions. Salts of copper[26,42,74–78] and silver[76,79] were also found to be active in solutions of amines. Salts of copper[80,81], silver, and mercury[82] are active in solutions of heptanoic acid and in biphenyl.

We shall not discuss these systems in the present review, since they have been examined in detail elsewhere[3,69,83,84]. It should be emphasised, however, that transition metal salts capable of catalysing the exchange and conversion of hydrogen and also the reduction of inorganic ions, may nevertheless not act as catalysts for the hydrogenation of organic compounds. Examples of such systems are provided by aqueous solutions of Cu^{II}, Ag^{I}, and Hg^{II} salts; in Halpern's opinion[85], there are two possible reasons for this: 1) these ions activate hydrogen but do not activate alkenes; 2) the ions themselves are reduced by hydrogen.

In some instances, however, reduction of transition metal salts by hydrogen does not take place in the presence of alkenes, and homogeneous hydrogenation of the alkenes takes place. Thus Flynn and Hulburt[86] observed the homogeneous hydrogenation of ethylene in the presence of the complex $C_2H_4.PtCl_2$. Precipitation of metallic platinum was observed as the ethylene was used up. In the present instance, complex formation with the alkene stabilises the valency state of the metal. An analogous picture is apparently observed in the homogeneous hydrogenation of maleic acid in the presence of $RuCl_3$ in an acidic aqueous solution[85] and in the hydrogenation of ethyl crotonate by means of palladium salts[87].

A curious feature is that in the catalytic reduction of oxidising ions $Cr_2O_7^{2-}$, IO_3^-, etc. by hydrogen in the presence of transition metal salts, the precipitation of metal is observed only after the oxidant is completely used up.

On the other hand, various transition metal ions which are not capable of activating hydrogen in ortho-para conversion or isotopic exchange may catalyse the hydrogenation of organic compounds. For example, aqueous solutions of Ni^{II} do not activate hydrogen[3], but hydrogenation of pent-2-ene and benzene takes place in aqueous $NiSO_4$ solution[88]. The apparent explanation is that the substrate first forms a complex with the metal salt, and this complex subsequently reacts with hydrogen. A large number of hydrogenating systems of this type involving transition metal salts was studied by Tulupov, who showed that solutions of the stearates and adipates of Ni^{II}, Fe^{III}, Co^{II}, Mn^{II}, Cr^{III}, and Zn^{II} in ethanol, liquid paraffin, and n-heptane catalyse the hydrogenation of cyclohexene and benzene (to cyclohexane), cyclohexanone (to cyclohexanol), and pentenes (to pentanes).[69,88-94] The rate of hydrogenation in the presence of transition metal salts under ordinary conditions is extremely low.

In the presence of copper and cadmium oleates under severe conditions (H_2 pressure 250–275 atm, temperature 260°C), unsaturated aliphatic acids are hydrogenated to the corresponding unsaturated aliphatic alcohols[95]. The hydrogenation of benzoquinone by means of copper acetate in quinoline[26] and of copper heptanoate in heptanoic acid solution[80] has been described. Rylander and coworkers[96] hydrogenated dicyclopentadiene, quinone-1,2, and naphthoquinone-1,4 by means of salts of metals of the platinum group in dimethylformamide (or dimethylacetamide) solution.

Finally, rhodium chloride in alcoholic solutions catalyses the homogeneous hydrogenation of hex-1-ene[97] and the hydrogenation of maleic acid to succinic acid[98] in acetamide.

b. Two-component Systems

Systems formed by the reaction of transition metal salts with reducing agents or with complex-forming reagents are much more effective catalysts for homogeneous hydrogenation than the transition metal salts themselves. This section deals with the $CoCl_2$–KCN system and catalysts of the Ziegler–Natta type. The investigation of the reaction mechanism and the nature of the active intermediate compound in these systems is an extremely complicated problem.

$CoCl_2$–KCN System. The absorption of hydrogen when potassium cyanide is added to an aqueous cobalt(II) chloride solution was first observed by Iguchi[99] in 1942, but this system only attracted special attention after the work of King[100] and Kwaitek[101,102].

Table 1. Hydrogenation of various substrates by means of the $CoCl_2$–KCN system in aqueous solutions (25°C; H_2 pressure = 1 atm).

Substrate	Reaction product	References
$[Fe(CN)_6]^{3-}$	$[Fe(CN)_6]^{4-}$	102
H_2O_2	H_2O	102
Ethylene	not hydrogenated	102
Propene	ditto	102
Cyclohexene	ditto	102,104
Styrene and substituted styrenes	ethylbenzene etc.	101,102,104
Propenylbenzene $CH_3CH{=}CHPh$	not hydrogenated	101
1,1-Diphenylethylene	not hydrogenated	101
Cyclohexene oxide	cyclohexanol	101
Styrene oxide	phenylethanol	101
Allyl chloride	propene	119
Butadiene	mixture of butenes	101,102,119–124,138
Isopropene	2-methylbut-2-ene	
	2-methylbut-4-ene	101,102,125,126
Cyclopentadiene	cyclopentene	102
1,3-Cyclohexadiene	cyclohexene	101,102
Unsaturated aldehydes (acrolein, tiglaldehyde, cinnamaldehyde)		101,102
Acrylic acid and its derivatives		101,102
Sorbic acid	2-hexenoic and 3-hexenoic acids	101,104,126–128
Cinnamic acid	phenylpropionic acid	101,104,118,129
Keto-acid oximes[a]		104,130–134
Keto-acids and keto-esters[a] (reductive amination)		104
Acetaldehyde[b]		102
Benzaldehyde	benzyl alcohol	102
$t\text{-}C_4H_9NO_2$	t-butylamine	136
Nitrobenzene and its derivatives	azoxy-, azo-, and hydrazobenzenes, aniline	102,135,139
Nitrophenols	aminophenols	136
Benzonitrile[c] etc.		136
Acrylonitrile[c]		136
Benzoquinone	hydroquinone	102
Azoxybenzene	azobenzene	101
Benzil	benzoin	101,104
Methylene Blue etc.		137

[a]Temperature 30–100°, H_2 pressure 50–100 at. [b]Condensation accompanied by absorption of hydrogen. Temperature of reaction 100°. [c]Reduction products not isolated, because they are hydrolysed.

The $CoCl_2$–KCN system can be used for the ready reduction of inorganic oxidising agents [H_2O_2, $Fe(CN)_6^{3-}$], benzoquinone, conjugated alkenes, unsaturated acids etc., and aliphatic and aromatic aldehydes (the reduction of aliphatic aldehydes is accompanied by condensation). Reductive amination of keto-esters also takes place in the presence of $CoCl_2$–KCN (see Table 1).

Monoalkenes[102-104] and non-conjugated dienes[102] are not hydrogenated under these conditions, however. α,β-Unsaturated acids and aldehydes show different behaviour on hydrogenation in the presence of the $CoCl_2$–KCN system[102]. Thus it was found that α-substituted acrylic acids—methacrylic, itaconic, and atropic acids—are hydrogenated quantitatively, but the corresponding aldehydes are not hydrogenated. On the other hand, crotonaldehyde is partly hydrogenated, and tiglaldehyde is quantitatively hydrogenated, whereas tiglic acid [*trans*-2-methyl-2-butenoic acid] is not hydrogenated at all. In the hydrogenation of acrylic acid at elevated temperature, it was unexpectedly found that α-methylglutaric acid is formed in addition to propionic acid.

The study of the extremely complicated process of complex formation in the $CoCl_2$–KCN system was begun by the work of Hume and Kolthoff[105] and Adamson[106]. Research workers have paid most attention to the problem of the nature of the complex activating the hydrogen (see for example Refs. 107–111). It has now been shown that the active species in the $CoCl_2$–KCN system is the complex $[Co^{II}(CN)_5]^{3-}$. The partial replacement of CN^- ligands in the complex $[Co(CN)_5]^{3-}$ by ethylenediamine produces new hydrogenation catalysts[112].

Griffith and Wilkinson[113,114] used the NMR method to detect the formation of a Co–H bond during the reduction of a solution of cobalt(II) chloride and KCN by sodium hydridoborate. A curious feature is that the hydrido-complex is present in the solution in concentrations of 3% even without treatment with $NaBH_4$.

King and Winfield[108] studied the ultraviolet spectra of cyanide solutions of cobalt salts after their reduction by hydrogen, $NaBH_4$, or electrolysis, and showed that in all instances a hydrido-complex with probable structure $[CoH(CN)_5]^{3-}$ ($\lambda = 305$ mμ) is formed. The formation of a hydridopentacyano-complex of cobalt was confirmed by De Vries[115], Burnett and coworkers[116], and others. This hydrido-complex was recently isolated in the form of the salt $NaCs_2CoH(CN)_5$.[117]

A number of authors[19,28,29,100,108] hold the view that the formation of the hydrido-complex $[CoH(CN)_5]^{3-}$ involves the simultaneous reaction of a hydrogen molecule with two molecules of the complex $[Co(CN)_5]^{3-}$ according to the scheme:

$$[Co] + [Co] \rightleftarrows [Co]_2; \quad [Co]_2 + H_2 \rightleftarrows 2H[Co]$$

where $[Co] = [Co(CN)_5]^{3-}$.

Simandi and Nagy[118] recently showed, however, that the activation of hydrogen is a two-stage process: a complex of H_2 with one molecule of the cyano-compound $[Co(CN)_5]^{3-}$ is formed first, after which rupture of the H–H bond in the complex takes place with the participation of a second $[Co(CN)_5]^{3-}$ anion:

$$[Co] + H_2 \rightleftarrows H_2 \cdot [Co]$$
$$H_2 \cdot [Co] + [Co] \rightleftarrows 2H[Co] \ .$$

CoF_2–NaF System. It has been reported[140] that the CoF_2–NaF system in water catalyses the hydrogenation of ethylene and butadiene.

Ziegler–Natta Catalysts. The reaction of compounds of transition metals (acetylacetonates etc.) with organometallic reducing agents (Alk_3Al, Et_3B, RMgBr, etc.) leads to the formation of soluble systems capable of catalysing the hydrogenation of various alkenes[141-148] at 30–50°C and a hydrogen pressure of 3–5 atm. The rate of hydrogenation by means of these systems is greater by several orders of magnitude than that for salts of transition metals without a reducing agent.

The metals can be arranged in the following order of decreasing activity in these systems[141,147]: Ni ≥ Co > Cu ≥ Fe > Mn ≥ Cr > V, and that the activity of the catalyst decreases with increase in the acceptor power of the ligands[147]. The rates of hydrogenation of mono- and disubstituted alkenes are approximately the same, but much greater than the rates of hydrogenation of trisubstituted and more particularly tetrasubstituted alkenes. Compounds containing a carbonyl group (ketones and aldehydes), and also compounds containing nitrile, nitro, azo, and other functional groups are not hydrogenated in the presence of these catalysts.

The hydrogenation of alkenes by means of these catalysts involves the initial formation of a compound with a transition metal–carbon bond, and hydrogenolysis of this compound gives the final product and the transition metal hydride[141,142,147] according to the scheme:

$$R_3Al + MX_n \rightarrow R_3AlX + RMX_{n-1}$$
$$RMX_{n-1} + H_2 \rightarrow RH + HMX_{n-1}$$
$$\begin{array}{c} | \quad | \\ C{=}C \\ | \quad | \end{array} + HMX_{n-1} \rightarrow \begin{array}{c} | \quad | \\ HC{-}C{-}MX_{n-1} \\ | \quad | \end{array}$$
$$\begin{array}{c} | \quad | \\ HC{-}C{-}MX_{n-1} \\ | \quad | \end{array} + H_2 \rightarrow \begin{array}{c} | \quad | \\ HC{-}CH \\ | \quad | \end{array} + HMX_{n-1}$$

or

$$\begin{array}{c} | \\ HC{-}CHX_{n-1} \\ | \end{array} + HMX_{n-1} \rightarrow \begin{array}{c} | \quad | \\ HC{-}CH \\ | \quad | \end{array} + (MX_{n-1})_2$$
$$(MX_{n-1})_2 + H_2 \rightarrow 2\,HMX_{n-1} \ .$$

Systems of this type can also be used for the hydrogenation of aromatic compounds. Thus Lapport and Schuett[149] showed that a solution of Et_3Al and Ni^{II} 2-ethylhexanoate in heptane or in benzene is an excellent catalyst for the hydrogenation of various aromatic compounds (150°C, 70–80 atm H_2).

The hydrogenation of aromatic derivatives by means of catalysts of the Ziegler–Natta type is apparently accompanied by the intermediate formation of a π-complex. In the opinion of Kalechits and coworkers[150], evidence of this is provided by the fact that hydrogenation takes place under conditions in which π-complexes are formed.

Catalysts of the Ziegler–Natta type also hydrogenate compounds with conjugated double bonds[151] and oils[152].

Individual Transition Metal Complexes

A large number of individual transition metal complexes capable of catalysing homogeneous hydrogenation are now known; the activities of some of these are greater than that of the most active of the catalysts examined in previous sections. The use of these catalysts has played an exceptionally important part in the investigation of the mechanism of hydrogenation, since the compositions and structures of these complexes have in most instances been reliably established.

Metal Carbonyls and Their Derivatives. Hydrogenation by means of metal carbonyls is closely related to hydroformylation. Hydrogenation generally takes place under the same conditions as hydroformylation (a high pressure of "synthetic" gas—a mixture of CO and H_2—ensures the presence of carbonyls in the reaction mixture). The hydrogenating power of various carbonyl hydrides has been briefly discussed by Davydov[153].

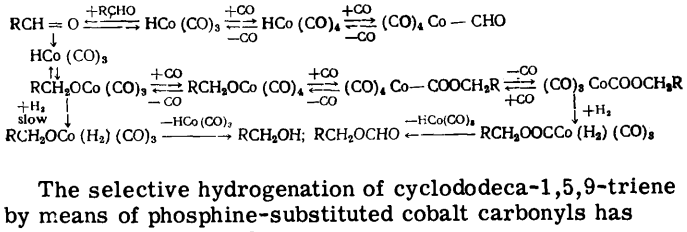
The hydrogenating power of cobalt carbonyl has been most extensively studied[154]. The ratio of the rates of the parallel reactions of hydroformylation and hydrogenation depends on the structure of the substrate. Thus simple alkenes give saturated aldehydes and the corresponding alcohols[155-159]; α,β-unsaturated ketones and aldehydes are hydrogenated to saturated carbonyl derivatives[155,160,161]; and conjugated alkenes give both hydrogenation products and hydroformylation products[154].

Cobalt carbonyl has been used for the hydrogenation of aldehydes[154,155,157,158,162-164], ketones[155,165], alcohols[155,160,165-169], aromatic compounds[155,166,170], azobenzene[171], poly-unsaturated acids[172], etc.

Two possible routes for the activation of hydrogen during hydrogenation by means of cobalt carbonyl have been discussed[154,160,162]: a) $Co_2(CO)_8 + H_2 \rightleftharpoons CoH(CO)_4$, that is the formation of cobalt hydride as homogeneous catalyst, and b) heterogeneous hydrogenation on metallic cobalt, formed by decomposition of the carbonyl:

$$Co_2(CO)_8 \rightleftarrows 2Co^0 + 8\,CO.$$

It may be taken that the homogeneous nature of catalytic hydrogenation by means of $Co_2(CO)_8$, in which the hydrogenating agent is $CoH(CO)_4$, has now been proved. This scheme involving the participation of $CoH(CO)_4$ was adopted, for example, by Marko[164] to explain the formation of alcohols in the hydrogenation of aldehydes. The same scheme explains the presence of a certain amount of formates in the reaction mixture.



The selective hydrogenation of cyclododeca-1,5,9-triene by means of phosphine-substituted cobalt carbonyls has also been described[173].

Recent work has shown that not only cobalt carbonyls, but also the carbonyls of other metals, can act as catalysts for homogeneous hydrogenation. Thus Imyanitov and Rudkovskii[174] studied the hydrogenation of alkenes in the presence of rhodium and iridium carbonyls. Hydroformylation takes place in parallel.

Heil and Marko[175], under the conditions of formation of rhodium carbonyl from $RhCl_3$, hydrogenated aliphatic aldehydes and benzaldehyde to the corresponding alcohols. Hept-1-ene and cyclohexene under these conditions first undergo hydroformylation, and are then hydrogenated to octanol and cyclohexylcarbinol.

The iron carbonyl $Fe(CO)_5$ is an effective catalyst for the homogeneous hydrogenation of poly-unsaturated fats. The hydrogenation of soya-bean oil in the presence of iron carbonyl at 180°C and 7–70 atm H_2 has been reported by Frankel and coworkers[176-178].

A complex of iron carbonyl with linoleate was isolated in the hydrogenation of methyl linoleate[177], and this complex was found to be a better hydrogenation catalyst than the original $Fe(CO)_5$.

The selective hydrogenation of unsaturated esters by means of π-complexes of $Fe(CO)_5$ [179-181] and by means of π-complexes of chromium carbonyl[182] has been described. In both instances the authors cited suggest that during the reaction these π-complexes dissociate with the formation of the species $Fe(CO)_3$ and $Cr(CO)_3$ respectively. The reaction of these species with hydrogen gives the hydrides $FeH_2(CO)_3$ and $CrH_2(CO)_3$, which then react with the substrate. Frankel[182] showed that the two hydrogen atoms are transferred to the substrate simultaneously.

Japanese workers[183] studied the mixed cyclopentadienylcarbonyl complex $Cp_2Ti(CO)_2$ as hydrogenation catalyst. They used this catalyst to hydrogenate various acetylenic derivatives in a hydrocarbon medium under comparatively mild conditions (50–65°C and H_2 pressure 50 atm). It was found that the rates of hydrogenation depend on the nature of the substituents R, decreasing in the order Ph > t-butyl > n-alkyl for the monosubstituted acetylenes RC≡CH or in the order Ph > n-alkyl for the disubstituted RC≡CR. Conjugated dialkenes have been hydrogenated by means of the π-complexes of iron, nickel, and cobalt carbonyls[151].

Complexes of Group VIII Metals with P-containing Ligands. In 1962, Vaska and coworkers[184] found that iridium complexes of the type $IrCl(CO)(Ph_3P)_2$ absorb molecular hydrogen reversibly at room temperature and atmospheric pressure with the formation of hydrides stable in air. Later, they also showed that hydrido-complexes of the type $IrH(CO)(Ph_3P)_3$ are effective catalysts for the homogeneous hydrogenation of ethylene[185,186]. The hydrogenation of alkenes is also catalysed by complexes of the type $IrHX_2L_3$, where X = Hal, L = PPh_3, Ph_3As, or Ph_3Sb;[187] alkenes with a terminal double bond are hydrogenated more rapidly than disubstituted alkenes, and further branching of the alkene chain leads to an even more marked decrease in the rate of hydrogenation. The use of iridium complexes as hydrogenation catalysts is also described in the patent literature[188,189]. In the presence of $IrH_3(PPh_3)_3$, aldehydes are hydrogenated with the formation of alcohols[190]. Unlike the iridium complex $IrCl(CO)(Ph_3P)_3$, the rhodium complex $RhCl(CO)(Ph_3P)_3$ was found to be inactive under the same conditions[185]. In a study of the hydroformylation of alkenes by means of $RhCl_3(Ph_3P)_3$, Osborn and coworkers[191,192] found that at high temperatures and pressures of the CO + H_2 mixture (1 : 1) the aldehyde obtained is converted into the alcohol. The complex $RhCl(Ph_3P)_3$ is an even more effective hydrogenation catalyst[193]. This catalyst has been used to hydrogenate a number of alkenes and alkynes (see Table 2); the rate of hydrogenation of the triple bond was found to be less than that of the double bond. As in the hydrogenation of alkenes, steric hindrance has a significant influence on the rates of hydrogenation of alkynes and the duration of the induction period.

Organic compounds with functional groups—ketones (aldehydes), alcohols, carboxylic acids, nitriles, chlorides, and nitro-compounds—are not hydrogenated in the presence of $RhCl(Ph_3P)_3$.[193] Butadiene and cyclo-octa-1,3-diene are hydrogenated only at 60°C, but are not hydrogenated at room temperature.

Non-conjugated dienes with double bonds in terminal positions (octa-1,7-diene) are hydrogenated more rapidly than hex-1-ene, which in turn is hydrogenated more rapidly than hex-2-ene; cis-alkenes are hydrogenated more rapidly than the trans-isomers. Unlike propene, ethylene is not hydrogenated under these conditions. The rate of hydrogenation depends on the concentration of substrate and catalyst, the H_2 pressure, and temperature, and increases considerably when a polar solvent is used. The addition of such complex-forming reagents as triphenylphosphine, thiophen, 8-quinolinol, pyridine, and acetonitrile decreases the reaction rate; ethylene, conjugated dienes, and O_2 poison the catalyst.

It has been shown that in the hydrogenation of alkenes in the presence of $RhCl(Ph_3P)_3$ the active compound is the dihydride $Rh(H_2)Cl(Ph_3P)_2$; one molecule of catalyst takes part in the transfer of hydrogen to the alkene.

Table 2. Hydrogenation of organic compounds in the presence of phosphine complexes of transition metals (25°C, H_2 pressure 1 atm).

Complex	Compound hydrogenated	Reaction product	References
$RhX(Ph_3P)_3$, where X = Cl, Br, or I	Ethylene	not hydrogenated	193, 194
	Alkenes (propene, butenes, hexenes, stilbene, etc.)	alkanes	193, 194, 202, 203, 206, 207

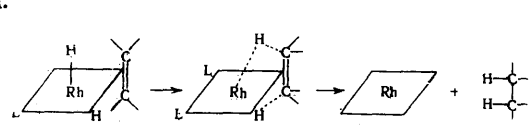
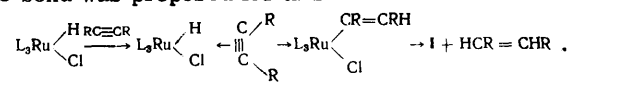
[a]Temperature 100°, H_2 pressure 50 atm. [b]Temperature 60°. [c]Temperature 50°; solvent—acetic acid.

The following hydrogenation scheme with simultaneous transfer of two hydrogen atoms to the substrate was proposed:



Complexes of rhodium with Ph_3As and more particularly Ph_3Sb ligands were found to be much less effective catalysts[194].

Evans and coworkers[195] showed that hept-1-ene and hex-1-yne are readily hydrogenated in the presence of ruthenium complexes of the type $RuCl_2L_4$ and $RuCl_2L_3$, where L = Ph_3P (at 25°C and 1 atm). A mechanism involving the formation and subsequent hydrogenolysis of an Ru–C bond was proposed for this reaction[196].



(I)

Alkyl phosphite complexes of univalent cobalt $CoXL_3$ and $CoXL_4$, where L = $(EtO)_3P$ and X = Cl, Br, or I, absorb hydrogen under mild conditions and act as catalysts for the hydrogenation of alkynes and various alkenes with activated double bonds (vinyl ethyl ether, vinyl acetate, etc.).[198,199]

The following scheme was proposed for the hydrogenation of alkynes by phosphite complexes of cobalt (in alcohol):

$$L_4CoCl + H_2 \rightarrow L_4CoH + HCl \quad (1)$$

$$L_4CoH + RC \equiv CH \rightarrow L_4CoH \quad (2)$$

$$L_4Co - H \rightarrow L_4Co - CH = CHR \quad (3)$$

$$L_4Co - CH = CHR \xrightarrow{H_2} L_4CoH + H_2C = CHR \quad (4a)$$

$$L_4Co - CH = CHR \xrightarrow{R'OH} L_4CoOR' + H_2C = CHR \quad (4b)$$

$$L_4CoOR' + H_2 \rightarrow L_4CoH + R'OH \quad (5)$$

To determine whether hydrogenation takes place with hydrogenolysis (4a) or alcoholysis (4b) of the intermediate compound with the Co–C bond, C_2H_5OD was used as solvent. It was found that the hydrogenation product did not contain deuterium. Thus the molecular hydrogen is the source of both hydrogen atoms in the hydrogenation of alkynes (scheme 4a). An interesting feature is that an alkyl phosphite complex of zero-valent cobalt[200] did not catalyse hydrogenation even at 150°C and a hydrogen pressure of 120 atm.

It was recently found[201] that the complex $CoH_2(Ph_3P)_3$ catalyses the hydrogenation of ethylene.

Complexes Containing the $SnCl_3$ Ligand. Cramer and coworkers[212] were the first to carry out the homogeneous hydrogenation of ethylene in an alcoholic solution of K_2PtCl_4 and $SnCl_2$ (H_2 pressure 1 atm, 25°C). This system also catalyses the hydrogenation of pent-1-ene[213], cyclohexene[214], and other alkenes[215]. In the hydrogenation of acetylene[212], a mixture of ethylene and ethane is formed. Cramer and coworkers[212] were able to isolate a compound containing a Pt–$SnCl_3$ bond and to show that $SnCl_2$ plays a dual role in complex formation in this system: 1) it promotes the coordination of ethylene to platinum; and 2) it stabilises the valency state of platinum relative to reduction by hydrogen.

Bailar and coworkers[216–219] showed that complexes of the type MX_2L_2 (where L = R_3P, R_3As, etc., X = Hal, and M = Ni, Pd, or Pt) in the presence of $SnCl_2$ are capable of catalysing the selective hydrogenation of compounds with two or more double bonds to compounds with a single isolated bond.

Khrushch and coworkers[220,221] studied the reaction kinetics and isotopic composition of the products of the hydrogenation of ethylene by means of platinum complexes of this type in the $C_2H_4 + D_2 + CH_3OH$ and $C_2H_4 + H_2 + CH_3OD$ systems, and found that in both instances the chief product is C_2H_5D. This shows that in the hydrogenation,

one of the hydrogen atoms is provided by the H_2 molecule and the other by the alcohol, according to the scheme:

$$[Pt] + C_2H_4 \rightleftarrows Pt(C_2H_4)$$

$$Pt(C_2H_4) \overset{H_2}{\rightleftarrows} \left[\begin{matrix} H \\ H \end{matrix}\!\!>\!PtC_2H_4\right] \rightleftarrows [^-HPtC_2H_4] + H^+$$

$$[^-HPtC_2H_4] \rightleftarrows PtC_2H_5^-$$

$$PtC_2H_5^- + H^+ \rightarrow [Pt] + C_2H_6$$

where [Pt] represents the active complex.

The complex $PtHCl(Ph_3P)_2$ in the presence of $SnCl_2$ catalyses the hydrogenation of norbornadiene and hex-3-yne-2,5-diol. The complex $Ir(H_2)(SnCl_3)(Ph_3P)_3$ does not exhibit hydrogenating power[196].

Complexes with Other Ligands. The influence of nitrogen-containing ligands (ammonia and amines) on the activity of hydrogenation catalysts has been studied.

Iguchi[222] observed the precipitation of metal in the hydrogenation of quinone, cinnamic acid, and other compounds in the presence of complexes of rhodium with ammonia.

A number of authors[8,62] have studied the influence of amines as ligands on the reduction of Ag^+ by hydrogen. It was found that the reactivity of the corresponding ionic complex decreases in the following order of ligands:

$$R_3N > R_2NH > RNH_2 > NH_3$$

The reaction of hydrogen with the complex $RhCl_3Py_3$ gives a hydride with assumed composition $RhHCl_2Py_3$, which hydrogenates hex-1-ene[223].

A number of effective catalysts for homogeneous hydrogenation have been prepared by Khidekel' and coworkers. Thus solutions of complexes of transition metals (Rh, Ru, Ir, or Mo), stabilised by π-donor quinonoid and aromatic ligands (duroquinone, mesitylene, etc.) in dimethylformamide (25°C, H_2 pressure 1 atm) catalyse the hydrogenation of alkenes; the activity of these catalysts is greater by several orders of magnitude than that of heterogeneous catalysts (rhodium on carbon, etc.).[224,225]

The reduction of rhodium salts in the presence of aminoacids (L-tyrosine, α-phenylalanine, etc.) and peptides leads to the formation of Rh^I complexes, which are extremely effective catalysts for the hydrogenation of unsaturated compounds under mild conditions[226-228]. An important property of the complexes of rhodium with aminoacids is their ability to catalyse the hydrogenation of aromatic compounds under mild conditions (anthracene > benzene > naphthalene).[229] When the ligand has an asymmetric centre (the complex with L-tyrosine), acetoacetic ester undergoes asymmetric hydrogenation to ethyl β-hydroxybutyrate[229]. According to the data obtained, these catalysts show a marked similarity to the enzyme hydrogenase.

The study of the structures of these complexes has shown that they are of the half-sandwich type, the aromatic ring of the aminoacid acting as π-ligand.

IV. GENERAL SYSTEMATIC FEATURES AND MECHANISM OF THE ACTIVATION OF HYDROGEN AND HOMOGENEOUS HYDROGENATION

Comparison of the results of the study of a number of catalytic systems makes it possible to distinguish various common regular features of homogeneous hydrogenation and the activation of hydrogen in the presence of transition metal complexes and to examine the part played by the transition metal and the ligands, the influence of solvents, the stereospecificity and selectivity of the catalysts, etc.

1. ACTIVATION OF MOLECULAR HYDROGEN BY TRANSITION METAL COMPLEXES

a. The Part Played by the Transition Metal

The H_2 molecule is a fairly inert molecule with a closed electron cloud, and its dissociation energy is 104 kcal mole^{-1}.

The activation of H_2 by transition metal compounds involves the reaction of the hydrogen molecule with the ion (or complex) of the metal; the H–H bond in the transition state (or in the intermediate compound) is weakened and then broken.

There are thus two possibilities in the activation of hydrogen. According to the first, the H_2 acts as electron donor, that is the bonding electrons of the hydrogen are partly transferred to vacant orbitals of the metal ion (donor–acceptor bond).[230] The other possibility in the activation of H_2 is that an electron is transferred from the metal atom rich in electrons to an antibonding orbital of the hydrogen molecule (dative bond), that is H_2 acts as an electron acceptor (in Halpern's opinion[230], this process may involve the $2p$ orbitals of the hydrogen). Dative bond formation makes it possible to explain the activation of hydrogen not only by ions (or complexes) of metals rich in electrons[193], but also by such ions as OH^-, NH_2^-, R^-, etc.[231]

Thus the transition states (or intermediate compounds) of these two extreme types, depending on whether hydrogen acts as electron donor or electron acceptor, can be represented as $M.....H_2^+$ and $M.....H_2^-$. The energies of rupture of the H–H bonds in the corresponding molecular ions H_2^+ and H_2^- are not the same and have the values 62 kcal mole^{-1} and 3.4 kcal mole^{-1} (or 18.6 kcal mole^{-1} according to other data) respectively[232].

Syrkin[233] suggested that in the activation of H_2 with the formation of a bond of the donor–acceptor type, a three-centre transition state with two electrons in the field of three nuclei may be realised:

$$M^+ : \begin{matrix} \cdot H \\ \vdots \\ \cdot H \end{matrix}$$

For a transition state of the type $M.....H_2^+$ to be realised in the activation of hydrogen, the M atom must have suitable vacant orbitals with sufficiently low energy. For transition metals these are primarily d orbitals.

In the earliest reviews of the homogeneous activation of hydrogen it was noted that the active species are primarily transition metal ions with a filled or almost filled d electron level[3]:

$$Cu^{II} - 3d^9;\ Cu^I - 3d^{10};\ Pd^{II} - 4d^8;\ Ag^I - 4d^{10};\ Hg^{II} - 5d^{10}$$

It is significant that for ions with a filled d level the difference in the energies of the d orbitals and the next vacant s and p orbitals is comparatively small, and the ease of the $d \rightarrow s$ and $d \rightarrow p$ transitions leads to the production of vacant d orbitals. It is interesting in this connection to note that although the ions Zn^{2+}, Cd^{2+}, and Hg^{2+} have similar d^{10} electronic configurations, only the Hg^{2+} ion is effective in the activation of hydrogen, since the difference in the energies of the d orbitals and the higher s orbital is much smaller for this ion than for the other ions of this series[8].

