Figure 6. Current–voltage characteristic of the photoeffect in 0.005 N H_2SO_4 + 0.495 N K_2SO_4; λ = 405 nm: *1*) $i^{0.4}$ against φ; *2*) $i^{0.5}$ against φ.

Other workers[11,42] have also reported "linearisation" of the voltage–current characteristics for the photoemission effect on ($I^{0.4}$, φ) or ($Q^{0.4}$, φ) co-ordinates. The spectral dependence of the photoeffect gives a reasonably good straight line when plotted as $Q^{0.4}$ against $\hbar\omega$ (Fig. 7). The current–voltage curves for different $\hbar\omega$ values intersect the potential axis to give increments ($\Delta e\varphi$) proportional to the change in the energy of the light quantum ($\Delta\hbar\omega$), the proportionality coefficient being unity. Barker[3] finds the same value for the ratio $\Delta\hbar\omega/\Delta e\varphi$: the values between 2 and 3 reported by Heyrovsky[27] are probably due to secondary reactions which were ignored.

† Throughout this review, potentials are quoted relative to the saturated calomel electrode unless accompanied by a statement to the contrary.

‡ Reported deviations[22] from Eqn. (2) in the threshold region (at 436–579 nm) are probably due to thermal excitation processes in the metal, producing a photocurrent larger than required by Eqn. (2). The form of the threshold factor for $\frac{\hbar\omega - \hbar\omega_0 - e\varphi}{kT} \simeq 1$ is given in Ref. 6.

This means that the transmission coefficient of the barrier is sensibly constant within the dense part of the electrical double layer, which confirms the initial assumption of the Brodskii–Gurevich theory that the red photoemission threshold is linearly related to the electrode potential. Experiments on the frequency dependence of the photoemission by varying $e\varphi$ and $\hbar\omega$ together in such a way that the energy of the emitted electrons ($\hbar\omega - \hbar\omega_0 - e\varphi$) remains constant have shown that the function $\chi(\omega)$ in Eqn. (2) is independent of the medium into which photoemission occurs and is determined by the light absorption law in the metal. This experiment is not applicable to photoemission into a vacuum because of the frequency dependence of the threshold factor. The function $\chi(\omega)$ is found[22] to be a cubic hyperbola (Fig. 8): $\chi \sim \frac{1}{\omega^3}$. This result is consistent with the theory of photoemission assuming that the amplitude E of the light wave vector does not exhibit a singularity at the metal surface.

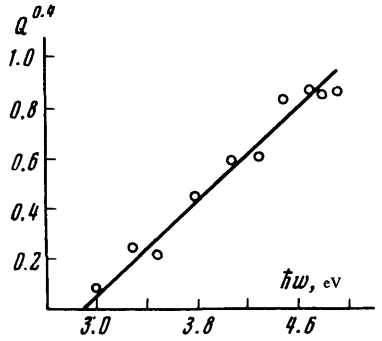

Figure 7. Spectral characteristic of the photoeffect in 0.1 N H_2SO_4; $\varphi = -0.8$ V.

When the energy of the emitted electrons is 1 eV and the energy of the absorbed photons is 3.52 eV, the quantum yield of the photoemission process is $(1.2 \pm 0.3) \times 10^{-4}$. This value agrees with the quantum yield of the photoemission into a vacuum[43] of electrons of 1 eV energy from a metal with a work function of 3.2–3.4 eV.

The work function from mercury into water W_0, calculated from spectral and current–voltage experiments by means of Eqn. (3), is 3.2 ± 0.05 eV (with H_3O^+ as the acceptor) or 3.13 ± 0.05 eV (with N_2O as the acceptor). This is close to the value of W_0 proposed by Frumkin from thermodynamic data[44] and to the "light quantum able to induce photocurrent at the point of zero charge" observed by Heyrovsky[27] with N_2O and H_3O^+ acceptors.

Many acceptors give current–voltage characteristics different from those described above for N_2O and H_3O^+ acceptors. The difference arises because the rate of the electrode reactions involving the products of electron capture by those acceptors varies with the potential[3,45].

We have shown[45] that in the presence of anionic acceptors both the current–voltage curve and the oscillographic $V(t)$ display of the photopotential depend on the Ψ' potential, on the acceptor concentration, and also on the ionic strength and on the pH of the solution. If the chemical reactions of the acceptors containing a captured electron are slow in comparison with the time of illumination, the trace of $V(t)$ does not follow the integral of the flash.

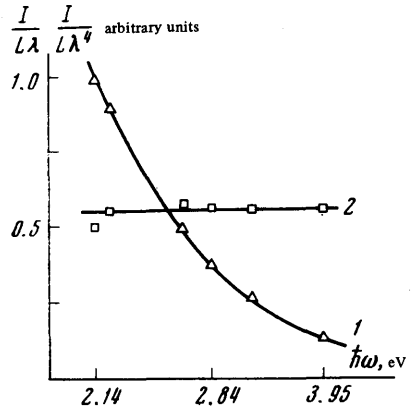

Figure 8. Frequency dependence of the photoemission current from mercury into 0.1 N KCl (acceptor N_2O); *1*) $I/L\lambda$; *2*) $I/L\lambda^4$; λ is the wave-length of the exciting light. Measured at constant $\hbar\omega - \hbar\omega_0 - e\varphi = 0.5$ eV.

Thus, in 1 M solutions of $NaNO_3$, KIO_3, and $K_2C_2O_4$ the current–voltage curves are S-shaped: at the more negative potentials the experimental points lie on straight lines in $Q^{0.4}(\varphi)$ plots, which can be extrapolated to give the shift from 3.2 eV of the threshold potential ($\Delta\varphi_b$).

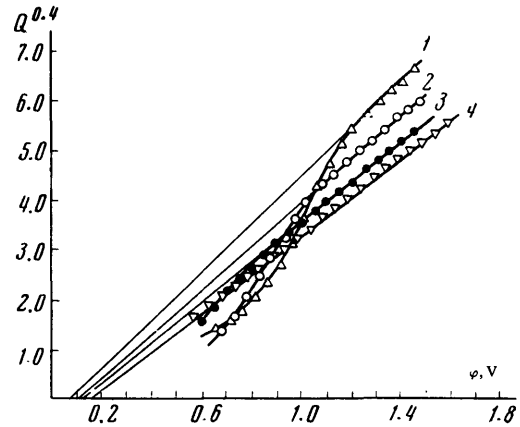

Figure 9. Emitted charge as a function of electrode potential in $NaNO_3$ solutions: *1*) M; *2*) 10^{-1} M; *3*) 10^{-2} M; *4*) 10^{-3} M (λ = 355 nm).

This can be negative ($\Delta\varphi_b = -0.4$ V for $NaNO_3$ and –1.1 V for $K_2C_2O_4$) or positive ($\Delta\varphi_b = 0.5$ V for KIO_3): see Figs. 9, 10, 11. However, when the contribution to the

photocurrent from secondary reactions can be ignored (acceptor concentration $10^{-3}-10^{-4}$ M, or alkaline medium) the function $Q^{0.4}(\varphi)$ becomes linear, and the work function approaches the value 3.2 V. In $K_2C_2O_4$ solutions we find, in addition to a cathodic photocurrent at negative potentials, an anodic photocurrent at $\varphi > \varphi_{z.c.}$, with a vanishingly small photoeffect in the intermediate potential region. KIO_3 solutions are distinguished by the presence of cathodic photocurrent at potentials more positive than the photoemission threshold.

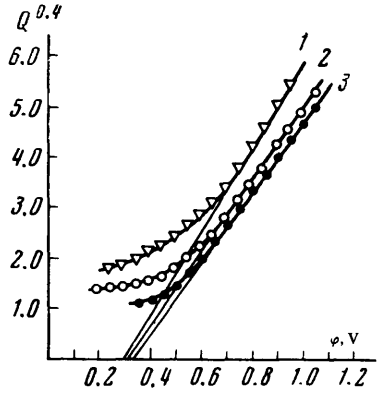

Figure 10. Emitted charge as a function of electrode potential in KIO_3 solutions: *1*) 10^{-1} M; *2*) 10^{-2} M; *3*) 10^{-3} M (λ = 355 nm).

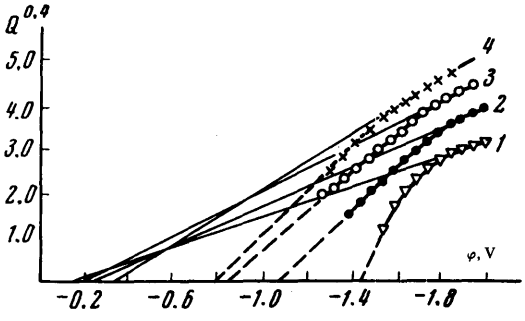

Figure 11. Emitted charge as a function of electrode potential in $K_2C_2O_4$ solutions: *1*) M; *2*) 10^{-1} M; *3*) 10^{-2} M; *4*) 10^{-3} M (λ = 355 nm).

The anodic photocurrent in oxalate solutions, and the cathodic photocurrent in iodate solutions at potentials more positive than the threshold potential, stem from the formation of a surface donor–acceptor complex. This can happen when $\varphi > \varphi_{z.c.}$, when the concentration of IO_3^- and $C_2O_4^{2-}$ in the electrical double layer suddenly increases. The anodic photocurrent is due to light-induced charge transfer to the electrode from the oxalate anion, which has a low ionisation potential, and the cathodic photocurrent to charge transfer (induced by light) from the metal to the iodate anion, which has a high electron affinity.

This conclusion was reached from a study of polarisation selectivity, an important feature of the surface photoeffect. This effect, associated with the polarisation of light absorption in metals, follows from the condition of conservation of momentum, which can be satisfied in the surface photoeffect only in a direction perpendicular to the surface[46]. Conversely, in the photocurrent model involving ionisation of surface complexes, polarisation selectivity seems improbable, since the binding energy of the complex is comparable to the molecular vibration energy, and complex formation leads to the interaction of vibrational states of different symmetry[47].

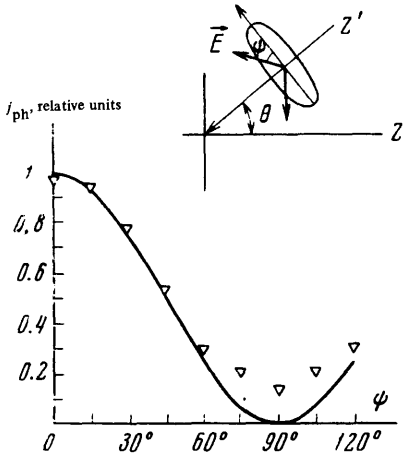

Figure 12. Polarisation dependence of the photoeffect in 0.1 N K_2SO_4 (φ = −1.4 V); z is the direction normal to the electrode surface, θ is the angle of incidence of the light, E is the vector of the electric component of the electromagnetic wave, ψ is the polarisation angle in the incidence plane (z,z'), j_{pH} is the measured photocurrent, the symbol ▽ denotes experimental points, the full line is a plot of $\cos^2\psi$.

Polarisation selectivity of the electrode photoeffect was predicted by Brodskii and Gurevich[6] and experimentally demonstrated by Korshunov and coworkers[10]. A decrease in photocurrent with a decrease in the normal component of the electric vector was observed at negative potentials in all the solutions examined (H_3O^+, N_2O, and anion acceptors). The polarisation ratio varied between 2.5 and 7, depending on the angle of incidence of the light on the photocathode (Fig. 12).

Since for the linear photoeffect $j \sim E_{\parallel}^2 = E_0^2 \sin^2\theta \cos^2\Psi$ (where θ is the angle of incidence, Ψ is the polarisation angle of the electric vector E of the electromagnetic wave in the incidence plane, j is the photocurrent), the angular dependence of the photocurrent is given by

$$j = j_0 \sin^2\theta \cos^2\psi, \qquad (4)$$

which satisfactorily describes the observed polarisation behaviour.

Polarisation of the cathodic photocurrents has been observed also in $H_2C_2O_4$ and $K_2C_2O_4$ solutions, but the

anodic photocurrents in these solutions show practically no polarisation selectivity.

The polarisation selectivity of the cathodic photocurrent is proof that the photoeffect is the result of photoemission of electrons from the metal into the solution. Conversely, the lack of selectivity of the anodic photocurrent can be taken as evidence that the photoeffect at $\varphi > \varphi_{z.c.}$ arises from light-induced electron transfer in the surface complex from the oxalate anion (which has a low ionisation potential) to the metal.

IV. STATUS OF THE "FIVE-OVER-TWO" LAW AND OF THE DISTRIBUTION FUNCTION OF SOLVATED ELECTRONS

The good qualitative and quantitative agreement between the spectral and current–voltage characteristics of the electrode photoeffect and Brodskii and Gurevich's photoemission theory[6] is evidence that we are dealing with an emission phenomenon, but it does not prove that the "five-over-two" law is in any way a fundamental one.

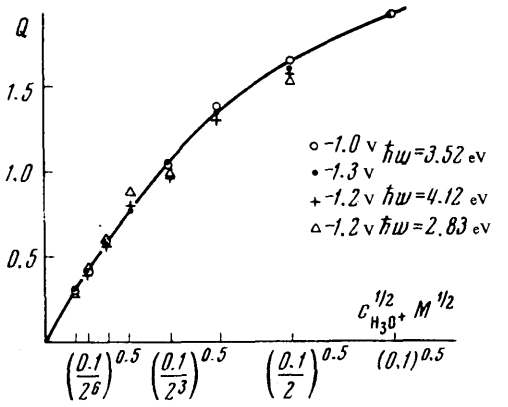

Figure 13. Emitted charge as a function of H_3O^+ acceptor concentration for different φ and $\bar{n}\omega$. The scale of Q is chosen so as to bring into coincidence the points for the maximum acceptor concentration ($c_{H_3O^+} = 0.1\ N$, far right of the curve).

Thus, as already stated, the experimental $I(\varphi)$ and $I(\bar{n}\omega)$ plots are determined not only by the characteristics of the emission current, but also by the dependence upon the energy of the emitted electrons of the distribution function describing the source of solvated electrons. Since the residence time of a solvated electron is much greater than its formation time, the trapping process may be described in terms of an initial distribution of solvated electrons, produced by the photoemission. With this assumption, the variation of the photocurrent (or emitted charge) with acceptor concentration at different photon energies and electrode potentials can be used to arrive at the form of the distribution for different initial electron energies. The charge emitted from mercury into an electrolyte solution under pulse illumination has been studied[48] over a range of concentrations of the electron acceptors H_3O^+, N_2O, and NO_3^-. In the absence of secondary reactions by the electron-filled acceptors, the experimental $Q(c)$ curve is related to the function of the source of solvated electrons $f(x)$ by Eqn. (3).

Fig. 13 shows a plot of $Q(c)$ for H_3O^+ at different values of φ and $\bar{n}\omega$. The arbitrary scale of Q is normalised so as to make the experimental Q values at the maximum acceptor concentration (0.1 M) coincide.

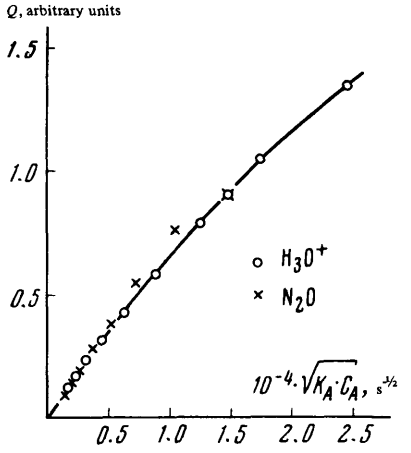

Figure 14. Emitted charge as a function of the parameter $\sqrt{kc}$.

Within experimental error (±5%), the measurements are described by a single curve, i.e. the source function is independent of the emitted electron energy over the range 0.5–1.6 eV. Measurements of Q as a function of the capture efficiency $(\kappa c)^{1/2}$ for different acceptors shows that the source function is also independent of the nature of the acceptor (Fig. 14). From these results we may conclude that the source function is finite at $x = 0$ and can be expressed by the summation

$$f(x) = \sum_i \left(\frac{kc}{D_s}\right)^{1/2} e^{-x/x_{0i}} \qquad (5)$$

Because the experimentally accessible range of $(\frac{kc}{D_s})^{1/2}$ measurements is limited, only the characteristic length x_0 of the distribution can be determined. If the source function is exponential,

$$\frac{Q(c)}{\sqrt{c}} + Q(c)\sqrt{\frac{k}{D_s}}x_0 = Q_0\sqrt{\frac{k}{D_s}}x_0\ , \qquad (6)$$

and a linear relation between $\frac{Q}{\sqrt{c}}$ and Q should be observed.

Eqn. (6) is satisfied at high values of Q, i.e. at high acceptor concentrations. For $D_S = 5 \times 10^{-5}$ cm^2 s^{-1} [3] and $k = 8.7 \times 10^{10}$, the results for H_3O^+ give $x_0 = 16$ Å (Fig. 15).

However, at lower values of Q we observe deviations from linearity: at $c \leqslant 5 \times 10^{-4}$ M for H_3O^+ and at $c < 10^{-3}$ M for NO_3^-. With N_2O ($c_{max} = 2.5 \times 10^{-2}$ M), $Q/\sqrt{c}$ is practically independent of Q. The deviation from linearity of the function $\frac{Q}{\sqrt{c}}(Q)$ may result from a decrease

in the rate constant of the reaction between the solvated electron and the acceptor, as indicated by radiation-chemical data[49,50], or alternatively it may be due to the failure of Eqn. (6) to provide a satisfactory approximation at small values of x. At low acceptor concentrations, when the major contribution to Q comes from the tail of the source distribution function, the observed non-linearity suggests that $f(x)$ falls off more sharply at large values of x than given by Eqn. (6) with $x_0 = 16$ Å.

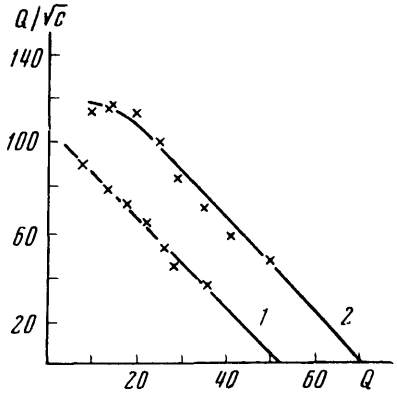

Figure 15. Plots of $Q/\sqrt{c}$ against Q for H_3O^+. Ionic strength held constant (1 N) by adding Na_2SO_4; $\lambda = 300$ nm: *1*) $\varphi = -1.0$ V; *2*) $\varphi = -1.2$ V.

The independence of the source function upon the energy of the emitted electrons in the range $0.5 \leq E \leq 1.5$ eV is also confirmed by the good fit to the "five-over-two" power law of the current–voltage curves at different acceptor concentrations. The results justify the conclusion that the experimentally observed "five-over-two" law has a fundamental significance, i.e. that the Brodskii–Gurevich model[6] of photoemission into a solution is essentially correct. This conclusion is also relevant to the MDM structure (metal–dielectric–metal), for which the photoemission model is similar to the model of photoemission into electrolyte solutions[7], with similar deviations form Fowler's law[51–56].

The escape distance of the electron from the electrode (16 Å for water) is consistent with the mean free path of the secondary electrons produced in the radiolysis of aqueous solutions, for which the values 16 Å and 30 Å have been obtained[57,58] by an analysis of the diffusion kinetics of the radiolysis process.

The value $x_0 = 16$ Å suggests that the main scattering mechanism for low-energy electrons is inelastic interaction. It may be assumed that the energy scattering process involves vibrational relaxation (for water, the relevant vibrational levels are 0.198, 0.474, and 0.488 eV)[59].

As already stated, x_0 has been evaluated on the assumption that the electron becomes solvated before being captured by an acceptor, but the value of x_0 is too small to exclude the possibility of direct capture of unsolvated ("dry") electrons. The diffusion equation holds true if the mean free path, determined by scattering processes (e.g. as a result of vibrations), under equilibrium conditions is larger than the wave packet[60]

$$\lambda = \frac{h}{(3m_0kT)^{1/2}} = 10\ \text{Å} \qquad (7)$$

so that the capture of "dry" electrons by acceptors, followed by release of the electrons to the electrode, can be treated as a diffusion process only at distances greater than λ, whereas x_0 is comparable to λ in magnitude. The relative contribution of solvated and "dry" electron interactions with the acceptor can be evaluated from the kinetics of electron release for irradiation times of the order of the diffusion time of solvated electrons to the electrode (10^{-8}–10^{-9} s).

The kinetics of the photocurrent integral have been studied with a nitrogen laser: in a 1 N H_2SO_4 solution the photocurrent integral is ($\Delta t = 10^{-8}$ s) within experimental error identical with the integral of the light pulse, recorded with a fast photomultiplier. The upper limit of the characteristic length x_0 follows directly from this result: for $\Delta t = 10^{-8}$ s, $x_0 < 70$ Å.

According to Wolf and coworkers[61], protons do not interact with "dry" electrons. It appears[61] that the observed value of x_0 relates to solvated electrons. At proton concentrations below 10^{-2} M (in a 1 N solution) the $V(t)$ curve includes a slowly rising portion of 100–150 ns duration which accounts for ~ 20% of the maximum signal amplitude. In N_2O solutions ($C_a \leq 2 \times 10^{-2}$ M) a signal of this form is observed at all acceptor concentrations. This slow increase needs to be investigated further in order to establish whether it is the results of electrode or of bulk reactions of the filled acceptors, or whether it is due to the variation of x_0 with acceptor concentration.

V. TUNNELLING OF EMITTED ELECTRONS THROUGH THE POTENTIAL BARRIER AT THE INTERFACE

One of the most significant differences between photoemission into electrolyte solutions and photoemission into a vacuum is the linear dependence of the long-wave limit of the photoeffect on the electrode potential, due to the fall in potential over distances of atomic dimensions from the metal surface. It follows that tunnelling penetration of the barrier by electrons having an energy lower than the work function by an amount $e\varphi$ becomes possible.

The tunnelling model satisfactorily describes photoemission into dilute solutions and solutions containing surface-active compounds. In the former case, in addition to the potential drop across the dense part of the double layer, we have to consider the Ψ' potential, acting over distances of tens or hundreds of Ångstroms and therefore unlikely to permit tunnelling. Thus, for the case of photoemission into dilute solutions the full potential drop in Eqn. (2) should be replaced by the potential drop across the dense part of the double layer, through which the emitted electrons are able to tunnel:

$$I_0 = L(t)\chi(\hbar\omega - \hbar\omega_0 - e\varphi + e\psi')^{s/2}, \qquad (8)$$

and dilute solutions should show deviations from linearity in the $Q^{0.4}$ versus φ plots, due to the $\Psi'(\varphi)$ variation.

Eqn. (8) has been tested[18] in potassium sulphate solutions of concentration between 10^{-1} and 10^{-5} N.

In Fig. 16 the Ψ' potentials given by Eqn. (8), corresponding to the horizontal shift of the $Q^{0.4}(\varphi)$ curves in K_2SO_4 solutions with increasing dilution (with respect to the straight line for the concentrated solutions drawn so as to intersect the dilute solution curve at the point of zero

intersect the dilute solution curve at the point of zero charge), are compared with the Ψ' potentials given by the Gouy–Chapman theory for electrolyte solutions without specific adsorption. Similar results have been obtained in acid solutions[18]. Other workers[11,42] also conclude that a correction for the Ψ' potential must be applied to the photocurrent equation, but in their view the correction should be smaller than Ψ'.

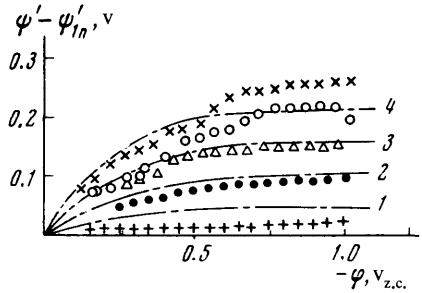

Figure 16. Shift of current–voltage curves in dilute solutions, relative to 1 N K_2SO_4 (N_2O acceptor). The broken curves correspond to the theoretical ψ' potential: *1*) 0.1 N; *2*) 0.01 N; *3*) 0.001 N; *4*) 0.0001 N.

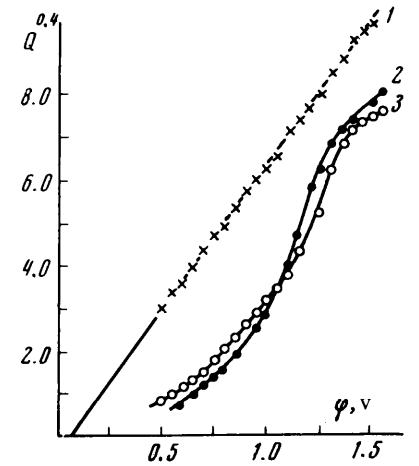

Figure 17. Current–voltage curves in solutions of caprylic and enantic acids: *1*) base solution 0.1 N KF; *2*) 0.1 N KF + 0.01 M $C_9H_{17}COOH$; *3*) 0.1 N KF + 0.01 M $C_6H_{11}COOH$.

In dilute solutions containing an acceptor, as well as in concentrated solutions, the rise time of the photopotential is the same as the duration of the light pulse, and the reverse diffusion current of solvated electrons follows any change in light intensity. In the absence of acceptors, however, the shape of the pulse changes: the initial rise is followed by a 30% fall of photopotential after approximately 5×10^{-4} s, and a more gradual decay with a time constant $RC = 0.1$ s. A signal of this form is consistent with hindered reverse flow of the solvated electrons to the electrode: a rate constant for the interaction between e_S and a water molecule agreeing with the published value[62] (2×10^3 s^{-1}) has been deduced from these data. The slope of the linear portion of the $Q^{0.4}(\varphi)$ plot increases with decreasing ionic strength of the solution, irrespective of the presence or absence of acceptors and of the kind of acceptor present, in contrast to the predictions of the theory of ionic reactions in solution[63]. This result evidently follows from the decrease in the number of electrons returning to the electrode in dilute solutions, caused by the effect of the Ψ' potential on the source function.

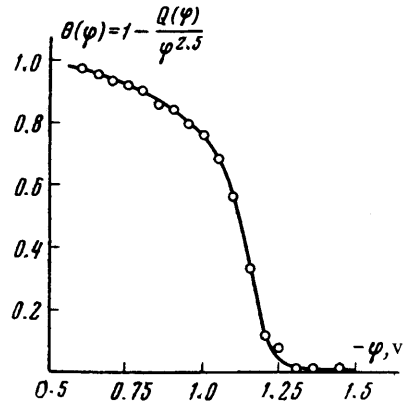

Figure 18. Coefficient $K = 1 - Q/\Delta\varphi^{5/2}$ against electrode potential in a solution of enantic acid.

The results for solutions of specifically adsorbed anions (Cl^-, Br^-, I^-) containing propanol and butanol[64,65] are in keeping with the dilution experiments. The photoemission current–voltage curve is linear when plotted as $Q^{0.4}(\varphi)$, and the work function is the same as in the solution without adsorbable ions. The tunnelling distance of the electrons is greater than the thickness of the dense part of the double layer (in NaF solution), but it is not more than 10 Å. In solutions containing surface-active compounds (s.a.c.) with molecules larger than 10 Å the $Q^{0.4}(\varphi)$ plots are S-shaped (see Fig.17)[65]. The function $\theta(\varphi) = 1 - \frac{Q}{(\hbar\omega - \hbar\omega_0 - e\varphi)2.5}$, which describes the deviation of the current–voltage curve from the "five-over-two" law, can be correlated with the coverage of the electrode surface by s.a.c. (Fig. 18), which suggests tunnelling of the electrons through surface sites not covered with adsorbed molecules. When s.a.c. are introduced into electrolyte solutions, it is necessary to allow for the effect of the adsorption Ψ' potential on the kinetics of the electrode reactions involving the species produced by the reaction between solvated electrons and acceptors (e.g. H_3O^+).[65]

VI. PHOTOEMISSION FROM METALS INTO ELECTROLYTE SOLUTIONS AS A METHOD OF STUDYING FAST REACTIONS

Photoemission from a metal into a solution has been used successfully to determine the rates of fast chemical reactions. This application of the photoemission method

is based on the separation (in time, or in terms of dependence on the electrode potential) of the primary photoemission current I_0 from the secondary currents resulting from electrode reactions of the dissolved species containing a captured emitted electron. Since photoemission itself is practically instantaneous ($\tau < 10^{-11}$ s), and the characteristic thermalisation time is even smaller, the time during which primary current flows is exactly the same as the time of illumination. The time associated with the reverse flow of solvated electrons to the electrode is of the order of $x_0^2/D_S \simeq 10^{-10}$ s, so that for illumination times $t \gg x_0^2/D_S$ the charge added to the solution by the photoemission current is

$$Q = Q_0 \frac{\left(\frac{kc}{D_s}\right)^{1/2} x_0}{1+\left(\frac{kc}{D_s}\right)^{1/2} x_0} \qquad (9)$$

It follows from Eqn. (9) that the electron-capture reaction can be investigated by measuring the function $Q(c)$. The upper limit of the illumination time ($T = 10^{-8}$ s) is set by the need to avoid complications from the relatively slow subsequent transformations of the acceptor. These slower reactions can be studied by using longer exposure times. Studies of reactions of this type, with nitrate or oxalate ions as the acceptors, have been reported[66,67].

The irreversible reactions of these acceptors involve the following scheme:

$$e_s^- + A \xrightarrow{k} A_s^-$$
$$\text{(a)}\ A_s^- \xrightarrow{\kappa_1(\varphi)} A + e_M^-$$
$$\text{(b)}\ A_s^- \xrightarrow{k_2} A_1^- + A_2$$
$$A_2 + e_M^- \xrightarrow{\kappa_2} A_2^-$$

where A is the acceptor molecule, e_S^- is the hydrated electron, A_S^- is an acceptor molecule containing a trapped electron, A_1 and A_2 are products derived from an acceptor molecule with a trapped electron, k is the rate constant of the reaction between a solvated electron and an acceptor molecule, κ_1 and κ_2 are the rate constants of the electrode reactions of A_S^- and A_2, k_2 is the rate constant for the decomposition of A_S^-. (In the range of potentials relevant to this work, κ_2 is usually large and independent of φ.)

The processes which consume A_S^- (decomposition in solution and oxidation at the electrode) are competing reactions, and can be separated by varying the electrode potential. In the potential region where κ_1 is small the electrode current is given by

$$I = I_0 - I_1 + I_{A_2}$$

When $k_2^{-1} \gg x_0^2/D$, the charge collected by the electrode due to the electrode reaction of A_2 particles is given by

$$Q_{A_2}(t) = \frac{D_{A_2} \cdot k_2}{2} \int_0^t \exp\left(-\frac{k_2 t'}{2}\right) \left\{I_0\left(\frac{k_2 t'}{2}\right) - I_1\left(\frac{k_2 t'}{2}\right)\right\} dt' \qquad (10)$$

where I_0 and I_1 are Bessel functions.

It is evident from Eqn. (10) that Q_{A_2} increases initially but tends to a constant value with a time-constant k_2. Part of the observed photocurrent ($I_0 - I_1$) follows instantaneously the intensity of the exciting light. Hence, we can distinguish the signal due to the electrode reaction of the A_2 particles from the background of the observed photocurrent, and we can evaluate k_2 (Fig. 19*a*). Thus, the lifetime of the hydrated NO_3^{2-} anion is $\tau = k_2^{-1} = 10^{-4}$ s, in good agreement with the value determined by pulse radiolysis[50].

When reactions (a) and (b) are both significant, the current–voltage characteristic of the observed photocurrent ($I = I_0 - I_1 - I_{A^-} + I_{A_2}$) is determined by the current–voltage characteristics of the individual components. For an exponential source function $f(x) = \frac{I_0}{x_0} \exp(-x/x_0)$ in the steady state,

$$I = \frac{I_0}{x_0}\left\{\frac{\lambda_1}{(\lambda_0+\lambda_1)\lambda_0} - \frac{\lambda_1^2 \varkappa_1}{[\varkappa_1 + (k_2 D_{A_2})^{1/2}](\lambda_0+\lambda_1)(\lambda_1+\lambda_2)(\lambda_0+\lambda_2)} + \right.$$
$$+ \frac{\lambda_1^2 \lambda_2}{2(\lambda_0^2-\lambda_1)^2}\left[\frac{(k_2 D_{A_2})^{1/2} - \varkappa_1}{(k_2 D_{A_2})^{1/2} + \varkappa_1} \cdot \frac{\lambda_0 - \lambda_1}{(\lambda_1+\lambda_2)(\lambda_0+\lambda_2)\lambda_2} + \right.$$
$$\left.\left. + \frac{1}{\lambda_1(\lambda_1+\lambda_2)} - \frac{1}{\lambda_0(\lambda_0+\lambda_1)} - \frac{1}{\lambda_1\lambda_2} - \frac{1}{\lambda_0\lambda_2}\right]\right\} = I_0 f(\lambda_0, \lambda_1, \lambda_2, \varkappa_1) \quad , \qquad (11)$$

where

$$\lambda_1 = \left(\frac{kc}{D_s}\right)^{1/2}; \quad \lambda_2 = \left(\frac{k_2}{D_{A_2}}\right)^{1/2}; \quad \lambda_0 = x_0^{-1} \quad .$$

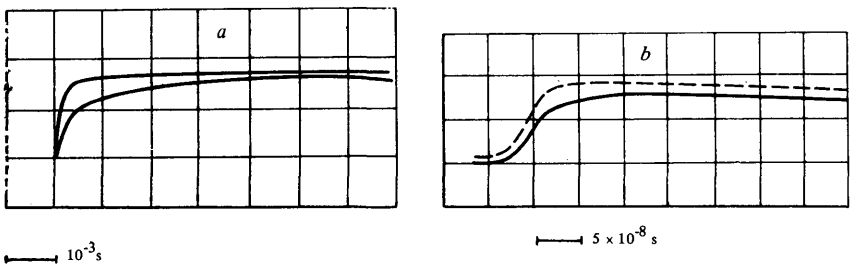

Figure 19. Photopotential in the presence of reactions in solution induced by the emitted electrons: (*a*) 1 *N* $NaNO_3$, upper and lower trace for $\varphi = -1.0$ and -1.4 V respectively; (*b*) 1 *N* $Na_2C_2O_4$, broken line is the integral of the light pulse.

Since λ_0 and λ_2 can be determined from Eqns. (9) and (10), we can evaluate the parameters of the electrode reaction of A^- by comparing the experimental function $\theta(\varphi) = Q(\varphi)(\Delta\varphi)^{-5/2}$, which gives the deviation from the "five-over-two" law, with the theoretical function $f(\lambda_0, \ldots \kappa_1)$. The function $f(\lambda_0, \lambda_1, \lambda_2, \kappa)$ is plotted against the parameter κ in Fig. 20 for $\lambda_0 = 10^6$ cm^{-1}, $\lambda_1 = 1.7 \times 10^7$ cm^{-1}, $\lambda_2 = 1.7 \times 10^4$ cm^{-1}, together with the experimental function $\theta(\varphi) = Q(\varphi)(\Delta\varphi)^{-5/2}$. The transfer coefficient $\alpha = 0.2$ and the constant

$$A = \ln k_s + \frac{\alpha e}{kT}\varphi_p = -7.6$$

can be determined by comparing the theoretical and the experimental curve.

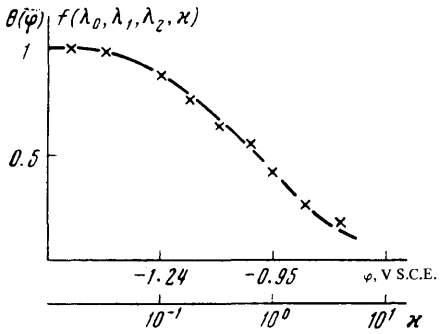

Figure 20. Comparison of the theoretical $f(\lambda_0, \lambda_1, \lambda_2, \kappa)$ (full line) and of the experimental $\theta(\varphi)$ functions.

The function $\theta(\varphi)$ in oxalate solutions is also S-shaped, with an inflection point around -1.65 V in 1 N solutions. As in the case of NO_3^- solutions, the shape of the function can be attributed to oxidation (at the electrode) of the CO_2^- ion produced from the capture of an emitted electron by an oxalate anion[27]. The resulting CO_2^- ion is oxidised at the electrode, or alternatively it can undergo chemical changes in solution when $\varphi < -1.7$ V and the rate constant of the electrode reaction is small. Since no changes in the oscillogram were noted in this region of potential, only the upper limit of the lifetime of the hydrated $C_2O_4^{3-}$ anion could be estimated ($\tau < 2 \times 10^{-6}$ s, see Fig. 19*b*).

VII. WORK FUNCTION OF ELECTRONS FROM METALS INTO POLAR SOLVENTS

The work function for the emission of electrons into water has been measured[68,69] for the following metals: Hg, Zn, Cd, Pb, Tl, Ga, Sn, Bi, Al, In, Sb, Pt, Ni, Fe, Cu, Ag, Au. With the metals whose polarisability is ideal over a sufficiently wide range, i.e. Bi, Ag, Pb, Zn, Sn, Sb, Hg, the relationship $Q^{0.4}(\varphi)$ is linear over the whole of the working range of potential, as shown in Fig. 21. The other metals have a narrower linearity region. The potential, extrapolated with respect to the reference electrode, is the same for all the metals: 0.15 ± 0.1 V S. C. E. The same conclusion was reached independently[11] for In and Tl amalgams.

The work functions of the metals, referred to published values[70] of the point of zero charge, are listed in Table 1. In most cases the difference between the water and the vacuum work function lies in the range 1.35 ± 0.15 eV.

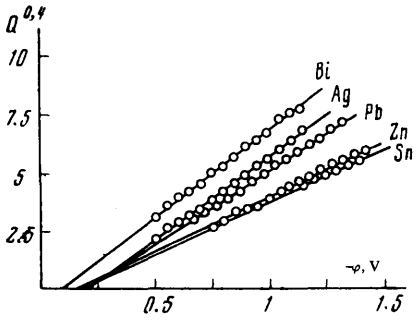

Figure 21. Emitted charge against electrode potential for various metals (0.1 N NaF + N_2O, λ = 355 nm).

The variation of the work function in water with zero-charge potential (relative to the normal hydrogen electrode) is shown in Fig. 22 for a number of metals. (The zero-charge potentials φ_0 are known with adequate precision for these metals.) The experimental dependence is described by the equation

$$\varphi_0 = \hbar\omega_0 - 3.44 \qquad (12)$$

Table 1.

Metal	Work function	Metal	Work function
Cd	2.70	Tl	2.87
Zn	2.77	In	2.90
Ag	2.77	Ga	2.90
Pb	2.91	Al	3.00
Sn	2.94	Ni	3.25
Bi	2.97	Fe	3.02
Hg	3.15	Sb	2.82
Cu	3.46	Pt	3.50
Au	3.72		

This equation allows us to convert the conventional potentials relative to the normal hydrogen electrode into the energy (relative to the free electron in a vacuum) needed to remove an electron from the metal. The constant, equal to the work function at zero hydrogen potential, can be equated to the standard hydrogen potential in electron-volts.

It should be noted that it is much simpler in practice to determine the work function from a metal into an electrolyte solution than into a vacuum, since surface states (which are known to affect the work function in vacuo) have no effect on the photoemission threshold in electrolyte solutions (see previous Section). Hence, $\hbar\omega_0$ values can be measured without special surface treatment provided that the light absorption and the electron emission take place in the metal itself.

Photoemission has been studied in polar solvents other than water in order to increase our understanding of the energetics of the process. The solvents examined include alcohols and dimethylformamide (DMF): their molecules have a capture efficiency for emitted electrons and for the products of their interaction with acceptors (H or OH') higher than the capture efficiency of water, a feature which complicates the measurement of work function.

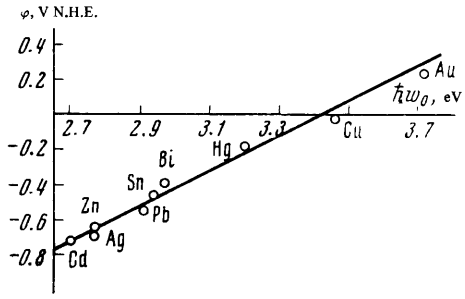

Figure 22. Work function of metals in water against potential at the point of zero charge.

Photopotential oscillograms of the normal form, and linearity of the $Q^{0.4}(\varphi)$ current–voltage characteristics, were taken as criteria for the correct choice of work function measurement conditions. With alcohols, these criteria were satisfied by using H^+ as the acceptor, and with DMF by using N_2O at sufficiently negative potentials ($\varphi < -1.1$ V S. C. E.).[69] The work functions from mercury into these solutions are given in Table 2.

Table 2. Work function of mercury in various solvents.

Solvent	$\hbar\omega_0$, eV	$W_0 - \hbar\omega_0$, eV
H_2O	3.15	1.35
CH_3OH	3.6	0.90
C_2H_5OH	3.75	0.75
DMF	3.95	0.55

The difference between the vacuum work function and the work function in the above solvents is much less than the intrinsic energy of a polaron in these media (over 3 eV). This suggests that only the electronic part of the polarisation is able to keep pace with the motion of the emitted electron at the moment when it enters the medium, and therefore $W_0 - \hbar\omega_0$ should correspond to the intrinsic energy of the electronic polaron in the medium. The slow part of the polarisation begins to relax only after the electron has been slowed down to thermal velocity ($\tau \geq 10^{-13}$ s). The calculated energies[72-74] of the electronic polaron ($E = e^2/d(1 - \varepsilon_\infty^{-1})$, where $a \simeq V_0^{1/3}$, V_0 is the volume occupied by one molecule, and ε_∞ is the optical dielectric permeability) correlate with the observed decrease of $W_0 - \hbar\omega_0$ in the sequence: water, alcohols, DMF.

Thus, the position of the conduction band in these solvents can be deduced from measurements of the work function $\hbar\omega_0$.

VIII. MULTI-PHOTON PHOTOEMISSION FROM MERCURY INTO ELECTROLYTE SOLUTIONS AND PULSE HEATING OF THE SOLUTION

When the wave-length of the exciting light is much longer than the threshold for one-electron photoemission two types of process are observed: 1) photocurrents arising from the pulse heating of the layer of solution in contact with the electrode[8] and 2) photoemission currents due to multi-photon absorption of light in the metal[9].

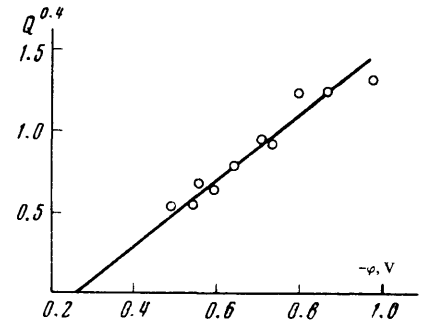

Figure 23. Emitted charge against electrode potential in 0.1 N $HClO_4$ illuminated with pulses from a ruby laser.

Table 3. Comparison of published[70] zero-charge potentials with the values obtained by the heating current method.

Metal	Potential of sign inversion	Assumed (Ref.70) values of φ_0, eV
Hg	−0.19	−0.19
Cd	−0.74	−0.72
Pb	−0.57	−0.56
Bi	−0.42	−0.40
Pt	0.10	0.11–0.19
Sn	−0.52	−0.46
Ag	−0.66	−0.70

The emission currents and the heating currents at a negatively charged mercury surface have different signs and are easily distinguished. With ruby laser light ($\hbar\omega = 1.785$ eV) the emitted charge is $Q \sim L^2$, where L is the light intensity. The current–voltage characteristic is linear in $Q^{0.4}(\varphi)$ coordinates (Fig. 23). The work function agrees with the single-photon value if the appropriate correction is made to Eqn. (2):

$$Q^{0.4} \sim 2h\omega - h\omega_0 - e\varphi. \qquad (13)$$

The characteristics observed indicate that in this case photoemission is caused by two-photon absorption in the metal. The magnitude of the emitted charge ($Q = 2.4 \times 10^{-7}$ C cm^{-2} at $\varphi = -0.5$ $V_{z.c.}$) is consistent with the theory of two-photon photoemission[75].

Upon illumination with neodymium laser light ($h\omega$ = 1.18 eV), $Q \sim L^3$, and the photoemission is associated with the absorption of three photons. The emitted charge is $Q = 8 \times 10^{-9}$ C cm^{-2} at $\varphi = -0.5$ $V_{z.c.}$.

The temperature gradient of the electrode potential on pulse heating ($10^{-3}-10^{-2}$ V deg^{-1}) is numerically equal to the temperature dependence of the double layer capacity ($\frac{1}{C}\frac{\partial Q}{\partial T} = 10^{-3}-10^{-2}$ V deg^{-1}).[76]

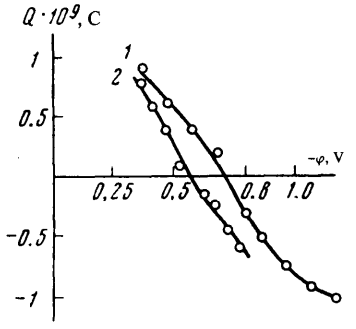

Figure 24. Integral of the heating photocurrent against electrode potential (0.1 N NaF): *1*) Cd; *2*) Pb.

The characteristics of the heating photocurrents due to the decrease in charge density of the double layer upon irradiation of the interface with pulses of long-wave light can be used to measure the point of zero charge for metals[8,77]. When $\varphi > \varphi_{z.c.}$ the heating photocurrents have a cathodic sign; on lowering the potential the photocurrent passes through zero and becomes anodic for $\varphi < \varphi_{z.c.}$ (see Fig. 24). The potentials for zero heating current, measured in this way, are consistent with the published points of zero charge for the metals[77] (Table 3).

The main advantages of this method are the ease of application to solid electrodes and the direct indication of the sign of the charge on the electrode surface.

IX. CHARGE TRANSFER THROUGH THE ELECTRODE–SOLUTION INTERFACE DURING PHOTOCHEMICAL REACTIONS IN SOLUTIONS

We have so far been concerned with the photocurrents produced by illumination of the metal–electrolyte interface. The solution was assumed to be unaffected by light, and the photocurrent was assumed to arise from emission of electrons from the metal or from ionisation of the surface donor–acceptor complexes involving the electrode as one of the components.

Photocurrents can also be produced by photochemical reactions in solution, or on the electrode surface, which are able to produce electrochemically active particles (electronically excited molecules, radicals, or stable molecules). The surface reaction is almost impossible to distinguish from ionisation of a surface complex. Photocurrents have been observed in aqueous and non-aqueous solutions of organic (aldehydes, ketones[78-80], quinones[81-83], dyes[84-86]) and inorganic compounds (metal ions of variable valency[87]). These photochemically and electrochemically active systems are highly relevant to the study of biologically important respiratory and photosynthetic processes[88,89], and also in the development of solar energy conversion devices[90,91]. Photoelectrochemistry was first widely used as a method of investigation by Berg[92], who used steady illumination in conjunction with polarography. The kinetics of formation and decay of photochemically-generated radicals were studied by solving the diffusion equation at a dropping electrode with allowance for photochemical reactions in solution and for the disappearance of radicals by various assumed mechanisms. Stable particles accumulate in the medium, and can be identified polarographically[92-95]. The mechanism of photo-reduction of quinoid compounds in aqueous solutions, and the nature of the photopotential, have been studied[92-95] by analysing the kinetic curves for the stable photolysis products constructed from polarographic data. The kinetic curve for the irreversibly formed photolysis products is S-shaped, showing that the formation reaction involves an intermediate step, and that the primary act consists in reversible photo-reduction (H_2O and OH^- being the electron donors). The photopotential varies linearly with the logarithm of the ratio of oxidised to reduced form of the compound, pointing to the reversible photolysis products[98] being the main potential-determining species in the system.

Berg[99] gave the first formulation of the problems concerning the study of excited states by electrochemical methods. The earlier workers[99-101] failed to detect photocurrents associated with electrode reactions of excited molecules because their experimental technique was inadequate: the excited states were formed too far from the electrode, and suffered deactivation before reaching the electrode by diffusion. However, Maricle and Maurer[102] were successful: they illuminated solutions of rubrene and zinc tetraphenylporphyrin in DMF through an optically transparent electrode (a film of SnO_2 deposited on glass).

For rubrene in the range of potential where the redox reaction does not give a dark current ($E_{1/2}^{Ox} = 0.95$ V, $E_{1/2}^{Red} = -1.34$ V S. C. E.), cathodic polarisation produced initially an anodic and then a cathodic photocurrent, the change of sign corresponding to a potential φ half-way between $E_{1/2}^{Ox}$ and $E_{1/2}^{Red}$. The observed photocurrent was assigned to the electrode oxidation or reduction of the rubrene singlet, whose energy is close to $E_{1/2}^{Ox} - E_{1/2}^{Red} = 2.29$ eV.[101] Illumination of zinc tetraphenylporphyrin revealed a triplet state ($E_T < E_{1/2}^{Ox} - E_{1/2}^{Red}$). Photocurrents due to the discharge of excited pyrene molecules at a semi-transparent gold electrode have also been observed[102].

Solutions of aromatic hydrocarbons in aprotic solvents are very interesting from the viewpoint of the electrochemistry of excited states, since they present the opposite problem: the electrochemical generation of excited states (electrochemiluminescence). The phenomenon has been observed during a.c. electrolysis (35–400 Hz) of rubrene, phenanthrene, pyrene, pyrylene, naphthacene, anthracene, 9,10-diphenylanthracene, 9,10-dimethylanthracene, and 3,4-benzpyrene in acetonitrile, benzonitrile, and DMF solutions with inert (usually platinum) electrodes and quaternary salts as supporting electrolytes[103-110]. Durst and Taylor[87] observed photocurrents due to excited ions at the reduction potentials of Ni^{2+} and Co^{2+}, but they did not allow for the photoemission current from the mercury electrode.

The most promising method of investigating metastable states is pulse illumination in conjunction with the relaxation methods of electrochemical kinetics[79,96]. The condition for observable photocurrent is that the lifetime of the metastable state (τ_0) should be comparable with the time of diffusion from the illuminated region to the electrode and with the time of the electrode reaction (τ_1), i.e. $\tau_0 \simeq 1/\epsilon_0^2 D$, $\tau_0 \geqslant \tau_1$, where ϵ_0 is the light absorption coefficient of the solution illuminated through the measuring electrode.

In order to observe electronically excited states ($A^* \xrightarrow{k_1} A^-$), we also require that the reverse electrode reaction of the resulting particle ($A^- \xrightarrow{k_2} A$) should be slow ($k_2 \ll k_1$).

Solution of the diffusion equation with allowance for the generation and decay of the excited states which can take part in electrode reactions gives the following expression for the total charge collected by the electrode:

$$Q = c\sqrt{\frac{D}{k_1}} \cdot \frac{\sqrt{\frac{\varkappa^2}{Dk}}}{1+\sqrt{\frac{\varkappa^2}{Dk}}} \quad , \qquad (14)$$

where c is the concentration of the particles, D is their diffusion coefficient, k is the unimolecular rate constant for the decay of excited species in solution, and κ is the rate constant of the electrode reaction.

The initial concentration of excited states is determined by the concentration of the initial compound and by the quantum yield of the photochemical reaction (usually $c \simeq 10^{-7}$ M cm^{-3}). It is found that the maximum charge collected by the electrode corresponds to $\kappa \geqslant 10^3$ cm s^{-1} for singlet excited states with $\tau_0 = 10^{-8}$ s, and to $\kappa \geqslant 10^{-1}$ cm s^{-1} for triplet states with $\tau_0 = 10^{-2}$ s. The second-order decay of the states in the bulk of the solution, e.g. by radical dimerisation or disproportionation, gives rise to a non-linear relation between the measured charge and the initial concentration of metastable states.

If the photochemical reaction in solution produces two metastable particles in a single event, the form of the electrode current will depend on the rate of the electrode reaction, the diffusion coefficient, and the direction of electron transfer through the interface for each of the particles.

We have studied[96] the photocurrents produced by illumination of aqueous solutions of riboflavin and sodium salts of the 1-, 2-, and 2,6-sulphonic acids of 9,10-anthraquinone in their absorption band, so that photoemission currents were negligible. The photocurrent pulse consists of two parts: a cathodic current with a rise time of $\leqslant 10^{-4}$ s, followed by an anodic current with a rise time of $\sim 5 \times 10^{-3}$ s. The variation of the initial part of the photocurrent with voltage, concentration, light intensity, and other parameters shows that this current is due to particles generated in the bulk of the solution, reaching the electrode by diffusion, and disappearing mainly in the bulk of the solution. The rate constant for the electrode reduction of this species is fairly large. The species could be an OH radical, formed by the reaction between an excited quinone molecule and a water molecule or a hydroxyl ion. The characteristics of the slow part of the signal indicate that the phenomenon involves oxidation and reduction at the electrode of the riboflavin semiquinones and of the anthraquinone derivatives.

Catalytic C_6-Dehydrocyclisation of Aliphatic Hydrocarbons on Oxide Catalysts

M.I.Rozengart and B.A.Kazanskii

The results obtained during the past two decades on the dehydrocyclisation of aliphatic hydrocarbons in the presence of oxide catalysts are reviewed. New work on catalysts (composition, properties, promotion, regeneration, "development") is surveyed. Recent results are given on the dehydrocyclisation of alkanes, alkenes, dienes, and alkynes, with information on the accompanying side-reactions. A possible multistage mechanism for the dehydrocyclisation of alkanes on alumina-chrome catalysts is examined. A list of 257 references is included.

I. Introduction	715
II. Catalysts for the dehydrocyclisation of hydrocarbons	716
III. Reactions involved in the dehydrocylisation of hydrocarbons on oxide catalysts	720

I. INTRODUCTION

The catalytic conversion of alkanes into aromatic hydrocarbons, discovered by Soviet chemists in 1936,[1-3] allowed for the first time these two types of hydrocarbon, apparently so different in chemical properties, to be interconverted by a simple transition, without recourse to intermediate compounds containing functional groups.

This reaction was of interest to the rapidly developing petroleum industry as a potential process for the production of aromatic hydrocarbons, and came to be studied intensively in the USSR and abroad. Numerous patents appeared on procedures and catalysts for accomplishing the reaction, and from 1939 also research papers by American[4], English[5], Dutch[6], and German[7] chemists, i.e. scientists in countries having an established industry for processing petroleum or for the manufacture of liquid fuel from coal. During recent years scientists of many countries have studied this reaction, not only in connection with its practical application but also with the aim of elucidating its mechanism and kinetics. Interest has not yet died away, and during 1967–1970 new patents and papers have been published on the aromatisation of alkanes. A detailed summary of all the work up to 1947 was given in Plate's exhaustive monograph[8]. (The later reviews by Hansh[9] and by Steiner[10] were somewhat incomplete and one-sided.) The aim of the present Review is to survey work published mainly during the past twenty years.

The aromatisation of alkanes has been termed "C_6-dehydrocyclisation"[11], in contrast to the "C_5-dehydrocyclisation" of alkanes discovered by Kazanskii, Liberman, et al.[12], which occurs on platinum catalysts and yields cyclopentane and its homologues. (Henceforward we shall use the term "dehydrocyclisation" instead of "C_6-dehydrocyclisation".)

In the case of n-hexane this reaction can be represented by the overall equation

$$C_6H_{14} \rightarrow C_6H_6 + 4H_2$$

It takes place on oxide catalysts (chromic oxide without a carrier; chromic, molybdenum, tungsten, and vanadium oxides deposited on aluminium oxide) and on metallic catalysts (platinum, palladium, nickel, and other Group VIII metals on various carriers or without a carrier). The present Review covers the dehydrocyclisation of aliphatic hydrocarbons on oxide catalysts.

II. CATALYSTS FOR THE DEHYDROCYCLISATION OF HYDROCARBONS

1. Composition and Properties of the Catalysts

Almost all the catalysts for the reaction known hitherto were found during the first decade after the discovery of the dehydrocyclisation of alkanes[8]. The most active was chromic oxide deposited specially on aluminium oxide, and molybdenum oxide on alumina was rather less active. This assessment has been confirmed by recent investigations. Thus McGrath[13] compared three types of catalysts used in the petroleum-chemical industry—alumina–platinum, alumina–molybdenum, and alumina–chrome—and found the last to be the most effective for the preparation of benzene from n-hexane, while the first was the least effective; in the preparation of benzene from cyclohexane the alumina–platinum and alumina–molybdenum catalysts were similar in activity and more active than the alumina–chrome catalyst. The highest yield of benzene from methylcyclopentane was given by the alumina–platinum catalyst, and the lowest by the alumina–chrome catalyst[14]. It is not fortuitous, therefore, that most work on the dehydrocyclisation of aliphatic hydrocarbons has been done with an alumina–chrome catalyst.

Investigations during the 1950s and 1960s added little that was fundamentally new to the list of oxide catalysts for dehydrocyclisation. It was found that alkanes can undergo dehydrocyclisation on aluminium oxide containing ferric oxide[15]. Neodymium and samarium oxides also showed dehydrocyclising activity[16,17]. Minachev et al. investigated[18–22] the dehydrocyclisation of n-heptane on the oxides of neodymium, samarium, gallium, holmium, erbium, and yttrium at 530–560°C. The content of aromatic hydrocarbons in the products (at 545°C) was 9–28% depending on the oxide taken. Gadolinium oxide possessed the highest specific activity, and yttrium oxide the lowest. The activities of the rare-earth oxides were somewhat improved by depositing them on activated carbon.

Finally, oxide catalysts were used in "oxidative dehydrocyclisation" processes. Thus the dehydrocyclisation of alkanes on an alumina–chrome catalyst in the presence of sulphur dioxide has been described[23,24]. The only C_8 aromatic hydrocarbons formed by the dehydrocyclisation of n-octane on magnesium oxide in the presence of sulphur dioxide are ethylbenzene and *o*-xylene[25]: i.e. under these conditions the dehydrocyclisation of octane is not accompanied by isomerisation, as is observed in other cases.

The industrial use of alumina–chrome catalysts for the dehydrogenation of alkanes and alkenes and of alumina–molybdenum catalysts for the reforming of gasolines has promoted the study during the past 10–12 years of many properties of these catalysts, especially those based on chromic oxide. The properties of the oxides of chromium themselves have been described in some detail in the monographs of Rode[26] and Udy[27] (see also Ref. 28). Pool and McIver[29] have recently published a very interesting review of the physicochemical properties of alumina–chrome catalysts. Burwell et al.[30] published a survey (based mainly on his own work) of the chemisorption and certain catalytic properties of pure chromic oxide. Information on the oxides of molybdenum can be found in monographs by Killeffer and Linz[31] and by Perel'man and Zvorykina[32], and also in papers by Rode and Lysanova[33,34].

Several workers[35–38] studied the relation between the dehydrocyclising activity of alumina–chrome catalysts and their content of chromic oxide. Special interest attaches to comparison of dehydrocyclising activity with certain other properties of alumina–chrome catalysts. Thus Eischens and Selwood[37] studied the dehydrocyclising activity and magnetic properties of alumina–chrome catalysts containing different contents (1.5–58 wt. %) of chromic oxide. They found that the specific activity of the chromic oxide dropped sharply with increase in its content from 2.9% to 9%, after which it diminished only slightly. The magnetic properties of the specimens indicated that the chromic oxide formed individual groups of microcrystals on the surface of the aluminium oxide, and that variation in catalytic activity was associated with variation in the degree of dispersion of these microcrystals, which depended on several factors, including the concentration of chromic oxide in the catalyst.

Griffith et al.[38–41] studied the dehydrocyclising activity of pure aluminium and chromic oxides and of the mixed catalysts with different contents of the latter, as well as their adsorption properties, specific surface, electrical conductivity, and crystalline structure. In agreement with Visser[35] they found that the yield of toluene from n-heptane passes through two maxima corresponding to 30% and 70–75% of chromic oxide in the catalyst. Griffith and his coworkers established a correlation between the activation energy for the dehydrocyclisation of n-heptane and the activation energy of electrical conduction for samples having different contents of chromic oxide, and explained it on the assumption that the rate-determining stage of the overall reaction was the transfer of electrons from active centres, on which heptane is chemisorbed, to the conduction band. In their opinion the activity of the catalyst was due to the presence of a superficial highly disperse solid solution of alumina in chromic oxide, which differed from the α-phase in crystalline structure. According to Davis et al.[41] and Visser[35] the function of the alumina was to produce a developed surface on the chromic oxide (the specific surface of the catalyst increased from 45 to 306 $m^2 g^{-1}$ from pure chromic oxide to aluminium oxide[39]) and to stabilise the chromic oxide in the solid solution as a cubic phase instead of the hexagonal α-phase characteristic of pure chromic oxide.

All oxide catalysts gradually become covered with carbon deposits ("coke") during use for the high-temperature transformation of hydrocarbons. This diminishes the activity of the catalyst, which can be restored by regenerating the latter, i.e. by heating it in a current of gas containing oxygen. As a consequence of the need for the periodic regeneration of oxide catalysts for dehydrocyclisation, they are located alternately in an oxidising atmosphere (during regeneration) and in a reducing medium (during the reaction). A characteristic feature of oxide catalysts for dehydrocyclisation, which distinguishes them from aluminosilicate catalysts and pure alumina, is the periodic oxidation or reduction of metals of variable valency. For example, chromium(III) oxides are partly converted into chromium(VI) oxides and back again depending on the conditions. Study of the oxidation and reduction of the catalysts could be important for an understanding of

their catalytic activity and necessary in the practical conduct of industrial processes using alumina–chrome and alumina–molybdenum catalysts.

These aspects have been most fully studied for alumina–chrome catalysts, whose oxidation and reduction have interested many investigators[42-59]. Since detailed information on the valency states of chrome and alumina–chrome catalysts has been given in a review[29] and for pure chromic oxide in a monograph[26], we note here merely that the chromium(VI) content of the oxidised catalysts increases with rise in temperature[47] and with increase in the concentration of oxygen in the gas used for regenerating the catalyst[51]. Increase in the content of chromic oxide in the catalyst results in a decrease in the proportion which is oxidised to chromium(VI).[47] This may be due to a weakening of the effect of the carrier (alumina) and to coarser crystals of chromic oxide as its content increases[37], for according to Matsunaga[47] the coarser the microcrystals of chromic oxide the more difficult are they to oxidise.

Different oxides are formed depending on the conditions under which catalysts containing chromium(VI) are reduced. The usual product is the sesquioxide containing chemisorbed water in the form of hydroxy-groups. But the reduction of chromium trioxide deposited on silica gel at not very high temperatures yields chromium(V) oxide, to which is attributed the polymerising activity of chrome–silica gel and chrome–aluminosilicate catalysts[29,56]. Balandin et al.[49] found that the reduction of an alumina–chrome catalyst with atomic hydrogen forms chromium dioxide. Many workers consider that a small quantity of chromium(II) oxide is formed on the surface, together with chromic oxide, in the reduction of alumina–chrome and chrome–silica gel catalysts. This possibility was first pointed out by Weller and Voltz[44]. Van Reijen et al.[52] reached the same conclusion from a study of the magnetic properties and the electron spin resonance spectra of the catalysts, and Steiner[53] and Slovetskaya et al.[54,55] from the formation of hydrogen when the reduced catalyst is treated with water at high temperatures. Whether this hydrogen is evolved as a result of the reaction $2CrO + H_2O = Cr_2O_3 + H_2$ or as a consequence of the displacement by water of hydrogen adsorbed on the reduced catalyst is a matter of debate[57,60,61]. On the basis of the optical spectra of chrome–silica gel catalysts Przheval'skaya et al.[58] consider that chromium(VI) contents below 1% are reduced by hydrogen or carbon monoxide almost completely to chromium(II), a situation somewhat resembling the effect of the quantity of chromic oxide in an alumina–chrome catalyst on the extent of its oxidation.