On the other hand, the formation of a dative M.....H_2^- bond, that is transfer of the electrons of the M atom to an antibonding molecular orbital of hydrogen, is favoured by a minimal positive charge on the metal. This explains the higher activating power of Cu^I compared with Cu^{II} in the reaction with hydrogen. A large proportion of catalysts for homogeneous hydrogenation known at present are compounds of transition metals with a low oxidation state.

Another factor facilitating the formation of dative bonds is the presence of electron-donating ligands on the metal atom. Thus the activation of hydrogen may be favoured by the presence of vacant orbitals and by a low degree of oxidation of the metal in the complex.

b. The Part Played by the Ligands and Solvent

A significant influence on the catalytic activity of a complex is shown by the nature of the ligands attached to the metal atom. The ability of various ligands to form both donor–acceptor bonds and dative bonds leads to the stabilisation of low valency states of the metal. Thus for example ligands of the type PR_3 can use the unshared pair of electrons of the tervalent phosphorus to form a donor–acceptor bond, and can use vacant *d* orbitals with comparatively low energy to accept electrons from the metal atom. Ligands of this type stabilise rhodium complexes[193] which absorb hydrogen reversibly and catalyse the homogeneous hydrogenation of organic compounds. With the analogous complexes formed by rhodium with amines, which are not capable of forming dative bonds, hydrogenation is accompanied by the formation of a metallic precipitate. The preferential formation of bonds of a given type by different ligands makes it possible to increase or decrease the electron density at the metal atom in the reaction with hydrogen or the substrate and thus to ensure the optimal conditions for the manifestation of catalytic properties by the complex. An interesting feature here is that the catalytic activity of rhodium complexes which absorb hydrogen readily and reversibly is extremely sensitive to small changes in the donor–acceptor properties of the ligand: the replacement of a phenyl group in triphenylphosphine by an ethyl group reduces considerably the activity of the rhodium complex[206] in hydrogenation.

A decrease in the positive charge of a metal ion is also brought about by its reaction with an anion acting as ligand. It is important, however, that the bond between this ligand and the metal ion be sufficiently labile to ensure the ready liberation of a coordination position for the H_2 molecule in the reaction with hydrogen. Thus for example silver acetate and sulphate are catalytically active, whereas the trifluoroacetate, chloride, and other silver salts are inactive. The catalytic activity of copper acetate and chloride, and also of $HgSO_4$, is greater than that of the corresponding salts with less nucleophilic anions.

A coordination position may also be vacated by dissociation of a complex, as shown by the complexes $RhCl(Ph_3P)_3$,[193] $RuCl_2(Ph_3P)_4$,[195] etc. This vacant position is apparently occupied by a solvent molecule, which is readily displaced by hydrogen. An attempt by Halpern[3] to correlate the catalytic activities of various metals with their stability constants is of interest in this connection.

The importance of a vacant (or readily liberated) coordination position for the catalytic activity of a complex in homogeneous hydrogenation can be demonstrated by a number of other examples. Thus the Cu^{2+} ion is active in aqueous medium, but its catalytic activity is decreased by the addition of chelating reagents which "screen" the orbitals accessible to hydrogen, and the catalytic activity may disappear completely at high concentrations of the chelating agent[52].

The catalytic activity of the complexes of rhodium and iridium with bidentate ligands $[Rh(Ph_2PCH_2CH_2PPh_2)_2]Cl$ and $[Ir(Ph_2PCH_2CH_2PPh_2)_2]Cl$ is much smaller than that of the corresponding complexes with unidentate ligands $RhCl(Ph_3P)_3$ and $IrCl(CO)(Ph_3P)_2$.[220] In the opinion of the authors cited, the chelate complexes form a very stable adduct with hydrogen, and this prevents further hydrogenation.

Triphenylphosphine complexes of rhodium react with such compounds as CO, $CH_2=CH_2$, $CF_2=CF_2$, and tolane to form complex compounds which are so stable that they do not activate hydrogen[193]. This explains the "poisoning" of rhodium catalysts by ethylene and carbon monoxide.

Thus in homogeneous hydrogenation the part of ligands may be played not only by groups introduced beforehand, but also by molecules of the substrate, reaction products, hydrogen, and the solvent.

The functions of the solvent in catalytic systems may be extremely varied. Thus the solvent takes direct part in complex formation. With strong electrolytes, such as aqueous solutions of perchlorates, the metal ion is solvated by water. (The absence of a perchlorate salt effect when copper perchlorate is used as hydrogenation catalyst indicates that it is the Cu^{II} ion, and not a perchlorato-complex of copper, which is active in this reaction.) Measurements of the molecular weight of copper acetate in pyridine and dodecylamine led Wright and coworkers[76] to suggest that the copper salt exists in the form of a complex in solutions of effective complex-forming reagents such as amines. This complex formation with the solvent explains the marked influence of substituents in quinoline and pyridine on the catalytic activity of Cu^{II} in these solvents[27,77]. Thus the introduction of a methyl group into the pyridine molecule leads to a significant increase in the activity of copper acetate compared with the activity of this salt in pyridine.

It has been suggested[193] that the rhodium complex $RhCl_3(Ph_3P)_3$, which dissociates readily in benzene, subsequently reacts with hydrogen and a substrate in the form of a solvated four-coordinated complex $RhCl(Ph_3P)_2(Sol)$, where Sol represents a solvent molecule. In the opinion of the authors cited, this is confirmed by the fact that hydrogenation does not take place in solvents which are more powerful complex-forming reagents. An interesting feature is that a fairly stable complex with the composition $Rh(H_2)Cl(AsPh_3)_2.0.5CH_2Cl_2$ was isolated from solutions of the analogous complex of rhodium with Ph_3As in CH_2Cl_2.[194]

The nature of the solvent has a significant influence on the nature of the rupture of the H–H bond in the hydrogen molecule. Thus in the activation of hydrogen by solutions of copper and silver salts in amines, heterolytic splitting of the hydrogen predominates over homolytic splitting in the absence of aqueous solutions of these salts. In Halpern's opinion, this is partly due to the fact that a solvent more basic than water combines with the H^+ ions formed.

Heterolytic rupture of the H_2 is facilitated not only by greater basic strength of the solvent but also by dilution of the solution and increase in temperature[56].

There is no doubt that the stability and hence the activity of the hydride formed by the reaction of hydrogen with the transition metal complex also depends to a marked extent on the nature of the solvent. In many instances the hydrogen atom of the hydride takes part in exchange reactions with the solvent, and this may have a significant influence on the kinetics and yield of reaction products.

In some instances it has been shown that a solvent containing labile hydrogen can take direct part in one of the hydrogenation stages by acting as a source of one of the H atoms, as for example with platinum complexes [221]:

$$^{-}H[Pt] + C_2H_4 \rightarrow PtC_2H_5^-$$
$$PtC_2H_5^- + ROH \rightarrow C_2H_6 + [Pt] .$$

The part played by ethanol in the catalytic reactions of complexes of Group VIII metals is considerable, and many of its aspects are not clear. The rhodium complexes mentioned above are more active when ethanol is introduced into the non-polar solvent; the efficiency of the $CoCl_2$–KCN system is greatly increased in alcoholic solutions; phosphite complexes of cobalt are also active only in the presence of alcohols [197]; and ruthenium complexes do not catalyse hydrogenation in the absence of traces of alcohol [195]. It should also be noted that side reactions involving alcohols may also deactivate a catalytic system: at elevated temperatures, the complex $RhCl(Ph_3P)_3$ may decarbonylate alcohol and be converted into the inactive $RhCl(CO)(Ph_3P)_3$. [193]

c. Mode of Activation of Molecular Hydrogen

The various possible reactions involved in the activation of hydrogen can be represented schematically as follows:

1) Heterolysis: $RuCl_6^{3-} + H_2 \rightleftharpoons RuHCl_5 + H^+ + Cl^-$
2) Homolysis: $2Co(CN)_5^{3-} + H_2 \rightarrow 2CoH(CN)_5^{3-}$
3) Insertion: $IrCl(CO)L_2 + H_2 \rightarrow IrCl(H_2)(CO)L_2$
4) Electron transfer: $Hg^{2+} + H_2 \rightarrow Hg^0 + 2H^+$.

Insertion, which is of independent interest, may also apparently be an intermediate stage in the homolytic or heterolytic splitting of hydrogen, for example:

$$MXL_n + H_2 \rightarrow M(H_2)XL_n \rightarrow MHL_n + HX \text{ etc.}$$

Published data indicate that activation of hydrogen may take place on a single metallic centre or on two such centres. In the latter instance the metal atoms may be the same, as in $Co_2(CO)_8$, [154] or different, as in complexes with a Pt–Ge bond [234]; the lowest value for the activation of rupture of the H–H bond (9 kcal mole^{-1}) was observed when these complexes were used. In some instances, ligands such as amines may act as second centre for the activation of hydrogen, for example:

$$(L{-}Ag{-}L)^+ + H_2 \rightarrow \left[\begin{matrix} L{-}Ag^+{-}L \\ \vdots \quad\quad \vdots \\ H^{-\delta} \ldots H^{+\delta} \end{matrix}\right] \rightarrow AgHL + H^+$$

where L represents an amine.

2. TRANSITION METAL HYDRIDES TAKING PART IN CATALYTIC REACTIONS OF HOMOGENEOUS HYDROGENATION

The intermediate formation of a hydride in the reaction of hydrogen with an active complex is the most important stage in catalytic hydrogenation. The study of the properties of hydride complexes of transition metals and their behaviour under the conditions of hydrogenation is of considerable assistance in reaching an understanding of the reaction mechanism.

In the earliest work on the activation of hydrogen, the intermediate formation of hydrides was assumed merely on the basis of kinetic and thermodynamic data (with the exception of CuH, which was actually prepared), but the position has now altered significantly. It has been possible to isolate a number of hydrides in the form of individual compounds. To confirm the formation of hydrides in the reaction mixture and to obtain information on their structures, extensive use is made of infrared spectroscopy and proton magnetic resonance spectroscopy [235,236].

The stability of hydride complexes depends to a marked extent on the nature of the metal, the ligand, and the solvent; the nature of the H atom in these complexes varies from strongly acidic in $CoH(CO)_4$ to labile hydrido in $PtHCl(Ph_3P)_2$.

The hydrogen in the hydride complex should be sufficiently labile to take part in hydrogen transfer with subsequent regeneration of the complex, capable of activating hydrogen again.

Hydride complexes with one, two, or three hydrogen atoms on one metallic centre are now known. In the discussion of reaction mechanisms, allowance must be made for the fact that with di- and tri-hydrides the hydrogen atoms may not be transferred to the substrate molecule simultaneously, since the properties of these H atoms may be different. Osborn and coworkers [193] discuss the alternative possibilities of simultaneous or consecutive transfer of hydrogen for the rhodium dihydride $Rh(H_2)Cl(Ph_3P)_2$.

Some authors regard the reaction of hydrogen with a transition metal complex as formal oxidation of the metal by hydrogen [184]:

$$Ir^{I}Cl(CO)(Ph_3P)_2 + H_2 \rightleftharpoons Ir^{III}(H_2)Cl(CO)(Ph_3P)_2$$
$$2[Co^{II}(CN)_5]^{3-} + H_2 \rightleftharpoons 2[Co^{III}H(CN)_5]^{3-} \text{ (Ref.108)}$$

With increase in the valency of the metal there is an increase in its coordinating power, and both these factors have a direct influence on the stability of the resulting hydride [235]. Vaska [185] suggests that in homogeneous hydrogenation by means of the hydrido-complex $IrH(CO)(Ph_3P)_3$ this monohydrido-compound reacts with H_2 with the formation of the even more active seven-coordinated trihydrido-compound $IrH_3(CO)(Ph_3P)_3$, which subsequently reacts with the substrate.

In the reaction of H_2 with the osmium complex $OsHL_5$ (where L represents a ligand), the 8-coordinated OsH_3L_5 is formed [185]. Complexes of this kind with an unusual coordination number are unstable and should give up hydrogen readily. In Vaska's opinion, it is necessary in the prediction of the catalytic activity of complexes to consider the relative stabilities of their electronic and stereochemical configurations, and also the stabilities of their potential active adducts with hydrogen, such as OsH_3L_5, $IrH_3(CO)L_3$, [185] or the proposed unstable 5-coordinated complex $[PtHCl_2(SnCl_3)(C_2H_4)]^{2-}$. [221]

Most catalysts of homogeneous hydrogenation absorb hydrogen reversibly. This property of complexes (or salts) is not essential, however, for the manifestation of catalytic power. Thus the complex $RhH(CO)(Ph_3P)_3$ does not absorb H_2, but it catalyses the hydrogenation of ethylene [208]. This is apparently due to the fact that the complex (in the present instance a hydrido-complex) first reacts with the substrate, and then activates hydrogen (hydrogenolysis of the metal–carbon bond).

3. ACTIVATION OF THE SUBSTRATE AND TRANSFER OF HYDROGEN

In hydrogenation it is possible to distinguish stages involving the activation of hydrogen, the activation of the substrate, and the transfer of hydrogen to the substrate.

In general, the sequence of these stages can be represented by the following basic schemes[69] (M represents the transition metal complex, and S the substrate):

Scheme I:

$$M + H_2 \rightleftarrows M\cdot H_2 \quad (a)$$

$$M\cdot H_2 + S \rightleftarrows S\cdot M\cdot H_2 \quad (b)$$

$$S\cdot M\cdot H_2 \rightarrow S\cdot H_2 + M \quad (c)$$

According to scheme I, activation of hydrogen takes place first with formation of a hydride, which then reacts with the substrate and hydrogen is transferred to the substrate.

Scheme II:

$$M + S \rightleftarrows M\cdot S \quad (a)$$

$$M\cdot S + H_2 \rightleftarrows H_2\cdot M\cdot S \quad (b)$$

$$H_2\cdot M\cdot S \rightarrow S\cdot H_2 + M \quad (c)$$

According to scheme II, the complex with the substrate is formed first, and this complex then activates hydrogen.

Scheme III:

$$M + S \rightleftarrows M\cdot S \quad (a)$$

$$M' + H_2 \rightleftarrows M\cdot H_2 \quad (b)$$

$$M\cdot S + M'\cdot H_2 \rightarrow M' + S\cdot H_2 + M \quad (c)$$

According to scheme III, the complex activates hydrogen and the substrate separately, and in the general case the activation of these reagents may be brought about by different complexes. Examples of reactions of this kind are provided by various reactions of enzymatic catalysis, in which the substrate and hydrogen are activated by different centres[237].

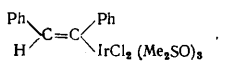
Activation of the substrate has been studied in most detail for the homogeneous hydrogenation of alkenes and alkynes. A theory of complex formation by alkenes and alkynes with transition metal compounds was put forward in 1952 by Dewar. A fairly large number of alkene and alkyne complexes have now been described, and a number of interesting reviews[238,239] have been devoted to these compounds. There is no doubt that the formation of a complex with the substrate is not sufficient for catalytic hydrogenation, which also requires that the bond between the substrate and the transition metal be fairly labile. Homogeneous hydrogenation is usually undergone only by those alkenes which react reversibly with the transition metal compound in solution[193]. Attempts to correlate the tendency of alkenes to undergo hydrogenation with the stability constants of the complex formed by the transition metal with these alkenes are extremely interesting in this connection[193,240]. According to the data of Osborn and coworkers[193], the equilibrium constant for the reaction of propene with the rhodium complex $RhCl(Ph_3P)_3$ is smaller by a factor of 2000 than that for ethylene, so that propene, unlike ethylene, is hydrogenated by means of this catalyst. The higher activity of $RhBr(Ph_3P)_3$ and $RhI(Ph_3P)_3$ compared with the corresponding chloride is in agreement with the lower stability of the complexes formed by the alkenes with the iodide and the bromide. The analogous complexes of rhodium with Ph_3As form more stable complexes with the alkene and are correspondingly less effective hydrogenation catalysts.

In the stage involving activation of the alkenes and acetylenes, both π- and σ-complexes with transition metal compounds may be formed. The hydride formed by the reaction of hydrogen with the transition metal compound according to scheme I (or introduced directly into the reaction mixture) may give a π-complex with the alkene (or alkyne), which is then converted into a σ-complex. This scheme was adopted, for example, by Jardine and McQuillin[196].

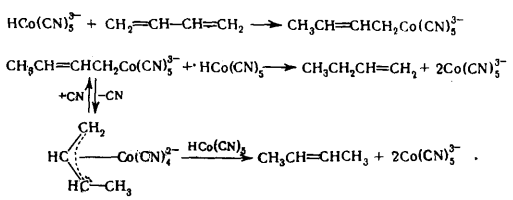
$$(Ph_3P)_3RuHCl + RC\equiv CR \rightarrow (Ph_3P_3)Ru\begin{matrix}H\\ \vdots\\ Cl\end{matrix}\cdots\begin{matrix}C\\ \|\\ C\end{matrix}\begin{matrix}R\\ \\ R\end{matrix} \rightarrow (Ph_3P)_3RuCR=CHR.$$

Examples of complexes containing both hydrogen and a π-bonded alkene on the same metallic centre are provided by the recently prepared complexes of iridium[241] $Ir_2HCl_2(C_8H_{12})_2$ and rhodium[242] $RhH_2(C_2H_4)(Ph_3P)_3$.

The organometallic σ-compound of iridium whose existence was assumed in the above scheme of Jardine and McQuillin was recently prepared[243]:

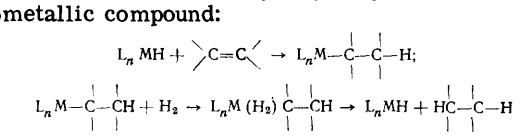


On acidification, this compound gives *cis*-stilbene. On the other hand, the reaction of the hydride with the substrate may involve the initial formation of a σ-complex, which is subsequently converted into a π-complex. Thus the following scheme was proposed to explain isomerisation during hydrogenation[119]:



The organometallic σ-compound formed may subsequently react with the transition metal hydride or undergo hydrogenolysis or hydrolysis (alcoholysis), depending on the conditions of the reaction. The hydrogenolysis of metal–carbon bonds is a fairly common phenomenon. Gilman[244] described the splitting of alkali metal compounds by hydrogen; Clauss and Bestain[245] described organometallic compounds of Mn and Ti, and Hein and Weiss[246,247] described compounds of chromium (the formation and properties of these derivatives have been reviewed[248,249]).

In a sense, the hydrogenolysis of a metal–carbon bond represents the activation of hydrogen by an intermediate organometallic compound:



A hydrogenation mechanism involving the formation of σ-alkyl complexes was assumed by Vaska[185] for an iridium complex, and has also been proposed for Ziegler–Natta catalysts[141,147], etc.

Although the formation of a σ-alkyl bond is widely encountered, this stage cannot always be observed in homogeneous hydrogenation. Thus in the hydrogenation of alkenes by means of a rhodium hydride, Osborn and coworkers[193], using the NMR method, were unable to detect the formation of a σ-C–Rh bond. In this instance, on the basis of the available experimental data, they put forward a hydrogenation scheme involving the simultaneous transfer of two hydrogens to the alkene.

The form in which the hydrogen is transferred to the compound being hydrogenated—ionic (see for example the review on hydride displacements[250]) or radical—depends to a large extent on the nature of the transition metal hydride, the substrate, the presence of a hydrogen carrier, the participation of the solvent, and other factors.

There is also the interesting possibility of carrying out catalytic hydrogenation without hydrogen transfer, by a mechanism involving electron transfer[251] (in this instance the solvent is the source of hydrogen):

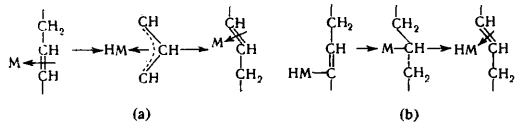
$$L_nM^{+m} + S \rightarrow L_nM^{+m+1}S^-$$
$$L_nM^{+m+1}S^- + H^+ \text{ (from solvent)} \rightarrow L_nM^{+m+1} + SH$$
$$L_nM^{+m+1} + H_2 \rightarrow L_nM^{+m} + 2H^+ \text{ etc.}$$

In most of the hydrogenating systems examined above, the activation of both hydrogen and the substrate was brought about by reaction with the same catalyst.

Complexes capable of activating hydrogen, however, are often not capable of simultaneously activating various substrates. On the other hand, the introduction, into a system containing a hydrogen activator, of substances capable of activating the substrate may extend considerably the range of application of the catalytic system. Khidekel'[229] points out that this method of activating the substrate differs fundamentally from the method of increasing the rate and specificity of homogeneous catalytic hydrogenation by modification of a catalyst activating molecular hydrogen. Thus organic compounds with carbonyl groups are not hydrogenated in the presence of the complex $RhCl(Ph_3P)_3$, which activates hydrogen. By adding zinc chloride, which forms complexes with carbonyl compounds, to the reaction mixture, however, Khidekel'[229] was able to hydrogenate carbonyl compounds under the same conditions.

4. ISOMERISATION OF THE SUBSTRATE DURING HOMOGENEOUS HYDROGENATION. THE SELECTIVITY AND STEREOSPECIFICITY OF HYDROGENATION CATALYSTS

Hydrogenation may be accompanied by a number of side reactions, depending on the nature of the substrate and the complex. One such reaction involving a transition metal hydride is the isomerisation of alkenes, described by many workers for complexes of Ir, Pt, Pd, Co, Ru, and Fe. It is now usual to consider "hydrido-σ-allyl" (a) and "hydrido-alkyl" (b) mechanisms of isomerisation, which can be represented schematically as follows[252-254]:



(a) (b)

Study of the distribution of isomers may give valuable information on the mechanism of homogeneous hydrogenation, since these processes involve the participation of a transition metal hydride with transfer of hydrogen by an "alkyl" or "allyl" mechanism. Work on the isomerisation of pent-1-ene in the presence of hydrogenation catalysts with a Pt–Sn bond is of interest in this connection[255].

In a number of instances, catalysts of homogeneous hydrogenation are extremely selective. Thus $LiAlH_4$ catalyses the homogeneous hydrogenation of pent-2-yne with the exclusive formation of pent-2-ene, and with conjugated alkenes, one C=C bond is preserved[41]; in the presence of the complex $Cp_2Ti(CO)_2$, hex-1-yne is hydrogenated to hex-1-ene[183]; the hydrogenation of sorbic acid by means of $[Co(CN)_5]^{3-}$ gives chiefly 2-hexenoic acid (see Table 1). The complex $Co_2(CO)_8$ can catalyse the hydrogenation of unsaturated aldehydes to saturated aldehydes, but at elevated temperature aliphatic aldehydes are hydrogenated to the corresponding alcohols. This property of the catalyst is extremely important for the control of hydroformylation. An important feature is that many catalysts of homogeneous hydrogenation, for example Ziegler–Natta systems[141] or the complex $RhCl(Ph_3P)_3$,[193] which are extremely active towards C=C and C≡C bonds, are incapable of reducing functional groups such as =CO, –CHO, –CN, –N=N–, $-NO_2$, etc.

Catalysts of homogeneous hydrogenation in a number of instances also show distinct stereospecificity. Thus in the hydrogenation of maleic acid by molecular deuterium in the presence of the complex $RhCl(Ph_3P)_3$, preferential cis-attachment of D_2 is observed, and the chief product is 1,2-dideuterosuccinic acid[193]. According to the observations of these authors, the quantity of *cis*-hex-2-ene obtained in the hydrogenation of hex-2-yne is twenty times the quantity of *trans*-hex-2-ene obtained.

The direction of hydrogenation sometimes depends on the conditions of the reaction. For example, the hydrogenation of butadiene by means of the $CoCl_2$–KCN system gives *trans*-but-2-ene at $CN^-/Co^{2+} \leqslant 5$, whereas but-1-ene is formed preferentially at $CN^-/Co^{2+} \geqslant 6$.[119]

V. ENZYMATIC CATALYSIS OF HYDROGENATION AND THE ISOTOPIC EXCHANGE AND CONVERSION OF HYDROGEN

Work by Stephenson, Strickland, and Green[256-259] laid the foundation for the study of a large class of micro-organisms capable of activating molecular hydrogen. This ability was ascribed to an enzyme or system of enzymes, named hydrogenase[260]. In the study of the catalytic power of hydrogenase, use is made of both the exchange and conversion of hydrogen[237,261-269] and hydrogenation[263-275].

Krasna and Rittenberg[264], on the basis of a study of the kinetics of these reactions, proposed the mechanism $H_2 + E \rightleftharpoons H:E^- + H^+$, where E represents hydrogenase, and the HE^- formed takes part in hydrogenation or the exchange or conversion of hydrogen.

When Methylene Blue or hexacyanoferrate(III) is added to an aqueous suspension of *Pr. vulgaris*, D_2–H_2O exchange is inhibited, and the rate of exchange increases to its previous value only after an induction period, during which hydrogenation of the substrate takes place[265,267]. In the opinion of the authors cited, this shows that the same intermediate compound is formed during hydrogenation and exchange.

The same opinion is held by Farkas and Fisher[237], who studied the hydrogenation of fumarate in the presence of inhibitors of two types (CN and urethane).

Peck and coworkers[266] cast doubt on the idea that the catalysis of isotopic exchange by hydrogenase is a necessary condition for hydrogenating power in hydrogenase, since the rate of exchange in the presence of *Az. vin.*[276,277] and *Rhod. rubrum*[278] is very low compared with the rate of hydrogenation. Study of the catalytic activity of a wide range of micro-organisms showed that the rate of reduction of Methylene Blue is also increased by enzymes which have no significant catalytic effect on exchange. The authors cited emphasise that these results do not agree with the mechanism of Krasna and Rittenberg[264], and they put forward a reaction scheme, according to which hydrogen is activated by an iron-containing enzyme; the reduced enzyme can be oxidised by Methylene Blue or by

other acceptors, with the participation of a flavine component:

$$H_2 + E(Fe^{3+}) \rightleftarrows E(Fe^{2+}) : 2H$$
$$\downarrow \text{flavine}$$
$$\text{Methylene Blue}$$

They do not, however, exclude an alternative mechanism, according to which a complex of the reduced enzyme may combine with flavine and be oxidised by one-electron acceptors such as viologen dyes, the reaction involving a second metal atom as a functional component of the hydrogenase:

$$E(Fe^{2+})\ \text{flavine} : 2H \xrightarrow{Mo} 2\ \text{viologen} \cdot \bar{e} + 2H^+$$

The presence of iron in hydrogenase was established by Hoberman and Rittenberg[263], Peck and coworkers[266], and Gest[272]; Peck and coworkers[266] also discuss the part played by Mo.

The activation of hydrogen according to the scheme proposed by Rittenberg and Krasna is heterolytic[3]:

$$\overline{Fe^{3+}} + : B \rightleftarrows \overline{FeH^+} + H : B^+$$

whereas according to Gest and coworkers it is homolytic, the rupture of the H–H bond taking place on two metallic centres.

In heterolytic rupture of H_2, the reduction of two-electron acceptors such as Methylene Blue becomes possible, whereas one-electron processes, such as the reduction of viologen dyes and D_2–H_2O exchange, require the participation of a second metal. This explains the observation that *Az. vin.* and *Rhod. rubrum* catalyse the reduction of Methylene Blue but do not catalyse exchange.

The main features of the results obtained by Krasna and Rittenberg[265,267] in the study of the catalytic activities of various micro-organisms agree with those obtained by Peck and coworkers[266]. They found, however, that exchange is observed in all instances when reduction of Methylene Blue takes place.

Comparison of the hydrogenating power of the bacterium *Ph. vulgaris* with the activity of $[Co(CN)_5]^{3-}$ led King and Winfield[137] to the conclusion that the mechanisms of hydrogenation by hydrogenase and pentacyanocobaltate are the same.

The activation energy for D_2–H_2O exchange by means of the bacterium *Pr. vulgaris* suspended in a phosphate buffer is 7.7 kcal mole^{-1};[263] other authors give the value 14 kcal mole^{-1}.[237] Couper and coworkers[269] determined the activation energy for the exchange and conversion of hydrogen, catalysed by *Pr. vulgaris* and *E. coli*. According to their data, for *Pr. vulgaris*, the activation energy for $D_2 + H_2O$ exchange is 7.47 ± 1.11 kcal mole^{-1}, and that for the ortho-para conversion of hydrogen 7.35 ± 0.46 kcal mole^{-1}.

Thus the enzymatic catalysis of hydrogenation by means of hydrogenase involves an extremely complicated chain of catalytic processes, responsible for the exceptional activity and stereospecificity of the processes under mild conditions. In this connection, the study of transition metal compounds as catalysts of homogeneous hydrogenation gives extensive material for constructing models of biochemical processes. An exceptionally important feature is the presence of a transition metal in hydrogenase. The part played by cobalamin (an enzyme containing Co[279-281]) in hydrogen transfer is extremely important. One example of the construction of a model of this enzyme is the use of cobaloxime—a model of vitamin B_{12S}—as hydrogen carrier in a system containing a rhodium catalyst which brings about the homogeneous activation of molecular hydrogen[282].

It can confidently be stated that the study of the mechanism of action of enzymatic systems is giving valuable information for the creation of new and effective complex catalysts for homogeneous hydrogenation. The introduction, into catalytic systems, of hydrogen carriers and additives capable of activating the substrate, together with modification of the hydrogen activation catalysts themselves, is now making it possible to obtain highly effective hydrogenation catalysts.

---o0o---

The number of known systems capable of activating hydrogen under the conditions of a homogeneous reaction—Lewis bases and acids, salts and complexes of transition metals—is now extremely large. Among compounds of these classes, the transition metal complexes show the greatest activity.

The catalytic action of transition metal complexes is observed under comparatively mild reaction conditions, and their activity in the hydrogenation of organic compounds in a number of instances is as high as or even greater than that of heterogeneous catalysts. An understanding of the mechanism of action of homogeneous hydrogenation catalysts is of assistance in the investigation of the mechanism of heterogeneous catalytic hydrogenation and also the mechanisms of polymerisation, hydroformylation, and other reactions.

Electron Spin Resonance Spectra, Conformation, and Chemical Properties of Free Radicals in Solid Polymers

P.Yu.Butyagin, A.M.Dubinskaya, and V.A.Radtsig

The structure and the chemical properties of polymeric radicals having their free valency on a carbon atom in the main chain are surveyed. Most of the information on radicals in solid polymers has been obtained by electron spin resonance. The first part of the review gives a detailed analysis of the hyperfine structure of the e.s.r. spectra, which is closely related to the structure and the conformation of the radicals. The second part deals with the chemical behaviour of polymeric radicals in solid matrices at low temperatures (80-300°K). All the data relate to radicals from polymers of the vinyl series, polyoxides, and polyamides. A list of 112 references is given.

CONTENTS

I. Introduction 290
II. Electron spin resonance spectra and conformation of polymeric radicals 291
III. Chemical properties and stability of polymeric radicals 297

I. INTRODUCTION

In the vinyl series of polymers, radicals having their free valency on carbon atoms of the main chain can have the structures

$$\underset{(I)}{-CXY-\dot{C}H_2} \quad \underset{(II)}{-CH_2-\dot{C}XY} \quad \underset{(III)}{-CH_2-\dot{C}X-CH_2-} \quad \underset{(IV)}{-CXY-\dot{C}H-CXY-}$$

where X = H, CH_3, C_6H_5, OH, $COOCH_3$, $OCOCH_3$, CN, etc. and Y = H, CH_3, etc. The radicals (I)-(IV) are formed in polymers by the action of ionising radiation, ultraviolet irradiation, exposure to a laser beam, mechanically, thermally, chemically, and also during polymerisation of the monomers.

Action of Ionising Radiation

The action of X-rays, γ-rays, fast electrons, ultraviolet radiation, etc. on a polymer chain most often detaches a light atom (hydrogen) or a group of atoms, with the formation of radicals (III) or (IV). These have been detected and examined by e.s.r. in polyethylene[1,2], polyamides[3,4], polyisobutylene[5,6], poly(vinyl alcohol)[7], and other polymers. In individual cases, e.g. in the γ-irradiation[8,9] and the photolysis[10] of polyacrylate polymers, radicals of type (II) are observed.

Mechanical Treatments

Bonds in the main chain of various heterochain and carbon-chain polymers are ruptured by cutting[11-13], grinding[14-16], stretching fibres[17,18], and other types of destruction and deformation of specimens. Radicals (I) and (II) are the primary degradation products. In polyethylene[19,20], polypropylene[19], poly(vinyl alcohol)[21], polystyrene[22], and other polymers both terminal radicals have been recorded during the mechanical degradation of macromolecules distributed in a matrix of an inert substance (method of dispersion of frozen dilute solutions of polymers[21,23]). In polyethylene[19], poly(methyl methacrylate)[13], polyamides[20], polyformaldehyde[21], and several other polymers the active primary radicals are converted by secondary reactions into radicals having the free valency in the middle of the chain.

Polymerisation of Monomers

Terminal radicals of only one type, $-CH_2-\dot{C}XY$ (or $-CH_2-\dot{C}HX$), are observed in all cases in the polymerisation of monomers. In the liquid phase the steady-state concentration is usually low (10^{-9} M), and the radicals have been detected only by the initiation of polymerisation by means of redox systems directly in the resonator of a highly sensitive e.s.r. spectrometer[24-27]. Well resolved e.s.r. spectra of a large number of radicals have been obtained by this method. It is considerably easier to observe radicals at the gelatinisation stage[28], in the polymerisation of monomers which undergo cross-linking[29,30], during heterogeneous polymerisation, when the polymer is precipitated[31,32], and also in solid-phase polymerisation initiated by γ-rays or ultraviolet irradiation of the monomers[31,33-36].

Action of Atomic Hydrogen

The action of atomic hydrogen and other simple radicals on macromolecules provides a convenient chemical method for initiating polymer radicals. The hydrogen atoms are obtained by passing hydrogen over an incandescent tungsten filament[37], in a high-frequency discharge[38,39], by the photolysis of redox systems [e.g. frozen aqueous solutions of iron(II) sulphate plus sulphuric acid[40]], among other methods. The interaction of hydrogen atoms with molecules yields radicals either by addition (to the benzene ring in polystyrene[41], and to pyrimidine and purine bases in deoxyribonucleic acids[42]) or by detachment ($H + RH \rightarrow \rightarrow H_2 + R^{\cdot}$) at the site of a weak carbon-hydrogen bond.

Thus the structure of the primary radicals is determined by the type of action on the polymer: mechanical cleavage of macromolecules yields two terminal radicals; reactions with hydrogen atoms should produce radicals having the free valency in the middle of the chain or on lateral groups; polymerisation should involve the formation of $-CH_2-\dot{C}XY$ radicals; etc. Radiolysis, ultraviolet irradiation, and mechanical working are usually accompanied by secondary free-radical reactions, and the structure of the final radicals, which are stable under the given conditions, will depend in considerable measure on the nature, state, and properties of the polymer. Secondary

reactions can be inhibited by lowering the temperature, using inert matrices, or other methods.

In many cases the generation of radicals is accompanied by changes in the structure and the properties of the polymer chain: new functional groups appear, the molecular weight diminishes, cross-links are formed between molecules, the secondary structure of the polymer changes, etc. These changes must be taken into account in analysing the properties of the radicals and the kinetics of the secondary free-radical reactions.

II. ELECTRON SPIN RESONANCE SPECTRA AND CONFORMATION OF POLYMERIC RADICALS

The chief characteristic of the e.s.r. spectra of polymer radicals is their hyperfine structure. The number and position of the lines constituting this structure depend on the location of the free valency in the macromolecule and the conformation of the radical, the angle of rotation about the $C(\alpha)-C(\beta)$ bond. The hyperfine structure of the spectra of alkylated radicals results from interaction of the unpaired electron with the magnetic nuclei of the α- and β-hydrogen atoms:

$$\rangle C_{(\beta)}H-\dot{C}_{(\alpha)}H-\dot{C}_{(\beta)}H\ .$$

The hyperfine interaction with α-protons comprises two parts—isotropic and anisotropic—the latter depending on the orientation of the $C(\alpha)-H$ bond in the magnetic field[43]. The position of a line in the e.s.r. spectra of polycrystalline and amorphous specimens is determined solely by the isotropic portion of the hyperfine interaction, while the anisotropic part merely broadens the line[44]. With oriented specimens the anisotropy of the hyperfine interaction leads to a considerable shift in individual components of the spectrum[2,45]. Hyperfine interaction with β-protons is mainly isotropic.

It is as yet impossible to calculate theoretically the hyperfine interaction in complicated radicals, and analysis of the spectra is based on semi-empirical relations established[24,26,46-50] from the study of dozens of spectra. Quantitative estimates of the isotropic hyperfine interaction constants are founded on measurements of the e.s.r. spectra of radicals of low molecular weight in the liquid phase, where the hyperfine structure is well resolved and the positions of the lines are fixed with great accuracy.

1. Semi-empirical Rules for the Analysis of Electron Spin Resonance Spectra

The width of an e.s.r. spectrum—the distance between the extreme lines of the hyperfine structure—is given by the sum of the values for the splitting on all the α- and β-protons:

$$\Sigma a_H = \Sigma a_H(\alpha) + \sum_i a_H(\beta_i)\ . \qquad (1)$$

According to McConnell[47] the spectroscopic splitting constant $a_H(\alpha)$ for each α-proton is given by

$$a_H(\alpha) = Q_\alpha \cdot \rho \qquad (2)$$

where ρ is the spin density of the unpaired electron on the α-carbon atom, and Q_α a coefficient of proportionality, whose value depends on the nature of the bonds and the type of substituents.

In substituted alkyl radicals the density of the unpaired electron on the α-carbon atom is determined by the nature of the substituents[46,49]. In radicals of the type

$$X-\dot{C}(Z)-Y$$

the value of ρ can be calculated by means of the formula

$$\rho = (1-\Delta X)(1-\Delta Y)(1-\Delta Z)\ . \qquad (3)$$

The quantity ΔX indicates the fraction of the spin density which the substituent X attracts to itself, it being assumed that each substituent behaves independently of the others. Table 1 gives the values of ΔX for various functional groups, all calculated from experimental data[46,49]. For the methyl groups theoretical calculations have also been made[51]. For the hydrogen atom $\Delta H = 0$, and the decrease in spin density for alkyl substituents and groups of the types CH_2R and COOR does not exceed 10%. The "strongest" substituents are the carbonyl, ether, and hydroxyl groups, where the diminution in density reaches 15–18%.

Table 1. Values of the parameter $\Delta(X)$ for various substituents in alkyl radicals[46,49].

X	Δ(X)	X	Δ(X)
—H	0.000	—COOR	0.072
$-CH_3$	0.081	—OCHO	0.136
$-C_2H_5$	0.082	$-OCH_2CH_3$	0.180
$-CH_2CH_2OH$	0.092	—OH	0.160
$-CH_2OH$	0.079	—CN	0.148
$-CH_2COOR$	0.080	$-C_6H_5$	0.290*
$-CH_2NH_2$	0.034	$-[CH_2-C(CH_3)(COOH)]_n$	0.101
—CH(OH)COOH	0.041	$-[CH_2-CH(COOH)]_n$	0.050
$-C(C_6H_5)_3$	0.044		

*For the radicals $C_6H_5\dot{C}(CH_3)_2$ of isopropylbenzene $a_H(CH_3) = 17.5$ oersteds. Hence according to Eqns. (3) and (11) $\rho = 17.5/29.3 \simeq 0.6$ and $\Delta(C_6H_5) \simeq 0.290$.

Table 2 gives values of the parameter Q_α for α-protons in alkyl and alkylated radicals. When the substituent X is bound to the α-carbon atom by a C–C bond (CH_2R, COOH, etc.), the values usually fluctuate within the limits $Q_\alpha = 24.1 \pm 0.7$ oersteds. The alkyl radicals $R_1\dot{C}HR_2$ (where $R = CH_3$, C_2H_5, etc.) form an exception, Q_α being rather larger. For radicals in which the substituent is bound to the α-carbon atom by a C–O bond, the parameter Q_α is almost 5 oersteds smaller: $Q_\alpha = 19.4 \pm 1.0$ oersteds.

The hyperfine structure constant for β-protons depends on the conformation of the radical[48]—the angle of rotation about the $C(\alpha)-C(\beta)$ bond:

$$a_H(\beta) = Q_\beta \cdot \rho \cdot \cos^2\theta, \qquad (4)$$

where Q_β is a constant whose value for alkylated radicals is 58.6 oersteds[24,26], and θ is the angle between the axis of the $2p_z$-orbital of the unpaired electron and the projection of the $C(\beta)-H$ bond on a plane perpendicular to the $C(\alpha)-C(\beta)$ bond (Fig. 1).

The relation (4) is valid provided the amplitude of oscillations of the $C(\alpha)-C(\beta)$ bond about the equilibrium position θ_0 is small. With large amplitudes (tens of degrees) we must replace $\cos^2\theta$ in Eqn. (4) by the value

$\langle\cos^2\theta\rangle$,[57] averaged over the internal motions in the radical (vibrations or rotation). The averaged value is connected with the equilibrium value by the formula

$$\langle\cos^2\theta\rangle = A + B\cos^2\theta_0 \qquad (5)$$

where A and B depend on the temperature and the form of the potential curve for the internal motions in the radical. As $T \to 0$, we have $A \to 0$ and $B \to 1$.

Table 2. Value of the parameter $Q(\alpha)$ for X–$\dot{C}$H–Y radicals (calculated from data of Refs. 24, 26, 46, 52–55).

X	Y: –H	Y: –CH_3, –CH_2CH_3	Y: –CH_2NH_2, –CH_2OH
–H	23.0	24.2±0.2	—

*Value obtained from $a_H(\alpha)$ = 16.4 oersteds for the benzyl radical[56].

In polymer radicals in the solid phase at low temperatures, movements in the radicals are usually strongly retarded, and Eqn. (4) can perfectly well be used for analysing the hyperfine structure of the e.s.r. spectra. Equation (5) must be employed to investigate the temperature dependence of the splitting on the β-protons.

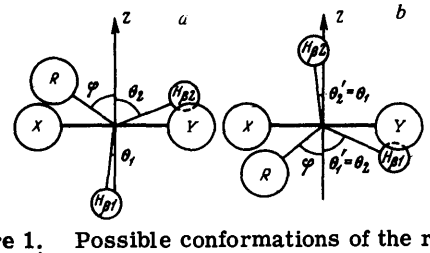

Figure 1. Possible conformations of the radical R–CH_2–$\dot{C}$XY.

The influence of the conformation of the radicals on the form of the e.s.r. spectra is best seen from the example of radicals have a β-methylene group

$$R-CH_2-\dot{C}(Y)-X.$$

In Fig. 1 the carbon atom C is located in the plane of the paper, the thick lines indicate the projections of the $C_{(\alpha)}$–X and $C_{(\alpha)}$–Y bonds, while the ordinary lines represent $C_{(\beta)}$–H and $C_{(\beta)}$–R bonds. The Z-axis is the axis of the orbital of the unpaired electron. The angle φ, where (see Fig. 1)

$$\theta_1 = \frac{\pi}{3} + \varphi, \quad \theta_2 = \frac{\pi}{3} - \varphi, \qquad (6)$$

characterises the conformation of the radical.

The two equilibrium positions (a) and (b) are energetically equivalent. The lifetime of the radical in each of these positions is

$$\tau = \tau_0 \exp\left(\frac{E}{RT}\right) \qquad (7)$$

where τ_0 is the period of the oscillations and E the height of the potential barrier which must be overcome for transition from one conformation to the other. The number of components of the hyperfine structure in the e.s.r. spectrum depends on the relation between the frequency of the conformational transitions and the quantity $\nu_a - \nu_b$,[58] in which ν_a and ν_b are the frequencies of hyperfine interaction for β-protons in conformations (a) and (b). This difference $\nu_a - \nu_b$ is usually close to 10^7–10^8 s^{-1}. Three cases are possible.

With a high barrier at low temperatures, $\tau \gg (\nu_a - \nu_b)^{-1}$, and the e.s.r. spectrum consists of the sum of the signals corresponding to conformations (a) and (b) (the β-protons are non-equivalent). Then

$$a_H(\beta\text{-}1) = Q_\beta \cdot \rho\cos^2\left(\frac{\pi}{3} + \varphi\right) \text{ and } a_H(\beta\text{-}2) = Q_\beta \cdot \rho\cos^2\left(\frac{\pi}{3} - \varphi\right). \qquad (8)$$

The constants $a_H(\beta\text{-}1)$ and $a_H(\beta\text{-}2)$ are interrelated. In Fig. 2 the ordinates represent $f_1 = \cos^2(\frac{1}{3}\pi + \varphi)$ and $f_2 = \cos^2(\frac{1}{3}\pi - \varphi)$, while the abscissae are the conformational angles φ. When $\varphi = 0$ and 90° the splitting is the same on the two β-protons. Over the range $20° < \varphi < 40°$ the splitting on one of the β-protons is small, and is hardly observable in poorly resolved e.s.r. spectra of polymer radicals.

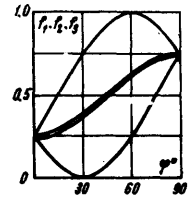

Figure 2. Graphs of the functions

$$f_1 = \cos^2\left(\frac{\pi}{3} + \varphi\right),$$

$$f_2 = \cos^2\left(\frac{\pi}{3} - \varphi\right)$$

and

$$f_3 = \tfrac{1}{2}\left[\cos^2\left(\frac{\pi}{3} + \varphi\right) + \cos^2\left(\frac{\pi}{3} - \varphi\right)\right]$$

(double line).

Rapid alternation of conformations results in an averaging of the hyperfine interaction constants, and when $\nu \ll (\nu_a - \nu_b)^{-1}$ the β-protons are equivalent:

$$a_H(\beta\text{-}1) = a_H(\beta\text{-}2) = \tfrac{1}{2}Q_\beta \cdot \rho\left[\cos^2\left(\frac{\pi}{3} + \varphi\right) + \cos^2\left(\frac{\pi}{3} - \varphi\right)\right]. \qquad (9)$$

The dependence of $f_3 = \frac{1}{2}[\cos^2(\frac{1}{3}\pi + \varphi) + \cos^2(\frac{1}{3}\pi - \varphi)]$ on φ for this case is shown by the double line in Fig. 2. The splitting is a maximum at $\varphi = 90°$.

In the intermediate case, when the frequency of interchange is comparable with the frequency of conformational transitions, i.e. $\tau \simeq (\nu_a - \nu_b)^{-1}$, exchange broadening of the central lines of the spectrum will be observed. This comparatively rare case has been examined in detail[24,46].

From Eqns. (8) and (9) it is seen that the total splitting on the β-protons is independent of the frequency of the transitions, being determined solely by the conformation of the radical. We always have

$$a_H(\beta\text{-}1) + a_H(\beta\text{-}2) = Q_\beta \cdot \rho \left[\cos^2\left(\frac{\pi}{3} + \varphi\right) + \cos^2\left(\frac{\pi}{3} - \varphi\right)\right] . \quad (10)$$

Calculation of the hyperfine interaction constants is considerably simplified for the radicals

$$CH_3-\dot{C}(Y)-X$$

containing a β-methyl group, since even at low temperatures the methyl groups rotate about the $C_{(\alpha)}-C_{(\beta)}$ bond at a frequency exceeding that of the hyperfine interaction (free rotation[46,59]), and all three β-protons are equivalent. With free rotation

$$\cos^2\theta = {}^1/_2\pi \int_0^{2\pi} \cos^2\theta d\theta = {}^1/_2 \text{ and } a_H(CH_3) = {}^1/_2 Q_\beta \rho = 29.3\rho . \quad (11)$$

Thus, in the analysis of the e.s.r. spectra of alkylated radicals, the hyperfine structure constants for α-protons and the protons of β-methyl groups can be estimated to ~ 5% from Eqns. (2), (3), and (11) and Tables 1 and 2. With $a_H(\alpha)$ and $a_H(CH_3)$ known, the total width of the spectrum depends solely on the splitting on the β-protons, of CH_2R or CHR_1R_2 groups, i.e. on the angle of rotation about the $C(\alpha)-C(\beta)$ bond. Consequently the conformation of the radical can be determined when the total width of the spectrum is known; and conversely, if the conformation is known, the position of all the lines in the spectrum can be predicted.

Actual examples of the analysis of e.s.r. spectra of polymer radicals belonging to various types will be examined in the following section.

2. Electron Spin Resonance Spectra of the Main Types of Polymer Radicals

Data on the e.s.r. spectra at 77°K of polymer radicals having the free valency at the ends and in the middle of the chain are assembled in Figs. 3–5. In most cases we have determined the values of ρ, Q, a_H, and φ from an analysis of the e.s.r. spectra published by various authors; the hyperfine structures were analysed according to the rules formulated in the preceding Section. Individual spectra and the corresponding schemes of energy levels are shown in Figs. 3 and 4. In most cases there is no doubt about the reliability of the interpretation of the spectra, which either is proved by direct methods (investigation of oriented specimens[2,4,60], deuteriated radicals[3,61], etc.) or is supported by many indirect data, from the method of preparing the radicals to analysis of the expected conformation.

In compiling the tables the hyperfine structure constants for α-protons $a_H(\alpha)$ and the protons of methyl groups $a_H(CH_3)$ were calculated by means of Eqns. (2) and (11). Values of ρ were estimated by means of Eqn. (3) with the data in Table 1 taken into account; the electron density drawn off by the polymer chain was taken to be 0.08. The constant Q_α was determined from Table 2. The splitting on β-protons of CHX and CH_2 groups was found as the difference between the total width of the spectrum† and the value of the expression $\Sigma a_H(\alpha) + \Sigma a_H(CH_3)$. The ratios between $a_H(\beta\text{-}1)$ and $a_H(\beta\text{-}2)$ and the conformational angle φ were determined from the graph in Fig. 2.

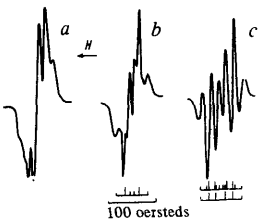

Figure 3. Electron spin resonance spectra of terminal radicals (at 80°K) in: *a*, *b*) poly(vinyl alcohol); *c*) polyethylene.

(*a*) R–$\dot{C}H_2$ radicals

Terminal CXY–$\dot{C}H_2$ radicals are distinguished by high chemical activity in reactions involving transfer of the free valency (see Section III, 1), so that it is very difficult to isolate and investigate them. Radicals of type (I) have been fixed by the low-temperature mechanical degradation of polymers (linear polyethylene[19,20], polycaprolactam[20]), by the dispersion of frozen dilute solutions of poly(vinyl alcohol)[21], polystyrene[22], and certain other polymers, and by the radiolysis of polyformaldehyde[60].

Radicals CXY–$\dot{C}H_2$ are formed together with radicals of other types (II) and (III), and the e.s.r. spectra are usually the result of the superposition of two or three signals. As a rule, however, lines belonging to radicals of type (I) are less easily saturated than are the remaining signals. This facilitates the isolation and interpretation of the spectra of CXY–$\dot{C}H_2$ radicals (Table 3). However, the accuracy with which the hyperfine interaction constants are determined remains low (1–3 oersteds).

Fig. 3 shows as example the spectra (*a*) and (*b*) of free radicals formed at the site of cleavage of the polymer chain of poly(vinyl alcohol) (1% frozen solution in D_2O after dispersion in a vacuum at 90°K). The spectrum 3*a* corresponds to a low microwave power and 3*b* to a high microwave power (~ 0.5 and ~ 50 mV respectively). With a low power the lines of the $CH(OH)\dot{C}H_2$ and $CH_2\dot{C}H(OH)$ signals make roughly the same contribution to the overall spectrum, whereas at high microwave powers the signal due to the latter radicals is saturated, and the symmetrical spectrum of CH(OH)–$\dot{C}H_2$ radicals predominates (Fig. 3*b*). The width of the latter is 80 oersteds, and the splitting on each α-proton is $a_H(\alpha) = Q_\alpha\rho = 24.4 \times 1 \times 1 \times (1 - 0.08) = 22$ oersteds. Hence $a_H(\beta) = 80 - 2 \times 22 = 36$ oersteds. The set of levels of the hyperfine structure is shown below the spectrum.

† The total width of the spectrum was determined with the finite width of individual components allowed for[62].

The e.s.r. spectrum of the terminal radicals $CH_2-\dot{C}H_2$ is obtained by the mechanical disintegration of linear polyethylene in an inert atmosphere at 80°K.[19,20] The total width of the spectrum[20] is 115 oersteds, while $a_H(\alpha) = 22$ oersteds, and the splitting on the β-protons is $a_H(\beta\text{-}1) + a_H(\beta\text{-}2) = \Sigma a_H - 2a_H(\alpha) = 115 - 2 \times 22 = 71$ oersteds. Hence with $Q_\beta = 58.6$ and $\rho = 0.92$, we have

$$\frac{^1/_2\,[a_H(\beta\text{-}1) + a_H(\beta\text{-}2)]}{58.6 \cdot 0.92} = 0.66.$$

In Fig. 2 the ordinate 0.66 intersects the double line of the graph at the conformational angle $\varphi = 68°$. With non-equivalent β-protons and $\varphi = 68°$, we have $a_H(\beta\text{-}1) = 53$ oersteds and $a_H(\beta\text{-}2) = 18$ oersteds. The upper set of hyperfine structural levels below the spectrum 3*c* corresponds to these values. The actual splittings on the β-protons, 50 and 21 oersteds respectively, differ by ±3 oersteds from the calculated values (see lower scheme in Fig. 3*c*). The difference may be due to strong internal motion about the $C(\alpha)-C(\beta)$ bond. The barrier to rotation in the $CH_2-\dot{C}H_2$ radical is probably low, and the exact equation (5) should be used instead of the approximate formula (4) for a rigorous calculation of $a_H(\beta)$.

In $CHX-\dot{C}H_2$ and CH_2-CH_2 radicals, in contrast to $\rangle C-CH_3$ radicals, there is no free rotation about the $C(\alpha)-C(\beta)$ bond, and the conformational angle φ depends on the nature of the substituent X (see Table 3). With radicals containing a single β-proton, the same value of $a_H(\beta)$ may correspond to two different conformations (the angles φ_1 and φ_2, where $\varphi_1 + \varphi_2 = 2\pi/3$). Table 3 gives only the angle φ_1.

(*b*) $CH_2-\dot{C}HX$ and $CH_2-\dot{C}(CH_3)X$ radicals

In most cases polymer radicals of type (II) can be obtained by the polymerisation of monomers in viscous and solid media. Hence there is no doubt that the e.s.r. spectra in Table 4 do actually belong to $CH_2-\dot{C}XY$ radicals.

Fig. 4*a* shows the spectrum of $CH_2-\dot{C}H(COOCH_3)$ radicals, which is a triplet of width 46 ± 1 oersteds. In this case $a_H(\alpha) = 23.5 \times 1 \times (1 - 0.08)(1 - 0.07) = 20$ oersteds. For the determination of $a_H(\beta\text{-}1)$ and $a_H(\beta\text{-}2)$ Fig. 4*a* shows a scheme of hyperfine levels corresponding to values of the angle φ from 0 to 22.5°. A triplet 46 oersteds wide can be obtained with $a_H(\beta\text{-}1) = 25$ oersteds and $a_H(\beta\text{-}2) = 3$ oersteds ($\varphi = 15°$).

The spectrum in poly-α-methylstyrene comprises 16 hyperfine components each separated by 5.5 oersteds (Fig. 4*c*), this splitting being due to interaction of the unpaired electron with the *ortho*- and *para*-protons of the benzene ring. A similar "aromatic" hyperfine structure has been observed in the spectra of the relatively simple radicals $C_6H_5\dot{C}H_2$, $C_6H_5\dot{C}H(CH_3)$, etc.[56,64] A 16-component spectrum of $CH_2-\dot{C}(CH_3)(C_6H_5)$ radicals can be obtained with two values of φ: when $\varphi = 6°$, we have $a_H(\beta\text{-}1) = 11$ and $a_H(\beta\text{-}2) = 5$ oersteds; the corresponding values with $\varphi = 15°$ are 17 and 2 oersteds. Choice of the correct alternative requires a knowledge of the relative intensities of the spectral lines: i.e. the spectrum in the liquid phase must be obtained.

No splitting on the protons of the benzene ring is detected in the spectrum of $CH_2-\dot{C}H(C_6H_5)$ radicals (Fig. 4*b*). In this case, perhaps, the "aromatic" hyperfine structure is obscured by the splitting of 3 oersteds on one of the β-protons of the methylene group.

Table 4 shows that $a_H(\beta\text{-}1) \neq a_H(\beta\text{-}2)$ for all radicals of type (II) at 77°K: i.e. the frequency of conformational transitions is low. In $CH_2-\dot{C}HX$ radicals other than $CH_2-\dot{C}H(CH_3)$ the angle of rotation about the $C(\alpha)-C(\beta)$ bond lies within the range $\varphi = 15-17°$: i.e. the nature of the substituent X (COOH, $COOCH_3$, C_6H_5, CN) has no great effect on the conformation of the radical. The conformation is also practically independent of X for all $CH_2-\dot{C}X(CH_3)$ radicals, the angle φ being in this case 0–5°. The appearance of a second substituent on the α-carbon atom leads to a diminution in the angle φ.

Electron spin resonance spectra of radicals have recently been obtained by the irradiation of frozen monomers such as isobutene[65], methyl methacrylate[36], and methacrylonitrile[33]. These spectra are attributed to $CH_2-\dot{C}(CH_3)X$ radicals, but the hyperfine structure constants for the β-protons differ from the values in Table 4. The discrepancy can be explained on the assumption that the angle φ in the radicals of the irradiated monomers is ~ 15° instead of 0–5°. The reasons for the appearance of such a conformation in the solid-phase polymerisation of monomers are still not clear.

With rise in temperature from 80° to 320°K the β-protons remain non-equivalent in the e.s.r. spectrum of $CH_2-\dot{C}(CH_3)X$ radicals[50]. The energy barrier to conformational transitions is lower in $CH_2-\dot{C}HX$ than in $CH_2-\dot{C}(CH_3)X$ radicals, and in the liquid phase at room temperature the β-protons become equivalent[24,27].

(*c*) $CXY-\dot{C}H-CXY$ and $CH_2-\dot{C}X-CH_2$ radicals

Table 5 gives the parameters of the e.s.r. spectra for "central" radicals of types (III) and (IV). In polymers containing quaternary carbon atoms in the main chain—poly(methyl methacrylate), polyisobutene, poly-α-methylstyrene—the spectrum of the $CXY-\dot{C}H-CXY$ radicals is a doublet with a separation of 21 oersteds. In polyformaldehyde ($O-\dot{C}H-O$ radicals) the splitting on the α-proton is considerably smaller: $a_H(\alpha) = 15$ oersteds. In polymers containing tertiary carbon atoms the hyperfine structure of the e.s.r. spectra of the $CH_2-\dot{C}X-CH_2$ radicals depends on the conformation of the radical.

The spectrum of the $CH_2-\dot{C}H-CH_2$ radicals in polyethylene comprises six hyperfine components, its overall width being 160–165 oersteds. With $a_H(\alpha) = 24.4 \times 0.84$ [? × 0.92 (Ed. of Translation)] = 22 oersteds the total splitting on the β-protons of each methylene group is $\frac{1}{2}(162 - 22) = 70$ oersteds. In order to obtain a six-component spectrum it must be supposed that the β-protons are already equivalent at 77°K: $a_H(\beta\text{-}1) = a_H(\beta\text{-}2) = 35$ oersteds. Barriers to internal movements are probably low in the polyethylene radical $-CH_2-\dot{C}H-CH_2-$.

The conformation of the chains in polymers of regular structure in the crystalline state has been established by means of X-ray and electron diffraction[74]. The conformation of a macromolecule, like that of a radical, can conveniently be characterised by the angles ψ of internal rotation about a C–C bond of the carbon skeleton. For the fragment $R_1-C_\beta H_2-C_\alpha HX-R_2$, for example, this is the angle between the projections of the $C-R_1$ and $C-R_2$ bonds on a plane perpendicular to the $C_\alpha-C_\beta$ bond.

For crystalline polymers having planar *trans*-bonds—polyethylene, poly(ethylene oxide), poly(vinyl alcohol)—the angle $\psi = 180°$. In polymers which crystallise in the form of 3_1-spirals (isotactic polypropylene and polybut-1-ene) the methylene groups on the left and on the right of the α-carbon atom ($CH_2-C_\alpha HX-CH_2$) are characterised by the angles $\psi_1 = 180°$ and $\psi_2 = 60°$.

The angle ψ may change on formation of a radical having its free valency in the middle of the polymer chain $CH_2-\dot{C}X-CH_2$. In all the polymer radicals investigated (Table 5) the two methylene groups are characterised by the same conformational angle (radicals have been observed in amorphous specimens of isotactic polypropylene and polybut-1-ene).

Table 6 gives the angles of internal rotation in polymeric molecules ψ and radicals ψ', together with the difference between them. The rotation of the portions of macromolecules about a C–C bond on abstraction of a hydrogen atom and formation of a radical is extremely large, amounting to several tens of degrees.

3. Conformations of Polymer Radicals

For all polymer radicals the hyperfine interaction constants of the α-protons vary within the range 15–22 oersteds depending on the nature and the number of substituents. The radical cannot contain more than two α-protons, and there is usually no difficulty about assigning their lines in the e.s.r. spectrum. The character of the spectrum—its width, number of components, intensity ratio—is determined in considerable measure by interaction of the unpaired electron with the β-protons, the number of which may reach 6–9. The splitting on each β-proton may vary from 0 to 50 oersteds, and is directly connected with the conformation of the radical, the angle of rotation about the $C(\alpha)-C(\beta)$ bond. When the conformational angles for the groups $C(\beta)H_2$ and $C(\beta)HX$ are known, the whole spectrum can be constructed for a given radical.

Theoretical calculation of the conformations of free radicals, like that of molecules, requires the many-elec-

$-C(CH_3)(C_6H)_5-\dot{C}H-$ $-C(CH_3)(C_6H_5)-$ Poly-α-methylstyrene	2	21	0.85	25	21	—	—	—	—	M	70

*For radicals containing two or three β-methylene groups they all have the same conformation. For the radical $CH\beta_1H\beta_2-\dot{C}X-CH\beta_3H\beta_4$, for example, $a_H(\beta_1) = a_H(\beta_3)$ and $a_H(\beta_2) = a_H(\beta_4)$.
**The structure of the radicals formed by the irradiation of polypropylene has not yet been established unambigously, in spite of the large amount of work done [71-73].

tron problem to be solved, and has not yet been accomplished. However, analysis of the experimental data enables several qualitative relations to be established for the effect of various substituents on the conformation of alkyl radicals and on the height of the potential barrier determining the frequency of conformational transitions.

The angle of rotation about the $C_{(\alpha)}-C_{(\beta)}$ bond is determined by interaction of the substituents on the α-, β-, and γ-carbon atoms both among themselves and with neighbouring molecules. At low temperatures the e.s.r. spectra of a given radical in different matrices are usually the same: i.e. the medium in which the radicals are distributed probably has no effect on their conformation, and intermolecular interactions can be disregarded to a first approximation‡.

In all alkyl radicals having a β-methyl group $H_3C-\dot{C}XY$ the barrier to rotation about the $H_3C-C_{(\alpha)}$ bond is low, not exceeding 100 cal mole^{-1}; the methyl groups rotate freely down to 10°K. [59,75] On passing to radicals containing a β-methylene group $R-CH_2-\dot{C}XY$ (and also $>CH-\dot{C}XY$) the height of the barrier to internal rotation about the $C_\alpha-C_\beta$ bond rises sharply (by factors of 10–100); the equilibrium conformation of the radical is governed by the energetically most favourable relative arrangement of the substituents attached to the α- and β-carbon atoms. The sharp rise in the barrier is connected with the change in symmetry of the substituent (from C_{3V} for the CH_3 group to C_{1V} for RCH_2) when one of the methyl hydrogen atoms is replaced by an alkyl group R. The rise in the barrier can be regarded as resulting from interaction of the group R with the α-substituents X, Y and the unpaired electron.

‡ The height of the potential barrier to internal movements in the radicals, i.e. the temperature dependence of the hyperfine structural constants, is probably connected with the nature of the matrix.