2. Effect of the Addition of Various Oxides on the Dehydrocyclising Activity of the Catalysts

Greensfelder et al.[62] reported the promoting action of the oxides of several alkali and alkaline-earth metals on an alumina–chrome catalyst in the dehydrocyclisation of n-heptane. Kazanskii et al.[63,64] studied the effects of additions of all alkali metals and most Group II elements to an alumina–chrome catalyst on the yields of aromatic compounds in the dehydrocyclisation of n-heptane and the dehydrogenation of cyclohexane. Except in the case of lithium, the introduction of oxides of the alkali and alkaline-earth metals diminished the cracking of the hydrocarbons and had a promoting effect on the catalyst, especially noticeable in the dehydrocyclisation of n-heptane (Fig. 1). Later Timofeeva et al.[65] observed that these oxides had a similar effect in the same reactions on an alumina–chrome catalyst prepared in a different way. The promotion of an alumina–chrome catalyst by potassium oxide diminishes the formation of carbon[66] (see also Fig. 2), by increasing the activation energy of the reaction limiting carbonisation[67]. Nowak and Vieweg[68-70] have also studied the action of lithium and potassium oxides on the dehydrocyclisation of n-heptane on alumina–chrome catalysts. Nicolescu et al.[71] showed that the particular alkali-metal ion added influenced not only the activity but also the selectivity of an alumina–chrome catalyst in the dehydrocyclisation of n-octane, i.e. the relative quantities of ethylbenzene and *o*-xylene formed. The dehydrocyclising activity of alumina–chrome catalysts promoted by alkali-metal oxides was found to increase from lithium to rubidium[63,65,68]. A parallel increase occurs in the chromium(VI) content of the oxidised catalysts[68-72].

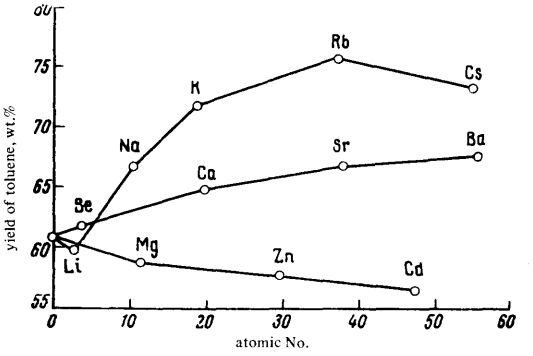

Figure 1. Yield of toluene from n-heptane on alumina–chrome catalysts to which have been added equivalent quantities of the oxides of various metals[63,64] (flow apparatus at 535°C).

It is noteworthy that the addition of potassium oxide to an alumina–chrome catalyst affects also its physicochemical properties[73-75], e.g. texture and electrical properties. Rubinshtein et al.[74] consider that addition of the potassium ion stabilises the lattice of γ-alumina.

In contrast to the promoting action of potassium oxide on an alumina–chrome catalyst, Kazanskii et al.[76] showed that it poisons pure chromic oxide for the aromatisation of n-heptane and cyclohexane at 450°C. Bridges et al.[77] later reached the same conclusion regarding the aromatisation of cyclohexane. Barium oxide has no effect on the activity of pure chromic oxide in the dehydrocyclisation of n-heptane, and somewhat increased its activity for the dehydrogenation of cyclohexane[78]. Addition of a small quantity of phosphoric acid, however, deactivated pure chromic oxide in both reactions[76].

Potassium oxide promotes also alumina–molybdenum catalysts for the dehydrocyclisation of hydrocarbons, as was shown by Bitepazh et al.[79] and independently by Rozengart and Kuznetsova[80]. Adzhieva[81] investigated the action of various quantities of magnesium oxide on an alumina–molybdenum catalyst in the dehydrocyclisation of heptane, and demonstrated a promoting effect with a small content[81]. Belen'kii and Skorupko[82] found that the yield of toluene from n-heptane on an alumina–molybdenum catalyst promoted with strontium oxide passed through a

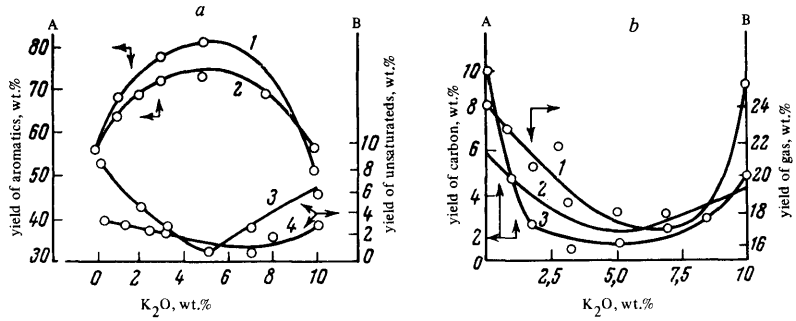

Figure 2. Effect of content of potassium oxide in alumina–chrome catalysts on yields of main products in the dehydrocyclisation of n-heptane[66] (in a flow apparatus):
(*a*): 1) aromatic hydrocarbons on catalysts of type KA-237 at 535°C; 2) aromatic hydrocarbons on catalysts of type A-30 at 550°C; 3) unsaturated hydrocarbons on KA-237; 4) unsaturated hydrocarbons on A-30.
(*b*): 1) gas on A-30; 2) carbon on KA-237; 3) carbon on A-30.

maximum (at 0.3 mole % SrO), but the yield of benzene obtained in the dehydrogenation of cyclohexane increased monotonically with increase in the strontia concentration in the catalyst.

The effect of an alkali-metal oxide depends on the quantity added to the catalyst. According to Visser[35] the maximum yield of toluene from n-heptane was obtained with the proportions $Cr_2O_3 : K_2O = 100 : 12$ with each series of catalysts containing the same total quantity of chromic oxide but different amounts of potassium oxide, independently of the proportion of the former oxide in the catalyst (over the range 40–70 mole %).

The work of Kazanskii[66], Dorogochinskii[83], and their coworkers shows that small amounts (up to 5–8 wt. %) of potassium oxide in an alumina–chrome catalyst act as a promoter, and the yield of toluene from heptane passes through a maximum as a function of this content (Fig. 2). However, comparison of the results suggests that the maximum shifts to higher contents with rise in the reaction temperature. With further increase in the content of potassium oxide (10% and above) the catalyst begins to be poisoned.

Clark[84] attributed the promoting action of alkaline additives to a diminution in the cracking and carbonising power of catalysts based on aluminium oxide. The same effect was noted by Kazanskii et al.[63], who ascribed it to a decrease in the acidity of the catalysts, and later by other workers[68] in a study of the dehydrocyclisation of hydrocarbons. Voltz et al.[85] showed that the introduction of potassium oxide into an alumina–chrome catalyst did in fact diminish its acidity. However, the role of the potassium oxide was subsequently found to be far more complicated than had been thought initially. Thus cracking and carbonisation are intensified at relatively high contents (8–10%) in the catalyst (Fig. 2*b*), which may be associated with a change in the mechanism of side reactions (see Section III, 3).[66]

It is noteworthy that the promotion of alumina–chrome catalysts produces a greater increase in the yield of toluene from heptane than in the yield of catalytic products[63,64]. Hence the promoting action of alkaline additions is not due solely to a change in the acidity of the catalyst. Starting with Voltz and Weller[45] several workers observed an increase in the content of chromium(VI) in the oxidised catalysts with increase in the quantity of potassium oxide. Results obtained by a number of workers[68,69,72,86–88,107] show that the activity of alumina–chrome catalysts increases to a limit in parallel with the increase in the chromium(VI) content in oxidised specimens, independently of whether this increase is due to the introduction of the same quantity of different alkaline additives or to different quantities of the same alkali-metal oxide. A similar parallelism between activity and chromium(VI) content is observed with samples of an alumina–chrome catalyst containing different quantities of chromic oxide[68] and with specimens which have undergone different heat-treatments[87]. All these results suggest that the activity of alumina–chrome catalysts is usually determined by the quantity of a finely dispersed microcrystalline chromic oxide phase formed on the reduction of oxygen compounds of chromium[73,107] as a carrier of active centres.

Rubinshtein et al.[73] showed that, when chromates present in an oxidised alumina–chrome–potash catalyst are reduced, the potassium ion migrates to the aluminium oxide to form surface aluminates. This was confirmed by determining the content of chromium and aluminium ions in aqueous extracts of oxidised and reduced catalysts[73,107].

Kim and Krieger[89] studied the effect of additions of silica on the dehydrocyclising activity and certain other properties of pure chromic oxide. Maximum activity for the dehydrocyclisation of n-heptane was found in a specimen containing 4.7 wt. % SiO_2. This effect was due to inhibition of the crystallisation of chromic oxide and of its dehydration during the experiments, so that deactivation of the catalyst was diminished.

3. Regeneration of Alumina–Chrome Catalysts

During the dehydrocyclisation of alkanes the activity of the catalyst varies with time (Fig. 3). If the reaction starts with an oxidised catalyst, the yield of the aromatic product increases initially, remains constant for some time, and then falls gradually, owing to the deposition of carbon on the surface of the catalyst[90]. The activity of oxide catalysts is usually restored when they are regenerated with oxygen-containing gases[91,92] or mixtures of steam and air[35,93]. No difficulties are usually involved in the regeneration of a catalyst in laboratory reaction

vessels of diameter up to 20 mm. With vessels of diameter 30 mm and larger up to industrial sizes, however, the considerable quantity of heat evolved by the combustion of carbon and the poor thermal conductivity of the layer of granulated catalyst[94] produce considerable temperature rises in the reaction vessel during regeneration of the catalyst.

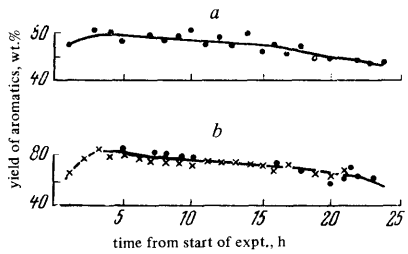

Figure 3. Variation in yield of aromatics during experiment[91] (flow apparatus, alumina–chrome catalyst, space velocity 0.35 h^{-1}) with: *a*) n-hexane at 550°C; *b*) n-heptane at 535°C.

When a stationary bed of an alumina–chrome catalyst, which has undergone carbonisation in the dehydrocyclisation of n-heptane, is regenerated with air, the carbon is burnt out layer by layer, as was established simultaneously by Modavskii and Kamusher[95] and also by ourselves[96,97]. The extent of the zone of intense combustion along the axis of the reaction vessel, the maximum temperature in this zone, and its rate of advance along the bed depend on the rate of supply of air and the distance from the start of the bed[96-98]. Oxidation of carbon in portions of the bed through which the temperature maximum has already passed takes place at a lower temperature, approximating to the temperature of the bed before regeneration began: i.e. two periods of combustion of the carbon are observed.

Comparison of the variation in the temperature of the layer of catalyst with the composition of the waste gases from the regeneration enabled Rozengart and Kazanskii to put forward in 1948 the hypothesis that the burning of carbon on an alumina–chrome catalyst occurs in the diffusion range or is subject to diffusion retardation. The presence of two periods of regeneration—the first at high temperatures and the second occurring more smoothly—is due to the different dimensions of the channels between the catalyst grains and of the pores in the grains. During the first period combustion of the carbon takes place mainly on the surface of the grains, and in the second period mainly in the pores of the catalyst.

Many workers have since arrived at similar conclusions on the presence of two periods in the regeneration of a catalyst under the influence of macrokinetic factors[86,99-101]. Rode and Balandin[102] found, in a thermographic study of alumina–chrome catalysts, including one which had become carbonised in the dehydrocyclisation of heptane, that the non-uniform composition of the carbon could also contribute to the appearance of these two periods of regeneration of the catalyst: the light components of the deposit burn out initially, and later the heavier components. The same view is held by Tyuryaev and Gusakova[103].

When regeneration is effected by a gas with a low (0.2–2%) oxygen content flowing at a high speed, the carbon burns uniformly throughout the length of the catalyst bed at a rate exceeding regeneration by air and also at a lower temperature, since part of the heat is removed by the inert gas. This method of regeneration is used in pilot plants and in industry[104]. The dynamics of combustion of the carbon is greatly influenced by its distribution and by the variation in its chemical composition along the catalyst bed. In a fluidised bed, which has good thermal conductivity and a quite uniform temperature distribution throughout the reaction vessel, carbon formed in the dehydrocyclisation of n-heptane has been shown by Novikova et al.[105] to burn uniformly throughout the bed even in a current of air in a vessel of diameter 40 mm. However, regeneration took longer in the fluidised bed than in a stationary bed.

The chemical composition of the catalyst, in particular its content of potassium oxide, has a substantial influence on regeneration[106]. The rate of combustion of the carbon was increased by the addition of 2–5% K_2O to the catalyst.

The regeneration of alumina–chrome catalysts is not confined to burning out the carbon. Restoration of their activity requires that part of the chromium(III) should be oxidised to chromium(VI).[42] This is explained by the role of oxygen compounds of chromium(VI) in producing a highly disperse chromic oxide phase, which acts as a carrier for the active centres (Section II, 2). The oxidation of chromic oxide is considerably slower than that of the carbon, and completes the regeneration of the catalyst[51].

4. "Development" and Thermal Deactivation of Catalysts

The yields of aromatic hydrocarbons obtained on regenerated oxide catalysts are extremely low initially, and gradually increase to a more or less constant level (Figs. 3 and 4).[62,90,108] This phenomenon, which has been termed "development" ("activation", "formation"[69]) of the catalyst, has considerable significance in the technology of processes using moving alumina–chrome catalysts, where they remain in the reaction zone for only 15–30 min. If a developing catalyst enters the reaction vessel, this period is so short that it functions with diminished activity, and a lower yield of aromatic hydrocarbons is obtained than on a catalyst operating with its maximum possible activity[109]. The development of alumina–chrome catalysts in the dehydrocyclisation of n-hexane and n-heptane has been studied in detail by Kazanskii, Rozengart, Dorogochinskii, and their coworkers[80,88,107-111] using a stationary bed and by Novikova et al.[112] using a fluidised bed.

When hydrocarbons are in contact with an oxidised catalyst (e.g. a regenerated catalyst) containing oxygen compounds of chromium(VI), these are reduced, while part of the hydrocarbon is oxidised to carbon monoxide, carbon dioxide, and water. This is accompanied by a rise in temperature of the layer of stationary catalyst[43,78] by 20–100 deg depending on the diameter of the reaction vessel, the initial temperature, and the chromium(VI) content of the regenerated catalyst.

Reduction of the catalyst with the formation of lower oxides of chromium is complete within a few minutes[107], but development lasts 30–40 min at 530°C. The duration of development is determined[88] by the rate of desorption of the water formed (Fig. 4), which poisons chrome catalysts for dehydrocyclisation (Ref. 8, p. 51). When the

temperature is lowered, and the rate of desorption diminishes, therefore, the development time increases, and at 470°C it is 12 h.[78] If the catalyst is first reduced with hydrogen or hydrocarbon gases, and water vapour is then desorbed by a stream of an inert gas, hardly any development of the catalyst is observed, and the latter functions with its maximum possible activity almost from the start of the reaction[88]. In industrial processes with a moving bed, therefore, the regeneration of alumina–chrome catalysts is followed by their reduction in special equipment, and only after this are they moved into the reaction vessel[113-115]. Addition to an alumina–chrome–potash catalyst of zinc oxide, boron oxide, or more aluminium oxide shortens the period of development[116]. Such rapidly developed catalysts may be of interest for processes with a fluidised bed of an alumina–chrome catalyst.

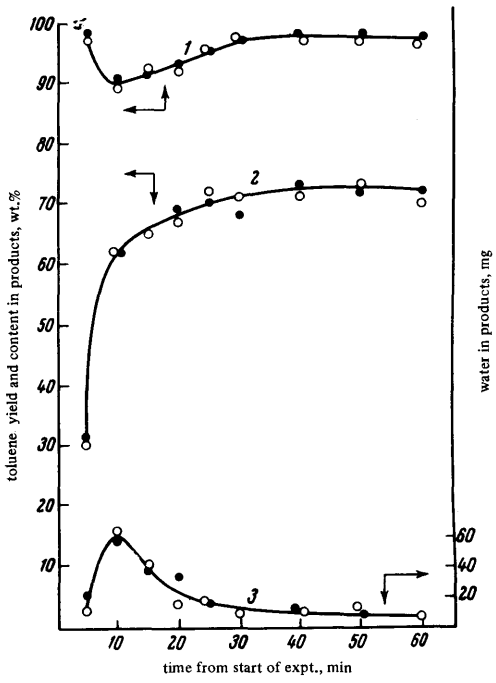

Figure 4. Variation during experiment[88] (flow apparatus at 535°C, space velocity 0.35 h^{-1}, regenerated alumina–chrome–potash catalyst) of: 1) content of aromatic hydrocarbons in products of catalysis; 2) yield of aromatic hydrocarbons; 3) content of water in products.

The development time of a stationary bed of regenerated alumina–chrome–potash catalyst in the dehydrocyclisation of alkanes corresponds to a very unusual variation in the content of aromatic hydrocarbons among the products during the experiment, represented by a characteristic "ladlelike" curve (Fig. 4, curve *1*). The left-hand, descending portion of the curve is due to increased oxidation and degradation of the less stable aliphatic hydrocarbons caused by the temperature rise at the start of the experiment. During the first 10–15 min the degradation diminishes rapidly, and the yield of catalytic products increases more rapidly than does the yield of aromatics, so that the content of the latter in the products falls. The continuing increase in the yield of aromatics, while the total yield of products remains stable, results in the content of aromatics rising to a maximum value. In a fluidised bed no rise in temperature occurs owing to its good thermal conductivity, so that the left-hand portion of curve *1* is absent[112]. The content of aromatics is lowest at the beginning of the experiment. Curves intermediate between these two extreme cases may be observed depending on the experimental conditions and the diameter of the reaction vessel, which govern the rise in temperature.

The promotion of alumina–chrome catalysts by oxides of alkali metals[107] and alkaline-earth metals[78] lowers the initial yield of aromatics and increases the development time. The principal reason is the increase in the quantity of oxygen combined with chromium(VI) on the introduction of an alkaline promoter into the catalyst, and the consequent increase in the quantity of water formed when hydrocarbons are in contact with the catalyst. Another reason is that the presence of potassium ions slows down the desorption of water[107]: i.e. it makes the surface more hydrophilic. Experiments on the dehydrocyclisation of n-heptane on an industrial alumina–molybdenum catalyst before and after promotion with potassium oxide[80] showed that development is characteristic of other dehydrocyclisation catalysts containing oxides of elements of variable valency.

According to Novikova and her coworkers[112,117] raising to 650–700°C the temperature of reduction of alumina–chrome catalysts by hydrogen or methane, or heating in a stream of helium at 700°C a catalyst which has been reduced at 530°C, halved the dehydrocyclising activity of an alumina–chrome–potash catalyst. It is noteworthy that deactivation of an alumina–chrome catalyst with rise in the reduction temperature had been observed earlier by Maslyanskii and Bursian[42] in the dehydrogenation of cyclohexane. Novikova's results[112], as well as investigations by Rozengart et al.[87], have shown that the thermal deactivation of reduced oxide–chrome catalysts is probably due to further dehydration, which facilitates recrystallisation of the microcrystals of chromic oxide. This decreases the surface associated with this oxide while having little effect, as experience shows, on the total specific surface of the catalyst. Heating in a current of air at 700°C usually restores both the activity of a catalyst deactivated in this way and apparently the surface area of chromic oxide in the catalyst which had been reduced at 530°C. In contrast to all other known cases of the thermal deactivation of catalysts, that of reduced alumina–chrome catalysts is reversible, provided that there is no change in the surface or the texture of the aluminium oxide.

III. REACTIONS INVOLVED IN THE DEHYDROCYCLISATION OF HYDROCARBONS ON OXIDE CATALYSTS

Dehydrocyclisation has been most fully studied on various alkanes; less is known about that of alkenes; and very little on the dehydrocyclisation of dienes, trienes, and alkynes.

1. Dehydrocyclisation of Alkanes

(*a*) Effect of molecular weight and structure of alkanes on composition of reaction products and yields of aromatic hydrocarbons

Oxide catalysts for dehydrocyclisation, even single-component catalysts like pure chromic oxide, and multifunctional, since dehydrocyclisation, dehydrogenation, and hydrogenation take place on them, as well as cracking, alkylation, dealkylation, and polymerisation; under certain conditions the disproportionation of unsaturated hydrocarbons can also occur. Therefore the composition of the products obtained on oxide catalysts from aliphatic hydrocarbons, in particular alkanes, is extremely complicated. The main products—the expected aromatic hydrocarbons and hydrogen—are accompanied by hydrocarbons containing either the same number of carbon atoms as the initial alkane or smaller or larger numbers. The quantitative proportions of the various groups of hydrocarbons and individual components in the products depend on the composition and the structure of the initial hydrocarbon, the reaction conditions, and the chemical nature of the catalyst.

The yields of aromatic hydrocarbon increase with the increase in molecular weight from n-hexane to n-nonane and n-decane. Values given in different papers vary within quite wide limits. The maximum yields obtained on alumina–chrome catalysts promoted with alkali metals are 65–80 wt. % based on the initial alkane.

Hexanes. Only n-hexane is able to undergo direct C_6-dehydrocyclisation: isohexanes form benzene on oxide catalysts after preliminary skeletal isomerisation [78]. The gaseous conversion products from n-hexane contain both straight-chain and branched-chain C_1–C_5 hydrocarbons (saturated and unsaturated). Rozengart et al. [78,90] found the product of catalysis (alumina–chrome–potash catalyst at 550°C) to contain, together with the initial hexane and the expected benzene, up to 3 wt. % of branched-chain hexanes, straight-chain hexenes (mainly hex-2-ene and hex-3-ene), and traces of branched-chain hexenes. The literature indicates that the catalytic conversion of hexanes yields also traces of hexadienes, cyclohexane, toluene, xylenes, ethylbenzene, and a higher aromatic. The detailed composition of the products of the dehydrocyclisation of hexanes on an alumina–chrome–potash catalyst is given by Shuikin et al. [118–121] and on an alumina–chrome catalyst by Pines and Csicsery [122]. The latter workers note that the xylenes formed by the dehydrocyclisation of hexanes usually have the equilibrium composition. The introduction of an alkaline promoter into an alumina–chrome catalyst almost completely suppresses the formation of toluene in the dehydrocyclisation of n-hexane [78]. Minachev et al. [123] obtained an appreciable quantity of toluene (up to 15% of the product at 520°C) by the dehydrocyclisation of n-hexane on an industrial alumina–molybdenum catalyst. The absence of heptanes and heptenes from the reaction products suggests that the formation of homologues of benzene in the dehydrocyclisation of n-hexane is most likely due to the alkylation of benzene by degradation products of the initial hexane.

Heptanes. Dehydrocyclisation of heptanes may be expected to yield toluene, but benzene is formed as well, and may reach up to 4 wt. % of the products obtained on an alumina–chrome–potash catalyst. Plate and Tarasova [124,125] showed that the unsaturated products of the dehydrocyclisation of n-heptane on an alumina–vanadium catalyst at 480°C comprised mainly hept-2-ene and hept-3-ene. Shuikin et al. [119] obtained a similar result. n-Heptane (on an alumina–chrome–potash catalyst) yields all n-heptenes, usually in proportions close to the thermodynamically equilibrium values, traces of branched-chain heptanes, mainly 2- and 3-methylhexanes, and also C_1–C_6 hydrocarbons with straight-chain and branched-chain structures [78].

Special attention was paid in the early work on dehydrocyclisation [8] to the effect of branching of the carbon skeleton in the alkane on the yield of aromatics. During recent years Pines and his coworkers have studied the dehydrocyclisation of isomeric heptanes (and also octanes). These investigations, which used ^{14}C-labelled hydrocarbons, gas–liquid chromatography, and sometimes also spectroscopic analysis, gave detailed information on the composition of the reaction products. Unfortunately, alumina–chrome catalysts were used, which were poisoned fairly rapidly (within 5–18 min) and in several cases also had a strong cracking effect. Therefore purely tentative conclusions concerning yields of aromatics can be obtained only from results with the initial samples during the first 5–9 min of an experiment.

Comparison of results obtained by Hoog et al. [6] with those of Pines and Dembinski [126] indicates that the yield of aromatics from n-heptane is very similar to that from 2-methylhexane and somewhat higher than the yield from 3-methylhexane. However, the latter workers themselves remark that the lower yields in the last case may be due to stronger poisoning of the catalyst.

Octanes. Study of the products of the dehydrocyclisation of octanes is of especial interest, since ring closure can occur in several ways. Thus n-octane should yield ethylbenzene and *o*-xylene.

In practice the catalytic products from n-octane contain every possible C_8 aromatic hydrocarbon, including styrene, together with benzene and toluene [127,128]. The latter are formed by the dealkylation of ethylbenzene and xylenes. Since ethylbenzene and *o*-xylene do not isomerise on oxide catalysts for dehydrocyclisation [127–131], the presence of *m*- and *p*-xylenes is explained by the isomerisation of n-octane into branched-chain octanes followed by cyclisation of the latter [128,132]. The expected aromatic hydrocarbons usually predominate on the cyclisation of any octane [127–141]. However, the catalytic products from n-octane have been found to contain also branched-chain octanes and octenes, octadienes (traces), and also lower hydrocarbons. n-Octane has been detected in the dehydrocyclisation of 3- and 4-methylheptanes [137]; n-octane, dimethylcyclohexanes, and other saturated and unsaturated cyclic hydrocarbons in the products from dimethylhexanes [135]; and small quantities of cycloalkanes, cycloalkenes, 3-ethyl-hexenes and -hexadienes, 3-methyl-hexenes and -hexadienes, and also 3-methylhexane from 3-ethylhexane [136]. On this basis Pines and his coworkers stated that the dehydrocyclisation of C_6–C_8 alkanes involves the intermediate formation of 5–8-membered cycloalkanes or their chemisorbed forms [130,131,133–137,141]. It must be noted that, by itself, the presence of any substance among the reaction products cannot prove that it is an intermediate in the main reaction: such proof requires additional evidence.

Several workers have studied the aromatisation of trimethylpentanes [142–149]. This probably requires preliminary isomerisation with lengthening of the main chain. The principal reactions of trimethylpentanes on oxide–chrome catalysts are degradation and dehydrogenation [147,148], accompanied by the formation of C_6–C_8 aromatic hydrocarbons. Among the products from 2,2,4-trimethylpentane Timofeeva et al. [145] found traces of 1,1,3-trimethylcyclopentane; but Lester, who also studied this reaction,

considers this to be a product of a secondary, not the main reaction[149].

Nonanes and higher alkanes. Relatively little work has been done on the dehydrocyclisation of nonanes and higher alkanes[118,119,140,150-157]. Several studies have been made of the dehydrocyclisation of n-alkanes of different molecular weights on alumina–chrome or alumina–molybdenum catalysts under comparable conditions: thus Shuikin et al.[118,119] studied the dehydrocyclisation of C_6-C_{10} n-alkanes, Perrée and Bloury[140] C_6-C_9, Suzumura and Yoshida[157] C_6-C_{12}, and Usov et al.[154,155] C_9-C_{16}. The bulk of the aromatic hydrocarbons are those containing the same number of carbon atoms as the initial alkane. Mono- and di-alkylbenzenes (mainly the *ortho*-isomers) are formed together with trialkylbenzenes, naphthalene, and its homologues; anthracene and phenanthrene could not be found.

The observation by the early investigators[1-3], that the composition and structure of the major portion of the aromatic hydrocarbons formed are determined by the modes of closure of a six-membered ring available to the initial alkane, can in general be regarded as confirmed. With increase in the number of carbon atoms in the initial alkane from 6 to 10 the yield of aromatic hydrocarbons becomes larger; further lengthening of the carbon chain in the alkane probably diminishes the yield.

(*b*) Influence of reaction conditions

Temperature and space velocity (contact time). There are numerous results of this type, since almost all investigators have studied more or less thoroughly the dependence of the yields of aromatic unsaturated hydrocarbons on the temperature and space velocity[8,78,117,120,125,128,152,155-164]. The general rules—increased yield of aromatic hydrocarbons with rise in the experimental temperature and increased contact time—apply to various hydrocarbons both in a stationary bed and in a fluidised bed of the catalyst.

At relatively low temperatures (300–450°C) and short contact times the main products are unsaturated hydrocarbons, chiefly alkenes[78,158,163]; under more severe conditions (500–600°C, longer periods of contact) aromatic hydrocarbons are mainly formed (50–80).[78,90,158] With rise in temperature over a wide range or increased contact time the yield of unsaturated hydrocarbons passes through a maximum (e.g. Fig. 5).[78,128,158,162] As a consequence of all the above generalisations, study of the effect of temperature or space velocity over not too wide ranges of variation in these parameters may reveal either parallel or opposite changes in the yields of aromatic and unsaturated hydrocarbons, as has been shown by Kazanskii et al.[160]

Levitskii showed convincingly[165] that the yield of alkenes and their content in the products of the dehydrocyclisation of alkanes are determined not only by the kinetics but also by the thermodynamics of the reactions. The concentration of alkenes during the dehydrocyclisation of alkanes is usually close or equal to the equilibrium value. In several cases, therefore, the decrease in the yield of alkenes beyond the maximum can be explained not only by the diminished rate of dehydrogenation of the alkane resulting from its diminished concentration but also by the displacement of the formation equilibrium of the alkene due to the rise in the concentration of hydrogen in the reaction mixture on formation of the aromatic.

Dilution and increased pressure. Plotnikov et al.[166] studied the effect of diluting n-hexane vapour with nitrogen or of a vacuum on the yield of benzene on an alumina–chrome–potash catalyst at 500°C. They found that the yield of benzene increased, while that of hexenes decreased, with decrease in the partial pressure of hexane, i.e. with increase in dilution by nitrogen or decrease in the total pressure. As these workers state correctly, the results can be explained on the assumption that benzene is formed via hexenes.

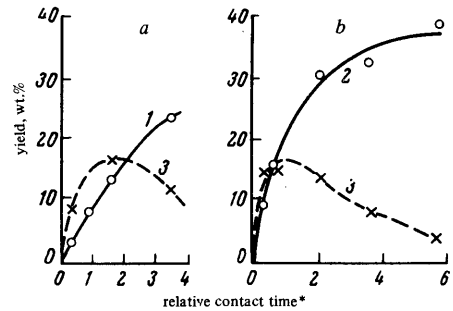

Figure 5. Effect of relative contact time* in flow apparatus[78] on yields of products from the dehydrocyclisation of: *a*) n-hexane at 550°C; *b*) n-heptane at 535°C: 1) benzene; 2) toluene; 3) unsaturated hydrocarbons.

*The relative contact time is a dimensionless quantity obtained by dividing the volume of the catalyst by the volume corresponding to the contact time adopted as unit.

Variation in the component partial pressures of the reaction mixture affects not only the total yield of aromatic hydrocarbons but also their composition. For example, Rozengart et al.[167] established that decreasing the partial pressures of all components in the dehydrocyclisation of n-octane under pulse conditions in a stream of helium produced considerable increases in the content and yield of styrene as compared with those observed in the usual flow equipment (for greater detail see Section III, 5).

Since hydrogen is a product of the dehydrocyclisation of alkanes, high pressures of the gas, as occur in the industrial process of hydroforming[14], have an especially unfavourable effect on the reaction. The influence of thermodynamic factors was examined also by Taylor and Turkevich[4] and later by Rossini et al.[168] (see also Ref. 8, p. 203) and several other authors[62,169]. It is noteworthy that the effect of the hydrogen pressure differed with alumina–chrome and alumina–molybdenum catalysts. According to Greensfelder et al.[62] the decrease in the yield of toluene from heptane with rise in the hydrogen pressure was smaller on the latter type of catalyst. This was noticed also by Maslyanskii et al.[169], who studied the hydroforming of ligroins on the two catalysts. Thus the adverse effect of hydrogen pressure on the dehydrocyclisation of alkanes is due not only to thermodynamic factors but also to the variation in the reaction velocity, which differs between the catalysts.

2. Dehydrocyclisation of Unsaturated Hydrocarbons

The catalytic dehydrocyclisation of unsaturated hydrocarbons has been studied less thoroughly than that of alkanes. However, sufficient results are known to leave no doubt that the presence of a multiple bond in a molecule facilitates its cyclisation with formation of an aromatic compound. The rate of dehydrocyclisation increases with the number of double bonds in the molecule, and hydrocarbons can be arranged in the sequence—alkanes, alkenes, dienes, trienes—with increasing rate of this reaction[170,171]. According to Kotlyarevskii et al.[172,173] alkynes are probably aromatised more rapidly than alkenes but more slowly than dienes.

(*a*) Alkenes

The structure of the aromatic hydrocarbon formed from alkenes and other unsaturated hydrocarbons is determined by that of the initial hydrocarbon, as in the dehydrocyclisation of alkanes. Therefore all that has been said concerning the composition of the aromatic products from alkanes applies also to the catalytic reactions of alkenes.

The alkene portion of the product usually comprises a mixture, in thermodynamic equilibrium, of isomers having the same carbon skeleton as the initial alkene but different positions of the double bond[78,125,140,174-177]. Arenes and alkenes in the products from alkenes are always accompanied by alkanes formed by hydrogenation of the initial hydrocarbon by hydrogen evolved in the dehydrocyclisation. Dienes[171,174,177] and traces of trienes have also been found in the products. According to Perrée and Bloury[140] the yield of aromatics rises with increase in the molecular weight of the alkene from n-hex-1- and -2-enes to the corresponding n-octenes.

Great attention has been paid to the effect of the position of the double bond in n-alkenes on the yield of aromatic hydrocarbons, since this is directly connected with the mechanism of dehydrocyclisation. According to Plate and Tarasova[124,125] the yields from hept-1-ene and hept-3-ene on an alumina–vanadium catalyst at 480°C were about the same, perhaps rather higher from the former hydrocarbon. It was observed at the same time that hept-3-ene poisoned the catalyst the more rapidly. Rozengart et al.[174] found that, on an alumina–chrome–potash catalyst at 450°C using an equimolar stream of helium in the usual flow equipment, the yield of toluene was larger from hept-2-ene than from hept-1-ene and smallest from hept-3-ene; the catalyst was poisoned most strongly by hept-3-ene, and least by hept-1-ene.

Panchenkov et al.[178,179] have recently obtained similar results to the above[174] from the dehydrocyclisation of hept-1-ene, hept-2-ene contaminated with hept-3-ene, and hept-3-ene itself on an alumina–chrome–potash catalyst in an ordinary flow apparatus. The strong effect which secondary reactions are now known to have on the main reaction, in particular the different degrees of poisoning of the catalyst in the dehydrocyclisation of individual isomers, does not always permit correct conclusions as to the reaction mechanism to be drawn from results obtained in the dehydrocyclisation of alkenes in an ordinary flow-type apparatus. This has been done by conducting the reaction under pulse conditions and analysing the reaction products by means of a capillary chromatograph.

Rozengart et al.[170,177] found that heptenes can be arranged in the sequence

cis-hept-2-ene > *cis*-hept-3-ene > *trans*-hept-3-ene > *trans*-hept-2-ene ⩾ hept-1-ene

of diminishing rate of dehydrocyclisation on an alumina–chrome–potash catalyst. Thus stereoisomerism has a greater effect than the position of the double bond on the rate of dehydrocyclisation of alkenes. The influence of branching of the carbon skeleton of alkenes on the yield of aromatics has not in fact been studied. It is interesting that 2,5-dimethylhexa-2,4-diene has been recommended as a starting material for the production of *p*-xylene[180]. Temperature and space velocity have the same effects on the yield of aromatics from alkenes as have been noted with alkanes. Cracking, the deposition of carbon, and poisoning of the catalyst are more marked in the dehydrocyclisation of alkenes[140,181].

(*b*) Dienes

Plate and Batuev[182] passed hexa-1,5-diene over an alumina–chrome catalyst at 300° and 400°C, and found 8–11% of benzene in the product. Shuikin et al.[183] studied the C_5- and C_6-dehydrocyclisation of various dienes on an alumina–chrome–potash catalyst in a vacuum, and showed that 42% of toluene is formed from hepta-1,3-diene at 600°C. When preparing *p*-xylene, Kotlyarevskii and Zanina[173] found that 2,5-dimethylhexadiene is aromatised better than is 2,5-dimethylhexene on an alumina–chrome catalyst promoted with magnesium oxide; the composition of the products from the dienes showed more individuality than those from the alkene. According to Akioshi et al.[138] the yield of aromatics obtained on a chrome–magnesia catalyst was higher from 2,5-dimethylhexa-2,4-diene than from 2,5-dimethylhexa-1,5-diene. The same yield of toluene was obtained from hepta-1,3- and -2,4-dienes on an alumina–chrome–potash catalyst at 450°C under pulse conditions[171], since the rate of migration of the double bond was higher in the dienes than in the alkenes. The heptenes (a mixture of all the n-heptenes), formed by hydrogenation of the initial diene, were accompanied in the reaction products by hepta-1,3,5-trienes, the yield of which reached 3 wt. %.[170]

(*c*) Trienes

The dehydrocyclisation of trienes on an alumina–chrome catalyst promoted with magnesium oxide has been described in a patent[184]. No other information was available on this topic before our work[170,171]. Aliphatic trienes readily undergo a peculiar thermal "cycloisomerisation" into cyclohexadienes[185-188]. According to Lewis and Steiner[188] only *cis*-hexatriene is directly cyclised, having the horseshoe configuration favourable for ring closure; other isomers first isomerise into the *cis*-form.

Rozengart et al.[170] found that hepta-1,3,5-triene is easily converted into toluene on an alumina–chrome–potash catalyst under pulse conditions in a stream of helium at 450°C. The products contained also heptadienes, formed by hydrogenation of the original triene with hydrogen resulting from the dehydrocyclisation. No cyclic hydrocarbons other than toluene and methylcyclohexadienes were detected. Komatsu has recently reported[189] that 3-methylhepta-1,4,6-triene, obtained by the dimerisation of butadiene, is converted on an alumina–chrome catalyst into a good yield of *o*- and *p*-xylenes at as low a temperature as 200°C.

(*d*) Alkynes

Information on the dehydrocyclisation of alkynes is extremely scanty. Levina et al.[190] showed that the passage of hex-1-yne and hept-1-yne over an alumina–chrome catalyst at 450°C gives yields respectively of ~25% of benzene and ~32% of toluene together with 2% of benzene.

Kotlyarevskii[191] obtained a 7% yield of aromatic hydrocarbons by passing hexadien-3-yne in a current of hydrogen over activated carbon at 500°C. On an alumina–chrome catalyst this alkenyne gave ~25% of aromatics at 450°C, and up to 85% at 500°C; in the latter experiments the products included 20% of benzene and 10% of anthracene together with naphthalene and other aromatic hydrocarbons. On the same catalyst at 400°C a yield of 24% of *p*-xylene was obtained from 2,5-dimethylhex-3-yne and up to 28% of toluene from 2-methylhexadien-3-yne.

Formation from alkynes themselves of the horseshoe configuration necessary for cyclisation may be supposed to be extremely difficult, since three or four carbon atoms lie in a straight line (in alk-1-ynes or in alk-2- and -3-ynes and hexadien-3-yne). As, however, the isomerisation of alkynes on chromic oxide yields conjugated dienes[192], it may be assumed that monocyclic aromatic hydrocarbons are formed from the dienes, not directly from the initial alkynes. Aromatic hydrocarbons having fused rings are probably formed from several molecules of the alkyne.

3. Secondary Reactions

The dehydrocyclisation of hydrocarbons on oxide catalysts is accompanied by several side reactions, which have a significant effect on the composition of the products and the yield of aromatic hydrocarbons. Amongst such reactions are cracking, the isomerisation of aliphatic hydrocarbons, the dealkylation and alkylation of aromatic hydrocarbons, carbonisation, and also the hydrogenation of unsaturated hydrocarbons. Since all these reactions other than the last are retarded when the catalysts are promoted with alkaline additions[63,66], it may be supposed that they are catalysed mainly by a carbonium mechanism involving acidic centres, and are connected with changes undergone by intermediate or initial unsaturated hydrocarbons. With a large excess of alkali-metal oxide in the alumina–chrome catalyst the mechanism of cracking and carbonisation probably changes, and these reactions begin to take place by a carbanion mechanism[66].

Cracking. This is intensified by increase in the molecular weight of the initial hydrocarbon[78,140], rise in the reaction temperature[67,140], and increase in the contact time[67,83]. Varshaver[67] has found that gas formation in the dehydrocyclisation of n-heptane on various alumina–chrome–potash catalysts is well described by a fractional linear equation.

Isomerisation. Hydrocarbons are observed to isomerise in many of their catalytic reactions, e.g. dehydrogenation of the lower alkanes[193,194]. Earlier results on the isomerisation of hydrocarbons during dehydrocyclisation were discussed in adequate detail by Obolentsev[195–197]. Isomerisation has little effect on the yield of aromatics in the dehydrocyclisation of n-hexane and n-heptane; it is responsible for the appearance of small quantities of alkanes and alkenes of branched-chain structure among the products. However, isomerisation becomes very noticeable in the dehydrocyclisation of ^{14}C-labelled heptanes and octanes. Migration of the radiocarbon atom, which has been established in these cases[122,130,141,144,198–202], is probably due to isomerisation of the carbon skeleton of intermediate unsaturated aliphatic hydrocarbons, not to peculiarities of the mechanism of dehydrocyclisation.

Hydrodealkylation. Appreciable hydrodealkylation of the aromatic hydrocarbon formed is already evident in the dehydrocyclisation of n-heptane, and leads to the formation of benzene from toluene, and to the appearance of benzene and toluene among the products of the dehydrocyclisation of octane, as stated above. On an alumina–chrome–potash catalyst the hydrodealkylation of ethylbenzene is more rapid than that of xylenes by factors of 2–10,[127] the formation of benzene from ethylbenzene probably occurring by two mechanisms—elimination of the ethyl group and initial elimination of a methyl group with subsequent detachment of a second methyl from the resulting toluene.

Alkylation. Hexane and heptane show especially appreciable alkylation of the aromatic hydrocarbons formed by dehydrocyclisation (see above discussion of the composition of the products of dehydrocyclisation). Alkylation probably occurs by a carbonium mechanism, since the introduction of potassium oxide into an alumina–chrome catalyst strongly inhibits this reaction, as has already been noted.

Carbonisation. In comparison with other side reactions carbonisation has the most adverse effect on the dehydrocyclisation of hydrocarbons, since it poisons the catalyst and makes regeneration necessary. Raising the temperature, increasing the space velocity, and extending the duration of the experimental result in increased quantities of carbon on the catalyst[67,78,203,204]. Under otherwise similar conditions the yield of carbon depends on the nature of the hydrocarbon, increasing in the sequence—cyclohexanes, alkanes, alkenes, and alkylcyclopentanes—which are converted into alkylcyclopentadienes. It follows from Section II, 2 that the yield of carbon is influenced also by the chemical composition and the properties of the catalyst, e.g. the nature of its porosity[205].

During dehydrocyclisation carbon is deposited non-uniformly along a stationary layer of catalyst[206]: the rate of deposition is highest at the beginning of the layer, and falls gradually to the end. The distribution of carbon depends also on the starting materials and the properties of the catalyst. This has been examined theoretically by Froment and Bischoff[207,208]. According to Novikova et al.[117,209] carbon is deposited uniformly throughout the mass of a fluidised bed of an alumina–chrome–potash catalyst during the dehydrocyclisation of n-heptane.

Equations for the dependence of catalyst poisoning on experiment duration in the dehydrocyclisation of alkanes have been given by Herington and Rideal[129] for an alumina–chrome catalyst, and later by Sterligov[156] for an alumina–molybdenum catalyst (see also Ref. 210 for equations describing the poisoning of a catalyst by carbon).

The carbon formed on catalysts itself catalyses the dehydrocyclisation of hydrocarbons[211], their dehydrogenation[212], and irreversible catalysis[213].

4. Kinetics of Dehydrocyclisation

Pitkethly and Steiner[5], Herington and Rideal[129], and Karzhev and Sorokin[214] assumed that the dehydrocyclisation of alkanes, in particular of n-heptane, was a first-order reaction. Griffith et al.[38] consider it to be of zero order. Tarasova and Kazanskii[158] found that dehydrocyclisation on an alumina–chrome–potash catalyst is a zero-order reaction with high rates of supply of hexane. According to Obolentsev[215] the yield of aromatic hydrocarbons and the total yield of aromatics and alkenes are exponential functions of the time of contact. Later Steiner[10] concluded that dehydrocyclisation may have a fractional order. Chinese workers[216] and later Skarchenko[217] considered that Frost's well known equation[218] gives a good description of the yield of aromatics from alkanes. According to Petrov[219] the total yield of benzene and alkenes from n-hexane can be represented by Frost's equation, but the yield of benzene requires a first-order rate equation. Panchenkov et al.[220] derived a fairly complicated kinetic equation for the dehydrocyclisation of alkanes, assuming that it involves the intermediate formation of alkenes and it accompanied by carbonisation.

Kazanskii, Rozengart, and their coworkers[206,221,222] have shown that the dehydrocyclisation of alkanes may be subject to internal diffusion retardation, which increases from hexane to heptane. The difference in the extent of diffusion retardation with different hydrocarbons depends on variations not so much in their diffusion coefficients as in their reactivities. This circumstance, and also the highly endothermic character of the reaction, leading to steep temperature gradients in the catalyst bed, together with the decrease in the activity of the catalyst during the experiments, have not always been taken into account in experiments serving as a basis for the deduction or the verification of the above kinetic equations. Therefore published kinetic parameters can be regarded only as a first approximation. Kinetic aspects of dehydrocyclisation merit special investigation in the light of modern ideas, methods, and techniques for the kinetic study of catalytic reactions[223-226].

5. Multistage Mechanism of Dehydrocyclisation

The mechanism of the dehydrocyclisation of alkanes has already been discussed for more than thirty years, but the problem has still not been finally solved. The results considered below will evidently permit a closer approach to its solution in the case of alumina–chrome–potash and alumina–molybdenum–potash catalysts, and very probably with certain other oxide catalysts.

Pitkethly and Steiner[5], Hoog[227], and later Herington and Rideal[129] assumed that the hydrocarbon molecule undergoes dissociative adsorption with formation of an alk-1-ene chemisorbed at the site of the double bond, which is converted into a chemisorbed cyclohexane and then into an aromatic hydrocarbon. Many authors have held the opinion, that an aromatic hydrocarbon is formed on chromic oxide catalysts via an alkene[219,220,228-232]. However, this has been proved for the dehydrocyclisation of alkanes only in the work of Rozengart, Kazanskii, and their coworkers with heptane on alumina–chrome–potash[174] and hexane on alumina–molybdenum–potash[233] catalysts and also with mixtures of n-hexane with labelled hex-1-ene[234].

According to the second alternative scheme of Pitkethly and Steiner[5] the alkane is present on the catalyst initially in a semi-hydrogenated state, and then forms a biradical with the chemisorbed first and sixth carbon atoms of the chain, which is subsequently converted into the aromatic hydrocarbon. The formation of alkenes is in this case a side reaction.

According to Kagan et al.[235] an alkane molecule, adsorbed on the catalyst by one carbon atom, can then be adsorbed by any other atom. If the latter is an adjacent atom, an alkene is formed; if, however, the other atom is the sixth, cyclisation occurs.

Plate and Tarasova suggested[8] that a sextet orientation of the hydrocarbon molecule is possible on an alumina–vanadium catalyst, since vanadium oxide, like chromic oxide and aluminium oxide, has the corundum type of lattice. On chemisorption on such sextets the alkane molecule forms an intermediate six-membered structure, which loses hydrogen and is converted into a benzene ring. In this case the formation of alkenes will be a side reaction, although they also are partly converted into aromatics. Plate and Tarasova do not exclude the possibility that, on a different catalyst with a distribution of active centres more favourable for the formation of alkenes, these may be the principal source of aromatic hydrocarbons. Lipovich et al.[236-238], from a study of the dehydrocyclisation on an alumina–chrome–potash catalyst of mixtures of n-heptane and n-heptenes in which one of the hydrocarbons was labelled with radiocarbon, also conclude that toluene is obtained by two routes—via alkenes desorbed into the gas phase and by a route independent of them—under the conditions of a flow experiment.

Davis[239] also supports the hypothetical sextet mechanism for the dehydrocyclisation of alkanes. He explains the fact that molybdenum oxide alone does not cause dehydrocyclisation, but is able to do so when deposited on aluminium oxide, by the absence of sextets from its crystal lattice, whereas in an alumina–molybdenum catalyst the molybdenum atoms are situated in the vacant octahedral cavities of the γ-alumina lattice, to form sextets on which the hydrocarbon molecule is chemisorbed.

Mitchell[199] explained the distribution of carbon-14 in toluene obtained from [^{14}C] heptane on the assumption that dehydrocyclisation involves the intermediate formation of a cyclopentane, which, with subsequent ring expansion or via the formation of a bicyclic hydrocarbon containing an endomethylene bridge, is converted into methylcyclohexane and then into toluene. As already mentioned, Pines and his coworkers[131,141] assume that the dehydrocyclisation of C_6-C_8 alkanes involves the formation of 5–8-membered rings, which are then converted into six-membered rings and into an aromatic hydrocarbon. However, Kazanskii, Rozengart, et al.[240-242] report that cyclohexanes or their adsorbed forms are not intermediate products on a chromic oxide catalyst, at least under pulse conditions. Hence the traces of cyclohexanes obtained in the catalytic aromatisation of alkanes are most probably products of secondary or side reactions.

Interesting information on the interaction between hydrocarbon molecule and catalyst has been obtained in a study of the adsorption and especially the chemisorption of hydrocarbons. Rubinshtein et al.[243-250] found that, contrary to the generally held view, alkanes and cyclohexane undergo chemisorption to a greater extent than alkenes or benzene on an alumina–chrome–potash catalyst, and that the chemisorption of hydrocarbons is related to their electron-accepting properties. In the opinion of Slovetskaya and Rubinshtein[250] the chemisorption of alkanes is directly connected with their subsequent dehydrogenation.

Usov et al.[252], using Balandin's method[252] to determine adsorption coefficients, also established that hexane at 490°C and heptane at 460–475°C are adsorbed on an alumina–chrome catalyst considerably better than is the corresponding aromatic hydrocarbon; at 500°C, however, the adsorption on n-heptane is almost the same as that of toluene. On an alumina–molybdenum catalyst at 480 to 490°C alkanes are adsorbed to the same extent as are aromatics.

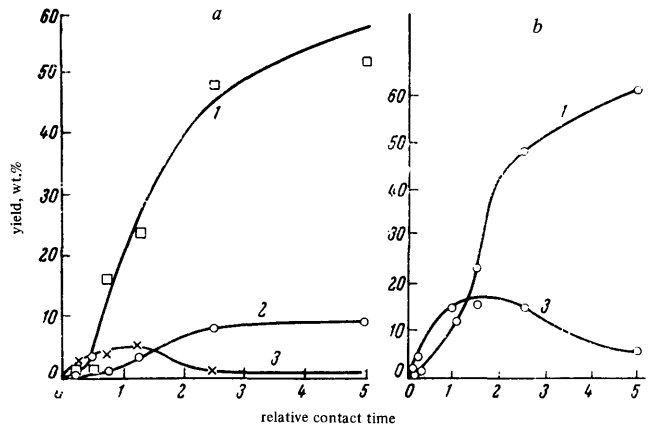

Figure 6. Dependence of yields of products of the dehydrocyclisation of hept-1-ene at 450°C on the relative contact time[172,175] (see footnote to Fig. 5) in: *a*) flow apparatus; *b*) pulse apparatus: 1) aromatic hydrocarbons; 2) n-heptane; 3) heptadienes.

A study in our laboratory of the effect of time of contact on the yield of aromatic and unsaturated hydrocarbons in the dehydrocyclisation of n-hexane, n-heptane, and n-octane on an alumina–chrome–potash catalyst in the usual flow (Fig. 5) and pulse types of apparatus has shown[78,128], in agreement with results obtained by other workers, that the yield of alkenes exceeds that of aromatics at short contact times, and passes through a maximum with increase in the contact time. The dehydrocyclisation of hept-1-ene in a stream of helium in both types of apparatus exhibits[171,174] an analogous relative arrangement of the curves for the yields of toluene and of heptadienes (Fig. 6), but in the dehydrocyclisation of hepta-1,3-diene under pulse conditions a very similar situation is observed[170,171] for the yields of aromatics and of heptatriene (Fig. 7). Indeed, it was not possible in the latter case to observe a higher yield of trienes than of toluene at short times of contact. The dehydrocyclisation of hepta-1,3,5-triene produces methylcyclohexadiene and toluene[170,171]. The yield of the latter increases with increased duration of contact with the catalyst, but the total yield of cycloalkadiene and arene remains almost constant and equal to the yield of methylcyclohexadiene in the thermal cyclisation of heptatriene under the same conditions (Fig. 8).

On the basis of the above facts Rozengart et al.[170] put forward the hypothesis that the dehydrocyclisation of alkanes is a multistage consecutive reaction:

alkane → alkenes → dienes → trienes → alkylcyclohexadienes → aromatic hydrocarbons.

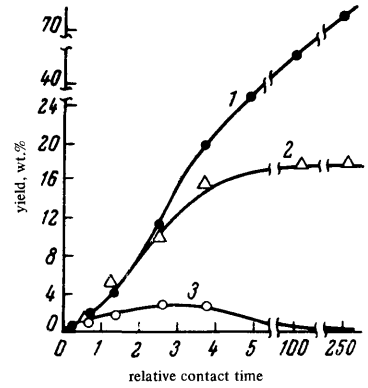

Figure 7. Dependence of product yields from the dehydrocyclisation of hepta-1,3-diene at 450°C on relative contact time (see footnote to Fig. 5) in a pulse apparatus[171,172]: 1) arenes; 2) n-heptenes; 3) heptatrienes.

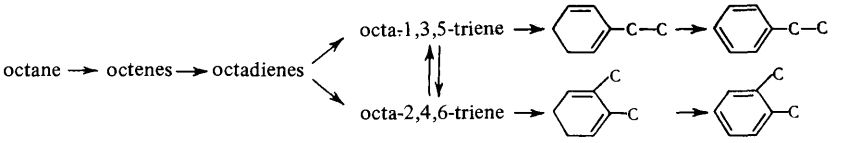
All dehydrogenation stages in this scheme are catalytic, but the cyclisation stage—formation of an alkylcyclohexadiene from a triene—is thermal. Two years after publication of our results, Krause[253] suggested that heptatriene is formed in the dehydrocyclisation of heptane. In his opinion, however, toluene is formed from the intermediate heptatriene by catalytic dehydrocyclisation in a single stage, which is inconsistent with the above experimental results. The rate-determining stage of the overall process of dehydrocyclisation is probably the first stage of dehydrogenation, whatever the initial hydrocarbon—alkane, alkene, or diene.

It must be noted that our results cannot exclude the possibility of simultaneous catalytic cyclisation of part of the intermediate dienes. Since we obtained fundamentally the same results for the dehydrocyclisation of n-heptane, hept-1-ene, and n-octane in the usual flow and pulse types of equipment, the above scheme can be assumed to apply also under the conditions of the usual flow-apparatus.

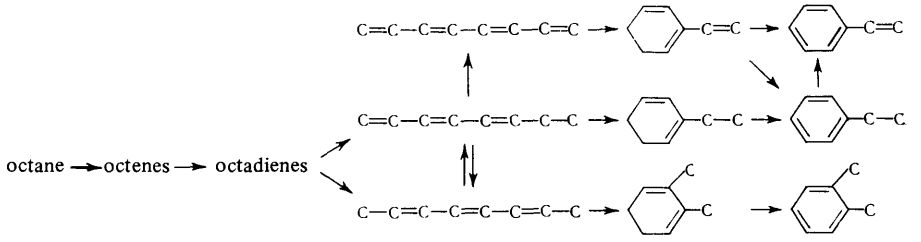
The above multistage consecutive reaction scheme has enabled us to understand certain features of the dehydrocyclisation of n-octane on an alumina–chrome–potash catalyst. Thus it has been found[167] in particular that, in experiments in pulse and flow type of apparatus, rise in temperature produces a greater increase in the yield of ethylbenzene, formed by closure of a bond between the first and sixth carbon atoms, than in that of *o*-xylene, which requires bond formation between the second and seventh carbon atoms. Variation in the relative yields of ethylbenzene and *o*-xylene cannot be a consequence of their

mutual isomerisation, because, as mentioned above, it has been established that aromatic hydrocarbons do not isomerise on chromic oxide catalysts. Since n-octane is obviously dehydrocyclised by the same scheme as has been established for heptanes, it may be supposed that in a flow apparatus ethylbenzene and *o*-xylene result from the intermediate formation of octa-1,3,5-triene and octa-2,4,6-triene respectively. The thermodynamic equilibrium of these trienes probably governs also the proportions of aromatic hydrocarbons formed in the main reaction:



From the variation in the relative yields of ethylbenzene and *o*-xylene in this series of experiments, the equilibrium shifts partly towards formation of octa-1,3,5-triene with rise in temperature.

When n-octane was diluted with helium, and especially on passing from experiments in the usual flow apparatus to pulse conditions, the yield of styrene increased[167] from 1% to 30% on an alumina–chrome–potash catalyst and to 43% on an alumina–molybdenum–potash catalyst. Analysis of the results indicated that, under pulse conditions with low partial pressures of all components of the reaction mixture (including the hydrogen formed), yields are increased in the dehydrogenation of ethylbenzene to styrene and of octa-1,3,5-triene to octa-1,3,5,7-tetraene; this last compound cyclises to vinylcyclohexadiene, which is dehydrogenated to styrene or may be partly isomerised to ethylbenzene. Therefore the scheme of conversion of hydrocarbons in the dehydrocyclisation of n-octane under pulse conditions is somewhat modified:



Under pulse conditions styrene is apparently formed in two ways, and the appearance of the second route also displaces the equilibrium between the octatrienes. As a consequence of the combined effects of dilution and rise in temperature, the products of ring closure between the first and sixth carbon atoms (with formation of ethylbenzene and styrene) come to exceed the product formed by closure between the second and seventh atoms (*o*-xylene), and the yield of styrene based on the n-octane which has reacted reaches 40% at 600°C.[167]

If the dehydrocyclisation of aliphatic hydrocarbons is assumed to comprise a series of successive dehydrogenation stages, the interaction of the hydrocarbon with the catalyst must also be considered from this point of view. The catalyst may be supposed to detach (or draw off) a proton from the hydrocarbon molecule, and the resulting carbanion is chemisorbed; or else the hydrocarbon molecule, on losing a hydrogen atom, is chemisorbed as an alkyl radical (semi-hydrogenated state). According to Myasnikov[254] such radicals, adsorbed on semiconducting oxides, are rapidly converted into a chemisorbed carbanion†. There follows detachment of a second hydrogen atom or hydride ion from an adjacent carbon atom with formation of a double bond according to the mechanism suggested by Kazanskii[255] on the basis of the atomic characteristics of chromium as a transition metal.

If the view is held that dehydrogenation begins with the detachment of one hydrogen atom, it becomes clear why dehydrogenation and then dehydrocyclisation of an alkene are more rapid than those of an alkane: detachment of a hydrogen atom or ion should occur more rapidly in the

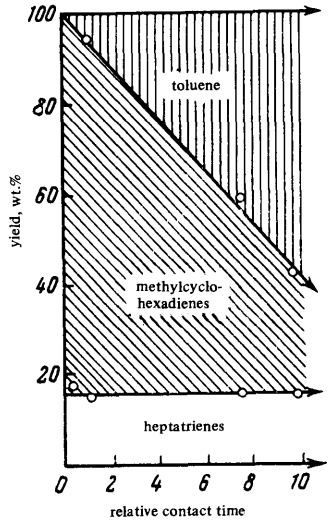


Figure 8. Dependence of product yields in the dehydrocyclisation of hepta-1,3,5-triene at 450°C in a pulse apparatus on relative contact time (see footnote to Fig. 5).[171]

† No experimental results are at present available which would allow us to assess whether the chemisorption of hydrocarbons involves rupture of a carbon–hydrogen bond or its deformation-polarisation.

allyl position, since the energy of bonding of an allylic hydrogen to carbon is smaller[256].

---o0o---

The information covered in this Review indicates that the dehydrocyclisation of aliphatic hydrocarbons is quite complicated and consists of a series of successive stages. Since this reaction is accompanied by several side reactions, elucidation of the fundamental laws of dehydrocyclisation presents great difficulties; as has been shown in the Review, certain aspects of the transformation of hydrocarbons on a catalyst and the mechanism of its action are still not known accurately or may not even have been revealed. However, since new methods of investigating complicated reactions have appeared during recent years, the dehydrocyclisation of aliphatic hydrocarbons may be expected to become a favourable subject for further study, which will make an important contribution to the understanding of the fundamental principles of organic catalysis. On the other hand, the appearance of publications on industrial processes based on such reactions[43,70,180,257] provides the hope that the production of individual aromatic hydrocarbons (primarily benzene) from alkanes present in petroleum will meet with practical success.

Lamellar Compounds of Graphite with Alkali Metals

Yu.N.Novikov and M.E.Vol'pin

The preparation, structure, and thermodynamic, physical, and chemical properties of lamellar compounds of graphite with alkali metals are surveyed. These compounds are shown to be mostly similar in methods of preparation, structure, and properties to complexes of aromatic hydrocarbons with alkali metals. A list of 100 references is included.

I. INTRODUCTION

Graphite is an allotropic modification of carbon having a layered structure. The carbon atoms are arranged in parallel planes, in each of which they form a network of hexagons in which the distance between the carbon atoms is close to the length of the carbon–carbon bond in the benzene molecule (1.415 and 1.397 Å respectively). The distance between parallel planes in graphite is rather smaller than the van der Waals thickness of aromatic molecules (3.35 and 3.4–3.5 Å), The absence of chemical bonding between the parallel carbon layers in graphite makes possible the intercalation of monatomic or monomolecular layers of various substances with formation of the so called layer or lamellar compounds of graphite. Alkali metals, halogens, strong acids, and metal halides are able to form such compounds.

Lamellar compounds of graphite with alkali metals were first obtained in 1926. They have continued to attract the attention of research workers, since they have much in common both with "solid solutions" and with the complexes formed by alkali metals with aromatic hydrocarbons. The unusual structure of lamellar compounds of graphite with alkali metals confers on them several interesting properties. Thus those with potassium, rubidium, and caesium are superconductors, react with hydrogen and nitrogen, catalyse the *ortho–para* conversion of hydrogen, and catalyse the isomerisation and the polymerisation of alkenes. We have surveyed methods for the preparation of lamellar compounds of graphite with alkali metals, their structure, and their thermodynamic, physical, and chemical properties.

II. PREPARATION OF LAMELLAR COMPOUNDS OF GRAPHITE WITH ALKALI METALS

Until recently the only method for preparing lamellar compounds of graphite with alkali metals was to heat a mixture of graphite and the alkali metal in a sealed ampoule. In this way Fredenhagen and his coworkers [1] first obtained compounds of graphite with potassium, rubidium, and caesium, having the compositions C_8M and $C_{16}M$ at 300° and 360–400°C respectively. They also investigated [2] the ability of potassium to be incorporated into graphite as a function of the pressure of its vapour. With graphite at a constant temperature (400° or 450°C) they varied the temperature of the potassium melt from 200° to 400–440°C, and obtained the compounds C_9K and $C_{18}K$. Table 1 shows that the former compound can be obtained with the graphite both at 400° and at 450°C, but this rise in temperature must be accompanied by an increase in the vapour pressure of potassium (i.e. the temperature of the melt).

Table 1. Dependence of composition of lamellar compounds with potassium on reaction conditions.

Temp. of graphite, °C	Temp. of potassium, °C	V.p. of K, mmHg	Composition of cpd.	Refs.
400	320	0.51	C_9K	2
	293	0.20	$C_{18}K$	
450	340	0.91	C_9K	2
	324	0.51	C_8K	
250–310	250	0.06	C_8K	3, 4, 5
390–425	250	0.06	$C_{24}K$	3, 4, 5
490	250	0.06	$C_{40}K$	3, 4, 5

Hérold [3–5] unlike Fredenhagen, investigated the reaction between potassium and graphite with the former at a constant temperature (250°C) while the temperature of the graphite was varied from 250° to 600°C. The isobar for the graphite–potassium system (Fig. 1) contains three plateaux at atomic K/C ratios of 0.125, 0.042, and 0.025, corresponding to the three compounds C_8K, $C_{24}K$, and $C_{40}K$. Compounds containing lower proportions of potassium could not be obtained.

Rüdorff and Schulze [6] heated a mixture of the alkali metal with graphite in a vacuum in a sealed ampoule at 300–400°C, and obtained a large number of lamellar compounds of graphite with potassium and with rubidium— C_8K, $C_{17.7}K$, $C_{21.3}K$, $C_{26.2}K$, $C_{27.7}K$, $C_{28.4}K$, $C_{29.3}K$, $C_{30.4}K$, $C_{32.7}K$, $C_{35.9}K$, $C_{38.3}K$, $C_{40.2}K$, $C_{41.3}K$, $C_{43.9}K$, $C_{44.6}K$, $C_{45.6}K$, $C_{47.9}K$, $C_{52.5}K$, $C_{56.9}K$, C_8Rb, $C_{8.6}Rb$, $C_{16.0}Rb$, $C_{24.3}Rb$, $C_{25.0}Rb$, $C_{34.8}Rb$, $C_{37.4}Rb$, $C_{50.5}Rb$, $C_{16.2}Rb$.