Table 6. Change in conformation of polymer chain on formation of "central" radicals.

Polymer	Radical	ψ^* (mol.)	ψ' (radical)	$(\psi - \psi)^\circ$
Polyethylene	$R-CH_2-\dot{C}H-CH_2-R$	180	160	20

		60	115	55
			65	5
Polybut-1-ene	$R-CH_2-\dot{C}(C_2H_5)-CH_2-R$	180	110	70
		60	110	50
			70	10

*From Ref. 74.
**The ambiguity in the value of the angle ψ' for the radical is due to the two possible orientations of the group R relative to the orbital axis of the unpaired electron.

In the simplest terminal radical $CH_2-CH_2-\dot{C}H_2$ (polyethylene, Table 3) let us denote by R the polymer chain beginning with the γ-carbon atom. The conformation of the radical is shown in Fig. 5*a*. The angle of rotation about the $C_{(\alpha)}-C_{(\beta)}$ bond is determined to a first approximation by the interaction of the group R with the α-substituents—the two hydrogen atoms and the unpaired electron—and has the value 68°. The group R is remote from the orbital of the unpaired electron (the *Z*-axis): i.e. it is more strongly repelled from it than from the hydrogen atoms.

In the radical $CH_2-\dot{C}(CH_3)_2$ (polyisobutene, Fig. 5*b*, $\varphi = 2°$) the substituent R is "overshadowed" by the orbital of the unpaired electron. Consequently the most important factor here is repulsion of the group R from the α-methyl groups, while interaction with the unpaired electron is less effective.

It is seen from these two examples that, in alkyl radicals, repulsion of the β-group R (CH_3, C_2H_5, etc.) from the α-substituents becomes stronger in the sequence

$$\text{Hydrogen atom} < \text{Unpaired electron} < \text{Alkyl substituent} . \qquad (12)$$

This sequence is consistent also with an analysis of a large number of e.s.r. spectra for the lower alkyl radicals, and can be used to predict the conformations of alkyl radicals having various structures.

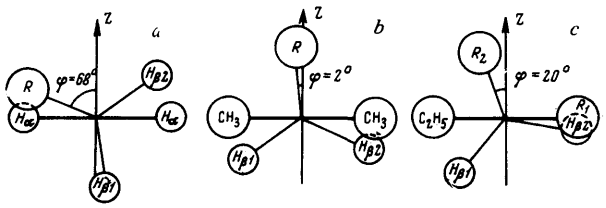

Figure 5. Conformation of polymer radicals:
a) terminal radical in polyethylene $R-CH_2-\dot{C}H_2$;
b) terminal radical in polyisobutene $R-CH_2-\dot{C}(CH_3)_2$;
c) central radical in polybut-1-ene $R_1-\dot{C}(C_2H_5)CH_2-R_2$.

The conformations of the radicals in polyalkenes (Tables 3–5) show good consistency with the requirements of the sequence (12). As example let us examine the conformation and the e.s.r. spectrum of radicals having the free valency in the centre of the chain in polybutene

$$R_1\underset{(3)}{-CH_2-}\underset{(1)}{\dot{C}}(C_2H_5)\underset{(2)}{-CH_2-}R_2$$

(Fig. 5*c*). There is no generally accepted interpretation of the e.s.r. spectrum of this radical[67,68]. We shall regard the 1-ethyl group and the right-hand part of the chain as substituents on the α-carbon atom. The group R_1 (the left-hand portion of the polymer chain) is repelled from the alkyl substituents CH_2-R_2 and C_2H_5 more strongly than from the unpaired electron; consequently the angle should be small, and from the graph in Fig. 2 the splitting on one β-proton will be negligible, while that on the other will be close to half the maximum value ($Q_{\beta\rho}$). The conclusion remains unchanged if the groups C_2H_5, R_1, and R_2 change places: i.e. only one β-proton will be involved in the splitting in each of the three methylene groups, and the e.s.r. spectrum should be a quadruplet 70–80 oersteds wide. The spectrum observed on the radiolysis and the mechanical degradation of amorphous polybutene actually comprises four hyperfine lines with $a_H(\beta) = 29$ oersteds.

Prediction of the conformations (and the e.s.r. spectra) of radicals containing the substituents CN, NH_2, COOH, $OCOCH_3$, C_6H_5, etc. is difficult because of differences in the nature of the forces of interaction between polar groups, groups capable of forming hydrogen bonds, etc. For radicals $CH_2-\dot{C}XY$, where X and Y are bulky substituents, the conformation can be established by constructing models.

Fig. 6 shows as example photographs of models of the terminal radicals in (*a*) polyethylene and (*b*) polyisobutene. The photographs illustrate the role of steric hindrance in determining the conformation of the radicals. In polyethylene the hydrogen atoms are freely arranged, and rotation to any angle is in principle possible about the $C(\alpha)-C(\beta)$ bond. In polyisobutene the chain is considerably more compact, and the angle of rotation about the $C(\alpha)-C(\beta)$ bond in the terminal radical is restricted to values at which the van der Waals radii of the substituents do not overlap. In poly(methyl methacrylate) and poly-α-methylstyrene the possible conformation of terminal radicals found from electron models agrees with results obtained by the e.s.r. method (Table 5).

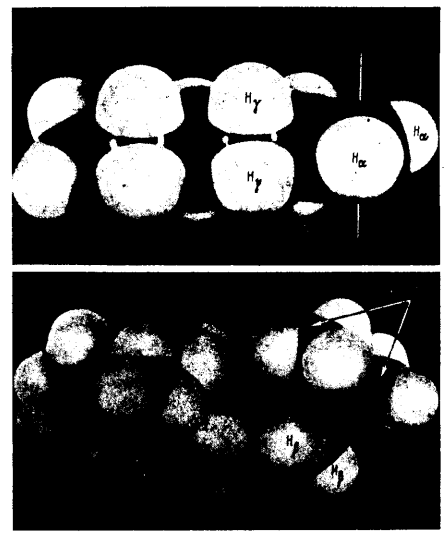

Figure 6. Models of the radicals $\sim CH_2-CH_2-\dot{C}H_2$ (polyethylene) and $\sim CH_2-C(CH_3)_2-CH_2-\dot{C}(CH_3)_2$ (polyisobutene). The axis of the orbital of the unpaired electron is shown by the white line.

Thus the conformations of alkyl radicals and certain complicated substituted radicals can be predicted from a consideration of the forces of interaction between the substituents and an examination of electron models. The accuracy with which the conformational angles can be predicted is not good (10–15°), but even such estimates are of great value in analysing poorly resolved e.s.r. spectra of polymer radicals in the solid phase.

III. CHEMICAL PROPERTIES AND STABILITY OF POLYMERIC RADICALS

The chemical behaviour of polymer radicals at low temperatures is governed primarily by the reactivity of the radicals and the molecules with which they interact, and secondarily by the possibility of encounters and contacts between the reactant species. These two factors are undoubtedly closely interlinked.

The lifetime of radicals in solid polymers may be unlimited, the reason being solely the impossibility of their moving and meeting one another. Under the most favourable conditions (rubbers of low molecular weight in a highly elastic state) the coefficient of self-diffusion at 370°K does not exceed 10^{-13}–10^{-14} $cm^2\ s^{-1}$:[76,77] i.e. several hours are required to overcome a distance of 10^2–10^3 Å [$x = (2Dt)^{\frac{1}{2}}$], where D is the coefficient of self-diffusion, x the diffusion

distance, and t the time]. In the vitreous state the movement of macromolecules is retarded, and radicals in such systems are said to be frozen.

The rate of diffusion of substances of low molecular weight in solid polymers is also low, usually less than the rate of many chemical reactions. Thus the rate of interaction with monomers of chain carriers is governed by the diffusion of these compounds to the polymer radicals [78]. The addition of oxygen molecules to polymeric alkyl radicals in films and massive specimens is also limited by the diffusion of oxygen [78,79].

In analysing the kinetics of reactions in highly viscous media use is made of the concept of a cage, cell, or element of volume, inside which the particles react with one another. In order to react, the particles must be present in the same cage. An important factor in decomposition reactions is the escape of the newly formed particles from the cage. This approach was first formulated by Frank and Rabinowitch [80], and is now generally accepted. The e.s.r. method has recently been used to detect polymer radicals [81] and those of low molecular weight [82] at distances of several Ångström units from one another.

The formal kinetic equation for the rate of a bimolecular reaction in the solid phase, which takes into account the stages of migration of active centres when their distribution is homogeneous§ and interaction of the reactant particles in a single element of volume, is [84]

$$\frac{dC_A}{dt} = k_m C_A \ln\left(1 - \frac{k_i V^* C_B}{k_i + k_m}\right) \qquad (13)$$

where C_A and C_B are the concentrations of the mobile reactant A particles and the stationary reactant B particles, k_m is the frequency (in s^{-1}) with which A particles jump from one cage to another, k_i (s^{-1}) the reaction rate constant inside the cage, and V^* the volume of the cage.

When $k_i V^* C_B \ll k_i + k_m$ the kinetic law is described by the usual second-order equation

$$-\frac{d\bar{C}_A}{dt} = k_{eff} C_A C_B \qquad (14)$$

where

$$k_{eff} = \frac{k_i \cdot k_m}{k_i + k_m} \cdot V^*. \qquad (15)$$

When radicals combine with one another in solid polymers, the rate of migration is always less than the reaction velocity in the cage ($k_m \ll k_i$), so that

$$\frac{dc}{dt} = 2k_m C \ln(1 - V^* C) \ . \qquad (16)$$

In most cases the rate constant and the activation energies for the reactions of radicals in solid polymers are characteristic of the process of migration of the free valency (k_m)¶, not the actual chemical activity of the reactant species (k_i). This category of experimental data includes the results of numerous kinetic investigations of the destruction of radicals in polymers [85-90], as well as individual measurements of the rate constants for reactions of radicals with monomers and chain-transfer agents [78].

Information on the reactivity of radicals has been obtained in systems in which polymer radicals are surrounded by reactant molecules. This case is realised firstly in the interaction of radicals with neighbouring molecules of their own polymer, and secondly in the reactions of polymer radicals distributed in a matrix of a chemically reactive substance of low molecular weight. The method of studying the reactivity of polymer radicals in frozen dilute solutions is based on this principle [23,91,92]. The polymer radicals are generated by mechanical treatment of the solution.

Mechanical grinding of frozen dilute solutions results in cleavage of the macromolecules at bonds in the main chain, with the formation of terminal polymer radicals $\cdot R_0$, which then react with the surrounding solvent molecules. In the course of grinding, fine particles are deformed, and individual layers of material are displaced relative to one another; under such conditions the reaction velocity is proportional to the reactant concentrations:

$$\frac{d[R_0^{\cdot}]}{d\tau} = W - k_i [R_0^{\cdot}] [M] \qquad (17)$$

and

$$\alpha = \frac{1}{k_i [M] \tau} (1 - e^{-k_i [M] \tau});$$

when

$$\tau \gg k_i [M] \quad \alpha \simeq \frac{1}{k_i [M] \tau} \qquad (18)$$

where W is the rate of formation of initial $\cdot R_0$ polymer radicals, while τ is the duration of dispersion, k_i is the rate constant for reaction of these radicals with surrounding molecules of the reactant M, and $\alpha = [\cdot R_0]/([\cdot R_0] + [R\cdot])$, with $[R\cdot]$ the concentration of radical reaction products and $1 - \alpha$ the degree of conversion.

The accuracy with which α can be determined from e.s.r. spectra is usually low, and only the order of magnitude of the rate constant can be estimated by this method.

The literature contains hardly any rigorous or systematic data on the temperature dependence of the rates of the elementary reactions undergone by polymer radicals in the solid phase, so that approximate procedures must be used to estimate activation energies. When the polymer radical and the reactant molecule are located in the same cage, in a state of continuous contact as it were, the reaction velocity will be a maximum, and the pre-exponential factor in the Arrhenius equation cannot exceed 10^{13} s^{-1}. Under ordinary conditions transformations of radicals can be detected if their concentration changes appreciably during the course of hours or tens of hours, i.e. if $k \simeq 10^{-4}$–10^{-5} s^{-1}. Hence

$$E \leqslant 2.3RT \lg \frac{k_0}{k} \quad \text{or} \quad E \leqslant 80T. \qquad (19)$$

Thus if the temperature at which a particular elementary reaction takes place is known, an upper limit to possible values of the activation energy can be estimated. For example, it follows from the relation (19) that reactions having an activation energy exceeding 6 kcal $mole^{-1}$ will not be observed at the boiling point of nitrogen (80°K).

Reactions involving addition, substitution, decomposition, and combination are characteristic of free radicals. All these classes of elementary reactions play an important part in the chemistry and the physical chemistry of polymers; they take place under the influence of ionising radiations, ultraviolet irradiation, mechanical constraints, aging and fatigue, chemical modification, thermal and thermo-oxidative degradation of polymeric materials, etc. Published data on elementary reactions in the solid phase are fragmentary, authors most often confining themselves

§ The kinetic laws of reactions in non-homogeneous non-uniform systems are considerably more complicated. An example of such a reaction is the "stepwise" recombination of radicals in irradiated solids, which has been analysed in Ref. 83.

¶ The form of the constant k_m is discussed in Ref. 78.

to reporting the fact of interaction and analysing the reaction products; more rarely rate constants are measured, and only in isolated cases are the activation energy and the pre-exponential factor determined. The results of investigations of the reactivity at low temperatures of polymer radicals in the principal classes of reactions are examined below. The elementary reactions of addition, substitution, and decomposition are analysed separately from those involving the destruction of radicals, the rates of which in solid polymers are always determined by processes of migration of the free valency.

1. Elementary Addition, Substitution, and Decomposition Reactions

Addition reactions

Addition reactions include the interaction of polymer radicals with substances containing double or triple bonds (including aromatic compounds), oxygen, nitric oxide, and other unsaturated molecules. The reactions between radicals and vinyl monomers have been studied in the greatest detail [22,78]†.

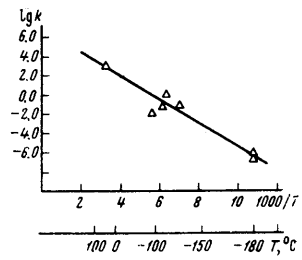

Figure 7. Temperature dependence of rate constant for the addition of certain monomers (styrene, α-methylstyrene, methyl acrylate, and acrylic acid) to $\sim CH_2-\dot{C}(CH_3)(COOCH_3)$ radicals.

Rate constants for addition of the monomers have been measured at low temperatures (80–100°K) in frozen solutions [22]. The dependence of the addition rate constant for radicals of poly(methyl methacrylate) on temperature over the range 100–400°K is shown in Fig. 7 plotted as $\lg k$ against $1000/T$. The upper left-hand point corresponds to the rate constant of chain growth in the liquid-phase polymerisation of methyl methacrylate; over the range 330–380°K we have $k = 6 \times 10^5 \exp(-4700/RT)$ M^{-1} s^{-1}, [93] and the slope of the straight line has been determined from these data. The points in the lower right-hand part of the graph correspond to measurements of the rate constant for the addition of various monomers (styrene, α-methylstyrene, methyl acrylate‡) to radicals of poly(methyl methacrylate) $CH_2-\dot{C}(CH_3)(COOCH_3)$ in frozen solutions [22]. The values of $k_{100°K}$ for various monomers lie in the range 10^{-5}–10^{-4} M^{-1} s^{-1}. The graph shows that to a first approximation the activation energy and the pre-exponential factor remain the same in the solid phase at low temperatures as in the liquid phase at 350–400°K.

Fused-ring aromatic compounds (anthracene, acridine) and quinones (benzoquinone, tetrachlorobenzoquinone) readily add to the terminal radicals of poly(methyl methacrylate), polystyrene, and other vinyl polymers at 100°K. [92] The addition rate constants for these compounds at 100°K vary over the range 10^{-6}–10^{-4} M^{-1} s^{-1}.

The polymer radicals $-CHX-\dot{C}H_2$, $-CH_2-\dot{C}H(OCOCH_3)$, and $-CH_2-\dot{C}H(COOCH_3)$ are the most active in addition reactions at low temperatures. They are approached by $-CH_2-\dot{C}H(C_6H_5)$ radicals. The last position in the sequence is occupied by $-CH_2-\dot{C}(CH_3)(COOCH_3)$ and $-CH_2-\dot{C}(CH_3)(C_6H_5)$ radicals. The addition of monomers to central radicals of the type $-CXY-\dot{C}H-CXY$ has not been observed in frozen solutions. The same sequence of activities is maintained in reactions with quinones, anthracene, and acridine [92].

In the solid phase at low temperatures $-CH_2-\dot{C}H(C_6H_5)$ radicals are more active than $-CH_2-\dot{C}(CH_3)(COOCH_3)$ radicals; this is inconsistent with the theory of ideal reactivity and results for the liquid-phase copolymerisation of monomers [93]. It may be assumed that the steric factor plays a more important part in the solid than in the liquid phase. Therefore radicals having the structure $-CH_2-\dot{C}HX$ are generally more active than $-CH_2-\dot{C}(CH_3)X$ radicals, while radicals having the free valency in the middle of the chains, of the type $-C(CH_3)X-\dot{C}H-C(CH_3)X-$, such as poly(methyl methacrylate), etc., do not undergo addition reactions at all in frozen solutions.

Oxygen reacts with all alkylated polymeric radicals at temperatures of 150–200°K and below [11,78,79,90,94,95], with the formation of peroxy-radicals ROO•, distinguished by a characteristic anisotropic e.s.r. signal [5]. Peroxy-radicals have been observed in polyethylene [8], polypropylene [5,96], poly(vinyl chloride) [89,94], polystyrene [78], poly(methyl methacrylate) [78,85,95], and other carbon-chain and heterochain polymers, including those which occur naturally. The addition of oxygen has been studied in massive specimens [79], films [96], turnings [78], and finely divided powders [95]. When the material is sufficiently thick, oxidation is limited by the diffusion of oxygen inside the polymer [78,79].

The activation energy of the reaction $R\cdot + O_2 \rightarrow ROO\cdot$ has the values 6, 5.3, 5.9, and 7.9 kcal $mole^{-1}$ for polytetrafluoroethylene [79], polystyrene [78], poly(vinyl acetate) [78], and poly(methyl methacrylate) [78].

A summary of kinetic results for the reactions of polymer radicals with various molecules (O_2, NO, etc.) from the gas phase will be found in Ref. 90.

Substitution reactions

The chief reactions studied have been those involving abstraction of a hydrogen atom by a polymer radical from neighbouring macromolecules [19,20,97] or compounds of low molecular weight having weak C–H, N–H, O–H, or S–H bonds [92]. Intermolecular transfer of a hydrogen atom probably plays an important part in the stabilisation of radical states in solid polymers.

Polymer radicals of the type $R-CXY-\dot{C}H_2$ exhibit the highest activity [92] in $R\cdot + HR_1 \rightarrow RH + R_1\cdot$ reactions. In frozen dilute solutions, with HR_1 representing an aromatic hydrocarbon (toluene, ethylbenzene, isopropylbenzene, etc.), reaction at 80–100°K yields the simple radicals

† Solid-phase polymerisation is not discussed in the Review.

‡ It is impossible by the e.s.r. method to observe the interaction of poly(methyl methacrylate) radicals with methyl methacrylate.

$C_6H_5\dot{C}H_2$, $C_6H_5\dot{C}HCH_3$, $C_6H_5\dot{C}(CH_3)_2$, etc., which have all been recorded by the e.s.r. method [64]. On passing from toluene to ethylbenzene the reaction rate constant increases several times to reach 10^{-5} M^{-1} s^{-1}, in conformity with the decrease in strength of the C–H bond. It follows from the relation (19) that the activation energy for abstraction of a hydrogen atom from toluene cannot exceed 7–8 kcal mole^{-1}. For the reaction of methyl radicals with toluene vapour at 400–600°K we have $k = 10^8 \exp(-8300/RT)$ M^{-1} s^{-1}: [98] i.e. the activation energy for transfer of a hydrogen atom to R–CXY–$\dot{C}H_2$ radicals in the solid phase is lower than—or in the extreme case equal to—the activation energy of the analogous reaction for simple methyl radicals in the gas phase.

The reaction of terminal radicals of polyethylene with a neighbouring chain

$$-CH_2-\dot{C}H_2+-CH_2-CH_2-CH_2- \longrightarrow -CH_2-CH_3+-CH_2-\dot{C}H-CH_2-$$

which occurs at a measurable rate at 140°K, has an activation energy of only 4 ± 1 kcal mole^{-1}. [19] Yet for the reaction of methyl radicals with butane in the gas phase E = 8.3 kcal mole^{-1}. [98] Thus the transfer of a hydrogen atom to R–$\dot{C}H_2$ radicals, whether in polyethylene or in frozen solutions of aromatic hydrocarbons (toluene, ethylbenzene, etc.), is possible at low temperatures (110–140°K), and has an unexpectedly low activation energy§.

The radicals R–CH_2–$\dot{C}HX$ and R–CH_2–$\dot{C}XY$ are less active than are R–$\dot{C}H_2$ radicals, and do not interact with hydrocarbons at low temperatures [92]. There is almost no information on the reactions of these radicals with "their own" macromolecules. Only in polypropylene at 140°K are terminal radicals CH_2–$\dot{C}H(CH_3)$ converted into central radicals [19]. In poly(methyl methacrylate), polystyrene, and several other polymers the terminal radicals are stable up to 330–350°K and above (see Tables 9 and 10), which is evidence of their low activity in reactions involving the transfer of a hydrogen atom.

Peroxy-radicals ROO• react with various types of polymer molecules—polycaprolactam, polystyrene, poly(methyl methacrylate), etc.—and in a vacuum at 200–270°K we can observe the conversion of ROO• into R• radicals, accompanied by a usually appreciable fall in the total concentration of radicals [97]. The primary act is transfer of a hydrogen atom to the peroxy-radical with formation of a polymer radical having the free valency in the middle of the chain. The rate constant of this reaction has been measured by two different methods (chemiluminescence and e.s.r.) in poly(methyl methacrylate) [97]. Over the temperature range 250–360°K,

$$k = 10^{6\pm1} \exp\left(-\frac{12000 \pm 2000}{RT}\right) \ M^{-1}\ s^{-1}$$

the product of the reaction being –$C(CH_3)(COOCH_3)$–$\dot{C}H$–$C(CH_3)(COOCH_3)$– radicals. In polypropylene [100] $k = 10^{5.3} \times \exp(-9000/RT)$ (at 380–410°K). There are no published data on the rate of this reaction for other polymers, but since the conversion ROO• → R• is observed over roughly the same temperature range, the activation energy will not greatly change on passing to other polymers.

Table 7 gives rate constants for reactions of the radicals R–$\dot{C}H_2$, R–CH_2–$\dot{C}HX$, R–CH_2–$\dot{C}XY$, and ROO• with a series of compounds containing a reactive hydrogen atom (aromatic amines, phenols, thiols, etc.) [92]. The rate constants were measured in frozen dilute solutions, where the polymer radicals were surrounded by molecules of the reactant (see relation 18).

Polymer radicals of varying structure differ from one another in reactivity considerably more strongly in substitution than in addition reactions. Radicals for which data are available on their chemical activity in hydrogen-transfer reactions from phenols, amines, and thiols can be arranged in the sequence [92]

$$\left\{\begin{array}{l} R-\dot{C}H_2 \\ -CH_2-\dot{C}H(OCOCH_3) \\ ROO^{\bullet} \end{array}\right\} > -CH_2-\dot{C}H(C_6H_5) > -CH_2-\dot{C}(CH_3)X$$

where X = CH_3, C_6H_5, $COOCH_3$. For R–$\dot{C}H_2$, –CH_2–$\dot{C}H(OCOCH_3)$, and ROO• radicals the transfer rate constants at 100°K always exceed 10^{-4} M^{-1} s^{-1}. The activity of the peroxy-radicals is almost independent of the structure of the carbon skeleton. The rate constant for the interaction of –CH_2–$\dot{C}(CH_3)(COOCH_3)$ radicals with phenols and amines at 100°K is less than 10^{-7} M^{-1} s^{-1}.

Table 7. Rate constants of elementary substitution reactions for alkyl (R•) and peroxide (ROO•) polymer radicals with certain compounds at 80–100°K.

Reactant	Initial radical	k, M^{-1} s^{-1}
$C_6H_5CH_3$, $C_6H_5CH_2CH_3$	R•*	10^{-6}–10^{-5}
	R•	$\sim 10^{-5}$
	ROO•	$\geqslant 10^{-4}$
C_6H_5–NH–C_6H_5	R•	10^{-6}–10^{-4}
	ROO•	$\geqslant 10^{-4}$
C_6H_5–SH	R•	—
	ROO•	$\geqslant 10^{-4}$
$(C_6H_5)_3$ C–Cl	R•	10^{-6}–10^{-5}

*R• = –CHX–$\dot{C}H_2$, –CH_2–$\dot{C}HX$, –CH_2–$\dot{C}XY$.

Decomposition reactions

The decomposition of polymer radicals plays an important part at high temperatures in processes of thermal and thermo-oxidative degradation [101,102]. Recently the decomposition of polymer radicals has been detected even at room temperature [97].

The simplest decomposition reaction is depolymerisation—detachment of a monomer from a terminal polymer radical:

$$-CH_2-CXY-CH_2-\dot{C}XY \rightarrow -CH_2-\dot{C}XY + CH_2{=}CXY$$

Elimination of a monomer is the opposite reaction to polymerisation, and its activation energy is $E_d = E_{gr} + Q$, where E_{gr} is the activation energy of chain growth during polymerisation and Q is the heat of polymerisation. Values of E_d, E_{gr}, and Q for various polymers are listed in Table 8. The activation energy of depolymerisation is largest in polyethylene, where it reaches 28 kcal mole^{-1}. Methyl methacrylate is characterised by low values of Q and E_{gr}, and depolymerisation is the principal way in which poly(methyl methacrylate) decomposes [101]. The rate of depolymerisation of poly(methyl methacrylate) to be expected at room temperature is

$$W = k_0 \exp\left(-\frac{18000}{1.98 \cdot 290}\right)[R^{\bullet}] = 10^{-8}[R^{\bullet}]$$

§ Methyl radicals also have enhanced activity in the solid phase: at 77°K they abstract a hydrogen atom from a polyphenylmethylsiloxane molecule [99].

The rate of separation of monomer is a specimen of the polymer containing 10^{17}-CH_2-$\dot{C}(CH_3)(COOCH_3)$ radicals was close to the calculated value[86].

Modes of decomposition of polymer radicals other than depolymerisation are also possible. Mainly alkylated derivatives of benzene—toluene, ethylbenzene, isopropylbenzene—separate in polystyrene[97]. These compounds are probably formed by the breakdown of central radicals with further separation of radicals of low molecular weight by reactions of the type

$$\sim R^{\cdot}\sim \rightarrow \sim \Pi + R^{\cdot}\sim$$
$$\sim R^{\cdot} \rightarrow \sim \Pi + r^{\cdot}$$

where Π represents the polymer and r• the simple radical.

Table 8. Some parameters of processes of polymerisation[93] and depolymerisation.

Monomer	Q, kcal mole^{-1}	E_{gr}, kcal mole^{-1}	E_d, kcal mole^{-1}
Ethylene	22.3	5.5[103]	27.8
Vinyl acetate	21.3	4.2	25.5
Styrene	16,1—16,7	7.2	23—24
Methyl acrylate	18.7	4.7	23.4
Methyl methacrylate	13.0	4.7	17.7

"Volatile" radicals r• have been detected by the e.s.r. method among the products of the radical degradation of polyethylene and polypropylene at high temperatures[102]. Whether breakdown of the central radical ~R•~ and ejection of the simple radical r• take place in a single act or in two stages in unknown.

No study has been made of the kinetics of the breakdown of radicals having the free valency in the middle of the chain. In poly(methyl methacrylate) the

radicals decompose at lower temperatures than do $-CH_2-\dot{C}(CH_3)(COOCH_3)$ radicals[86]. Radicals having their free valency in the middle of the chain probably break down more easily than do terminal radicals in other polymers, too. However there is as yet no direct evidence to support this suggestion.

2. Nature of Processes of Migration of the Free Valency and the Destruction of Radicals

The loss of radicals in solid polymers is the most convenient reaction for investigating the nature of the processes involving migration of the free valency. Decay of polymer radicals may be due either to diffusion or to chemical mechanisms of transfer of the free valency. Analysis of the conditions for destruction will give the first information on the nature of processes involving migration of the free valency in polymers of various structures. Data on the stability of alkylated and peroxide radicals of various types in vinyl polymers and in polyoxides are assembled in Table 9¶. The measure of stability adopted in compiling Table 9 was the temperature range within which the concentration of radicals of the given type drops sharply when the specimens are heated. In some polymers, radicals of one type disappear by being converted into other, more stable radicals; in this case the total radical concentration either diminishes or remains constant.

Table 9. Temperature range of destruction of polymer radicals.

Polymer	T_{ds}, °K Refs.104, and 105	Temperature of stability, °K			
		R—$\dot{C}H_2$	R—$\dot{C}XY$	"central radicals"	ROO•
Polyethylene	188	120—140[19, 20]	—	260—280[106, 107]	260—280[106, 108]
Polypropylene	256	<90	120—140[19]	250—290[19]	300[108]
					300—340[96]
Polyisobutene	200	<90	200—220	200—220	200—220
Polystyrene	370	120—140*	330—350[111]	—	260—280[111]
Poly(methyl methacrylate)	380—390	<90*	330—350[85, 86, 111]	250—270[86]	260—280[86, 97]
Poly(vinyl alcohol)	358	120—140[21]*	—	330—360[109]	200—220

Polycaprolactam	320	120[20]	—	280—290[17]	

*Data for frozen solutions of polymers in inert solvents.

In a rigorous approach the stability must be characterised by the rate constant of destruction or by the constants k_0 and E in the Arrhenius expressions. Such measurements are collected together in Table 10. They relate to cases in which the loss of radicals obeys a second-order equation. With the values of k_0 and E known, we can estimate the temperature limits of stability, i.e. the range within which the lifetime of the radicals decreases to minutes ($10^4 > \tau > 10^2$ s), while the destruction rate constants lie in the range $10 > k_{ds} > 10^{-1}$ M^{-1} s^{-1} {with destruction having second-order kinetics $k_{ds} \simeq 1/\tau[R^{\cdot}]$; usually $[R^{\cdot}] = 0.001$ M}. In several polymers radicals of different types (terminal, central, and peroxide) are destroyed under roughly the same conditions, at temperatures above the glass point of the polymer, in air and in a vacuum; in such a case diffusion may be expected to make a great contribution to migration of the free valency. The primary example of such polymers is polyisobutene (Table 9). In polystyrene, poly(methyl methacrylate), and other polymers radicals of different types differ markedly in their stability. It may be assumed that in these polymers the mechanism of migration of the free valency is determined not so much by the flexibility of the macromolecules as by the structure and the chemical activity of the radical.

Radicals of type R-$\dot{C}H_2$

The radicals are usually stable at temperatures below 150°K. Under these conditions at a diffusion mechanism of migration is excluded, and their disappearance is most likely due to their great activity in reactions involving the intramolecular and intermolecular transfer of a hydrogen atom. The example of polyethylene (subsection 1) shows that the term "destruction" is inexact in relation to R-$\dot{C}H_2$ radicals: they interact with a neighbouring polymer chain, and are converted into more stable radicals with the free

¶ The stability of radicals depends on the state of the polymer, but this aspect has not yet been investigated systematically. Radicals are more stable in crystalline than in amorphous specimens (polypropylene[110], polybutadiene[67]).

valency in the middle of the chain[19]. At low temperatures this process is limited. At higher temperatures (260–280°K) the loss reactions develop further, and the total concentration of radicals falls.

The activity of R–CHX–$\dot{C}H_2$ radicals depends little on the nature of the substituent X, and under otherwise similar conditions the reaction velocity is determined by the stability of the C–H bonds in the polymer molecule. The stability of these bonds is greatest in polyethylene, and therefore R–$\dot{C}H_2$ radicals are most easily detected in this polymer. The radicals R–O–$\dot{C}H_2$ are less active than R–CHX–$\dot{C}H_2$, and in polyformaldehyde transfer of a hydrogen atom begins to play a part at temperatures above 250°K.