Ottmers and Rose [7] modified this method by using a potassium–sodium alloy, which enabled the reaction temperature to be lowered and the compounds—C_8K, $C_{24}K$, $C_{36}K$, $C_{48}K$, and $C_{60}K$—to be obtained. Penetration of sodium into graphite was not observed.

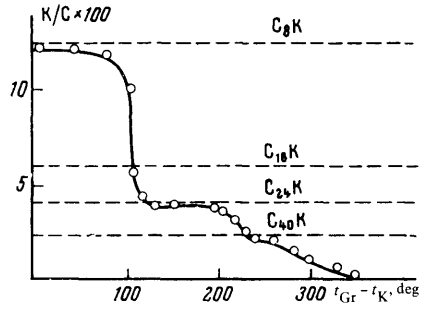

Figure 1. Dependence of composition of lamellar compounds on difference in temperature between graphite and potassium [3–5].

Salzano and Aronson [8,9] investigated the thermal decomposition of lamellar compounds of graphite with potassium, rubidium, and caesium having the composition C_8M, and discovered the existence of $C_{10}M$ between C_8M and $C_{24}M$. However, these compounds are stable only at high temperatures: $C_{10}K$ is stable at 315°C, $C_{10}Rb$ at 293°C, and $C_{10}Cs$ at 324°C.

For a long time it proved impossible [1,2,6] to obtain lamellar compounds by the direct reaction of graphite with lithium and sodium vapours. McDonnell et al. [10] and also Hennig [11] considered the formation of such compounds to be impossible, as the reduction potentials of these metals are lower than that of potassium. This view was regarded as supported by Hérold's observations [5] that a lamellar compound containing both sodium and caesium (ratio Na : Cs = 0.12) is formed by the action of an alloy on graphite, since the reduction potential of the alloy is higher than that of metallic sodium. An alloy of potassium and sodium does not produce the corresponding lamellar compound.

However, Asher and Wilson [12] showed that heating a mixture of graphite with molten sodium in an atmosphere of helium yields the same lamellar compound $C_{64-68}Na$, whose composition is independent of the temperature (120–500°C) or the duration of the reaction (from 15 min to 6 h).

Dzurus et al. [13] were unable to reproduce Asher and Wilson's results [12], and cast doubt on the existence of a lamellar sodium compound. However, Recht et al. [14] investigated the ability of graphite to absorb sodium vapour, confirmed the earlier results [12], and showed that $C_{64}Na$ is formed at 450°C after 7 days. Recht demonstrated also that the low degree of penetration of sodium is mainly kinetic in origin, since a fall in temperature leads to an increase in the equilibrium content of sodium in graphite, but considerably decreases the reaction velocity, so that below 400°C equilibrium is established with extreme difficulty.

A lamellar compound having the same composition ($C_{64}Na$) was obtained by Sleppy [15] by electrolysing molten sodium nitrate with a graphite cathode in an atmosphere of argon at 400°C. Like Hennig [13] this worker considers that the reaction is catalysed by oxygen chemisorbed on the graphite. In a study of the dependence of the diamagnetism of the compounds on the quantity of sodium incorporated Sleppy discovered a compound containing 1.95% of sodium, which corresponds to the formula $C_{96}Na$.

A small quantity of lithium was introduced into graphite [5] by electrolysing an equimolecular melt of potassium and lithium chlorides with a graphite cathode at 400°C. However, a greater amount was introduced [5] by heating lithium with graphite in a high vacuum at 500°C. Thus heating for several hours yielded a product of which the formula C_4Li was assigned. It was contaminated with lithium carbide, and increasing the duration of the reaction to 5 days resulted in complete conversion of the lithium into the carbide.

In 1965 Juza and Wehle [16] investigated the reaction between graphite and lithium vapour, and established that, depending on the conditions, lamellar compounds—C_6Li, $C_{12}Li$, and $C_{18}Li$—were formed, contaminated with lithium carbide and other lamellar graphite–lithium compounds. Bagouin et al. [17] have repeated these results, and also obtained two new compounds—$C_{36}Li$ and $C_{72}Li$.

Thus lamellar compounds of graphite with all the alkali metals can be obtained by direct reaction between the components. With potassium, rubidium, and caesium a whole set of compounds from C_8M to $C_{60}M$ have been prepared. With lithium the series begins at C_4Li and ends at $C_{72}Li$. The sodium series begins at $C_{64}Na$, probably because the conditions have not been found for preparing lamellar compounds with a high sodium content.

Table 2. Redox potentials of various aromatic hydrocarbons relative to biphenyl.

Hydrocarbon	E, V	Hydrocarbon	E, V
Biphenyl	0	Dibenz[*a*,*h*]anthracene	0.69
Naphthalene	0.09	Coronene	0.70
Phenanthrene	0.17	Perylene	1.12
Chrysene	0.38	Tetracene	1.28
Pyrene	0.60		

However, a fundamentally different method is possible for obtaining lamellar compounds of graphite with alkali metals, which utilises the aromatic character of the carbon layers in graphite. It is well known that aromatic hydrocarbons (naphthalene, anthracene, coronene, etc.) react with alkali metals in strongly ionising solvents—ammonia, amines, dimethoxyethane, hexamethylphosphoramide, etc.—to form aromatic radical-anions [18,19]. The position of equilibrium and the rate of reaction are substantially dependent on the redox potentials of the aromatic hydrocarbons under otherwise similar conditions. Paul et al. [20] and also Haijitink et al. [21] determined the redox potentials of aromatic hydrocarbons, and arranged the latter according to their electron affinity. Table 2 gives the latter workers' results [21], E being the reduction potential corresponding to formation of a monoanion.

Table 2 shows that the electron affinity increases with the number of fused aromatic rings in the hydrocarbon molecule. Therefore graphite—a compound with an infinite number of aromatic rings in a plane—should have

the highest reduction potential of all fused aromatic hydrocarbons. In such case two new methods become available for preparing lamellar compounds of graphite with alkali metals—by the reaction of graphite with solutions of (1) alkali metals and (2) aromatic radical-anions (of biphenyl, naphthalene, benzophenone, etc.).

Rüdoff et al.[22-24] showed that lamellar compounds could be prepared by the action of solutions of alkali metals on graphite. They examined the reaction of graphite with solutions of lithium, sodium, potassium, rubidium, and caesium in ammonia, methylamine, and pyridine, and found that ~2 moles of solvent per 1 g-atom of alkali metal were both incorporated into the graphite between −100° and −50°C. By using various quantities of alkali metals these workers obtained the following large number of lamellar compounds

$C_{10.6}Li(NH_3)_{1.5}$	$C_{12.5}K(NH_3)_{2.1}$	$C_{13.4}Na(NH_3)_{2.0}$
$C_{13.6}Li(NH_3)_{2.2}$	$C_{12.3}K(NH_3)_{2.3}$	$C_{16.5}Na(NH_3)_{2.2}$
$C_{15.6}Li(NH_3)_{2.0}$	$C_{23.4}K(NH_3)_{2.3}$	$C_{20.5}Na(NH_3)_{2.2}$
$C_{28.8}Li(NH_3)_{1.7}$	$C_{11.4}K(CH_3H_2)_{1.0}$	$C_{26.9}Na(NH_3)_{2.3}$
$C_{12.1}Li(CH_3NH_2)_{1.9}$	$C_{12.2}K(Py)_{1.0}$	$C_{11.9}Rb(NH_3)_{2.0}$
$C_{28}Li(H_2NCH_2CH_2NH_2)_{1.0}$	$C_{20.9}K(Py)_{0.84}$	$C_{13.8}Rb(NH_3)_{2.1}$
		$C_{12.8}Cs(NH_3)_{2.2}$

Rüdoff also found[24] that treating the potassium, rubidium, and caesium lamellar compounds with liquid ammonia resulted in the formation of ternary graphite–alkali-metal–ammonia lamellar compounds. It is interesting that part of the potassium in the compound C_8K passes into solution, and a lamellar compound $C_{12.5}K(NH_3)_2$ is formed. When, however, the compound $C_{24}K$ is treated with liquid ammonia, hardly any potassium is removed from the graphite, and the C : K ratio remains at ~28: i.e. the product has the formula $C_{28}K(NH_3)_{2.8}$. The quantity of a solvent S which is incorporated depends on its molecular size. Thus in the potassium lamellar compounds with ammonia the ratio K : S = 1 : 2; but with methylamine and with pyridine the corresponding ratio is 1 : 1.

Ginderow and Setton[25] used solutions of lithium and sodium in hexamethylphosphoramide to obtain lamellar compounds. The blue solutions of these metals react with graphite within a few seconds to form $C_{32}Li(S)$ and $C_{27}Na(S)$. Attempts to obtain lamellar compounds of potassium, calcium, magnesium, and ytterbium by this method were unsuccessful[25]. Only potassium among these four metals is slightly soluble in hexamethylphosphoramide, but the solution is unstable, and the results are difficult to reproduce. Stabilising the solution by the addition of benzene[26] results in the formation of an intense red solution, from which metal is not absorbed by graphite.

On the basis of the above principles Stein et al.[27-31] showed experimentally that lamellar alkali-metal compounds could be prepared by exchange between graphite and aromatic radical-anions. They found[31] that treating graphite with a 0.114–1.0 *N* solution of the alkali-metal–naphthalene compound in oxolan yields lamellar compounds whose composition, determined by decomposing them with acid, depends on the specimen of graphite used (Table 3).

Later investigations[27-29] indicated the following relations.

1. The equilibrium quantity of alkali metal incorporated into graphite is independent of the nature of the radical-anion (naphthalene, biphenyl, phenanthrene). However, the rate of establishment of equilibrium is sensitive to the radical-anion employed. For example, the equilibrium $ArH^{\cdot-}Li^{+}$ + graphite ⇌ ArH + graphite-Li^{+} is established more rapidly when ArH represents biphenyl than with naphthalene[28]. These results were regarded as consistent with the effect of the electrochemical potential, since the reduction potential of naphthalene relative to biphenyl is +0.9 V.

Table 3. Composition of intrusion products of alkali metals in different varieties of graphite resulting from the action of a solution of naphthalene and the alkali metal in oxolan.

Madagascar (flaky)	Ceylonese (finely ground)
$C_{41.5\pm1.5}Li$	$C_{17.5\pm1.5}Li$
$C_{120\pm4}Na$	$C_{30.5\pm1.5}Na$
$C_{81\pm2}K$	$C_{24.5\pm1}K$

2. The rate of penetration of metal into graphite varies with time during the reaction. Thus 80% of the maximum possible quantity of potassium penetrates into graphite during the first 5 h of the reaction of a potassium–naphthalene solution; the remaining 20% required 35–45 h.

3. The quantity of metal incorporated depends on the sample of graphite, far more penetrating powdered Ceylon graphite than the flaky Madagascar variety.

Table 4. Comparison of methods of analysis of products of the intrusion of an alkali metal into graphite (composition of lamellar compound from analytical data).

Metal	Ceylon graphite—analysis of		Madagascar graphite—analysis of	
	solution	compound	solution	compound
Li	$LiC_{17.6\pm1.0}$	$LiC_{17.5\pm1.5}$	$LiC_{18.8\pm1.0}$	$LiC_{43\pm3}$
Na	$NaC_{30.5\pm0.5}$	$NaC_{30.5\pm0.5}$	$NaC_{50.5\pm1.5}$	$NaC_{121\pm5}$
K		$KC_{24.5\pm1.0}$	$KC_{25.2\pm1.0}$	$KC_{32\pm2}$

4. Neither oxolan nor naphthalene is introduced with the alkali metal into the graphite. This was established by chromatography of the products of extraction at room temperature.

However, other workers have since shown conclusions 3 and 4 above to be incorrect. Thus Nominé and Bonnetain[32] have demonstrated that the different contents of alkali metal in Ceylon and Madagascar graphites are due not to differences in the structure of these specimens but to an incorrect choice of method for analysing the lamellar compounds. Since the particle size of Madagascar graphite considerably exceeds that of Ceylon graphite, the alkali metal separates completely from the latter on hydrolysis, but only partly from the Madagascar specimen. Hence the composition determined was that of the remaining solution of radical-anion, not the lamellar compound formed. Comparative data are given in Table 4.

Nominé and Bonnetain[33] also showed that the thermal decomposition products of the lamellar compounds are not binary (graphite and alkali metal) but contain also the quantities of oxolan indicated in Table 5. They found that the lamellar compound of graphite with lithium contains three phases—φ_1(Li), φ_2(Li), and φ_3(Li)—differing in the degree of solvation of lithium and in the structure of the solvate sheath of the Li^+ ion. Two phases—φ_1(Na) and φ_2(Na)—were found with sodium. It is interesting that at ~100°C the phases φ_2(Li), φ_3(Li), and φ_2(Na) pass into φ_1(Li) and φ_1(Na) with separation of part of the oxolan.

Table 5. Ratios of carbon to metal and of oxolan to metal in graphite–alkali-metal–oxolan lamellar compounds.

Metal	C/M	Ox/M
K	24±0.5	1.3±0.2
Na	32±1.5	3.5±0.3
Li	20±2.0	2.2±0.2

The graphite–potassium compound exists as a single phase. After standing at room temperature for a long time, this compound loses its oxolan completely, and passes into the binary compound $C_{24}K$. Rose et al.[34] confirmed the presence of oxolan in the compound. They also showed that lamellar compounds of graphite with alkali metals contain also small quantities of naphthalene, 1,2-dihydronaphthalene, and tetrahydronaphthalene.

Table 6. Content of oxolan (molar ratio Ox/M) in compounds formed by different varieties of graphite with alkali metals.

M	Ceylor	Madagascar
Li	0.115	0.122
Na	0.133	0.04
K	0.09	0.5

Thermogravimetric examination[34] of the specimens in a vacuum showed that only part of the oxolan is lost at 20°C and 0.001 mmHg (Table 6). With gradual rise in temperature two inflections appear on the thermogravimetric curve, which supports Bonnetain's suggestion[33] that several phases, differing in degree of solvation, exist in a single compound.

Ketyls, as well as aromatic radical-anions, are able to function as carriers of the alkali metal to the graphite. Genderow and Setton[35] established that sodium and potassium benzophenone ketyls react with graphite (particle size < 50 μm) in oxolan (Ox) solution to form the ternary lamellar compounds $C_{64}Na.Ox$ and $C_{72}K.Ox$ respectively.

Thus the reactions of graphite with solutions of alkali metals and with radical-anions show an analogy between the properties of graphite and those of aromatic hydrocarbons: (1) like aromatic hydrocarbons[36] graphite forms complexes with alkali metals (mainly with potassium) in the absence of a solvent; (2) in the presence of solvents graphite, like aromatic hydrocarbons[37], forms complexes with lithium and sodium; and (3) since the redox potential of graphite would be higher than those of aromatic hydrocarbons, graphite undergoes exchange reactions with the latter

$$ArH\div M^+ + Ar'H \rightleftarrows ArH + Ar'H\div M^+$$

to form lamellar compounds.

III. THERMODYNAMIC PROPERTIES OF LAMELLAR COMPOUNDS OF GRAPHITE WITH ALKALI METALS

Many studies have been made of the thermodynamic properties of the alkali-metal compounds of graphite[2,5,8–10,38–52].

Table 7 gives the calorimetrically determined heats of formation of lamellar compounds C_8M with potassium, rubidium, and caesium and of $C_{24}K$ from graphite and the molten metal. The stability of the C_8M compounds is seen to increase from potassium to rubidium. The heat of reaction is substantially dependent on the type of graphite, the value for the artificial material exceeding by 10 kcal g^{-1} that for natural graphite in the reaction with potassium.

Table 7. Heats of reaction of graphite with alkali metals in the range 66–95°C.

Reaction (solid)	(liq.)	(solid)	kcal g-atom^{-1} M	Ref.
8C	+K	$\rightarrow C_8K$	7.8	38
			8.35	39
			8.35	48
			6.60	52
8C	+Rb	$\rightarrow C_8Rb$	11.1	39
			11.1	48
8C	+Cs	$\rightarrow C_8Cs$	15.3	39
			15.3	48
24C	+K	$\rightarrow C_{24}K$	11.9	52

From the vapour pressure of the metal over the potassium, rubidium, and caesium lamellar compounds Hérold[5] determined the heats of formation of C_8M from $C_{24}M$ [$C_{24}K + 2K(liq.) \rightarrow 3_8K + 2Q$] in the temperature range 417–669°C as respectively 3.4, 5.85, and 10.1 kcal g-atom^{-1} M, where M = K, Rb, Cs. Later, however, Salzano and Aronson[9,40–42] cast doubt on the reliability of these values, since Hérold had been unaware of the existence of the compound $C_{10}M$ between C_8M and $C_{24}M$. Setton[45,50] calculated the work required to separate the carbon networks of graphite and the energy of bonding of 1 g-atom of potassium with carbon as respectively H_C = 2.25 kcal g-atom^{-1} C and H_K = −10.4 kcal g-atom^{-1} K at 420°K; the corresponding values calculated for 620°K were 1.73 and −6.85. The work necessary to separate the carbon networks to infinity has also been determined by several authors, and lies in the range 0.9–1.5 kcal g-atom^{-1} C.[42,53–56] From these data Setton calculated

the heats of formation of C_8K and $C_{24}K$ as respectively 6.87 and 13.3 kcal g-atom^{-1} K, which agreed with the results in Ref. 52 (see Table 7).

The thermodynamic properties of graphite–alkali-metal systems have been investigated in greatest detail by Salzano and Aronson[9,40-44]. They examined the variation in the rate of decomposition of the lamellar compounds C_8M (M = K, Rb, Cs) over the range 400–750°C, and showed that the curve contains a series of breaks corresponding to formation of the compounds $C_{10}M$, $C_{24}M$, $C_{36}M$, $C_{48}M$, and $C_{60}M$. The portions between the breaks were linear, and corresponded to the two-phase regions

(solid) (gas) (solid)

$$4\,C_{10}M + M \rightleftarrows 5\,C_8M$$
$$^5/_7\,C_{24}M + M \rightleftarrows {}^{12}/_7\,C_{10}M$$
$$2\,C_{36}M + M \rightleftarrows 3\,C_{24}M$$
$$3\,C_{48}M + M \rightleftarrows 4\,C_{36}M$$
$$4\,C_{60}M + M \rightleftarrows 5\,C_{48}M$$
$$5\,C_{72}M + M \rightleftarrows 6\,C_{60}M$$

Table 8. Thermodynamic properties of potassium, rubidium, and caesium compounds of graphite ($-\Delta H^\circ$ in kcal g-atom^{-1} M; $-\Delta S^\circ$ in cal deg^{-1} g-atom^{-1} M).

Stage	Equilibrium reaction (solid) (gas) (solid)	Graphite-K		Graphite-Rb		Graphite-Cs	
		$-\Delta H^\circ$	$-\Delta S^\circ$	$-\Delta H^\circ$	$-\Delta S^\circ$	$-\Delta H^\circ$	$-\Delta S^\circ$
Ia	$C_{24}M + M \rightleftarrows C_8M$	27.4	25.7	—	—	—	—
Ib	$4C_{10}M + M \rightleftarrows 5C_8M$	38.0	44	33.9	42.2	43.8	43.4
II	$5/7C_{24}M + M \rightleftarrows 12/7C_{10}M$	24.0	24	25.3	19.2	29.6	19.6
III	$2C_{36}M + M \rightleftarrows 3C_{24}M$	27.7	20.6	27.2	17.0	32.7	18.7
IV	$3C_{48}M + M \rightleftarrows 4C_{36}M$	30.0	20.7	29.5	17.6	34.2	18.6
V	$4C_{60}M + M \rightleftarrows 5C_{48}M$	30.6	20.8	31.0	12.3	34.9	18.6
VI	$5C_{72}M + M \rightleftarrows 6C_{60}M$	—	—	31.8	18.1	35.8	18.8

Salzano and Aronson found that the decomposition curves for lamellar compounds of composition intermediate between C_8M and $C_{24}M$ or between $C_{24}M$ and $C_{36}M$ coincide with those for C_8M: i.e. breaks are observed on the curves at the same compositions, and the rates of decomposition of the intermediate compounds are equal to those of C_8M. This was regarded as indicating that the composition and the structure of any compound are independent of its method of preparation. Thus the decomposition of lamellar compounds with alkali metals is an equilibrium process, since the constancy of the rate of decomposition with time in each two-phase region can be explained by equilibrium between the phase undergoing decomposition and that which is formed. However, the form of the decomposition curve remained unchanged for lamellar compounds with alkali metals and in a vacuum (i.e. in the absence of the metal vapour). From this it was concluded that the rate of decomposition was determined by the rate of removal of metal adsorbed on the surface of the specimen:

$$\text{M (in sample)} \overset{\text{rapid}}{\rightleftharpoons} \text{M (on surface)} \overset{\text{slow}}{\rightleftharpoons} \text{M (in vapour)}$$

This enabled ΔH° and ΔS° to be calculated for the different stages of decomposition (Table 8). The heat and the entropy of formation of the alkali-metal compounds of graphite from the elements (ΔHform and ΔSform) are given in Table 9.

The heats of formation of C_8M (M = K, Rb, Cs) found by these workers agree with calorimetric values[9] when it is remembered that the heats of evaporation of these three alkali metals (in kcal g-atom^{-1} M) are respectively 20.2 (at 550°), 17.8 (800°), and 16.8 (800°C) (cf. Tables 7 and 9). Comparison of the enthalpy and the entropy of reaction between the gaseous metal and the alkali-metal–graphite compounds (Table 8) for potassium, rubidium, and caesium shows that compounds at the same stages are formed in all three systems.

Table 9. Entropy and heat of formation of alkali-metal compounds of graphite from the elements ($-\Delta H$form in kcal g-atom^{-1} M; $-\Delta S$form in cal deg^{-1} g-atom^{-1} M).

Reaction (solid) (gas) (solid)	Graphite-K		Graphite-Rb		Graphite-Cs	
	$-\Delta H_{form}$	$-\Delta S_{form}$	$-\Delta H_{form}$	$-\Delta S_{form}$	$-\Delta H_{form}$	$-\Delta S_{form}$
$8C + M \rightarrow C_8M$	28.5	24.0	28.8	23.3	34.2	24.0
$10\,C + M \rightarrow C_{10}M$	27.0	22.5	27.5	18.5	32.2	19.2
$24C + M \rightarrow C_{24}M$	30.4	20.7	30.6	17.6	34.8	18.7
$36C + M \rightarrow C_{36}M$	31.7	20.7	32.2	18.0	35.8	18.7
$48C + M \rightarrow C_{48}M$	32.3	20.7	33.1	18.1	36.4	12.8
$60C + M \rightarrow C_{60}M$	32.8	20.8	33.6	18.1	36.7	18.8

The heat of reaction is largest for stage (Ib), is least for stage (II), and increases slightly on passing from stage (III) to stage (VI). The entropy of reaction is approximately the same for the lower stages, and has the approximate values 20.7, 17.8, and 18.7 kcal deg^{-1} g-atom^{-1} M for the potassium, rubidium, and caesium lamellar compounds. Nevertheless, the entropy is very high (42–44 kcal deg^{-1} g-atom^{-1} M) for stage (Ib) (Table 8). The large entropy changes for this stage are regarded by the authors as attributable both to the increase in concentration of alkali-metal ions in a layer and to a strengthening of interaction between adjacent layers of alkali-metal atoms.

IV. STRUCTURE OF LAMELLAR COMPOUNDS OF GRAPHITE WITH ALKALI METALS

The X-ray method usually employed for studying lamellar compounds with alkali metals enables us to determine the stage reached in compound formation, i.e. to determine the number of carbon networks of graphite associated with one layer of the metal (Fig. 2), to calculate the identity period I_c along the c-axis, to determine the thickness I_c' of a filled layer, to determine the structure of a layer of alkali metal in the graphite, and also to ascertain whether the carbon layers undergo mutual displacement on the intrusion of alkali metal.

1. Structure of Binary Systems formed by Graphite with Potassium, Rubidium, and Caesium

Several investigations have been made on the structure of lamellar compounds of graphite[5-7,57-59]. Schleede and Wellmann[59] showed that the structure of the compounds C_8M (M = K, Rb, Cs) corresponds to stage (I): i.e. a

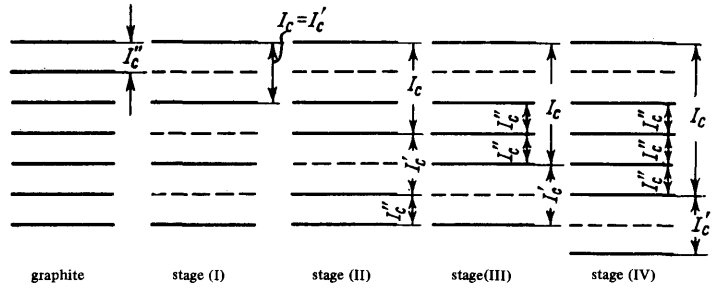

Figure 2. Arrangement of layers of graphite and of alkali metals in lamellar compounds: full line = carbon layer; broken line = intercalated metal layer; I_c'' = thickness of unfilled layer in lamellar compound; I_c = identity period in inclusion compounds; I_c' = thickness of filled layer in lamellar compound.

metal layer alternates with a graphite layer. The composition $C_{16}M$ represents the second stage of lamellar compounds. In both cases the metal atoms form a monatomic layer midway between adjacent carbon layers of the graphite. In an actual layer the metal atoms form a triangular network, the distance between them being 4.90 Å (Fig. 3). It was assumed that the carbon networks underwent no relative displacement on penetration of the alkali metal, and the identity period I_c for these compounds was determined from reflections of the type $00l$ (Table 10). If the thickness of a filled layer (Fig. 3) is assumed to be the same in compounds of both stages (I) and (II), the interplanar distance in an unfilled graphite layer is the same as in the original graphite (Table 10).

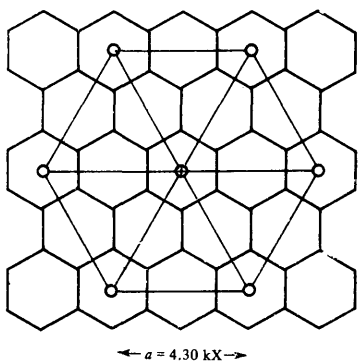

Figure 3. Triangular arrangement of potassium atoms relative to carbon network of graphite.

Subsequently Hérold [5] and especially Rüdorff and Schulze [6] made a more detailed investigation of the structure of the potassium and rubidium lamellar compounds, with the results indicated below.

1. The composition $C_{16}M$ represents a mixture of compounds of stages (I) and (II) (Table 11), the latter compound having the formula $C_{24}M$. Thus the lamellar compounds have the following compositions depending on the stages—C_8M (stage I), $C_{24}M$ (II), $C_{36}M$ (III), $C_{48}M$ (IV), and $C_{60}M$ (V).

Table 10. Identity period I_c, thickness of filled layers I_c', and thickness of unfilled layers I_c'' in lamellar compounds of graphite with potassium, rubidium, and caesium.

Metal	Colour	Stage	I_c, Å	I_c', Å	I_c'', Å
K	brown	I	5.33	5.33	3.41
	black	II	8.74	5.33	
Rb	brown	I	5.68	5.68	3.29
	black	II	8.97	5.68	
Cs	brown	I	5.94	5.94	3.31
	black	II	9.25	5.94	

Table 11. Composition and stages of compounds of graphite with potassium and rubidium.

Potassium compounds				Rubidium compounds	
composition	stage	composition	stage	composition	stage
C_8K	I	$C_{38,3}K$	III	$C_{8.2}$ Rb	I
$C_{17.7}K$	II+I	$C_{40,2}K$	III+IV	$C_{8,8}$ Rb	I
$C_{21.3}K$	II	$C_{41.3}K$	III+IV	$C_{16.0}Rb$	I+II
$C_{26.2}K$	II	$C_{43,9}K$	IV+III	$C_{24.3}Rb$	II
$C_{27.7}K$	II	$C_{44,6}K$	IV+III	$C_{26.6}Rb$	II
$C_{28.9}K$	II+III	$C_{45.6}K$	IV	$C_{34.8}Rb$	III

$C_{30.4}K$	II+III	$C_{52,5}K$	V+IV	$C_{50.5}Rb$	IV
$C_{32.7}K$	III+II	$C_{56.9}K$	V	$C_{61.2}Rb$	V
$C_{35.9}K$	III				

2. Determination of the identity periods for the lamellar compounds of stages (I)–(V) (Table 12) indicated that the thickness of a filled graphite layer is the same for all stages with a given metal, and depends only on the nature of the metal. These workers also confirmed that interplanar distances in an unfilled graphite layer were the same as in graphite itself (Table 12).

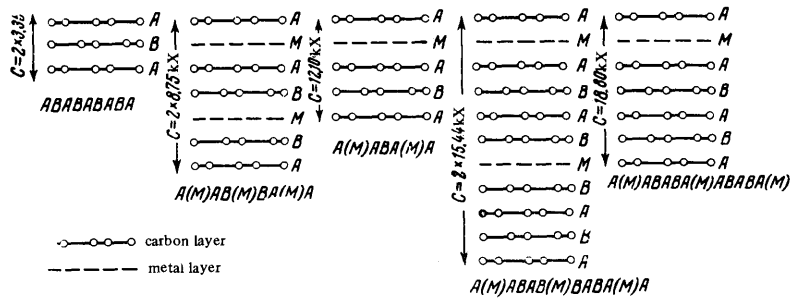

Figure 4. Relative positions of carbon networks and layers of alkali metal in lamellar compounds of graphite.

3. On passing from (I) to higher stages not only does the number of carbon networks per metal layer increase, but also the structure of the metal layer changes. Whereas the metal atoms in the compound C_8M are arranged in a triangular pattern (Fig. 3), on passing to stage (II) they are rearranged into a hexagonal network.

Table 12. Repeat periods of lamellar compounds of graphite with potassium found from 00*l* reflections.

Stage	Potassium cpd.	Rubidium cpd.
I	5.40=5.40	5.65=5.65
II	8.75=5.40+3.35	9.02=5.67+3.35
III	12.10=5.40+2·3.35	12.34=5.64+2·3.35
IV	15.46=5.41+3·3.35	15.75+5.70+3·3.35
V	18.80=5.40+4·3.35	19.08=5.68+4·3.35

This requires that the central atom (denoted by a "plus" in Fig. 3) should move out of the lattice. This could not be demonstrated by means of X-rays, since the lines *h*0*l* and *hkl* were absent from the Debye diagrams. Their absence was attributed to the great mobility of the metal atoms in the graphite planes.

4. On the formation of lamellar compounds with alkali metals the carbon networks adjacent to a metal layer shift and become superimposed (AA... BB). The remaining carbon networks are arranged as in graphite (ABAB...) (Fig. 4).

5. The identity period for the first stage should be quadrupled in comparison with that found from 00*l* reflections, since the 10*l* and 11*l* reflections have established that the alkali-metal layers are displaced relative to one another by $\frac{1}{2}0$, $\frac{1}{2}\frac{1}{2}$, and $0\frac{1}{2}$. For stages (II) and (IV) the identity period I_C calculated from 00*l* reflections should be doubled, as is indicated by the value of I_C calculated from 10*l* reflections. For stages (III) and (V) the same value of I_C is obtained by calculation from 00*l* and from 10*l* reflections.

6. Metal atoms are located below the centres of the carbon hexagons in the graphite network, and the distance between the metal atom and a carbon atom is 3.05 and 3.16 Å in the compounds C_8K and C_8Rb respectively.

More recent investigations by Nixon and Parry[57] have shown that the carbon networks adjacent to a potassium layer undergo a complete displacement: i.e. these carbon networks are equivalent. However, carbon networks remote from the potassium layer are only partly displaced. Thus some turbostrasis is observed in the arrangement of the carbon networks in lamellar compounds of graphite with potassium of stages (I)–(IV). These workers therefore suggest the arrangement

II stage — AB (K) BC (K) CA (K) A
III stage — ABA (K) ACA (K) A
IV stage — ABAB (K) BCBC (K) CACA (K) A

for the carbon networks in the potassium compounds of stages (II)–(IV).

The identity period I_C calculated by these workers for the potassium compound of stage (II) would cover three filled layers (each 5.4 Å) and three unfilled layers (each 3.3 Å), and should be 26.25 Å. In stage (III) it would contain two filled and four unfilled layers and be 24.2 Å in stage (IV) three filled and nine unfilled layers would make the identity period 46.35 Å. Good agreement was found between experimental and calculated values of the identity period.

2. Structure of Binary Compounds of Graphite with Sodium

In studying the structure of the lamellar compounds with sodium Asher and Wilson[12,60] found that graphite lines of the type 00*l* had disappeared from the Debye powder diagrams, while the graphite lines 10*l*, 112, 202, and 123 remained; i.e. the lattice parameter varied along the *c*-axis, but the structure of the carbon network of graphite remained unchanged. Indexing the X-ray diagram showed that a compound of stage (VIII) had been formed with an identity period I_C = 28 Å. On the assumption that the interplanar spacing in the unfilled graphite layer was the same (3.35 Å) as in graphite itself, the thickness of an unfilled layer was found to be I'_C = 4.5 Å (28 − 7 × 3.35). Carbon networks adjacent to sodium layers are arranged similarly (AA, BB), but the others alternate as in graphite (ABAB...). The sodium atoms in a layer are arranged in a triangular pattern, like the potassium atoms in C_8K.[6] It is not clear why the sodium atoms are most densely packed (C_8Na) in the stage (VIII) compound, whereas the packing is less compact ($C_{12}M$) in the graphite compounds of potassium, rubidium, and caesium beginning with stage (II); and in the lithium compound, beginning from stage (IV), one metal atom in a layer is associated with twelve carbon atoms from each graphite network adjacent to the lithium layer, although the atomic radius of lithium is smaller than that of sodium.

3. Structure of Binary Compounds of Graphite with Lithium

Juza and Wehle [16] found that the compounds C_6Li, $C_{12}Li$, and C_8Li all have a hexagonal crystal lattice. Table 13 gives the parameters along the a- and c-axes (I_a and I_c) together with the thickness of a filled layer (I'_c). These workers found [16] that the carbon layers are arranged in the same sequence (ABAB...) as in graphite. The carbon–carbon distance in a layer is somewhat greater than in graphite.

Table 13. Structure of lamellar compounds of graphite with lithium.

Compound	I_a, Å	I_c, Å	Stage	I'_c, Å
C_6Li	4.29_0	3.73_7	I	3.73_7
$C_{12}Li$	4.29_0	7.02_9	II	3.67_9
$C_{18}Li$	4.2_8	10.4_4	III	3.7_4

Bagouin et al. [17] have since established that the compounds— C_6Li, $C_{18}Li$, $C_{36}Li$, and $C_{72}Li$—also have a hexagonal lattice. Table 14 gives the parameters I_a and I_c together with I'_c. These authors attribute the composition $C_{18}Li$ to a compound of stage (II), and consider that the transition from stage (I) to stage (II) is accompanied by an increase in the number of carbon layers per metal layer and a decrease in the lithium content of a layer, as in the potassium compound [6]. The carbon–carbon distance in a layer is the same as in graphite.

Table 14. Structure of lamellar compounds of graphite with lithium.

Compound	I_a, Å	I_c, Å	Stage	I'_c, Å
C_6Li	4.28	3.70	I	3.70
$C_{18}Li$	7.40	7.05	II	3.70
$C_{36}Li$	—	13.75	IV	3.70
$C_{72}Li$	—	27.05	VIII	3.65

4. Structure of Graphite–Metal–Solvent Ternary Compounds

The structure of lamellar compounds of graphite with alkali metals and ammonia or amines was investigated by Rüdorff et al. [22-24], who determined the identity periods (Table 15) and established the following generalisations.

1. Intrusion of a solution of a metal into the graphite lattice yields inclusion compounds analogous in structure to those formed in the absence of a solvent (stages I, II, etc.), with the ammonia or amine molecules situated in the same layer as the metal atoms.

2. The carbon networks adjacent to a metal layer are arranged similarly, but the other networks alternate, as in the original graphite. Hence the identity period must be doubled for even stages.

3. The thickness of a filled layer in a graphite–alkali-metal–ammonia compound is 6.6 Å, and is independent of the nature of the metal (lithium, sodium, potassium, or rubidium) or the stage of the compound (I or II). It is considerably larger than the thickness of a filled layer in an alkali-metal compound containing no solvent (cf. Tables 12–14): i.e. the size of the metal atom does not affect the interplanar spacing, which is determined by the size of the solvated ion. The increase in molecular size of the solvent on passing from ammonia to methylamine and to ethylenediamine leads to an increase in thickness of the filled layer to 6.9 and 8.5 Å respectively.

Table 15. Composition and identity period I_c of alkali-metal compounds of graphite containing ammonia and amines (py = pyridine; en = ethylenediamine).

Stage I		Stage (II)	
composition	I_c, Å	composition	I_c, Å
$C_{10.6}Li(NH_3)_{1.6}$	6.6_2	$C_{28.8}Li(NH_3)_{1.7}$	9.9_3
$C_{13.4}Na(NH_3)_{2.0}$	6.6_3	$C_{26.7}Na(NH_3)_{2.3}$	9.9_7
$C_{12.5}K(NH_3)_{2.1}$	6.5_6	$C_{28.7}K(NH_3)_{2.8}$	9.9_4
$C_{11.9}Rb(NH_3)_{2.0}$	6.5_8		
$C_{12.0}Cs(NH_3)_{2.2}$	6.5_8		
$C_{12.1}Li(CH_3NH_2)_{1.9}$	6.9		
$C_{11.4}K(CH_3NH_2)_{1.0}$	6.8		
		$C_{28}Li(en)_{1.0}$	11.85=8.5+3.35
$C_{12.2}K$ (py) $_{1.0}$		$C_{20.9}K(py)_{0.84}$	

4. In the ternary graphite compounds of stage (I) one alkali-metal atom is associated with twelve carbon atoms, as in the binary lamellar compounds of stages (II)–(V). This is due to the presence of solvent molecules between alkali-metal atoms in the layer.

5. The metal atoms in the lattice are solvated, the number of solvent molecules per alkali-metal atom decreasing with increase in size of the solvent molecule (Table 15).

These conclusions have been confirmed by Ginderow and Setton's investigation [25] of the structure of the lithium and sodium compounds containing hexamethylphosphoramide $C_{32}Li.HMP$ and $C_{27}Na.HMP$. These compounds were found to be of stage (I), with the parameters

$C_{32}Li \cdot HMP$: $I_a = 19.68$ Å; $I_c = 30.48$ Å
$C_{27}Na \cdot HMP$: $I_a = 12.73$ Å; $I_c = 15.24$ Å

The alternation of carbon networks in the compound is AAA..., not ABAB... as in graphite itself. One metal atom is solvated by one solvent molecule, with the P=O bond perpendicular to the carbon lamellae. As a consequence, the thickness of a filled layer is the same in the two compounds: $I'_c = 7.62$ Å, considerably greater than for the binary compounds (4.5 and 3.7 Å) and for compounds of graphite with the alkali metals and ammonia ($I_c = 6.6$ Å). The layers of solvated atoms are displaced relative to one another. Therefore the identity period for this compound must be quadrupled: $I_c = 4 \times 7.62 = 30.48$ Å.

5. Structure of Compounds of Graphite with Alkali Metals and Oxolan

The structure of interstitial products of graphite with a metal and oxolan was investigated by Stein et al. [27-29] (cf. also Ref. 38) by means of X-rays. However, they were

unable to index the powder diagrams obtained or to determine the identity periods. From the diagrams these workers established that the products were indeed lamellar compounds, since the most characteristic lines of graphite 002 and 004 were absent (indicating a change in the identity period along the c-axis, i.e. penetration of the alkali metal between the carbon networks), while the "graphite" lines 100, 110, and 112 were present (indicating the unchanged structure of the carbon networks).

Nominé and Bonnetain [33,61] discovered that three phases were present in the lithium compound, two phases with sodium, and one phase with potassium, distinguished by their degrees of solvation. Table 16 gives the identity periods for these phases. Independently of the phase, all are stage (I) compounds. Consequently the differences in identity periods are due to differences in structure between the solvate sheaths of the alkali-metal ions. On the assumption that the thickness of a filled layer is the sum of the thicknesses of a graphite layer (3.35 Å) and a layer of solvated ions e_I, these workers calculated values of $e_I = I_c - 3.35$ (Table 16).

Table 16. Structural parameters of various phases in graphite–alkali-metal–oxolan compounds.

Phase	I_c, Å	e_I
φ_1(Li)	7.24	3.89
φ_2(Li)	12.45	9.10
φ_3(Li)	17.2	13.85
φ_1(Na)	7.24	3.89
φ_2(Na)	11.12	7.77
φ_1(K)	7.18	3.88

The use of models to study the structure of the solvated ions showed that, in the phases φ_1(Li), φ_1(Na), and φ_1(K), the oxolan molecules are oriented parallel to the plane of the graphite. Each alkali-metal layer is surrounded by three oxolan molecules. In the phases φ_2(Li) and φ_2(Na) a metal ion is surrounded by four oxolan molecules located at the vertices of a tetrahedron. With lithium the tetrahedron is regular, but in the case of sodium it is somewhat flattened between two graphite layers. In the phase φ_3(Li) the lithium ion is surrounded by oxolan molecules at the corners of an octahedron, a diagonal of which, like the planes of the oxolan molecules, is perpendicular to the graphite layers.

V. PHYSICAL PROPERTIES AND NATURE OF BONDING

1. Electrical Conductivity of Compounds of Graphite with Alkali Metals

The electrical conductivity of alkali-metal lamellar compounds has been investigated only on binary systems [7,10,62–69,74]. Since detailed discussions of the results will be found in reviews [70–72], we shall consider here only the main conclusions.

1. Incorporation of an alkali metal into graphite leads to an increase in the conductance of the latter, by factors of 10 and 200 along the a- and c-axes respectively.

2. Alkali-metal complexes of graphite exhibit a considerable positive temperature coefficient of the resistance.

3. Increase in the potassium content is accompanied by a continuous fall in resistance along the c-axis, whereas the resistance reaches a limit along the a-axis at compositions far removed from saturation [62].

It is interesting that similar generalisations apply to the solid alkali-metal compounds of aromatic hydrocarbons [73,74]. Thus the solid complexes of anthracene with lithium, sodium, and potassium have a considerable positive temperature coefficient of resistance. The graphite compounds C_8M (where M = K, Rb, Cs) are superconductors [63,75], their superconductivity appearing at 0.55°, 0.151°, and 0.135°K respectively. The compound $C_{24}K$ is not a superconductor, which was explained on the assumption that only every other interlayer space was occupied by potassium. However, Salzano and Strongin have since shown [63] that this may be due to a decrease in the potassium content of a layer on passing from C_8K to $C_{24}K$.

Table 17. Magnetic susceptibilities of graphite, potassium, and their lamellar compounds (χ_m calculated as 10^{-6} c.g.s. g-atom^{-1} C).

Material	90° K		195° K		288° K		Bulk density, g cm^{-3}
	χ_s	χ_m	χ_s	χ_m	χ_s	χ_m	
K	+0.540	+21.1	+0 538	+21.0	+0.539	+21.1	0.849
Graphite	−7.909	−94.81	−6.757	−81.08	−6.04	−72.48	0 783
$KC_{8.47}$	+1.01	+16.78	+1.01	+16.78	+1.00	+16.61	0.730
$KC_{7.79}$	+0.953	+16.23	+0.951	+16.17	+0.953	+16.23	0.713

2. Magnetic Susceptibility of Lamellar Compounds of Graphite with Alkali Metals

Measurements of the magnetic susceptibility of lamellar compounds of graphite with potassium [10,76–78] showed that intercalation of the metal had replaced the abnormally high diamagnetism of graphite by weak paramagnetism, which remained unchanged when the compound was treated with liquid ammonia. McDonnel et al. [10] found that the paramagnetism of these lamellar compounds exceeded the additive value calculated from the contributions of potassium and of graphite. However, the paramagnetism is independent of temperature, like the susceptibility of potassium (Table 17), and cannot be explained by the presence of isolated potassium atoms, whose susceptibility would be inversely proportional to the temperature. Rüdorff et al. [6,23,24] found that the susceptibility of lamellar compounds of graphite with potassium and with rubidium of stages (I)–(V) was strongly dependent on the field strength. Comparable values (Table 18) were obtained by extrapolating the results to H_∞. In contrast to previous papers, these workers showed that the paramagnetism of the compounds diminished with fall in temperature. No explanation was given for this fact. Measurement of the magnetic susceptibility of the sodium compound has shown [15] that the diamagnetism of graphite decreases with increase in the sodium content (Fig. 5), and completely disappears when 1.95% of sodium, corresponding to the composition $C_{96}Na$, has been incorporated.

The electron spin resonance spectra of compounds of graphite with lithium, sodium, and potassium [76] prepared from solutions of the metals in liquid ammonia showed

that the line width was unaffected by the presence of ammonia. Furthermore, the relaxation time was found to be of the same order as predicted by theory for metallic conductors. The metallic character of the bond in the compounds was confirmed also by the temperature dependence of the line width (Table 19).

Table 18. Magnetic susceptibility of lamellar potassium and rubidium compounds at 295°K.

Stage	Potassium compounds		Rubidium compounds	
	composition	$10^6\chi_{mol}$	composition	$10^6\chi_{mol}$
Graphite		−110		−110
I	$CK_{0.120}$	+10.0	$CRb_{0.119}$	+5.0
II	$CK_{0.037}$	+8.7	$CRb_{0.040}$	+5.1
III	$CK_{0.027}$	+8.5	$CRb_{0.028}$	+5.6
IV	$CK_{0.021}$	+5.7	$CRb_{0.019}$	+6.2
V	$CK_{0.015}$	+4.0	$CRb_{0.014}$	+3.7

Ginderow and Setton [25] examined the e.s.r. spectra of the lithium and sodium compounds with hexamethylphosphoramide (HMP), and detected a signal. With H = 280 Mc/s the g-factor and the line width were found to be

$C_{32}Li \cdot HMP$ $g = 2.0023$ $\Delta H = 0.470$ G
$C_{27}Na \cdot HMP$ $g = 2.0023$ $\Delta H = 0.436$ G

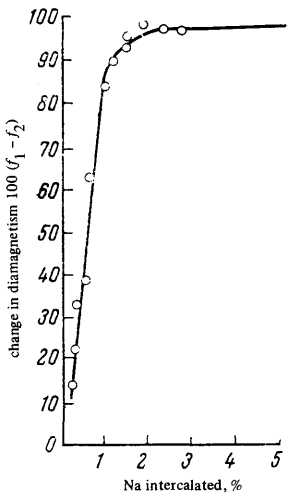

Figure 5. Dependence of diamagnetism of graphite on quantity of intercalated sodium.

The calculated spin densities of the lithium and sodium compounds were respectively 2.1×10^{22} and 7.0×10^{22} spins mole^{-1}. On the assumption that the spin density was due solely to unionised atoms, these workers calculated the percentage of unionised metal as respectively 4% and 15% for lithium and for sodium. They investigated also [35] the e.s.r. spectra of the inclusion products obtained by the action of a solution of sodium or potassium benzophenone ketyl on graphite (Table 20), and obtained rather different contents of unionised metal (9% with sodium, and 6% with potassium).

Table 19. Line widths in e.s.r. spectra of alkali-metal lamellar compounds.

Metal	ΔH_1 (300°K), mG	ΔH_2 (77°K), mG
Li (conc.)	100	70
Li (dil.)	86	60
Na	115	77
K[a]	350[b]	—
K	275	275

[a] Compound obtained in a vacuum; it contains no ammonia.
[b] Measured at 425 Mc/s.

However, Rose et al. [79] suggested that the signals in the e.s.r. spectra were due, not to compounds of graphite with alkali metals, but to complexes of the latter with aromatic hydrocarbons which had penetrated the graphite. They examined [79] the e.s.r. spectra of inclusion products obtained by the action of oxolan solutions of the lithium, sodium, and potassium derivatives of naphthalene, and found that the paramagnetism of all the compounds disappeared irreversibly when they were heated in a vacuum to 180–300°C. This was accompanied by separation of all the oxolan and a small quantity of naphthalene from the compound (Fig. 6). Values of the g-factor close to 2 were obtained for the different graphite compounds—2.0023, 2.0028, and 2.0023 for lithium, sodium, and potassium respectively—which are characteristic of the free radical-anion of naphthalene (g = 2.0026) (Table 21).

Table 20. Data on e.s.r. spectra of alkali-metal lamellar compounds obtained from benzophenone ketyls and graphite.

Property	Compound	
	$NaOxC_{64}$	$KOxC_{12}$
ΔH, G	~1.3	~2.5
g-factor	1.999	1.997
Spins g^{-1}	$6.21 \cdot 10^{19}$	$3.44 \cdot 10^{19}$
Spins mole^{-1}	$5.34 \cdot 10^{22}$	$3.41 \cdot 10^{22}$
Unionised metal, %	8.9	5.7

The graphite complexes are relatively insensitive to traces of water vapour. This is regarded [79] as indicating that the complex of naphthalene with the alkali metal is not simply adsorbed on the graphite but enclosed between its planes. The absence of hyperfine splitting in the spectra of these compounds is explained by the absence of free movement of the naphthalene molecules enclosed between the graphite planes.

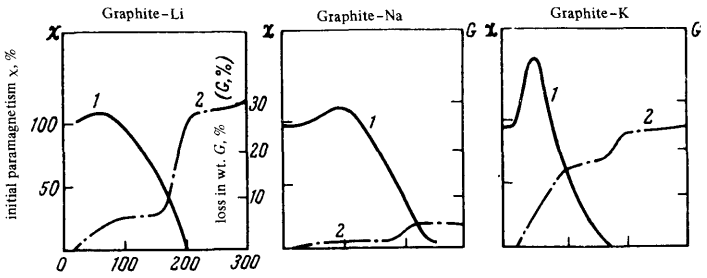

Figure 6. Dependence of paramagnetism of alkali-metal lamellar compounds on temperature of specimen: 1) paramagnetism; 2) loss in weight (oxolan, naphthalene).

3. Nature of Bond in Lamellar Compounds of Graphite with Alkali Metals

Salzano and Aronson have proposed a model [9,41-44], representing the type of bonding in lamellar compounds of graphite with potassium, rubidium, and caesium, in which the compounds comprise "metallic" carbon networks and layers of metal ions M^+. They suggest that a positive ion is formed by transfer of an electron from a metal atom to the conduction band of an adjacent graphite layer. Thus the metal atoms in the lamellar compounds are completely ionised, and the bond between the alkali metal and the carbon network is formed by electrostatic interaction of positive metal ions with free electrons in the conduction band of adjacent graphite layers, as in the bond between metal ions and aromatic radical-anions and dianions. This model is supported by the facts indicated below.

Table 21. Data on e.s.r. spectra of alkali-metal lamellar compounds prepared from radical-anions of naphthalene and graphite.

Parameter	Proportion of spins of various compounds		
	$C_{18}LiOx_{1.4}\cdot Naph_{0.020\pm0.010}$	$C_{50}NaOx_{0.6}\cdot Naph_{0.10\pm0.005}$	$C_{24}KOx_{1.6}\cdot Naph_{0.003}$
10^{-19} spins g^{-1}	2.1 2.5 2.5 —	— 0.9 0.4 —	0.2 0.4 0.6 1.6
10^{-19} spins g^{-1} based on naphthalene	3.7 ± 1.8	0.9 ± 0.4	0.4 ± 0.25
g-factor	2.0029 2.0028	2.0027 2.0029	2.0021 2.0025

1. The lamellar compounds of graphite with alkali metals are more highly conducting than graphite itself [7,10], and those of composition C_8M are even superconducting [75].

2. The resistance of the compounds has a positive temperature coefficient [69-71]. A similar relation is observed with the solid alkali-metal compounds of aromatic hydrocarbons [72,73].

3. Investigation of the optical properties of the compounds has revealed [80] that electrons are transferred from the alkali metal to the carbon networks.

4. The Mössbauer spectra of the caesium compounds indicate [81] that the metal in them is completely ionised.

5. Calculations by Setton show [82] that the interplanar spacing in a filled layer is the sum of the radii of the metal ions M^+ and the van der Waals thickness of a carbon layer.

6. The thickness of a filled layer is the same for compounds of different stages.

This model enabled Salzano and Aronson [43,44] to explain the variation in the heat and entropy of decomposition of the lamellar compounds with potassium, rubidium, and caesium. According to Table 8 the formation of C_8M from $C_{10}M$ is accompanied by the largest heat effect, since work must be done, in all stages other than (Ib), to increase the separation between the carbon networks from 3.35 Å (in the original graphite) to 5.4–6.0 Å (in the alkali-metal compounds) so that metal is able to penetrate into the space between the planes. The formation of C_8M from $C_{10}M$ does not require the separation of graphite planes, since in $C_{10}M$ all the planes are already separated. The compound C_8M is formed by the incorporation of additional M atoms into each layer. Therefore the heat evolved in the formation of C_8M from $C_{10}M$ exceeds the heat of formation of other phases by the work required to move the carbon layers apart from 3.35 to 5.4–6.0 Å. The increased heats of formation of compounds from $C_{10}M$ to $C_{60}M$ was explained by these workers by a diminution in the repulsion between adjacent layers of metal ions, since they are separated by increasing numbers of carbon layers. On the basis of this model they used a Born–Haber cycle to calculate the energy of bonding of caesium with graphite in the lamellar compounds [42] as between −67 and −55 kcal g-atom^{-1} Cs, in agreement with the value found from thermodynamic data (55 kcal mole g-atom^{-1} Cs).

Calculation of the thermodynamic stability of the caesium compounds of various stages has shown [40] that the phases—$C_{24}M$ (stage II), $C_{36}M$ (III), $C_{48}M$ (IV), and $C_{60}M$ (V)—should be the most stable. For stage (I), however, the model predicts that the phases $C_{12}M$, $C_{16}M$, and $C_{20}M$ should be more stable by an order of magnitude than C_8M and $C_{10}M$. Thus the proposed model represents correctly the composition, the structure, and the nature of the bond in compounds from $C_{24}M$ to $C_{60}M$. Yet it is of little use for compounds C_8M and $C_{10}M$ (*a*) repulsion between adjacent layers of metal ions should be strongest for these compounds, since they are separated by only one carbon network, so that C_8M should have the smallest heat of formation, which is contrary to the experimental result; (*b*) this model does not predict the stability of these compounds C_8M and $C_{10}M$, although it has been shown experimentally that C_8M—not $C_{12}M$ or $C_{16}M$—is formed; and (*c*) heats of formation of C_8M and $C_{10}M$ from the elements, calculated on the basis of models, differ substantially from the experimental values [40].

Nevertheless, the suggested model provides a qualitative explanation of the fact that lamellar compounds are formed either with difficulty or not at all by the direct reaction of lithium and sodium vapours with graphite. According to the views of McDonnel et al.[10] the incorporation of an alkali metal into graphite can be represented by the scheme

$$K_{gas} \rightarrow K^+_{gas} + [\bar{e}];\ \Delta H_1 = +101{,}1$$
$$[\bar{e}] + [C]_{lamell} \rightarrow [C]^-_{lamell}$$
$$K^+_{gas} + [C]_{lamell} \rightarrow C_8K + \Delta H_2$$
$$K_{gas} + [C]_{lamell} \rightarrow C_8K + \Delta H;\quad \Delta H = \Delta H_2 + 101{,}1$$

The calculated value of ΔH_2 is -126 kcal g-atom^{-1} K. These authors assume that the energy evolved (ΔH_2) is necessary to balance the ionisation energy of potassium. In view of the ionisation potentials of the alkali metals, they consider that the energy evolved in the third stage is sufficient for the formation of compounds of graphite with potassium, rubidium, and caesium, and insufficient to form the compounds C_8Li and C_8Na. Since Salzano and Aronson's model is similar to that of the alkali-metal compounds of aromatic hydrocarbons, solvation may be supposed to be the additional energetic factor favouring the formation of lamellar compounds with lithium and sodium. Indeed, results obtained by Rüdorff[22-24] and also by Ginderow and Setton[25] show that lithium and sodium atoms, solvated by ammonia, amines, or hexamethylphosphoramide, penetrate graphite at $-50°$ and 20°C respectively, to form stage (I) compounds.

VI. CHEMICAL PROPERTIES

Little information has been published on the chemical properties of the alkali-metal lamellar compounds. Rüdorff[6] reported that hydrogen was evolved by the action of water on the potassium, rubidium, and caesium compounds. Hydrogen is evolved also by the action of water on the compounds of graphite with lithium[16,17], on the ternary compounds with an alkali metal and oxolan[27,31], and on the ternary compounds containing lithium, potassium, or sodium and ammonia[24]. It is interesting that hydrogen is evolved also when these graphite complexes are heated, amides of the alkali metals being formed[24]. In none of these cases was the quantity of hydrogen determined, although it may be expected (from the similarity between the alkali-metal lamellar compounds and aromatic radical-anions) that the graphite will be hydrogenated by the action of water.

Saehr and Hérold[83-85] have shown that the compound C_8K absorbs hydrogen slowly even at room temperature, the reaction being accelerated by heating. Products C_8KH_x are formed in which x varies with temperature to a limiting value of 0.67. The compounds of C_8Rb and C_8Cs are less active than C_8K: the maximum value of x in C_8RbH_x is 0.05, reached at 60°C; C_8Cs does not react with hydrogen between $-78°$ and +150°C. The compound $C_{24}K$ absorbs hydrogen to form $C_{24}KH_{0.25}$. Investigation of the structure of $C_8KH_{0.67}$ by the Debye–Scherrer method showed that the lines corresponding to C_8K had disappeared, while potassium hydride and graphite phases were not formed. The powder photographs contained distinct lines due to a new phase with identity periods I_c = 11.9 Å and I_a = 4.92 Å. The authors give no interpretation of this structure. The heat of sorption of hydrogen is found to be 8.1 kcal g-atom^{-1} K for the compound C_8K. Although C_8Cs does not absorb hydrogen[84], this compound catalyses the isotopic exchange of hydrogen with deuterium and the conversion of *ortho*-hydrogen into *para*-hydrogen[86].

According to Diebold and Hérold[87,88] gaseous chlorine and also the vapours of bromine and iodine react very vigorously with C_8K and C_8Cs to form the metal halides, the structure of the lamellar compound being completely destroyed. X-Ray examination shows that the product comprises a graphite phase and a metal-halide phase. Almost all the salt can be washed out with water. Thermogravimetric results show[89] that the salt in the graphite melts at the same temperature as the pure salt.

In 1969 it was reported[90] that oxygen and carbon monoxide react with C_8K to form a KO_2 or K_2CO_3 phase mixed with graphite. According to Sudo et al.[91] C_8K absorbs nitrogen at room temperature.

Jensen et al.[92] demonstrated the reducing properties of C_8K in its reaction with bis(trialkyl phosphite)nickel(II) dichlorides and excess of the trialkyl phosphite to form a zerovalent nickel complex—tetrakis(triethyl phosphite) nickel(0).

The alkali-metal lamellar compounds catalyse the polymerisation of alkenes[84,93-96], the isomerisation of alkenes[97], and also the alkylation by alkenes of benzene derivatives in the ring and in the side-chain[98]. With ethylene at 1000 atm on C_8K at 200°C the products are C_8–C_{14} *trans*-monoalkenes together with a small quantity of a solid polyethylene of low molecular weight[93]. Greater catalytic activity is found with C_8K than with pure potassium dispersed in its chloride or oxide. According to Hambling and Alderson[95] treatment of the compounds—C_8K, $C_{16}K$, $C_{24}K$, $C_{36}K$, $C_{48}K$, $C_{60}K$, and $C_{64}K$—with alkyl or aryl halides and halides of transition metals (titanium, zirconium, vanadium, chromium, molybdenum) modifies them in such a way that the products catalyse the polymerisation of ethylene, propene, and butene at 50–250°C with the formation of products of high molecular weight. The rate of polymerisation of styrene on C_8K and $C_{24}K$ is lower[94], but the molecular weight of the polymer is higher, than in the presence of pure, finely divided potassium.

Golé and Stein[96] have shown that $C_{32}K$ also catalyses the polymerisation of styrene in various solvents (oxolan, benzene, cyclohexane, hexane, carbon tetrachloride) at 25–30°C. In the polymerisation of dienes—butadiene and isoprene[94,96,99]—on C_8K, $C_{24}K$, and $C_{32}K$, the mode of addition is 1,2 and *trans*-1,4 with the former compound, and 1,2, *trans*-1,4, and 3,4 with isoprene. No *cis*-1,4-addition product is formed.

In 1958 Podal and Foster[98] discovered that C_8K catalyses not only the polymerisation of ethylene but also the alkylation of benzene and toluene in the ring and in the side chain. With ethylene at 700 atm and 110°C benzene yields 2-butylbenzene (35%), dialkylbenzenes, and higher monoalkylbenzenes. Ethylbenzene was not detected. These results are opposite to those obtained with organosodium compounds as catalysts[100]. Raising the temperature to 200°C leads to the formation of biphenyl (19%) together with s-butylbenzene (23%). The appearance of biphenyl was attributed to dimerisation of benzene radical-anions formed from benzene and the graphite–potassium complex. The reaction between toluene and ethylene yields triphenylpentane (at 120°C) or n-propylbenzene (55°C). t-Pentylbenzene is formed from isopropylbenzene (200°C).

Ottmers and Rase[97] studied the isomerisation of pent-1-ene into *cis*- and *trans*-pent-2-enes in the presence of

C_8K, $C_{24}K$, $C_{36}K$, $C_{48}K$, and $C_{60}K$ at temperatures between 75° and 235°C. They found that the reaction velocity and the *trans/cis* ratio increased with rise in temperature. At a given temperature the activity of the catalysts varied in the sequence—$C_{60}K > C_{48}K > C_{36}K > C_{24}K > C_8K$. The activity of the catalyst decreases during the reaction, and this decrease is more rapid the higher the temperature.

Comparison of the catalytic activity of these compounds with that of an industrial aluminosilicate catalyst [97] shows that the potassium complex of graphite is more active at low temperatures, and the aluminosilicate catalyst at high temperatures.

The Chemistry of Trialkyloxonium Fluoroborates

V.G.Granik, B.M.Pyatin, and R.G.Glushkov

The preparation and the chemical properties of trialkyloxonium fluoroborates—highly effective alkylating agents—are surveyed. Special attention is paid to the *O*-alkylation of organic compounds (ethers, epoxides, oxo- and hydroxy-derivatives, *N*-oxides, etc.). The bibliography contains 104 references.

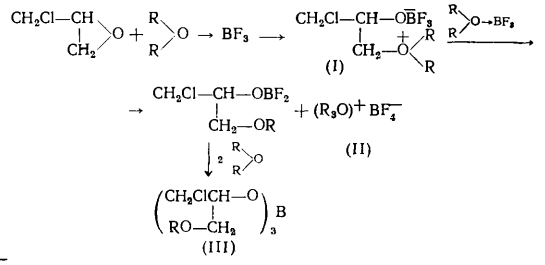
I. INTRODUCTION

The discovery in 1937 by Meerwein and his coworkers[1] of a new class of highly effective alkylating agents—trialkyloxonium salts—considerably extended the field of application of alkylation reactions in organic chemistry. In the course of the investigation of tertiary oxonium salts methods were developed for the preparation of hitherto unknown classes of organic compounds, such as acetals of amides, lactams, and lactones, azidinium salts, etc. New and more effective procedures were found for obtaining known types of compounds (e.g. imidic esters, orthoesters, lactimidic esters, etc.). Among the large number of trialkyloxonium salts which have now been obtained, trimethyloxonium and triethyloxonium fluoroborates have found the widest use in preparative organic chemistry. A considerable number of interesting investigations have been made during recent years on the use of these alkylating agents for the preparation of complicated organic compounds, the results of which do not appear in Meerwein's brief review[2] of the chemistry of various types of oxonium salts. The present Review summarises available information on the synthetic application of trialkyloxonium fluoroborates, primarily the trimethyloxonium and triethyloxonium salts†.

II. PREPARATION OF TRIALKYLOXONIUM FLUOROBORATES

The most widely used method for preparing trialkyloxonium fluoroborates is based on the reaction between 2-chloromethyloxiran and the appropriate ether complex of boron trifluoride in excess of the ether[1,4]:

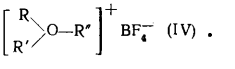


† The Review does not include information on triaryloxonium salts[3], nor on the applications of trialkyloxonium salts in the chemistry of macromolecular compounds.

The above mechanism is supported by the isolation of intermediate inner salts of type (I: R = CH_3, C_2H_5), and the fact that (I: R = C_2H_5) gives triethyloxonium fluoroborate (II: R = C_2H_5) with diethyl ether and its boron trifluoride complex. The boric esters formed in this reaction can be converted into 2-alkoxymethyloxirans:

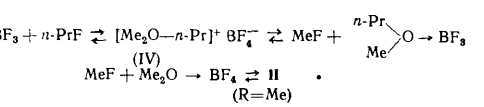
The latter in turn are able to give trialkyloxonium fluoroborates[5].

The above method can be used to prepare trimethyloxonium and triethyloxonium fluoroborates (II: R = CH_3, C_2H_5). However, when R = n-C_3H_7, the yield of (II) does not exceed 30%, and oxonium salts containing higher alkyl radicals could not be obtained at all. Furthermore, it is evident from the above scheme that this method cannot be used to prepare unsymmetrical oxonium salts of the type



Such oxonium salts can in principle be obtained by the reaction of alkyl fluorides with the ether complexes of boron trifluoride[3]:

Thus the corresponding oxonium salts are obtained in satisfactory yields by keeping the reactants in a sealed tube for a long time. The compounds (II: R = C_2H_5), (IV: R = R′ = CH_3; R″ = C_2H_5), and (IV: R = R′ = C_2H_5; R″ = CH_3) have been prepared by this method. However, the method is not universally applicable to the preparation of salts of type (IV). For example, reaction between the dimethyl ether complex of boron trifluoride and propyl fluoride yields merely (II: R = CH_3) instead of the expected (IV: R = R′ = CH_3; R″ = n-C_3H_7):



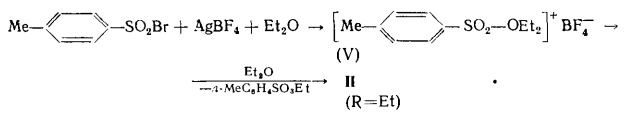
Evidently formation of the more symmetrical cation is energetically more favourable in this reaction. The above scheme agrees well with the easier elimination of methyl rather than other alkyls from the cations (see

Section III). The formation of (II: R = CH_3) is seen to be based on a series of reversible reactions. The decomposition of triethyloxonium fluoroborate when heated above the melting point provides evidence that oxonium salts are in equilibrium with the alkyl halides and the ether complexes of boron trifluoride: the diethyl ether complex and ethyl fluoride were isolated in high yields[1].

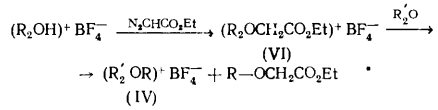
Although the above method enables various oxonium salts (including unsymmetrical salts) to be obtained, the considerable duration of the process (several months) and the relatively low yields make it unsuitable for practical preparations.

Trialkyloxonium fluoroborates can be prepared more conveniently by the reaction of alkyl halides with ethers in the presence of silver fluoroborate[6,7]:

This reaction can be used to obtain not only trialkyloxonium but also mixed acylalkyloxonium salts. For example, treatment of a mixture of ether and silver tetrafluoroborate with toluene-*p*-sulphonyl bromide at −70°C gives the corresponding oxonium salt (V), from which triethyloxonium fluoroborate (II: R = C_2H_5) is obtained on further reaction with ether[8]:



Trialkyloxonium fluoroborates can be prepared also by the reaction of dialkyloxonium fluoroborates with diazomethane or with ethyl diazoacetate[9]



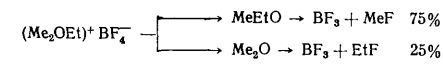
The oxonium salt (VI) formed in the first stage of the reaction is further alkylated by an ether molecule to give the tertiary oxonium salt (IV).

The reaction of a trialkyloxonium fluoroborate with an ether, which is discussed in Section IIIA, 1, provides another method for the preparation of trialkyloxonium fluoroborates.

III. PROPERTIES AND REACTIONS OF TRIALKYLOXONIUM FLUOROBORATES

Trialkyloxonium fluoroborates, like ammonium salts, are typical ionic compounds, whose solutions in anhydrous sulphur dioxide are electrically conducting[4]. They are readily soluble in polar solvents such as nitrobenzene, nitromethane, anhydrous sulphur dioxide, etc. Their solubility in less polar solvents is determined by the length of the alkyl radicals: "loading" the hydrophobic alkyl radicals produces an increase in solubility in these solvents, so that e.g. (II: R = C_2H_5) dissolves well in dichloromethane, whereas (II: R = CH_3) is almost insoluble. All the lower oxonium fluoroborates are solids which melt with decomposition; their melting points fall regularly with increase in length of the alkyl[1,4].

A characteristic property of tertiary oxonium salts is their dissociation at high temperatures with the separation of ether complexes of boron trifluoride and alkyl fluorides. Methyl is detached more readily than other alkyl radicals. For example, the decomposition of ethyldimethyloxonium fluoroborate when heated above 120°C occurs as follows[1]:



Trialkyloxonium salts decompose not only at high temperature but also when their solutions are allowed to stand. In particular, triethyloxonium fluoroborate is unstable in solution, decomposing comparatively readily into diethyl ether, boron trifluoride, and ethyl fluoride[10]. Decomposition is accelerated by the addition of ethers to the solutions[10].

A. *O*-ALKYLATION BY TRIALKYLOXONIUM FLUOROBORATES

1. Reactions with Hydroxylated Compounds, Ethers, and Epoxides

The simplest and most thoroughly studied reaction of this type is the hydrolysis of tertiary oxonium salts[1]:

Hydrolysis is accompanied by the formation of an alcohol and an ether, so that the electrical conductivity of the solutions falls gradually[4]. Table 1 gives the rate of hydrolysis of several salts, determined from the variation in the conductivity of aqueous solutions[4]. The results show that "loading" the alkyl radicals, as well as including positively charged oxygen in a ring, leads to considerable stabilisation of tertiary oxonium salts towards water.

Table 1. Times (min) for complete hydrolysis (at 18°C).

$(Me_3O)^+BF_4^-$	8
$(Et_3O)^+BF_4^-$	80
$(n\text{-}Pr)_3O^+BF_4^-$	120
	220

The relatively low rate of hydrolysis enables ion exchange to be effective with the formation of water-insoluble oxonium salts containing complex anions[4]:

where R = CH_3, C_2H_5; X = $AuCl_4$, $SnCl_4$, HgI_3, $SbCl_6$, etc. Double decomposition of (II: R = C_2H_5) with sodium tri-iodomercurate can be used for the quantitative determination of triethyloxonium fluoroborate[4]. Similarly, the reaction of (II: R = CH_3, C_2H_5) with 2,4,6-trinitrobenzenesulphonic acid yields the corresponding trinitrobenzenesulphonates, which also serve as alkylating agents[11].

When nucleophilic agents other than the hydroxide ion are present in aqueous solution, two competing processes—hydrolysis of the salts and formation of RX

may occur. Table 2 gives the yields of ethylation products obtained when various anions react with triethyloxonium fluoroborate in water[3]. It is evident that the yields of alkylation products usually increase with increase in the polarisability of the anion[4].

Trialkyloxonium fluoroborates react with hydroxylated compounds such as alcohols, phenols, and carboxylic acids with formation of the corresponding *O*-alkyl derivatives[1,2] (a reaction similar to hydrolysis or the ethylation of anions):

$$(R_3O)^+ BF_4^- + R'OH \rightarrow RO_2 + HBF_4 + R'OR \ .$$

Use of the sodio-derivatives of the hydroxylated compounds (i.e. alkylation of the anion $R'O^-$) increases the yields of alkylated products owing to the considerable increase in electron density on the oxygen atom[1,2].

Table 2.

X⁻	F⁻	Cl⁻	Br⁻	I⁻	CNS⁻	CN⁻
Yield of C_2H_5X, %	trace	12	23	53	64	55

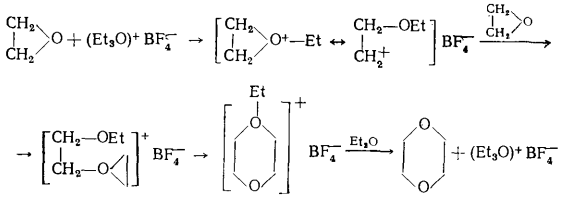
The alkylation of alcohols, phenols, and carboxylic acids does not in all cases, of course, require the use of such strong alkylating agents as trialkyloxonium salts. However, where mild conditions are necessary (e.g. in stereospecific synthesis) or when other methods of alkylation give low yields of the desired products, the application of tertiary oxonium salts acquires considerable preparative value. For example, triethyloxonium fluoroborate is employed for the ethylation of chloroalkanols[1,2] (these compounds cannot be alkylated in alkaline medium[1,2] owing to the elimination of hydrogen chloride with formation of an epoxide) and for the alkylation of (+) (*S*)-pinacolyl alcohol[12].

The alkylation of ethers occupies a special position among the reactions of trialkyloxonium fluoroborates, since it results in new oxonium salts[2]:

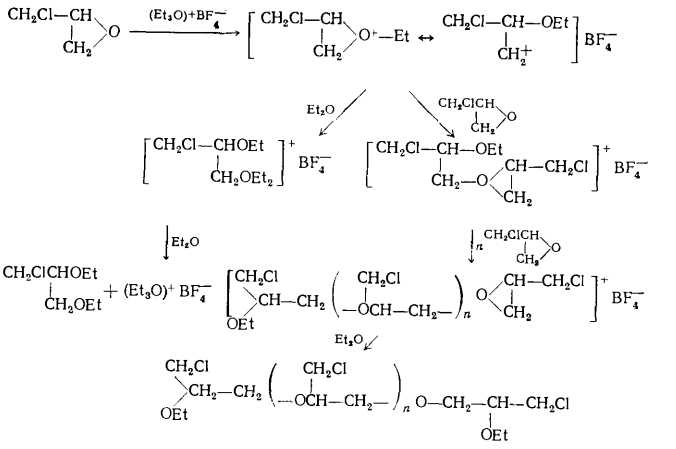
$$(R_3O)^+ BF_4^- + R'_2O \rightleftarrows (R'_2OR)^+ BF_4^- + R_2O \ .$$

As the reaction between oxonium salts and ethers is reversible, the yield of newly formed fluoroborates depends both on the stability of initial and final salts and on their solubility in the reaction medium. In the reaction of (II: R = C_2H_5) with dimethyl ether, for example, a 92% yield of (II: R = CH_3) is formed, whereas in the reaction of the same salt with oxan the yield of ethyloxanium fluoroborate is only 52%.

The first stage in the reaction of trialkyloxonium fluoroborates with epoxides[13] resembles their reaction with ethers. However, the subsequent reactions of the resulting oxonium compounds depend on the structure of the initial epoxide. Thus dioxan has been isolated as final product of the reaction of triethyloxonium fluoroborate with oxiran in ether[13]:



With chloromethyloxiran reaction can occur in two ways[13]:



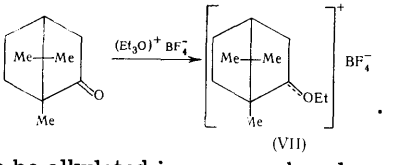
products of different degrees of polymerisation being formed depending on the reaction conditions.

2. Reactions with Carbonyl Compounds

A detailed study of reactions of this type enabled Meerwein et al.[14] to arrange carbonyl compounds in the following sequence according to their capacity for alkylation by oxonium salts: aldehydes < ketones < esters < lactones < acid amides < lactams. This sequence will be adopted in the present survey.

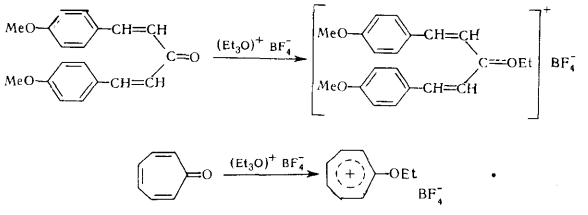
(*a*) Alkylation of aldehydes, ketones, and carboxylic esters

The reaction of aldehydes and ketones with tertiary oxonium salts yields only aldol condensation products[2]: owing to the low basicity of these compounds, they do not usually undergo *O*-alkylation. In some cases, nevertheless, alicyclic ketones are alkylated, and camphor, for example, gives the corresponding fluoroborate (VII) in 78% yield[1]:



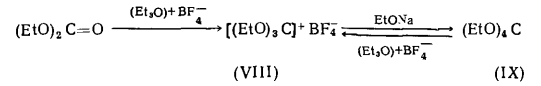
(VII)

The ability to be alkylated increases sharply on passing from simple to $\alpha\beta$-unsaturated ketones, as a consequence of the considerable stabilisation of the resulting cation. Quantitative yields are obtained, for example, in the reactions of triethyloxonium fluoroborate with di-*p*-methoxystyryl ketone[1] and with tropone[15]:



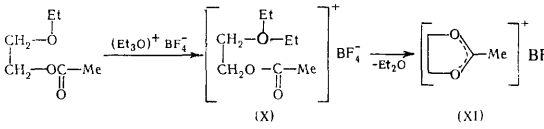
In esters, as in saturated aldehydes and ketones, the electron density on the carbonyl is usually insufficient for

alkylation by oxonium salts[2]. When, however, the resulting cation is largely stabilised by conjugation, as e.g. in the ethylation of carbonic ester, it is possible to obtain the corresponding fluoroborate salt (VIII)[16], whose structure has been proved by conversion into tetraethoxymethane (IX):



(VIII) (IX)

Alkylation of ethers occurs appreciably more readily than that of carbonyl compounds. When the molecule contains both functions, e.g. 2-ethoxyethyl acetate, the first stage is *O*-alkylation of the ether[14]:

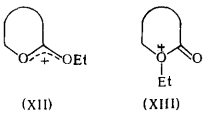


(X) (XI)

The resulting cation (X) is stabilised by elimination of a molecule of ether with the formation of 2-methyl-1,3-dioxolenium fluoroborate (XI).

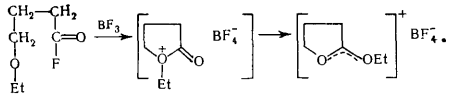
(*b*) Alkylation of lactones

Trialkyloxonium fluoroborates alkylate lactones solely at the carbonyl oxygen[16]. The explanation of such selectivity is that the resulting cation (XII) is stabilised by conjugation, unlike the cation (XIII), which might have been obtained by alkylation of the cyclic oxygen atom.

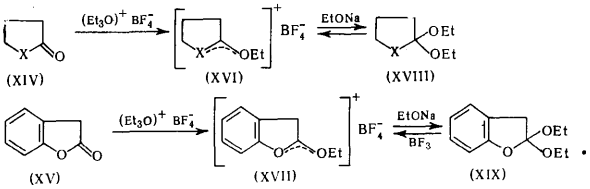


(XII) (XIII)

If, however, only cations of type (XIII) can be formed, they immediately pass into stabilised cations of type (XII)[16]:



Examples of the reaction of triethyloxonium fluoroborate with lactones are provided by the alkylation of compounds (XIV: X = O, S) and phthalide (XV)[17]:

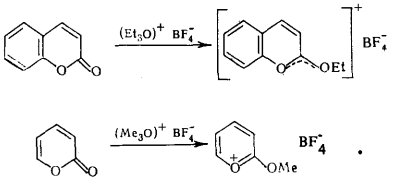


(XIV) (XVI) (XVIII)

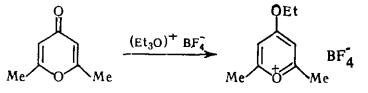
(XV) (XVII) (XIX)

Treatment of the salts (XVI) and (XVII) with sodium ethoxide converts them into lactone acetals (XVIII) and (XIX)[16].

Lactones which can form fluoroborates with stable cations are especially readily alkylated[1,18]:

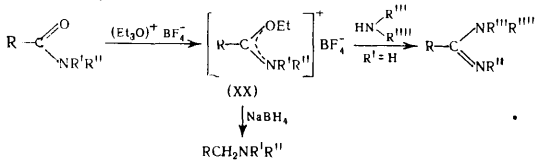


Similarly, the action of triethyloxonium fluoroborate on 2,6-dimethyl-4-pyrone readily forms the stable 4-ethoxy-2,6-dimethylpyrylium fluoroborate[1]:



(*c*) *O*-Alkylation of amides

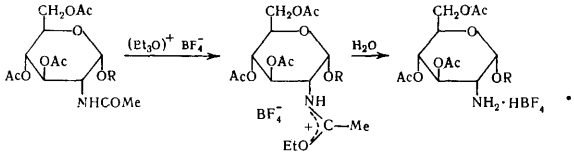
The reaction of trialkyloxonium fluoroborates with compounds containing an amide function is one of the most promising for synthetic purposes. It is sufficient to note that this reaction has opened up a new pathway for the preparation of such important and extremely reactive compounds as imidic and lactimidic esters[18]. Several members of a new class of organic compounds—amide and lactam acetals—have also been synthesised[19-21]. Meerwein first accomplished the reaction of trialkyloxonium fluoroborates with amides and lactams in the case of acetamide[1], and subsequently extended the reaction to a large number of diverse compounds containing an amide function[16,20]. The salts of imidic esters formed by alkylation are easily converted by amines into amidines[22]:



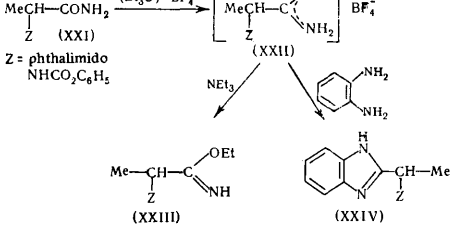
(XX)

Fluoroborates of imidic esters (XX) can be reduced by sodium tetrahydroborate under mild conditions to give high yields of the corresponding amines[23]. Since amides are usually reduced by means of the considerably less selective lithium tetrahydroaluminate, the new method shows great promise for the preparation of various amines, including polyfunctional compounds, which are difficult to obtain by other methods.

The availability of salts of type (XX) also provides opportunities for the selective detachment of *N*-acyl groups under exceptionally mild conditions, for salts of imidic esters are easily hydrolysed by water. This has been utilised for removing a protective *N*-acetyl group while preserving acetoxy-groups[24]:

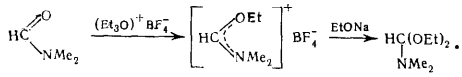


In substituted alaninamides (XXI) only the carbamoyl group is affected by triethyloxonium fluoroborate, in spite of the simultaneous presence of a phthalimido- or a phenoxycarbonylamino-group. The structure of the resulting fluoroborates (XXII) was proved by converting them into imidic esters (XXIII) and substituted benzimidazoles (XXIV)[25]:

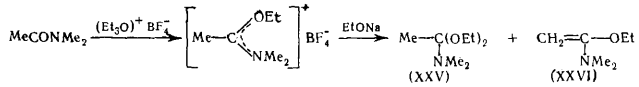


(XXI) (XXII) (XXIII) (XXIV)

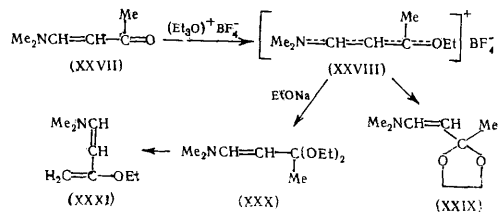
The reaction of trialkyloxonium fluoroborates with *NN*-disubstituted amides yields, after treatment of the intermediate fluoroborates with sodium ethoxide, the corresponding amide acetals: e.g. [20]



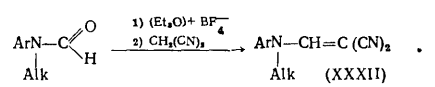
The alkylation of *NN*-dimethylacetamide with (II: R = C_2H_5) produces a fluoroborate salt, treatment of which with sodium ethoxide gives a mixture of the corresponding acetal (XXV) and the "*ON*-keten-acetal" 1-ethoxyvinyldimethylamine (XXVI)[20]:



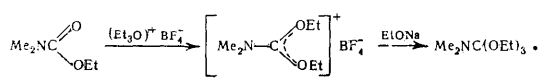
Alkylation of the vinylogue (XXVII) of *NN*-dimethylacetamide proceeds similarly. If the resulting fluoroborate (XXVIII) is decomposed with sodium glycollate, a stable cyclic acetal, *NN*-dimethyl-2-2'-methyldioxolan-2'-ylvinylamine (XXIX), is formed[20]. Reaction of (XXVIII) with sodium ethoxide gives an unstable diethyl acetal (XXX), vacuum distillation of which is accompanied by elimination of a molecule of alcohol with formation of the corresponding "keten-acetal" (XXXI)[20]:



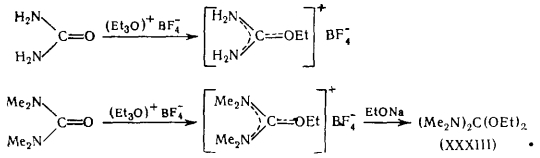
Amide acetals react very vigorously with various nucleophilic reagents[21]. It is not usually necessary to isolate the amide acetal (as in the preparation of amidines from amides—see above), and the intermediate fluoroborate salts can be used for further syntheses[25-27]. For example, *N''*-alkylanilinomethylenemalononitriles (XXXII) have been synthesised by the reaction of *N*-alkyl-*N*-arylformamides with trialkyloxonium fluoroborates followed by treatment with malononitrile in the presence of triethylamine[27]:



Urethanes and urea derivatives react similarly to amides with trialkyloxonium salts[4,20]. Thus triethyloxonium fluoroborate and ethyl *NN*-dimethylcarbamate give the corresponding salt, which is further converted by sodium ethoxide into orthocarbonic dimethylamide—a stable compound which is not hydrolysed under normal conditions[20]:

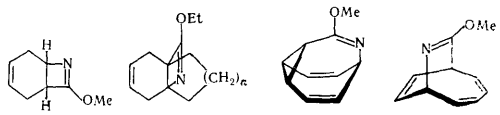


Similarly, the alkylation of urea[4] yields the fluoroborate of *O*-ethylisourea, and that of tetramethylurea the corresponding salt, from which diethoxy-*NNN'N'*-tetramethylmethylenediamine (XXXIII) was prepared by the action of sodium ethoxide[20]:

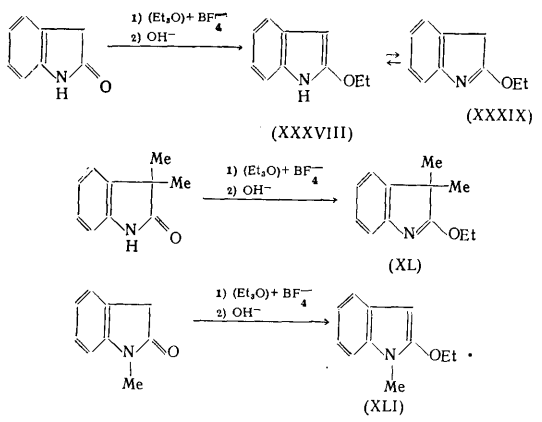


The reaction of trialkyloxonium fluoroborates with cyclic amides (lactams) has found wide application in organic synthesis. The resulting *O*-alkylated lactams have been starting materials for a large number of heterocycles, including members of novel heterocyclic systems[19].

The alkylation of simple lactams—2-oxopyrrolidine, 2-oxopiperidine, ϵ-caprolactam—by trialkyloxonium salts followed by treatment of the resulting fluoroborates with alkaline reagents gives high yields of the corresponding lactimidic esters[19,28,29]. This method has been used also to prepare lactimidic esters of phthalimidine[30], 1,2,3,4-tetrahydro-2-oxoquinoline[31,32], 3,5,7-trimethyl-2-oxoazepine[33], 2,3,4,5-tetrahydro-10-methyl-1-oxoazepino[3,4-*b*]indole[34], and also more complicated bi- and tri-cyclic lactams (XXXIV)–(XXXVII)[35-37].

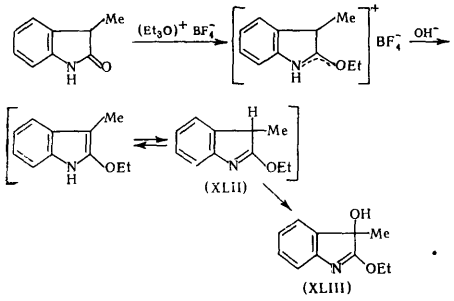


Interesting results have been obtained for the alkylation of oxindole and its derivatives with triethyloxonium fluoroborate[38-40]. Oxindole itself yields 2-ethoxyindole (XXXVIII), which on sublimation is converted into the lactimidic ester (XXXIX). The tautomeric equilibrium between (XXXVIII) and (XXXIX) in solution is demonstrated by comparing their infrared and proton magnetic resonance spectra with those of a model imine (XL) and a model enamine (XLI)[38]:



Comparison of the ionisation constants and also spectral data for the lactimidic esters of 3-substituted and 3,3-disubstituted 2-oxopiperidines (prepared from the corresponding lactams and triethyloxonium fluoroborate) indicate that such tautomerism is probably a general feature of lactimidic esters[41]. When 3-methyloxindole was alkylated with triethyloxonium fluoroborate, the product isolated was

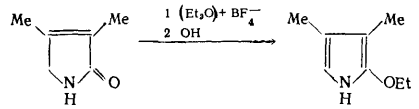
not the lactimidic ester (XLII) but (unlike what occurs with oxindole and 3,3-dimethyloxindole) an oxidation product, 2-ethoxy-3-hydroxy-3-methylindole (XLIII)[40]:



(XLII)

(XLIII)

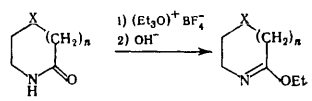
The alkylation of 3,4-dimethyl-2-oxopyrroline (XLIV) with triethyloxonium fluoroborate does not yield the corresponding lactimidic ester but a 2-ethoxypyrrole derivative (XLV):



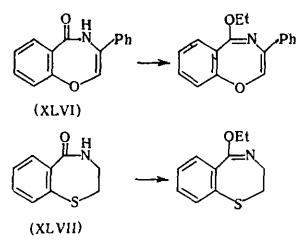
(XLIV) (XLV)

Migration of the double bonds probably occurs with formation of the stable aromatic ring[42].

Lactams containing a second heteroatom in the ring are alkylated selectively at the lactam carbonyl. Alkaline treatment of the products yields the corresponding lactimidic esters[18,32,43-48]:



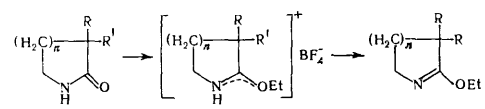
where $n = 1$, 2 and X = O, S, N.CO.CH$_3$. The corresponding lactimidic esters are obtained also from bicyclic lactams (XLVI) and (XLVII)[49,50]:



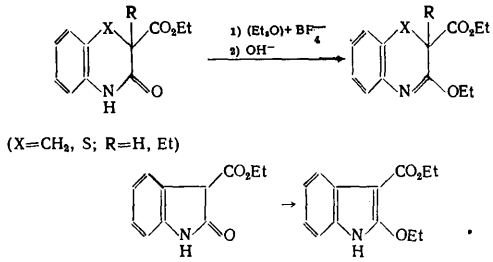
(XLVI)

(XLVII)

A considerable amount of work has been done on the alkylation of compounds containing other functional groups in addition to the lactam group[39,41,47,51-65]. In particular, the alkylation of a series of simple 3-mono- and 3,3-disubstituted lactams has been studied in connection with the synthesis of fused pyrimidine systems from lactimidic esters[41,51-56,58-62]:

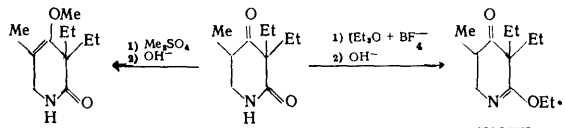


where with $n = 1$: R = COOC$_2$H$_5$ and R′ = H; with $n = 2$: R = H, C$_2$H$_5$, C$_6$H$_5$, Cl, Br, CH$_3$, OC$_2$H$_5$ and R′ = H, COOC$_2$H$_5$; and with $n = 3$: R = COOC$_2$H$_5$, CN and R′ = H. It was established that alkylation occurs selectively at the lactam carbonyl, the functional substituents remaining unaffected. The alkylation of benzo-derivatives of 3-ethoxycarbonyl-lactams proceeds similarly[39,47,63,66]:



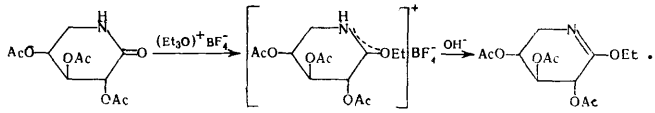
(X=CH$_2$, S; R=H, Et)

Alkylation of 3,3-diethyl-5-methyl-2,4-dioxopiperidine by triethyloxonium fluoroborate goes smoothly to the corresponding lactimidic ester (XLVIII)[51]. It is interesting that, with dimethyl sulphate as alkylating agent, the 4-carbonyl is alkylated with formation of the lactam (XLIX)[51]:

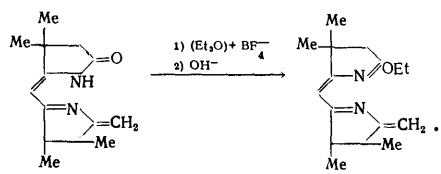


(XLIX) (XLVIII)

The mild conditions under which alkylation by tertiary oxonium salts takes place makes this method almost irreplaceable when the lactam ring contains such functional substituents as the acetoxy-group[57]:

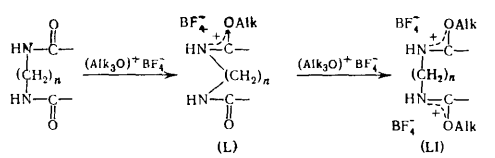


The great readiness of tertiary oxonium salts to alkylate a lactam carbonyl has been used for the preparation of intermediate products in the synthesis of corrin derivatives[64]:



Results have been published for the alkylation of compounds containing two amide functions. For example, triethyloxonium fluoroborate gives lower yields than usual of the lactimidic esters from 1-acetyl-3-oxopiperazine and its methyl 2-carboxylate[44,45,56], and also from ethyl 1-benzoyl-1,2,3,4-tetrahydro-3-oxoquinoxaline-2-carboxylate[47]. Together with the isolation of considerable quantities of the initial lactams, this can be explained by the simultaneous alkylation of the $N_{(4)}$-carbonyls.

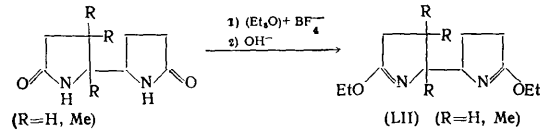
Examination of the scheme of alkylation of compounds containing two (or more) amide carbonyls reveals that, after the first amide group has been alkylated, attack by the alkylating agent on the second amide carbonyl is impeded by the electron-accepting action of the positively charged group in (L):



(L) (LI)

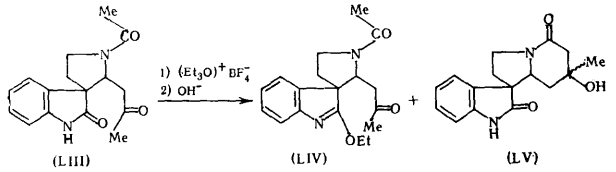
It is quite clear that this effect is weakened by large values of n, so that the decrease in electron density on the second amide carbonyl is insufficient to prevent formation of the dication (LI). As n becomes smaller, the electron density on this carbonyl decreases, and electrophilic attack by the alkylating agent will consequently be hindered.

The above principles can be illustrated by published results. Derivatives of 5,5'-dioxo-2,2'-bipyrrolidinyl react with triethyloxonium fluoroborate[6] to give high yields of bislactimidic esters (LII)[67,68]:



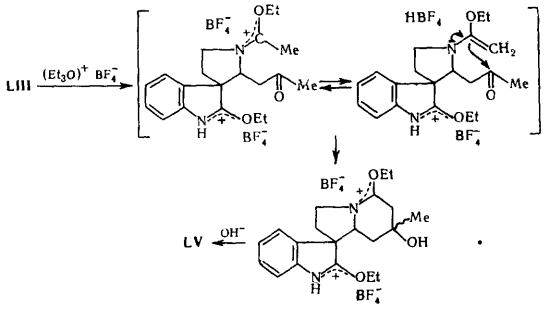
(R=H, Me) (LII) (R=H, Me)

Alkylation of the spiro-compound (LIII) with the same agent gave not only the corresponding lactimidic ester (LIV) but also a tetracyclic compound (LV)[69]:

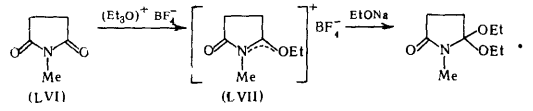


(LIII) (LIV) (LV)

Formation of the latter was regarded[70] as a consequence of alkylation of both amide groups:



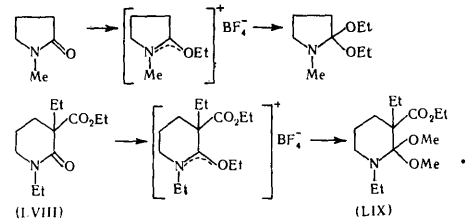
Nevertheless, only one carbonyl group is involved in the alkylation of N-methylsuccinimide (LVI) by triethyloxonium fluoroborate[71]:



(LVI) (LVII)

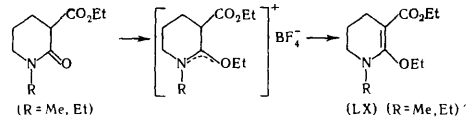
Indeed, it is difficult to imagine that under normal conditions the cation (LVII) could undergo further alkylation at the second carbonyl.

As in the alkylation of N-methylsuccinimide, the reaction of trialkyloxonium fluoroborates with N-substituted lactams yields lactam acetals after treatment with bases[2,20]. The examples of the N-methyl-2-oxo-derivatives of pyrrolidine, quinoline, benzoxazole, and benzothiazole show that this is probably a general method for the preparation of lactam acetals which are unsubstituted in position 3 of the ring[20]. The alkylation of a 3,3-disubstituted N-methyl-2-oxopiperidine (LVIII) also goes smoothly with formation of the corresponding acetal (LIX)[61]:

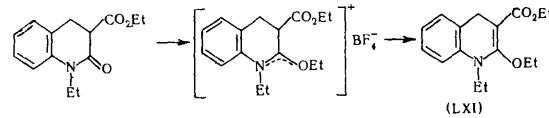


(LVIII) (LIX)

However, lactams containing a 3-ethoxycarbonyl group give enamines (LX) and (LXI)[59,63]—cyclic analogues of "*ON*-keten-acetals" (see beginning of this subsection)—as final products:

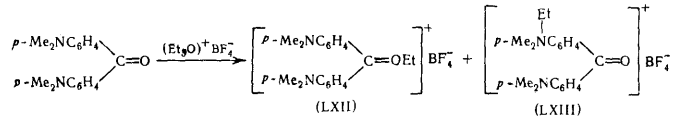


(R = Me, Et) (LX) (R = Me, Et)



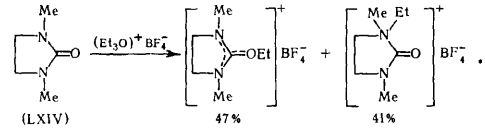
(LXI)

The results discussed above show that trialkyloxonium fluoroborates are excellent alkylating agents for the preparation of *O*-alkyl derivatives of amides, lactams, and related compounds, especially with respect to selectivity: when a lactam molecule contains several active groups, it is usually only the amide carbonyl that undergoes alkylation. However, examples are known in which alkylation by tertiary oxonium salts takes place ambiguously. Thus Michler's ketone yields not only the *O*-ethyl derivative (LXII) but also the isomeric N-alkyl compound (LXIII)[20]:



(LXII) (LXIII)

1,3-Dimethyl-2-oxoimidazolidine (LXIV) also gives a mixture of *O*- and N-alkylated products[20]:

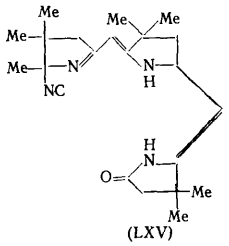


(LXIV)

It should be noted that triethyloxonium fluoroborate acts on the benzo-derivative of (LXIV) unambiguously with the formation of 2-ethoxy-1,3-dimethylbenzimidazolium fluoroborate[20].

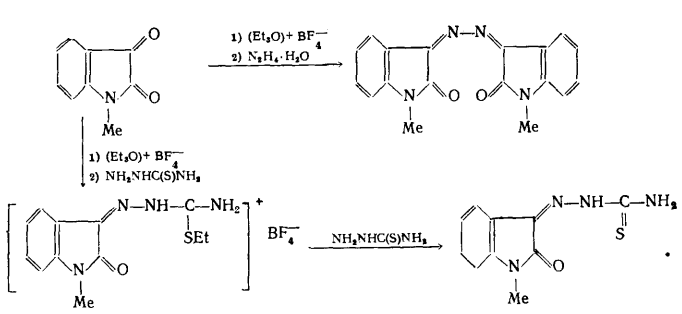
Until recently no cases were known of the N-alkylation of lactams by tertiary oxonium salts. However, it has

been reported recently that the reaction of the tricyclic lactam

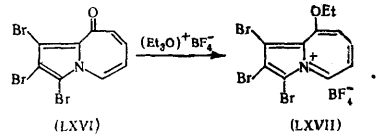


(LXV)

proceeds ambiguously to give a mixture of *N*- and *O*-isomers[72]. Treatment with hydrazine hydrate or thiosemicarbazide of the reaction mixture obtained from *N*-methylisatin and triethyloxonium fluoroborate yields the azine and the thiosemicarbazone of *N*-methylisatin[65]:



In concluding this subsection we must note a reaction which is closely related to the alkylation of lactams and their vinylogues—the action of triethyloxonium fluoroborate on the dicyclic oxoazepine (LXVI), resulting in the formation of an ethoxyazonia-azulene fluoroborate (LXVII)[73]:

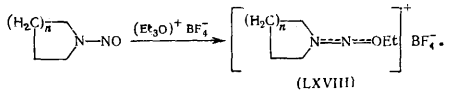


(LXVI) (LXVII)

3. Other *O*-Alkylations

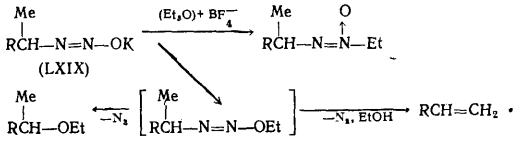
Another reaction of tertiary oxonium salts is the *O*-alkylation of *N*-oxides[4] and *N*-nitroso-compounds[74]:

Investigation of the alkylation of *N*-nitrosoazacycloalkanes led to a new class of organic compounds—*O*-alkylnitrosoimmonium salts (LXVIII)[74]:



(LXVIII)

The alkylation of compounds containing nitrogen–oxygen bonds does not always occur unambiguously. Thus the reaction of triethyloxonium fluoroborate with diazoates (LXIX) yields not only *O*-alkylated products but also *N*-alkyl derivatives[75]:

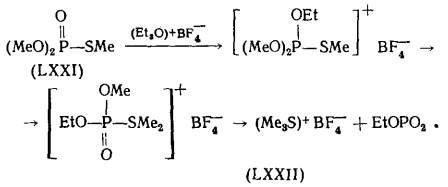


(LXIX)

As with *N*-oxides the alkylation of compounds containing an *S*-oxide group takes place at the oxygen atom with the formation of high yields of *S*-alkoxysulphonium salts (LXX)[4]:

(LXX)

Interaction of the thioester (LXXI) with triethyloxonium fluoroborate gives trimethylsulphonium fluoroborate (LXXII). This process of alkylation was represented by the scheme[76]

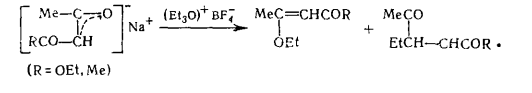


(LXXI) (LXXII)

The structure of the salt (LXXII) was proved[76] by its preparation from trimethylsulphonium iodide and triethyloxonium fluoroborate:

B. REACTIONS OF TRIALKYLOXONIUM FLUOROBORATES WITH AMBIDENT ANIONS

The molecules of ambident anions react with strongly electrophilic reagents mainly at the site of highest electron density[77,78]. This explains why the action of triethyloxonium fluoroborate on the sodium derivatives of acetoacetic ester‡ and penta-2,4-dione yields considerably greater proportions of *O*-alkylated products than when alkyl halides are used[79]. It is important to note that the reaction was conducted under heterogeneous conditions, which usually favour *C*-alkylation[80]:



(R = OEt, Me)

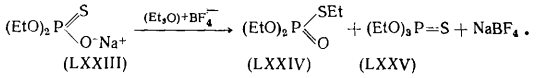
These results are consistent with the view that tertiary oxonium salts are considerably more strongly electrophilic than are alkyl halides.

Another study of the alkylation of metal derivatives of acetoacetic ester in hexamethylphosphoramide and in dimethyl sulphoxide has established that the use of triethyloxonium fluoroborate gives no higher yields of *O*-alkyl derivatives than are obtained with dialkyl sulphates, although the latter are considerably less electrophilic[81].

‡ The reaction of triethyloxonium fluoroborate with sodium acetoacetic ester had been accomplished earlier[1], but only the *C*-isomer had then been isolated (in 47% yield).

This anomaly was explained[81,82] on the assumption that the alkylating agent was not the tertiary salt but its reaction product with the solvent. This hypothesis is supported by the increased yields of *O*-ethyl derivatives obtained when the alkylation is conducted in a mixture of hexamethylphosphoramide and dichloromethane, and also by the ability of triethyloxonium fluoroborate to ethylate dimethyl sulphoxide[4].

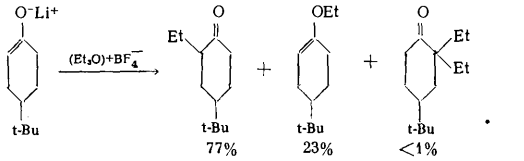
Comparison of results for the alkylation of dialkyl phosphorothionate anions (LXXIII) by various alkylating agents, including triethyloxonium fluoroborate[83], also indicates the tendency of this reagent to attack at the site of highest electron density. Indeed, whereas the alkylation of (LXXIII) by alkyl halides and esters of mineral acids produces solely the *S*-derivatives (LXXIV), when the oxonium salt is used (LXXIV) is accompanied by the *O*-isomer (LXXV) in 8% yield:



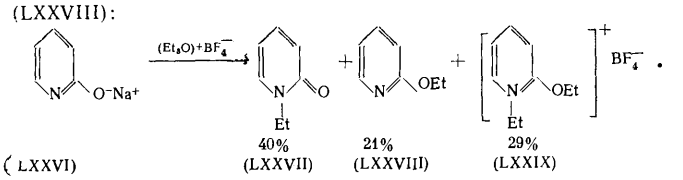
(LXXIII) (LXXIV) (LXXV)

Since in the presence of triethyloxonium fluoroborate the *O*-isomer (LXXV) is partly converted into the *S*-isomer (LXXIV), the actual yield of the former may even be rather higher than the above value[83]:

Similarly, when triethyloxonium fluoroborate acts on the enolate anion [of 4-t-butylcyclohexanone], *C*-alkylation is accompanied by *O*-alkylation, whereas with methyl iodide as alkylating agent no *O*-alkylation products are found[84]:



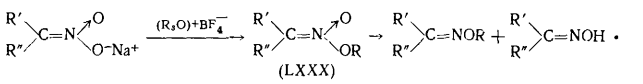
Results for treatment of the sodium salt of 2-hydroxypyridine (LXXVI) with triethyloxonium fluoroborate also support the principle that the more electrophilic alkylating agents show a greater tendency to *O*-alkylation. With alkyl halides this compound is alkylated at the nitrogen atom[85], the method being used most frequently for the preparation of 1-alkyl-1,2-dihydro-2-oxopyridine derivatives. On the other hand, when the tertiary oxonium salt is used, the *N*-ethyl derivative (LXXVII) is accompanied by a quite considerable quantity of 2-ethoxypyridine (LXXVIII)[85]. Another product is the *ON*-diethyl derivative (LXXIX), which results from further alkylation of the monoethylated compounds (LXXVII) and (LXXVIII):



(LXXVI) (LXXVII) (LXXVIII) (LXXIX)

The salt (LXXIX) also is an alkylating agent and capable of alkylating the initial compound (LXXVI)[85]. However, since it is less strongly electrophilic than triethyloxonium fluoroborate, it produces the *O*-ethyl derivative (LXXVIII) in considerably smaller yield (up to 9%), and the yield of the *N*-isomer (LXXVII) increases correspondingly (to 79%).

A fairly detailed investigation has been made of the alkylation of the sodium salts of nitroalkanes by trialkyloxonium fluoroborates[5,86,87]. The primary products are esters of the *aci*-nitro-derivatives (LXXX)[87], which are then converted into oximes and their ethers:

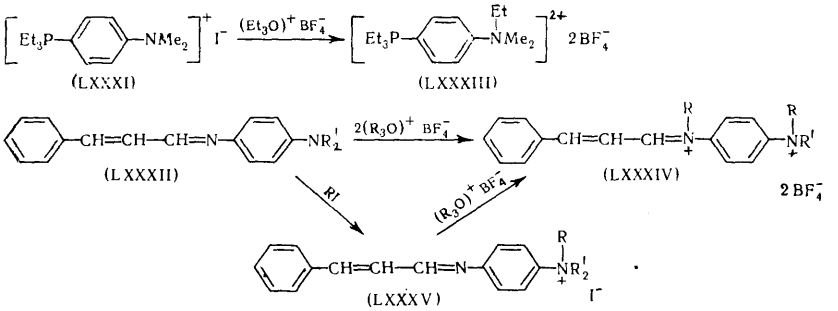


(LXXX)

It should be noted that triethyloxonium fluoroborate always gives higher yields than does the trimethyloxonium salt. Since alkylation is conducted in aqueous medium[4], this difference is probably due to the greater tendency of methyl derivatives to be hydrolysed.

C. *N*-, *P*-, AND *S*-ALKYLATION BY TRIALKYLOXONIUM FLUOROBORATES

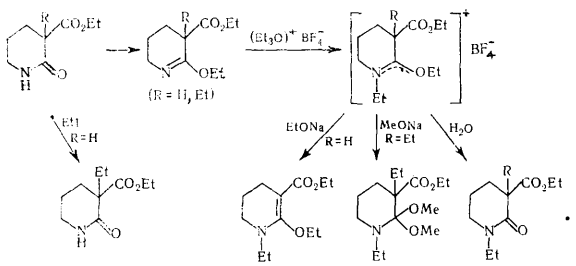
Oxonium salts have not found wide application for the alkylation of amines, since such strongly electrophilic reagents are not needed for this purpose. However, they can be usefully applied to the alkylation of compounds containing also strongly electron-accepting substituents, which weaken the nucleophilic character of the amino-group. Examples are provided by the alkylation of *p*-dimethylaminophenyltriethylphosphonium iodide (LXXXI)[88] and the cinnamylideneaniline derivative (LXXXII)[89], which yield the bivalent salts (LXXXIII) and (LXXXIV). The latter salt can be prepared in stages, in the first of which alkyl halides can be used to obtain the ammonium salt (LXXXV), but a trialkyloxonium fluoroborate is needed for the second stage[88]:



(LXXXI) (LXXXIII) (LXXXII) (LXXXIV) (LXXXV)

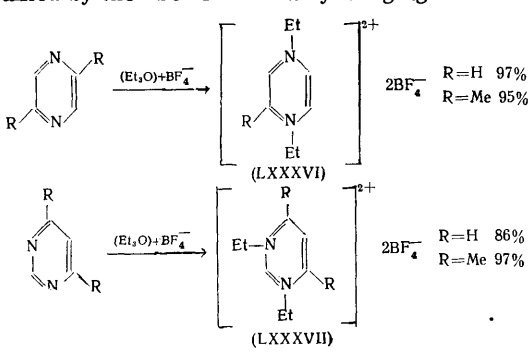
The strongly electrophilic character of trialkyloxonium salts enables several reactions to be accomplished that cannot be effected by other alkylating agents. Considerable interest therefore attaches to the use by Wittig et al. of trimethyloxonium fluoroborate for the quaternisation under mild conditions of sterically hindered amines such as e.g. *cis*- and *trans*-*N*-methyl-12-aza-1,2:3,4:7,8:9,10-tetrabenzocyclotrideca-1,3,5,7,9-pentaenes[90]. Furthermore, the reactions of a series of saturated heterocycles with tertiary oxonium salts reveal that not only axial but also equatorial isomers undergo alkylation, which is not observed with ethyl iodide[91].

Triethyloxonium fluoroborate has been successfully used to alkylate lactimidic esters of 2-oxopiperidines and 1,2,3,4-tetrahydro-2-oxoquinolines[59-61,63]. It is significant that this reaction takes place even when position 3 of the lactam ring is occupied by an electron-accepting substituent, and direct introduction of an *N*-alkyl group into the lactam cannot be achieved. Isolation of the intermediate fluoroborates then enables them to be used directly for preparing the corresponding α-alkoxy-enamines and acetals of the lactam[61]: e.g.

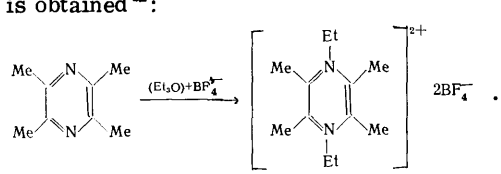


The above scheme shows that the use of tertiary oxonium salts makes possible the *N*-alkylation of compounds containing C=N double bonds.

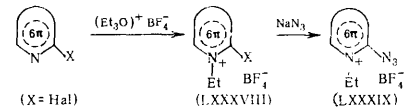
Heteroaromatic compounds similarly undergo smooth alkylation. Thus triethyloxonium fluoroborate acts on pyridine to give the *N*-ethylpyridinium salt[1], and pyrazine and pyrimidine derivatives yield the corresponding diquaternary salts (LXXXVI) and (LXXXVII), which cannot be obtained by the use of other alkylating agents[92]:



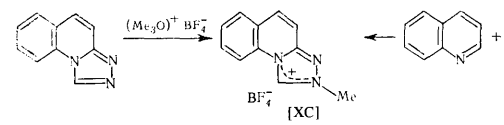
The yields of diquaternary salts decrease sharply when methyl groups are present in the $\alpha\alpha$-positions relative to the cyclic nitrogen atoms[92], and e.g. in the case of 2,3,5,6-tetramethylpyrazine only a 6% yield of the alkylation product is obtained[92]:



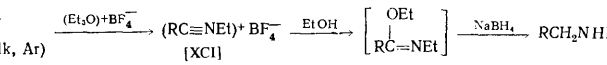
The alkylation of derivatives of thiazole, benzothiazole, naphtho[2,1-*d*]thiazole, benzoselenazole, benzimidazole, pyridine, isoquinoline, and 1,2,4-triazole also yields the corresponding fluoroborates (LXXXVIII), from which members of a new class of organic compounds—azidinium salts (LXXXIX)—have been prepared by reaction with sodium azide[93]:



Methylation of triazolo[4,3-*a*]quinoline with trimethyloxonium fluoroborate yields the corresponding fluoroborate (XC), whose structure has been proved by synthesis from quinoline and 2-ethoxy-1,1-dimethyldiazenium fluoroborate[94]:

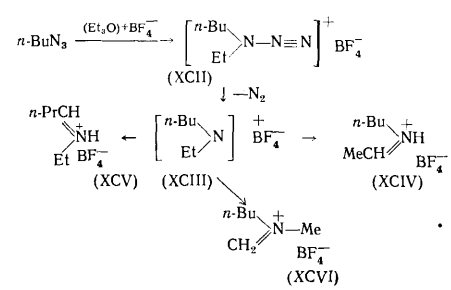


Trialkyloxonium fluoroborates act on nitriles to form nitrilium salts (XCI)[28,95,96], which on reduction with alcoholic sodium tetrahydroborate yield secondary amines[96]:



It should be noted that nitriles themselves are not reduced by alkali-metal tetrahydroborates.

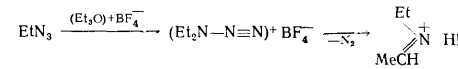
Alkyl azides also undergo alkylation by triethyloxonium fluoroborate. With butyl azide, for example, the fluoroborate (XCII) is probably formed initially[97], and is then converted into a new salt (XCIII). The latter yields fluoroborates of Schiff bases (XCIV) and (XCV) together with an isomerisation product (XCVI):



These compounds have not themselves been isolated, but their intermediate formation has been deduced from the presence of the corresponding amines and aldehydes after hydrolysis of the reaction mass[97].

The alkylation of triphenylsilyl azide proceeds rather differently, for the intermediate fluoroborate (which likewise was not isolated) undergoes cleavage without the evolution of nitrogen[98]:

If the reaction mixture contains excess of triethyloxonium fluoroborate, the ethyl azide undergoes further alkylation with the formation of ethylethylideneammonium fluoroborate[98]:



Tervalent phosphorus compounds react similarly to nitrogen-containing compounds, with the formation of quaternary phosphonium salts[88,99]:

$$PR_3 \xrightarrow{(Et_3O)^+BF_4^-} (EtPR_3)^+BF_4^-$$

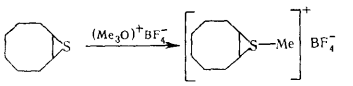
where R = OCH_3, OC_6H_5, $OCH_2CH_2C_6H_5$.

A considerable number of papers have been published on the *S*-alkylation of sulphur-containing compounds. Diethyl sulphide[4] and dimethyl disulphide[11] yield the corresponding sulphonium fluoroborates:

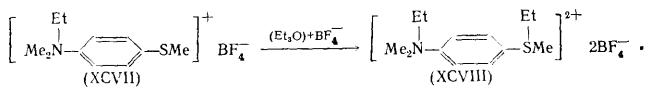
$$Et_2S \xrightarrow{(Et_3O)^+BF_4^-} (Et_3S)^+ BF_4^-$$

$$Me{-}S{-}S{-}Me \xrightarrow{(Me_3O)^+BF_4^-} (Me{-}S{-}SMe_2)^+ BF_4^-.$$

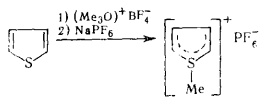
The alkylation of cyclo-octene sulphide occurs similarly[11]:



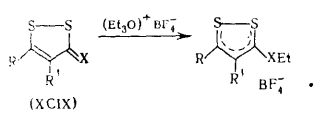
S-Alkylation takes place even when the sulphur atom is considerably depleted of electrons. Thus triethyloxonium fluoroborate acts smoothly on a *para*-substituted methyl phenyl sulphide (XCVII) containing in the ring such a strong electron acceptor as an ammonium group, with formation of a sulphonio-ammonium salt (XCVIII)[88]:



Even thiophen, in which the lone pair of the sulphur atom forms part of an aromatic sextet, has been alkylated[100]:

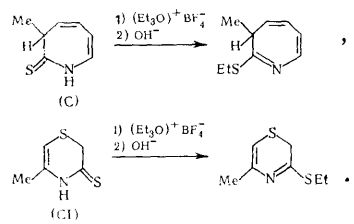


Thiocarbonyl compounds undergo alkylation by oxonium salts extremely readily. Thus the compounds (XCIX: X = S) give almost quantitative yields of the corresponding fluoroborates[101]:



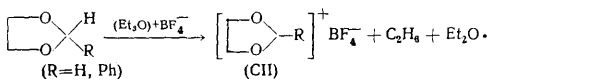
Appreciably lower yields of alkylation products are usually obtained when X = O[101].

Several examples have been described of the alkylation by triethyloxonium fluoroborate of thiolactams, e.g. thiocaprolactam[30], an azepinethione (C)[33], and a thiazinethione (CI)[102]. In all cases the final reaction products are the corresponding thiolactimidic esters:



D. TRIETHYLOXONIUM FLUOROBORATE AS ACCEPTOR OF THE HYDRIDE ION

Triethyloxonium fluoroborate can act not only as an alkylating agent but also as a hydride-ion acceptor[10,103,104]. It reacts with hydride-ion donors, e.g. dioxolan derivatives, to form carbonium ions (CII), ethane, and diethyl ether[10,103]:



It has also been reported[104] that triethyloxonium fluoroborate can act in this way with lithium tetrahydroaluminate and sodium tetrahydroborate.

The results surveyed in the present Review show that study of the chemistry of trialkyloxonium fluoroborates has proved extremely fruitful from both synthetic and theoretical points of view. The great reactivity of these salts, together with the relative simplicity of their preparation, makes them valuable starting materials for the synthesis of various organic compounds.

The Chemistry of Ecdysones

A.A.Akhrem, I.S.Levina, and Yu.A.Titov

Ecdysones ara a group of structurally similar steroid compounds with hormonal activity in the moulting and metamorphosis of insects. The review deals with the sources from which ecdysones are isolated, their structure determination, and methods for their partial synthesis. The principal features of the biological activity of ecdysones and their synthetic analogues are also briefly outlined.
The bibliography includes 193 references.

IV.	Analogues of ecdysones	769

I. INTRODUCTION

A group of polyhydroxylated sterols with related chemical structures, isolated from arthropods and plants, is combined under the name of ecdysones (see the relevant reviews[1-9]). The group is of interest from both chemical (their unusual structure distinguishes them from all previously known steroid compounds) and biological standpoints, since ecdysones exhibit an extremely interesting physiological activity. The most common characteristic of the biological action of ecdysones is their capacity to cause the moulting and metamorphosis of insects. Depending on the source from which they are isolated (from plants or animals), these substances are divided into zooecdysones and phytoecdysones.

Zooecdysones are present in the organisms of various insects[10-13] and crustaceans[14-16], but their amounts are negligibly small. Thus 25 mg of α-ecdysone[17] was isolated from 500 kg of the pupae of the silkworm moth *Bombyx mori* and 9 mg of ecdysterone was obtained from two tons of the pupae[18,19]. The isolation of α-ecdysone corresponds to enrichment by a factor of 2×10^7 compared with its content in the initial biological material; the substance isolated in a pure form constitutes about 50% of the amount of hormones present in the initial material (according to biological assay). Only 2 mg of ecdysterone could be isolated from one ton of the crayfish *Jasus lalandei*[15]. Both the total content of zooecdysones and the relative amounts of the various components in their mixture depend on the insect species and the stage of development of the insect; for example, in some cases up to five individual active fractions were obtained[20].

The postembryonic development of insects is controlled by several hormones the interaction of which may be represented as follows[6]. Ecdysones (the moulting and metamorphosis hormones—MMH) are produced in the prothoracic gland of insects or in the analogous Y-organ of crustaceans. The secretion of ecdysones is controlled by the polypeptide ecdysiotropic hormone (ETH, also called the activating hormone), produced by the neurosecretory brain cells. Finally, the type of moulting induced by the MMH is determined by the Juvenile Hormone (JH), which is produced in the so called corpora allata). In the presence of the Juvenile Hormone larval moulting takes place and in its absence the metamorphosis of the larva to the pupa and of the pupa to the adult form (the imago). Ecdysones induce the moulting not only of insects but also of other classes of arthropods[21,22]. Probably steroids of this type already controlled the moulting of the common ancestors of anthropods in the Precambrian period (600 million years ago), i.e. ecdysones are the oldest steroid animal hormones. The MMH activity of ecdysones is determined in assays developed on various insects (see Karlson's review[23]). The most sensitive assay is on the housefly *Musca domestica*[24,25] and the simplest assay involves the rice pest *Chilo suppressalis*[26]. However, the commonest assay involves the blow-fly *Calliphora erythrocephala*[4,23,27]; the amount of ecdysones is sometimes expressed in "Calliphora units"—CE (1 CE $\simeq$ 0.01 μg of α-ecdysone, varying somewhat depending on the strain of the fly). One should bear in mind that the relative MMH activities of ecdysones found in various assays are different[28-30]. Biological control using assays of MMH activity proved particularly useful in the isolation of ecdysones from natural sources.

Ecdysones control physiological processes in insects associated with moulting and metamorphosis; their role in the formation of the puparium in the sclerotisation of the larval cuticle in the pupation process has been most thoroughly investigated. Ecdysones influence the carbohydrate, proteins, and nucleic acid metabolism[31-38]. The primary site of the action of ecdysones is the cell nucleus, more precisely its genetic material (see the relevant reviews[39-45]). Initially specific regulator genes are activated, then messenger RNA is synthesised, and finally proteins, in particular enzymes involved in the sclerotisation of the cuticle are synthesised. This mechanism of their action is satisfactorily consistent with the sequence of events in time. α-Ecdysone penetrates the cell nucleus 15–20 min after injection, causes the formation of chromosome "puffs" (i.e. gene activation) after 30–60 min, and increases the rate of synthesis of messenger RNA after 1–2 h, of microsomal RNA after 3–4 h, and of sclerotisition enzymes after 6–8 h.

The biosynthesis of zooecdysones in insects begins with cholesterol obtained from food (the insect organism is incapable of independent synthesis of steroids); the first step is dehydrogenation to 7-dehydrocholesterol[46-48]. Hydroxylation of the side chain apparently precedes the formation of the structural elements of the steroid skeleton; the C-25 and C-26 positions are hydroxylated faster than C-20.[49] α-Ecdysone is the precursor of ecdysterone in insects and crustaceans[50]. Zooecdysones are rapidly inactivated (cleaved) in insect tissues, the principal site

of their metabolism being the fat body [51-53]. The mechanism of the enzymatic cleavage of zooecdysones has not been established; it has only been shown that one of the first stages in the metabolism of ecdysterone may be the dissociation of their C-22–C-23 bond [54].

Numerous reports [55-63] on the isolation from plants of substances with MMH activity (phytoecdysones) appeared in 1966–1967. It has now been established that these substances are present in the fruit, leaves, bark, and roots of more than 100 plant species-mainly evergreen trees and ferns [64-67]; in higher fungi and algae compounds with MMH activity were not detected [56]. General methods have been developed for the extraction of total phytoecdysones from plants and for the chromatographic isolation of their individual components [68-70]. The content of phytoecdysones in plants depends on the species and the part of the plant; it usually exceeds by several powers of 10 the content of zooecdysones in crustaceans. For example, the amount of ecdysterone in the inflorescence of the saw-wort (*Serratula inermis*) can reach 2% of the dry weight [71].

The physiological role of phytoecdysones has not so far been elucidated. They may be the final products of the metabolism of sterols in plants or they can play a role in their growth and development (analogously to zooecdysones in insects). The hypothesis of the protective role of phytoecdysones in relation to insect plant pests [55,72] is apparently not confirmed by direct tests on their toxicity [73,74]. The biosynthesis of phytoecdysones in *Podocarpus* and *Taxus* species involves the usual sterol mechanism—via mevalonate and cholesterol, and their subsequent biochemical modification. The hydroxy-group at C-25 of the side chain is introduced after the hydroxy-groups at C-20 and C-22. [75-79]

Ecdysones exhibit physiological activity in relation to many groups of organisms. It has been reported that α-ecdysone accelerates plant growth [67,70] and induces the sexual cycle in protozoan symbionts of the insect *Cryptocercus* sp. [81] The effect of ecdysones on mammals is of special interest. In the first place both zooecdysones and phytoecdysones are fairly active anabolic agents (their activity is at the level of 4-chlorotestosteron) [82-87] and there are no toxic effects even after their prolonged administration [88]. The anabolic effect is probably associated with the mechanism of the action of ecdysones, which includes stimulation of protein synthesis; this is evidence that the transmission and counting processes in genetic information are common to insects and mammals. *In vitro* ecdysones inhibit the growth of sarcoma-180 cells and of embryonic fibroblasts [89,90], but they do not affect the growth of the Yoshida ascitic sarcoma [91]. α-Ecdysone shows virtually no hypocholesterolemic activity [92]. It should be remembered that human tissues do not exhibit MMH activity [93].

Three principal factors are of interest in the chemistry of ecdysones—the determination of their structures, their synthesis from other groups of steroids, and finally the relation between activity and structure and the preparation of structural analogues of ecdysones which maintain or enhance the type of physiological activity of practical importance to man.

II. THE STRUCTURE OF ECDYSONES

The study of the structure of ecdysones began in the 1950's with their isolation from insects in a crystalline state. The main obstacle in this work was the exceptionally low content of zooecdysones in biological material.