Table 10. Rate constants of the destruction of alkyl and peroxide polymer radicals.

Polymer	Radicals	E, kcal mole^{-1}	$\lg k_0$ (M^{-1} s^{-1})	Refs.
Poly(vinyl acetate)		23	15	111*

*Values of k_0 given in Ref. 111 are probably wrong. The values of k_0 in Table 10 have been calculated by us from the data in Fig. 1 of Ref. 111.
**Values of E and k_0 calculated by us from data of Fig. 3 in Ref. 111.

Radicals of type R–CH_2–$\dot{C}XY$

The loss rate constants and activation energies for radicals of this type have been measured in poly(methyl methacrylate), polystyrene, poly(vinyl acetate), and certain other polymers (Table 10). These radicals differ markedly among themselves in stability. In polypropylene (see Table 9) transformations begin at 120–140°, but in poly(methyl methacrylate) and polystyrene the radicals are stable in a vacuum up to 350°K. Let us examine these extreme cases.

The CH_2–$\dot{C}H(CH_3)$ radicals in polypropylene probably disappear by the same mechanism as radicals of type R–$\dot{C}H_2$: The primary act is detachment of a hydrogen atom from a neighbouring chain. The former radicals should be more active than –CH_2–$\dot{C}H_2$ radicals in this reaction, but the C–H bonds are a few kilocalories less stable in polypropylene than in polyethylene. Therefore intermolecular transfer of the free valency is possible for both radicals at low temperatures.

In the activity sequence for substitution reactions CH_2–$\dot{C}(CH_3)(COOCH_3)$ radicals are nearly last (see subsection 1), and furthermore in the poly(methyl methacrylate) chain the methylene group containing the active hydrogen atom is located between quaternary carbon atoms carrying bulky substituents, so that migration of the free valency is sterically hindered. Nevertheless, breakdown (depolymerisation) of these radicals is quite rapid even at room temperature[86]. During depolymerisation the free valency moves along the chain at a speed of k_d chain units per second, and the possibility arises of encounters between radicals. If it is supposed that no energy barrier opposes the combination of radicals with each other, the loss rate constant with this mechanism of migration of the free valency is $k_m = k_d M/1000$ M^{-1} s^{-1}, where M is the molecular weight of the chain unit. At 330°K

$$k_d = 10^{12} \cdot \exp\left(-\frac{18000}{1.98 \cdot 330}\right) 10\ s^{-1}$$

whence $k_m \simeq 1$ M^{-1} s^{-1}, which coincides in order of magnitude† with the actual rate of loss at 330°K (Table 10), the conbination of each pair of radicals being accompanied by the separation of several monomer molecules[86]. At higher temperatures the rate of loss comes to exceed the calculated value ($E_{ds} = 28$ kcal, while $E_d = 18$ kcal). It is probable that, as the glass point is approached, migration of the free valency by a diffusion mechanism is not excluded.

Radicals with free valency in middle of chain

In poly(methyl methacrylate) these radicals become unstable at 250–270°K, and it may be supposed that the mobility of the free valency is largely due not to diffusion but to chemical reactions. At 250–300°K both hydrogen transfer and breakdown of the radicals may play a part. The relative rates of these reactions depend on the nature of the polymer:

$$\frac{W_{tr}}{W_d} = \frac{k_{o,tr}[M]}{k_{o,d}} \cdot \exp\left(\frac{E_d - E_{tr}}{RT_{st}}\right) \qquad (20)$$

where [M] is the concentration (molarity) of the polymer (in most cases $10 < [M] < 30$), $k_{o,tr}$ and E_{tr} are the preexponential factor and the activation energy for transfer of a hydrogen atom (it may be supposed that in solid polymers $k_{o,tr} \simeq 10^{6 \pm 1}$ M^{-1} s^{-1}—see subsection 1), and $k_{o,d}$ and E_d are the corresponding parameters for decomposition of the radicals (in order of magnitude $k_{o,d} \simeq 10^{12}$–10^{13} s^{-1}). Thus $W_{tr}/W_d = 10^{-5 \pm 1} \exp[(E_d - E_{tr})/RT_{st}]$. At $T_{st} = 250$–300°K with $E_d - E_{tr} > 8$ kcal mole^{-1}, we always have $W_{tr} > W_d$; conversely, when $E_d - E_{tr} < 6$ kcal mole^{-1}, the rate of decomposition will be higher than that of migration of the free valency.

In polyethylene and polypropylene $E_d > 25$ kcal mole^{-1}, while $E_{tr} < 15$ kcal mole^{-1}, i.e. $E_d - E_{tr} > 10$ kcal mole^{-1}, and near the stability temperature the rate of migration of the free valency should be much greater than the rate of decomposition of the radicals.

In polymers containing quaternary carbon atoms in the main chain E_d does not exceed 15–20 kcal mole^{-1} (Table 8) and $E_d - E_{tr}$ is small. In poly(methyl methacrylate)

† Under real conditions the probability of the reverse reaction increases as the monomer accumulates, and migration of the free valency takes place as a result of depolymerisation–polymerisation processes.

$E_d - E_{tr} \leq 5-6$ kcal mole^{-1}: i.e. the loss of radicals having the free valency in the middle of the chain would be due to decomposition reactions. This conclusion is supported by experiment: in poly(methyl methacrylate)[86], polystyrene[97], and other polymers of analogous structure loss is always accompanied by the ejection of products of low molecular weight, the quantity of which equals or exceeds the concentration of radicals [in polyalkenes the quantity of volatile products evolved at $T \leq T_{st}$ is smaller by factors of 10–1000 than in poly(methyl methacrylate)[113]].

Breakdown is followed by a series of further changes, leading to migration of the free valency and combination of the radicals. In poly(methyl methacrylate) the following reactions are possible[86]:

1. Breakdown of radicals:

$$-CXY-\dot{C}H-CXY- \longrightarrow -CXY-\dot{C}H_2 + CXY=CH-CXY-.$$

2. Depolymerisation with the separation of several monomer units.

3. Stabilisation

$$-CXY-\dot{C}H_2 + -CXY-CH_2-CXY- \rightarrow CXY-CH_3 + -CXY-\dot{C}H-CXY-$$

$$-CXY-\dot{C}H_2 + CH_2=CXY \rightarrow -CXY-CH_2-CH_2-\dot{C}XY;$$

4. Combination of mobile active radical $-CXY-\dot{C}H_2$ with fixed radicals $-CXY-\dot{C}H-CXY-$ or $-CH_2-\dot{C}XY$.

In polystyrene[97] decomposition is accompanied by the separation of the simple radicals $C_6H_5\dot{C}H_2$, $C_6H_5CH_2\dot{C}H_2$, etc., which diffuse into the interior of the polymer, and either combine with fixed radicals or abstract a hydrogen atom and are converted into saturated compounds—toluene, ethylbenzene, etc.

Breakdown always leads to migration of the free valency, which may occur as a consequence of construction of the ends of the disintegrated chain, depolymerisation, the formation and diffusion of simple radicals, etc. As a consequence of migration, radicals having the free valency in the middle of the chain are partly destroyed and partly stabilised, i.e. converted into a more stable form [in poly(methyl methacrylate) and polystyrene, for example, into radicals of the types $-CH_2-\dot{C}XY$ and $-CH_2-\dot{C}HX$]. The proportion of radicals lost

$$\omega = \frac{[R_0^{\cdot}] - [R_{st}^{\cdot}]}{[R_0^{\cdot}]} \qquad (21)$$

depends on the relative rates of combination and stabilisation. In poly(methyl methacrylate) $\omega \simeq 0.4$.[86,97]

Peroxy-radicals

In most vinyl polymers peroxy-radicals are lost in almost the same temperature range as are radicals having the free valency in the middle of the chain. The conversion of alkylated radicals of types (II) and (III) into the peroxide form

$$R^{\cdot} + O_2 \rightarrow ROO^{\cdot} \qquad (22)$$

is almost always equivalent to an increase in activity in hydrogen-transfer reactions

$$ROO^{\cdot} + HR_1 \rightarrow ROOH + R_1^{\cdot}. \qquad (23)$$

It would seem that repeated alternations of reactions (22) and (23) in the presence of oxygen should lead to migration of the free valency and loss of radicals[111]. Such a mechanism of migration represents an unbranched chain oxidation of the polymer. In most cases, however, the chain is relatively short, the number of oxygen molecules absorbed in the loss of one radical being respectively 5, 3–6, 3–7, and 1.5 in polyethylene[106], polypropylene[96], poly(vinyl chloride)[94,96], and poly(methyl methacrylate)[97]. Thus this mechanism, though at first glance extremely simple, cannot be regarded as the principal or only mechanism of migration of the free valency in the presence of oxygen.

A peculiar feature of reaction (23) is that abstraction of a hydrogen atom results in the formation of radicals having the free valency in the middle of the chain, whose stability is roughly the same as that of the ROO• radicals. Consequantly reaction (23) causes further migration of the free valency by a mechanism which is specific for a given polymer. In polyalkenes this may be stepwise transer of the free valency[94,107]. In poly(methyl methacrylate) and polystyrene, radicals having the free valency in the middle of the chain break down with the separation of products of low molecular weight[97]. The migration is accomplished quite rapidly—more rapidly than oxidation of the alkylated radicals formed—and the next oxygen molecule adds to the already stabilised decomposition products. Therefore many similar rules apply to the loss of peroxy-radicals and of radicals having the free valency in the middle of the chain[97] (volatile products having the same composition, same stability, etc.).

---o0o---

Of the two parts of the review the first—the e.s.r. spectroscopic section—will probably leave a more complete impression than the second, more chemical part. The non-equivalence of these sections reflects the present-day state of research into the structure and the properties of polymer radicals.

One of the chief tasks of the e.s.r. spectroscopy of polymer radicals is to study the relation between the structure of radicals and their e.s.r. spectra. Work in this field is still far from complete, but considerable progess has been made during the past few years. Two or three years ago tens of investigations were devoted to deciphering a single spectrum, but now the possibility is already being discussed of predicting the hyperfine structure of the spectra due to very simple radicals.

Research on elementary radical reactions in solid polymers is at an earlier stage of development: theoretical concepts have not yet been established, and there is no generally accepted view on the formal kinetic laws, while many conclusions must for the present be compared with results for analogous reactions in liquid and gaseous phases. However, estimates have already appeared for the kinetic constants of radical reactions in the solid phase, and the elementary mechanism of complicated processes, such as the migration and destruction of radical states, oxidation, etc., is being discussed. It may be hoped that in the near future more serious generalisations will appear, with conclusions on the nature of the reactions undergon by radicals in solid polymers.

Progress in the Study of the Degradation and Stabilisation of Siloxane Polymers

T.N.Balykova and V.V.Rode

The most recent achievements in the study of the degradation and the stabilsation of polyorganosiloxanes, including those containing other atoms in the chain, are surveyed. The effect of polymer structure on their thermal stability is examined, and the part played by catalytic impurities in developing processes of thermal and thermo-oxidative degradation is shown. Known schemes for the decomposition of polyorganosiloxanes are discussed. Data are given on methods of stabilising siloxane polymers. The list of references contains 141 items.

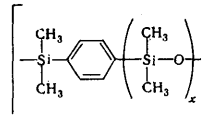
1. INTRODUCTION

The chemistry of monomeric and polymeric organosilicon compounds has made great advances during recent years. Polyorganosiloxanes possess several extremely important properties, in virtue of which they have found widespread and effective application in electrical engineering, radio engineering, and the coal, rubber, aircraft, and other industries. Such important properties of siloxane polymers as their resistance to the action of moisture, heat, cold, ultraviolet rays, oxygen, and ozone, their slight change in viscosity and modulus of elasticity with temperature, and their high dielectric properties are largely determined by the character of the siloxane chain and the organic radicals attached to the silicon atom. Polyorganosiloxanes can be regarded as occupying an intermediate position between organic and inorganic polymers. Several monographs[1-7] on the synthesis and investigation of the properties of siloxane polymers have been published during the thirty years since the appearance of the first papers in this field. However, problems of thermal and thermo-oxidative degradation and of stabilisation are inadequately dealt with in these works. The present review summarises available published data on the aging and stabilisation of polyorganosiloxanes published up to June 1967.

2. EFFECT OF THE STRUCTURE OF POLYORGANOSILOXANES ON THEIR THERMAL STABILITY

The spiral structure of the molecules of polyorganosiloxanes containing 3–6 silicon atoms in a loop of the spiral creates favourable conditions for the formation of rings. It is obviously for this reason that the decomposition of polydimethylsiloxane is accompanied by cleavage of the silicon–oxygen bond and separation of cyclic products of low molecular weight without appreciable disturbance of the silicon–carbon bond. It is therefore supposed[1,2] that the decisive factor in the thermal degradation of linear polysiloxanes is not the difference in energy between silicon–oxygen and silicon–carbon bonds but the spiral structure of the molecules.

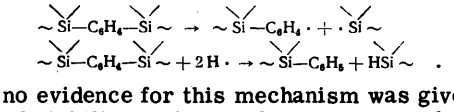
Enlarging the organic radicals attached to the silicon atoms diminishes the tendency of the polymer chain to coil into a spiral, so that depolymerisation of polydiethylsiloxane takes place with considerably greater difficulty and at a higher temperature than that of polydimethylsiloxane[2]. Polymers containing silaphenylene links possess fairly high thermal stability[8-14]. Those having the following structure



(I)

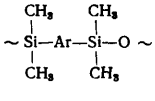
where $x = 1-4$, are considerably more thermostable than are ordinary polydimethylsiloxanes[14]. The maximum rate of loss of weight (1.4–1.9% min^{-1}) during the pyrolysis of such polymers is observed at 520–540°C, whereas with polydimethylsiloxane the maximum rate (2.1% min^{-1}) is already observed at 420°C. The polymer in which $x = 1$ proved to be the most stable.

It was assumed that cleavage of the silaphenylene link at temperatures above 450°C comprised the following reactions



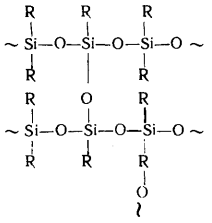
However, no evidence for this mechanism was given. The high thermal stability of these polymers was explained by the greater difficulty of breaking the silicon–carbon than the silicon–oxygen bond in polydimethylsiloxane.

Goldovskii, Kuz'minskii, and their coworkers[11] obtained comparative data on the thermal stability of the polymers



where Ar represents a *pp'*-phenyleneoxyphenylene or a *p*- or *m*-phenylene radical, and also data on the effect of small numbers of these units introduced into the chain of polydimethylsiloxanes. The polymer containing diphenyl oxide units proved to be the most stable, its decomposition temperature being 100 deg above that of polydimethylsiloxane, while the least stable polymer was one containing *m*-phenylene links. The introduction of up to 3 mole% of silarylene units into the chain of polydimethylsiloxanes has no significant effect on their thermal stability[11]. However, there are indications[13] that polymers containing biphenylylene and naphthylene bridges in the chain are stable even at 600°C, and will yield very strong thermostable films whose properties remain unchanged up to 400°C.

The thermal stability of polyorganosiloxanes is substantially influenced also by the structure of the polymer chains. Rupture of one silicon–oxygen bond is sufficient for the cleavage of linear macromolecules, but with polymers having a three-dimensional structure it is necessary to rupture siloxane bonds at two or even three points. Therefore the thermal stability of the latter is considerably higher than that of linear polymers. For example, polymers having the branched structure



undergo hardly any changes when heated in a vacuum at 550°C for 16 h.[15]

The thermal stability of polyorganosiloxanes is improved by vulcanisation with peroxides or γ-rays, the radiation products being the more thermostable[16–18]. The difference in thermal stability between these two types of vulcanised products is explained by a difference in the character of the cross-links[19]. In peroxide vulcanisates cross-linking is effected mainly by methylene bridges or silicon–silicon bonds. In radiation vulcanisates $Si-CH_2-CH_2-Si$ links are mainly formed, by the recombination of $Si-CH_2^{\cdot}$ free radicals. The thermal stability of radiation vulcanisates is higher because carbon–carbon bonds are more stable than silicon–carbon or silicon–silicon bonds, and also because at high temperatues a certain number of double bonds can be formed in the rubbers by the reaction

The rupture of cross-linking double bonds is difficult, and prevents degradation.

It is characteristic of thermal oxidation that the oxygen acts directly only on the organic groups attached to the silicon atom. The structure of the groups framing the main chain exerts a strong influence, of course, on the thermal stability of the polyorganosiloxanes. As the alkyl side-chain becomes larger, the thermo-oxidative stability becomes lower. Thus polydimethylsiloxanes[15] begin to oxidise appreciably at 200°, polydiethylsiloxanes at 138°, and polydibutylsiloxanes at 120°C.[20] Replacing the methyl by vinyl groups also somewhat lowers thermal stability[21,22].

On the other hand, replacing the methyl by phenyl groups considerably improves the thermo-oxidative stability of polyorganosiloxanes[23–25]. Thus at 350°C the loss in weight of polyphenylsiloxane is insignificant, but after heating at 450°C for 24 h about 3.7% of carbon and 0.76% of hydrogen remain in it[3]. The enhanced stability of polyphenylsiloxanes is explained[26] by the screening effect of the phenyl groups on the siloxane bond. The introduction of one chlorine atom into the phenyl group has no substantial effect on the thermal stability of polyphenylmethylsiloxanes, but with two or more chlorine atoms the thermal stability falls[27]. Thus the temperature at which decomposition begins drops from 357° for the unchlorinated polymer to 312°C for a polymer containing four chlorine atoms in the phenyl ring[28].

In polydimethylphenylsiloxane containing methyl-3,3,3-trifluoropropylsiloxy-groups processes of rearrangement of the siloxane link occur at an appreciable rate, which increases with increase in the content of these groups[29]. Half-decomposition times have been calculated[24] for polyorganosiloxanes containing various framing groups. Depending on such groups, these polymers can be arranged in the sequence

$$C_6H_5 > ClC_6H_4 > Cl_3C_6H_2 > Cl_2C_6H_3 > CH_2{=}CH > CH_3 > C_2H_5 > C_3H_7 > C_4H_9$$

according to their resistance to thermal oxidation.

Sobolevskii and Nazarova[30] investigated whether the thermal properties of organosiloxanes are determined by the arrangement of methyl and phenyl groups in the chain or by the overall CH_3/C_6H_5 ratio, and concluded that the principal thermal properties of these polymers are almost identical at similar values of the ratio, whether their structure is regular or irregular. The thermo-oxidative stability of polyorganosiloxanes is enhanced by the introduction of aromatic rings into the main chain[9–11]. The temperature at which a polydimethylsilarylene begins to be oxidised is 40–60 deg higher than with ordinary polydimethylsiloxanes, while the rate of elimination of methyl groups is smaller by factors of 5–8.[11] The introduction of *m*-phenylene links into the siloxane chain has an especially large effect on resistance to oxidation.

The thermal stability of polyorganosiloxanes containing arylene units in the main chain is slightly better than that of the corresponding polymers containing framing aryl groups when the ratio of these groups to the total number of siloxane units is the same[9].

A weak site in polymethylphenylsiloxanes is found at their terminal trimethylsiloxy-groups, which determine the thermo-oxidative stability[31]. Replacement of these groups by triphenylsiloxy-groups leads to an improvement in the thermal stability of the polymer of 50 deg.

The processes which occur during the thermo-oxidative degradation of polyorganosiloxanes depend in considerable measure on the structure of the polymer. These polymers can be either linear, branched, network, cyclolinear, or cyclo-network. The rate of elimination of organosilicon compounds is considerably lower when a three-dimensional polyorganosiloxane (R/Si = 1) is heated than in linear polymers, as is also the case in the absence of oxygen. Thus heating polydimethylsiloxane in air at 400°C for 3 h produces a loss of weight of 57%, whereas polymono-organosiloxanes under hardly any loss in weight up to 450°C.[2]

In the thermal oxidation of polyorganosiloxanes of three-dimensional cyclic structure $(RSiO_{1.5})_n$ having rings of different but definite size, it was found that polydimethylsiloxanes containing an even number of units in the ring are degraded more slowly than those with odd rings[32]. This is observed both at 350°C, when decomposition of the polymer is not yet complete, and also at 400°C. This effect of the parity factor was explained by the presence of polar forces, the strengthening of which was accompanied

by increased density of packing, so that the polymer became less subject to degradation. With polyethylsiloxane, however, the opposite phenomenon is observed: a polymer containing an odd number of units in the rings is the more heat-resistant.

The more frequent the cross-links in polyorganosiloxanes the greater their resistance to thermal oxidation, even if the total functionality of the polymer is lower[33]. Thus polymers of the type T–D–D–T are more thermostable than are T–D–D–D–T–T and T–T–D–D–D–D–T–T, where T and D represent tri- and di-functional units.

The considerably lower thermal stability of linear polyorganosiloxanes than of the three-dimensional polymers is explained by many authors on the one hand by the spiral form of the linear molecules, which creates favourable conditions for the cleavage of chains with the formation of cyclic products, and on the other hand by the fact that detachment of a chain segment in a linear molecule involves rupture of a smaller number of bonds[2–4].

The rate of oxidation of methyl groups also diminishes as the R/Si ratio falls[24,34].

From all the above discussion it follows that, to obtain the most thermostable polyorganosiloxanes, three-dimensional polymers must be synthesised containing arylgroups in the side-chains or in the main chain. Unfortunately, however, this is not always acceptable, since such polymers are less elastic.

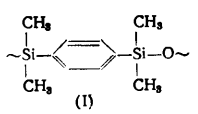
3. COMPOSITION OF DEGRADATION PRODUCTS OF POLYORGANOSILOXANES

The composition of the thermal degradation products of polydimethylsiloxanes was first studied by Patnode and Wilcock[35], who found that, in an atmosphere of nitrogen, polydimethylsiloxane decomposes at 350–400°C to form the following percentages of cyclic compounds of low molecular weight

$[(CH_3)_2SiO]_3$	44
$[(CH_3)_2SiO]_4$	24
$[(CH_3)_2SiO]_5$	9
$[(CH_3)_2SiO]_6$	10
above the hexamer	13

Compounds having a complicated cyclic structure were identified[36] among the products of the thermal degradation of three-dimensionally cross-linked polyorganosiloxanes.

When the silarylene polymer



(I)

was heated to 500°C (at a rate of 2.7 deg min^{-1}) and kept at that temperature for 3 h, hydrogen, methane, ethane, and ethylene were detected among the gaseous pyrolysis products, as well as dimethylsilane and tetramethyldisiloxane. The liquid products contained Si–H or Si–C_6H_4–Si groups. Elementary analysis, determination of the molecular weight, and spectroscopic data showed the solid reaction product to be a dimer. Thus the pyrolysis products indicate that degradation of the polymer chain takes place solely by rupture of silicon–phenylene bonds[14].

Thermo-oxidative degradation also yields solid and liquid products, among which a cyclic trimer—hexamethyltrisiloxane—predominates[19,24], but polymethylcyclosiloxanes of higher molecular weight are also present. Cyclic difunctional compounds mainly separate in the degradation of polymethylphenylsiloxane rubber[37].

Thus the thermo-oxidative degradation of polydiorganosiloxanes, like the thermal process, involves rupture of the silicon–oxygen bond to form cyclic products of low molecular weight. Substances indicating oxidation of organic side-chains are also found among the products of thermo-oxidative degradation. Thus in 1947 Atkins and Murphy[38] detected formaldehyde and formic acid among the thermal oxidation products of polydimethylsiloxanes. Subsequently carbon monoxide, carbon dioxide, methanol, water, and hydrogen have also been detected[21,24]. Furthermore, methane has been found in the oxidation of a siloxane rubber at 400°C.[39] These products are formed as a result of the oxidation and detachment of organic radicals.

As a consequence of the great resistance of phenyl groups to oxidation, only degradation of the main chain takes place in polyphenylsiloxanes up to 300–400°C.[21] From elementary analyses of polydi(and mono)methylsiloxanes which had been oxidised in air at 250–300°C Andrianov and Sokolov established[24] that the atomic ratio of hydrogen to carbon remained approximately 3 until a considerable degree of oxidation had occurred: i.e. methyl groups were split off during oxidation. Vinylated polymers form an exception among the polyorganosiloxanes. The vinyl groups do not split off from the main chain, since after oxidation at 200°C the carbon, hydrogen, and silicon contents of the residue do not differ appreciably from those of the original polymer. Infrared-spectroscopic data showed that the volatile products were siloxanes of low molecular weight, of the same composition as the initial material but containing carboxyl groups[21].

The oxidation of polyorganosiloxanes is accompanied by cross-linking: the viscosity of soluble polymers increases, and with further oxidation a gel is formed[39,21,23]; insoluble polymers show a rise in their glass point[40]. The fact that the rate of increase of the viscosity increases with increase in the oxygen content[38] suggests that the cross-linking is actually due to the action of oxygen. Electron-microscopic examination of the changes in a polydimethylsiloxane film when heated in air at 200°C show a coarsening of the macromolecular aggregates[41]. This is probably explained by cross-linking of the polymer chains under these conditions. Since the infrared spectra contained no bands corresponding to silicon–silicon bonds, it was assumed that the bridges between the chains were formed by siloxane bonds at the points of detachment of methyl groups[3]. The mechanism will be discussed below. Andrianov and Sokolov showed[24] that, as long as the molar ratio H/C = 3, approximately one oxygen atom replaces every two methyl groups eliminated. At the present time most scientists consider that the cross-links formed in the oxidation of polyorganosiloxanes are siloxane bonds[1,3,5,39], but inadequate grounds are given for this view.

4. THERMAL DEGRADATION OF POLYORGANOSILOXANES

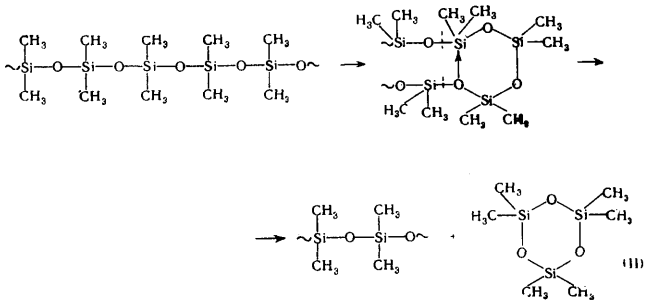
A limited amount of work has been done on the kinetics of the depolymerisation of polyorganosiloxanes in the absence of air. Andrianov et al.[42] investigated the kinetics of thermal degradation from the variation in the viscosity and the weight of the polymer. A striking fact is that the intrinsic viscosity begins to rise before loss of weight starts: with polydimethylsiloxane the latter is observed at 220°C, whereas the intrinsic viscosity has already begun to increase at 170°C. As the temperature

rises the viscosity increases, reaches a maximum value at 300°C, and then diminishes with further rise in temperature. The increase in viscosity was regarded as probably due to increase in the molecular weight of the polymer as a result of polycondensation involving the terminal hydroxyls. Above 220°C the structural changes begin to be accompanied by thermal breakdown of the polymer with the separation of products of low molecular weight which is responsible for the loss in weight; above 300°C depolymerisation becomes the dominant process.

In the initial stage the thermal degradation conforms to a first-order kinetic equation, but as the extent of conversion increases to 30–35% the order of the reaction increases slightly. The explanation given for this increase is that, together with the formation of cyclic compounds resulting from depolymerisation, other processes occur, leading to structural changes in the polymer.

Until recently, only fragmentary data of tentative character were available on the mechanism of the thermal decomposition of siloxane polymers. It was found in particular that linear organosiloxanes break down in the ionisation chamber of a mass spectrometer at 150–200°C to form dialkylsiloxanes[43,44]. From this it was suggested that the depolymerisation of linear organosiloxanes involves an intermediate stage in which dialkylsilanes are formed, these polymerising to cyclic products. However, in this case rupture of the siloxane bonds occur under the ionising action of the chamber of the mass spectrometer, not by the action of heat on the polymer under conditions of thermal degradation.

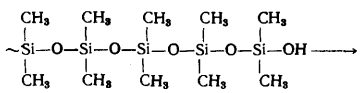
A mechanism has also been suggested for the formation of cyclic products in which depolymerisation of polydimethylsiloxane produces an intermediate compound which lowers the energy barrier to the rupture of silicon–oxygen bonds:

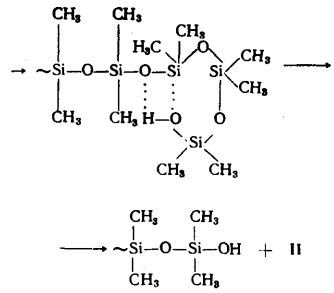


(III)

Unfortunately, no experimental data were given to support this mechanism.

The dependence of the depolymerisation rate constant on the degree of polymerisation of polydimethylsiloxanes was found to correspond to initiation of this reaction by terminal groups[45,46]. Examination of the thermal degradation of polydimethylsiloxane containing various kinds of end-groups showed that the rate of depolymerisation is diminished considerably when the terminal hydroxyls are replaced by methyl groups or by groups containing copper, iron, or titanium atoms. The following scheme was therefore proposed for the depolymerisation of polydimethylsiloxane:





Formation of an activated transition complex is favoured by the presence of hydroxy-groups and a spiral structure of the siloxane chains. The proposed mechanism is supported by the fact that, with decrease in the degree of polymerisation of the polydimethylsiloxane, the experimental values of the effective activation energy of depolymerisation (14–16 kcal mole^{-1}) approach the calculated energy of formation of the activated complex.

With increase in molecular weight, random cleavage of the chain plays an increasingly important part, so that the activation energy increases (to 32 kcal mole^{-1}).[40]

On the basis of thermogravimetric results Andrianov et al.[72] put forward a two-step mechanism of the degradation of polyorganosiloxanes. The first stage of decomposition (loss in weight 15–20%) has an activation energy of around 40 kcal mole^{-1}, and was regarded as involving the degradation of polydimethylsiloxane chains having terminal hydroxyls, with the formation of a network structure. In the second stage the polymeric networks undergo thermal cleavage, as indicated by the high activation energies of this process (60–80 kcal mole^{-1}).

5. THERMO-OXIDATIVE DEGRADATION OF POLYORGANOSILOXANES

Much work has been done on the kinetics of the thermal oxidation of polyorganosiloxanes. A kinetic investigation has been made of the separation of formaldehyde, the separation of formic acid, and the change in viscosity at low degrees of oxidation of a polydimethylsiloxane rubber[38], and also of the loss in weight of the polymers[21]. The time variation in the quantity of formaldehyde and formic acid which separated in a stream of oxygen at 200°C was approximately linear. However, the process cannot be assessed from these kinetic results, since formaldehyde and formic acid are not the only products of the oxidation of methyl groups. Furthermore, these results related only to the initial period, and differed markedly for different specimens, the difference in whose compositions was not indicated. Results for the variation in viscosity also cannot be applied as a quantitative measure, since they were not converted to the number of cross-links formed. It is impossible to assess the course of oxidation by means of curves for the loss in weight, since the latter is caused not only by the oxidation of methyl groups but also by breakdown of the main chain.

A characteristic feature of the kinetics of the decrease in weight of polymonomethylsiloxanes and other polymonoorganosiloxanes[24,37,39] is the sharp decrease in rate of loss of weight after the initial period. Approximately half the loss takes place in the first hour. Since the weight losses in such polymers are due merely to oxidation of lateral groups (when these polymers are heated, no separation of

products of low molecular weight is observed up to 400–500°C), these results enable the course of oxidation of the polymer to be assessed. A rapid decrease in the rate of the process after the initial period was observed by Scala et al.[21] also in a kinetic study of the absorption of oxygen by a polydimethylsiloxane resin at 250°C. Heating a phenylsiloxane rubber[37] in air established that the rate of decrease in weight obeys the empirical equation

$$\frac{df}{dt} = ke^{-k_1 f}$$

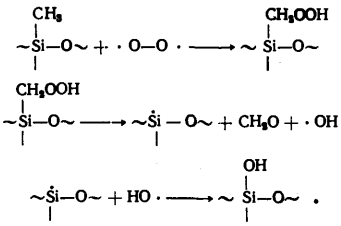
where f is the loss in weight of the specimen, and k and k_1 are constants. It was found that removal of the strongly oxidised upper layer of the specimen led to an increase in the rate of loss of weight. The explanation given was that, owing to cross-linking during oxidation, the diffusion of volatile products was impeded, and their concentration in the specimen increased. The activation energy of the thermo-oxidative degradation of a phenylsiloxane rubber was 22.2 kcal mole^{-1}.