The structure of α-ecdysone was the first to be determined. X-Ray diffraction analysis and mass spectra made it possible to establish its empirical formula as $C_{27}H_{44}O_6$. [94] Dehydration of α-ecdysone (II) gave a low yield of the so called "Diels hydrocarbon" (I), which demonstrates the presence of the steroid skeleton in (II).

Table 1. Proton signals in the NMR spectrum of α-ecdysone (in C_5D_5N). [94]

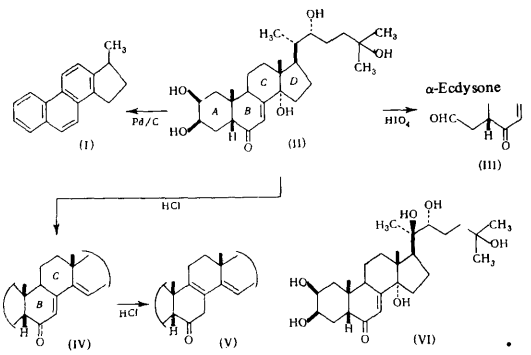
δ, p.p.m.	No. of protons	Functional groups
0.70	3	>C—CH_3 (angular methyl group)
1.05	3	>C—CH_3 (angular methyl group)
1.19	3	R>CH—CH_3 (doublet)
1.30		R>C(OH)—
1.38	6	R—$C(CH_3)_2$
1.92	21	CH and —CH_2—
4.18	1+2	HO— and HC<
5.75	4	HO
6.31	1	R—CO—CH=C(R)R
	44	

NMR spectroscopy proved to be particularly useful in the determination of the structure of α-ecdysone (Table 1) [94]—it made it possible to assign all 44 protons in the molecule to particular groups. The two angular methyl groups, the presence of which constitutes additional proof of the steroid structure of α-ecdysone, have the lowest chemical shifts. The third methyl group linked to a CH group, was assigned to the side chain (C-21). The two terminal methyl groups of the side chain were not found at a CH group as would be expected for a cholesterol derivative but at quaternary carbon atoms (six-proton singlet with δ = 1.38 p.p.m.). Hence it was concluded that, together with the two methyl groups, at C-25 there is also a hydroxy-group (if the methyl group were located at a double bond, the resonance signal would be observed at higher values of δ). This hydroxy-group gives rise to a hydroxyl proton signal at 4.18 p.p.m. In the NMR spectrum of α-ecdysone there is also a single signal corresponding to an olefinic proton (6.31 p.p.m.). It is suggested that this proton forms part of the structural element $RCOCH{=}CR_2$. The presence of a keto-group conjugated with a double bond in the α-ecdysone molecule is also confirmed by the ultraviolet ($\lambda_{max}^{CH_3OH}$ = 242 nm) and infrared (ν = 1657 cm^{-1}) spectra. The high degree of substitution of this group follows from the failure of its catalytic hydrogenation over palladium or platinum even under severe conditions [95]. The position of the $\alpha\beta$-unsaturated keto-groups in the ring system was established by comparing the spectra of a large number of model steroids [96] and by investigating their colour reactions [97]. These data led to the conclusion that the α-ecdysone molecule contains Δ^7-6-oxo-groups; this was confirmed in a study of the reactions of α-ecdysone under the influence of acids. When α-ecdysone is treated with HCl in

ethanol, a derivative with λ_{max} = 293 nm is formed initially and is then converted into a product with λ_{max} = 244 nm. These data were interpreted as indicating the initial dehydration of the readily eliminated tertiary 14-hydroxy-group with formation of a doubly unsaturated ketone (IV), which, as a result of the steric strain of the B ring, gradually isomerises to the unconjugated dienone (V).[95] These reactions also establish the position of the hydroxy-group at C-14; thus, of the six oxygen atoms in the α-ecdysone molecules, the positions of three were identified.

The ready cleavage of α-ecdysone by periodate to the corresponding dialdehyde (III)[95] demonstrates the presence in its molecule of a vicinal glycol group. The absence of volatile cleavage products in this oxidation indicates that the glycol group is in a steroid ring and not in a side chain. Biogenetic data suggest that one of the glycol hydroxy-groups is at C-3, as in all other natural steroids; then the second hydroxy-group can be at C-2 or C-4. The lack of similarity between model 3,4-diols and α-ecdysone[98] permits a choice in favour of a 2,3-diol. The position of the last hydroxy-group was established by studying the mass spectrum of α-ecdysone[94,95]. This yielded very intense peaks with m/e = 81 ($C_6H_9^+$) and m/e corresponding to $C_6H_{11}O^+$. Such fragments can be split off only from a side chain of the steroid molecule with dissociation of the C-20–C-22 bond, which establishes the location of the remaining hydroxy-group at C-22.

The final proof of the structure of α-ecdysone (II) was obtained by X-ray diffraction analysis, which confirmed all the conclusions arrived at above on the basis of chemical and spectroscopic data and in addition made it possible to establish the configuration of the hydroxy-groups in the steroid skeleton and in the side chain (2β-, 3β-, 14α-, 22R-) and the *cis*-junction of the A and B rings[99,100]:



Another representative of the group of ecdysones isolated from various natural sources[101,102] is ecdysterone (VI), which has one hydroxy-group more than α-ecdysone (II). Since according to the mass spectrum both hormones are identical up to C-19 and beyond C-22, this hydroxy-group can be located only at C-20. Comparison of the NMR spectra of ecdysterone and α-ecdysone leads to the same conclusion. The signals of the protons in the methyl groups at C-18 and C-21 in ecdysterone are displaced by 0.3–0.4 p.p.m. towards lower field compared with the analogous signals in the spectrum of α-ecdysone. Such changes are characteristic when a 20-hydroxy-group is introduced into a steroid molecule; this was confirmed by a comparative study of the NMR spectra of model compounds. The chemical properties and infrared and ultraviolet spectra of ecdysterone confirm the assignment of formula (VI).[103,104] On the basis of data for the interconversions of ecdysones in living organisms and the mode of their synthetic reactions, the 20*R*,22*R*-configuration of the hydroxy-groups in the side chain has been assigned to the majority of ecdysones, although it cannot be regarded as finally proved.

The structures of more than 30 zooecdysones and phytoecdysones have now been determined (Table 2). The elucidation of their structures is significantly aided by the knowledge of the structures of α-ecdysone (II) and ecdysterone (VI). Therefore in the determination of the structures of newly isolated ecdysones their structural similarity to (II) and (VI) is established on the basis of the infrared and ultraviolet spectra with the study of chemical reactions reduced to a minimum (usually only with HCl and HIO_4). The structural details are determined

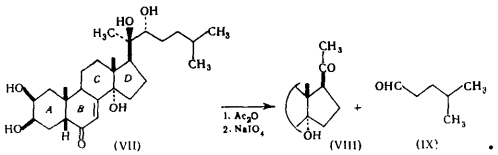
*See Section III.

from the mass spectra, which yield information primarily about the structure of the side chain [105], and from NMR spectra, which in addition give information about the positions and configurations of the hydroxy-groups in the steroid skeleton†. A striking example is provided by the determination of the structure of the phytoecdysone ponasterone A. [107,109,110]. Apart from the corresponding

†It should be noted that such neglect of chemical methods for structural determinations can lead to significant errors. For example, a 2α,3α-configuration of the hydroxy-groups in the A ring of ponasterone C was assigned on the basis of spectroscopic studies [106,107]. A more careful reinvestigation [108] made it necessary to invert this configuration to 2β,3β- and moreover led to the detection in the ponasterone C molecule of an additional 5β-hydroxy-group, the presence of which had been overlooked as a result of the incorrect interpretation of the mass spectrum.

biological activity, its classification as an ecdysone is demonstrated also by ultraviolet and infrared spectra, which are similar to those of ecdysterone. Ponasterone A ($C_{27}H_{44}O_6$) has six oxygen-containing groups, one of which is part of the $\alpha\beta$-unsaturated ketone group (ultraviolet and infrared spectra and NMR signal of the olefinic proton at 6.17 p.p.m.). The formation of a diacetamide indicates the presence of four hydroxy groups in two vicinal diol groups; this is also confirmed by oxidation with $NaIO_4$, which involves the consumption of two moles of the oxidant. The location of the fifth hydroxy-group at C-14 follows (by analogy with α-ecdysone) from the successive formation of compounds with λ_{max} = 294 and 241 nm when ponasterone A is treated with HCl and its 14α-configuration follows from a comparison of the chemical shifts of the protons in the methyl groups at C-18 and C-19 in the NMR spectra of ponasterone A and ecdysterone. Ponasterone A readily forms a triacetate; the NMR spectrum of the latter ($CDCl_3$) has signals at 4.82, 5.05, and 5.32 p.p.m., which can be attributed to three carbonyl protons at C-22, C-2, and C-3. Therefore three hydroxy-groups are secondary and the remaining two are tertiary. Moreover, in the NMR spectrum of ponasterone A there is a doublet at 0.82 p.p.m. corresponding to the methyl groups at C-26 and C-27, which demonstrates the absence of a hydroxy-group at C-25 (in the spectra of α-ecdysone and ecdysterone these signals are at 1.38 and 1.34 p.p.m. respectively). Comparison of the signals due to the protons at C-18, C-19, and C-21 (at 1.16, 1.03, and 1.51 p.p.m. in ponasterone A and at 1.19, 1.06, and 1.55 p.p.m. in ecdysterone) leads to the conclusion that the corresponding methyl groups have the same environment and to the assignment of formula (VII) to ponasterone A. The formula is confirmed by the results of the oxidation of ponasterone A 2-monoacetate by $NaIO_4$ which results in the formation of the 20-ketone (VIII).[107] The identity of this ketone with the product of the analogous oxidation of ecdysterone and the intermediate in the partial synthesis of α-ecdysone [111,112] demonstrates unambiguously that the tetracyclic structures of all three ecdysones are the same up to C-21. The structure of the side chain of ponasterone A is confirmed by the isolation of isohexanal (IX) in oxidation with $NaIO_4$ and also by the presence in the mass spectrum of an intense peak with m/e = 83 corresponding to the $C_6H_{11}^+$ fragment formed on dissociation of the C-20–C-22 bond [107]. It should be noted that the structures of α-ecdysone, ecdysterone, ponasterone A, and also rubrosterone have been demonstrated by their synthesis (see section III).



(VII) (VIII) (IX)

Other physicochemical research methods have proved very helpful in the determination of the structure of ecdysones. The optical rotatary dispersion (ORD) curves are used mainly to determine the type of junction between A and B rings. The Δ^7-6-oxo-group of ecdysones exhibits a Cotton effect at about 240 nm ($\pi \rightarrow \pi^*$ transition) and at about 340 nm ($n \rightarrow \pi^*$ transition). In both cases the amplitude for the *trans*-A/B isomers is much higher than for the *cis*-A/B isomers [102,106,107,109,113]. Apart from the amplitudes, there is a significant difference (by 8–10 nm) between the positions of the peaks in the ORD curves for the *cis*- and *trans*-isomers. Thus in the region of the $n \rightarrow \pi^*$ transition natural α-ecdysone has peaks at 377 and 361 nm, while its *trans*-A/B isomer has peaks at 366 and 351 nm.[114]

The circular dichroism (CD) curves also show a shift of the maximum by 7–8 nm towards longer wavelengths on passing from the *trans*- to the *cis*-A/B junction[114]. A similar shift is observed when a 5β-H atom in the ecdysone molecule is replaced by a 5β-hydroxy-group, which makes it possible to determine the position of the latter [108,115]. The CD curves for the α-glycol dibenzoates of the ecdysone series have been used to determine their chirality in the elucidation of the structures of ponasterones A–C, polypodine B, and ajugasterone [108,116,117]. The use of the fluorescence spectra of ecdysterone and inokosterone for the analysis of a mixture of these compounds, which occur together in many plants, is also noteworthy [118].

The names and formulae of the ecdysones known at the present time are given in Table 2. According to the number of carbon atoms in the molecule they can be divided into four groups 19C-, 27C-, 28C-, and 29C-ecdysones. Phytoecdysones belonging to all four groups have been found, but zooecdysones occur only in the second group (with the sole exception of callinecdysone B, which apparently has 28 carbon atoms). The majority of ecdysones have the same characteristic set of substituents in the steroid skeleton: 2β, 3β, 14α-hydroxy-groups, a Δ^7-6-oxo-group, and a *cis*-A/B junction. The side chain always contains (except in rubrosterone which has no side chain) a hydroxy-group at C-22 and frequently at C-20; in certain cases oxygen-containing substituents occur at C-24, C-25, C-26, C-28, or C-29 carbon atoms of the side chain. Thus not only the MMH activity but also the common features of the chemical structures of the known ecdysones justify their classification as a special group of natural compounds.

The deviations from the above typical structure are comparatively small. Polypodine B, ponasterone C, and sengosterone have an additional 5β-hydroxy-group and ajugasterone C an 11α-hydroxy-group. The 2α,3α-configuration of the hydroxy-groups in the A-ring of ponasterone B has been demonstrated, instead of the 2β, 3β-configuration characteristic of the remaining ecdysones, and shidasterone apparently has a 14β- and not a 14α-hydroxy-group. In cheilanthones A and B there is no Δ^7-linkage and podecdysone B has a $\Delta^{8(9),14}$-diene system, which may be formed during its isolation as a result of the scission of the 14α-group.

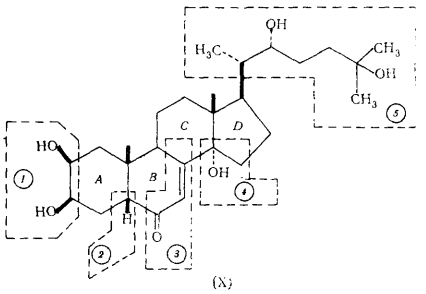
In natural sources so far only two ecdysone derivatives substituted at a hydroxy-group have been found—viticosterone E (ecdysterone 25-acetate) and ponasteroside A (ponasterone A 3β-glyucoside).

III. SYNTHESIS OF ECDYSONES

The synthesis of ecdysones, which was achieved almost immediately after the determination of their structure, is evidence of a high level of development and considerable

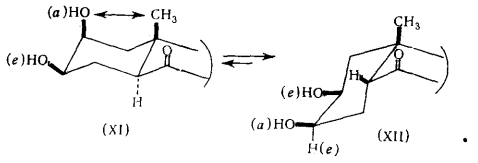
advances in steroid chemistry. Several groups of investigators have now developed four schemes for the partial synthesis of ecdysones (X). Unfortunately none of the investigators quote the yields in all the stages, which precludes an exact quantitative comparison of the effectiveness of these schemes.

In the ecdysone (X) molecule it is possible to isolate five principal structural elements, which distinguish this group of natural compounds from other steroids. These are the vicinal 2β,3β-diol group in the A ring (1), the 5β-hydrogen atom between the A and B rings (2), the Δ^7-6-oxo-group in the B ring (3), the 14α-hydroxy-group between the C and D rings (4), and finally the side chain in the 17β-position of the D ring (5).



(X)

These structural elements are introduced by various methods depending on the structure of the initial compound. For example, the 2β,3β-diol group is introduced into Δ^2-compounds by the *cis*-hydroxylation of the double bond and into 3-oxo-5α-steroids either by bromination in the 2α-position with subsequent replacement of bromine by a 2β-acetoxy-group (with silver acetate) or by auto-oxidation in an alkaline medium and subsequent reduction of the resulting 2,3-diketone with $NaBH_4$.[153] The Δ^7-bond is as rule introduced on bromination–dehydrobromination of 6-oxosteroids, but the Δ^7-6-oxo-group can be formed also directly by the oxidation of $\Delta^{5,7}$-steroids[154,155]. The 14α-hydroxy-group is likewise introduced into the molecule by several methods. The most common is the allylic oxidation of Δ^7-6-oxosteroids with SeO_2.[156] The pathway via the formation of enol acetates of these compounds with subsequent oxidation by peracids is also used[157]. Finally, microbiological hydroxylation[158] and photochemical oxidation of $\Delta^{8(14)}$-6-oxosteroids for this purpose have been described[159,160]. The reaction of steroid 20-ketones or 22-aldehydes with lithium or magnesium derivatives of the corresponding acetylene alcohols containing all the necessary substituents serves as the usual method for the introduction of the side chain. The problem of ensuring the 5β-configuration, i.e. the *cis*-junction of the A and B rings merits special attention. In the usual 6-oxosteroids the 5α-isomer is much more stable than the 5β-isomer[161]. However, in 2β,3β-dihydroxy-6-oxosteroids, specific examples of which are ecdysones, the *meta*-diaxial interaction between the 2β-hydroxy-group and the methyl at C-19 in the 5α-isomer (XI) lowers its stability compared with the 5β-isomer (XII), where such interaction is absent. Therefore the 5β-isomer predominates in the equilibrium mixture [the ratio 5β : 5α = (2 – 4) : 1, depending on the structure of the steroid]; this fact is used in the synthesis of ecdysones from 5α-steroids.



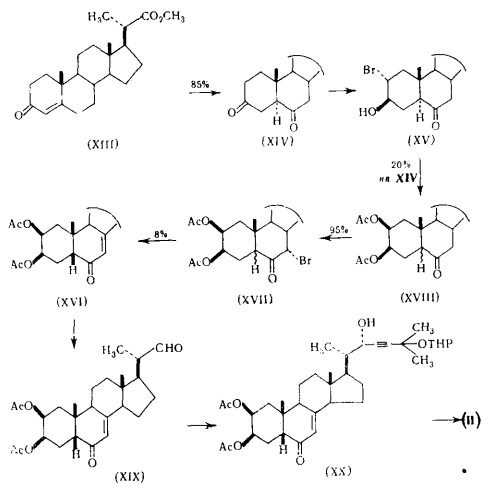
(XI) (XII)

The schemes for the synthesis of ecdysones which have not been developed differ not only in the types of reactions used to introduce various structural elements but also in the order of their introduction. In considering them particular attention must be paid to the syntheses of α-ecdysone, since these were in fact used to develop the main synthetic procedures. The syntheses of ecdysterone usually differ only in the methods of introduction of the side chain and the syntheses of rubrosterone, a metabolite of active ecdysone, are not usually of independent importance‡. In addition plants constitute a rich source of the last two ecdysones, whereas the requirements for α-ecdysone are mainly satisfied by the synthetic product.

In 1966 a group of Swiss chemists described a partial synthesis of α-ecdysone (II) in which the structural elements [see formula (X)] were introduced according to the scheme *1* → *3* → *2* → *4* → *5*.[163–167] The initial compound in this synthesis is the methyl ester of bisnorcholenoic acid (XIII) obtained from ergosterol or stigmasterol. The formation of ethyleneketal, the epoxidation of the Δ^5-bond with peracetic acid to a mixture of 5ξ,6ξ-epoxides, and the isomerisation of this mixture under the influence of perchloric acid led to the 3,6-diketone (XIV). The bromination and selective reduction of the 3-oxo-group with $LiAl(t\text{-}C_4H_9O)_3H$ yielded the 2α-bromo-3β-hydroxy-compound (XV), the acetylation of which and the replacement of bromine by an acetoxy-group led to a mixture of the 2β,3β-diacetates (XVIII) epimeric at C-5. The Δ^7-bond was introduced by bromination under acid conditions; the mixture of 5- and 7-bromoketones formed initially isomerises to the 7α-bromo-derivative (XVII). The elimination of HBr from the latter yields the Δ^7-6-oxo-compound, which is also a mixture of isomers at C-5. Alkaline isomerisation at the C-5 centre is accompanied in this case by epimerisation also at the C-20 centre and the shifte of the Δ^7-bond to the $\Delta^{8(14)}$-position; therefore halogenolysis (LiI in boiling lutidine) was employed to obtain the 5β-isomer (XVI). The 22-methoxycarbonyl group of compound (XVI) was reduced to the corresponding aldehyde (XIX) by allowing $LiAl(t\text{-}C_4H_9O)_3H$ to react with the carbonyldi-imidazole derivative. The side chain was introduced by a Grignard reaction with the MgBr derivative of the tetrahydropyranyl (THP; C_4H_9O) ether of 2-methylbut-3-yn-2-ol. This reaction yielded a mixture of the required 22*R*-isomer (XX) and the corresponding 22*S*-derivatives, which were separated by chromatography on silica and were treated separately. Catalytic hydrogenation of the triple bond in the side chain, the introduction of the 14α-group by the action of SeO_2 in dioxan, and acid hydrolysis of the

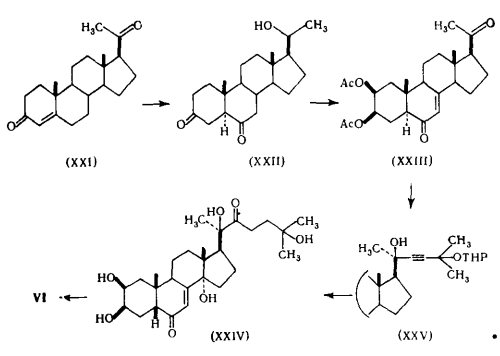
‡A novel synthesis of rubrosterone via *i*-steroids was developed recently[162], but it has not been extended to active ecdysones.

protecting groups (acetate, THP ether) yielded α-ecdysone (II). Analogous treatment of the 22*S*-epimer (XX) made it possible to obtain 22-iso-α-ecdysone. Rubrosterone was synthesised according to the same scheme [168].



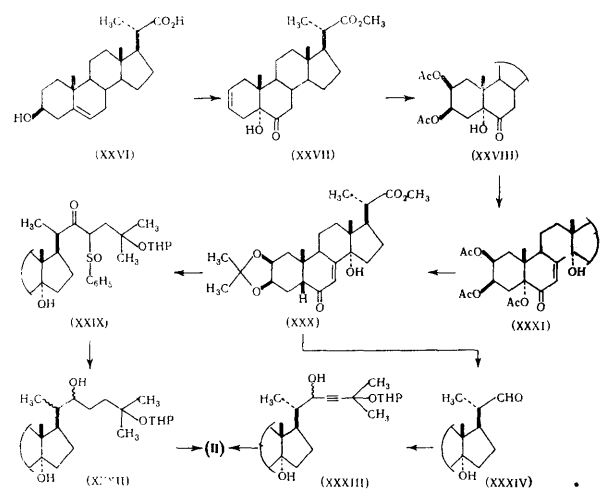
The chief disadvantage of the above method of synthesis is a low yield in the (XVII) → (XVI) isomerisation stage. Therefore in the synthesis of ecdysterone by the same group of investigators the formation of the 5β-configuration was transferred to the end of the synthesis and was combined with the alkaline hydrolysis of the protecting groups.

Ecdysterone (VI) was synthesised according to the following scheme [169]. The 3,6-diketone (XXII) obtained in four stages from progesterone (XXI) as in the synthesis of α-ecdysone [the (XIV) → (XV) → (XVIII) → (XVII) → (XVI) transition], was converted in seven stages into the intermediate (XXIII) containing the 2β,3β-diol and Δ⁷-6-oxo-groups. The side chain was introduced into this compound by the reaction with the MgBr derivative of the THP ether of 2-methylpent-4-yn-2-ol.



This yielded a 4 : 1 mixture of the 20*R*-isomer (XXV) and the 20*S*-isomer. The oxygen-containing substituent at C-22 was introduced by the catalytic hydration of the triple bond in the side chain [in the presence of $Hg(OAc)_2$]. The subsequent introduction of the 14α-hydroxy-group by oxidation with SeO_2 and alkaline hydrolysis of the protecting groups, accompanied by inversion at C-5 led to compounds (XXIV), which differs from ecdysterone (VI) only by the presence of an oxo-group at C-22. The reduction of this oxo-group with $LiAl(t\text{-}C_4H_9O)_3H$ led to a mixture of natural ecdysterone (VI) and its 22-isomer, which were separated chromatographically. Direct catalytic hydrogenation of compound (XXV) with subsequent treatment according to the above scheme made it possible to obtain 22-deoxy-ecdysterone, which is used in the study of the biosynthesis of ecdysterone [170,171].

Another synthesis of α-ecdysone and ecdysterone according to the *1* → *3* → *4* → *2* → *5* scheme was proposed in 1966 by a group of chemists in the USA. [172-175] The synthesis began with a derivative of bisnorcholenoic acid (XXVI), which was converted by acetylation and treatment with diazomethane into the 3-acetate of the methyl ester. Hydroxylation of the latter and the Δ^5-bond, hydrolysis of the 3-acetoxy-group, oxidation at C-6 with *N*-bromosuccinimide, tosylation, and the elimination of TsOH by treatment with Li_2CO_3 led to compound (XXVII) with an overall yield up to 50% with respect to the initial acid (XXVI). *Cis*-hydroxylation of the Δ^2-bond with silver acetate and molecular iodine in acetic acid and subsequent acetylation gave compound (XXVIII), in which a Δ^7-bond was introduced by bromination in an acid medium and subsequent elimination of HBr by treatment with Li_2CO_3. The acid-catalysed acetylation of the tertiary 5α-hydroxy-group and the introduction of the 14α-hydroxy-group by allylic oxidation with SeO_2 yielded compound (XXXI), which already contains three fragments of the α-ecdysone structure. The introduction of the next fragment (a 5β-hydrogen atom) was achieved in four stages. The 5α-acetoxy-group was removed by reduction with $CrCl_2$; next the alkaline hydrolysis of the 2,3-diacetate was carried out, the diol group was protected by the formation of an acetonide, and finally isomerisation at C-5 by heating with an aqueous-methanolic solution of potassium carbonate gave a 1 : 3 mixture of the 5α- and 5β-isomers. The pure 5β-isomer (XXX) was isolated from this mixture by chromatography on silica.

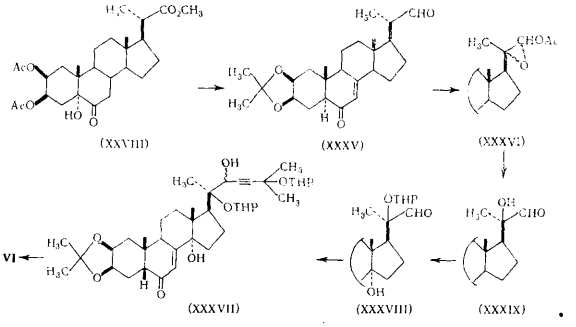


The introduction of the side chain characteristic of α-ecdysone into compound (XXX) was achieved by two methods. In the first version [173] the 6-oxo-group was reduced with $LiAl(t\text{-}C_4H_9O)_3H$ to a mixture of 6α- and 6β-hydroxy-derivatives; its alkylation at C-22 with the

lithium salt of the THP ether of 2-methyl-4-sulphoxyphenylbutan-2-ol by the method of Corey and Chaykowsky[176] led to compound (XXIX). Hydrogenolysis of the sulphoxyphenyl group of this compound with aluminium amalgam and reduction of the 22-oxo-group with $LiAlH_4$ (the 6-oxo-group is reduced at the same time) gave the 22-hydroxy-derivative (XXXII), which is a mixture of epimers at C-20 and C-22. Resynthesis of the 6-oxo-group by oxidising this mixture with MnO_2 (only the allylic 6ξ-hydroxy-group is affected) and hydrolysis of the protecting groups with dilute HCl led to a mixture of the corresponding isomers of α-ecdysone, from which the natural hormone (II) was isolated in 12% yield with respect to compound (XXX) by chromatography on silica.

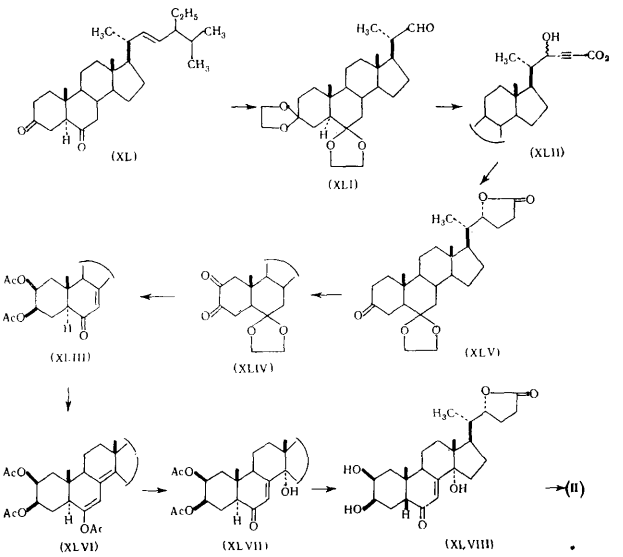
The inadequate stereospecificity of this synthesis made necessary a modification in which the introduction of the side chain into compound (XXX) does not involve isomerisation at the C-20 centre[11]. The methyl ester (XXX) was converted into the aldehyde (XXXIV) by a fairly complex procedure. Reduction of the 6-oxo-group with $LiAl(t\text{-}C_4H_9O)_3H$, reduction of the 22-carboxymethyl group with $LiAlH_4$, and resynthesis of the 6-ketone by oxidation with MnO_2 made it possible to obtain from (XXX) the corresponding 22-hydroxy-derivative. Its oxidation to the aldehyde (XXXIV) was achieved by treatment with dicyclohexylcarbodi-imide in dimethyl sulphoxide in the presence of trifluoroacetic acid as a catalyst[177]. The reaction of the aldehyde (XXXIV) with the lithium derivative of the THP ether of 2-methylbut-3-yn-2-ol gave a mixture of 22-hydroxy-compounds (XXXIII) epimeric at C-22. Its separation by preparative thin-layer chromatography on silica, catalytic hydrogenation of the triple bond, and hydrolysis of the protecting groups yielded α-ecdysone (II) and 22-iso-α-ecdysone.

The synthesis of ecdysterone (VI) was achieved by a similar scheme[178,179]. The starting material in this synthesis is compound (XXVIII), already described, which was converted in eight stages into the 22-aldehyde (XXXV) [similarly to the conversion (XXVIII) → (XXXI) → (XXX) → → (XXXIV) in the synthesis of α-ecdysone by the method of the same group of investigators]. Acetylation of the enol of the aldehyde (XXXV) and oxidation of the resulting enol acetate with *m*-chloroperbenzoic acid gave a mixture of isomers of the 20ξ,22ξ-epoxide (XXXVI). Its hydrolysis with $KHCO_3$ in aqueous methanol yielded the 20*R*-hydroxy-22-aldehyde (XXXIX) and its 20*S*-isomer in proportions of 5 : 3; the isomers could be separated by chromatography on silica. Protection of the 20-hydroxy-group by the THP ether and the introduction of the 14α-hydroxy-group by oxidation with SeO_2 led to compound (XXXVIII), which was used directly to introduce the side chain. Reaction with the MgCl derivative of the THP ether of 2-methylbut-3-yn-2-ol and its isomerisation at C-5 (K_2CO_3–H_2O–CH_3OH) led to compound (XXXVII) (in $5\alpha : 5\beta = 1 : 3$ equilibrium mixture). Finally, catalytic hydrogenation of the triple bond in the side chain (5% Pd/C)§ and hydrolysis of the protecting groups with dilute HCl gave ecdysterone (VI). An advantage of this method of synthesis of ecdysones is the use of the convenient procedure for the introduction of the 2β,3β-diol group by the *cis*-hydroxylation of the Δ^2-bond; the disadvantages include primarily the unsatisfactory choice of bisnorcholanoic acids as starting materials (in view of the laborious nature of the method of their conversion into the 22-aldehydes selected by the authors).



(XXVIII) (XXXV) (XXXVI) (XXXVII) (XXXVIII) (XXXIX)

The third method of synthesis of ecdysones according to the scheme *5a* → *1* → *3* → *4* → *2* → *5b* (the side chain is built up in two stages) was published in 1967–1968 by a group of Japanese chemists. The starting material for the synthesis of α-ecdysone[181] was the 3,6-diketone (XL) obtained from stigmasterol and converted by ketalisation, ozonolysis, and the reduction of the ozonide with zinc dust in acetic acid into the diketal of the 22-aldehyde (XLI). Partial synthesis of the side chain was achieved through the introduction of the ethynyl group by reaction with BrMgC≡CH and subsequent reaction of the MgBr derivative of the resulting ethynylmethanol with carbon dioxide. Catalytic hydrogenation and acid hydrolysis of the acetylenic hydroxyacid (XLII) gave a mixture of 3,6-diketones epimeric at C-22, in which the required 22*R*-isomer predominated. Selective reduction of the 3-oxo-group with $NaBH_4$, ketalisation of the 6-oxo-group, and oxidation of the 3-hydroxy-group to the 3-ketone by the CrO_3 complex of pyridine resulted in the 6-monoketal (XLV) required for further synthesis. Auto-oxidation of this compound in the presence of $t\text{-}C_4H_9OK$ gave an oily mixture of the two possible enolic forms of the 2,3-diketone (XLIV). Reduction of this mixture with $NaBH_4$ and subsequent chromatographic separation made it possible to isolate the 2β,3β-diol, which was converted into the corresponding diacetate.



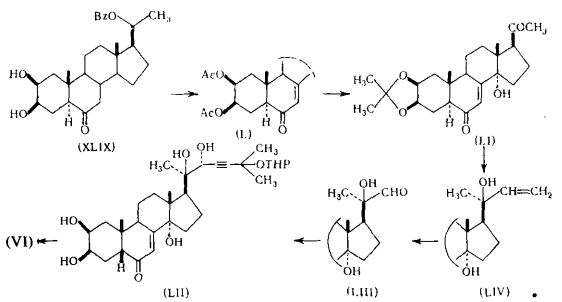
(XL) (XLI) (XLII) (XLIII) (XLIV) (XLV) (XLVI) (XLVII) (XLVIII) (II)

§The hydrogenation is also accompanied by the hydrogenolysis of the 25-hydroxy-group and the 25 deoxy-derivative of ecdysterone (ponasterone A) is formed as a side product[180].

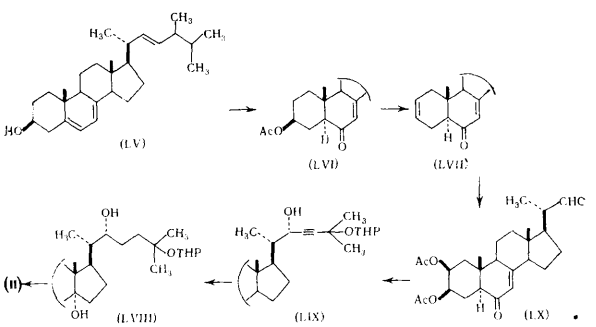
Bromination at C-7 with subsequent dehydrobromination by treatment with Li_2CO_3 yielded the Δ^7-6-oxosteroid (XLIII). The 14α-hydroxy-group was introduced into the latter by conversion into the enol acetate (XLVI) (acetic anhydride and perchloric acid) and its oxidation with monoperphthalic acid. The acetate groups in the resulting product (XLVII) were hydrolysed on heating under mild alkaline conditions (K_2CO_3–H_2O–CH_3OH) and there was inversion at C-5 with formation of compound (XLVIII). For conversion into α-ecdysone (II), this compound required only the attachment of the side chain, which was achieved by a Grignard reaction via the lactone group with a large excess of CH_3MgBr. 22-iso-α-ecdysone was synthesised according to a similar scheme from the 22*S*-lactone, which is isomeric with compound (XLV).[182] The scheme for the synthesis of the ecdysone nucleus described in the above studies has also been applied in the synthesis of rubrosterone[183].

The synthesis of ecdysterone (VI) by the same group of investigators[184] begins with pregnenolone, which was converted in nine stages into compound (XLIX) (the introduction of the 2β,3β-diol group was achieved via the 3,6-diketone, as in the synthesis of α-ecdysone[35]). Acetylation, bromination, and dehydrobromination made it possible to obtain from (XLIX) the Δ^7-6-oxosteroid (V) into which the 14α-hydroxy-group was introduced by oxidation of the enol acetate with monoperphthalic acid. Alkaline isomerisation at C-5, protection of the diol group in the A ring by the formation of an acetonide, and oxidation at C-20 with the CrO_3–pyridine complex yielded the 20-ketone (LI), which has all the structural elements of ecdysterone except for the side chain. The latter was built up in five stages. The Normant reaction and the corresponding ozonolysis of the resulting vinylmethanol (LIV) gave the aldehyde (LIII), which was introduced into a Grignard reaction with the MgBr derivative of the THP ether of 2-methylbut-3-yn-2-ol, forming compound (LII). Hydrogenation of the triple bond, hydrolysis of the protecting groups, and chromatographic separation of the C-22 isomers formed yielded ecdysterone (VI), which was identical with the natural hormone.

The third scheme for the synthesis of ecdysones described above begins directly with 22-aldehydes, which facilitates the introduction of the side chain. Its principal disadvantage is the large number of stages involved in the introduction of the 2,3-diol group and the side chain.



The synthesis of α-ecdysone (II) from ergosterol (LV) with introduction of the structural elements according to the scheme *3 → 1 → 5 → 4 → 2* developed by Swiss chemists is free from the majority of the disadvantages of the schemes for the synthesis of ecdysones discussed above[154,155]. Oxidation of ergosteryl acetate with CrO_3 gives the 5α-hydroxy-6-oxo-derivative, which on reduction with zinc dust in acetic acid is converted into compound (LVI) in which the Δ^7-6-oxo-structure is already formed[185]. Further synthesis was performed via several pathways, of which only one proved to be successful. The two-stage substitution of the 3β-acetoxy-group in compound (LVI) by the 3β-methanesulphonyloxy-group with subsequent cleavage of the methanesulphonate with Li_2CO_3 gave the Δ^2-steroid (LVII). *cis*-Hydroxylation of the Δ^2-bond (silver acetate and iodine), protection of the resulting 2β,3β-diol group by formation of the diacetate, and ozolysis under controlled conditions resulted in the stereospecific formation (without inversion at C-20) of the 22-aldehyde (LX). Treatment of this aldehyde by the Grignard reagent obtained from the THP derivative of 2-methylbut-3-yn-2-ol led to a mixture of isomeric 22ξ-hydroxy-derivatives in which the required 22*R*-component (LIX) predominated; the mixture was separated by chromatography on silica. Catalytic reduction of the triple bond in the C-23–C-24 position¶ and subsequent introduction of the 14α-hydroxy-group by treatment with SeO_2 yielded compound (LVIII). Isomerisation at C-5 and hydrolysis of the acetoxy-groups under mild alkaline conditions (K_2CO_3–H_2O–CH_3OH) gave the corresponding 2β,3β-diol with the *cis*-junction of the A and B rings and hydrolysis of the THP group with dilute HCl yielded α-ecdysone (II). The above scheme constitutes the simplest procedure for the synthesis of ecdysones: the conversion of ergosterol (LV) into α-ecdysone (II) requires 14 stages in this scheme. The yield of compound (LVIII) is 0.063% with respect to ergosterol[155] (the yields in the last two stages are not indicated).



In the other versions of this scheme for the synthesis of α-ecdysone, the order of introduction of the principal structural elements of the molecule was altered[155]. For example, an attempt was made to achieve the isomerisation at C-5 already in the stage of the 2β,3β-diol obtained by the hydroxylation of the Δ^2-steroid (LVII); however, this involves also isomerisation at C-14 to the *cis*-C/D derivative. Evidently, before isomerisation at C-5 it is necessary to protect the C-14 position by introducing a 14α-hydroxy-group into the molecule. At the same time

¶The use of tritium instead of hydrogen in the hydrogenation of compound (LIX) (and other intermediates with a triple bond in the side chain obtained by other procedures) leads to α-ecdysone and its 25 deoxy-derivative (formed as a side product), labelled with tritium at C-23 and C-24; these compounds have been used in biological studies[49,180].

the introduction of this group before constructing the side chain caused an undesirable alteration in the stereochemistry of the Grignard reaction: the 14α-hydroxy-analogue of the aldehyde (LX) gave rise only to the 22*S*-isomer, which was converted in two stages as in the synthesis described above, into 22-iso-α-ecdysone. Thus in this case it is necessary to introduce initially the side chain into the molecule, then the 14α-hydroxy-group, and the isomerisation at C-5 must be carried out only in the last stage (i.e. the structural fragments must be introduced according to the scheme *5* → *4* → *2*). This is evidence of a considerable importance of the correct choice of the sequence of stages in the synthesis.

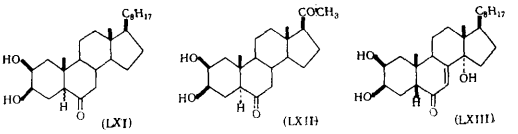
IV. ANALOGUES OF ECDYSONES

The study of analogues of ecdysones is of great practical importance, since these substances, which act as insecticides and chemosterilants, make it possible to control the numbers of insect pests. In the first place it is necessary to examine the effect of the structure of ecdysones on their MMH activity, which permits the elucidation of the relative importance of various structural elements of the molecule for its biological activity.

At the present time, the role of the hydroxy-groups in the steroid skeleton and in the side chain of ecdysones has been mainly investigated. The importance of the hydroxy-groups in the A ring of the ecdysone molecule can be assessed from the following facts: while the activity of 2-deoxyecdysterone, which has a 3β-hydroxy-group, is equal to that of ecdysterone [124], its 3α-epimer is three times less active [186]. Thus the hydroxy-group at C-2 is of no importance for MMH activity, while the presence of the hydroxy-group at C-3 and its equatorial configuration play a significant role. The importance of the 14α-hydroxy-group is even greater, its removal lowering the activity by a factor of 15 compared with α-ecdysone [187]. The introduction of an additional 5β-hydroxy-group into the molecule (polypodine B) greatly increases the MMH activity [128].

The presence in the steroid molecule of a long side chain at C-17 is necessary for MMH activity, since rubrosterone and its analogue with an acetyl side chain (VIII) do not show this activity [112, 120]. The complete absence of a hydroxy-group from the side chain also sharply reduces the activity (by a factor of 50 compared with α-ecdysone [187]). The removal or isomerisation of the 22*R*-hydroxy-group leads to a sharp fall or complete disappearance of MMH activity [111,155,170]; the introduction of an additional 26-hydroxy-group has the same consequences [126]. On the other hand, an additional 24-hydroxy-group or a Δ^{24}-bond do not have a significant effect on the activity, while a 20*R*-hydroxy-group increases it somewhat [134,135]. The presence of an ethyl-group at C-24 in 29C-ecdysones does not affect the activity [139,149]; nor is the activity reduced in the presence in the side chain of lactone groups (capitasterone, cyasterone) [113,148]. At the same time an epoxy-group in the side chain (stachysterone D) virtually eliminates the MMH activity of the compound [135].

Many synthetic analogues of ecdysones can inhibit the moulting and metamorphosis in the development of insects (i.e. they can act as ecdysone antagonists); also they can have a general toxic effect on adult forms. The toxic effect of ecdysone analogues—derivatives of androstane, pregnane, and cholestane—was investigated on the bug *Pyrrocoris apterus* [188-190] and certain other insects [174]. Compounds (LXI)-(LXIII) proved to be the most active.



(LXI) (LXII) (LXIII)

Compounds with a low MMH activity are the most toxic for insects and conversely. The presence of a hydroxy-group at C-2 and the configuration of the hydrogen atom at C-5 proved to be unimportant for toxicity. The toxicity fell somewhat on introduction of a Δ^7-bond and disappeared completely on acetylation of the 3-hydroxy-group or on reduction of the 6-oxo-group. At the same time it was not possible to establish a definite link between toxicity and steroid structure: probably in this case there is a superposition of various toxic effects, which depend in different ways on the structure. The direct cause of the death of *P. Apterus* larvae proved to be the breakdown of the integrity of the cell membranes in consequence of a change in the surface tension of the haemolymph caused by the introduction of the steroid [189]. It is noteworthy that the susceptibility of different insect species to steroid insecticides is variable [67,74]. This necessitates a large-scale programme of tests in each case and at the same time leads to the possibility of choosing compounds which selectively supress a given insect species.

The observation of a sterilising effect by many ecdysone analogues on the females of the housefly and other Diptera is also of considerable interest [74,191,192]. It was not possible to observe rigorous correlations between structure and activity in this case either, but the presence of a 6-oxo-group in the steroid molecule is apparently necessary both for sterilising activity and for toxicity. Synthetic analogues of ecdysones are a new class of specific insect chemosterilants, which are safe for warm-blooded animals [193].

Thus synthesis of ecdysone analogues gives rise to the possibility of fundamentally new hormonal insecticides. One may expect that, apart from their high activity, these compounds will exhibit selectivity of action in relation to a chosen insect species and that insect pests will be unable to adapt to these insecticides.

Investigation of Keto-Enol Tautomerism by Nuclear Magnetic Resonance Spectroscopy

A.I.Kol'tsov and G.M.Kheifets

The review considers methods for the determination of tautomeric composition from NMR spectra and gives a systematic account of the results of studies on keto-enol tautomerism. The bibliography includes 160 references.

I. INTRODUCTION

The introduction of physical (primarily spectroscopic) methods into organic chemistry made it possible to achieve in a short period considerable advances in the study of the phenomenon of tautomerism. The most recent of these methods (nuclear magnetic resonance) is the most promising and offers universal procedures for such investigations. High-resolution NMR spectra yield a wide variety of information about a tautomeric system: the chemical and steric structures of the tautomers, the positions and strengths of hydrogen bonds, the amounts of different tautomers, and the rate and mechanism of their interconversion. The advantages of the NMR method and the interest in tautomeric problems—a field which allows a wide scope for the application and verification of the fundamental concepts of organic chemistry [1-2]—resulted in a rapid growth of the number of relevant publications (from a few in 1960† to hundreds at the present time). Despite the evident interest of the investigators of tautomerism in NMR spectroscopy, there are no reviews in either Soviet or foreign literature giving a systematic account of the results from the large-scale application of NMR in the study of tautomerism in the last few years.

The available review literature comprises short illustrative chapters in certain monographs [4-9] and papers [10-15]. In the present review an attempt has been made to fill this gap and to describe the advances in the field of tautomerism made using NMR. Within the limits of a single review, it is not possible to examine in sufficient depth the NMR studies on tautomerism of all types. The authors restricted themselves to prototropic‡ tautomerism as a result of the migration of a proton between carbon atoms and a heteroatom (N, O, S) or between two heteroatoms.

† The first study in which NMR was employed to investigate tautomerism was published in 1953 [3].

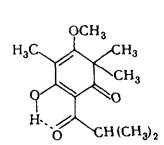
‡ NMR has been successfully employed to investigate the prototropic tautomerism associated with the migration of a proton between carbon atoms and also various types of non-protrotopic tautomerism [15].

In the discussion of the tautomerism of various classes of organic compounds attention has been concentrated on the equilibrium tautomeric composition and the factors which determine it. The chemical shifts are quoted on the τ-scale.

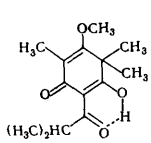
II. METHODS OF ANALYSIS OF TAUTOMERIC SYSTEMS BY NMR SPECTROSCOPY

In slow tautomeric transformations, which satisfy the inequality $1/t_A + 1/t_B \ll |\nu_A - \nu_B|$ (ν_A and ν_B are the NMR signal frequencies and t_A and t_B are the average lifetimes of the tautomers A and B), the NMR spectra of forms A and B can be observed separately and the tautomeric composition can be readily determined from the intensities of the corresponding spectral lines (to within 1%) [4-8].

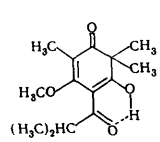
Thus in the NMR spectrum of the natural dye tasmanone dissolved in $CDCl_3$ [16] the signals of all the methyl groups consist of two very close components with an intensity ratio of 1 : 1.9 and in addition there are two signals due to the chelate enolic protons (−9.4 and −8.7 p.p.m.). The lines merge when the solution is made alkaline but the splitting reappears on neutralisation of the added alkali. This leads to the conclusion that the system consists of a mixture of two enolic tautomeric forms (1A and 1B)§, the rate of the interconversion of which is greatly accelerated in the presence of a base, which increases the concentration of the anion.



(IA)



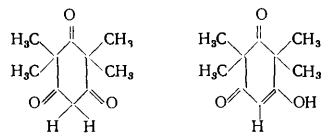
(IB)



(II)

§ This rules out the alternative structure of tasmanone, in which there is only the enolic form (II).

The next stage of the analysis, involving the assignments of the spectral lines to specific tautomeric forms, is based on the ^{1}H NMR data for tetramethylphloroglucinol (III)—a model compound. These data show that the enolisation of the carbonyl group leads to the descreening of the adjacent geminal methyl groups. Therefore the low-field (less intense) signal of the corresponding groups of tasmanone was assigned to form (IB). Clearly the other less intense signals are also due to the form (IB), the content of which is 35%.



(IIIA) (IIIB)

If the interconversions of tautomers A and B take place at a frequency exceeding $|\nu_A - \nu_B|$, their NMR signals merge and are characterised by an average chemical shift $\tau = p_A\tau_A + p_B\tau_B$, where τ_A and τ_B are the chemical shifts¶ and p_A and p_B the fractions of forms A and B ($p_A + p_B = 1$). A similar expression is valid also for the spin–spin coupling constants (SSCC):† $J = p_AJ_A + p_BJ_B$.[4-8] In this case the fraction of any form (for example A) is found from the following formulae:

$$p_A = (\tau - \tau_B)/(\tau_A - \tau_B), \quad (1)$$

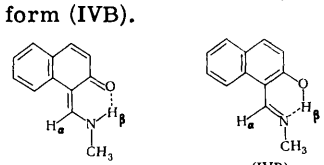
$$p_A = (J - J_B)/(J_A - J_B). \quad (2)$$

The case where appreciable spin–spin coupling obtains between the given nuclei in only one tautomer is frequently encountered (for example, $J_B = 0$). Then

$$p_A = J/J_A. \quad (3)$$

The accuracy of the determination of the proportions of tautomers in fast tautomeric interconversions is much lower than in slow interconversions. The absolute error for p_A and p_B amounts at best to several per cent. The principal sources of error are the inaccuracies in the values of τ_A, τ_B, J_A, and J_B, which are usually assumed equal to the corresponding values for model non-tautomeric compounds. In certain studies[17,18] corrections have been applied for the change in the chemical shifts in ^{1}H NMR on methylation of aromatic and heteroaromatic compounds at the oxygen and nitrogen atoms, which permits a more accurate prediction of the values of τ for the tautomeric forms modelled.

As an example, we shall determine the tautomeric composition of the Schiff base (IV). The $H_\alpha - H_\beta$ spin–spin coupling constant is close to 13 Hz‡ for form (IVA) and is zero for form (IVB).



(IVA) (IVB)

¶ In this review the proton chemical shifts are expressed on the τ-scale (p.p.m.)[5].

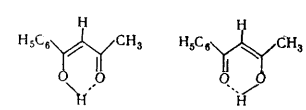
† The interaction of nuclei not involved in rapid intermolecular exchange is considered here. Otherwise the splitting of the NMR signals due to spin–spin coupling is not observed.

‡ This value is characteristic of the *trans*-form of the fragment =CH–XH, where X = O [19] or NR.[20]

Measurement of $J_{\alpha\beta}$ (9.8 Hz at 0°C in $CDCl_3$) makes it possible to estimate by Eqn. (3) the content of form A (75%). A similar value (83% of A) was obtained by comparing the $H_\beta - NCH_3$ spin–spin coupling constant (4.6 Hz) with the corresponding values for forms A (5.5 Hz) and B (0 Hz). Finally, more accurate data can be obtained from the ^{15}N–H spin–spin coupling constant. For the aminoketone forms, J_{NH} is close to 95 Hz and is zero for the iminoenol forms. The observed value of J_{NH} for (IV) is 72.3 Hz, which corresponds to 76% of form A [20,21].

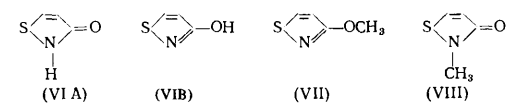
The problem of the short-lived internal tautomers A and B of benzoylacetone and other β-diketones cannot be readily solved with the aid of ^{1}H NMR spectroscopy, since the chemical shifts of the stable protons differ only slightly for the two forms and the values of τ_{OH} for these forms are unknown. The ^{17}O NMR spectra are more informative[22,23]. The ^{17}O nuclei of the carbonyl groups absorb near 495 p.p.m. and those of the enol groups near 35 p.p.m. relative to the signal for water (data from the spectra of model compounds).

In acetylacetone, where the enolisation of a given carbonyl group is equally probable, the average ^{17}O chemical shift is 265 p.p.m. However, the ^{17}O signal of the benzoyl group of benzoylacetone (V) is displaced towards higher fields (230 p.p.m.), which indicates the presence of an excess of tautomer A. Using Eqn. (3), it is possible to estimate the tautomeric composition (56% of A and 44% of B). The acetyl oxygen signal is displaced towards low fields (300 p.p.m.) in accordance with the lower probability of the enolisation of this group:



(VA) (VB)

In conclusion we shall quote an example of the determination of tautomeric compositions from the chemical shifts and spin–spin coupling constants of stable protons. 3-Hydroxyisothiazole in dimethyl sulphoxide exists as a mixture of forms (VIA) and (VIB), which are rapidly interconverted. The average chemical shifts and spin–spin coupling constant of the protons in the 4- and 5-positions (3.41 and 1.22 p.p.m.; 5.1 Hz) are closer to those for the fixed-configuration compound (VII) modelling form (VIB) (3.25 and 1.12 p.p.m.; 4.7 Hz) than to the values for the model compound (VIII) (3.81 and 1.55 p.p.m.; 6.3 Hz). Calculations by formulae (1) and (2) agree and show that the fraction of form (VIB) is 75%: [24]



(VI A) (VIB) (VII) (VIII)

In many cases the presence of a small amount of one of the tautomeric forms, the NMR signals of which cannot be observed, can be detected indirectly, namely from the deuterium exchange involving this form. Thus measurements by ^{1}H NMR spectroscopy of the rate of deuteration of the alkyl groups of ketones, which like bromination proceed via the enol form, not only makes it possible to confirm the presence of the enol but also allows the determination of the predominant enolisation pathway in asymmetric ketones.

For example, 4,4-dimethyl-2-pentanone (IX) can exist in two enolic forms.

$H_3C-CO-CH_2-C(CH_3)_3$ (IX A) $H_2C=C(OH)-CH_2-C(CH_3)_3$ (IXB) $H_3C-C(OH)=CH-C(CH_3)_3$ (IXC)

The rate constants for the deuterium exchange involving the methyl (8.1×10^{-6} s^{-1}) and methylene (2.4×10^{-6} s^{-1}) groups were determined from the decrease of the methyl and methylene group signal intensities in the ^1H NMR spectrum as a result of the deuteration of forms (IXB) and (IXC). These data show that the preferred enolic form is (IXB) [25]. An analogous procedure may be employed in more complex cases [26].

The NMR method permits a quantitative estimation of the rates of both rapid and slow chemical reactions [4,5,27-31], in particular tautomeric transformations [27,32-34]. The methods used in such estimations differ, depending on the rate of interconversion of the tautomeric forms.

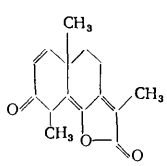
III. KETO-ENOL TAUTOMERISM

1. MONOCARBONYL COMPOUNDS

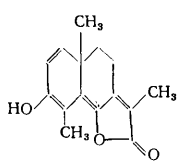
In the simplest ketones enolisation is slight [35] and cannot be detected directly by spectroscopic methods. Nevertheless, the presence of the enolic form can be deduced indirectly from the deuteration of α-carbon atoms, which proceeds via the enolate anion or the enolic form.

Rappe and Sachs [25,36-40] and other workers [41-45] measured the rate constants for deuterium exchange from ^1H NMR spectra, determined the predominant enolisation pathway for a number of asymmetric ketones, and investigated the effect of the solvent on the rate of deuterium exchange. In particular, it was shown that enolisation takes place most readily in the direction of the methyl group and least so in the direction of the methylidyne group of ketones.

In more complex systems where enolisation leads to the formation of conjugated bonds, the content of the enolic form may prove to be significant and susceptible to direct measurement. Thus the contents of the keto-form (XA) and enol form (XB) of santonin (X) and dihydrosantonin were determined from the intensities of the corresponding ^1H NMR lines in various solvents [46]. Santonin (100% of the keto-form in the crystalline material) is enolised very weakly in chloroform (less than 5%) and considerably in methanol (39%) and pyridine (70%). Dihydrosantonin (100% enol in the solid state) is almost completely enolised in pyridine and less so in methanol (84%) and chloroform (43%). The shift of the equilibrium towards the enol in proton-accepting solvents is probably associated with the formation of an intermolecular hydrogen bond stabilising the enolic form. The keto-enol interconversion in santonin takes place at low rates, which is indicated by the slow substitution of the proton at C-4 by deuterium in the presence of D_2O even at high temperatures.

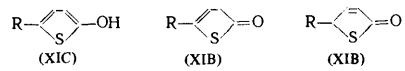


(X A)



(X B)

Hörnfeldt investigated the tautomerism of various hydroxythiophens [47-49]. ^1H NMR spectra revealed 25-30% of the hydroxy-form (XIA) of 5-aryl- and 5-thiono-2-hydroxythiophens (XI) in methanol, whereas in carbon tetrachloride this form was absent.



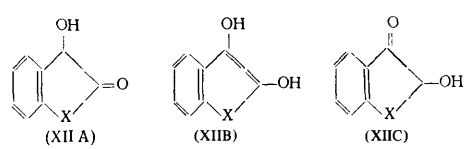
(XIC) (XIB) (XIB)

Form (XIA) was not detected in 5-alkyl-substituted 2-hydroxy-thiophens. In the presence of catalytic amounts of acids or bases, there is a rearrangement to an equilibrium mixture of the keto-forms (XIB) and (XIC), the composition of which depends on the hyperconjugation effect of the substituent and on the polarity of the solvent. The kinetics of the rearrangement (XIB) $\rightleftharpoons$ (XIC) have been investigated [47,48].

In alkyl-substituted 3-hydroxythiophens, the hydroxy-form (enol) is present in considerable amounts even in a non-polar solvent (carbon disulphide) (80, 55, and 30% for 5-methyl-, 5-t-butyl-, and 2,5-dimethyl-derivatives respectively). The chemical shifts of the signal due to the enolic proton are in the range between 3.3 and 3.8 p.p.m. [47]; 2- and 3-mercaptothiophens exist in the thiol form [50].

3-Hydroxythionaphthene was investigated by two groups of workers [51-53]. Their results show that the freshly sublimed substance exists entirely in the keto-form.

Sterk et al. [54] showed that in polar solvents the lactone of *o*-hydroxymandelic acid exists in the 3-oxo-form (XIIC, X = O). The 2-oxo-form (XIIA, X = O) predominates in non-polar media at high temperatures. The dienol form (XIIB, X = O) form was not detected.

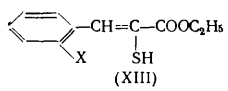


(XII A) (XIIB) (XIIC)

In dihydroxyindole solutions in bromoform there is an equilibrium between forms (XIIA, X = NH) and (XIIB, X = NH), which on raising the temperature is displaced towards the dienol form (XIIB, X = NH).

2. α-DICARBONYL COMPOUNDS

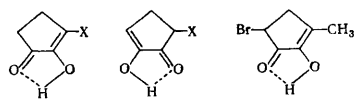
Acyclic 1,2-dicarbonyl compounds are as a rule weakly enolised. However, some of their aryl-substituted derivatives may contain significant amounts of the enolic form in a slow equilibrium with the diketo-form [55]. The ^1H NMR spectra show that, in contrast to pyruvic acid and its esters which do not contain an enolic form [56], aryl-substituted derivatives of thiopyruvic acid (XIII, X = H, CH_3, or Cl) exist largely in the thiol form [57]:



(XIII)

The degree of enolisation of cyclic α-diketones depends on ring size. The smaller the ring the more pronounced is the electrostatic repulsion between the adjacent dipoles of the carbonyl groups, which reduces the stability of the diketo-form [58].

Five-membered α-diketones are as a rule completely enolised in non-polar solvents as well as in aqueous solutions[58,59]. The ^{1}H NMR spectrum of 3-methylcyclopentane-1,2-dione in chloroform[60,62] not only fully confirms complete enolisation but also gives information about its direction. The absence from the spectrum of the vinyl proton signal and the chemical shift of the unsplit methyl group signal (8.07 p.p.m.)[61] support the structure (XIVA, X = CH_3). The structure (XIVA, X = Br) was also proved for 3-bromocyclopentane-1,2-dione, which is completely enolised in acetone[62]. 5-Bromo-3-methylcyclopentane-1,2-dione exists in acetone in the enolic form (XV)[58].



(XIVA) (XIVB) (XV)

3-Bromo-3-methylcyclopentane-1,2-dione, which exists in the diketo-form in a freshly prepared acetone solution, is gradually converted into the enolic form[15], the enolisation being accompanied by the migration of the halogen from the 3-position to the 5-position[62].

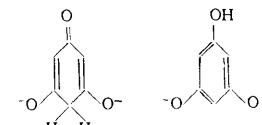
Six-membered cyclic α-diketones contain the diketo-form in addition to the enolic form[9,63]. Judging from the ^{1}H NMR spectra, in dilute aqueous solutions cyclohexane-1,2-dione is enolised approximately to the extent of 50%[64]. The rate of the keto–enol transformation is low but increases in the presence of acids and alkalis. At the same time there is a marked shift in the tautomeric equilibrium. Bakule and Long[64] determined the enthalpy and entropy of the keto–enol transformation in an aqueous medium (6 kcal mole^{-1} and −21 e.u. respectively). According to ^{1}H NMR and ^{17}O NMR data, in benzene cyclohexane-1,2-dione is completely enolised and the rate of exchange between the two equivalent enolic forms is low[22]. In the first case a distinct triplet due to the vinyl protons is observed and in the second case the individual signals of equal intensity due to the carbonyl and hydroxyl oxygen atoms. Freshly prepared cyclohexane-1,2-dione is fully enolised, but after two days 14% of the diketo-form appears[61].

Seven-membered cyclic α-diketones exist predominantly in the diketo-form[55]. In contrast to β-diketones (see below), α-diketones cannot form a mesomeric monoanion common to the two enolic forms; the interconversion of these enolic forms can therefore only occur via the diketo-form. The rates of these transitions are determined by the rates of their keto–enol interconversions, which are slow under the usual conditions. Chemical shifts of the enolic protons of α-diketones are in the range of positive values of τ. For example, τ_{OH} = 3.38 p.p.m. for 3-methylcyclopentanedione in chloroform[61]. This shows that the intramolecular hydrogen bond of the five-membered chelate ring is weak[5].

3. PHENOLS AND SIMILAR COMPOUNDS

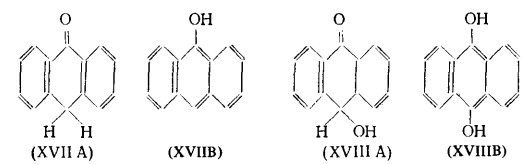
Phenols may be regarded as specific keto–enol systems[9,65]. However, the amount of the keto-form of simple phenols, if it exists at all, is too small to be measured. The keto-enol interconversion is considered as one of the pathways of the exchange of aromatic protons for deuterons in pyrogallol and β-naphthol in an alkaline medium[66].

Forms other than enolic have not been detected for phloroglucinol (a pyrogallol isomer) and its monoanion. However, the dianion exists in the keto-form (XVIA)[65]. This conclusion was arrived at using data obtained by a number of methods, but the ^{1}H NMR spectra are the most convincing[67]. The aromatic form of the dianion (XVIB) has not been detected in appreciable amounts.



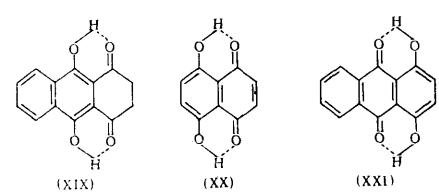
(XVI A) (XVIB)

Sterk investigated the effects of temperature on the anthrone (XVIIA)–anthrol (XVIIB) and oxanthrone (XVIIIA)–9,10-dihydroxyanthracene (XVIIIB) keto–enol equilibria in various solvents[68].



(XVII A) (XVIIB) (XVIII A) (XVIIIB)

The content of anthrone increases from 5% in bromoform to 50% in pyridine and 73% in dimethyl sulphoxide (at 40°C). The (XVIIIA) ⇌ (XVIIIB) equilibrium depends only slightly on the solvent (5–30% of the enol at 40°C) but is strongly displaced towards the enol (XVIIIC) when the temperature is raised. Dihydroquinizarin exists entirely in the diketo-form (XIX) regardless of the medium and temperature[68,69].