Scala et al.[39] investigated the effect of the air pressure on the thermal oxidation of polymethylphenylsiloxanes (at 700, 600, 500, 300, 100, and 50 mmHg). Comparison of the final losses in weight in air and in argon showed that the purely thermal effect was responsible for 70% of the losses over the pressure range 700–300 mmHg, and for 92% at 50 mmHg of air. From the variation in the ratio of the quantity of gaseous compounds formed to the amount of oxygen absorbed it was suggested that oxidation takes place by different mechanisms at air pressures of 700–300 and below 300 mmHg.

While studying the relaxation of stress in preoxidised specimens of a polydimethylsiloxane rubber, Kuz'minskii and Goldovskii established[47] that the rate of relaxation diminishes with increase in density of the three-dimensional network. Such a relation is observed if cleavage takes place predominantly in the main chain, not at cross-links. The results given in this paper suggest that some kind of active groups accumulate in the polymer during oxidation. The kinetic curves representing the separation of organosilicon compounds of low molecular weight are S-shaped, which indicates the presence of a period of autocatalysis[48], also associated with accumulation in the polymer of active centres capable of breaking down the main chain. The rate of separation of these compounds increases for a certain time, after which it begins to fall, probably owing to the formation of cyclic segments, which impede further cleavage of the siloxane chain.

Thus oxygen does not act directly on the siloxane bond, but is responsible for the formation of active groups which accelerate depolymerisation. However, the mechanism of such acceleration has not been elucidated. It has merely been suggested that the process is hydrolytic in character, and that the active groups influencing cleavage of the main siloxane chain are Si–OH groups[49–51].

In view of the structure of polydimethylsiloxane, the mechanism of the oxidation of the lateral radicals should have much in common with the mechanism of the oxidation of organic polymers such as polypropylene. It has been suggested that oxidation of the side-chains involves formation of hydroperoxides[24] by a mechanism similar to the oxidation of polypropylene[52–55]. Andrianov and Sokolov[24] consider that oxygen attacks a carbon atom attached to silicon in the polymer molecule; a hydroperoxide is first formed, and rapidly decomposes with the separation of formaldehyde and the HO· radical, the latter adding to the silicon atom:



Condensation of the polymer molecules then takes place by means of the hydroxysilyl groups. The thermal decomposition of formaldehyde yields carbon monoxide and hydrogen, and its oxidation produces carbon dioxide and formic acid.

An analogous mechanism was suggested by Scala[39], who regards the process as a chain reaction;

chain initiation: $RCH_3 + O_2 \rightarrow RCH_2^{\cdot} + HO_2^{\cdot}$

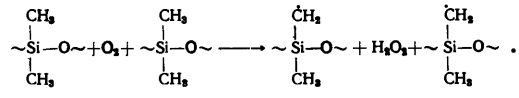
chain growth:
$RCH_2^{\cdot} + O_2 \rightarrow RCH_2O_2^{\cdot}$
$RCH_2O_2^{\cdot} + RCH_3 \rightarrow RCH_2O_2H + RCH_2^{\cdot}$
$RCH_2O_2H \rightarrow RCH_2O\cdot + HO\cdot$
$RCH_2O\cdot \rightarrow R\cdot + CH_2O$

where R is a polymer radical having its free valency on a silicon atom.

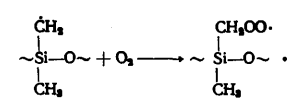
It has been established[56] that the rate at which methyl groups are split off increases with increase in the thickness of a film. The rate of oxidation increases up to a certain thickness, after which it decreases. Thus an "optimum" thickness corresponds to each temperature: 0.3, 0.75, 2.5, and 4 mm at 300°, 270°, 250°, and 230°C respectively.

The increase in the rate of oxidation is explained by the catalytic action of the oxidation products (perhaps formaldehyde), but when the optimum thickness is reached, delays involved in the diffusion of oxygen overlap the first factor. From these conclusions it can be assumed that the oxidation of methyl groups has a chain mechanism. Formaldehyde causes branching of the catalytic chain in the thermal oxidation of the side-groups in polydimethylsiloxane[57]. A chain mechanism is supported also by the sharp decrease in rate of oxidation produced by introducing antioxidants, e.g. 0.5–1.0 wt.% of di-2-naphthyl-*p*-phenylenediamine, into the polymer[56]. An analogous phenomenon is observed when such compounds as titanium dioxide and powdered silica gel are added to the polymer[49].

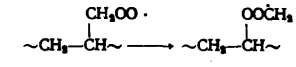
Oxidation is said[57] to be initiated by the abstraction of a hydrogen atom from a methyl group by an oxygen molecule:



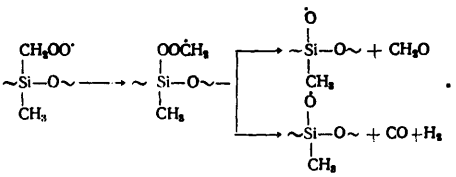
As in the oxidation of hydrocarbons, radicals with a free valency on a silicon atom should react preferentially with oxygen:



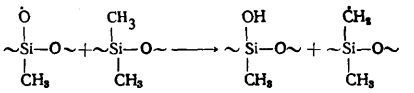
The most probable reaction of the peroxy-radical is its rearrangement by analogy with that of a peroxy-radical of polypropylene[53–55]:



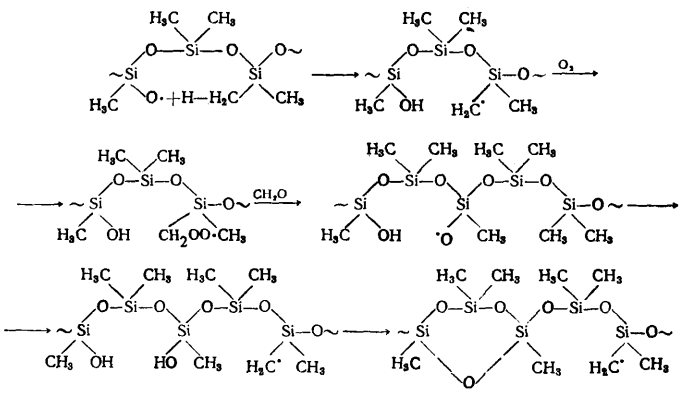
This reaction would be still more probable in polydimethylsiloxane, since its methylene C–H bonds are more stable than those in polypropylene: i.e. the $\geqslant SiCH_2OO^{\cdot}$ radical is more active than $\geqslant C-CH_2OO^{\cdot}$. In the authors' opinion the peroxy-radical undergoes the following reactions[48]



The resulting radical reacts with a methyl group of the same or a neighbouring molecule to form a hydroxy-group:



Since the number of methyl groups split off during the initial period of oxidation considerably exceeds the number of intermolecular siloxane bonds formed, the authors suppose that the start of oxidation involves predominantly the formation of intramolecular siloxane bonds:



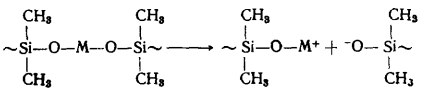
6. EFFECT OF CATALYTIC IMPURITIES ON THE THERMAL STABILITY OF POLYORGANOSILOXANES

Polydimethylsiloxane, when free from acidic or basic impurities, is extraordinarily stable at relatively high temperatures. In most cases polydimethylsiloxanes are obtained by the anionic polymerisation of cyclic compounds, and the presence of catalysts in them is inevitable. Several papers have shown that the presence of polymerisation catalysts lowers the thermal stability considerably.

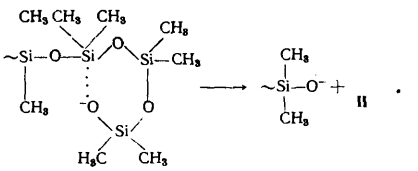
The thermal stability of polymers is greatly dependent on the type of catalyst used for their preparation. Thus the losses in weight of the SKTV brand of siloxane rubber, produced with an acid catalyst, are 25% on heating in a vacuum at 350°C for 2 h, but when an alkaline catalyst is used the same loss in weight is already observed at 265°C.[58] Under conditions of thermal oxidation, polymers prepared with acid catalysts possess diminished thermal stability, since acids accelerate the oxidation of the side-groups. Kučera et al.[59] studied the depolymerisation and oxidation of the lateral groups in polydimethylsiloxanes prepared by anionic polymerisation and neutralised with several acidic agents. The smallest losses in weight were observed in a polymer stabilised with benzoic acid, whereas carbon dioxide had hardly any stabilising effect. The greatest resistance to depolymerisation is exhibited by a mixture of polymers obtained with caustic potash and sulphuric acid as catalysts: depolymerisation of this mixture is completely suppressed at 350°C and 10 mmHg. However, the additives do not protect the polymer from thermo-oxidative degradation: the mixture of polymers obtained with the two catalysts undergoes change in structure especially rapidly.

The two polymers obtained with potassium hydroxide and tetrabutylphosphonium hydroxide as catalysts undergo similar thermal degradation, but the latter polymer undergoes great changes in the course of thermo-oxidative degradation. This is due to breakdown of the catalyst with the formation of acidic products, which accelerate the oxidation[60]. It has been established[59] that the rate of oxidation is a function of the dissociation constant of the acid used as catalyst.

Lewis[61] observed a sharp increase in the rate of decomposition of the polymer after the loss in weight had reached 20%, and assumed this acceleration to be caused by certain components, present in the polymer, which catalysed the process of thermal decomposition. Spectral analysis established the presence of metallic impurities in the polymer (0.05% of barium, 0.01% of lead, 0.0005% of silver, 0.005% of aluminium, and 0.001% of magnesium). Since the concentration of these impurities was too small to catalyse the fission of a silicon–oxygen bond, they were assumed to react with the ends of the chain or to split "abnormal bonds" (silicon–silicon or oxygen–oxygen). This involved formation of so called "live" active centres, which accelerated depolymerisation[61,62]. The polymer molecules underwent dissociation at the point of incorporation of the impurity atom:

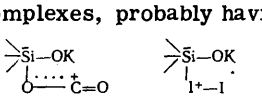


the resulting ions causing depolymerisation with the formation of volatile cyclic products of low molecular weight:



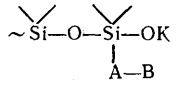
The rate of depolymerisation has been shown to be directly proportional to the square root of the concentration of active centres[63] and to increase with rise in temperature[59].

Several methods have been described for deactivating the active centres, such as the use of thermolabile catalysts, rinsing catalytic impurities out of the polymer, or else neutralising them. Kučera et al.[60] noted that the thermal stability of polydimethylsiloxanes was improved by the introduction of carbon dioxide or iodine. They assumed that these substances form with the active centres relatively stable complexes, probably having the structure



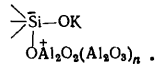
The carbon dioxide complex is stable only up to 150°C. The iodine complexes are considerably more stable, probably because of breakdown initially with the formation of potassium hypoiodite, which then disproportionates into the iodide and the iodate. Both the latter compounds are inert towards the siloxane bond, and neither catalyses the oxidation of methyl groups.

References have been made to the possible formation of stable complexes of the active centres with phenol, anisole, diphenylamine, and other compounds[64]. The stability of a complex, which can be represented by the general formula

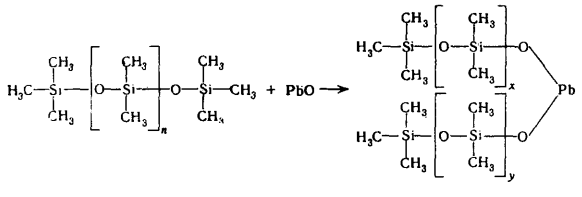


(where A is an electronegative group (oxygen, a halogen), while B is a hydrocarbon group or a metal atom), is determined by the nature of the donor and the type of atom or group combined with it.

Several papers[23,38,60] have dealt with the effect of metals and their oxides, employed for the polymerisation of siloxanes, on the thermal and thermo-oxidative stability of these polymers. Investigation of polymers contaminated with the oxides—ZnO, TiO_2, CdO, MgO, Fe_2O_3, Al_2O_3, BeO, SiO_2, etc.—showed the stabilising effect of these compounds to be very small. However, alumina and beryllium oxide are capable of completely suppressing depolymerisation for a very short time[60]. Only oxides with cations of small radius are able to form complexes with the active centres, which, perhaps, have the structure

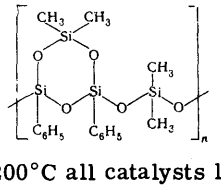


An investigation was made of the action of metals (tin, antimony, copper, lead, aluminium, nickel, selenium, silver, tellurium, zinc, and iron) on the thermal and thermo-oxidative stability of polydimethylsiloxane and polymethylphenylsiloxane. Lead and tellurium accelerated gel formation and the evolution of volatile products, but the other metals had no significant effect[23,38]. It was suggested[38] that lead oxide ruptures the chain under the influence of heat, and then reacts with the fragments to form larger fragments:

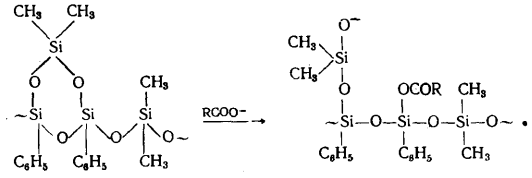


This compound is unstable, and decomposes into smaller fragments. This hypothesis is supported by the turbidity of solutions of the polymer in the presence of lead and tellurium.

Since siloxane polymers are often used as protective coatings and lacquers, it is interesting to examine the action of various pigments and hardening and drying catalysts on the thermal degradation. Andrianov and Fromberg[65] investigated the effect of drying accelerators for varnish films on the heat-resistance of a polymer having the cyclolinear structure



It was found that at 200°C all catalysts lower the heat-resistance of the coatings to roughly equal extents, although the naphthenates of zinc, cobalt, and magnesium have a rather stronger effect. The catalysts are supposed to promote rearrangement of the siloxane chains accompanied by opening of the rings and their recombination, which leads to the formation of cross-linked structures:



The mechanism of degradation varies with the chemical nature of the catalyst. Zinc naphthenate promotes only cleavage of the main chain, but does not affect oxidation of side-groups; whereas lead naphthenate catalyses both oxidation and the cleavage of the main chain. Among pigments (oxides of titanium, chromium, and lead) only chrome yellow catalyses the process of oxidation at 400°C. The remaining pigments do not lower the thermal stability of the films[65].

Investigation of the effect of fillers (titanium dioxide and powdered silica gel) on the thermal oxidation of polydimethylsiloxane showed that, when the degradation products are removed from the sphere of reaction, fillers enhance the thermal stability; if volatile products are not removed, the fillers lower the thermal stability[66]. The authors explain this by the occurrence of hydrolytic processes in the polymer, caused by water adsorbed on the filler (~ 6%).

With the aim of enhancing the thermal stability and improving the mechanical properties of polyorganosiloxanes containing active centres, Berlin et al.[67] proposed subjecting these polymers to a preliminary heat-treatment at 350°C for 1 h. In their view[67] this process occurs by a radical mechanism and comprises the following reactions—degradation of the chains at the weakest bonds and formation of macroradicals, chain transfer by the macroradicals, and cross-linking of the system by recombination of macroradicals with the formation of bonds which are quite stable under the conditions of heat-treatment.

Thus pigments, catalysts, and fillers have a substantial influence on the thermal stability of siloxane polymers. Although the action of these impurities on the silicon–oxygen bond can be quite easily diminished, it is considerably more difficult to inhibit their influence on the oxidation of the side-groups.

7. THERMAL AND THERMO-OXIDATIVE DEGRADATION OF POLYORGANOSILOXANES CONTAINING HETEROATOMS

In spite of the fairly high stability of polyorganosiloxanes, the limits of the fatigue life of these polymers no longer satisfy present-day demands of technology. In order to improve the thermal stability of polysiloxanes, polymers containing various heteroatoms in the chain have been prepared. Introduction into the siloxane chain of fragments the energy of whose bonds is considerably higher than that of the silicon–oxygen bond should increase the thermal stability of polyorganosiloxanes.

Polymers containing heteroatoms were first investigated by Andrianov. Great progress has now been made in the synthesis and investigation of several properties of polyorganosiloxanes containing titanium[68-74], tin[75,76], aluminium[77-80], boron[81-86], and other heteroatoms[87,88] in the chain. Chapters in monographs by foreign authors deal with these polymers[89-91].

The thermal stability of several such heterochain polyorganosiloxanes is far higher than that of polyorganosiloxanes themselves, and depends on the properties of the element introduced into the chain. Polymers containing titanium atoms in the chain exhibit the greatest thermal stability[92-96], and those containing boron and phosphorus atoms are hardly inferior to them. Thus the losses in weight in a vacuum at 450°C after 2 h were 12.7% and 19.3% in polyphosphaborasiloxanes and a polytitanasiloxane. A control specimen of polydimethylsiloxane containing no heteroatoms was completely degraded at 450–500°C.[92]

In an atmosphere of oxygen at 280°C the loss in weight of a phosphaborasiloxane polymer after 28 h was 12.2%, and that of a titanasiloxane polymer 2.47%. Polyborasiloxane retains its elasticity in air up to 390–400°C, polyphosphasiloxanes up to 400–420°C, and polyphosphaborasiloxanes up to 410–430°C; in a vacuum all these polymers remain elastic up to 540–570°C.[92]

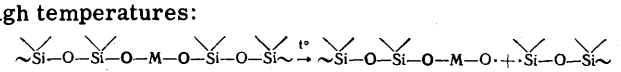
Thermogravimetric analyses indicate that the temperature at which polymethylstannasiloxane begins to decompose is 480°C, the corresponding temperatures for polyethylstannasiloxane and polyphenylstannasiloxane being 462° and 460°C.[97] Introduction of a germanium atom into the chain does not have a favourable effect on the thermal stability of a polyorganosiloxane[98].

The introduction of stannasiloxane copolymers into silicone rubber mixtures produces no improvement in the properties of the vulcanised products[99].

Adequate thermal stability is exhibited by polyphenylchromasiloxanes[100] (losses in weight at 300° and 450°C after 2 h were 12.23% and 43.2%), and also by polyorganoferrasiloxanes and polyorganoferra-alumasiloxanes[101]. Thus polyphenylferrasiloxane is highly stable and loses few volatiles at temperatures of 200–320°C.[101] A striking feature is the lack of correspondence between solubility and infusibility, which is associated with structural characteristics of these polymers.

On the basis of the elementary composition and the infrared spectra Andrianov and his coworkers[102-104] established that heterochain polyorganosiloxanes have a cyclolinear structure. The thermal stability of such rings is very great[103]. Differential thermal analysis indicates that ring-opening occurs at temperatures considerably higher than those at which the organic groups framing the inorganic part of the molecule are stable. The introduction of such groupings as B–O, P–O, P=O, Ti–O, Al–O, and Sn–O into the chain of polyorganosiloxane elastomers raises their thermal stability. It was suggested[95] that this was a consequence of the formation of supermolecular structures and the resultant orderliness of individual segments of the polymer chains.

Poddubnyi and Aver'yanov[105] explain the higher thermal stability of heterochain polyorganosiloxanes (420–430°C) compared with vulcanised SKT and SKTV silicone rubbers (370-380°C) by the inhibiting action of the metal heteroatom on chain radical processes of chain degradation at high temperatures:



where the more polar and stable M–O bond stabilises the Si–O bond and prevents chain cleavages at high temperatures from extending further than the heteroatomic unit. This hypothesis is consistent with the rupture of a silicon–oxygen bond in the immediate vicinity of a chain unit containing a heteroatom requiring the consumption not only of the energy evolved in its formation but also an additional quantity of energy equal to the difference between the internal energies of the radicals ≥Si· and ·O–M.[106]

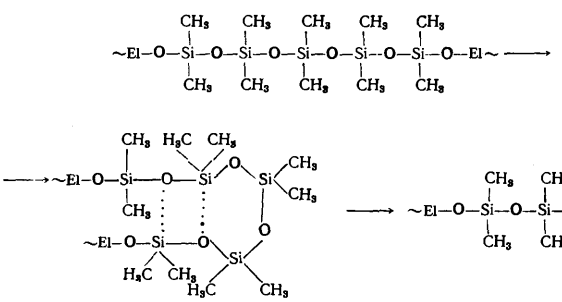
Andrianov[2] put forward the hypothesis that the enhancement of the thermal stability of the polymer by the introduction of heteroatoms into the chain was due to the possibility of forming coordinate bonds between the metal atoms and the oxygen of neighbouring chains.

It has also been established[41] that increasing the functionality and the coordinating power of the heteroatom leads to an improvement in thermal stability, while strengthening the basic power and diminishing the energy of the heteroatom–oxygen bond impair the thermal stability of heterochain polydimethylsiloxanes. Heteroatoms form the sequence—Al < B < Fe < Ti—according to their effect in improving the thermal stability of polymers.

Investigation of the thermal degradation of heterochain polyorganosiloxanes of regular structure containing aluminium, titanium, and boron atoms has shown that, as with polyorganosiloxanes themselves, the major part of the volatile products responsible for the losses in weight consists of hexamethylcyclotrisiloxane formed by cleavage of the silicon–oxygen bond. At high temperatures homolytic cleavage of silicon–hydrogen and carbon–hydrogen bonds also takes place, with the evolution of small amounts of hydrogen, methane, and ethane[41,107,108].

It has also been found[41] that the introduction of heteroatoms leads to a change in the mechanism of degradation. As a consequence of the presence of heteroatoms in the siloxane chain, the formation of an activated complex takes place according to the law of chance, not at the end-groups, as in linear polydimethylsiloxane. It is possible that depolymerisation at terminal groups ceases at the nearest heteroatom, and plays no part in the overall process.

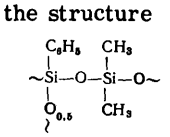
In view of the spiral structure of the siloxane chains, with three silicon atoms in a loop, formation of an activated complex followed by the elimination of cyclic products can be represented as



This hypothesis is supported by the good agreement between experimental and calculated values of the activation energy (29–33 and 32 kcal mole^{-1}) of formation of the transition complex shown. Formation of a transition complex involving a heteroatom is energetically unfavourable, since the activation energy will then considerably exceed 32 kcal mole^{-1}.

The thermo-oxidative stability of polyorganosiloxanes is strongly influenced by the introduction of a small quantity of polyorganoalumasiloxanes[109-111]. Thus the addition of polyphenylalumasiloxane to polydimethylpolyphenylsiloxane shifts the start of rapid decomposition under conditions of thermal oxidation from 400° to 450–500°C, while the loss in weight diminishes from 60% to 30%.[109]

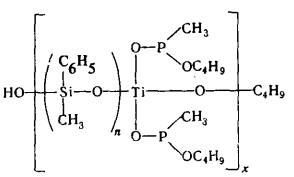
Andrianov and Petrashko[110] investigated the polyorganosiloxane having the structure



and its copolymers with polyphenylalumasiloxane containing 0.05%, 0.1%, 0.25%, and 0.5% of aluminium. Oxidation of the organic groups was found to be more vigorous in the copolymers than in the homopolymer. However, the losses in weight did not exceed the weight fraction of the organic portion, as in the case of polydimethylpolyphenylsiloxane. Hence no cleavage of the main chain takes place in the copolymers, and no organosilicon compounds of low molecular weight are evolved. The authors explain this by the formation in the copolymer of aluminium–oxygen coordinate bonds, which give rise to cross-linking and impede the formation of compounds of low molecular weight.

Thus the rate of thermo-oxidative degradation in the copolymers was found, on the one hand, to be increased in comparison with the homopolymer, owing to the more vigorous oxidation of the phenyl groups, and on the other to be decreased by cross-linking of the polymer. One or other process prevails depending on the aluminium content.

No published data are available on the effect of elements, introduced into the siloxane chain, on the mechanism of thermo-oxidative degradation, or on the composition and quantity of degradation products. Only in one paper is it noted that the thermal oxidation at 400°C for 4 h of poly-bis(organophosphinoxy)titana-methylphenylsiloxanes[112]

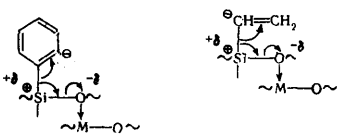


where n = 30, 50, 90, 120, 200, yields carbon dioxide together with liquid and solid organosilicon compounds of low molecular weight. With increase in the distance between the bisorganophosphinoxytitanoxane groups the quantity of cyclic products evolved diminishes, while the amount of carbon dioxide somewhat increases.

Very interesting work was done by Petrashko and Andrianov[96] on the effect of metal atoms in the siloxane chain on the rate of detachment of various organic groups during thermal oxidation. A polymer containing organosilasesquioxane units was investigated, whose thermal oxidation did not involve cleavage of silicon–oxygen bonds, so that the losses in weight could serve as a criterion of the stability of the organic radicals in this process. The rates of elimination of the radicals were compared by means of the dependence of the R/Si ratio on the time of heating. It was found that phenyl groups were eliminated considerably more vigorously than vinyl groups from the heterochain polymers, whereas the opposite relation was observed in the polyorganosiloxanes themselves. The intensity of detachment of a phenyl radical depends on the metal in the siloxane chain, increasing in the sequence Ti < Sn < Al. When the same metals are introduced into polydimethyl- and polydiethyl-siloxanes the stability of such polymers increases in the sequence Ti < Al < Sn.

The reason for the different effects of the organic radicals on thermal stability in polyorganosiloxanes and in the heterochain polymers is that phenyl and vinyl radicals exert a negative induction effect on the silicon atom. These radicals will therefore tend to attract a pair of electrons away from the silicon atom:

A bond of this type produces enhanced resistance to oxidation. When an Si–O–M bond is present in the molecule, the metal atom coordinates with the oxygen in the chain. The coordinate bond causes deformation of the electron sheath of the siloxane bond towards the oxygen atom, and the silicon atom acquires an induced positive charge +δ. The electron pair of the silicon–carbon bond shifts in the opposite direction to that caused by interaction of this electron pair with the π-bonds of the radical. This bond is thereby weakened:



Allyl radicals exert a positive induction effect on the silicon atom. The positive charge on the silicon atom induced by the metal–oxygen coordinate bond produces a displacement of the electron pair in the same direction as the induced effect of the radical. The stability of the radical is thereby raised.

8. STABILISATION OF POLYORGANOSILOXANES

The literature contains references to the possibility of stabilising polyorganosiloxanes, but there is no common approach to this problem. Since thermo-oxidative degradation comprises two independent processes—oxidation of side-groups and cleavage of the main chain with the evolution of volatile products of low molecular weight—all stabilisers which have been recommended can be provisionally divided into two groups—those which inhibit the oxidation of side-groups, and stabilisers which prevent rupture of the main chain in siloxane polymers.

Since the oxidation of side-groups in siloxane polymers has much in common with the oxidation of aliphatic groups in organic polymers (e.g. polypropylene), many authors suggest the use of antioxidants, which have proved to be very satisfactory for the stabilisation of polypropylene. The use of amines as stabilisers in the oxidation of a liquid polyethylsiloxane at 175–200°C increased the induction period of the increase in viscosity, the most effective at 200°C being phenyl-1-naphthylamine[113,114], aldol-1-naphthylamine[114], diphenylamine[115], Neozone D[113,115], and dinaphthylamine[115].

With liquid polydimethylsiloxane an increase in the duration of oxidation before a gel is formed at 200–400°C is observed[116] in the presence of antioxidants like aromatic amines and phenols. Since the latter may themselves decompose at high temperatures, the use of phenoxazine is recommended. The stability of polyorganosiloxanes can be improved[117] by means of amides (e.g. adipamide and urea). The use of antioxidants containing phosphorus is also advised, in particular phosphites of the type $P(OR)_3$ where R is an alkyl or an aryl group[118].

A solution of a polyorganosiloxane resin to which hardening catalysts have been added is stabilised against change in viscosity during storage by the addition of 0.5 wt.% of a

monohydric aliphatic alcohol containing four or more carbon atoms (e.g. 2-ethylhexanol).[119]

The thermal stability of polyphenylethyl- and polyphenylmethyl-siloxanes enamels at 250°C can be enhanced by the use of ethylated and butylated amine–formaldehyde resins[120].

To raise the stability of liquid polydimethylsiloxanes to gelatinisation under the influence of high temperatures it is recommended that 0.5–5 wt.% of bromine should be introduced[121]. The time of gelatinisation is then increased from 24 h for an unstabilised specimen to 1900 h for a specimen containing 0.9 wt.% of bromine (after degradation at 250°C).

Bass, Berlin, et al.[122] proposed stabilising siloxane polymers against thermo-oxidative aging by means of fused aromatic compounds, e.g. anthracene, previously in a vacuum at 300–450°C.

Substances capable of forming stable complexes with the active centres have been proposed as stabilisers to prevent cleavage of the main chain. Thus 0.06 wt.% of iodine[51] or 0.01–0.5 wt.% of partly dehydrated hydroxides of aluminium and iron[123] have been suggested; oxides of various metals—Fe, Al, Be, Si, Ti,[59] Co and Cu,[124] Ni, Mn, Cr[125]—are employed for the same purpose.

It has been observed that, when various compounds of metals are introduced into polyorganosiloxanes, the rate of depolymerisation falls considerably. Therefore most authors propose the addition of a great variety of metal compounds. Especially good results are given by compounds of transition metals, among which such salts have been suggested as the acetates and octanoates of iron[126], the naphthenates of lead[127], zinc, cobalt, iron, and manganese[65], the naphthenates and octanoates of indium and cerium[128]. The use has been proposed of the chlorides, acetates, fluorides, sulphates, nitrates, naphthenates, and oxides of such rare-earth metals as lanthanum, neodymium, praseodymium, samarium, gadolinium, and ytterbium[129].

More complicated compounds have also been recommended, such as cerium complexes[130], and Schiff bases with copper, cobalt, nickel, lead, cadmium, and tin ions[131]. The most effective is a stabiliser formed from the Schiff base *NN'*-bis-2-hydroxy-1-naphthylidene-ethylenediamine with copper ions, which increases the stability to thermal oxidation ninefold.

Compounds of ferrocene—acetylferrocene, 1,1'-diacetylferrocene[132], 1,1'-bisdimethylethoxysilylferrocene, and 1,3-bis-(1,1'-ferrocenylene)tetradimethylsiloxane—have been suggested as stabilisers[133].

Good results are obtained by using as stabilising additives dialkyl sebacates[134] and also dialkyltin oxide[135,136]. A stabilising effect has been noted with the acetylacetonates of chromium, zinc, magnesium, nickel, and cobalt[137], and also with trihexyloxyiron and tributoxyzirconium[138]. The authors showed that the improvement in stability of polydimethylsiloxanes produced by adding the above compounds was due to the formation, in the process of thermal degradation, of a new polymer having heteroatoms in the chain[139].

There are also references to the stabilisation of siloxane oils by treating them at 100–200°C with compounds capable of forming monofunctional trialkylsilyl groups in the presence of cation-exchange polymers of natural type[140].

Gruber, Klebanskii, et al.[141] recommend improving thermal stability by introducing compounds capable of acting as centres of orientation and thereby creating an ordered secondary structure. Among such recommended additives are oxides, both similar in nature to and different from the siloxane chain, as well as certain finely divided metals and oxides.

Although quite a wide range of stabilisers have already been proposed for polyorganosiloxanes, the problem of their stabilisation still remains a complicated task. The most effective would obviously be stabilisers combining the properties of an antioxidant with the ability to increase the stability of the main siloxane chain. Since polyorganosiloxanes are thermostable polymers, their thermal stability can probably be improved also by using thermally stable, non-volatile compounds which develop a stabilising action at high temperatures.