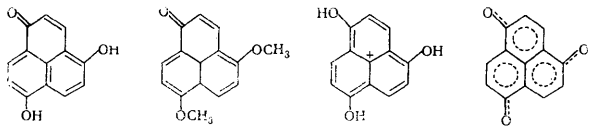


(XIX) (XX) (XXI)

Tautomerism associated with rapid migration of the proton involved in the intramolecular hydrogen bond between the oxygen atoms has been observed in 1,4-dihydroxynaphthoquinone (XX), in contrast to quinizarin, which exists in form (XXI)[69].

An unusual tautomerism was observed by the ^{1}H NMR method in 4,7-dihydroxyphenalenone (XXII)[70]. The spectrum of (XXII) should contain three quartets of type AB due to the three pairs of interacting aromatic protons in the three non-equivalent rings. Precisely this type of spectrum has been observed for 4,7-dimethoxyphenalenone (XXIII). The non-equivalence of the rings of (XXIII) is shown not only in different screening of the protons but also in different spin–spin coupling constants (J_{23} = 8.4 Hz, J_{56} = 9.2 Hz, and J_{89} = 10.1 Hz). However, the spectrum of (XXII) contains only one quartet, common to the three pairs of protons, which can be explained by the effective equivalence of all the rings achieved as a

result of the rapid interconversion of three equivalent structures of type (XXII).

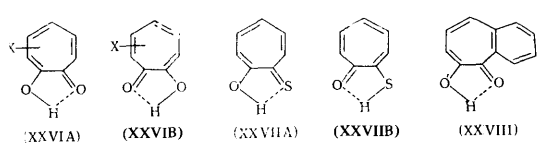


(XXII) (XXIII) (XXIV) (XXV)

This conclusion is confirmed by the value of J_{AB} for (XXII) (9.2 Hz), which is equal to the mean of the three J_{AB} constants for (XXIII). The first stage in these tautomeric transformations may be the formation of the cation (XXIV) or the dianion (XXV).

Tropolones (XXVI) (non-benzenoid aromatic α-diketones) are completely enclosed[71]. The ^{1}H NMR [71,72] and ^{17}O NMR [22] spectra confirm both their complete enolisation and the averaging of the electronic environments of the protons and oxygen nuclei in the left-hand and right-hand parts of the molecules of tropolone and its 5-substituted derivatives as a result of the rapid exchange between the equivalent enolic forms. The merging of the ^{17}O NMR signals of the hydroxy- and carbonyl groups indicates that the lifetimes of these forms are not more than 10^{-5} s. The rapid interconversion of the enolic forms of tropolones, in contrast to saturated α-diketones, is due to the presence of a mesomeric anion common to both enolic forms and reduces to the migration of a proton from one oxygen atom to the other with a corresponding π-electron shift.

In the case of asymmetrically substituted tropolones, the question arises of the preferential direction of enolisation, i.e. the proportions of forms (XXVIA) and (XXVIB). It has been shown[73] that the equilibrium in 3-bromotropolone is somewhat displaced towards the form (XXVIA, X = Br).



(XXVIA) (XXVIB) (XXVIIA) (XXVIIB) (XXVIII)

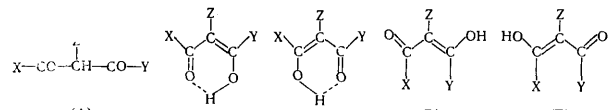
The enolic protons of tropolones in $CDCl_3$ and CCl_4 absorb in the range 0–3 p.p.m., i.e. they are more descreened than the enolic protons of saturated α-diketones. One cannot rule out the possibility that this effect is due not only to the descreening effect of the aromatic rings but also to the stronger intramolecular hydrogen bonds[71] in tropolones, the existence of which is indicated by infrared spectra[74].

Evidence of the predominance of the thiono-form (XXVIIA) of 2-mercaptotropolone (XVII) and its 4- and 6-alkyl-substituted derivatives has been obtained by ^{1}H NMR (in carbon tetrachloride) and other spectroscopic methods[75]. The chemical shift of the enolic proton[56] is 0.12 p.p.m.

In contrast to tropolone, 6,7-benzotropolone exists in form (XXVIII), in which the aromaticity of the benzene ring is unaffected[76].

4. OPEN-CHAIN β-DICARBONYL COMPOUNDS

In general β-dicarbonyl compounds, which include diketones, ketoaldehydes, ketoacids, and their esters and amides, may exist in five tautomeric forms: the diketo-form (A), two *cis*-enolic forms (B) and (C), and two *trans*-enolic forms (D) and (E). The reported presence of appreciable amounts of the dienolic form[77] has not been confirmed[78]. In water and alcohols the keto-form (A) can exist as hydrates and hemiacetals, readily revealed by the NMR method§.



(A) (B) (C) (D) (E)

The interconversion of structures (B) and (C) does not require the dissociation of the intramolecular hydrogen bond and reduces to the migration of a proton between two oxygen atoms. Therefore it is very rapid. The lifetime of the tautomer is less than 10^{-4} s.[33] All other tautomeric transformations in this system are as a rule slow. The half-life associated with the attainment of the keto–enol equilibrium at room temperature after separation of the tautomers amounts to minutes for acetylacetone[82], hours for α-phenylformylacetic acid esters[32], and days for β-carbonyldithioacid acid esters[83]. Thus in the general case the NMR spectra of the above tautomeric compounds should contain the individual signals of forms (A), (D), and (E) and the common signal of forms (B) and (C).

(a) Keto–enol Equilibrium

Here we shall consider the effect of molecular structure, temperature, and medium on the position of the keto–enol equilibrium, i.e. on the contents of forms (A) and (B $\rightleftharpoons$ C). The presence of *trans*-enolic forms is observed only in rare cases, which will be discussed separately.

Effect of structural factors and temperature (Tables 1–11). According to NMR data, malonodialdehyde and almost all the aldoesters and ketoaldehydes investigated are completely enolised in both non-polar solvents and as pure liquids (Table 1). On passing from ketoaldehydes to the corresponding diketones and particularly to ketoesters and ketoamides, the percentage of enol falls. For example, in carbon tetrachloride the fractions of the enolic form of acetoacetaldehyde, acetylacetone, acetoacetic ester, and the *N*-benzylamide of acetoacetic acid (in $CDCl_3$) are 100%,[79] 94% [100], 20% [108], and 5% [120] respectively. This effect is associated with the increasing electron density at the carbon atom of the carbonyl group in the above series and the corresponding decrease of the ionisation constants of the dicarbonyl forms[1,9]. It is noteworthy that the ester and amide groups are hardly enolised, in conformity with their low tendency towards nucleophilic addition reactions involving the carbonyl group. The failure of malonic ester to enolise[9] and the increasing degree of enolisation with increasing electron-accepting capacity of the substituents X and Y are consistent with this view[94,121] (Tables 2–4 and 9). A satisfactory linear corelation between the fraction of the enolic form and Hammett's σ constants and particularly Brown's σ^+ constants has been observed for

§ The presence of 76% of the hydrated keto-form of formylacetone in aqueous solution has been demonstrated[79]. For a number of trifluoro-β-diketones in water and alcohols, an equilibrium between the enolic and hydrated or hemiacetal forms has been observed[80,81].

meta- and *para*-substituted benzoyl derivatives of acetic ester[99], acetophenone[94], cyclohexanone[122], and cyclopentanone[121].

Table 1. The screening of the enolic and aldehyde protons, the constants for the spin–spin coupling between them, and the mode of enolisation of β-dialdehydes, β-ketoaldehydes, and β-aldoesters (A ⇌ B, Y = H)[a].

b. Several per cent of the formylketone form was observed. All other compounds were fully enolised.
c. 5% of the *trans*-enolic form was detected.

Enolisation is also promoted by the increasing size of the terminal substituents X and Y (Tables 3 and 10), which is apparently due to the instability of the diketo-form owing to the steric interactions between the substituents[95]. Burdett and Rogers[95] attribute to this interaction the lower degree of enolisation of ketoesters compared with diketones. Indeed in ketoesters the alkyl substituent and the carbonyl group are separated by the small oxygen atom and the steric interaction is weakened. However, for large alkyl substituents, such as t-butyl, the stability of the diketo-forms falls and the percentage of the enol increases (Table 3). Such behaviour is characteristic also of ketoamides[124].

The α-substituent (Z) has a very marked influence on the keto–enol equilibrium (Tables 5, 6, 8, and 10). Electronegative substituents increase sharply the degree of enolisation. α-Alkyl substituents cause a marked decrease of the percentage of enol. However, here the cause is mainly steric—repulsion between the α- and ring substituents, which makes the chelate ring of the *cis*-enolic form unstable. For example, whereas dibenzoylmethane is fully enolised, its α-methyl analogue exists exclusively in the diketo-form[100]. The replacement of the oxygen of the carbonyl group by sulphur leads as a rule to almost complete enolisation (Tables 7 and 8)[110,125–127]. In alicyclic β-ketoesters the degree of enolisation depends in a complex manner on ring size (Table 7). Possibly this is due to conformational changes on passing from one ring to another[108,109].

A strong intramolecular hydrogen bond is also an important factor stabilising the *cis*-enolic form. The weakness of the intramolecular hydrogen bond in five-membered alicyclic compounds accounts for the relatively low degree of their enolisation (Tables 1 and 7).

With increase of temperature, the content of the enol falls. The thermodynamic parameters of enolisation have been determined for a number of β-dicarbonyl compounds by the NMR method (Table 10). The energy gain on formation of an intramolecular hydrogen bond ($\Delta H < 0$) promotes enolisation but, in view of the higher entropy of the keto-form ($\Delta S < 0$), the latter is not only present in significant amounts in a number of systems but actually predominates[55,78]. Ultimately the position of tautomeric equilibrium is determined by the competing energy and entropy factors. Table 10 shows that the enthalpy of enolisation (ΔH) increases with the dimensions of the terminal substituents and falls with increasing size of the α-substituent.

a. In carbon tetrachloride.
b. In $CDCl_3$.

Effect of the medium. On dissolution in solvents of low polarity, the percentage of the less polar *cis*-enolic form increases. Conversely polar solvents displace the equilibrium towards the polar diketo-form (Table 11). This can be explained by the solvation of the carbonyl groups by the polar solvent molecules, which increases the stability of the diketo-form[97,100,118]. Thus in dimethyl sulphoxide the enthalpy of enolisation (ΔH) of acetylacetone is lower by more than 1 kcal mole^{-1} compared with pure acetylacetone, which apparently corresponds to an energy gain on solvation of the diketo-form in dimethyl sulphoxide.

Reeves[114] and also Rogers and Burdett[118] compared the experimental keto–enol equilibrium constants for acetylacetone and acetoacetic ester with the values calculated taking into account the dielectric constant of the solvent[128]. For a number of solvents, in particular benzene and acetic acid, satisfactory agreement was obtained between theory and experiment. In other cases (pyrrole, triethylamine) there is a discrepancy between the calculations and experimental data owing to the specific interactions with solvent molecules[114]. The intermolecular hydrogen bond between pyrrole and the carbonyl groups of acetylacetone and acetoacetic ester stabilises the diketo-form. At the same time pyrrole does not interact significantly with the enolic form, as shown by the constancy of the chemical shift of the enolic proton when the concentration of the solution in pyrrole is altered[97,129].

In contrast to pyrrole, acetic acid, which is dimerised, does not form hydrogen bonds with acetylacetone[114] and has little effect on the position of its keto–enol equilibrium (Table 10).

b. Mode of Enolisation

NMR apparently provides a unique possibility of a quantitative estimation of the amounts of the two *cis*-enolic tautomeric forms (B) and (C). Aldo- and keto-esters and their thioanalogues enolise only at the carbonyl oxygen. This has been confirmed in a number of examples (XXIX–XXXIII). For (XXIX) and (XXX), the spin–spin coupling constants $J_{\alpha\beta}$ are characteristic of hydroxymethylene forms, amounting to 13.3 Hz [82] and 13.5 Hz [83] respectively, and are independent of temperature [87].

e. Chemical shift of the overall signal of the enolic protons and the hydroxyl protons of the alcohol.

In contrast to aldoesters, β-aldoketones exist in both *cis*-enolic forms (B) and (C). Table 1 presents data on the mode of enolisation in cyclic α-formylketones determined from the chemical shift of the aldehyde (hydroxymethylene) proton; these agree with the spin–spin coupling constants ($J_{=CH-OH}$) [19]. According to Garbisch [130], the differences in the mode of enolisation are associated mainly with the conformations of the rings and their strain. The predominance of the hydroxymethylene form (B) in five-membered rings and of form (C) in six-membered rings is consistent with quantum-chemical calculations indicating that exocyclic carbon–carbon double bonds are energetically favourable for five-membered rings [131]. The ^{1}H NMR data for α-formylcyclohexanone and 3-formylcamphor are also satisfactorily consistent with the results obtained from ^{17}O NMR spectra [22].

Deutsch and Deutsch [87], who investigated the same compounds as Gabrisch, believed erroneously that rapid (B) ⇌ (C) exchange should lead to the disappearance of the multiplet structure of the hydroxymethylene (aldehyde) and enolic proton signals (as happens in intermolecular exchange). Therefore the very fact that these signals are split was incorrectly interpreted as evidence for the existence of the hydroxymethylene form only. Their work [87] was criticised in detail in a later paper by Garbisch [132].

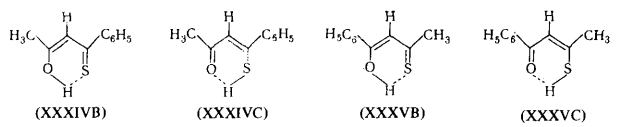
a. The ^{17}O signal of the diketo-form is observed ($\delta_0^{(1)} \simeq \delta_0^{(2)} \simeq 540$ p.p.m.).

Forsen and Nilsson [86] observed a temperature variation of the $J_{=CH-OH}$ constant for α-phenylacetoacetaldehyde. Possibly it reflects a shift in the (B) ⇌ (C) equilibrium.

Gorodetsky et al [22] succeeded in estimating the contents of the two *cis*-enolic forms for a number of alicyclic β-diketones (Table 12) and benzoylacetone from ^{17}O NMR spectra. Table 12 shows that in β-diketones the effect of ring size on the mode of enolisation is similar to that found for aldoketones. Replacement of a methyl group in the side chain by a phenyl group leads to an increase in the amount of the form with exocyclic double bonds. The stabilisation of this form by the benzene ring owing to the increase in the length of the conjugated chain was predicted by quantum-mechanical calculation [133]. Probably for this reason the enolisation of benzoylacetone (V) at the carbonyl group adjacent to the benzene ring is preferred (about 56%) [22]. These quantitative data were contradicted in a later study by Sardella et al. [94], who did not observe spin–spin coupling between the methyl and vinyl protons of benzoylacetones and thereby concluded that more than 90% is present as the form with an enolised benzoyl group. The resolution of this contradiction requires additional studies, but we believe the data of Gorodetsky et al. [22] to be more convincing.

The problem of the mode of enolisation of thionoketones is interesting. Klose et al. [125] observed the spin–spin splitting of the enolic proton signal by the protons of the methyl group of thiobenzoylacetone (XXXIV) and concluded that thionoketones are enolised at the carbonyl group.



(XXXIVB) (XXXIVC) (XXXVB) (XXXVC)

$J_{CH_3-\overset{\|}{C}-OH} = 0{,}32$ Hz $J_{CH_3-\overset{\|}{C}-SH} = 0{,}20$ Hz

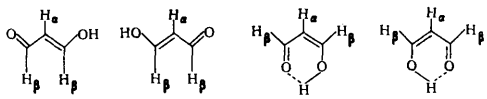
However, Duus and Lawesson [110] observed a splitting of the signal due to the chelate proton in benzoylthioacetone (XXXV) [110], and in accordance with infrared spectroscopic data, suggested that thionoketones are enolised at the thiono-group. The presence of both forms in comparable amounts is quite likely. The sharp increase of the screening of the chelate proton of thionoketones with increase of temperature [110,125] is explained by the shift of the equilibrium towards the thienol form¶ [125] or the dissociation of the intramolecular hydrogen bond [126].

One can postulate a parallel variation of the capacity for enolisation of the RCO–group in aldoketones and diketones, on the one hand, and in the corresponding ketoesters, on the other, with the nature of the substituent R. Indeed a correspondence is observed between the content of the enol in ketoesters (Table 7) and the fraction of the chelate aldo-form (C) in the corresponding aldoketones (Table 1). Furthermore, the preferential enolisation of the benzoyl group of benzoylacetone is consistent with the greater ease of enolisation of the benzoylacetic ester compared with acetoacetic ester (Table 3). Consequently the more pronounced enolisation of ring-substituted benzoylacetic esters with increasing electronegativity of the substituent [93,99] (Table 4) should correspond to an increase of the content of the chelate form with an enolised benzoyl group in the analogous benzoylacetones. This is consistent with the results of a study [93] based on an analysis of the chemical shifts of enolic protons.

¶ The signal of the chelate proton of the thienol form is located in higher fields (Table 8).

c. *trans*-Enolisation

On the basis of the $J_{\alpha\beta} = 9.69$ Hz constant, Bothner-By and Harris[84] concluded that malonodialdehyde exists in chloroform mainly in the *trans*-transoid form (XXXVI, D and E).



(XXXVID) (XXXVIE) (XXXVIB) (XXXVIC)

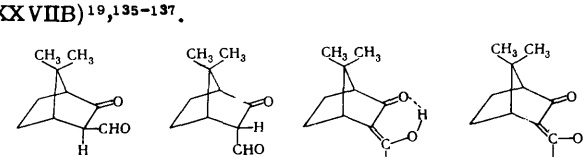
However, according to the data of Shapet'ko et al.[85], this constant is 4.2 Hz in chloroform and acetone and therefore the authors attributed the *cis*-cisoid structure (XXXVI, B and C) to malonodialdehyde. This structure is also indicated by the marked descreening of the enolic proton (about 0 p.p.m.). George and Mansell[79] confirmed Shapet'ko's data ($J_{\alpha\beta} = 3.4-3.8$ Hz in carbon tetrachloride, chloroform, and methylene dichloride), i.e. the structure (XXXVI, B and C). They explained the results of Bothner-By and Harris[84] by the presence of polar impurities in chloroform.

In aqueous solution the enolic forms of malonodialdehyde ($J_{\alpha\beta} = 10.3$ Hz) and also of α-formylacetone ($J_{\alpha\beta} = 9.1$ Hz) have the *trans*-transoid structure according to George and Mansell[79]. This behaviour can evidently be explained by competition between intramolecular hydrogen bonding and strong intermolecular hydrogen bonds with water molecules.

Freshly prepared solutions of α-phenylformylacetic esters in chloroform contain the *trans*-enolic form but after a time are fully converted into the *cis*-enolic and aldo-forms[84].

In 1967 a Japanese group[103] reported the presence of large amounts (up to 50%) of the *trans*-enolic forms of a number of α-alkylacetylacetones in carbon tetrachloride. This conclusion contradicts other data[101,102,134] (^{1}H NMR and bromometric titration), which show that the enolisation of the above compounds is insignificant (about 1% or less) in various media, the enolic tautomer being in the *cis*-form. Possibly the Japanese workers were not dealing with the *trans*-enols but with the enol esters[101].

The *trans*-enolic form of 3-formylcamphor (XXXVIID) was observed in various solvents in slow equilibrium with the aldo-form (XXXVIIA) and the *cis*-enolic form (XXXVIIB)[19,135-137].



(XXXVIIA) (XXXVIIB) (XXXVIID)

In carbon tetrachloride the ratio of the concentrations of the *trans*- and *cis*-forms of the enol D/B increases according to ^{1}H NMR data from 5/95 in 10% solution to 31/69 in 26% solution[19]. The addition of dimethyl sulphoxide to carbon tetrachloride sharply increases the content of the *trans*-enolic form[19,135] (D/B = 78/22 for 14% solution in carbon tetrachloride with 8% of dimethyl sulphoxide). In 10% solution in ether, D/B = 55/45.[136] The increased content of the *trans*-enolic form of 3-formylcamphor is probably due to a competition between intramolecular and intermolecular hydrogen bonding.

The fact that in non-aqueous media the *trans*-enolic form has so far been detected only in 3-formylcamphor (among a large number of compounds investigated) may be tentatively accounted for by the weakness of intramolecular hydrogen bonding in this compound (see below).

On the basis of a private communication by Duus et al., Wamhoff et al.[113] state that α-thioacetyl-γ-butyrolactone contains 37% of the *trans*-enolic form in carbon tetrachloride.

d. Intramolecular Hydrogen Bonds in β-Dicarbonyl Compounds

Intramolecular hydrogen bonding determines the stability of the *cis*-enolic form and with other factors, the position of the keto–enol equilibrium. Therefore here we shall examine the factors which influence the chemical shift of the chelate enolic proton (τ_{OH}). The chemical shift may be a quantitative characteristic of the strength of intramolecular hydrogen bonding in a series of similar compounds. The stronger the intramolecular hydrogen bond, the lower is the value of τ_{OH}.[5] On the other hand, τ_{OH} contains, in principle, information about the enol–enol equilibrium.

The weak dependence of the chemical shift of the ^{1}H NMR signal of the *cis*-enolic proton on temperature[78,102,126] and on the medium (Table 11)[90,138] and also the spin–spin splitting of this signal observed in many cases indicate the stability of the chelate ring with an intramolecular hydrogen bond.

Tables 2, 3, 5, and 6 show that τ_{OH} decreases with increasing size of both the terminal groups and (to an even greater extent) the size of the α-substituent (Z). This finding can be explained by the repulsion of the groups, as results of which the chelate ring contracts, the oxygen atoms come closer together, and the intramolecular hydrogen bond is strengthened[91,95,139]. On the other hand, steric effects account for the shift of the chelate proton signal of α-formyl, α-acetyl, and α-ethoxycarbonyl-pentanones and particularly α-formylcamphor towards higher fields by 2–3.5 p.p.m. relative to the corresponding acyclic compounds (Tables 1, 7, and 9). With increase of the valence angles at the unsaturated carbon atoms in the rings of the above compounds to 107–111°, the intramolecular hydrogen bond becomes weakened owing to the increased distance between the oxygen atoms[19,108].

The more pronounced descreening of the enolic proton in diketones compared with aldoketones and particularly compared with ketoesters is associated with the increase of the electronegativity of substituents in the series Alk < H < OAlk.

In β-ketoesters τ_{OH} depends only slightly on the electronegativity of the terminal substituent (Table 3). This effect is almost absent from *para*-substituted benzoylacetic esters (Table 4).

In β-diketones the electronic influence of the terminal substituent is much more marked. Electronegative substituents reduce the strength of the intramolecular hydrogen bond (Table 2) evidently due to the decreased electron density at the carbonyl oxygen[91]. The benzene ring supplies electrons to the chelate ring and stabilises the intramolecular hydrogen bond, provided that it is conjugated† with the chelate ring. When the mesityl

† The coplanarity of the benzene and chelate rings is confirmed by the descreening of the *ortho*-protons of the ring on the side of the carbonyl group[90].

group is displaced from conjugation, it does not have a significant influence on τ_{OH} (Table 2).

In the majority of compounds the effect of the electronegativity of the α-substituent (Z) on τ_{OH} is masked by steric effects. But if the dimensions of the substituents are similar, ^{1}H NMR data indicate that the screening of the enolic proton decreases with increasing electronegativity in both ketoesters and diketones (cf. Z = Cl and Z = CN, Tables 5 and 6).

The replacement of the −COOAlk group by −CSSAlk in aldo- and keto-esters leads to a marked shift of the enolic chelate proton signal towards lower fields (by 2−3 p.p.m.) (Table 8). On the other hand, the replacement of the acyl group of ketoesters by the thioacyl group causes a sharp shift (by 4−5 p.p.m.) of the resonance of the chelate proton towards higher fields. In β-thionoketones the chelate proton is more highly screened than in the corresponding diketones.

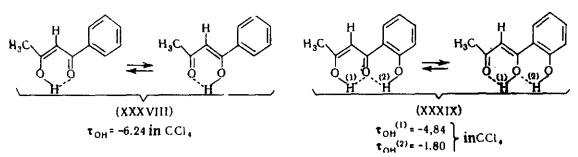
e. Effect of the Enol−Enol Equilibrium on the Chemical Shift of the Enolic Proton

As a result of the migration of the proton of the intramolecular hydrogen bond between the donor atoms, an average chemical shift of the two *cis*-enolic forms (B) and (C) is observed. The marked dependence of τ_{OH} for β-diketones (Y = Alk) on the nature of the terminal substituent X is largely due to changes in electron density at the oxygen atom of the adjacent carbonyl group in the tautomer (B).

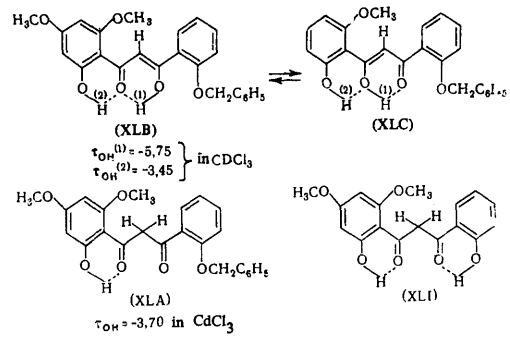
In β-ketoesters (Y = OAlk) the form (B) is absent and the change in electron density at the remote carbonyl group of the tautomer (C) is insignificant. Hence the weak dependence of τ_{OH} on the electronegativity of the substituent in β-ketoesters becomes understandable[93]. The closer the values of τ_{OH} for two chelate forms, the weaker is the influence of the displacement of the intrachelate equilibrium on the observed chemical shift of the enolic proton.

f. Compounds with two Intramolecular Hydrogen Bonds

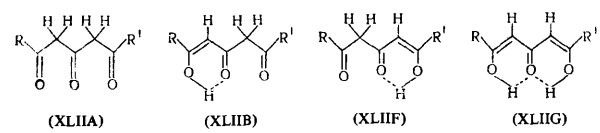
The formation of a second intramolecular hydrogen bond with a chelate oxygen atom reduces the strength of the first intramolecular hydrogen bond. This conclusion was reached after comparing the values of τ_{OH} for compounds (XXXVIII) and (XXXIX) and also for analogous toluene and naphthalene derivatives[140].



Possibly the effect of the second intramolecular hydrogen bond (with the phenolic proton) is one cause of the low content of the enolic form (about 30%) in compound (XL) and other similar compounds[141] compared with dibenzoylmethanes without a hydroxy-group (Table 2). Indeed, in compound (XLI), where both carbonyl groups are stabilised by intramolecular hydrogen bonds, there is no appreciable enolisation[141]. Wagner et al.[141] suggest that, of the two possible enolic forms of (XL), the form (XLB) where the free carbonyl group is enolised, is the more stable:



In the triketones (XLII, R, R′ = CH_3 or C_6H_4X), the contents of the tautomers (A), (B), (F), and (G), (3, 40, 18, and 39% respectively for H = C_6H_5 and R′ = CH_3 in $CDCl_3$) have been determined[99,142]. The low content of the form (G), i.e. the reduced capacity for enolisation of the acetyl and benzoyl groups relative to the corresponding diketones, may be associated with the lower strength of the two intramolecular hydrogen bonds.



The greater tendency of the benzoyl group towards enolisation compared with the acetyl group is noteworthy.

5. TRIACYLMETHANES AND SIMILAR COMPOUNDS

In general three enolic forms (external tautomers[88]), differing in the group outside the chelate rings (B, C, D), are possible for acyclic tricarbonyl compounds related to triacylmethanes (Table 13). In cyclic tricarbonyl compounds there may be two non-equivalent chelate forms (Table 14). Usually tricarbonyl compounds do not contain the triketo-form (A) in an appreciable amount. However, the compounds with even a single large substituent, such as t-butyl, are not enolised at all[143] and certain acyldibenzoylmethanes and tricarbonyl compounds with ester groups are only partly enolised (Table 13). The content of the enolic forms of these compounds decreases in polar solvents[116]. The interconversions of the external tautomers, which require the dissociation of intramolecular hydrogen bonds, are slow under the usual conditions and the observed ^{1}H NMR spectrum contains the individual signals of the tautomers. The rate of exchange increases sharply in the presence of bases[88,106].

A stronger intramolecular hydrogen bond is characteristic of tricarbonyl compounds compared with the corresponding dicarbonyl compounds (lower values of τ_{OH} and of the vibration frequencies of the C=O and O−H groups in the infrared spectra)[88,148]. The high enthalpy of enolisation of dibenzoylethoxycarbonylmethane (Table 10) and the slow deuterium exchange involving the chelate protons in 2-acetyldimedone[5] are also consistent with the high stability of the intramolecular hydrogen bonds in tricarbonyl compounds. The high stability of the chelate enolic forms of tricarbonyl compounds can be understood by regarding them as β-dicarbonyl compounds with an

Table 13. Tautomeric composition and the screening of the enolic protons of acyclic tricarbonyl compounds.

a. The triketo-form (A) was not detected.
b. Overall signal. The signals due to the protons at the carbon atoms are observed separately.

electronegative α-substituent (–COX). The dependence of τ_{OH} for di- and tri-carbonyl compounds on the substituent and ring size is analogous.

Many studies have been made to determine the mode of chelation of tricarbonyl compounds. In a number of cases the problem has been solved (Tables 13 and 14) despite the difficulty associated with the similarity of the chemical shifts of the acyl groups in the chelate and outside it‡. Nonhebel[143] showed by infrared and ^1H NMR spectroscopy that in diacetylaroylmethanes the aryl group is not incorporated in the chelate and in acetyldiaroylmethanes the acetyl group must be involved in the formation of the chelate (Table 13). The data in this table also show that the ester groups are preferentially located outside the enolic chelate ring.

The contents of the external tautomers of a number of complex tricarbonyl compounds (mainly natural compounds) have been investigated[16,120,149,150]. The intrachelate tautomerism of tricarbonyl compounds has not been specially investigated, but in a number of studies it has been discussed on the basis of indirect data[86,147,150].

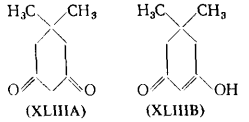
6. CYCLIC β-DIKETONES

In contrast to acyclic and alicyclic β-diketones, in the enolic forms of the cyclic β-diketones considered in this section intramolecular hydrogen bonds stabilising the enolic form cannot be formed owing to steric factors when the ring is not unduly large. Therefore in dilute solutions in non-polar media the contents of the enolic forms of cyclohexane-1,3-dione and dimedone (XLIII) are low. The percentage of the enolic form of the cyclic ketone increases sharply with concentration (in contrast to acyclic β-diketones). With increased concentration of dimedone in chloroform from 0.020 to 0.094 M, the content of its enolic form increases from 5 to 28%.[151] Cyclohexane-1,3-dione is enolised to a greater extent than dimedone, but the form of its concentration dependence is the same for both compounds. A similar variation

‡ 7.89 and 7.72 p.p.m. for triacetylmethane[143].

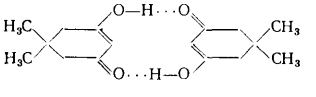
of the tautomeric composition of the compounds with concentration is observed also in acetonitrile, despite its high polarity, probably due to the relatively weak proton-acceptor properties of acetonitrile. In proton-accepting solvents the enolic form predominates at all concentrations[16,152]. At higher temperatures, the content of the diketo-form of dimedone and cyclohexane-1,3-dione increases[117]. The dependence of the degree of enolisation on concentration, solvent, and temperature can be explained by the formation of intermolecular hydrogen bonds by the enolic forms with one another and with the proton-accepting solvent molecules.

The ^{1}H NMR spectrum of dimedone contains the signals of both the keto- and enolic forms[72]. The individual signals of the non-equivalent methylene groups of the enolic form§ indicate a low rate of interconversion (the lifetime exceeds one second) of the two equivalent enolic forms of the type (XLIIIB), in contrast to the intrachelate enol-enol transformation of acyclic β-diketones (lifetime $< 10^{-4}$ s).



(XLIIIA)

(XLIIIB)



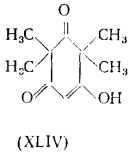
(XLIIIC)

Cyr and Reeves[117] suggested that the tautomerism of dimedone and cyclohexane-1,3-dione in non-polar media can be described by the equilibrium ketone (A) ⇌ monomeric enol (B) ⇌ dimeric enol (B′).

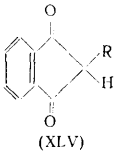
However, Yoge and Mazur[151] demonstrated the presence also of polymeric enolic forms, the fraction of which increases with concentration.

In contrast to β-diketones with intramolecular hydrogen bonds, the enolic proton signal of cyclic β-diketones is significantly displaced towards higher fields on dilution with a non-polar solvent (for dimedone, the values of τ_{OH} extrapolated to high and low concentrations are +0.34 and −2.32 p.p.m. respectively[117]). The observed enolic proton signal is the common signal of the monomeric and all the polymeric enolic forms in view of their rapid interconversion and the increase of τ_{OH} reflects the increase of the relative content of the monomeric form (B) with the free OH group.

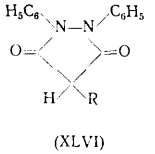
^{1}H NMR data[151] indicate a higher rate of inversion of the ring of the diketo-form of dimedone compared with the ring of the enolic form. Bick and Horn[16] showed that the content of the enolic form of syncarpic acid (XLIV) is insignificant in chloroform but increases sharply in the presence of small amounts of water and dimethyl sulphoxide. In acetone the form (XLIV) predominates. The rate of the keto-enol transformation increases sharply (until the merging of the corresponding ^{1}H NMR signals) in the presence of traces of bases.



(XLIV)



(XLV)

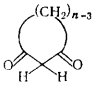


(XLVI)

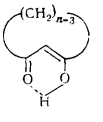
§ The chemical shifts of the methylene group protons of the enol are close to those of the methyl ether of dimedone[153,154].

The ^{1}H NMR data for five-membered cyclic β-diketones are restricted to indanedione (XLV, R = H) and its 2-phenyl derivative (XLV, R = C_6H_5).[95] The spectra did not show the signals of the enolic form in chloroform and dioxan, in agreement with the general hypotheses concerning the tautomerism of indanediones[155,156]. The enolic form was not observed in any of the 4-alkyl-3,5-dioxo-1,2-diphenylpyrazolidines (XLVI)[157].

There are no literature data on the tautomerism of β-diketones containing between 8 and 10 atoms in the ring¶. For steric reasons, the chelate enolic forms with intramolecular hydrogen bonds are impossible in these compounds. β-Diketones with a large number of ring atoms were investigated by Kirrman and Wakselman[158]. The chelate enolic forms (XLVIIB) of these compounds have been detected; their content increases with ring size (20% for $n = 11$, 60% for $n = 12$, and more than 95% for $n = 14$ and 17 in carbon tetrachloride). The enolic proton signals are close (5 p.p.m.) to the values of τ typical for acyclic β-diketones.



(XLVIIA)



(XLVIIB)

¶ Cyclobutane-1,3-dione[159] and cycloheptane-1,3-dione[160] are weakly enolised.

Primary Photoionisation Processes and Ion-Molecule Reactions in Organic Compounds

V.K.Potapov

This review deals with studies on primary photoionisation and molecular decomposition processes and ion-molecule reactions in the gas phase. Problems concerning the nature of the electronic and vibrational states arising on photoionisation and their role in unimolecular and bimolecular reactions of organic compounds are discussed.
Various pathways for the formation of secondary products in ion-molecule reactions have been determined. Data are presented on the energy relations of ion-molecule reactions and the proton affinities of molecules.
The bibliography includes 69 references.

I. INTRODUCTION

During recent years a new field has developed in the photochemistry of organic compounds—the photochemistry of gaseous ions, considering the elementary photoionisation processes and ion–molecule reactions (IMR) involving the ions formed on photoionisation. The development and application of the mass-spectrometric photoionisation method[1-3] yielded information about the excited and electronic states of radical-cations and the role of these states in the unimolecular decomposition reactions of the radical-cations into cations and radicals. The use of the appearance potentials of fragment ions made it possible to determine the heats of formation of cations of different structures and to refine the heats of formation obtained earlier by the electron impact method.

The data thus obtained on the electronic states and heats of formation of ions made it possible to consider the problem of the mechanisms and the pathways of ion–molecule reactions, which play an important role in high-energy chemistry and in the two-quantum photochemistry of organic compounds[4]. In the first place this concerns the elucidation of the role of the excitation of primary ions in ion–molecule reactions with the aim of investigating the mechanism by which the energy of the colliding species is redistributed. In the second place, for the study of the mechanism of ion–molecule reactions, it is important to know the different pathways for the formation of secondary ions and radicals both by hydrogen atom transfer from various groups of the molecule to the radical-cation and as a result of the involvement in the reactions of primary fragment ions. In the third place the elucidation of the way in which molecular properties such as basicity and polarisability influence the nature of ion–molecule reactions is very important.

In the present review these problems are considered in the discussion of studies on photoionisation and ion–molecule reactions occurring in the photoionisation of simple molecules and organic compounds—saturated and unsaturated hydrocarbons, aromatic hydrocarbons, aromatic compounds with heteroatoms, and aromatic hydrocarbons.

The studies on ion–molecule reactions by the electron impact methods have been reviewed[5-7]. The review of Tal'rose and Karachevtsev[5] deals with the study of ion–molecule reactions by the so called method of "internal" ionisation of molecules by electrons (the method of pulse withdrawal of ions). This method was first developed and applied by Tal'rose and Frankevich to measure the rate constants for ion–molecule reactions[8,9] and also to determine the proton affinities of molecules[10,11]. In subsequent studies the method of pulse withdrawal of ions was successfully employed in investigations of the mechanism of ion–molecule reactions involving thermal ions.

Important information about ion–molecule reactions was obtained by applying methods which permit the determination of the kinetic energies of ions produced in the reactions. The deflecting field method was used to determine the average kinetic energies of secondary ions and yielded information about the redistribution of the energy of the colliding species in ion–molecule reactions among the internal and translational degrees of freedom[12,13]. Measurement of the product energies for ion–molecule reactions by determining the changes in the momenta of secondary ions compared with the momentum which the primary ion receives when the molecule is ionised by an electron yielded data on the mechanism of ion–molecule reactions[14].

We may note that other aspects of ion–molecule reactions have also been elucidated[6,7,15]: the dependence of the cross-sections on the kinetic energy of the ions, angular distribution of products, etc.

Ion–molecule reactions in simple systems have been examined theoretically in studies on bimolecular gas-phase reactions[16,17]. It has been shown that ion–molecule reactions proceed via two pathways[16], namely via an intermediate complex mechanism and via a direct mechanism involving the "scission" of an ion from the incident species or the "capture" of a neutral species by the incident ion.

II. PHOTOIONISATION AND ION–MOLECULE REACTIONS IN SIMPLE MOLECULAR AND NOBLE GASES

1. Hydrogen

The ion–molecule reactions which occur on photoionisation of hydrogen were first investigated by Chupka et al.[3], who showed that the formation of the secondary H_3^+ ions involves the participation both of molecular hydrogen ions H_2^+ and excited hydrogen atoms. The primary molecular hydrogen ions H_2^+ were obtained in various excited vibrational states when hydrogen molecules were acted upon by monochromatic radiation (the energy spread was 0.002–0.05 eV) (Fig. 1):

$$H_2\,(X^1\Sigma_g^+,\ v''=0)+h\nu \rightarrow H_2^+\,(^2\Sigma_g,\ v'\geqslant 0)+e\,. \qquad (1)$$

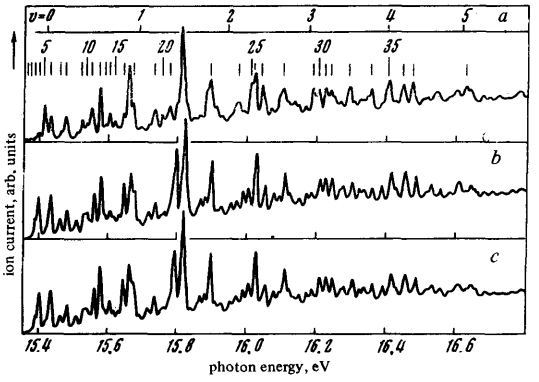

Figure 1. Appearance curves for H_2^+ and H_3^+ ions recorded with a resolution of 0.4 Å: *a*) H_2^+ from normal hydrogen; *b*) H_2^+ from parahydrogen; *c*) H_3^+ from parahydrogen.

Hydrogen atoms in the excited metastable state 2*S* were formed as a result of the predissociation of hydrogen molecules in the excited electronic state $D^1\Pi_u$:

$$H_2\,(X^1\Sigma_g^+,\ v''=0)+h\nu \rightarrow H_2\,(D^1\Pi_u,\ v'\geqslant 3) \rightarrow H_2\,(B^1\Sigma_u^+) \rightarrow H\,(1S)+H\,(2S)\,. \qquad (2)$$

This predissociation region of hydrogen molecules converges to a threshold of 14.66 eV. At the predissociation threshold the hydrogen atoms in the 2*S* state are formed with thermal kinetic energy, while for photon energies of 14.77 and 15.01 eV the hydrogen atoms in the 2*S* state are mainly produced as a result of the deactivation of hydrogen molecules in the excited vibrational states $v = 3$ and $v = 4$ respectively. The kinetic energies of the metastable hydrogen atoms corresponding to photon energies of 14.77 and 15.01 eV have been shown to be[18] 0.18 and 0.27 eV.

The cross-section of an ion–molecule reaction involving molecular hydrogen ions in the ground and excited vibrational states (Fig. 2),

$$H_2^+\,(^2\Sigma_g,\ v'\geqslant 0)+H_2\,(X^1\Sigma_g^+,\ v''=0) \rightarrow H_3^+ + H\,(1S)\,, \qquad (3)$$

decreases by 15–20% with increase of photon energy from the hydrogen ionisation potential (15.425 eV) to 16.6 eV. A decrease of the cross-section of reaction (3) with increasing vibrational excitation of the molecular ions H_2^+, i.e. with increase of the vibrational quantum number v from 0 to 5 is observed for kinetic energies of the primary ions less than 2 eV (laboratory system).

Studies on ion–molecule reactions in hydrogen on a double mass-spectrometer[19] showed that H_3^+ ions are formed via two pathways: both via proton and hydrogen atom transfer. With increase of the kinetic energy of molecular hydrogen ions from 1 eV upwards, the contribution of the process involving hydrogen atom transfer to the formation of secondary H_3^+ ions increases. For these kinetic energies of the molecular ions, both processes involve a direct mechanism, since their cross-sections are independent of the vibrational excitation energy of the molecular ions and the cross-section of the proton transfer process actually increases with increasing vibrational excitation of H_2^+ to 2 eV. For kinetic energies close to thermal energies, the proton transfer process contributes significantly to the formation of H_3^+ ions.

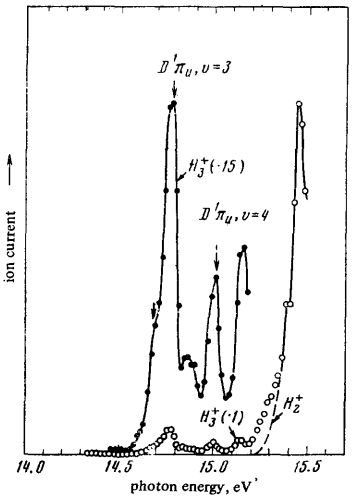

Figure 2. Appearance curves for H_2^+ and H_3^+ ions in the chemi-ionisation region recorded with a resolution of 2.5 Å. The arrow indicates the dissociation threshold of the hydrogen molecule (14.66 eV).

Fig. 2 shows that, in the range of photon energies below the hydrogen ionisation potential, the formation of H_3^+ ions involves the reaction of metastable hydrogen atoms with hydrogen molecules:

$$H\,(2S)+H_2\,(X^1\Sigma_g^+,\ v''=0) \rightarrow H_3^+ + e\,. \qquad (4)$$

Reaction (4) is exothermic, since at the predissociation threshold of the hydrogen molecule (14.66 eV) it involves metastable hydrogen atoms with thermal velocities. This finding serves as a basis for the determination of the heat of formation of H_3^+ ions:

$$\Delta H_f[H_3^+] \leqslant \Delta H_f[H(2S)] = 12.455\ \text{eV},$$

which corresponds to the lower limit of the proton affinity of the hydrogen molecule (3.396 eV).

On passing to photon energies of 14.77 and 15.01 eV, for which metastable hydrogen atoms are formed with an excess kinetic energy, the cross-section of reaction (4) has been shown[18] to decrease as v^{-n}, where v is the

velocity of the hydrogen atom and $n = 2-3$. In the range of photon energies between 15.20 eV and the hydrogen ionisation potential (15.425 eV), the observed increase of the yield of secondary H_3^+ ions must be attributed to reactions involving electronically excited hydrogen molecules:

$$H_2^* + H_2 (X^1\Sigma_g^+, v'' = 0) \rightarrow H_3^+ + H^- , \quad (5)$$

$$H_2^* + H_2 (X^1\Sigma_g^+, v'' = 0) \rightarrow H_3^+ + H(1S) + e . \quad (6)$$

It is important to note here that the contribution of reaction (4) to the formation of H_3^+ ions in this range of energies is insignificant for the reason indicated above. It has been shown[20] that highly excited long-lived states of the hydrogen molecule with a principal quantum number $n > 5$ play a significant role in reactions (5) and (6). The energies of such states lie in the region 0.1–0.2 eV below the ionisation potential of the hydrogen molecule.

2. Hydrogen and Noble Gases

The studies on the ion–molecule reactions observed in the ionisation of hydrogen molecules and noble gases by electron impact have dealt mainly with the identification of the reaction products and the investigation of the dependence of their cross-sections on the kinetic energies of the colliding species[21-25]. The ion–molecule reactions occurring on photoionisation of hydrogen molecules and helium, neon, and argon atoms and leading to the formation of the ions HeH^+, NeH^+, and ArH^+ have been investigated[26]. It has been shown that the formation of the HeH^+ and NeH^+ ions is associated with the involvement in the ion–molecule reactions of thermal molecular hydrogen ions in excited vibrational states:

$$H_2^+ (^2\Sigma_g, v' \geqslant 3) + He \rightarrow HeH^+ + H , \quad (7)$$

$$H_2^+ (^2\Sigma_g, v' \geqslant 2) + Ne \rightarrow NeH^+ + H . \quad (8)$$

Reactions (7) and (8) are observed for photon energies in excess of 16.20 and 15.97 eV, which corresponds to the formation of secondary HeH^+ and NeH^+ ions from vibrationally excited H_2^+ ions with quantum numbers $v \geqslant 3$ and $v \geqslant 2$ respectively. It has also been shown[26] that the cross-sections of ion–molecule reactions (7) and (8) increase with the vibrational excitation energy of the primary ions.

The formation of HeH^+ and NeH^+ ions involving hydrogen ions in the ground vibrational state is also observed, but in this case the ion–molecule reactions occur at the threshold of the kinetic energy of the initial H_2^+ ions[27].

On the basis of the foregoing data, one may conclude that the ion–molecule reactions leading to the formation of HeH^+ and NeH^+ ions proceed via an intermediate "complex", which ensures a redistribution of the internal and translational energy of the colliding species. It must be noted that the data obtained[26,27] on the role of excited vibrational states of molecules in ion–molecule reactions in hydrogen and noble gases are consistent with the results of the above electron impact studies.

On the basis of the photon energy thresholds for reactions (7) and (8), which are 16.20 and 15.97 eV, it is possible to determine the proton affinities of helium and neon. For helium, this quantity is 1.835 eV, while the proton affinity of neon determined from the energy threshold for reaction (8) is 2.08 eV. This value is consistent with the proton affinity of 2.15 ± 0.3 eV obtained by the electron impact method[21].

Ion–molecule reactions leading to the appearance of ArH^+ ions on photon ionisation of hydrogen and argon are exothermic, since they involve the primary H_2^+ and Ar^+ ions in both ground and excited states:

$$H_2^+ (^2\Sigma_g, v' \geqslant 0) + Ar \rightarrow ArH^+ + H , \quad (9)$$

$$Ar^+ (^2P_{3/2} \text{ or } ^2P_{1/2}) + H_2 \rightarrow ArH^+ + H . \quad (10)$$

With increase of the photon energy from the hydrogen ionisation potential (15.425 eV) upwards, the cross-section of reaction (9) hardly changes, i.e. it is independent of the energy of the vibrational excitation of the initial molecular hydrogen ions. The cross-section of reaction (10), which involves argon ions in the excited state $^2P_{1/2}$, exceeds the cross-section of the same reaction for argon ions in the ground state $^2P_{3/2}$. These results are consistent with the theoretical estimates of the rate constants for the ion–molecule reaction (10).[28]

It has also been shown[26] that the formation of ArH^+ ions begins below the ionisation potentials of the hydrogen molecule and the argon atom for photon energies exceeding the predissociation threshold of the hydrogen molecule in the $D^1\Pi_u$ state (14.66 eV) and therefore may be attributed to the reaction of metastable hydrogen atoms with argon atoms:

$$H(2S) + Ar \rightarrow ArH^+ + e . \quad (11)$$

Argon atoms in the excited electronic state $4d[\frac{1}{2}]_1^0$ (14.71 eV) can also contribute to the formation of ArH^+ and Ar_2^+ ions in collisions with hydrogen molecules and other argon atoms:

$$Ar[4d[1/2]_1^0] + H_2 \rightarrow ArH^+ + (H + e) , \quad (12)$$

$$Ar[4d[1/2]_1^0] + Ar \rightarrow Ar_2^+ + e . \quad (13)$$

The lower limit of the proton affinity of argon determined on the hypothesis that reaction (11) involves thermal hydrogen atoms in the 2S state is 3.397 eV.

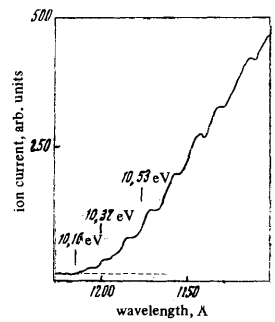

Figure 3. Photoionisation curve for ammonia.

3. Ammonia and Water

The photoionisation of ammonia molecules is characterised by a structure of the vibrational and autoionisation levels on the appearance curve for molecular ions at the first ionisation potential, which is 10.16 eV and corresponds to the removal of an electron from the ^2P_z orbital of the lone electron pair of nitrogen[29-31]. Fig. 3 shows that the initial section of the ammonia photoionisation curve consists of a series of steps, which is evidence of direct ionisation of the molecules in this range of photon

energies. At photon energies of 10.32 and 10.53 eV, the deformation and stretching vibrations of the radical-cations NH_3^+ are excited[30]. A contribution by autoionisation states appears with increase of photon energy.

The formation of excited electronic states of the ammonia radical-cations is observed at higher photon energies (15.31 eV) and involves the removal of an electron from the σ_{NH} orbital[32].

Ion–molecule reactions in ammonia have been investigated by the electron impact method[10,33,34]. Thus, using the method of the pulse withdrawal of ions, it has been shown[10] that the formation of NH_4^+ ions involves radical-cations at thermal velocities, starting with the ammonia ionisation threshold:

$$NH_3^{+\cdot} + NH_3 \rightarrow NH_4^+ + NH_2^{\cdot}. \qquad (14)$$

It has also been shown by the photoionisation method that the appearance potentials of NH_4^+ and $NH_3^{+\cdot}$ ions agree very closely (to within 0.01 eV)[30,31]. These findings suggest that reaction (14) involves the radical-cations $NH_3^{+\cdot}$ in the ground and excited vibrational states.

With increase of photon energy from the primary ionisation potential of ammonia (10.16 eV) upwards by 1.4 eV, the cross-section of the ion–molecule reaction (14) decreases approximately by 20%. This suggests that the yield of NH_4^+ ions in reaction (14) decreases with increasing vibrational excitation of the primary ammonia radical-cations when the vibrational quantum number increases from zero to nine.

Table 1. Heats of formation of molecules, radicals, and ions employed in the thermochemical calculations.

Species	$\Delta H_f^{298°K}$, eV	References	Species	$\Delta H_f^{298°K}$, eV	References
H	+2.26	37	CH_3OH	−2.08	41

H_3O^+	+6.20±0.05	36	CH_3COCH_2	−0.52	38
CH_3O	+0.08±0.09	38	$(CH_3)_2CHOH$	−2.84	41
CH_3OH	−0.35±0.13	38	$(CH_3)_3COH$	−3.24	41
C_2H_5O	−0.30±0.09	38	C_6H_6	+3.12	38
CH_3CHOH^+	−0.80±0.13	38	$C_6H_5CH_2$	+1.92	38
			$C_6H_5^+$	+0.86	39
$CH_2{=}OH^+$	+7.25±0.05	40	$C_6H_5CH_3$	+0.52	39
$CH_3CH{=}OH^+$	+6.10±0.05	40	1,3-$C_6H_4(CH_3)_2$	+0.18	39
$(CH_3)_2COH^+$	+5.10±0.05	40	cyclohexa-1,3-diene	+1.11	39
$CH_3OH_2^+$	+6.00±0.13	11	CH_3	+1.47	38
$C_2H_5OH_2^+$	+5.05±0.4	11			

It has also been shown[31] that the change in the kinetic energy of the primary radical-cations $NH_3^{+\cdot}$, achieved by altering the gradient of the electric field withdrawing ions from the ionisation chamber of the mass-spectrometer, does not affect significantly the variation of the cross-section of reaction (14) with the internal energy of the primary radical-cations. This enabled the authors[31] to conclude that reaction (14) involves the formation of an intermediate "complex" in accordance with the statistical theory of ion–molecule reactions[35]. According to this theory, at the ammonia ionisation threshold reaction (14) proceeds via only one pathway with formation of NH_4^+ ions. With increase of the internal energy of the primary radical-cations $NH_3^{+\cdot}$, the probability of the reverse reaction increases, which leads ultimately to a decrease of the yield of NH_4^+ cations as the photon energy rises.

In contrast to reaction (14), the cross-section for the formation of NH_4^+ ions in the reaction between ammonia radical-cations and water molecules, which involves the transfer of a hydrogen atom, is independent of photon energy in the range from the ionisation potential upwards:

$$NH_3^{+\cdot} + H_2O \rightarrow NH_4^+ + HO^{\cdot}. \qquad (15.1)$$

Another pathway in this reaction involves the formation of H_3O^+ cations by transfer of a proton from the ammonia radical-cation to a water molecule:

$$NH_3^{+\cdot} + H_2O \rightarrow NH_2^{\cdot} + H_3O^+. \qquad (15.2)$$

Thermochemical calculations[36] based on the heats of formation of the cations NH_4^+ and H_3O^+ (Table 1) show that the heats of the exothermic ion-molecule reactions (14), (15.1), and (15.2) are 2.0, 1.3, and 0.2 eV respectively. The proton affinities of ammonia (9.0 eV) and water (7.16 eV) were also determined from the heats of formation of the cations NH_4^+ and H_3O^+.

III. ION–MOLECULE REACTIONS IN SATURATED AND UNSATURATED HYDROCARBONS

1. Olefins

The photoionisation of olefins in the region of the first ionisation potential involves the formation of radical-cations in the ground and excited states as the result of the removal of an electron from an upper π-type molecular orbital, which has a maximum electron density at the C–C bond. The interaction of π electrons with the electrons of the σ orbitals is fairly strong[42].

In the photoionisation of ethylene, deformation and stretching vibrations of the C–C bond at frequencies of 440 and 1400 cm^{-1} respectively are excited in the radical-cations at the ionisation threshold[43]. With increase of photon energy by 1–2 eV, the C–H bond vibrations and combination vibrations at a higher frequency are excited.

The radical-cations thus obtained exhibit a high reactivity in ion–molecule reactions in the photolysis and radiolysis of olefins and unsaturated hydrocarbons.

In the study of ion–molecule reactions in olefins, the mass-spectrometric photoionisation method was first employed by Koyano and coworkers[44,45]. It enabled them to determine various pathways in the formation of secondary products comprising ions of different structures, radicals, and molecules in the reaction between the radical-cations and molecules of the given olefin.

Ethylene[46]:

$$C_2H_4^{+\cdot} + C_2H_4 \rightarrow C_3H_5^+ + CH_3^{\cdot}, \qquad (16.1)$$

$$\rightarrow C_4H_7^+ + H^{\cdot}. \qquad (16.2)$$

Propene[44]:

$$C_3H_6^{+\cdot} + C_3H_6 \rightarrow C_3H_5^+ + C_3H_7^{\cdot} + H_2, \qquad (17.1)$$

$$\rightarrow C_3H_7^+ + C_3H_5^{\cdot}, \qquad (17.2)$$

$$\rightarrow C_4H_7^+ + C_2H_5^{\cdot}, \qquad (17.3)$$

$$\rightarrow C_4H_8^{+\cdot} + C_2H_4, \qquad (17.4)$$

$$\rightarrow C_5H_9^+ + CH_3^{\cdot}. \qquad (17.5)$$

But-1-ene[45]:

$$C_4H_8^{+\cdot} + C_4H_8 \rightarrow C_4H_7^+ + C_4H_9^\cdot , \quad (18.1)$$
$$\rightarrow C_4H_9^+ + C_4H_7^\cdot , \quad (18.2)$$
$$\rightarrow C_5H_9^+ + C_3H_7^\cdot , \quad (18.3)$$
$$\rightarrow C_5H_{10}^{+\cdot} + C_3H_6 , \quad (18.4)$$
$$\rightarrow C_5H_{11}^+ + C_3H_5^\cdot , \quad (18.5)$$
$$\rightarrow C_6H_{11}^+ + C_2H_5^\cdot , \quad (18.6)$$
$$\rightarrow C_6H_{12}^{+\cdot} + C_2H_4 . \quad (18.7)$$

But-2-ene[45]:

$$C_4H_8^+ + C_4H_8 \rightarrow C_4H_7^+ + C_4H_9^\cdot , \quad (19.1)$$
$$\rightarrow C_4H_9^+ + C_4H_7^\cdot , \quad (19.2)$$
$$\rightarrow C_5H_9^+ + C_3H_7^\cdot . \quad (19.3)$$

Isobutene[45]:

$$C_4H_8^{+\cdot} + C_4H_8 \rightarrow C_4H_7^+ + C_4H_9^\cdot , \quad (20.1)$$
$$\rightarrow C_4H_9^+ + C_4H_7^\cdot , \quad (20.2)$$
$$\rightarrow C_5H_9^+ + C_3H_7^\cdot . \quad (20.3)$$

Buta-1,3-diene[44]:

$$C_4H_6^{+\cdot} + C_4H_6 \rightarrow C_3H_3^+ + C_5H_9^\cdot , \quad (21.1)$$
$$\rightarrow C_4H_5^+ + C_4H_7^\cdot , \quad (21.2)$$
$$\rightarrow C_4H_7^+ + C_4H_5^\cdot , \quad (21.3)$$
$$\rightarrow C_6H_6^{+\cdot} + C_3H_6 , \quad (21.4)$$
$$\rightarrow C_5H_7^+ + C_3H_5^\cdot , \quad (21.5)$$
$$\rightarrow C_6H_7^+ + C_2H_5^\cdot , \quad (21.6)$$
$$\rightarrow C_6H_8^{+\cdot} + C_2H_4 , \quad (21.7)$$
$$\rightarrow C_7H_9^+ + CH_3^\cdot . \quad (21.8)$$

The ion–molecule reactions occurring in the photoionisation of olefins involving radical-cations can be divided into three main types.

1. Reactions (18.1), (19.1), (20.1), and (21.1), in which a hydrogen atom is transferred from the radical-cation to the olefin molecule (but-1-ene, but-2-ene, isobutene, and buta-1,3-diene) and which lead to the formation of the corresponding cations and alkyl radicals.

2. Reactions (17.2), (18.2), (19.2), (20.2), and (21.3), which lead to the formation of cations with a mass exceeding the molecular mass by unity and of radicals. It has been shown[47] that reactions of this type in propene and buta-1,3-diene involve the transfer of a hydrogen atom from the molecule to the radical-cation of the olefin.

3. Reactions involving a complex rearrangement of the atoms in the radical-cation and the molecule during collision. This applies in the first place to the formation of secondary ions and neutral species via the dissociation of C–H and C–C bonds in the initial species. Analysis of the velocity distribution of the ion–molecule reaction products in ethylene showed that reactions of this type proceed via a long-lived intermediate "complex", which ensures a redistribution of the energies of the colliding species among different degrees of freedom[45]. However, there are also exceptions for reactions of this type. For instance, the ion–molecule reaction in buta-1,3-diene leading to the formation of $C_3H_3^+$ ions and C_5H_9 radicals involves a direct mechanism.

2. Saturated and Unsaturated Hydrocarbons

Ion–molecule reactions play a significant role in the formation of secondary products in the radiolysis and photolysis of saturated and unsaturated hydrocarbons in the gas phase. The application of the mass-spectrometric photoionisation method permitted the determination of the principal pathways in these ion–molecule reactions and yielded information about the nature of their intermediate states.

Ion–molecule reactions of the first type include processes involving the transfer of H_2^- from the molecule to the radical-cation:

$$C_nH_m^{+\cdot} + AH_2 \rightarrow C_nH_{m+2} + A^{+\cdot} , \quad (22)$$

where AH_2 is a saturated hydrocarbon molecule and $C_nH_m^+$ the radical-cation of an unsaturated hydrocarbon or cyclopropane[48,49]. An example of this type of ion–molecule reactions occurring in the radiolysis of saturated hydrocarbons is the reaction between the propene radical-cations, formed in the decomposition of cyclopentane radical-cations, and cyclopentane molecules[50]:

$$C_3D_6^{+\cdot} + \text{cyclo-}C_5D_{10} \rightarrow C_3D_8 + C_5D_8^{+\cdot} . \quad (22.1)$$

The most systematic data on the mechanism of the ion–molecule reactions occurring in the photolysis of propene and unsaturated hydrocarbons and involving an H_2^- transfer have been obtained by Gorden and Ausloos[51]:

$$C_3D_6^{+\cdot} + AH_2 \rightarrow CD_3CDHCD_2H + A^{+\cdot} , \quad (22.2)$$

where AH_2 is a saturated hydrocarbon molecule (cycloalkanes, straight-chain and branched-chain alkanes). The contribution of other ion–molecule reactions to the formation of secondary products was excluded, since the experiments were performed at a photon energy of 10.0 eV, which is less than the ionisation potentials of the saturated hydrocarbons AH_2.

It is seen that the ion–molecule reaction in the photoionisation of propene and isobutane proceeds via an intermediate state the structure of which ensures the transfer of the HD^- species from the isobutane molecule to the propene radical-cation:

$$C_3D_6^{+\cdot} + (CH_3)_3CD \rightarrow C_3D_7H + C_4H_8^{+\cdot} . \quad (22.3)$$

It has been shown[51] that such an intermediate state ensures the transfer of a hydrogen atom from the CH_3 group of isobutane to the central atom of the $C_3D_6^{+\cdot}$ radical-cation and the formation of the propane molecule CD_3CDHCD_3. Such stereospecificity of the intermediate state in reactions of this type occurs also in the interaction between the propene radical-cation and the n-butane molecule:

$$C_3D_6^{+\cdot} + CD_3CH_2CH_2CD_3 \rightarrow C_3D_7H + CD_2CHCH_2CD_3^{+\cdot} . \quad (22.4)$$

The second important type of ion–molecule reactions in the photoionisation of the molecules in mixtures of saturated and unsaturated hydrocarbons includes H_2 transfer processes[50]:

$$C_nH_m + AH_2^{+\cdot} \rightarrow C_nH_{m+2} + A^{+\cdot} , \quad (23)$$

where C_nH_m is a cyclopropane or an unsaturated hydrocarbon molecule and $AH_2^{+\cdot}$ is the radical-cation of a saturated hydrocarbon. This type of reaction between the cyclohexane radical-cation and the cyclopropane molecule,

$$\text{cyclo-}C_6H_{12}^{+\cdot} + \text{cyclo-}C_3D_6 \rightarrow C_6H_{10}^{+\cdot} + C_3D_6H_2 , \quad (23.1)$$

involves the transfer of H_2 from the radical-cation and its addition to two carbon atoms with simultaneous ring opening and the formation of the propane molecule $CD_2HCD_2.CD_2H$.

It should be noted that in ion–molecule reactions of type (23), there is a competing process involving the

transfer of a hydrogen atom from the radical-cation to the molecule:

$$C_nH_m + AH_2^{+\cdot} \rightarrow C_nH_{m+1}^{\cdot} + AH^+. \quad (24)$$

Ion–molecule reactions at a high pressure (p = 20 torr) in a mixture of cyclobutane with saturated hydrocarbons, aliphatic amines, and other compounds have been investigated by the photoionisation method[52].

In a mixture of cyclobutane with alkanes and cycloalkanes, ion–molecule reactions proceeding via two pathways were observed: via the transfer of H^- and H_2^- from the AH_2 molecule (alkane or cycloalkane) to the radical-cation $C_4H_8^{+\cdot}$ formed in the photoionisation of cyclobutane ($h\nu \simeq 10.3$ eV):

$$C_4H_8^{+\cdot} + AH_2 \rightarrow C_4H_9^{\cdot} + AH^+, \quad (25.1)$$

$$C_4H_8^{+\cdot} + AH_2 \rightarrow C_4H_{10} + A^{+\cdot}. \quad (25.2)$$

Ion–molecule reactions involving charge transfer in mixtures of cyclobutane with cyclohexane, trimethylamine, and nitric oxide were also observed in the same study.

IV. PHOTOIONISATION AND ION–MOLECULE REACTIONS IN KETONES AND ALCOHOLS

1. Alcohols

Systematic studies on the primary photoionisation and decomposition processes of aliphatic alcohols were first performed by Potapov and Sorokin[40] and Refaye and Chupka[53]. The application of the accurate photoionisation method made it possible to resolve the structure of the electronic and vibrational levels of the radical-cations on the photoionisation curves for alcohols recorded automatically on an MKh-1311 mass-spectrometer[1] and to determine the formation energies of fragment ions of different structures.

It was shown that ethanol radical-cations are formed mainly in excited electronic states at photon energies of 10.49 and 11.6 eV, which correspond to the removal of an electron from the $n(2P_y)$ orbital of the lone pair of oxygen and from the highest occupied σ orbital of the ground state respectively[40].

Data on the nature of the vibrational states of methanol and ethanol radical-cations excited in photoionisation have been obtained[40] by automatic differentiation of the initial sections of the photoionisation curves. The vibrational spectra of methanol (CD_3OH, CH_3OH, and CH_3OD) radical-cations shown in Fig. 4 are characterised by the presence of two principal bands. The first band (0–0 transition) corresponds to the first adiabatic ionisation potential of methanol, involving the removal of an electron from the lone pair of oxygen. The second band (900 cm^{-1}) may be assigned to the excitation of vibrations associated with the C–O bond. The relative intensity of these vibrations does not change when the hydrogen atom is substituted by a deuterium atom in the hydroxy-group but increases when the three hydrogen atoms in the methyl group are replaced by deuterium atoms. The probability of the formation of vibrationally excited radical-cations of ethanol is higher than the probability of their formation in the ground state. These findings indicate an increase of the C–O equilibrium bond length in the radical-cation on passing from CH_3OH to CD_3OH and C_2H_5OH.

Data on the mechanism of the decomposition of methanol and ethanol radical-cations on photoionisation were obtained[40] by analysing the simple mass spectra and appearance potentials of the fragment ions of the deuterated compounds CD_3OH and CH_3CD_2OH:

$$CD_3OH + h\nu \rightarrow CD_3OH^{+\cdot} + e, \quad (26.1)$$

$$CD_2OH^+ + D + e, \quad (26.2)$$

$$CH_3CD_2OH + h\nu \rightarrow CH_3CD_2OH^{+\cdot} + e, \quad (27.1)$$

$$CH_3CDOH^+ + D + e, \quad (27.2)$$

$$CD_2OH^+ + CH_3 + e. \quad (27.3)$$

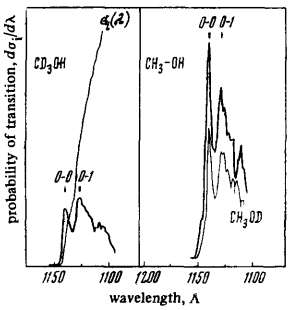

Figure 4. Vibrational spectra of radical cations.

Table 2. Appearance potentials of methanol and ethanol ions.

Compound	m/e	Type of ion	Appearance potential, eV
CD_3OH	35	$CD_3OH^{+\cdot}$	10.85±0.01
	34	$(CD_3O)^+$	12.0±0.05
	33	$CD_2{=}\overset{+}{O}H$	11.6±0.05
CH_3CD_2OH	48	$CH_3CD_2OH^{+\cdot}$	10.49±0.01 11.6±0.1
	46	$CH_3CD{=}\overset{+}{O}H$	10.8±0.05 11.7±0.1
	33	$CD_2{=}\overset{+}{O}H$	11.2±0.05
t-C_4H_9OH	59	$(CH_3)_2C{=}\overset{+}{O}H$	9.87±0.05 11.0±0.1 12.2±0.2

Table 2 shows that the decomposition processes which are energetically the most favourable are the decomposition reactions involving the dissociation of C–D and C–C bonds in the vibrationally excited radical-cations [reactions (26.2) and (27.2)] obtained by the removal of an electron from the lone pair of oxygen. These reactions involve a change in the initial electronic-nuclear configuration of the radical-cations with formation of the cations $CD_2{=}\overset{+}{O}H$ and $CH_3CD{=}\overset{+}{O}H$. The formation of $(CD_3O)^+$ ions from methanol is observed at a photon energy of 12.0 eV, which exceeds by 0.4 eV the appearance potential of the $CD_2{=}\overset{+}{O}H$ ions derived from CD_3OH [reaction (26.2)], but their yield is low. The $(CD_3O)^+$ ions formed via a rearrangement of the hydrogen and deuterium atoms have a structure of the type $CH_2{=}\overset{+}{O}H$, since the formation of CD_3O^+ ions by a direct removal of an electron from the σ orbital should occur at higher energies.

It is noteworthy that, according to the data of Brehm et al. [55], the dissociative photoionisation of methanol in the range of energies between the first and second ionisation potentials can also proceed via autoionisation states. However, in the case of ethanol the contribution by autoionisation states to the formation of fragment ions is already insignificant. The formation of $(CH_3CDOH)^+$ ions from CH_3CD_2OH at a photon energy of 11.7 eV, i.e. higher by 0.1 eV than the second ionisation potential, is associated with the decomposition of electronically excited radical-cations.

A characteristic feature of the photoionisation of t-butyl alochol [40] is the absence from the mass spectrum of an appreciable yield of molecular ions. The main dissociation process of t-butyl alcohol is the formation of $(CH_3)_2C{=}\overset{+}{O}H$ cations and methyl radicals in the range of energies from 9.87 eV upwards:

$$(CH_3)_3COH + h\nu \rightarrow (CH_3)_2C{=}\overset{+}{O}H + CH_3 + e \quad . \qquad (28)$$

The yield of $(CH_3)_2C{=}\overset{+}{O}H$ cations increases appreciably at energies of 11.0 and 12.2 eV, corresponding to the second and third ionisation potentials of the t-butyl alcohol molecule.

Table 3. Ion–molecule reactions in methanol and ethanol [46].

Reactions		$-Q^{298°K}$*, eV	Reaction cross-section**
$CH_3OD^{+\cdot} + CH_3OD \rightarrow CH_3\overset{+}{O}D_2 + CH_3O$	(29.1)	0.6±0.1	1.0
$\rightarrow CH_3\overset{+}{O}DH + CH_2OD$	(29.2)	1.0±0.1	0.6
$CH_2\overset{+}{O}D + CH_3OD \rightarrow CH_3\overset{+}{O}D_2 + CH_2O$	(29.3)	0.4±0.1	2.7
$CH_3CD_2OH^{+\cdot} + CH_3CD_2OH \rightarrow CH_3CD_2\overset{+}{O}H_2 + CH_3CD_2O$	(30.1)	0.9±0.4	1.0
$CH_3CD_2OH^{+\cdot} + CH_3CD_2OH \rightarrow CH_3CD_2\overset{+}{O}HD + CH_3CDOH$	(30.2)	1.2±0.4	0.3
$\rightarrow CH_3CD_2\overset{+}{O}H_2 + CH_2CD_2OH$	(30.3)	1.2±0.4	0.06
$CD_2\overset{+}{O}H + CH_3CD_2OH \rightarrow CH_3CD_2\overset{+}{O}H_2 + CD_2O$	(30.5)	0.8±0.4	1.5
$CH_3CD\overset{+}{O}H + CH_3CD_2OH \rightarrow CH_3CD_2\overset{+}{O}H_2 + CH_3CDO$	(30.6)	0.2±0.4	

*Q is the heat of the ion–molecule reaction.
**The relative cross-sections for the reaction paths indicated in the Table correspond to a single dissociated bond.

The ion–molecule reactions occurring in the photon ionisation of methanol and ethanol [54] are exothermic, since the appearance potentials of the secondary cations agree to within 0.02 eV with the first ionisation potentials of methanol (10.85 eV) and ethanol (10.49 eV). This finding is consistent with data for ion–molecule reactions in alcohols obtained by the electron impact method using pulse withdrawal of ions [11].

Analysis of the changes in the mass spectra of methanol (CD_3OH, CH_3OD) and ethanol (CH_3CD_2OH, CD_3CH_2OH) as a function of the concentration of the alcohol in the ionisation chamber and of photon energy, carried out by Potapov and Sorokin [54], made it possible to determine the relative cross-sections for different pathways of ion–molecule reactions in both methanol and ethanol.

Table 3 shows that a general characteristic of ion–molecule reactions in alcohols involving primary radical-cations is that reactions (29.1) and (30.1), which yield secondary oxonium cations and the alkoxy-radicals CH_3O and CH_3CD_2O respectively, are more probable than reactions (29.2) and (30.2) involving the formation of secondary cations and methanol and ethanol radicals, despite the fact that the latter processes are energetically more favourable. In ethanol oxonium cations and the radicals CH_2CD_2OH are also formed but with a lower probability than that of the processes described above.

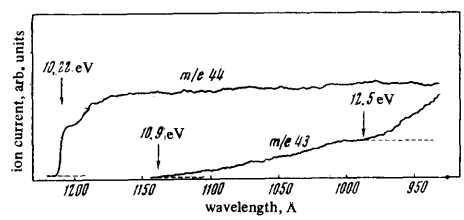

Figure 5. Appearance curves for molecular and fragment ions of acetaldehyde.

The different probabilities of ion–molecule reactions in alcohols by various pathways are determined by the interaction of the positive ion with the induced molecular dipole, which is a specific feature of polar molecules. In this case such an interaction between the radical-cation and the molecule leads to preliminary orientation of the molecule relative to the ion, which ensures the maximum probability of the ion–molecule reaction involving the transfer of a hydrogen atom (proton) from the O–H group. The probability of the reaction via this pathway relative to the reaction yielding secondary cations and radicals by the dissociation of the C_α–H bond is higher in ethanol than in methanol, probably owing to the greater polarisability of ethanol.

As already mentioned above, the electronic states of the methanol and ethanol radical-cations formed by the removal of an electron from the lone pairs of oxygen are characterised by the presence of a free valence localised at the oxygen atomic orbital. This explains the high reactivity of the alcohol radical-cations in their decomposition into cations of the type $CH_2{=}\overset{+}{O}H$ (methanol) and $CH_3CH{=}\overset{+}{O}H$ (ethanol). This feature should of course be observed also in ion–molecule reactions involving methanol and ethanol radical-cations. For this reason, one may postulate that the formation of heavier ions and radicals proceeds via the dissociation of the O–H (C–H) bond in the molecule and the addition of a hydrogen atom to the free valence of the radical-cation. This naturally does not rule out the possibility that ion–molecule reactions involving radical-cations can proceed via a proton transfer, for example from the OH group of the radical-cation to the molecule.

It has been shown [30,54] that near the first ionisation potentials the cross-sections of ion–molecule reactions in methanol and ethanol involving radical-cations are independent of the energy of the ionising photons and hence of the vibrational excitation of the radical-cations on photoionisation (Fig. 6). For reactions (29.2) and (30.2), which

lead to the formation of oxonium ions and methanol and ethanol radicals, the variation of the cross-section with photon energy persists also at photon energies exceeding the second ionisation potential of ethanol. This type of relation between the ionisation cross-sections for ion–molecule reactions and the internal energy of radical-cations is characteristic of processes involving the transfer of a hydrogen atom.

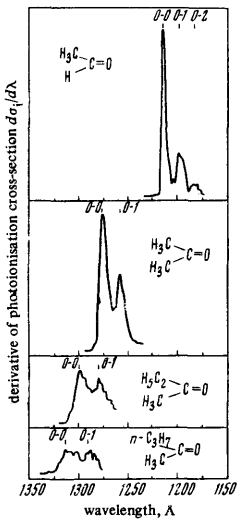

Figure 6. Vibrational spectra of the radical-cations of aliphatic ketones.

The cross-sections of ion–molecule reactions leading to the formation of oxonium ions $CH_3\overset{+}{O}D_2$ from CH_3OD and $CH_3CD_2\overset{+}{O}H_2$ from CH_3CD_2OH begin to increase at photon energies coresponding to the appearance potentials of the cations $CH_2{=}\overset{+}{O}D$ (CH_3OD) and $CH_3CD{=}\overset{+}{O}H$ (CH_3CD_2OH). This finding is evidence of the involvement of the cations $CH_2{=}\overset{+}{O}H$, $CH_3CD{=}\overset{+}{O}H$ and $CD_2{=}\overset{+}{O}H$ in the ion–molecule reactions (29.3), (30.4), and (30.5). This conclusion is consistent with the hypothesis of the involvement in ion–molecule reactions of fragment ions formed by electron impact[56]. Table 3 shows that these reactions are exothermic and proceed via the transfer of a proton from the hydroxy-group of the cation to the molecule with formation of the corresponding secondary oxonium ions and formaldehyde and acetaldehyde molecules.

2. Ketones

A characteristic feature of the electronic structure of aliphatic ketones is that the upper level of the ground state is occupied by the lone electron pair of oxygen[57]. This feature is clearly reflected in the presence of sharply rising sections in the photoionisation curves for acetaldehyde and acetone (see, for example, Fig. 5) near the first ionisation potentials, corresponding to the formation of radical-cations in the ground vibrational state by the removal of an electron from the $n(2P_y)$ orbital of the carbonyl oxygen[2]. The electronic states of the radical-cations formed in this way are characterised by the presence of a free valence localised at the atomic orbital of the heteroatom.

The vibrational spectra of the radical-cations of acetaldehyde, acetone, ethyl methyl ketone, and methyl n-propyl ketone, obtained by the automatic differentiation of the initial sections of the photoionisation curves and presented in Fig. 6, indicate the position of the 0–0 transition corresponding to the adiabatic ionisation potential and the 0–1 transition associated with the excitation of the vibrations of the C–O bond in the radical-cation[40]. The energies of these vibrations are in the range 0.14–0.15 eV for all the ketones mentioned above. This assignment of the vibrational bands of the radical-cations is consistent with data[58] showing that the vibrational energy of the C=O group in ketones, in excited electronic states, is of the order of 0.16 eV. The relative probability of the formation of the ketone radical-cations in the vibrational ground state, formed by the removal of an electron from the lone pair of oxygen, is a maximum, It decreases on passing from acetaldehyde to methyl n-propyl ketone, which is evidence that, with increase in the length of the aliphatic chain, the change in the equilibrium internuclear distance in the C=O bond of the radical-cations increases compared with the equilibrium internuclear distance in molecules in the ground state. It is of course reflected in a decrease of the relative intensity of the electronic 0–0 transition compared with the intensity of the 0–1 band corresponding to the C=O bond vibration. The mechanism of the interaction of the electrons of the radical-cation, leading to a change in bond length and order, depends on the change in the degree of overlap of the wave function of the unpaired electron of the lone pair of oxygen with the wave functions of the σ and π orbitals on passing from acetaldehyde to methyl n-propyl ketone.

The decrease in the adiabatic ionisation potentials of the ketones of the above series is correlated with the decrease of the C=O bond order of the molecule in the ground state and it has been shown[59] to be related to the increased polarity of this bond (increased negative charge at the oxygen atom).

At higher vibrational excitation energies, i.e. at ionising photon energies of 10.89 eV (acetaldehyde) and 10.42 eV (acetone), the interaction of the unpaired oxygen electron with the electrons of the σ orbitals leads to a change of the electronic-nuclear configuration of the radical-cation as a whole and its decomposition into the ion $CH_3-C{\equiv}O^+$ and the radical R:

$$\begin{matrix} R \\ H_3C \end{matrix}\!\!>\!C{=}O + h\nu \rightarrow \begin{matrix} R \\ H_3C \end{matrix}\!\!>\!C{=}O^{+\cdot} + e\ , \qquad (31.1)$$

$$\rightarrow CH_3{-}C{\equiv}O^{+} + R + e\ , \qquad (31.2)$$

where R = H or CH_3.

In the region of photon energies of 11.7 eV, the appearance curve for fragment ions of acetone shows an appreciable increase of the yield of the ions. The increased yield for this energy may be attributed to the decomposition of electronically excited acetone radical-cations:

$$(CH_3)_2CO + h\nu \rightarrow CH_3{-}\overset{+}{C}{=}O + CH_3 + e\ . \qquad (32)$$

The cations formed in this way have a structure different from that of $CH_3-C{\equiv}\overset{+}{O}$ formed in the decomposition of vibrationally excited radical-cations by reaction (31.2). For acetaldehyde, the formation of fragment ions with a mass of 43 by this pathway takes place at a higher energy (12.5 eV), corresponding to the second ionisation potential.

It has been shown[30] that at higher vapour pressures of acetaldehyde and acetone the mass spectra of these compounds reveal secondary cations, the origin of which may be accounted for as follows. In the collisions between radical-cations and molecules, the unpaired electron of the heteroatom enters into an exchange interaction with the electrons of the C–H bond of the molecule, which may become very intense (in the presence of the necessary overlapping of the electron clouds of the colliding species) and may lead to the dissociation of the C–H bond and the formation of a new bond in the ion:

$$CH_3CH=\overset{+\cdot}{O} + CH_3CH=O \rightarrow CH_3CH=\overset{+}{O}-H + CH_3CO\,, \qquad (33)$$

$$(CH_3)_2C=\overset{+\cdot}{O} + (CH_3)_2C=O \rightarrow (CH_3)_2C=\overset{+}{O}-H + CH_3COCH_2\,. \qquad (34)$$

The heats of the exothermic ion–molecule reactions (33) and (34) involving the transfer of a hydrogen atom, determined from the heats of formation of the reactant species, are −0.87 and −0.75 eV. The cross-section of reactions (33) and (34) in the range of photon energies between the first ionisation potential of acetaldehyde (10.22 eV) and acetone (9.71 eV) and above are independent of the photon energies. The increase of the yield of secondary cations, observed, for example, for acetone at an energy of 11.7 eV, is probably associated with the participation of cations formed in the decomposition of the molecule via mechanism (32):

$$CH_3-\overset{+}{C}=O + (CH_3)_2CO \rightarrow [(CH_3)_2COH]^+ + CH_3CO\,. \qquad (35)$$

Reaction (35) involves the dissociation of two bonds and the formation of two new bonds, the bond dissociation and formation processes occurring simultaneously in a single step during the collision period, i.e. via an intermediate "complex". Cations of the type $R-C\equiv\overset{+}{O}$ do not contribute to the formation of secondary cations, since thermochemical calculation shows that ion–molecule reactions with their participation are endothermic.

The knowledge of the heats of formation of the ions $CH_2=\overset{+}{O}H$, $CH_3CH=\overset{+}{O}H$, and $(CH_3)_2C=\overset{+}{O}H$, obtained by the photoionisation method[40], permits the determination of the proton affinities of formaldehyde (7.4 ± 0.05 eV), acetaldehyde (8.05 ± 0.05 eV), and acetone (8.5 ± 0.1 eV).

Studies on the photoionisation processes of acetone at a pressure of 10^{-3}–10^{-2} mmHg[68] led to the observation of ion–molecule reactions leading to the formation of a high yield of the associated ions M_2^+ and $(M+1).M_n^+$, where $n = 1, 2,$ or 3.

3. Ketones and Alcohols

Ion–molecule reactions in the photoionisation of the molecules in mixtures of ketones and alcohols have been investigated[60]. To identify different pathways of such reactions, deuterated specimens of acetone and ethanol were employed.

Analysis of the mass spectra of the molecules in the binary systems $(CH_3)_2CO-C_2H_5OD$ and $(CD_3)_2CO-C_2H_5OH$ showed that reactions involving acetone and ethanol radical-cations have the following mechanisms:

$$(CH_3)_2CO^{+\cdot} + C_2H_5OD \rightarrow (CH_3)_2C\overset{+}{O}D + C_2H_5O\,, \qquad (36)$$

$$(CD_3)_2CO + C_2H_5OH^{+\cdot} \rightarrow CD_3COCD_2 + C_2H_5OHD^+\,. \qquad (37.1)$$

The formation of the stable ions $(CH_3)_2C\overset{+}{O}D$ and $C_2H_5\overset{+}{O}HD$ involves the transfer of a deuterium atom from the molecules to the radical-cations $(CH_3)_2CO^{+\cdot}$ and $C_2H_5OH^{+\cdot}$ in the range of photon energies between the ionisation potentials of acetone (9.71 eV) and ethanol (10.49 eV) and above. Thermochemical calculation shows that the heats of these exothermic reactions [reactions (1) and (2)] are respectively −0.25 and −1.3 eV.

It has also been shown[60] that at photon energies from the ionisation potential of C_2H_5OD (10.48 eV) upwards, rapid formation of $(CH_3)_2C=\overset{+}{O}D$ ions is observed, which suggests that they are produced in reactions of molecular and fragment ions of C_2H_5OD with the molecules of acetone $(CH_3)_2CO$:

$$(CH_3)_2CO + C_2H_5OD^{+\cdot} \rightarrow (CH_3)_2C=\overset{+}{O}D + C_2H_5O\,, \qquad (37.2)$$

$$(CH_3)_2CO + CH_3CH=\overset{+}{O}D \rightarrow (CH_3)_2C=\overset{+}{O}D + CH_3CHO\,, \qquad (38)$$

$$(CH_3)_2CO + CH_2=\overset{+}{O}D \rightarrow (CH_3)_2C=\overset{+}{O}D + CH_2O\,. \qquad (39)$$

Reactions (37.2), (38), and (39) are exothermic (the heats are −1.0, −0.48, and −1.13 eV) and involve the transfer of a deuteron from ethanol ions to acetone. In this case the deuteron adds to the lone pair of oxygen. The neutral products of this reaction are the ethoxy-radical, acetaldehyde, and formaldehyde respectively. It is noteworthy that the fragment ions of ethanol make the principal contribution to the yield of the proton-transfer reactions between acetone and ethanol.

The reactions between the ions and the molecules of acetophenone and ethanol also proceed via two pathways. The reaction of the acetophenone radical-cations with ethanol molecules is accompanied by the transfer of a deuterium atom from C_2H_5OD and its addition at the oxygen free valence in the acetophenone radical-cation:

$$H_5C_6-\underset{H_3C}{C}=O^{+\cdot} + C_2H_5OD \rightarrow C_6H_5-\underset{H_3C}{C}=\overset{+}{O}D + C_2H_5O\,. \qquad (40)$$

The increase of the yield of the secondary acetophenone ions $C_6H_5\overset{+}{C}ODCH_3$ in the range of photon energies from 10.8 eV upwards is probably associated with reactions involving the transfer of a deuteron from ethanol fragment ions to the acetophenone molecule:

$$H_5C_6\diagdown\underset{H_3C}{}\!\!>C=O + CH_3CH=\overset{+}{O}D \rightarrow H_5C_6\diagdown\underset{H_3C}{}\!\!>C=\overset{+}{O}D + CH_3CHO\,, \qquad (41)$$

$$H_5C_6\diagdown\underset{H_3C}{}\!\!>C=O + CH_2=\overset{+}{O}D \rightarrow H_5C_6\diagdown\underset{H_3C}{}\!\!>C=\overset{+}{O}D + CH_2O\,. \qquad (42)$$

The ion–molecule reactions in ketones and alcohols involve the radical-cations formed by the removal of an electron from the upper orbital of the lone pair of the heteroatom and fragment ions. The reactions of the radical-cations with molecules involve the transfer of a hydrogen atom from the molecule to the radical-cation. The hydrogen atom adds to the heteroatom, which has a free valence, without a significant change in the structure of the radical-cations, i.e. without a complete redistribution of the energies of the colliding species among the degrees of freedom during the period of their interaction. This conclusion is confirmed by the independence of the cross-sections for these ion–molecule reactions of the excitation energy of the initial radical-cations. The reactions of the alcohol fragment ions with the molecules of alcohols and ketones take place via the transfer of a proton from the OH group of the fragment ion to the molecule. Here it is noteworthy that processes of this type make the principal contribution to the formation of the secondary ion–molecule reaction products in alcohols and ketones.

V. ION–MOLECULE REACTIONS IN AROMATIC HYDROCARBONS

Studies on ion–molecule reactions in aromatic hydrocarbons by the electron impact method have shown[61–63] that the formation of secondary products involves only fragment ions produced by the ionisation of the molecules (benzene, toluene). In these studies the failure to observe ion–molecule reactions between radical-cations and molecules which are not prohibited on energy grounds shows the passivity of the electronic states of the radical-cations of aromatic hydrocarbons produced by the removal of an electron from the π orbital of the ground state.

The problem of the mechanism of the ion–molecule reactions occurring in the photoionisation of "aromatic hydrocarbon–alcohol" mixtures was examined by Potapov and Sorokin[64]. To identify the reactions between ions and molecules of the "benzene–ethanol" system, two mixtures, $C_6D_6-C_2H_5OH$ and $C_6H_6-C_2H_5OD$, were chosen. By analysing the variation of the mass spectrum of the molecules of the mixtures with photon energy and concentration of the components, it was shown that the ion–molecule reactions in benzene and ethanol proceed via two paths (Fig. 7*a*):

$$C_6D_6 + C_2H_5OH^{+\cdot} \rightarrow C_6D_5 + C_2H_5OHD^+ , \quad (43)$$

$$C_6H_6 + CH_2{=}\overset{+}{O}D\,(C_2H_5OD) \rightarrow C_6H_6D^+ + CH_2O . \quad (44)$$

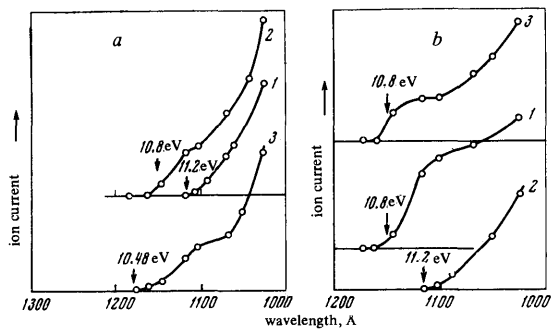

Figure 7. *a*) Appearance curves for the secondary ions of $C_6H_6D^+$ (curve *1*), toluene $C_7H_8D^+$ (curve *2*), and *m*-xylene $C_8H_{10}D^+$ (curve *3*); *b*) appearance curves for the primary ions of deuteroethanol CH_2OD^+ (curve *2*) and CH_3CHOD^+ (curve *1*) and secondary ions of naphthalene $C_{10}H_8D^+$ (curve *3*).

The heat of the exothermic reaction (43), involving the transfer of a deuterium atom from benzene to the radical-cation with formation of phenyl radicals, is 0.73 eV. Reaction (44), in which the benzene cations $C_6H_6D^+$ are formed, involves the transfer of a deuteron from the hydroxy-group of the $CH_2{=}\overset{+}{O}D$ cation. This is indicated by the identity of the appearance potentials of the $C_6H_6D^+$ and $CH_2{=}\overset{+}{O}D$ cations. This conclusion is consistent with data for the formation of $C_6H_7^+$ ions in benzene and ethanol, which was observed by the electron impact method at higher energies[65].

The appearance potentials of the secondary and primary ions show that three ion–molecule reactions take place between toluene and ethanol ($C_6D_5CD_3-C_2H_5OH$ and $C_6H_5CH_3-C_2H_5OD$ mixtures)[64]:

$$C_6D_5CD_3 + C_2H_5OH^{+\cdot} \rightarrow C_6H_5CD_2 + C_2H_5OHD^+ , \quad (45)$$

$$C_6H_5CH_3 + CH_3CHOD^+\,(C_2H_5OD) \rightarrow C_7H_8D^+ + CH_3CHO , \quad (46.1)$$

$$C_6H_5CH_3 + CH_2OD^+\,(C_2H_5OD) \rightarrow C_7H_8D^+ + CH_2O . \quad (46.2)$$

In contrast to the reactions in benzene and ethanol, in the "toluene–ethanol" system the secondary cations $C_7H_8D^+$ are formed by the transfer of a deuteron from the cation CH_3CHOD^+, which is evidence of a similarity of the appearance potentials of the cations $C_7H_8D^+$ and CH_3CHOD^+. A comparative estimate of the heats of ion–molecule reactions in toluene and ethanol showed that the cations $C_7H_8D^+$ can also be formed as a result of the transfer of a deuteron from the radical-cation $C_2H_5OD^{+\cdot}$. However, the yield of this reaction is probably much lower than those of reactions (46) and (47).

Ion–molecule reactions in *m*-xylene and ethanol, involving the transfer of protons from the ethanol radical-cation and fragment ions of the above type, have also been observed[64].

In view of the occurrence of the exothermic reactions (44) and (46), it is possible to determine the lower limits of the proton affinities of benzene and toluene: 7.44 and 8.05 eV. The proton affinity obtained for benzene agrees well with the value 7.46 eV determined[64] by the photoionisation method from the appearance potential of $C_6H_7^+$ ions derived from cyclohexa-1,3-diene.

The ion–molecule reactions occurring in the photoionisation of the molecules of "naphthalene–ethanol" and "anthracene–t-butyl alcohol" mixtures have been investigated[66] and it was shown that the secondary cations of naphthalene $C_{10}H_8D^+$ (see Fig. 7*b*) and anthracene $C_{14}H_{11}^+$ are formed in the reactions by the transfer of deuterons (protons) from the alcohol cations to the molecules of the aromatic hydrocarbons:

$$C_{10}H_8 + CH_3CHOD^+\,(C_2H_5OD) \rightarrow C_{10}H_8D^+ + CH_3CHO , \quad (47.1)$$

$$C_{10}H_8 + CH_2OD^+\,(C_2H_5OD) \rightarrow C_{10}H_8D^+ + CH_2O , \quad (47.2)$$

$$C_{14}H_{10} + (CH_3)_2COH^+\,((CH_3)_3COH) \rightarrow C_{14}H_{11}^+ + (CH_3)_2CO . \quad (48)$$

The lower limits of the proton affinities of naphthalene and anthracene determined from reactions (47.1) and (48) are respectively 8.05 and 8.5 eV.

Ion–molecule reactions involving the radical-cations of aromatic hydrocarbons A and leading to the formation of the cations AH^+ have not been observed[64,66]. Thermochemical calculation shows that in benzene and toluene reactions of this type are endothermic. However, as already mentioned above, despite the absence of an energy prohibition, bimolecular ion–molecule reactions involving benzene and toluene radical-cations also do not occur[61,62].

The low reactivity of the radical-cations of aromatic hydrocarbons may be due to the nature of the electronic states of the radical-cations generated on photoionisation by the removal of an electron from the occupied molecular π orbitals.

Trimolecular ion–molecule reactions involving the molecular ions of benzene and leading to the formation of the ions $C_{12}H_{12}^+$ have been observed[69]. The excess excitation energy of the "complex" is removed in this case by a third body.

VI. PROTON AFFINITY OF MOLECULES

Data on photoionisation and ion–molecule reactions yielded information about the structural characteristics of

the molecules A which determine their capacity to form stable cations AH^+ by combining with a proton. The stability of the cations is determined by the proton affinities of the compounds, which are listed in Table 4.

The formation of the cations AH^+ by aliphatic compounds containing the $\rangle C{=}O$ and O–H groups takes place as the result of the addition of a proton to the lone pair of electrons of the heteroatom. The stability of the alcohol cation increases on passing from methanol to ethanol, i.e. on replacement of a hydrogen atom by a methyl group, which results in an increase of electron density at the oxygen atom. In this case the proton affinity increases from 7.8 eV (methanol) to 8.4 eV (ethanol). The same type of variation in the stability of the cations is observed in the series formaldehyde < acetaldehyde < acetone. The proton affinity of these molecules increases from 7.4 to 8.5 eV for the same reason.

Table 4. Proton affinities of atoms and molecules.

Compound	Proton affinity, eV	Method of determination	References
H	2.70	Photoionisation	3
H_2	3.40	Chemi-ionisation	3
He	1.83	IMR in photoionisation	26
Ne	2.83	IMR in photoionisation	26
Ar	3.40	Chemi-ionisation	26
NH_3	9.0±0.05	Electron impact	36
H_2O	7.16±0.05	Electron impact	36
CH_3OH	7.8±0.13	IMR in electron impact	11
C_2H_5OH	8.4±0.4	IMR in electron impact	11
CH_2O	7.40±0.05	Photoionisation	60
CH_3CHO	8.05±0.05	Photoionisation	60
$(CH_3)_2CO$	8.5±0.05	Photoionisation	60
C_6H_6	7.46±0.03	Photoionisation	64
$C_6H_5CH_3$	8.05	IMR in photoionisation	64
Naphthalene	8.05	IMR in photoionisation	66
Anthracene	8.5	IMR in photoionisation	66

In aromatic hydrocarbons the stability of the cations formed in ion–molecule reactions increases with the number of rings, i.e. with decrease of the localisation energy, which is equal to the difference between the energies of the π-electron systems of the cation AH^+ and the molecule A. This feature is clearly reflected in the ion–molecule reactions involving aromatic hydrocarbons and alcohols and leading to the formation of the cations AH^+ as a result of proton transfer, and allows the conclusion that the addition of a proton to aromatic hydrocarbon molecules takes place by an electrophilic substitution mechanism. This implies that the proton adds to the carbon atom at which the π-electron density is a maximum and is accompanied by the formation of the cations AH^+ with the structure of a σ complex.

The high stability of the AH^+ cations of benzene, naphthalene, and anthracene formed in ion–molecule reactions (the affinity increases from 7.46 to 8.5 eV) is determined by the formation of a new σ_{CH} bond and a marked polarisation interaction, which becomes more intense with increasing number of π electrons in the aromatic hydrocarbons. The substitution of hydrogen atoms in benzene by an electron-donating group such as CH_3 also leads to an increase of the stability of the cations AH^+.

The data obtained on the stabilities of the cations are correlated with the basicity constants of the aromatic hydrocarbons[67].

Chemically Induced Polarisation of Electrons and Nuclei

A.L.Buchachenko and F.M.Zhidomirov

The polarisation, in excess of the equilibrium value, of electrons and nuclei in the species generated in chemical reactions was observed in ESR and NMR spectra quite recently and during the last 2-3 years studies of this kind have developed vigorously. The aim of the present review is to present the principal results of studies on chemically induced polarisation of electrons and nuclei, to formulate the ideas and concepts concerning the nature of the phenomena discussed, and also to attempt an assessment of their importance and prospects.
The bibliography includes 70 references.

I. INTRODUCTION

The ESR or NMR spectrum of a radical, ion, or molecule constitutes a kind of "portrait" of the species or fragment. The spectra contain information about the chemical structure of the species, its orientation (in a solid), the frequencies of molecular motion, and the energies of electron–electron and electron–nucleus magnetic interactions.

The usual magnetic resonance spectra do not of course provide any information about the elementary steps in the generation of the species, i.e. about the nature of the states preceding the species. The reason for this is that the magnetic resonance spectra usually recorded are the absorption spectra of the species in which the populations of the magnetic Zeeman (electronic or nuclear) levels correspond to thermal equilibrium, i.e. obey the Boltzmann distribution. However, in the steps involving the generation of the species (radicals or molecules) or in the states from which these species are produced (triplet states, radical pairs, etc.), there is a possibility of a non-equilibrium population of the Zeeman levels. Then the species generated will not give rise to the usual magnetic resonance spectra corresponding to equilibrium absorption but to spectra with an anomalously strong absorption or to emission spectra. The first case corresponds to positive polarisation of electrons or nuclei in the species in excess of the equilibrium value and the second to negative polarisation.

The observation of the effects of non-equilibrium polarisation of electrons or nuclei in ESR or NMR spectra is of course only possible immediately after the generation of the species when they "remember" the non-equilibrium polarisation induced in them during the electronic (10^{-7}–10^{-5} s) or nuclear (1–30 s) relaxation time; after this period, the species lose their polarisation in excess of the equilibrium value.

II. CHEMICALLY INDUCED NUCLEAR POLARISATION

Chemically induced nuclear polarisation (CINP)† is shown in the NMR spectra of the products of reactions occurring in the magnetic field of the NMR spectrometer. It is observed as an intense radiofrequency absorption (positive polarisation) or a radiofrequency emission (negative polarisation). The intense nuclear polarisation (exceeding by several factors of ten and sometimes hundreds the equilibrium polarisation) constitutes unambiguous evidence for the involvement in its generation of unpaired electrons and observation of the effects of nuclear polarisation constitutes a reliable criterion of the existence of radical stages in the reaction. To illustrate CINP, Fig. 1 presents the NMR spectra of the products obtained in the thermal decomposition of benzoyl and acetyl benzoyl peroxides, the spectra were recorded during the reaction.

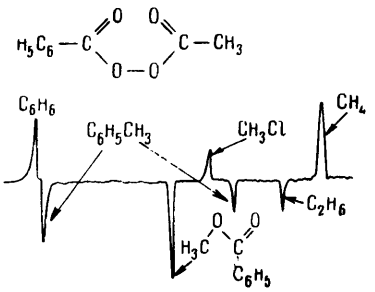

Figure 1. NMR spectrum of products with polarised nuclei in the decomposition of acetyl benzoyl peroxide at 100°C in tetrachloroethylene.

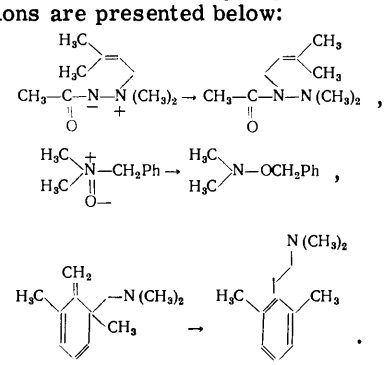
CINP was first observed by Fischer and coworkers[1] in the decomposition of benzoyl peroxide in cyclohexanone when instead of the expected benzene absorption signal an emission signal was noted.

At the present time CINP has been observed and investigated in numerous thermal decomposition reactions of peroxides and azo-compounds[1-9], thermal rearrangements of quaternary ammonium salts[10-13] and quaternary amine oxides[14], and other processes involving isomerisation with migration of molecular groups[15-17]. Examples of such reactions are presented below:



† [Usually referred to a Chemically Induced Dynamic Nuclear Polarisation in English (Ed. of Translation)].

In all these cases CINP of the migrating groups in the products was observed.

The reactions of alkyl halides with lithium alkyls have been investigated in greatest detail[18-25]. CINP has been observed in alkanes and olefins produced in the reactions and also in the molecules of alkyl halides; in the latter case CINP is shown in chemical chain reactions of the type $\dot{R} + XR \rightarrow RX + \dot{R}$. These results led to the conclusion that the reactions of alkyl halides with lithium alkyls have a radical mechanism, the first stage of which is probably a one-electron transfer.

CINP in chemical chain reactions has also been observed in the decomposition of peroxides in the presence of alkyl iodides[26], the chain processes being initiated by peroxide radicals.

Recently CINP was found in reactions of organomercury compounds, for example:

$$PhCH_2HgBr + Ph_3CBr \rightarrow PhCH_2CPh_3 + HgBr_2 ,$$

in which not only the protons of the products but also those of the initial triphenylmethyl bromide are polarised[27].

In reactions of a Grignard reagent with alkyl halides, the olefins and saturated hydrocarbons produced by the reaction of the alkyl radicals derived from the initial reaction components are polarised[28]: the observation of CINP in these reactions constitutes sufficient evidence to assume that the first stage is electron transfer from the Grignard reagent to the alkyl bromide[28].

A distinctive example of CINP in redox reactions is the emission by benzene in the reactions of phenyldiazonium salts with electron-donating reagents (alkalis, *p*-phenylenediamine, the phenoxide anion, and others)[29,30]. It is suggested that the reaction proceeds as follows:

$$PhN_2^+ \xrightarrow{D} (Ph\dot{N}_2) \rightarrow \dot{P}h + N_2 \rightarrow \text{benzene}.$$

CINP has also been observed in the products of many chemical reactions. The protons of anthraquinone were polarised in its photolysis[31]; it is postulated that CINP arises in the deactivation of the excited triplet state of the quinone to the singlet state. In the photolysis of benzophenone CINP was observed in the products of "cage" recombination[32]:

$$Ph_2CO \xrightarrow{h\nu} Ph_2CO^* + HR \rightarrow (Ph_2\dot{C}(OH)\ \dot{R}) \rightarrow Ph_2C(OH)-R .$$

In the photolysis of benzaldehyde, CINP (of the proton in the aldehyde group) was observed in addition to that of the products of the cage recombination of the above kind; it is believed that it arises as a result of chain reactions[33].

This brief description shows that the range of "reactions tested for CINP is fairly large. In most cases new, interesting, and frequently unexpected information about the reaction mechanisms, was obtained with the aid of CINP, and new concepts concerning the course of many chemical reactions have appeared and have become firmly established.

1. Characteristics of the Chemically Induced Polarisation of Hydrogen Nuclei

Reactions in which CINP has been observed are extremely varied. However, analysis of all the results obtained hitherto shows that CINP is determined mainly by the nature of the radical precursers of the product molecules and by the type of the elementary chemical

steps in which the products are formed. On this basis, a fairly simple and complete classification of nuclear polarisations is possible (Tables 1–4).

Tables 1 and 2 show the results on the CINP of the products formed in radical recombination steps. Table 1 summarises those cases where the polarisation of each group of equivalent protons is of the same sign—positive (*A*) or negative (*E*).

* The polarised nuclei are indicated in italics [Indicated by the symbols *A* and *E* (Ed. of Translation)].

Table 2 gives a compilation of the results for the CINP of molecules which give rise to NMR spectra with a multiplet structure. The spin multiplets in such molecules exhibit unusual behaviour, of a kind never observed before: the components of the multiplets in high and low fields correspond to polarisation of different signs. Thus the sign of the polarisation of any one group of equivalent nuclei depends on the spin state of another group of nuclei with which the observed group is involved in spin–spin coupling. Fig. 2 illustrates this unusual behaviour of multiplets in CINP, which has been called the multiplet effect (ME). The symbol *A/E* in Table 2 implies that the components at low field correspond to positive polarisation and those at high field to negative polarisation; the symbol *E/A* denotes the opposite situation. The multiplet effect is a property of CINP only and constitutes one of its most remarkable and distinctive features.

As in recombination reactions, the products of abstraction reactions exhibit CINP of two types—integral and multiplet. Table 3 presents the results for the CINP in the products of the abstraction of H, Cl, etc. atoms. Here the polarisation of each group of equivalent nuclei is of one sign. It is interesting to note the behaviour of the methyl radical: it gives rise to negative polarisation in the recombination products and to positive polarisation in the products of abstraction reactions.

Thus the sign of CINP depends on the type of elementary chemical reaction from which the product is formed. Attention should also be drawn to the fact that the sign of CINP is positive for radicals with a negative hyperfine coupling constant ($\dot{C}H_3$, PhH_2) and negative for the $(CH_3)_3\dot{C}$ radical, which has a positive hyperfine coupling constant.

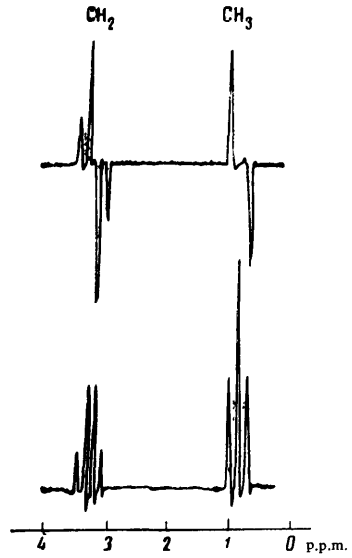

Figure 2. NMR spectrum of ethyl iodide with polarised nuclei in the reaction of ethyl lithium with alkyl iodides (the multiplet effect).

In the phenyl radical mainly the *ortho*-protons are polarised (in relation to the localised unpaired electron); the hyperfine coupling with these protons is in fact a maximum. This conclusion was based on analysis of CINP in the decomposition products of chloro-derivatives of benzoyl peroxide[8]. Trozzolo did not observe the CINP of pentadeuterobenzene in the decomposition of the fully deuterated benzoyl peroxide[8]; on this basis, it was concluded that the nucleus of the hydrogen atom transferred to the phenyl group is not polarised. The difference in the signs of the CINP of benzene in the decomposition of benzoyl and acetyl benzoyl peroxides is very remarkable (Table 3).

Table 4 summarises the results for the CINP of the products of abstraction reactions with a multiplet effect. The following relation governs the multiplet effect in abstraction reactions; a multiplet effect of type A/E is observed in the products, while in the reactants consumed (particularly in chemical relay reactions) the sign of the multiplet effect is reversed to E/A; a theoretical interpretation of these phenomena will be given below.

We may note that the sign of the multiplet effect as well as the sign of the integral polarisation depends on the type of reaction involving the formation of the product. Thus in ethyl chloride the multiplet effect has a sign corresponding to A/E, in butane to E/A, and in thiophenetole CH_3CH_2SPh (Table 1) the multiplet effect is completely absent, although the formation of all these products involves an ethyl radical.

In olefins produced by the disproportionation of radicals a multiplet effect is also observed; for example, the multiplet effect in propene is presented in Fig. 3.

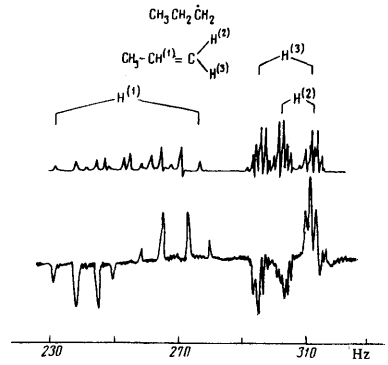

Figure 3. NMR spectrum of propene with polarised nuclei in the reaction of n-propyl iodide with butyl lithium.

The multiplet effect is of type E/A and in the spin multiplet of the proton $H^{(1)}$ only the outer doublet, corresponding to the $\alpha\alpha$ (negative polarisation of $H^{(1)}$) and $\beta\beta$ (positive polarisation of $H^{(1)}$) states of the $H^{(2)}$ and $H^{(3)}$ nuclei, is polarised. (The J_{12} and J_{13} coupling constants are positive). CINP of this type implies that the states $\beta\alpha\alpha$ and $\alpha\beta\beta$ are mainly populated in the molecules (in the series of the spin functions of $H^{(1)}$, $H^{(2)}$, and $H^{(3)}$). It is interesting that the nature of CINP in propene is independent of whether the propene is formed from the $CH_3CH_2\dot{C}H_2$

radical or from $CH_3\dot{C}HCH_3$. The nature of CINP in other olefins (butene, isobutene, etc.) is the same as in propene.

CINP has a number of surprising properties, which are not shown by the usual dynamic nuclear polarisation with radiofrequency pumping at the ESR frequency (see below). The multiplet effect and the dependence of the sign of the multiplet effect and the integral polarisation on the type of chemical reaction are two distinctive features of CINP.

2. The Magnitude of Chemically Induced Nuclear Polarisation.

A third remarkable feature of CINP is the large enhancement factor, greatly exceeding the limiting enhancement attainable in nuclear polarisation with radiofrequency pumping.

We shall now define the enhancement factor E of CINP in terms of the following equivalent relations:

$$E = \frac{M}{M_0} = \frac{I}{I_0} , \qquad (1)$$

where M is the nuclear magnetisation, I the NMR signal, and M_0 and I_0 are their equilibrium values. The value of E shows by what factor the nuclear magnetisation of the molecule exceeds the equilibrium Boltzmann magnetisation. The factor E is an important characteristic of CINP, which is necessary for the verification and experimental tests of any hypotheses and theories of CINP; its determination should be part of the study of CINP in any reaction.

It follows from the definition of E that the kinetics of CINP are associated, firstly, with the kinetics of the chemical reaction and, secondly, with the kinetics of the relaxation processes in the electronic and nuclear spin systems. The establishment of such a relation is of interest for a number of reasons: firstly, in order to be able to use CINP as a method for investigating the kinetics and mechanisms of chemical reactions; secondly, for predicting the kinetic reaction conditions necessary for the maximum development of the CINP expected in the given reactions; thirdly, for the investigation of the physical and chemical mechanisms of CINP.

In the general case the kinetics of CINP in any reaction are described by the equation[36,37]

$$\frac{dM}{dt} = E\frac{dM_0}{dt} - \beta(M - M_0) . \qquad (2)$$

Its first term determines the rate of accumulation of polarisation and is related to the kinetics of the reaction via dM_0/dt, the second term determines the rate of nuclear depolarisation, and $\beta = T_{1n}^{-1}$.

In principle, it is possible to solve Eqn. (2) for any kinetic reaction conditions. The simplest solution is obtained for first-order reactions of the type $A \xrightarrow{k} P$ (for example, decomposition, rearrangement, isomerisation, reactions etc.), when

$$\frac{dM_0}{dt} = \mu_n p_{n0} k A_0 e^{-kt} , \qquad (3)$$

where k is a first-order rate constant and μ_n the magnetic moment of the nucleus:

$$p_{n0} = th\frac{h\gamma_n H_0}{2kT} .$$

When condition (3) holds, solution (2) becomes

$$M(t) = \mu_n p_{n_0} A_0\left[\frac{Ek-\beta}{\beta-k}(e^{-kt} - e^{-\beta t}) - (1 - e^{-\beta t})\right] \qquad (4)$$

It is convenient to convert the magnetisation M into the NMR signal I [see Eqn. (1)] and into the experimentally determined effective enhancement factor K:

$$K = \frac{I(t) - I_{0\infty}}{I_{0\infty}} = \frac{Ek-\beta}{\beta-k}(e^{-kt} - e^{-\beta t}) - e^{-\beta t} \qquad (5)$$

(here $I_{0\infty}$ is the equilibrium signal at $t \to \infty$).

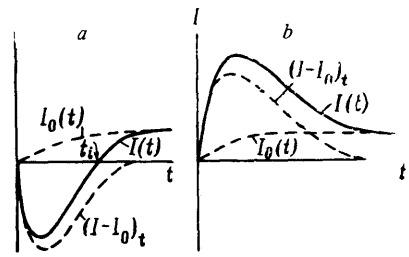

Figure 4. Theoretical CINP kinetic curves; *a*) negative CINP; *b*) positive CINP.

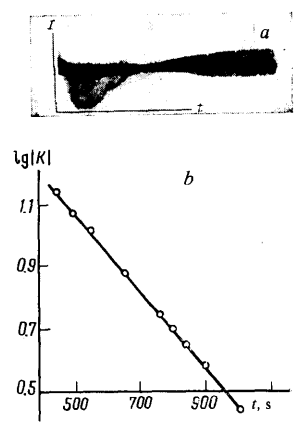

Figure 5. Kinetics of the CINP of protons in the methyl group of methyl benzoate in the decomposition of acetyl benzoyl peroxide: *a*) an experimental record obtained with a rapid scan; *b*) analysis of the kinetics in terms of Eqn. (7).

Fig. 4 presents the theoretical CINP kinetic curves and shows [as was to be expected from Eqn. (5)] that the rate of CINP passes through a maximum. The time required for the attainment of the maximum is

$$t_{max} = \frac{\ln\frac{(E-1)\beta}{Ek-\beta}}{\beta-k} . \qquad (6)$$

In the specific but very common case of fairly slow reactions ($k \ll \beta$), Eqn. (5) is

$$K = (EkT_{1n} - 1)e^{-kt} . \quad (7)$$

Fig. 5 presents an example of experimental CINP kinetics; the satisfactory agreement with the theoretical curve (Fig. 4) is evident. Fig. 5 also presents an analysis of CIPN kinetics on the basis of Eqn. (7); k and E can be immediately determined from a plot of lg $|K|$ against t.

In many cases it is convenient to saturate or invert the NMR signal during the course of the reaction by radiofrequency pulses[38]. This leads to a simplification of the initial kinetic equation (2). Thus at saturation $M - M_0 = 0$ and it is then easy to show that

$$E = \frac{(dI/dt)_{t \to t'}}{I_{\infty} k e^{-kt'}} . \quad (8)$$

Here t' is the instant of saturation (or signal inversion) and $(dI/dt)_{t \to t'}$ is the initial rate of recovery of the CINP signal after saturation (or inversion) (Fig. 6). It is significant that this method does not require a knowledge of the quantity ... [part of Russian text missing (Ed. of Translation)].

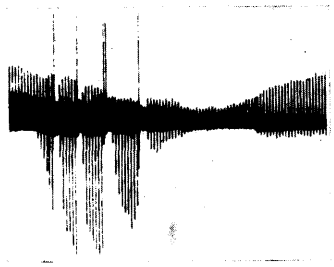

Figure 6. CINP kinetics with signal inversion by radiofrequency pulses.

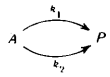
In chemical kinetics situations very frequently arise where the same substance is formed by different pathways, some of which have a radical mechanism and lead to CINP, while others are non-radical and are not accompanied by CINP. Suppose, for example, that in the scheme



one of the pathways in the conversion of A into P with a constant k_1 leads to CINP, while the other pathway is non-radical.

In this case

$$K = \frac{Ek_1 + k_2 - \beta}{\beta - \Sigma k}(e^{-\Sigma kt} - e^{-\beta t}) - e^{-\beta t} , \quad (9)$$

where $\Sigma k = k_1 + k_2$. If the reaction is slow, i.e. $\Sigma k \ll \beta$, then

$$K = (Ek_1T_{1n} + k_2T_{1n} - 1)e^{-\Sigma kt} . \quad (10)$$

Using Eqns. (9) and (10) it is possible, in principle, to decide whether there really is a competition between radical and non-radical mechanisms and also to determine their kinetic parameters.

The CINP kinetics and their relation with the kinetics of chemical reactions have been considered in greatest detail by Buchachenko[39], who also examined various kinetic situations (consecutive and competing reactions, bimolecular reactions, etc.).

Eqn. (2) postulates, of course, that the product formed in the reaction, containing polarised nuclei, is not consumed in other reactions, is not precipitated, does not evaporate, etc. However, these conditions frequently break down and this must be borne in mind in the calculation of the factor E.

In particular, a method has been proposed[40] for the determination of E for a volatile product (a gas: methane, CO_2, etc.).

Finally, equations have been presented[36] for the kinetics of nuclear polarisation when, together with chemically induced polarisation, there is also radiofrequency pumping at the ESR frequency of the radicals involved in the reaction.

* Polarised protons are designated by italic symbols.

** The enhancement factors were calculated per group of equivalent nuclei.

It is noteworthy that all the kinetic equations presented for the determination of E are independent of the mechanism of nuclear polarisation: E refers to a molecule or to a group of equivalent nuclei in the molecule. All the known values of E for CINP are listed in Table 5.

We may note that for integral polarisation the factor E in most cases greatly exceeds the maximum enhancement factors in nuclear polarisation with radiofrequency pumping (−330 for dipole relaxation and +660 for scalar relaxation[41]).

The factors E for multiplet CINP are also high. For example, for the proton in the CH group (last row of Table 5) the quadruplet lines with $m_{CH_3} = \pm\frac{1}{2}$ (inner lines) correspond to a polarisation of $\pm(1300 \pm 200)$.

The kinetic equations for CINP permit the use of such polarisation as a new kinetic method for the investigation of chemical reaction mechanisms, i.e. as a

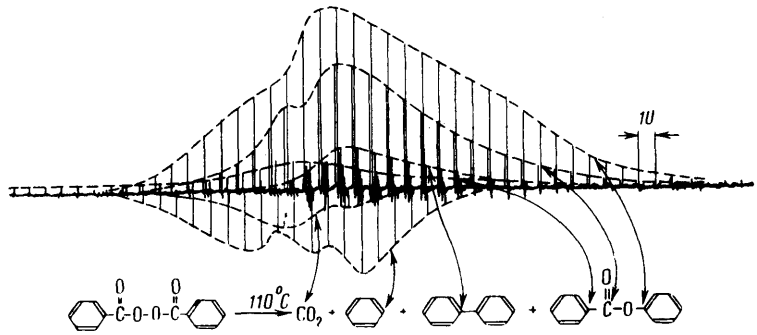

Figure 7. Kinetics of the chemically induced polarisation of ^{13}C nuclei in the decomposition of benzoyl peroxide in cyclohexanone at 110°C (proton signal saturated).

method for the determination of the rate constants and nuclear polarisation factors E. We may note that these equations are independent of the physical mechanism of CINP, since the physical information is contained in the factor E. The experimental determination of these factors and their relation with the lifetime of radicals and other experimental conditions (magnetic field strength, temperature, viscosity, the presence of radical acceptors, etc.) are important for the elucidation of the physical mechanism of CINP.

3. Chemically Induced Polarisation of ^{19}F, ^{13}C, and ^{31}P Nuclei

Tables 1–5 present the results for the chemically induced polarisation of protons. In a series of recent investigations, CINP of many-electron atoms was also observed. Fischer and coworkers[2] discovered the positive polarisation of ^{19}F in the decomposition of benzoyl peroxide in *p*-fluorobenzaldehyde and *p*-fluorostyrene. It was suggested that in the first case nuclear polarisation is induced chemically in the reaction products of aldehyde radicals of the type $-\dot{C}=O$ and in the second in the products of addition to styrene (polymerisation products). However, detailed studies on the nature of the products with CINP were not made.

Rakshys[43] observed chemically induced polarisation of ^{19}F nuclei in a fluoro-derivative of dibenzyl and in pentylbenzene (fluorine was successively substituted in the aromatic rings in the *ortho*-, *meta*-, and *para*-positions). These products were obtained by the reaction of fluorine-substituted benzyl fluoride with n-butyl-lithium. In contrast to the previous investigation, here chemically induced polarisation of ^{19}F nuclei exhibits a strong multiplet effect, which is fairly complex, so that it is difficult to interpret it unambiguously from the NMR spectra.

Chemically induced polarisation of ^{13}C nuclei forming part of the skeleton of organic molecules is of greatest interest. It was first observed[44] in the decomposition of benzoyl and acetyl benzoyl peroxides. Fig. 7 presents the kinetics of the chemically induced polarisation and the assignments of the polarised ^{13}C nuclei in the molecules. The chemically induced polarisations of ^{13}C and H nuclei are compared in Table 6. The differences in sign are discussed below.

It is remarkable that the carbonyl carbon atoms in the phenyl ester of benzoic acid and in carbon dioxide are polarised with different signs (Fig. 7) although both products are formed from the benzoyloxy-radical. Saturation of ^1H NMR (heteronuclear double resonance) does not influence the chemically induced polarisation of ^{13}C nuclei; the latter is[45] about 10^4 and, like chemically induced polarisation of protons, greatly exceeds the polarisation with radiofrequency pumping.

Table 6. Signs of the chemically induced polarisation of protons and ^{13}C nuclei.

Molecule	Group of atoms	Sign of CINP	
		protons	^{13}C
CH_4	CH_4	*A*	*E*
$Ph-C(=O)-O-CH_3$	CH_3	*E*	*A*
$Ph-CH_3$		*E*(*ortho*)	*A*(*ortho*)
	CH_3	*E*	*A*
		E	*E*

We may note finally that a recent communication[46] reports the observation of chemically induced polarisation of ^{13}P nuclei in various reactions involving phosphites, phosphates, and peroxides. The polarisation exhibits an extremely wide variety of signs and values but it is difficult to give a sufficiently reliable and unambiguous interpretation in these reactions owing to their complexity.

III. THEORY AND MECHANISM OF CHEMICALLY INDUCED NUCLEAR POLARISATION

The simplest mechanism of CINP depends on the Overhauser effect in free radicals during their lifetime—from the instant of generation to the instant of their conversion into diamagnetic products. This mechanism of CINP was in fact proposed in the early investigations[1,19].

We shall now examine the Overhauser effect in qualitative terms. Consider the simplest electronic-nuclear system consisting of one electron and one proton: its Zeeman levels are shown schematically in Fig. 8. If there is magnetic coupling between the unpaired electrons and the proton (isotropic or dipolar) in such a system, then in principle there exist four types of relaxation processes between the Zeeman electronic and nuclear levels: (1) purely electronic transitions when the magnetic quantum number of the electron M changes but the nuclear spin quantum number m does not; these are $\Delta M = \pm 1$ and $\Delta m = 0$ vertical transitions corresponding to ESR; (2) purely nuclear transitions--$\Delta M = 0$ and $\Delta m = \pm 1$ horizontal transitions (NMR transitions); (3) $\Delta M = \Delta m = \pm 1$ flip-flop transitions; (4) $\Delta M = -\Delta m = \pm 1$ flip-flop transitions. In the last two transitions there is simultaneous flipping of the spins of the electron and of the nucleus in the same or in the opposite directions; there is at the same time a change in the population of the Zeeman levels of the electronic and nuclear spin systems[47].

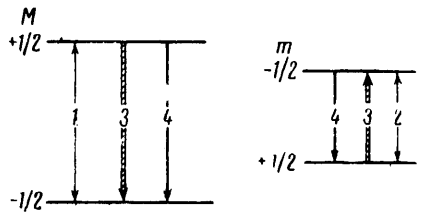

Figure 8. A schematic representation of the Zeeman levels and transitions in an electron–nucleus system with a spin of 1/2.

Usually in the observation of nuclear polarisation two frequencies are used: one for the saturation of the vertical transitions (ESR) and for the equalisation of the populations of the electron levels and the other for the detection of changes in the populations of the nuclear Zeeman levels (NMR). After the removal of the saturating field at the ESR frequency, the electronic Zeeman system tends to return to equilibrium, corresponding to the Boltzmann distribution of electron spins among the Zeeman levels. Then processes (1) are accompanied by transitions (4), in which there is an increase in the population of the lowest nuclear level (positive polarisation), and transitions (3), which increase the population of the highest nuclear level and can actually lead to inversion of the populations (negative polarisation). Positive polarisation predominates when the main contributions to relaxation come from isotropic hyperfine coupling and negative polarisation predominates when dipolar coupling is dominant. Negative polarisation is usually employed in radiofrequency masers[47].

In principle, nuclear polarisation may be induced by a chemical reaction and not radiofrequency pumping of the electronic levels. If the chemical reaction involves the formation of radicals, it may happen that the electronic Zeeman levels will have equal populations or, in the general case, non-equilibrium populations. Next a Boltzmann distribution of the populations of the electronic levels is established in the radical with an electronic relaxation time T_{1e} and a new population of nuclear levels (polarisation of nuclei) arises owing to transitions (3) and (4). If the radical is further converted into a molecule (by a chemical reaction) nuclear polarisation appears in the product molecule and is detected in it. It is then necessary that the lifetime of the radical τ_R should be longer than or comparable to T_{1e}, i.e. that there is sufficient time for the occurrence of the relaxation processes (3) and (4). However, τ_R must not be too long so that the nuclear polarisation can be transferred to the molecule before disappearing in the radical with a nuclear relaxation time $T_{1n}^{(R)}$. Thus $T_1 \ll \tau_R < T_{1n}^{(R)}$, or

$10^{-7}-10^{-6}$ s $< \tau_R < 10^{-4}-10^{-5}$ s.

Within the framework of the above mechanism, chemically induced polarisation differs from the usual polarisation only by the method of pumping to electronic Zeeman levels. If this mechanism of CINP is valid, there should be three main consequences.

1) The sign of the nuclear polarisation of the radical and hence the sign of the CINP of the product molecules into which it is converted is predictable on the basis of its chemical structure. Thus the radical $\dot{C}H_3$ should have negative polarisation, while in the $CH_3\dot{C}H_2$ radical one may expect positive polarisation of the protons in CH_3 and negative polarisation of the protons in CH_2, etc.

2) The products derived from the radicals should exhibit the polarisation established in the radicals and its sign should be determined solely by the nature of the radical and should be independent of its origin, of its further reactions, and of the nature of the product formed.

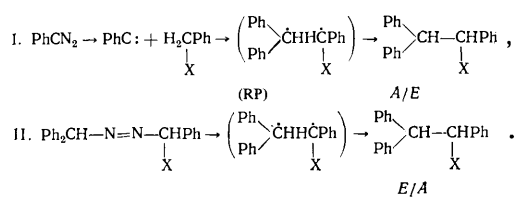
3) The magnitude of CINP should not exceed –330 for dipolar electronic-nuclear relaxation in the radical and +660 for scalar relaxation.