The Radical Addition and Telomerisation of Conjugated Dienes

I.B.Afanas'ev and G.I.Samokhvalov

Reactions are reviewed involving the radical addition and telomerisation of conjugated dienes with halogeno-derivatives of aliphatic hydrocarbons, thiols, sulphonyl chlorides, stannanes, t-butyl hypochlorite, chlorine, and hydrogen bromide. The mechanisms are examined of reactions occurring under the influence of the usual radical-generating initiators, and also of redox systems based on salts of metals of variable valency, peculiarities of the reaction of the growing chain in the allyl radical caused by its low reactivity. A considerable part of the paper deals with problems of the structural and steric isomerism of the addition products, the kinetics of the reactions under consideration, and the reactions of several analogues of conjugated dienes. A list of 86 references is included.

I. INTRODUCTION

An unsaturated isoprenoid chain with regularly arranged methyl groups constitutes the basis of the structure of very important naturally occurring compounds, such as the carotenoids, vitamin A, the terpenes, natural rubber, side-chains of ubiquinones, and vitamins K and E. Its cyclisation yields cyclic mono-, di-, and tri-terpenes, and also their structural analogues, on which the structure of the steroid hormones, steroidal alkaloids, and several other natural compounds is based.

Considerable progress has been made during recent years in studying the biogenesis of natural isoprenoids, in identifying the intermediate compounds which form building blocks in their biosynthesis. However, much still remains obscure in understanding the processes of formation of unsaturated isoprenoid chains with their rigorous steric and structural specificity[1].

The reactions of the radical addition and telomerisation of conjugated dienes, leading to isoprenoids or their close analogues, have several specific features. The low activity and hence great selectivity of the growing allyl radical, the structural and steric isomerism of the telomers are of interest for the theory of free-radical reactions. Furthermore, investigations on the free-radical isomerisation and cyclisation of unsaturated compounds, in particular telomers of conjugated dienes, may open up a route to the synthesis of cyclic analogues of natural compounds.

The present review may be of interest to research workers concerned with the chemistry of free-radicals and to those dealing with the synthesis of natural compounds.

II. MECHANISM OF RADICAL REACTIONS OF CONJUGATED DIENES

In 1936 Kharasch et al.[2] discovered that peroxides influence the relative proportions of the isomeric bromobutenes formed by the reaction of buta-1,3-diene with hydrogen bromide. They therefore suggested a free-radical mechanism for the formation of the 1,4-isomer, which has since been confirmed many times. In the case of radical reactions of conjugated dienes the Kharasch mechanism can be represented by the general scheme

$$AX + R_i\cdot \rightarrow A\cdot + R_iX \quad \text{initiation} \qquad (1)$$

or

$$AX \xrightarrow{h\nu} A\cdot + X\cdot$$

$$A\cdot + \text{Diene} \rightarrow A(\text{Tel})\cdot \qquad (2a)$$

$$A(\text{Tel})\cdot + (n-1)\,\text{Diene} \rightarrow A(\text{Tel})_n\cdot \quad \text{chain growth} \qquad (2b)$$

$$A(\text{Tel})_n\cdot + AX \rightarrow A(\text{Tel})_nX + A\cdot \quad \text{chain transfer} \qquad (3)$$

$$2A\cdot \rightarrow \text{Products}$$

$$A(\text{Tel})_n\cdot + A(\text{Tel})_m\cdot \rightarrow \text{Products} \quad \text{chain termination} \qquad (4)$$

Here R_i is an initiator radical, AX a molecule of the compound (telogen) which adds to the diene. Addition of more than one diene molecule to the telogen radical A· leads to formation of a telomeric radical $A(Tel)_n$· and then to telomeric products $A(Tel)_nX$.

A fundamental difference between this mechanism and the mechanism of radical telomerisation of alkenes and unconjugated dienes is that in the present case the telomeric radical is allyl, which is relatively unreactive. Therefore the dissociation energy of the A–X bond and the

heat of reaction of the chain transfer (3) play a decisive part in effecting a chain mechanism. If the dissociation energy $D(A-X)$ is relatively high, and the heat of reaction ΔH of stage (3) negative, reaction becomes impossible (at ordinary temperatures) owing to the low activity of the radical $A(Tel)_n^{\cdot}$.

Table 1 gives tentative values of $D(A-X)$ and ΔH for the reactions of dienes $CH_2:CRCH:CH_2$ ($R = H$, CH_3) with several halogenated compounds. Since in this case addition should take place mainly at the 1,4-positions (Table 2), it was assumed in the calculations that

$$D\,(ACH_2CR{=}CHCH_2{-}X) \approx D\,(CH_2{=}CHCH_2{-}X).$$

In conformity with these calculations, investigation of the reactions of isoprene with the compounds listed in Table 1 has shown[4] that, in the presence of benzoyl peroxide or azoisobutyronitrile in glass ampoules, or also on ultraviolet irradiation at 20–100°C, only bromotrichloromethane reacts, the chain-transfer stage being least endothermic (almost thermoneutral) for this compound.

Table 1. Energy of dissociation of bonds $D(A-X)$ and heat of reaction of chain transfer ΔH for the addition of halogenated alkanes to conjugated dienes.

A–X	D(A–X)(Ref.3), kcal mole^{-1}	$D(ACH_2CR:CHCH_2-X)$ (Ref.3), kcal mole^{-1}	ΔH, kcal mole^{-1}
CCl_3—Br	49,5±3	47,5±2	−2±3
CCl_3—Cl	67	60,4±3	−7±3
C_2H_5—I	51	34,1±1,5	−17±1,5
CCl_3—H	90±3	77	13±2

An important variation of the Kharasch mechanism is the scheme of radical telomerisation of dienes initiated by redox systems based on salts of metals of variable valency. In this case the metal salts are involved in the stages not only of initiation but also of chain transfer. For example, carbon tetrachloride reacts readily with buta-1,3-diene[5,6] and isoprene[4] if the iron(III) chloride–diethylamine hydrochloride-benzoin system is used as initiator. It is supposed[6] that initiation and chain transfer take place by means of the following reactions (with butadiene):

$$FeCl_2 + CCl_4 \rightleftarrows FeCl_3 + CCl_3\cdot \qquad (5)$$

$$CCl_3(C_4H_6)_n\cdot + FeCl_3 \rightleftarrows CCl_3(C_4H_6)_nCl + FeCl_2\,. \qquad (6)$$

Both reactions are probably reversible. Since $D(FeCl_2{-}Cl) = 50$ kcal mole^{-1},[3] the heat of reaction (6) is $\Delta H \simeq +10$ kcal mole^{-1}: i.e. iron(III) chloride is a considerably more effective chain carrier than is carbon tetrachloride.

Another possible explanation of the action of redox systems is that the solvents used for homogenising the reaction mixture with redox initiation probably also take part in the reaction. Very reactive intermediate compounds ("mediators") can then be formed, which are efficient chain carriers. This mechanism was suggested[7] for the initiation by iron salts of the telomerisation of ethylene with carbon tetrachloride in propan-2-ol, it being assumed that the mediator is the chlorocarbinol $(CH_3)_2CCl(OH)$.

III. REACTIONS INVOLVING FISSION OF C–X BONDS (X = H, Hal) IN THE TELOGEN MOLECULE

In contrast to unconjugated dienes and alkenes, conjugated dienes react with great difficulty by a free-radical mechanism with compounds where chain transfer involves the C–X bond (X = H, Hal). This is explained by the relatively high dissociation energies of the bonds and the low activity of the telomeric allyl radical. The most detailed study has been made of the reactions of bromotrichloromethane, which reacts readily with buta-1,3-diene[8–12,14], isoprene[4,13], 2,3-dimethylbuta-1,3-diene[13], 2-t-butylbuta-1,3-diene[15,16], 1,1,3-trifluorobuta-1,3-diene[17], cyclopentadiene[18], and cyclohexa-1,3-diene[18]. Peroxides and exposure to visible light, ultraviolet radiation, X-rays, and γ-rays have been used to initiate these reactions. Thermal initiation is also possible. The main reaction product was the telomer $CCl_3(Tel)Br$ (n_1) with a chain length $n = 1$. In several cases products of high molecular weight were formed[9,11–13], the content of these compounds increasing with the duration of the reaction. This suggests that the telomer n_1 reacts in stages:

$$CCl_3(Tel)\,Br + CCl_3\cdot \rightarrow CCl_3Br + CCl_3(Tel)\cdot \qquad (7)$$

$$CCl_3(Tel)\cdot + Diene \rightarrow CCl_3(Tel)_2\cdot \xrightarrow{CCl_3Br} CCl_3(Tel)_2Br + CCl_3\cdot \qquad (8)$$

not in conformity with Eqn. (2b).

Isoprene reacts similarly with carbon tetrabromide (under the influence of γ-rays[19]), and butadiene with ethyl tribromoacetate (on ultraviolet irradiation[20]), with pentadecafluoro-1-iodoheptane (in the presence of azoisobutyronitrile[21] and on heating[22]), and with carbon tetrabromide (in the presence of potassium peroxodisulphate[23]). The addition of trichloroiodomethane to perfluorobutadiene under the influence of ultraviolet radiation has been described in the patent literature[24,25]. The reactivity of these telogens is close to that of bromotrichloromethane.

Telomerisation of carbon tetrachloride with buta-1,3-diene[26,27] and piperylene[27] in the presence of benzoyl peroxide, and that of chloroform with butadiene[29] in the presence of acetyl peroxide, have also been reported. The reactions with carbon tetrachloride were conducted only in steel autoclaves[26]. As mentioned in Section II, the allyl radical is unable to react at ordinary temperature with the C–Cl bond in carbon tetrachloride. The above results[26,27] therefore, are probably explained by the presence in the steel autoclaves of catalytic quantities of iron salts, which form redox initiator systems.

In the reaction of butadiene with chloroform[28] a large amount of initiator was used (molar ratio of acetyl peroxide to butadiene 1 : 2). The authors state that only the telomer n_2 was obtained, isomeric composition (45% 1,4-1,4-, 45% 1,2-1,2-, and 10% 1,4-1,2-isomers) being inconsistent with a radical reaction mechanism. Perhaps a side-reaction involving acetyl peroxide took place in this case.

An American patent[29] has described the reaction between chloroform and perfluorobutadiene in the presence of trichloroacetyl peroxide, but the structure of the reaction products was not determined.

The use of redox systems based on salts of metals of variable valency has recently enabled addition and telomerisation reactions to be accomplished between conjugated dienes and unreactive telogens. It has already been mentioned that carbon tetrachloride reacts with buta-1,3-diene[5,6] and isoprene[4] at 100–140°C under the influence of redox systems based on iron and copper salts. In the reaction with butadiene the telomer n_2 was isolated[6] as

Table 2. Content of isomers in products of addition (n_1) to conjugated dienes.

well as n_1. Chloroform reacts under similar conditions with butadiene[5,30,31], with the formation mainly of 1,5,5-trichloropent-2-ene:

$$CHCl_3 + CH_2{=}CHCH{=}CH_2 \xrightarrow{(FeCl_2,CuCl_2)} CHCl_2CH_2CH{=}CHCH_2Cl \qquad (9)$$

i.e. chloroform reacts with cleavage of the C–Cl bond. This confirms that chain transfer involves the metal salt ("ligand" transfer) or "carrier"[7], since chain transfer involving chloroform is accompanied predominantly by cleavage of a C–H bond[32].

When solutions of iron(II) chloride in acetonitrile are used, buta-1,3-diene reacts at 90–120°C with mono-, di-, and tri-chloroacetonitrile, allyl chloride, and 1,3-dichloropropene, isoprene with dibromoacetonitrile, chloroprene with but-2-enyl chloride and dichloroacetonitrile, and 2,3-dimethylbuta-1,3-diene with dibromoacetonitrile and trichloroacetonitrile[33]. In all cases the main product of the reaction was the telomer n_1. The reactions were accompanied by cleavage of C–Cl and C–Br bonds in the telogen molecules.

IV. REACTIONS INVOLVING FISSION OF Si–X, Sn–X, N–X, P–X, O–X, S–X, Cl–X, and Br–X BONDS (X = H, Hal) IN THE TELOGEN MOLECULE

1. Compounds of Group IV Elements (other than Carbon)

Trichlorosilane reacts with buta-1,3-diene at 300°C to form 1-trichlorosilylbut-2-ene [34], but in the presence of azo-compounds at 65–115°C readily hydrolysable telomers having $n = 7–8$ are obtained [35]. Trichlorosilane probably reacts similarly with perfluorobutadiene [36]. According to Steele et al. [37] the dissociation energy of the $Cl_3Si–H$ bond is 93 ± 4 kcal mole^{-1}, so that the chain-transfer stage should be strongly endothermic ($\Delta H \simeq -16$ kcal mole^{-1}). It has already been pointed out (Section II) that, with such a value for the heat of reaction of the chain-transfer stage, the addition of organic compounds to conjugated dienes is not very probable. It must be borne in mind, however, that the dissociation energies of bonds in organoelementary compounds have not been determined too reliably (see below). The dissociation energy of the Sn–H bond in organotin hydrides is relatively small (~50 kcal mole^{-1}) [38], and therefore alkyl- and aryl-stannanes (dimethyl-, trimethyl-, triethyl-, tricyclohexyl-, dibutyl-, triphenyl-, and di-isobutyl-stannanes) add easily to buta-1,3-diene [39,41] isoprene [41], piperylene [40,41], 2,3-dimethylbuta-1,3-diene [41], cyclopentadiene [41], and cyclohexa-1,3-diene [41] on heating, on exposure to ultraviolet radiation, and in the presence of azoisobutyronitrile, e.g.

$$(C_2H_5)_3SnH + CH_2{=}CHCH{=}CH_2 \rightarrow (C_2H_5)_3SnC_4H_7. \quad (10)$$

2. Compounds of Group V Elements

It has been reported in the patent literature that the telomerisation of buta-1,3-diene with ammonia can take place under the influence of γ-rays [42]. Telomers of general formula $NH_2[C_4H_6]_nH$ are obtained, where $n = 6, 7$. Since the dissociation energy of the N–H bond in ammonia is 103 kcal mole^{-1}, [43] the heat of reaction of the chain transfer (3) is $\Delta H \simeq -26$ kcal mole^{-1}. Therefore a radical chain reaction mechanism is improbable in this case.

Nitrogen compounds containing reactive N–Hal bonds may be expected to react by a free-radical mechanism. In fact, nitryl chloride NO_2Cl [44] and dialkylchloramines [45] add readily to buta-1,3-diene with cleavage of the C–Cl bond. However, a radical mechanism has been suggested only for the reaction with dialkylchloramines, the radicals being assumed to react in the protonated form (radical-cations). The addition of aliphatic azo-compounds to conjugated dienes undoubtedly occurs by a radical mechanism [46]. For example, azoisobutyronitrile reacts with butadiene at 75°C to form telomers having $n_{av} = 2–5$:

$$NC(CH_3)_2C{-}N{=}N{-}C(CH_3)_2CN \rightarrow 2(CH_3)_2CCN + N_2 \quad (11)$$

$$2(CH_3)_2\dot{C}CN + nC_4H_6 \rightarrow NC(CH_3)_2C(C_4H_6)_nC(CH_3)_2CN. \quad (12)$$

The chain-transfer stage (3) is probably absent from this reaction, the telomers being formed by the recombination of growing radicals.

Only one example of the addition of phosphines to conjugated dienes is known: dibutylphosphine reacts with buta-1,3-diene in the presence of azoisobutyronitrile to form the telomers n_1 and n_2. [47]

3. Compounds of Group VI Elements

According to Kochi [48] t-butyl hypochlorite adds to buta-1,3-diene under the influence of ultraviolet radiation:

$$(CH_3)_3COCl + C_4H_6 \rightarrow (CH_3)_3COC_4H_6Cl. \quad (13)$$

This reaction is the sole example of a radical chain addition to conjugated dienes with rupture of the O–X bond in the chain-transfer stage†.

Besides bromotrichloromethane, thiols mostly take part in free-radical addition reactions of dienes. Published values of D(RS–H) are 88 at 75 kcal mole^{-1} for methanethiol and benzenethiol [43]. It can therefore be expected that only thiophenol will react relatively easily, since in this case the heat of reaction of stage (3) is $\Delta H = +2$ kcal mole^{-1}. However, aliphatic thiols, for which $\Delta H \simeq -(10–11)$ kcal mole^{-1}, react quite well with conjugated dienes. It seems to us that the difference in reactivity between thiols and derivatives of aliphatic hydrocarbons (carbon tetrachloride, chloroform, etc.) may be apparent, since the above values of D(S–H) are not very reliable, and according to Refs. 49 and 50, for example, $D(CH_3S–H) = 83.1$ kcal mole^{-1}. Therefore further discussion of the energetics of chain transfer in the reactions of thiols will be possible only after values for the dissociation energies of the bonds involved have been refined.

The reactions of aliphatic thiols, thiophenol, thioacetic acid, β-thionaphthol, etc. have been described with buta-1,3-diene [52–59], isoprene [52,58], piperylene [52,60], 2,3-dimethylbuta-1,3-diene [52], 2-t-butylbuta-1,3-diene [16], 2,5-dimethylhexa-2,4-diene [61], chloroprene [52], cyclopentadiene [62], cyclohexa-1,3-diene [62], cyclo-octa-1,3-diene [62], 2,3-dimethylenebicyclo[2,2,1]heptane [62], 1,2-dimethylenecyclohexane [63], and 3-methylenecyclohexene [63]. Although the formation of telomers of high molecular weight was observed in several cases, the main products of the reaction were adducts of chain length $n = 1$.

In the absence of an initiator, sulphur chloride pentafluoride readily adds to buta-1,3-diene at 100°C: [64,65]

$$SF_5Cl + CH_2{=}CHCH{=}CH_2 \rightarrow SF_5C_4H_6Cl. \quad (14)$$

Similarly, alkane- and arene-sulphonyl chlorides react with conjugated dienes with cleavage of the S–Cl bond. In these compounds, however, the dissociation energy of the bond is probably quite high, and addition occurs only in redox systems based on salts of metals of variable valency. In these reactions, therefore, a "ligand" chain-transfer mechanism involving the metal salt should be operative (Section III), e.g. [66]

$$CH_3SO_2Cl + Cu^{1+} \rightarrow CH_3SO_2\cdot + Cu^{2+}Cl \quad (15)$$

$$CH_3SO_2\cdot + CH_2{=}CHCH{=}CH_2 \rightarrow CH_3SO_2C_4H_6\cdot \quad (16a)$$

$$CH_3SO_2C_4H_6\cdot + Cu^{2+}Cl \rightarrow CH_3SO_2C_4H_6Cl + Cu^{1+}. \quad (16b)$$

With the use of solutions of copper(II) chloride in acetonitrile (with or without the addition of diethylamine hydrochloride) or in dichloromethane at 70–100°C, buta-1,3-diene and isoprene react with benzenesulphonyl, benzene-*m*-disulphonyl, *p*-chlorobenzenesulphonyl, and toluene-*p*-sulphonyl chlorides [66–68].

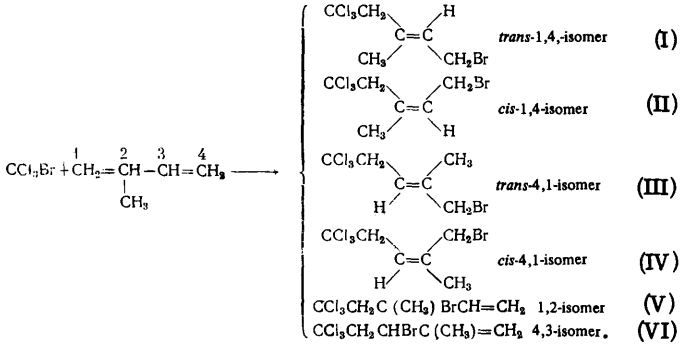
†The addition of peroxides ROOR and hydroperoxides ROOH [48,51] to dienes has a radical chain mechanism. However, instead of the chain transfer (3), the radicals here undergo oxidation by metal salts (Section V).

4. Compounds of Group VII Elements

Although the addition of halogens and hydrogen halides to conjugated dienes is well known, the free-radical character of the reaction has been demonstrated only in a few cases. As already mentioned (Section II), a radical mechanism was first suggested[2] actually for the reaction of hydrogen bromide with butadiene in the presence of peroxides. Even in this case, however, it is not possible to suppress ionic addition completely. In 1966 Poutsma showed[69] that the chlorination of buta-1,3-diene in the dark at −9°C in the absence of oxygen takes place mainly by a free-radical mechanism, although this reaction had previously been regarded as a classical example of electrophilic addition. The radical nature of the reaction was proved by the formation of chlorocyclohexane on the addition to the reaction mixture of cyclohexane, which does not undergo ionic chlorination. In the presence of oxygen—which inhibits the free-radical reaction—the quantity of chlorocyclohexane in the reaction products dropped sharply. On irradiation radical chlorination took place even in solvents. The reaction resulted in the adduct ClC_4H_6Cl, and the formation of higher telomers and tetrachloroalkanes was also noted. A free-radical mechanism is evidently possible also in the reactions of dienes with hydrogen chloride, bromine, and in other similar cases.

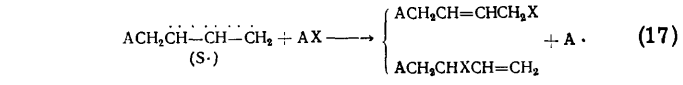
V. STRUCTURAL ISOMERISM OF TELOMERS. COMPETITION BETWEEN 1,2- AND 1,4-ADDITION

Even with the chain length $n = 1$ telomerisation products of conjugated dienes constitute a complicated mixture of both structural isomers and stereoisomers. As example a scheme is given below for formation of the n_1 telomer from bromotrichloromethane and isoprene (an unsymmetrical diene):



The possible reaction products are not exhausted by the six compounds given above, but the remaining compounds (2,1- and 3,4-isomers) are hardly formed at all, since free radicals attack mainly the terminal carbon atoms of the diene molecule. In the case of symmetrical dienes (buta-1,3-diene, 2,3-dimethylbuta-1,3-diene, etc.) the number of isomers diminishes to three (I, II, and V).

From the scheme for the chain-transfer reaction



which is mainly responsible for the ratio of 1,4- and 1,2-isomers (I and V) produced, it is seen that the relative quantities of these isomers should be determined by the dual reactivity of the allyl radical (S·), and hence should depend on the structure of the diene and the telogen. This radical S· exists predominantly in the form of the secondary radical, which is further stabilised by hyperconjugation of the unpaired electron with the ACH_2 group.

The relative proportions of 1,4- and 1,2-isomers found experimentally are given in Table 2. (It should be noted that reliable quantitative determination of the ratio (I) : (V), and also of other stereoisomers and structural isomers, has become possible only during recent years as a consequence of the development of methods of high-efficiency gas–liquid chromatography and nuclear magnetic resonance spectroscopy. Therefore papers and patents[5,6,10,11,21,22,26,33] which noted the formation only of 1,4-isomers—without the requisite careful analysis—require further checking, and are not included in Table 2.) It is seen from Table 2 that, even in the reactions of the same diene (e.g. buta-1,3-diene, which has been studied in greatest detail), the ratio (I) : (V) varies within wide limits (from ~ 100 : 0 to 10 : 90) depending on the nature of the telogen. This ratio is evidently determined mainly by the rate of reaction (17). The greater the rate of this reaction (i.e. the weaker the A–X bond which is cleaved and the greater the heat of reaction of chain transfer), the more probable is reaction of the more stabilised and consequently less active secondary radical S·, and hence the larger the amount of the 1,2-isomer formed. Thus among the products of reactions for which $\Delta H_{17} \leqslant 0$ (bromotrichloromethane, ethyl tribromoacetate, thiols, dialkylchloramines) the content of the 1,4-isomer is close to 100%, whereas when $\Delta H > 0$ (alkylstannanes, chlorine, and probably t-butyl hypochlorite) it is 75–80%.

Chain transfer is probably accomplished with still greater ease in the catalytic addition of peroxides[48,70]. In these reactions transfer of an electron by scheme (6) i.e. the redox reaction between the free radical and an ion of the metal of variable valency, takes place instead of the "ligand" chain transfer. For example, the following mechanism has been suggested[48] for the addition of acetyl t-butyl peroxide to buta-1, 3-diene in the presence of copper acetate:

$$(CH_3)_3COOCOCH_3 + Cu^{1+} \rightarrow (CH_3)_3CO\cdot + Cu^{2+}OCOCH_3 \quad (18)$$

$$(CH_3)_3CO\cdot + C_4H_6 \rightarrow (CH_3)_3COC_4H_6\cdot \quad (19)$$

$$(CH_3)_3COC_4H_6\cdot + Cu^{2+}OCOCH_3 \rightarrow (CH_3)_3COC_4H_6OCOCH_3 + Cu^{1+}. \quad (20)$$

Although the heat of reaction (20) is unknown, it is probably quite high, since the content of the 1,4-isomer falls to 10–30% (Table 2). "Ligand" chain transfer involving metal salts probably occurs at a lower rate, and therefore, in the addition of t-butyl hydroperoxide to butadiene in the presence of iron and copper halides, the content of the 1,4-isomer in the mixture of reaction products is 65%.[48]

The addition of the electrochemically generated methyl radical to buta-1,3-diene has been reported[72]. The ratio of 1,4- and 1,2-isomers is then 78 : 22, but in this case the ratio may be determined to a considerable extent by adsorption of radicals on the electrode.

The above reactions were conducted at temperatures between −10° and +100°C. Available data do not enable the dependence of the ratio of 1,4- and 1,2-isomers on the reaction temperature to be assessed, although rise in temperature must be expected to increase the content of the 1,2-isomer, which is formed by reaction of the less active secondary radical.

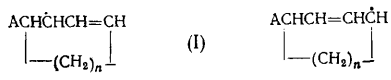
The structure of the diene also can influence the ratio of 1,4- and 1,2-isomers. Addition to isoprene produces an isomeric ratio (1,4 + 4,1) : 1, 2 which is close to the

corresponding ratio with butadiene (Table 2). In the reactions of *cis*- and *trans*-piperylene, both 1,2- and 1,4-isomers are formed from secondary radicals $ACH_2\dot{C}HCH:CHCH_3$ and $ACH_2CH:C\dot{C}HCH_3$, and therefore products of the reactions of thiols and stannanes with both isomeric piperylenes contain increased amounts of the 1,2-isomers in comparison with the reaction products obtained with buta-1,3-diene[60]. Moreover, the 4,1-isomer is formed, but the 4,3-isomer is absent. This result was to be expected, since the former isomer is produced from a primary radical, and the latter from a secondary radical. The ratio of 1,2- and 1,4-isomers in the reaction products of bromotrichloromethane, stannanes, and thiols with 2,3-dimethylbuta-1,3-diene[13,41,52] and with buta-1,3-diene changes little on passing from one diene to the other.

In the reactions of 2,5-dimethylhexa-2,4-diene[61], however, the 1,2-isomer becomes the main product (68–92% of the total composition of the telomer n_1), since formation of the 1,4-isomer involves the still less active tertiary radical $AC(CH_3)_2CH:C\dot{C}(CH_3)_2$.

1,2-Isomers are absent among products of the addition of bromotrichloromethane and butanethiol to 2-t-butylbuta-1,3-diene[16].

The addition of a telogen radical to cyclic conjugated dienes yields only secondary radicals (I) and (II)



(I)

(II)

so that in these cases formation of 1,4- and 1,2-isomers should be about equally probable. The quantities of 1,4- and 1,2-isomers found experimentally vary respectively within the limits 40–90% and 10–60% (Table 2). The reaction products obtained from conjugated methylenecycloalkenes (3-methylenecyclohexene, 1,2-dimethylenecyclohexane, 2,3-dimethylenebicyclo[2,2,1]heptane[63]) comprise almost entirely 1,4-isomers, since the radicals leading to 1,2-isomers are tertiary.

VI. STRUCTURAL ISOMERISM OF TELOMERS. COMPETITION BETWEEN 1,4- AND 4,1-ADDITION

Structural 1,4–4,1-isomerism is possible for the products of addition to unsymmetrical dienes, the relative content of the two isomers depending on the nature and position of the substituent in the diene molecule. If the substituent is attached to a quaternary carbon atom, the radical from which the 1,4-isomer is formed is secondary, i.e. more stable. Furthermore, in this case steric hindrance to attack by the free radical on the substituted end of the diene molecule is possible. Both effects tend to prevent formation of 4,1-isomers, and therefore the content of 1,4-isomers in the products from *cis*- and *trans*-piperylenes with thiols[60] exceeds by factors of 3–10 the content of the 4,1-isomers.

The influence of substituents in position 2 of a conjugated diene on the distribution of 1,4- and 4,1-isomers is more complicated. Both radicals ($ACH_2CY:CHCH_2^{\cdot}$ and $ACH_2CH:CYCH_2^{\cdot}$) responsible for formation of the corresponding isomers are primary, and their reactivity can be differentiated only by means of an indirect (polar, resonance, or steric) effect of the substituent Y. Results obtained for additions to isoprene show (Table 2) that the introduction of a methyl group into a diene molecule leads to the formation mainly of 1,4-isomers‡. The predominance of 1,4-isomers in this case is probably explained by greater stabilisation of the radical $ACH_2C(CH_3):CHCH_2^{\cdot}$ than of $ACH_2CH:C(CH_3)CH_2^{\cdot}$, by hyperconjugation of the unpaired electron with the methyl group. The polar effect of the methyl group can probably be neglected. This is seen from the example of the reactions of bromotrichloromethane and thiols with isoprene, 2-t-butylbuta-1,3-diene, and chloroprene: reaction of bromotrichloromethane with isoprene yields 71.9% of the 1,4-isomer and 26.1% of the 4,1-isomer[13], but in the reaction with 2-t-butylbuta-1,3-diene 50% of each isomer is formed[16]. Thus, although the polar effect of the t-butyl group exceeds that of the methyl group (the Taft constant $\sigma^*_{(CH_3)_3C} = -0.300$ [73]), the absence of α-hydrogen atoms makes the group almost incapable of hyperconjugation with the unpaired electron, so that it does not influence the distribution of 1,4- and 4,1-isomers resulting from attack by the trichloromethyl radical. On the other hand, the distribution of 1,4- and 4,1-isomers in the addition products of thiols to chloroprene[52] is the same as in reactions with isoprene[52], although such a strongly electronegative substituent as chlorine ($\sigma^*_{Cl} = 2.9$ [73]) should have more strongly prevented attack by the electrophilic radicals RS$^{\cdot}$ in position 1 than in position 4. The predominance of the 1,4-isomer in this case is probably explained by stabilisation of the corresponding radical by hyperconjugation with the chlorine atom.

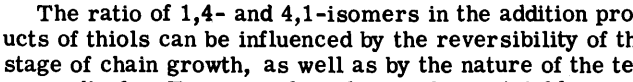
As already remarked, the ratio of 1,4- and 1,2-isomers is determined primarily by the molecular structure of the conjugated diene and the rate of chain transfer. However, 1,4—4,1-isomerism of addition products is probably influenced to a considerable extent also by the nature of the attacking free radical. A radical containing polar substituents will obviously add to the diene in such a way that unfavourable interactions with polar substituents of the diene will be minimised. In the reaction of bromotrichloromethane with 1,1,2-trifluorobuta-1,3-diene, for example, the trichloromethyl radical adds to the diene only at the fourth carbon atom, which then leads to formation of the 1,4-isomer $BrCF_2CF:CHCH_2CCl_3^{\cdot}$:

Stabilisation of a telogen radical increases its selectivity, so that the less active a free radical the greater the probability of formation of a more stabilised radical by reaction with a diene. It is therefore likely that the difference in reactivity between free radicals explains the diminished content of the 4,1-isomer in the reactions of isoprene with the radicals $CCl_3^{\cdot}$ [13] and $CH_3OOC[CH_2]_5^{\cdot}$ [71] respectively. The influence of the nature of the telogen radical can be traced most clearly in the reactions of isoprene with thiols as example. Reaction of isoprene with ethanethiol, as in the case of bromotrichloromethane, yields 75% of the 1,4-isomer and 25% of the 4,1-isomer[52]. In the reactions with thioacetic acid and thiophenol, however, the content of the 4,1-isomer falls to 10% and 2.5% respectively[52]. The reason for this change in the ratio of the isomers is evidently increased stabilisation and hence diminished reactivity of the free radicals in the sequence $C_2H_5S^{\cdot}$, $CH_3COS^{\cdot}$, $C_6H_5S^{\cdot}$. Thus determination of the relative rates of addition to the first and the last carbon atom of an

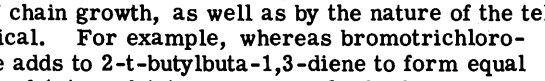
‡An exception is Neumann and Sommer's paper[41], in which it is stated, on the basis of an analysis of the infrared spectra, that predominantly 4,1-isomers are formed by the reaction of alkylstannanes with isoprene. In our opinion, however, this assertion, which contradicts the results of other investigations, requires further confirmation.

unsymmetrical diene can be used to estimate the resonance stabilisation of the added free radical.

The ratio of 1,4- and 4,1-isomers in the addition products of thiols can be influenced by the reversibility of the stage of chain growth, as well as by the nature of the telogen radical. For example, whereas bromotrichloromethane adds to 2-t-butylbuta-1,3-diene to form equal amounts of 1,4- and 4,1-isomers, only the former isomer is obtained with butanethiol[16]. The authors explain this anomaly by the reversibility of the addition of thiyl radicals to the diene:



(21)



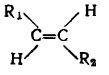
(22a)

(22b)

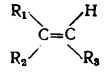
The probability of the formation of radicals (A) and (B) on the addition of $C_4H_9S^{\cdot}$ is the same as in the case of the trichloromethyl radical, but if, owing to steric hindrance due to screening of the reaction centre by the t-butyl group, the rate of chain transfer (22b) is considerably lower than the rate of reaction (21), the 4,1-isomer will be almost completely absent. It is interesting that, if the suggested mechanism is correct, the ratio of 1,4- and 4,1-isomers for analogous reactions should depend on the thiol : diene ratio, since the rate of reaction (22b) depends on the thiol concentration, whereas the rate of reaction (21) is independent thereof.

VII. STEREOISOMERISM OF TELOMERS

As already mentioned (Section V), stereoisomerism (*cis–trans*) is possible in the reaction products of 1,4- and 4,1-addition. In most of the work, unfortunately, the spatial configuration of the telomers has been determined only by infrared spectroscopy without separation of the isomers. Infrared spectra enable the presence only of a *trans*-isomer having two substituents adjacent to the double bond



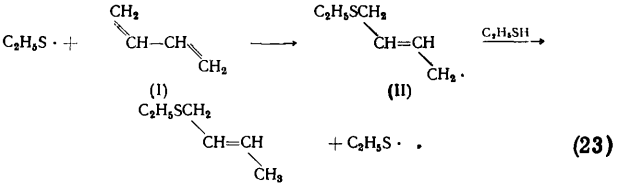
to be established reliably (frequency of deformation vibration of C–H bond 965 cm^{-1}), whereas the absorption frequency of the corresponding *cis*-isomer (728–675 cm^{-1}) is not characteristic[74]. Determination of the steric configuration of compounds containing three substituents adjacent to the double bond



is probably impossible from the infrared spectra, so that there are hardly any data on the *cis–trans*-isomerism of addition products to conjugated dienes containing substituents attached to the second carbon atom.

Most authors consider that radical 1,4-addition to buta-1,3-diene yields only the *trans*-isomer (Table 2). Although relatively small amounts of the *cis*-isomer might be formed and remain undetected for the reason indicated above, the predominant formation of the *trans*-isomer can evidently be accepted as proved. For example, Poutsma[69] showed by gas–liquid chromatography that the 1,4-isomer formed by reaction of chlorine with buta-1,3-diene was identical with the known *trans*-isomer, while the *cis*-isomer was absent from the mixture of reaction products. In contrast to the results obtained by most other authors, Jacobs and Illingworth[53] found that ethanethiol reacts with butadiene in the presence of azoisobutyronitrile at 70°C to form a mixture of addition products comprising 80% of the *trans*-isomer and 20% of the *cis*-isomer. However, the products of the same reaction under the influence of ultraviolet radiation at 20°C contain not more than 6% of the *cis*-isomer[52].

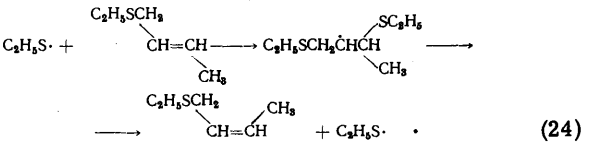
The configuration of telomers is evidently determined by the steric structure of the diene[60] and the possibility of isomerisation of the resulting addition product. At ordinary temperatures buta-1,3-diene occurs mainly (> 96%) in the more stable transoid conformation (I).[75] If, therefore, the initial conformation of the diene molecule is preserved during addition of the telogen radical and the subsequent chain-transfer reaction, the resulting telomer will have the *trans*-configuration:



(23)

With rise in temperature the content of butadiene in the *cis*-conformation increases, and the probability of change in the spatial conformation of the radical (II) also increases, which should lead to an increase in the yield of the *cis*-1,4-isomer. In fact, raising the temperature from 0° to 100°C in the radical polymerisation of butadiene leads to an increase in the *cis*-units in the polymer from 12% to 35%.[76]

Conducting the reaction at a low temperature and excluding the effect of metallic walls of the reaction vessel enable thermal and catalytic isomerisation of the products to be avoided. However, the presence of free thiyl radicals, as well as bromine and iodine atoms, in the reaction medium may cause isomerisation of the telomers as a consequence of the ability of these radicals to add reversibly at a double bond:



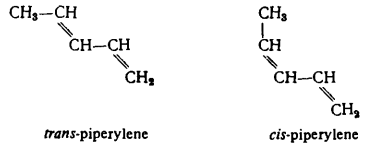
(24)

Therefore the increase in the yield of the *cis*-product of the addition of ethanethiol to butadiene with rise in reaction temperature from 20° [52] to 70°C [53] can be explained both by increase in the relative content of butadiene in the cisoid conformation and by isomerisation of the *trans*-isomer by thiyl radicals.

As in the case of buta-1,3-diene, the interaction of thiols with 2,5-dimethylhexa-2,4-diene[61] involves predominant formation of the *trans*-1,4-isomer compared with the *cis*-1,4-isomer.

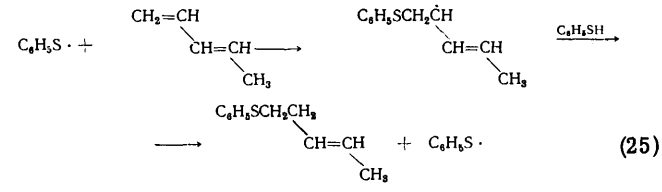
A detailed study has been made[60] of the stereoisomerism of addition products of thiols with *cis*- and *trans*-piperylene, when it was assumed that, as with buta-1,3-diene,

both isomers of piperylene exist in the more stable transoid conformation:

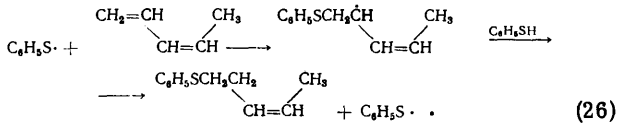


trans-piperylene *cis*-piperylene

Therefore the 1,4-isomers of the addition products, independently of the spatial structure of the initial diene, had the *trans*-configuration. Investigation of the isomerism of the 1,2-addition products enabled the dependence of the steric structure of the radical on the structure of the telogen (thiol) to be determined. It was found that 1,2-isomers of the reaction products with thiophenol were formed from radicals which preserved the configuration of the diene: i.e. *trans*-piperylene yielded mainly the *trans*-1,2-isomer, whereas *cis*-piperylene gave the *cis*-1,2-isomer:



(25)



(26)

When thiophenol was replaced by aliphatic thiols, the stereospecificity of 1,2-addition dropped sharply. Thus the reaction of *cis*-piperylene with methanethiol (at 96% conversion of the latter) led to the formation of 14% of *cis*- and 13.4% of *trans*-1,2-isomers. The loss of stereospecificity is explained by a decrease in the rate of chain transfer via methanethiol molecules (in comparison with benzenethiol), and hence an increase in the lifetime of the free allyl radical, this in turn increasing the probability of change in its steric configuration.

The principal factors influencing the relative proportions of structural isomers and stereoisomers in the mixture of reaction products from conjugated dienes can be summarised as—(1) the structure of the dienes, (2) the structure of the telogens, (3) stabilisation of the telomeric (allyl) radical, (4) the polar effect of the reaction, (5) the temperature of the reaction, (6) the relative rates of forward and reverse reactions in the addition of the telogen radical to the diene, and (7) isomerisation of the reaction products.

VIII. KINETIC INVESTIGATIONS

Few kinetic data are available on the free-radical addition and telomerisation of conjugated dienes. Investigations have been made of the kinetics of the radical addition of ethyl tribromoacetate to butadiene[20] and of bromotrichloromethane to butadiene, isoprene, and 2,3-dimethylbuta-1,3-diene[12,13]. It was found that the reaction velocity was independent of the diene concentration but increased with the concentration of the telogen. These data suggest that even at high telogen : diene ratios the rate-determining stage of the reaction is chain transfer. With a bromotrichloromethane : diene ratio of 3 the reaction velocity is approximately proportional to the square root of the rate of initiation, and in the case of ethyl tribromoacetate to the rate of initiation to the power 0.83. Thus with bromotrichloromethane chain termination is bimolecular, whereas with ethyl tribromoacetate termination is possible also by a unimolecular mechanism. The overall activation energies for the reactions of bromotrichloromethane with butadiene, isoprene, and dimethylbutadiene are respectively 5.45, 3.96, and 3.09 kcal mole^{-1}.

Chain-transfer constants have been determined for the telomerisation of buta-1,3-diene with aliphatic thiols[77,78]. The values obtained (at 0–60°C) lie in the range from 3–6 (for tertiary thiols) to 15–25 (for primary thiols). Sivertz and his coworkers[79] used the rotating sector method to determine the chain-transfer rate constant for the telomerisation of isoprene with butanethiol (93 M^{-1} s^{-1} at 25°C).

Table 3. Ratio of rate constants for the addition of free radicals to butadiene and to ethylene.

Radical	Temp., °C	$\frac{k_{Bu}}{k_{Et}}$	Ref.
CH_3[b]	25	94	80
CH_3[b]	65	53	81
CH_3[c]	65	43	8
CCl_3[c]	50—60	18[a]	82
CF_3[c]	65	11.6	80

[a] Compared with the rate of addition to oct-1-ene.
[b] In the gas phase.
[c] In the liquid phase.

The addition of several free radicals to buta-1,3-diene in both gaseous and liquid phases has been investigated. Table 3 shows that the rate constants for addition of free radicals to butadiene are considerably higher than to ethylene, which is undoubtedly explained by resonance stabilisation of the allyl radical formed. Because of the high rate constants for addition of the radicals, the rate-determining stage in telomerisation and addition to conjugated dienes is chain transfer.

IX. ANALOGUES OF CONJUGATED DIENES

The free-radical additions of thiols to conjugated alkenynes—butenyne, 2-methylbutenyne, etc.—investigated by Sulimov and Petrov[83] are of considerable interest. These workers found that, of the six possible structural isomers in the reaction of thiols with butenyne, only four—e.g. (I) $CH_3SCH_2CH_2C:CH$ (39%), (II) $CH_3SCH_2CH:C:CH_2$ (40%), (III) $CH_2:C(SCH_3)CH:CH_2$ (18%), and (IV) $CH_3SCH::CHCH:CH_2$ (3%)—were formed. (The mixtures of isomers were analysed by gas–liquid chromatography and also by infrared and nuclear magnetic resonance spectroscopy.) The results show that thiyl radicals attack the butenyne molecule mainly at the double bond, the 1,2- and 1,4-isomers (I) and (II) being formed in roughly equal quantities. It is noteworthy that in this case the radical

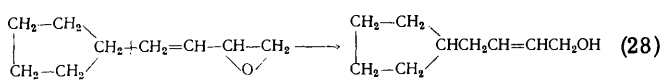
$CH_3SCH_2CH:C:CH^{\bullet}$, from which the 1,4-isomer is formed, is not allylic, and is probably considerably less stabilised than is the secondary radical $CH_3SCH_2\dot{C}HC:CH$. The reactions of butenyne with benzenethiol, and of substituted butenynes with ethanethiol and butanethiol, yield only two isomers, corresponding to (I) and (II).

Compounds in which a double bond can be conjugated with a three-membered ring can also be regarded as analogues of conjugated dienes. Work has been done on the addition and telomerisation of vinylcyclopropane [84,86], isopropenylcyclopropane [85], and also their oxygen-containing derivatives [86] and butadiene monoxide [84] with bromotrichloromethane, carbon tetrachloride, thiols, propan-2-ol, and cycloalkanes in the presence of benzoyl peroxide and under the influence of radiation. Vinylcyclopropane and isopropenylcyclopropane reacted with cleavage of the three-membered ring to form 1,5-isomers, e.g.

$$CCl_3Br + CH_2{=}CH\text{–}\underset{\diagdown\,CH_2\,\diagup}{CH}\text{–}CH_2 \longrightarrow CCl_3CH_2CH{=}CHCH_2CH_2Br . \qquad (27)$$

An exception was provided by the reaction with thiols, which, depending on the structure of the vinylcyclopropane derivatives, produced, owing to their high reactivity, a mixture of rearranged and unrearranged (without ring cleavage) products or even one of the possible isomers [85,86].

A study of the three-dimensional structure of the reaction products of vinylcyclopropane with bromotrichloromethane showed [84] that the 1,5-isomer is an equilibrium mixture of *cis*- and *trans*-forms. The establishment of equilibrium was proved by the fact that additions of iodine and methanethiol do not affect the proportions of the stereoisomers. On the other hand, since 1,5-isomers formed from butadiene monoxide with cycloalkanes and isopropyl alcohol in conformity with the scheme



$$\begin{matrix} CH_2\text{–}CH_2 \\ | \qquad\quad \diagdown \\ CH_2\text{–}CH_2 \end{matrix} CH_2 + CH_2{=}CH\text{–}CH\text{–}CH_2 \longrightarrow \begin{matrix} CH_2\text{–}CH_2 \\ | \qquad\quad \diagdown \\ CH_2\text{–}CH_2 \end{matrix} CHCH_2CH{=}CHCH_2OH \qquad (28)$$

have the *trans*-structure, it was considered that the reaction of bromotrichloromethane with cyclopropane at first also yields exclusively (or predominantly), the *trans*-isomers, which only then are converted, under the influence of bromine atoms, into an equilibrium mixture of the two isomers. (Bromine atoms are formed from bromotrichloromethane at the stage of initiation by ultraviolet radiation.) In conformity with this, the telomers formed by the reaction of cyclohexane with vinylcyclopropane (in which no atoms or free radicals capable of reacting reversibly with a double bond are present) are probably *trans*-isomers [84].

Electronic Factors in Catalytic Reactions Under the Influence of Ionising Radiation

G.M.Zhabrova and V.I.Vladimirova

A comprehensive analysis of published data on catalytic reactions under the influence of ionising radiations is given. The combination of heterogeneous catalysis and ionising radiation effects is shown to be a new area in which the study of electronic factors leads to an understanding of the role of free and of localised charge carriers in the elementary acts of catalytic reactions. Some problems in the electronic theory of catalysis involving the effect of radiation are formulated, and data on the role of the catalytically active centres produced by prior irradiation of the catalyst are reported. Catalytic reactions taking place under the influence of ionising radiation are discussed, and possible mechanisms (usually involving electronic and free-radical steps) are considered. 138 references.

I. PROBLEMS IN THE ELECTRONIC THEORY OF CATALYSIS INVOLVING THE EFFECT OF RADIATION ON SOLIDS

The use of ionising radiation in the study of heterogeneous catalysis offers the possibility of controlled modification of the electronic properties of solid catalysts.

It is well established[1-5] that the main effect of ionising radiation on solids is to generate excess charge carriers (electrons and holes). In some cases structural defects are produced.

These effects, often accompanied by colour changes, enhanced electrical conductivity, and paramagnetic properties, are intimately connected with the catalytic activity of the solid. Therefore, the use of ionising radiation in the study of catalysis and catalytic reactions can provide additional information on the role of various defects and impurities, and also on the formation of catalytically active centres and on the effect of the concentration of excess current carriers on the catalytic properties of solids†.

Thus, the purpose of using an agency as powerful as radiation in heterogeneous catalysis is to generate structural defects able to act as catalytically active centres. From the standpoint of the electronic theory of catalysis the main interest lies in the appearance of excess charge carriers in solids exposed to irradiation, i.e. of electrons and holes, which can take part in the elementary acts of chemical reactions on catalyst surfaces.

Over 30 years ago the founder of the electronic theory of catalysis (Pisarzhevskii[6]) carried out the first investigations of the combined effect of radiation and catalysts on chemical reactions. He was able to show that the rate of oxidation of hydrogen on platinum is significantly increased by the action of u.v. radiation. The effect of u.v. and X-rays on hydrogen peroxide decomposition catalysts (platinum, graphite, lead dioxide) was more complicated: depending on the experimental conditions and on the pretreatment of the catalyst, the reaction could be accelerated or inhibited. Pisarzhevskii's explanation of this behaviour relies on the relative number of active centres, which can increase or decrease on different parts of the surface.

† This review is not concerned with photocatalytic and photoadsorption effects, which constitute a self-contained field of study.

We need not dwell on this early period of the study of radiation effects in catalysis: the development of radiation catalysis as a field of study began in the late 1950's, following the advances in nuclear technology and in solid-state physics and physical chemistry. Significant advances in the study of the electronic mechanism of catalytic reactions and of their elementary acts were also made at about this time[7-9].

The modern electronic theory of catalysis, based on the band model of the solid state, is primarily concerned with catalysts having semiconductor properties[9]. However, the conclusions of the electronic theory are equally applicable to dielectrics, because these two classes of solids differ only in the width of the forbidden gap. According to the electronic theory, the entities responsible for the adsorption and catalytic properties of solids are electrons and holes, which can be either free or localised on lattice defects. The equilibrium concentrations of these carriers are determined by the position of the Fermi level at the surface, itself a function of the bulk Fermi level. Various factors, known to influence the position of the Fermi level, can be expected to affect the adsorption and catalytic properties of the semiconductor.

Attempts are now being made to apply the electronic models of the theory of adsorption and catalysis to the effect of radiation on the catalytic and adsorption properties of semiconductors. Vol'kenshtein[10-13] treats radiation as a factor with a profound effect on the electronic structure of solids. Two limiting cases can be envisaged. In the first case the effect of radiation is confined to direct ionisation, i.e. to the generation of non-equilibrium concentrations of charge carriers in the semiconductor, and hence to a perturbation of the electronic equilibrium in the solid. The perturbation decays very rapidly when the source of radiation is removed. "Memory" effects, i.e. permanent changes in the catalytic and adsorption properties, are practically non-existent in semiconductors. A radiation-induced "memory", on the other hand, can persist for a long time in the second limiting case, when the preliminary irradiation (e.g., by neutrons) induces a nuclear reaction in the semiconductor and is therefore equivalent to chemical doping. There is also an intermediate, and very common, case in which irradiation produces structural defects without altering the chemical composition of the semiconductor.

The resulting radiation "disorder" of the lattice shifts the Fermi level and thus displaces the electronic equilibrium. On ceasing the irradiation electronic equilibrium in the semiconductor is gradually re-established. This process is accelerated by heating. Vol'kenshtein discusses also the case of an anomalous radiation-induced "memory", which can persist for relatively long periods after irradiation is discontinued even though no structural defects have been produced. The anomalous memory effect manifests itself as a change in the catalytic and adsorption properties of the catalyst, and is ascribed to trapping of the radiation-induced non-equilibrium current carriers on intrinsic surface defects (i.e. defects originating otherwise than by the action of radiation). Thus, the anomalous radiation-induced memory is closely associated with the concept of F, V, and other centres, which can be treated as electrons and holes trapped at cation and anion vacancies. The existence of these centres has been established by extensive investigations of the radiation physics of solids[1,4,5]. In the following section we shall discuss experimental evidence that centres of this type can be catalytically active in previously irradiated catalysts (mainly in insulators).

On the basis of the general ideas of the electronic theory, Vol'kenshtein[12,13] has discussed the mechanism by which previous irradiation can affect the kinetics and the equilibrium of adsorption processes, and the rate of catalytic reactions. He has shown, in particular, that for a given set of irradiation conditions the magnitude and the sign of the effect are determined by the temperature and by the initial value of the Fermi level.

Baru and Vol'kenshtein[14,15] have considered, from the standpoint of the electronic theory of chemisorption and catalysis, the mechanism of charge formation and of ionisation in a semiconductor subjected to radioactive self-irradiation (i.e. doped with a radioactive element). They were able to define the conditions under which one or the other of these competing mechanisms is predominant.

Coekelbergs and coworkers[16] gave a theoretical analysis of the effects stemming from a change in the steady-state concentration of charge carriers, and calculated the influence of this change on the kinetics and the equilibrium of heterogeneous catalytic reactions.

Thus, the use of ionising radiation has stimulated further developments in the electronic theory of catalysis. It must be stressed that existing theoretical ideas are as yet largely qualitative, because of the lack of key experimental data on the localised energy levels of various defects and impurities in the solid or arising from adsorbed molecules. There are no data on excess carrier concentrations, surface barrier heights, etc. after irradiation. Special investigations, and refined experimental techniques, are needed to obtain this type of information.

II. NATURE OF THE ACTIVE CENTRES FORMED BY PRIOR IRRADIATION OF THE CATALYST

The physical and chemical processes induced by prior irradiation give rise to "long-lived" active centres on the surface of the catalyst. Catalysts which have been thus modified by radiation can then be used in ordinary heterogeneous catalytic reactions.

The effect of prior irradiation on catalyst activity has been the object of extensive investigations: references to the early work can be found in existing review articles[17-22]. It should be noted that the formation of active centres is only one of the phenomena which can determine the influence of prior irradiation on the catalytic activity of the sample. Thus, there are reports of prior irradiation causing poisoning of the catalyst[23], desorption of catalytic poisons from the surface[24,25], and enhanced gas adsorption[26,27], which also affects the catalytic activity. Prior irradiation can also influence the topochemical stage of catalyst preparation, and thus affect its properties[28]. Hence, it is essential to exclude all these complicating factors when studying the effect of radiation on catalytic activity: in particular, the catalysts must be thoroughly degassed before irradiation to ensure reproducible results.

Since most catalytic reactions take place at elevated temperatures, the stability of the radiation-induced active centres becomes an important consideration. For the same reason, the model reactions chosen to investigate the effect of irradiation on catalytic activity are usually relatively simple, low-temperature reactions, such as hydrogen isotope exchange, hydrogen peroxide decomposition, ethylene hydrogenation, oxidation of carbon monoxide, etc. For convenience, we shall classify the published data by catalyst type (metals, semiconductors, and insulators).

With metallic catalysts, prior irradiation with gamma rays usually produces only a very small increase or decrease in the activity towards low-temperature reactions such as the decomposition of hydrogen peroxide[29,30], the oxidation of hydrogen on platinised alumina–silica[31], and the hydrogenation of nitrobenzene on nickel and platinum catalysts[32].

With high-temperature reactions (e.g. the dehydrogenation of cyclohexene on platinised alumina–silica[29] and the dehydrogenation of cyclohexane on a copper catalyst[33]), prior irradiation had no effect on the activity of the catalyst. More significant changes in activity were observed after bombarding metallic catalysts with inert gas ions[34,35] or neutrons[33].

Prior irradiation of catalysts of the semiconductor or insulator type can also produce either an increase or a decrease in catalytic activity, depending on the particular catalyst, on the irradiation conditions, and on the type of radiation, and also on the chosen reaction.

The radiation-catalytic effects of gamma radiation invariably show a fast decay (annealing) on raising the temperature. Thus, the catalytic activity of silica gel and alumina towards the hydrogen–deuterium isotope exchange reaction induced by gamma irradiation disappears even at 0°C.[36] Changes in catalytic activity produced by neutron irradiation are much more stable[24,36-39].

Small changes in catalytic activity after irradiation have been observed in the oxidation of carbon monoxide on cuprous oxide[40], nickel oxide, and zinc oxide[41], in the dehydrogenation of ethanol on copper oxides[42], in the oxidation of formic acid on a carbon catalyst[43], and in the decomposition of hydrogen peroxide on nickel oxide[44].

Irradiation has a much greater effect on the catalytic activity of insulators, such as alumina, silica gel, magnesium oxide, and alumina–silica. The hydrogen–deuterium exchange reaction is outstanding in its sensitivity to prior irradiation of the catalyst. By using a gamma-irradiated catalyst (e.g. alumina[24,25], titanium dioxide[45], silica gel[36,37,46-53], alumina–silica[54]), the rate of this reaction at 77°K can be increased by several orders of magnitude. A significant increase in reaction rate following irradiation of the catalyst has been observed with magnesium oxide[55], and a somewhat smaller increase with zinc oxide[50].

Irradiation of silica gel[36], magnesium oxide[56,57], and alumina[58] had an appreciable effect on the rate of *ortho–para* hydrogen conversion. Leffler and Ostar[59] found that the rate of this reaction is strongly influenced by prior mixed irradiation (neutrons and gamma rays) of low-activity

catalysts (aluminas with small admixtures of transition-metal salts).

Hentz[60,61] noted a sharp increase in the activity of an alumina–silica catalyst towards the decomposition of isopropylbenzene at room temperature after gamma irradiation.

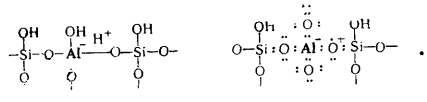
Both increases and decreases in catalyst activity after irradiation have been reported also for reactions of the acid–base type[38,39,60-68]. Particularly interesting in this respect is the work of Mikovsky and Weisz[39], who showed that the catalytic activity of silica gel and alumina–silica samples towards the isomerisation of butene could be increased drastically and stably by prior irradiation in a nuclear reactor using a neutron flux of integrated intensity 10^{20} cm^{-2}, the activity of the silica gel being increased almost 50-fold. Surprisingly, the activity of the catalyst did not fall on heating, suggesting the formation of active centres of the impurity or structural type on irradiation.

Barter and Wagner[67] found that silica gel becomes catalytically active in the isomerisation of cyclopropene and butene after being irradiated with 3 MeV electrons.

The most detailed studies of the hydrogen–deuterium exchange reaction were reported by Kohn and Taylor[24,25,36,37,45-50], and also by Mishchenko and coworkers[51-53]. According to the former, the activity of silica gel increases with content of alumina, probably because the electrons and holes produced by irradiation can be trapped on active centres present in the solid. Kohn and Taylor studied the colour centres and the paramagnetic centres of irradiated silica gel[46-48], and concluded from their results that both the colouration and the appearance of adsorption and catalytic activity after irradiation are associated with the capture of the resulting charge carriers (holes) by impurity atoms (in particular, aluminium). The adsorption centres and the catalytic centres in irradiated silica gel are believed to be of different kind. The authors have not definitely identified the catalytically active centres on the surface of the irradiated catalyst, but they believe that the paramagnetic and the catalytic centres are somehow related.

Kohn and Taylor's conclusion that the specific activity of identically irradiated silica gel samples increases with alumina content has been confirmed[51-53] by independent workers. However, and in contrast to Kohn and Taylor's results, the latter found that the adsorption and catalytic activity in irradiated silica gel change in the same sense as the intensity of the ESR signal on changing the temperature (Fig. 1). This suggests that the surface centres responsible for hydrogen adsorption and for isotope exchange are identical. The formation of these surface centres for adsorption and catalysis is related to the presence of aluminium impurities in the silica gel: the impurity atoms create acidic centres in the surface layer of the silica gel, and the free electrons produced by irradiation are captured by protons with formation of hydrogen atoms.

The charge which appears on an aluminium atom when a proton is expelled under the influence of radiation is compensated by a hole which is stabilised by an oxygen atom adjacent to the aluminium atom:



The correlation between the formation of colour centres during irradiation of alumina–silica catalysts and the appearance of catalytic activity was stressed also by Hentz[69], who studied the decomposition of isopropylbenzene on previously gamma-irradiated alumina–silica catalysts of different composition. He concluded that activation centres created by the irradiation and related to solid-state defects are the source of energy for the decomposition of isopropylbenzene with formation of benzene, unsaturated hydrocarbons, and hydrogen. Aluminium atoms, which can trap a positive hole, play the role of defects in alumina–silica catalysts. Other centres, unrelated to colour centres, but active towards the dealkylation of isopropylbenzene, have been postulated in addition to these activation centres.

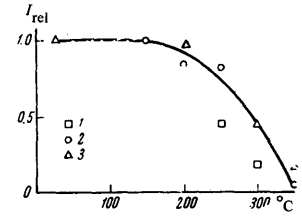


Figure 1. Catalytic activity (*1*), intensity of the sextet in the ESR spectrum (*2*), and adsorption capacity (*3*) of irradiated silica gel, in relative units, as a function of vacuum baking temperature[51].

Lunsford and Leland[55,57] explained the increased catalytic activity of magnesium oxide towards the hydrogen–deuterium exchange and *ortho–para* hydrogen conversion reactions after neutron irradiation, and also the appearance of an ESR signal, in terms of a change in the electronic structure of magnesium oxide. They postulate the formation of electron traps consisting of radiation defects but similar to impurity defects such as tervalent iron cations.

Studies of the action of radiation on alumina–silica butene isomerisation catalysts[65], and of the cracking of isopropylbenzene on alumina–silica after irradiation with protons or gamma rays[70], have revealed parallel changes in catalytic activity and in the strength of the ESR signals from paramagnetic centres.

Sazonov and coworkers[71] showed that prior irradiation of rare-earth oxides (lanthanum, samarium, gadolinium) increases the rate of oxygen isotope exchange by two orders of magnitude. Catalytically active centres are assumed to be formed during irradiation by the trapping of free electrons on anion vacancies. The analogy between the active centres formed by heat treatment in a vacuum and those found in irradiated samples was stressed[72], and it was suggested that the active centres in both cases are metal ions associated with an oxygen vacancy, since the binding energy of an excess electron is different at these sites.

Thus, summarising the results of various investigations, we note that the most widely held view of the nature of the catalytically active centres produced in insulating and in semiconducting oxide catalysts by irradiation is that the centres consist of electric charge carriers localised on various types of surface defects. The active centres created by irradiation can be analogous to the active centres which operate in ordinary catalytic reactions.

The use of ionising radiation offers new methods of creating active centres and of studying their nature and their role in catalytic and chemisorption processes. The

most stable active centres appear, as a rule, in insulators, which are characterised by a wide forbidden gap.

III. FEATURES OF CATALYTIC REACTIONS TAKING PLACE UNDER THE INFLUENCE OF IONISING RADIATION

The width of the forbidden gap of the catalyst, the main factor in determining the stability of radiation-induced catalytic centres, is particularly important in catalytic reactions taking place under the influence of radiation, since in this case the elementary act of a multistage radiation–catalytic reaction can involve the less active centres as well: electrons and holes held in "shallow" traps, and free excess carriers.

The lifetime of radiation-induced defects in a solid is a very sensitive function of temperature for a given set of irradiation conditions. Therefore, catalytic reactions with simultaneous irradiation can be divided into two groups: those taking place at relatively high temperatures, such as are used in ordinary catalysis, and reactions carried out at low temperatures, whose rate would be negligibly small but for the influence of radiation.

1. Catalytic Reactions Under the Influence of Radiation at High Temperatures

In radiation–catalytic reactions at temperatures high enough for the rate to be appreciable even in the absence of radiation, the effect of the radiation is to contribute an additional term to the overall reaction rate. A critical temperature can usually be found, depending on the nature of the reaction, of the catalyst, and of the radiation, above which the radiation ceases to have any effect and the contribution of the radiation term to the overall reaction rate practically vanishes. A similar relationship is found also in studies of the effect of radiation on the electrophysical properties of solids. Unfortunately, no simultaneous studies of the effect of temperature on the electrophysical properties and on the catalytic activity of solids in radiation–catalytic reactions appear to have been made. Data of this type would be very difficult to obtain with the highly disperse solids used as catalysts.