The three main characteristics of CINP formulated in the preceding section quite unambiguously contradict these conclusions. This implies that the mechanism of CINP based on the simple Overhauser effect cannot account for its characteristics and the relations which it exhibits. One must assume that elementary chemical steps involved in the generation and destruction of radicals are responsible for CINP and therefore the mechanism of such polarisation should be sought in the chemical steps.

1. Theory and Mechanisms of Chemically Induced Nuclear Polarisation Involving $S-T_0$ Transitions.

The concepts concerning the mechanisms of CINP arose from simple and elegant experiments by Closs and coworkers[48,49], in which the same products were obtained in different ways and CINP was observed in them. An example of the preparation of the same product in different ways is presented below. Pathway I consists of the decomposition (photochemical or thermal) of diphenyldiazomethane; this yields diphenylcarbene, which has a triplet ground state. One may assume that, regardless of the state in which the carbene is generated, during its lifetime it passes to the ground state and reacts in the triplet state, abstracting a hydrogen atom from a neighbouring molecule in the solution. This results in the formation of a radical pair (RP) in the triplet state, which can subsequently give rise to either recombination products (for this, a preliminary triplet–singlet transition in

the radical pair is necessary) or the radical pair can dissociate into individual radicals, which are released into the bulk phase:



Pathway II consists of the dissociation of the azo-compound accompanied by the liberation of a nitrogen molecule and the formation of the same radical pair as in the first case but only in the singlet state. Recombination of radicals with the radical pair yields the same product as in the first case.

Thus in the first case the precursor of the final reaction product is the radical pair in the triplet state and in the second case the radical pair in the singlet state. Different types of CINP in the final product correspond to the different spin multiplicities of the precursor: in the first case the multiplet effect in the CH−CH group corresponds to A/E and in the second to E/A.

Hence one can immediately conclude that a possible mechanism of CINP is a selection of nuclear-spin states in the radical pairs (precursors of the products) as a result of singlet−triplet transitions.

We shall now consider briefly the simplest theories of CINP based on $S-T$ transitions[48-52] in radical pairs. Suppose that we have the radical pair

$$(H\dot{R}_1\dot{R}_2) \begin{cases} \nearrow HR_1{-}R_2 \text{ (recombination)} \\ \searrow H\dot{R}_1 + \dot{R}_2 \text{ (radical pair dissociation),} \end{cases}$$

which can either recombine or dissociate: suppose further that the radical pairs liberated participate in substitution reactions (for example, they abstract atoms from solvent molecules, becoming thereby converted into stable products).

We shall now calculate the probabilities of the transfer to the recombination products of an $H\dot{R}_1$ proton with a spin α_n and β_n. We shall consider the singlet state of the pair with the wave function $S = 1/\sqrt{2}(\alpha\beta - \beta\alpha)$ and the triplet state $T_0 = 1/\sqrt{2}(\alpha\beta + \beta\alpha)$ (other triplet states, T_{+1} and T_{-1}, will be disregarded at present, since they are separated from the S and T_0 levels by the energy of the electronic Zeeman interaction).

The complete wave functions of the pair consist of the combination of the states S and T_0:

$$\begin{aligned} \psi^+(t) &= [c_S^+(t)\,S + c_{T_0}^+(t)\,T_0]\,\alpha_n\,, \\ \psi^-(t) &= [c_S^-(t)\,S + c_{T_0}^-(t)\,T_0]\,\beta_n\,; \end{aligned} \qquad (11)$$

$c_S^{\pm}(t)$ and $c_{T_0}^{\pm}(t)$ determine the proportions of the states and the superscripts + and − refer to states with nuclear spins α_n and β_n respectively.

Suppose that the pair is initially in a triplet state, i.e. $|c_S^{\pm}(0)|^2 = 0$ and $|c_{T_0}^{\pm}(0)|^2 = 1$. The problem is to find the evolution of the triplet wave function in the system to the singlet wave function under the influence of the perturbing Hamiltonian:

$$\mathcal{H} = \beta H_0(g_1S_1 + g_2S_2) - JS_1S_2 + aIS_1\,. \qquad (12)$$

Here the first term describes the energy of the Zeeman interaction (g_1 and g_2 are the g-factors of the radicals in the pair), the second term is the exchange energy operator, and the third term describes the hyperfine interaction.

The exchange interaction in the pair alters as a result of fluctuations in the geometry of and the distances in the pair under the influence of thermal motion in the liquid; the mixing of the S and T_0 states takes place as a result of the difference between the Zeeman energy $(g_1 - g_2)\,\beta H_0$ and the hyperfine coupling energy.

The result of operation using the Hamiltonian (12) may be obtained by solving the Schrödinger equation for the coefficients $c_S^{\pm}(t)$ and $c_{T_0}^{\pm}(t)$. Then

$$\begin{aligned} c_S^{\pm}(t) &= -i\frac{{}^1/_2\beta H_0\Delta g \pm {}^1/_4 a}{D^{\pm}}\sin D^{\pm}t\,, \\ c_{T_0}^{\pm}(t) &= \cos D^{\pm}t - \frac{iJ}{D^{\pm}}\sin D^{\pm}t\,, \end{aligned} \qquad (13)$$

where $D^{\pm} = [({}^1/_2\beta H_0\Delta g \pm {}^1/_4 a)^2 + J^2]^{1/2}$.

The probability of the formation of the recombination product from the triplet pair at time τ is equal to the proportion of the S state $|c_S^{\pm}(\tau)|^2$ at this instant:

$$|c_S^{\pm}(t)|^2 = \frac{{}^1/_2\Delta g\beta H_0 \pm {}^1/_4 a}{(D^{\pm})^2}\sin^2 D^{\pm}\tau\,. \qquad (14)$$

By averaging over the lifetime of the radical pair, we finally obtain the rates of population of the nuclear-spin states in the recombination product:

$$w^{\pm} = k_0\frac{2\,(1/2\,\Delta g\beta H_0 \pm 1/4\,a)^2\tau^2}{1 + 4\,(D^{\pm})^2\tau^2}\,, \qquad (15)$$

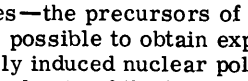
where k_0 is the overall rate of formation of the radical pair and τ is its lifetime.

It follows from Eqn. (15) that the rates of formation of molecules with hydrogen spins α_n and β_n are proportional to $(\Delta g\beta H_0 + {}^1/_2 a)^2$ and $(\Delta g\beta H_0 - {}^1/_2 a)^2$ respectively. Clearly the probabilities of observing the α or β spins of the proton in the molecule formed on recombination of the radical pair are different and depend on the magnitude and sign of $\Delta g = g_1 - g_2$ and the hyperfine coupling constants. Thus, when $\Delta g < 0$ and $a < 0$, we have $w^+ > w^-$, i.e. positive polarisation obtains in the recombination product from the triplet pair, while the radicals liberated from the radical pair and converted into other products in the bulk phase are negatively polarised.

If the initial pairs are in the singlet state, then $w^- > w^+$ since pairs with an α spin are more rapidly converted into the triplet state and then dissociate. In this case the recombination products are depleted in α spins and an excess of β spins remains, i.e. the polarisation is negative; positive polarisation now appears in the reaction products of the free radicals.

Thus for specified values and signs of a and Δg, the sign of CINP depends on the spin multiplicity of the radicals in the pair and hence on the spin multiplicity of the reacting species—the precursors of the radical pair.

Similarly it is possible to obtain expressions for the multiplet chemically induced nuclear polarisation by considering a radical pair of the type



The rates of population of different nuclear-spin states or the rates of $S-T_0$ transitions are proportional to

the squares of matrix elements of the type $\langle S|\mathcal{H}|T_0\rangle$ calculated with the Hamiltonians

$$\mathcal{H}_{\mathrm{I}} = \beta H_0(g_1S_1 + g_2S_2) - JS_1S_2 + a_1S_1I_1 + a_2S_2I_2\ , \quad (16)$$

$$\mathcal{H}_{\mathrm{II}} = \beta H_0(g_1S_1 + g_2S_2) - JS_1S_2 + (a_1I_1 + a_2I_2)S_2\ , \quad (17)$$

for pairs of types I and II respectively.

Table 7. Relative rates of $S-T_0$ transitions.

Nuclear-spin states	Pair (I)	Pair (II)
$\alpha_n\alpha_n$	$(\Delta g\beta H_0/2+a_1/4+a_2/4)^2$	$(\Delta g\beta H_0/2+a_1/4-a_2/4)^2$
$\alpha_n\beta_n$	$(\Delta g\beta H_0/2+a_1/4-a_2/4)^2$	$(\Delta g\beta H_0/2+a_1/4+a_2/4)^2$
$\beta_n\alpha_n$	$(\Delta g\beta H_0/2-a_1/4+a_2/4)^2$	$(\Delta g\beta H_0/2-a_1/4-a_2/4)^2$
$\beta_n\beta_n$	$(\Delta g\beta H_0/2-a_1/4-a_2/4)^2$	$(\Delta g\beta H_0/2-a_1/4+a_2/4)^2$

Table 7 lists the relative rates of population of various states of a system of two nuclei (protons) in the recombination product.

For example, when $a_1 < 0$ and $a_2 < 0$ and the initial type I radical pair is in the triplet state, the populations of the nuclear-spin states $\alpha_n\alpha_n$ and $\beta_n\beta_n$ in the recombination product $\diagdown$CH−CH$\diagup$ increase and the $\alpha_n\beta_n$ and $\beta_n\alpha_n$ states become depleted. This leads to the appearance of chemically induced nuclear polarisation with an A/E multiplet effect (the populations and polarisations are illustrated schematically in Fig. 9). A multiplet effect of this type was in fact observed by Closs[48] in the decomposition of diphenyldiazomethane. Clearly the sign of the multiplet effect in the reaction products of the radicals liberated from the radical pair is opposite to that of the multiplet effect in the recombination products, since the nuclear states $\alpha_n\beta_n$ and $\beta_n\alpha_n$ in the liberated radicals become enriched.

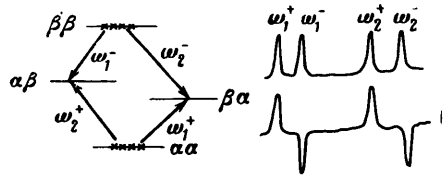


Figure 9. Schematic representation of multiplet CINP in the $\diagdown$CH−CH$\diagup$ molecular fragment from a triplet radical pair.

Within the framework of the theory of chemically induced nuclear polarisation involving $S-T_0$ transitions in radical pairs, it is possible to predict the signs of the integral CINP and of the multiplet effect as a function of the signs of Δg and a; these results are summarised in Tables 8 and 9.

It is now possible to make a number of generalisations concerning CINP.

1. The integral polarisation and the multiplet effect in the products of the recombination of the radicals in pairs and of the reactions of free individual radicals should have opposite signs.

Table 8. Integral CINP in recombination products.

Multiplicity of radical pair	$\Delta g<0,\ a<0$ $\Delta g>0,\ a>0$	$\Delta g<0,\ a>0$ $\Delta g>0,\ a<0$
Singlet	*E*	*A*
Triplet	*A*	*E*

A—positive polarisation (absorption).
E—negative polarisation (emission).

2. If $\Delta g = 0$ in the pair, only multiplet CINP should be observed, its value being proportional to a^2; if $\Delta g \neq 0$, integral CINP proportional to $\Delta g\beta H_0 a$ should be observed. Frequently both types of CINP may be observed.
3. The signs of the integral CINP and of the multiplet effect depend on those of Δg and a (as shown in Tables 8 and 9) and also on the type of radical pairs [(I) or (II)] and their spin multiplicity.

Table 9. Multiplet CINP in recombination products.

Multiplicity of radical pair	Pair (I)		Pair (II)	
	$a_1<0,\ a_2<0$	$a_1<0,\ a_2>0$	$a_1<0,\ a_2<0$	$a_1<0,\ a_2>0$
Singlet	*E/A*	*A/E*	*A/E*	*E/A*
Triplet	*A/E*	*E/A*	*E/A*	*A/E*

Extensive experimental data have now been obtained in various laboratories, which makes it possible to verify the consequences and characteristics of CINP formulated above. It was found that in the vast majority of cases the experimental data are consistent with these consequences, i.e. at least in the region of high fields (of the order of several thousand gauss) the mechanism based on $S-T_0$ transitions in radical pairs generates CINP fairly effectively and gives a correct qualitative description of its characteristics.

2. Analysis of the Mechanisms of Chemical Reactions from the Standpoint of Chemically Induced Nuclear Polarisation

We shall now consider the significance of CINP for chemistry and chemical physics.

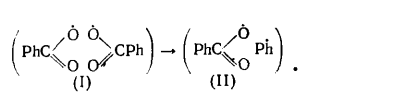
1. In the first place the very fact of the observation of CINP indicates the presence of radical stages in the reaction, i.e. the involvement in the reaction of intermediate paramagnetic species—ions or radicals. In this sense detection of CINP has become a new and powerful method for the investigation of the mechanisms of chemical reactions.

2. The appearance in chemical reactions of CINP with the properties described above implies that the reactions involve the formation of radical pairs. It is also possible to determine whether the g-factors of the radicals differ, whether there is hyperfine coupling, and the type of the radicals in the pair [(I) or (II)]. Moreover, at the present time CINP is used with increasing frequency as a quantitative method for the determination of the g-factors of the radicals in the pair (or their differences) and also the values and signs of the hyperfine coupling constants.
3. When the values of a and Δg for the radicals in the pair are known, it is possible to determine from the signs of the integral CINP and of the multiplet effect the spin multiplicity of the radical pairs (precursors of the products) and hence the spin multiplicity of the reacting species generating the radical pairs. Analysis of CINP shows that thermal and photochemical decomposition reactions of peroxides and azo-compounds take place in the singlet state and that the primary radical pairs are in this state. Singlet pairs are also formed in thermal rearrangement and isomerism reactions, in the Wurtz and Grignard reactions, and others. Photochemical decomposition of peroxides sensitised by ketones and also thermal decomposition of diazo-compounds take place with formation of primary triplet pairs. The multiplicity of the reacting species is an extremely important characteristic of the reaction mechanism and this information is carried by CINP.

Above (see p. 808) it was shown how Closs and coworkers obtained the same products from singlet and triplet radical pairs. The third method consisted in an independent generation of the same radicals as separate species, new radical pairs with so called non-correlated spins being subsequently generated in the encounters between these radicals in solution. Since the S and T_0 states are being produced statistically in the same way, one may assume that CINP should not be observed in the products from such secondary radicals of pairs (the CINP in the singlet and triplet pairs should mutually cancel out). However, experiments showed that the recombination products from secondary pairs exhibit the CINP characteristic of triplet pairs[52]. This implies that the lifetime of the triplet pairs is longer than that of the singlet pairs and consequently the steady-state concentration of the triplet pairs in solution is higher than that of the singlet pairs. This is an important and non-trivial result for the dynamics of chemical reactions.
5. It follows from the previous two conclusions that the products obtained from primary radical pairs and those generated from secondary radical pairs, i.e. from pairs of freely colliding radicals, may be resolved. This permits a deeper and more detailed understanding of the chemistry of the processes, i.e. the mechanisms of the chemical reactions.

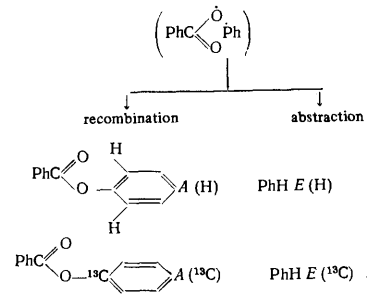
We shall now consider the mechanisms of a number of reactions from the standpoint of CINP.

The decomposition of benzoyl peroxide takes place with formation of a radical pair:



(I) (II)

The radical pair (I) can be either converted into (II) or can recombine with formation of the initial molecule. Such recombination is well known from experiments involving the transfer of an ^{18}O tracer from the carbonyl to the ester group[53]. However, neither H nor ^{13}C nuclei show CINP, since $\Delta g = 0$ in pair (I). In pair (II) $\Delta g \neq 0$ and CINP should obtain in its reaction products:



In the phenyl radical $a_{^{13}C} > 0$, $a_{H(ortho)} > 0$, and $g_{PhCOO} > g_{Ph}$ and consequently the signs of the chemically induced polarisation of the H and ^{13}C nuclei in the recombination products correspond to recombination in a singlet pair (Table 8). In benzene formed from the liberated radicals the CINP is of the opposite sign, as predicted by the theory.

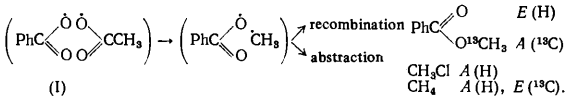
There is reason to believe that $a_{^{13}C} < 0$ ($\rho^{\pi}_{^{13}C} < 0$, as in the allyl fragment) in the $Ph^{13}C(=O)O\cdot$ radical, so that the ^{13}C nucleus in the product of the recombination of this radical with the phenyl radical in pair (II) should exhibit positive chemically induced polarisation if pair (II) is in the singlet state. This prediction is found to be valid (Fig. 7). Moreover, in the radicals $Ph^{13}C(=O)O\cdot$ liberated from the pair ^{13}C should be negatively polarised and, in the decarboxylation of these radicals, the CO_2 molecules should be negatively polarised; this prediction is also fulfilled (Fig. 7).

Thus the signs of the chemically induced polarisation of the H and ^{13}C nuclei in the principal thermal decomposition products of benzoyl peroxide show that the decomposition takes place in the singlet state. The same signs are observed in direct photolysis and photochemical decomposition sensitised by aromatic hydrocarbons, which implies that the decomposition in this case proceeds via excited singlet states. In the photochemical decomposition sensitised by ketones having the energy of the lowest triplet level (>56 kcal mole^{-1}), the signs of CINP in the decomposition products are reversed (for instance benzene protons are positively polarised and the *ortho*-protons of the phenoxy-ring in phenyl benzoate are negatively polarised). This implies that the decomposition of the peroxide in the presence of ketones proceeds via the triplet state[54,55].

We may note that, according to theory, chemically induced polarisation of the nuclei in the adjacent carbon atoms of the two benzene rings of biphenyl should have the same sign as in benzene if both these products are obtained from phenyl radicals liberated from the primary singlet pair (II). In fact the sign of the chemically induced polarisation of the ^{13}C nucleus in biphenyl is opposite to that of the ^{13}C nucleus in benzene. This implies that benzene is mainly obtained directly from the radicals liberated from the pairs, whereas biphenyl is obtained from radicals which had sufficient time after

liberation from the primary pair to be involved in collisions with other radicals of the type $PhC(=O)O\cdot$. In such secondary pairs with non-correlated electron spins CINP of the same sign as in triplet pairs is generated. Thus the "short-lived" phenyl radicals are converted into benzene and the "long-lived" radicals participate in secondary collisions and yield biphenyl with chemically induced polarisation of ^{13}C nuclei of the opposite sign.

Acetyl benzoyl peroxide is decomposed by the same mechanism:



(I)

Evidently the signs of CINP in the CH_3 group of the recombination products correspond to their formation from a singlet pair (see Table 8; $\Delta g < 0$, $a_H < 0$, and $a_{^{13}C} > 0$).

CINP in the reaction products of radicals liberated from pair II has the opposite sign (in agreement with theory). It is interesting that, as for biphenyl, the ethane formed in the decomposition of benzoyl peroxide is negatively polarised (in contrast to methane). This implies that methane (and CH_3Cl) are formed from the "short-lived" methyl radicals, whereas ethane is formed mainly from the "long-lived" radicals involved in secondary (triplet) collisions in which they acquire negative polarisation.

We shall now consider the mechanism of the reactions of secondary radicals generated in the decomposition of benzoyl peroxide in the presence of various additives. Fischer and coworkers investigated CINP in the decomposition of benzoyl peroxide in the presence of a mixture of molecules of different types (RX and R'X'); the free radicals $\dot{R}$ and $\dot{R}'$ appeared in the system independently under these conditions [56]. The signs of CINP in the asymmetric recombination products R–R' corresponded to the case where the same products were produced from triplet pairs. This implies that the recombination of independently generated radicals takes place in the pairs with non-correlated spins (in agreement with the results of Closs and coworkers [52]; (see p. 808 above).

The signs of CINP in the reaction products of radicals liberated from asymmetric pairs (i.e. in R'R', RR, R'X, and RX') are opposite to those of CINP in the asymmetric recombination products (as would be expected from the theory of CINP with $S-T_0$ transitions).

Rykov et al. [34] investigated the decomposition of benzoyl peroxide in the presence of methyl iodide. Here $\dot{C}H_3$ radicals were generated independently and it might have been expected that in the CH_3 group of methyl benzoate and in methane the signs of CINP should correspond to *A* and *E* respectively (as in the products formed from pairs with non-correlated spins). In fact it was found that the signs of CINP in these products correspond to *E* and *A*, i.e. as in the products from singlet pairs. In order to account for this effect, one may assume that the radicals $PhC(=O)O\cdot$ (or $\dot{P}h$) react with CH_3I in the primary pair (I) or (II); this involves the immediate formation of the singlet secondary pair ($PhC(=O)O\cdot\ CH_3$) resembling pair (II) in the decomposition of acetyl benzoyl peroxide.

CINP of the CH_3 protons in methyl benzoate and in methane arises in this secondary pair. CINP in ethane and in the CH_3 group of toluene is negative, which is consistent with the formation of these products from the "long-lived" CH_3 radicals, i.e. from pairs with non-correlated spins.

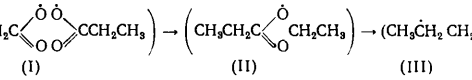
The hypothesis that the primary pair is immediately converted into a secondary pair is equivalent to the hypothesis of a comparatively high reactivity of radicals in the primary pairs. Subsequently we shall consider other examples consistent with this hypothesis.

The decomposition of acetyl peroxide takes place with successive formation of pairs:

(I) (II) (III)

In the OCH_3 group of methyl acetate and in CH_4 (or CH_3Cl) the signs of CINP correspond to *E* and *A* respectively; this implies that these products are formed mainly from the singlet pairs (II). However, in the products of the recombination of CH_3 with solvent radicals ($PhSCH_3$ in thiophenol and $CH_3-CCl_2COCCl_3$ in hexachloroacetone), the signs of CINP of the CH_3 groups should be positive, since these products should be formed from pairs with non-correlated spins (random collisions). In fact the signs of CINP of these products are negative (as in singlet pairs). Thus here too one must assume that the radicals in the primary pairs exhibit an enhanced reactivity and therefore the primary pairs are rapidly converted into secondary singlet pairs of the type ($\dot{C}H_3$ $\dot{S}Ph$) or ($\dot{C}H_3$ $\dot{C}Cl_2COCCl_3$). CINP of ethane is negative. Its origin can be explained if it is assumed that the ethane is formed from the pair (III) and the polarisation in the latter persists from the preceding pair. Possibly this is also the explanation of the CINP of biphenyl formed from benzoyl peroxide.

The decomposition of propionyl peroxide is interesting:



(I) (II) (III)

The decomposition proceeds via singlet pairs, because in butane the sign of the multiplet effect corresponds to *E/A* and in CH_3CH_2Cl [the reaction products of the $CH_3\dot{C}H_2$ radical liberated from the pair (II) or (III)] the multiplet effect has the opposite sign (corresponding to *A/E*). In the photochemical decomposition of this peroxide sensitised by ketones the signs of the CINP of these products are reversed [54], which implies that the decomposition proceeds via an excited triplet state.

$PhS-CH_2CH_3$ with CINP of the CH_2 (*E*) and CH_3 (*A*) groups is formed in the decomposition of propionyl peroxide. The signs of CINP correspond to the formation of this product from the singlet pair ($\Delta g < 0$, $a_{CH_2} < 0$, $a_{CH_3} > 0$) and not from pairs with non-correlated spins as would have been expected. Thus here too one must assume that the primary singlet pairs are rapidly converted into secondary pairs, i.e. the reactivity of the radicals in the primary pairs is enhanced, so that their reactions in the pair successfully compete with the liberation of the radicals from the pair by diffusion.

We shall now consider CINP in chemical chain reactions. The iodide $CH_3(CH_2)_9CH_2I$ with an *A/E* multiplet effect is formed in the decomposition of undecyl peroxide $[CH_3(CH_2)_9CH_2COO]_2$ in the presence of ethyl iodide [26]. This corresponds to the liberation into the bulk phase of the radical $CH_3(CH_2)_9\dot{C}H_2$ from the primary singlet pair.

At the same time $CH_3\dot{C}H_2$ is generated and is in turn transformed by a chemical chain reaction into ethyl iodide with an E/A multiplet effect. This sign of the multiplet effect arises in radicals liberated from pairs with non-correlated spins. Thus ethyl radicals produced in the decomposition of the peroxide undergo random collisions and form pairs with non-correlated spins. On liberation from such pairs, they acquire multiplet E/A CINP and, on being converted into ethyl iodide, transfer this polarisation to the molecule of the latter.

This mechanism accounts for the previously mentioned (p. 804) characteristics of CINP in chain reactions: the signs of the multiplet effect in the products formed and in the reactants consumed (iodides) are opposed. The explanation is that the products are generated from singlet pairs and CINP in the reactants arises in radical pairs with non-correlated spins.

The CINP of the iodides formed and consumed in Wurtz reactions can be explained in the same way. Thus, in the reaction of CH_3CH_2Li with $(CH_3)_2CHI$, ethyl iodide has a multiplet effect with the sign corresponding to A/E and isopropyl iodide has the sign corresponding to E/A. Other examples are presented in Table 4.

It is interesting that in the reaction of ethyl-lithium with ethyl iodide both radicals are identical and the opposite signs of the multiplet effects in the ethyl iodide molecules consumed and formed should cancel out. In fact a multiplet effect with the sign corresponding to A/E is observed, which implies that the CINP of ethyl iodide formed from the primary singlet pair predominates.

Analysis of the CINP of the products of the Wurtz reaction, thermal isomerisation, and rearrangements shows that the products are formed mainly from primary pairs on disproportionation or recombination and their CINP is generated in the primary pairs. The results for CINP show that, as in the thermal decomposition of peroxides, the primary pairs in the Wurtz and thermal isomerisation reactions are in the singlet state.

3. Mechanisms of the Chemically Induced Nuclear Polarisation Involving $S-T_{-1}$ Transitions.

The behaviour of the singlet and triplet levels in molecules dissociating into radicals (or conversely in a pair of recombining radicals) is shown in Fig. 10. The above mechanism of CINP in radical pairs involving $S-T_0$ transitions postulates that the distances R between the radicals in the radical pair are fairly large, i.e. one considers radical pairs beyond the point of intersection of the S and T_{-1} levels when the S and T_0 levels converge closely and the T_{-1} levels are separated by the Zeeman interaction energy. In $S-T_0$ transitions the nuclear spins are not inverted and there is only a selection, i.e. sorting of the radicals with respect to nuclear spins, some of which, with a specific orientation of the nuclei, pass to the recombination products, while others, with the opposite orientation of the nuclei, are liberated into the bulk phase and are converted into other molecules. $S-T_0$ transitions are induced by changes in the exchange energy J in fluctuations of the distances in the radical pairs and are due to the secular component of the hyperfine coupling. Thus in $S-T_0$ transitions the elementary chemical step itself does not give rise to polarisation. However, CINP can be generated also by another mechanism, namely one involving $S-T_{-1}$ transitions which are due to the non-secular component of the hyperfine coupling, $\mathcal{H}_{\text{non-sec}} = \frac{1}{2}a\,(I_+S_- + I_-S_+)$, and which are accompanied by a reorientation of the nuclear spins in the recombination or dissociation step.

The $S-T_{-1}$ transition should be particularly effective at the quasi-intersection point of these levels (Fig. 10). The point is at $R \simeq 3-4$ Å‡.

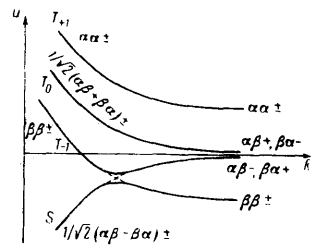


Figure 10. Behaviour of energy levels in the radical pair.

Fig. 10 shows on the left the states of molecules or radical pairs and on the right the states formed non-adiabatically (i.e. when the point of intersection is rapidly traversed). If the motion along the levels takes place slowly and adiabatically, then, for example in dissociation in the singlet state, the matrix elements $\langle\alpha\beta^-|\mathcal{H}_{\text{non-sec}}|\beta\beta^+\rangle$ are not zero and consequently triplet pairs will be enriched in the $\beta\beta^+$ states and singlet pairs will be depleted in the $\alpha\beta^-$ states. This implies that in the products of the recombination of singlet pairs there will be an excess of nuclear spins with negative polarisation and in the radicals liberated from triplet pairs there will be positive polarisation. Clearly in this case the reaction plays an active role in the generation of CINP, since the nuclei are reoriented in the elementary chemical recombination steps itself.

According to this mechanism, the sign of CINP should be independent of the signs of a and Δg (in contrast to the mechanism involving $S-T_0$ transitions). These features make it possible to distinguish these two mechanisms. Analysis of the experimental data shows that in high fields the mechanism with $S-T_0$ transitions mainly operates. This means that the dissociation and recombination processes take place non-adiabatically, i.e. the point of intersection of the levels is traversed rapidly and apparently only once. This conclusion is important for the understanding of the physical mechanisms of chemical processes.

Evidently in weak fields (of the order of tens or hundreds of gauss when the Zeeman interaction is comparable to the hyperfine interaction) the point of intersection of the levels is displaced to the region where $R \simeq 6-8$ Å; clearly in this region the contributions of $S-T_{-1}$ transitions to the generation of CINP will increase appreciably owing to the repeated traversing of the point of intersection in the fluctuations of the geometry of the radical pair. In general, in weak fields all $S-T$ transitions will contribute to CINP.

‡ This quantity may be estimated from the approximate relation $J \simeq J_0 e^{-\alpha R}$, where J_0 is the exchange integral corresponding to the bond energy, J is of the order of magnitude of the energy of the Zeeman interaction, and $\alpha \simeq 1$ Å^{-1}.

This is also indicated by the behaviour of the sign of CINP as a function of field strength. Thus, it has been shown[9,57] that in the decomposition of benzoyl peroxide benzene protons are positively polarised in weak fields. This polarisation increases with field strength to a maximum at 20 G and then falls, reaching zero at about 100 G. When $H_0 > 100$ G, CINP becomes negative. A change in the sign of CINP as a function of the field has also been observed in many other investigations. In all these cases the reaction was performed in weak fields (outside the magnetic field of the NMR spectrometer) and the specimen was then rapidly transferred to the NMR transducer of the spectrometer and CINP generated in weak fields was detected in high fields. In one study[5] the reaction (decomposition of benzoyl peroxide) was carried out and CINP was detected in fields of 30–47 G. The observed CINP was negative, but this result does not contradict other data[8,57], since in NMR detection in weak fields the overall NMR signal of all kinds of protons is observed and one cannot rule out the possibility that the main contribution to the NMR signal comes from the negative CINP of products other than benzene.

The next step in the theory of CINP will probably consist in a correct allowance for all the transitions in radical pairs and the calculation of their probabilities. In chemical kinetics, the solution of this problem will yield information about the states and interactions in radical pairs, about the dynamics of the motion of radicals in the pair, and about the probability of the recombination or collision of the radicals.

4. Chemically Induced Nuclear Polarisation in Atom Transfer Steps

The CINP of products of substitution reactions (or atom transfer reactions) has the same properties as in recombination (Tables 3 and 4). The mechanisms of CINP were examined in the preceding Sections. They are based on the hypothesis of $S-T$ transitions in the radical pairs, the dissociation of which gives rise to free radicals with polarised nuclei. These mechanisms have received reliable experimental confirmation.

However, the problem of whether CINP can be generated in elementary atom transfer steps and whether there are mechanisms capable of generating CINP in such steps is significant. The idea that CINP can arise in atom transfer steps was put forward by Rykov et al.[34] It arose from the following experimental finding: in the decomposition of peroxides in carbon tetrachloride, chloroform with negative CINP is detected. It was postulated that this polarisation arises in the steps involving the abstraction of hydrogen atoms by $\dot{C}Cl_3$ radicals from solvent molecules. However, this evidence is not unambiguous; CINP could arise in chloroform owing to the disproportionation of radicals in radical pairs by the mechanism discussed above (p. 809).

We have seen that in recombination reactions selection with respect to states takes place in triplet–singlet transitions. By analogy with recombination, the involvement of excited states in atom transfer steps can also be postulated. Such an analogy was drawn by Gerhart and Osterman[58].

The transition state in the transfer reaction $\dot{R} + XR' \rightarrow RX + \dot{R}'$ is regarded formally as a set of three radicals ($\dot{R}X\dot{R}'$) in the doublet state. As in the recombination reactions, the mixing of multiplet states owing to hyperfine coupling is considered and by analogy only the secular component of the isotropic hyperfine coupling is taken into account as a perturbation and the non-secular component and dipole–dipole interactions of the radical spins are neglected. The starting point in this treatment is the concept of a symmetrical wave function (s) of the transition state. Next follows the hypothesis that the decomposition of the state (activated complex) into the final products is facilitated by the mixing of the symmetrical (s) and antisymmetric (a) states owing to isotropic hyperfine coupling. Such mixing leads to the preferential population of levels with a minimum overall projection of nuclear spins (as in the recombination steps in the singlet state).

The introduction of antisymmetric spin states is equivalent to allowance for the excited states of the activated complex (by analogy with $S-T$ transitions in radical pairs in recombination). This hypothesis has evident consequences for CINP.

1. In the product RX of the reaction $R + XR' \rightarrow RX + \dot{R}'$ the states with the minimum overall projection of nuclear spins will be more populated and therefore in R'X these states will be depleted. This implies that the signs of the multiplet effect will be opposed and will correspond to A/E in RX and to E/A in R'X. This behaviour does indeed obtain (see Table 4 and the relevant comments).
2. The sign of the multiplet effect can also change when the direction of the reaction alters, i.e. the reaction $R + XR' \rightarrow \dot{R}X + R'$ is transformed into $\dot{R}' + XR \rightarrow R'X + \dot{R}$. This corollary has not been tested directly.
3. If R' = R, the multiplet CINP should be zero. This corollary hardly ever holds.
4. The enhancement factor E should depend on the nuclear spin in the multiplet because the probabilities of the transitions between the symmetrical and antisymmetrical states in the activated complex depend on the hyperfine interaction energy.

Despite the apparent confirmation of the idea of transitions between symmetrical (s) and antisymmetric (a) states there are two arguments which give rise to serious doubts about the validity of this mechanism.

Firstly, $s-a$ transitions are considered only in the step involving the decomposition of the activated complex. However, reverse transitions of the same type should occur in the formation of the activated complex, which should apparently lead to the cancellation of CINP in the atom transfer step.

Secondly, the magnitude of CINP should depend on the difference Δ between the energies of the s and a states and should be defined by the approximate relation $E \simeq a/\Delta$. Since $a \simeq 10^8-10^9$ s^{-1} and $E \simeq 10^3$, it follows that $\Delta \simeq 10^{11}-10^{12}$ s^{-1}. Thus, to be effective, the mechanism of CINP invoking excited states of the activated complex must involve the mutual approach of the ground and excited levels to within an energy of the order of a vibrational quantum. It is unlikely that such a situation can be realised; the real energy is of the order of one electron-volt.

Thus CINP in atom transfer steps can hardly be explained by invoking excited states of the activated complex. The problem of the intrinsic mechanisms of CINP in steps involving the transfer of atoms from the molecule to the radical remains open.

IV. CHEMICALLY INDUCED ELECTRONIC POLARISATION

Chemically induced electronic polarisation (CIEP) is revealed in the ESR spectra of atoms and radicals.

As in CINP, the polarisation of electrons is of two types - multiplet and integral. CIEP was observed for the first time by Fessenden and Schuler[59] in the ESR spectrum of hydrogen atoms in the radiolysis of liquid hydrocarbons: the low field component of the doublet corresponded to emission and the high field component corresponded to strong absorption. The hyperfine coupling constant for the hydrogen atom is positive and therefore the above spectrum implies that the hydrogen atoms are generated predominantly in the $\alpha\alpha_n$ and $\beta\beta_n$ spin states (the first symbol denotes the spin function of the electron and the second of the proton; the α-electron is oriented along the field and occupies the upper Zeeman level, because $\gamma_e < 0$). The $\alpha\alpha_n$ states give rise to an emission spectrum and the $\beta\beta_n$ states to an absorption spectrum (multiplet effect of type E/A). An analogous spectrum with multiplet polarisation was obtained for deuterium atoms[59].

Initially this effect was not understood; an attempt was made to attribute it to the technical conditions in the observation of ESR (modulation amplitude and phase, level of microwave power, etc.). However, five years after the publication of the paper of Fessenden and Schuler[59] a similar multiplet effect was observed by Smaller et al.[60] in the ESR spectra of radicals in the pulse radiolysis of liquid hydrocarbons. Thus all the low field components of the ESR spectrum of cyclopentyl radicals with $m_\alpha = \pm\frac{1}{2}$ and $m_\beta > 0$ corresponded to emission and all the high field components with $m_\alpha = \pm\frac{1}{2}$ and $m_\beta < 0$ corresponded to absorption (m_α and m_β are the quantum numbers of the projections of the nuclear spins of the α- and β-hydrogen atoms in the radical). Since the hyperfine coupling constant for β-protons is positive, such a spectrum corresponds to exactly to the same population of the electronic-nuclear spin levels as in hydrogen and deuterium atoms: the electron with an α-spin "escapes" to nuclei with α-spins and the electron with a β-spin "escapes" to nuclei with β-spins. One may postulate that, for a negative hyperfine coupling constant, the $\alpha\beta_n$ and $\beta\alpha_n$ states will be populated preferentially.

It was also shown[60] that the multiplet ESR spectrum is converted into the usual spectrum over a period of several microseconds. The kinetics of the variation of the emission signal from one of the hyperfine components are presented in Fig. 11. As in CINP (p. 805) a polarisation maximum is observed; the electronic relaxation times may be determined from the rate of depolarisation: they vary in the range 6–60 μs and depend on m_β, i.e. on the hyperfine interaction energy.

The problem of the mechanism of the multiplet polarisation of electrons will now be considered. If radicals are formed in the dissociation of molecules, all the processes occurring under these conditions can be treated as in recombination, i.e. the concept of $S-T$ transitions in dissociating radical pairs may be invoked (by analogy with the previous treatment of CINP in terms of recombining pairs). Then $S-T_0$ transitions will lead to multiplet CIEP, while $S-T_{\pm1}$ transitions can give rise to appreciable integral CIEP; in this case there is clearly a complete analogy with the mechanisms of CINP in recombination products.

The difference consists in the model adopted to describe the motion along the dissociation reaction coordinate. We shall consider as an example a study by Fischer[61], in which it was postulated that motion along the reaction coordinate is so slow that the S and T_0 states vary adiabatically. The spin-Hamiltonian for a pair of radicals is of the usual type:

$$\mathcal{H} = g\beta H_0(S'+S) - {}^1/_2 J(1+4\,SS') + h\Sigma a I_z S_z + h\Sigma a' I'_z S'_z .$$

Within the framework of the approximation employed, the problem reduces to the solution of a quadratic equation and for adiabatic conditions we obtain

$$\psi^+ = \frac{1}{\sqrt{2}}(AS + BT_0); \qquad (18)$$

$$\psi^- = \frac{1}{\sqrt{2}}(AT_0 - BS); \qquad (19)$$

$$A = \left(1 + \frac{1}{\sqrt{1+x^2}}\right)^{1/2}; \; B = \frac{x}{|x|}\left(1 - \frac{1}{\sqrt{1+x^2}}\right)^{1/2};$$

$$S = \frac{1}{\sqrt{2}}(|\alpha\beta m_1 m_{1'}\rangle - |\beta\alpha m_1 m_{1'}\rangle); \qquad T_0 = \frac{1}{\sqrt{2}}(|\alpha\beta m_1 m_{1'}\rangle + |\beta\alpha m_1 m_{1'}\rangle);$$

$$x = \frac{\Sigma a m_I - \Sigma a' m_{I'}}{2|J|}; \; J = J_0 e^{-t/\tau} .$$

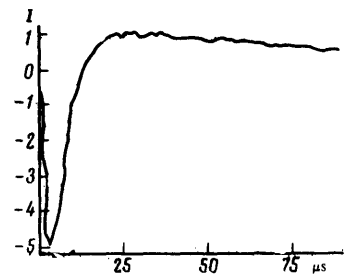

Figure 11. Kinetics of the variation of the amplitude of the component with $m_\beta = +1$ and $m_\alpha = -1/2$ in the ESR spectrum of cyclopentyl radicals.

Next it is postulated that at a certain instant $t = \tau'$ there is an instantaneous breakdown of the radical pair, which leads either to decomposition into free radicals, or to recombination, or transfer reactions. Since these processes are assumed to be fast (in the sense that they do not involve a change in the population of the magnetic states), the resulting populations are calculated by a simple projection of Eqns. (18) and (19) on to the relevant states of free radicals or molecules. Thus we have the following relative populations of the states of radicals in the decomposition of a singlet molecule:

$$a_{\alpha\alpha m_1 m_{1'}} = 0; \qquad a_{\alpha\beta m_1 m_{1'}} = {}^1/_4(A+B)^2; \qquad a_{\beta\alpha m_1 m_{1'}} = {}^1/_4(A-B)^2;$$

$$a_{\beta\beta m_1 m_{1'}} = 0; \; J = J_0 e^{-\tau'/\tau} .$$

These populations explain qualitatively the multiplet polarisation of electrons. The value of Fischer's work consists in the fact that he clearly formulated the principal reason for the change in the populations of the magnetic states in the dissociation step. This consists in the fact that the conditions which obtain for motion along the dissociation reaction coordinate are adiabatic.

However, an important comment must be made concerning the calculation itself. The point is that the redistribution of populations takes place mainly in the region where $J \simeq a$, i.e. when the traversal is never adiabatic. On the other hand, the applicability of

adiabatic conditions, discussed by Fischer refers to the region where $J \gg a$, which should not apparently make a significant contribution to chemically induced polarisation of nuclei and electrons.

A somewhat different dissociation model was considered by Kaptein and Oosterhoff[62]. Suppose that a molecule HX dissociates via the mechanism

$$H{-}X \rightarrow (\dot{H}\ \dot{X}) \rightarrow \dot{H} + \dot{X}$$

and one has to calculate the probability of the population of the levels of the hydrogen atom formed. The Hamiltonian for the pair is of the form

$$\mathcal{H} = \omega_e (S_1^z + S_2^z) - JS_1S_2 + a(S_1^z + S_2^z) I^z .$$

Here the non-secular terms are neglected and only the $T_0 - S$ transitions are considered (as for CINP, p. 809). It is postulated that in the dissociation J falls sharply to a value of the order of a, the pair remains in the singlet state, and subsequently dissociates with formation of an H atom in one of the states. (We may note that these are in fact the same approximations as those employed by Voss to account for the multiplet CINP in recombination products). Suppose that the nuclear spin is α_n; then the state of the radical pair is described by the wave function

$$\varphi^+(t) = [c_S(t)\, S + c_{T_0}(t)\, T_0]\alpha_n .$$

On substituting this function into the time dependent Schrödinger equation, we obtain a set of equations for the coefficients $c_S(t)$ and $c_{T_0}(t)$:

$$i\dot{c}_S = Jc_S + Ac_{T_0} ,$$
$$i\dot{c}_{T_0} = Ac_S - Jc_{T_0} ,$$

where $A = \frac{1}{4}a$. After finding the coefficients for the boundary conditions $c_S(0) = 1$ and $c_{T_0}(0) = 0$, we have

$$\varphi^+(t) = [\cos \omega t S - i\omega^{-1} \sin \omega t (JS + AT_0)]\alpha_n ,$$

and for the wave function with a nuclear spin β we have

$$\varphi^-(t) = [\cos \omega t S - i\omega^{-1} \sin \omega t (JS - AT_0)]\beta_n ,$$

where $\omega = (A^2 + J^2)^{1/2}$. Now the (oscillating) spin density at the H atom may be calculated:

$$\rho^{\pm} = 2\langle \varphi^{\pm}(t) | S_1^z \delta(r_1) | + S_2^z \delta(r_2) | \varphi^{\pm}(t) \rangle = \pm 2AJ\omega^{-2} \sin^2 \omega t .$$

This equation shows that the electron with a nuclear spin α has a higher density at the α nucleus.

If the spin density is now averaged over the lifetime of the pair $(\dot{H}\ \dot{X})$, we obtain the selectivity parameter

$$\delta^{\pm} = \frac{1}{\tau} \int_0^{\infty} \rho^{\pm}(t) e^{-t/\tau} dt = \pm \frac{4AJ\tau^2}{1 + 4\omega^2\tau^2} .$$

The rates of population of the levels in the H atom are

$$\alpha\alpha_n\ {}^1/_4 k(1 + \delta^+), \qquad \beta\alpha_n\ {}^1/_4 k(1 - \delta^+),$$
$$\alpha\beta_n\ {}^1/_4 k(1 + \delta^-), \qquad \beta\beta_n\ {}^1/_4 k(1 - \delta^-),$$

where k is the rate constant for the formation of the pairs. Evidently the $\alpha\alpha_n$ and $\beta\beta_n$ states are populated preferentially; this leads to a multiplet effect in the ESR spectrum of the hydrogen atom and the multiplet polarisation is proportional to δ and depends on J, a, and τ in the radical pair. Evidently the sign of ME in the ESR spectrum depends on the state in which the atom or radical is formed—the singlet or triplet state (as in CINP).

The multiplet polarisation of electrons has been observed in radicals formed not only in dissociation steps but also in transfer steps. Fischer and coworkers[63] investigated the electron spin resonance of the radicals $\dot{C}H_2CH_2COOH$ and $CH_3\dot{C}HCOOH$ from propionic acid by a flow method in the $Ti^{3+} - H_2O_2$ redox system. As in the work of Smaller et al.[60], the hyperfine coupling components with $m_\alpha = \pm 3/2$ gave rise to emission; other lines with $m_\beta > 0$ were found to have a lower amplitude, since here absorption was partly compensated by emission.

We must now note the following important factor. Since the probabilities of the population of various electronic-nuclear levels of the radical in a chemical reaction are different, one can consider the variation of the rate constant for the chemical reaction with nuclear spin, i.e. with the hyperfine coupling energy in the radicals formed (and possibly also destroyed). Thus the multiplet effects in the chemically induced polarisation of nuclei and electrons can be explained even when the difference between the rate constants amounts to only a few per cent. However, usually the rate constants measured in chemical kinetics are overall quantities averaged over the nuclear-spin states and there is no point in considering their variation with the spin. In other words, the integral rate constants k (see above). are independent of the spin, while the quasidifferential constants $k(1 \pm \delta)$ do depend on the nuclear spin. At present the only method for the measurement of the differential (with respect to the nuclear spin) reaction cross-sections is based on chemically induced polarisation. It would be interesting to attempt to find this type of relation between reaction cross-section and the spin in experiments with magnetically oriented molecular beams (provided that this is possible in principle).

The ESR spectra do not reveal solely multiplet CIEP. Recently reports have appeared[64,65] of the preparation of radicals with a completely inverted population of the Zeeman electronic levels; their ESR spectrum exhibited total emission over a period of several microseconds after preparation and was then converted into the normal ESR absorption spectrum. The radicals were obtained by pulse or continuous illumination of benzophenone, benzaldehyde, 2- and 4-chlorobenzaldehydes, acetophenone, dibenzyl, and anthraquinone by light from a nitrogen gas laser (λ = 3371 Å) or from a mercury lamp.

The causes of the total emission are so far obscure. One can only put forward certain hypotheses. On irradiation, excited triplet states are formed, which on reaction with the solvent form triplet radical pairs. If one of the radicals relaxes rapidly, then, owing to the non-secular component of the exchange interaction $JS_{\pm 1}S_{\mp 2}$, there may be an inversion of population in the second radical (as in the Overhauser effect). It is also possible that some of the triplet excited states (for example T_0 and T_1) are rapidly deactivated; the remaining T_{+1} states react with formation of a T_{+1} pair, which dissociates into radicals with electron spins α. Such selective deactivation of triplets in a magnetic field was observed in a solid on the basis of ESR and phosphorescence spectra[66], but it is not clear whether such a mechanism can operate in a liquid. A mechanism involving $S - T_{-1}$ transitions should also be effective (as in CINP, p. 813).

Finally, we may note that cosmic radiofrequency emission by hydroxyl radicals is also associated with the inverted population of their magnetic-rotational states[67]. This emission comes from regions of ionised gas near young and newly formed stars; such a region with a high concentration of hydroxyl radicals with an inverted population operates as a gigantic cosmic oscillator or

possibly as an amplifier—a celestial maser. Little is known about the mechanisms of inverted population; optical pumping has been mainly considered, but this hypothesis involves many difficulties and therefore one cannot rule out the possibility of chemical pumping[67-70].

V. THE IMPORTANCE AND PROSPECTS OF CHEMICALLY INDUCED NUCLEAR POLARISATION

In order to understand how chemically induced polarisation of electrons and nuclei takes place, it is first necessary to discover how the elementary chemical step occurs, what is its physical mechanism, and what is its physical model. It is already quite clear that many details of elementary chemical reactions may be understood with the aid of chemically induced polarisation of electrons and nuclei. This is in fact why chemically induced polarisation constitutes at present a "hot spot" at the junction of a number of disciplines: theory of the elementary step, magnetic relaxation, radiofrequency spectroscopy, chemical kinetics, and others; this has given rise to much interest in the phenomena of chemically induced polarisation.

Many fundamental problems in the theory of chemically induced polarisation are still obscure. However, what has already been achieved has proved very fruitful. The dual role of elementary chemical reactions is clear in principle: the passive role, consisting in the selection of radicals and molecules with respect to electronic-nuclear and nuclear spin states, and the active role, leading to the induction of polarisation in the elementary steps themselves. Such separation has already significantly aided the solution of the problem. Clearly CINP and CIEP contain information about electron–electron and electron–nucleus interactions in the activated reaction complex, about the time variation of these interactions, about the behaviour of the energy levels in the activated complex, etc. There is no doubt that the development of the theory of chemically induced polarisation will be closely related to the development of the theory of the elementary step.

The role of CINP as a new and powerful research method for the kinetics and mechanisms of chemical reactions must be emphasised; the sensitivity of CINP as a method for the identification of radical stages is higher by several powers of 10 than the sensitivity of the ESR method.

It is significant that CINP is shown not only in the reaction products of alkyl and phenyl radicals, where there is a powerful electron–nucleus magnetic interaction, but also in the reaction products of oxy-radicals where such interaction is weak[6]. This greatly extends the scope of the CINP method. A large-scale application of the CINP method in the study of various chemical reactions is at present of great interest both for the reactions and the method itself. The phenomena of chemically induced polarisation are also of some interest for physicists, since they give rise to new methods for the polarisation of nuclei and electrons.

The fundamental tasks in the field of chemically induced polarisation are, firstly, further development of the qualitative and quantitative theories of the phenomena associated with the theory of the elementary chemical steps and, secondly, a large-scale application of the chemically induced polarisation methods in a wide variety of chemical and biological processes.

Methods of Synthesis of αω-Difunctional Oligosiloxanes with Two Organic Substituents Per Unit

M.G.Voronkov and N.G.Sviridova

The methods of preparation of oligosiloxanes with two organic substituents per unit, containing the functional groups $X(R_2SiO)_nSiR_2X$ (X = Cl, OCOR, OR, NR_2, OH, or ONa) at the terminal silicon atom, have been considered and a critical assessment of the possibility of employing the methods for the synthesis of oligomers with specified n and X has been made.
The bibliography includes 187 references.

I. INTRODUCTION

Recently organosilicon oligomers containing reactive substituents at the ends of the chain have assumed increasing theoretical and practical interest. These compounds occupy an intermediate position between organosilicon monomers and polymers, which have been thoroughly investigated and widely described in the chemical literature.

The most important application of αω-difunctional organosilicon oligomers is the synthesis of polymers with regular structures. By controlling the sequence of fragments in the main chains of the macromolecules, it is possible to alter sharply the properties of the polymers without affecting or only slightly altering their composition. Condensation of αω-difunctional oligomers with organic and inorganic monomers, organic derivatives of the elements, and also with one another makes it possible to obtain new types of polymers with valuable technical properties. This reaction has already found wide application in the synthesis of organosilicon block polymers, siloxanes with a number of atoms of other elements, and other types of silicon-containing high-molecular-weight compounds.

Organosilicon oligomers can also be used themselves as heat exchangers, stabilisers for rubber mixtures based on organosilicon polymers, etc.

The methods of preparation of αω-difunctional organosilicon oligomers have not so far been adequately treated in monographs on organosilicon chemistry and in reviews. The aim of the present paper is to fill this gap. It deals with the methods of synthesis of αω-difunctional oligosiloxanes which can be isolated in a pure form.

II. METHODS OF SYNTHESIS OF αω-DIHALOGENO-OLIGOSILOXANES

1. Partial Hydrolysis of Chlorosilanes with an Organic Substituent

Hydrolysis of chlorosilanes with an organic substituent is one of the most important reactions in organosilicon chemistry. This reaction makes it possible to convert such chlorosilanes, obtained by direct synthesis from silicon and halogeno-derivatives of hydrocarbons[1-5], directly into siloxane polymers with organic substituents.

Hydrolysis of dichlorosilanes with two organic substituents by an excess of water usually leads to the formation of cyclosiloxanes and only an insignificant amount of linear siloxanes[6-8]. In the presence of a deficiency of water, the principal hydrolysis products are linear oligosiloxanes with chlorine atoms at the ends of the chain. As a rule, hydrolysis yields a mixture of oligomers with various contents of silicon atoms in the molecule:

$$n\,RR'SiCl_2 + (n-1)\,H_2O \rightarrow Cl(RR'SiO)_{n-1}SiRR'Cl + 2(n-1)\,HCl,$$

where $n \geqslant 2$. The hydrolysis is usually carried out in a solvent, sometimes in the presence of a hydrogen chloride acceptor.

Thus αω-dichloro-oligodimethylsiloxanes with the general formula $Cl[(CH_3)_2SiO]_{n-1}Si(CH_3)_2Cl$ are obtained in the hydrolysis of dichlorodimethylsilane with water, the reactants being in molar proportions of 2:1.[9,10] The maximum yields of these oligomers (28% for $n = 2$, 24% for $n = 3$, 15% for $n = 4$, 6% for $n = 5$, 3% for $n = 6$, and 2% for $n > 6$) can be achieved by hydrolysis in a homogeneous medium using a mixture of ether and dioxane as a solvent. Under these conditions, 22% of the initial $(CH_3)_2SiCl_2$ does not react.

In hydrolysis in the absence of a solvent (a two-phase system), the yield of αω-dichloro-oligosiloxane falls and the amount of unreacted dichlorodimethylsilane increases. At the same time octamethylcyclotetrasiloxane (D_4) and decamethylcyclopentasiloxane (D_5) appear in the reaction mixture.

The increase of the content of higher oligomers in the reaction mixture is promoted by a decrease of the $(CH_3)_2SiCl_2:H_2O$ molar ratio from 2 to 1.8–1.5.[11] For the ratio 1.5:1, the yield of oligomers with $n \geqslant 3$ increases by a factor greater than 2.

Hydrolysis of dichlorodimethylsilane or dichloromethylsilane in ether at −70°C yielded αω-dichloro-oligodimethylsiloxanes with $n = 1-3$ [12] or $1-5$ [13] and αω-dichloro-oligomethylsiloxanes $Cl(CH_3SiHO)_nSi(CH_3)HCl$ with $n = 1-4$ [13] respectively.

When a 1 : 18 : 1 (wt.%) mixture of $(CH_3)_3SiCl$, $(CH_3)_2SiCl_2$, and CH_3SiCl_3 was treated with a 62% solution of hydrogen chloride in water under pressure, 1,3-dichlorotetramethyldisiloxane and 1,5-dichlorohexamethyltrisiloxane were obtained in yields of 33.4 and 20.4% respectively[14].

$\alpha\omega$-Dichloro-oligomethylphenylsiloxanes have been obtained by the hydrolysis of dichloromethylphenylsilane with a deficiency of water in the presence of a solvent[15]. Under optimum conditions, the yields of oligomers containing 2, 3, 4, 5, and 6 silicon atoms in the molecule were 32, 25, 7, 4, and 4% respectively; 21% of $CH_3(C_6H_5)SiCl_2$ does not react. The reaction mixture also contains *sym*-trimethyltriphenyl cyclotrisiloxane and *sym*-tetramethyltetraphenylcyclotetrasiloxane.

Hydrolysis without a solvent results in the formation of only 8% of a mixture of distillable oligomers containing 2% of 1,3-dichloro-1,3-dimethyl-1,3-diphenyldisiloxane and 47% of higher $\alpha\omega$-dichloro-oligosiloxanes. The amount of unreacted $CH_3(C_6H_5)SiCl_2$ increases to 45%.

1,3-Dichloro-1-methyl-1,3,3-triphenyldisiloxane was obtained by the simultaneous hydrolysis of dichloromethylphenylsilane and dichlorodiphenylsilane in toluene at 80°C.[16] 1,3-Dichloro-1,3-dimethyl-1,3-diphenyldisiloxane is formed when moist dichloromethylphenylsilane is distilled (yield 16.4%)[17] or in the hydrolysis of $Cl(CH_3)C_6H_5Si(OC_6H_4C_6H_5\text{-}o)$[18]. $\alpha\omega$-Dichloro-oligodiphenylsiloxanes have been obtained by the hydrolysis of dichlorodiphenylsilane[19,20]. With a $(C_6H_5)_2SiCl_2 : H_2O$ molar ratio of 2 : 1, mainly 1,3-dichlorotetraphenyldisiloxane and 1,5-dichlorohexaphenyltrisiloxane are formed[19]. At the same time the formation of hexaphenylcyclotrisiloxane is observed. When the reactant ratio is reduced to 1.5, the yield of 1,3-dichlorotetraphenyldisiloxane falls and the yields of 1,5-dichlorohexaphenyltrisiloxane and hexaphenylcyclotrisiloxane increase. The theoretical yield of cyclosiloxane is reached when the $(C_6H_5)_2SiCl_2 : H_2O$ molar ratio is reduced to 1 − 0.67.

Hydrolysis of dichloromethylsilanes with an organic substituent, of the type $CH_3(RCH_2CH_2)SiCl_2$ (R = CF_3 or C_3F_7), in an autoclave by water saturated with hydrogen chloride (24 − 30°C, 28 − 48 h) yielded $\alpha\omega$-dichlorooligomethylsiloxanes with an organic substituent per unit, $Cl[CH_3(RCH_2CH_2)SiO]_nSiCH_3(RCH_2CH_2)Cl$, containing fluorine atoms in the organic group[21]. The oligomer $ClCH_3(CH_2Cl)SiO[CH_3(ClCH_2)SiO]_3SiCH_3(CH_2Cl)Cl$ was obtained similarly[22].

Hydrolysis of dichlorosilanes with two organic substituents can be carried out in the presence of salts of heterocyclic bases, acid amides, or triphenylphosphine. For example, when water is added to a mixture of dichlorodiphenylsilane and $C_5H_5N.HCl$ in toluene [molar ratio $(C_6H_5)_2SiCl_2 : H_2O = 2.5 : 1$] at 80 − 85°C, 1,3-dichlorotetraphenyldisiloxane is formed in 81.5 yield. The residue contains 1,5-dichlorohexaphenyltrisiloxane. $\alpha\omega$-Dichloro-oligomethyl- and $\alpha\omega$-dichloro-oligomethylphenyl-siloxanes were obtained similarly[23].

A conductimetric study of the hydrolysis of chlorosilane in a homogeneous medium (in a mixture of ethylene glycol with ether) showed that a decrease of reaction temperature and an increase of HCl content suppress the hydrolysis of Si − Cl bonds and promote the formation of the corresponding oligomers $Cl(R_2SiO)_nSiR_2Cl$.[24]

Linear $\alpha\omega$-difluoro-oligodiethylsiloxanes $F[(C_2H_5)_2SiO]_nSi(C_2H_5)_2F$ and also 8 − 10% of $(C_2H_5)_2SiF_2$ are formed in the hydrolysis of dichlorodiethylsilane with a saturated aqueous solution of potassium fluoride[25]. The study of the mechanism of the partial hydrolysis of dichlorosilanes with two organic substituents is of great importance for the determination of the optimum conditions in the preparation of $\alpha\omega$-dichloro-oligosiloxanes. This reaction is a complex process and the nature and proportions of the hydrolysis products depend on many factors ($R_2SiCl_2 : H_2O$ ratio, structure of R_2SiCl_2, solvent, reaction temperature, etc.). The formation of linear oligomers is promoted by an increase of the concentration of R_2SiCl_2, the homogeneity of the medium, and a low process temperature. It has been suggested[6,26] that partial hydrolysis is accompanied by a stepwise condensation:

$$Cl(R_2SiO)_nSiR_2Cl + H_2O \rightarrow Cl(R_2SiO)_nSiR_2OH,$$

$$2\,Cl(R_2SiO)_nSiR_2OH \rightarrow Cl(R_2SiO)_{2n+1}SiR_2Cl + H_2O \text{ etc.}$$

Evidence for this mechanism comes from the formation, during the hydrolysis of oligosiloxanes and polysiloxanes with two organic substituents per unit and mainly with a linear structure and from the high polydispersity of the oligomers and polymers obtained.

Low-molecular-weight $\alpha\omega$-dichlorosiloxanes are formed when t-butyl alcohol reacts with dichloromethylphenylsilane[15]. t-Butyl chloride, hydrogen chloride, polyisobutylene, and benzene are formed at the same time. The process is probably based on the hydrolysis of chlorosilanes by the water formed in the reaction of the liberated hydrogen chloride with t-butyl alcohol.

2. Telomerisation of Cyclosiloxanes with Halogenosilanes Having Organic Substituents

The telomerisation of cyclosiloxanes with halogenosilanes having organic substituents, which takes place according to the general mechanism

$$RR'SiCl_2 + n(R''R'''SiO)_x \rightarrow ClRR'Si(OSiR''R''')_{nx}Cl, \quad (x \geqslant 3)$$

was first achieved in 1960.[27-30] The reaction is carried out in sealed tubes (without a catalyst) at 250°C for 3 − 5 h. The difunctional oligomers $ClR(CH_3)Si(OSiR'R'')_{3n}Cl$ (R = R′ = R″ = CH_3; R = H, R′ = R″ = CH_3; R = CH_2=CH, R′ = R″ = CH_3; R = C_6H_5, R′ = R″ = CH_3; R = R′ = CH_3, R″ = C_6H_5; R = CH_3, R′ = R″ = C_6H_5) were obtained in this way from $R(CH_3)SiCl_2$ and $(R'R''SiO)_3$ [27,28,30-36]. The reactivities of halogenosilanes and cyclosiloxanes decrease in the series $CH_3SiHCl_2 > (CH_3)_2SiCl_2 > CH_3(CH_2=CH)SiCl_2 > CH_3(C_6H_5)SiCl_2$; $[(CH_3)_2SiO_3] > [(C_2H_5)_2SiO]_3 > [CH_3(C_6H_5)SiO]_3 > [CH_3(CH_2=CH)SiO]_3$. In all cases, instead of individual telomers, their mixtures are formed. A decrease of the molar ratio $RR'SiCl_2 : (R''R'''SiO)_3$ leads to a fall of the yield of low-molecular-weight telomers and a sharp increase of high-boiling telomerisation products.

With an equimolar ratio of dichlorodimethylsilane and hexamethylcyclotrisiloxane (D_3), telomers with $n = 1$ (64.4%), $n = 2$ (15.6%), $n = 3$ (4.1%), and $n \geqslant 4$ (10.9%) were obtained[31]. Telomers with $n = 1$ (83.1%), $n = 2$ (7.1%), $n = 3$ (3.1%), and $n \geqslant 4$ (3.9%) were obtained from dichloromethylsilane and D_3 (in proportions of 1 : 1); with a molar ratio of 1 : 2, the products were telomers with $n = 1$ (31.8%), $n = 2$ (42.8%), $n = 3$ (9.5%) and $n \geqslant 4$ (14.3%).[34] The reaction of dichloromethylvinylsilane with D_3 leads to the formation of a mixture of telomers with $n = 1$ (71.2%), $n = 2$ (11.8%), and $n \geqslant 3$ (8.7%). When the ratio is 1 : 2, the yields of telomers are 67.1% for $n = 2$ and 25.5% for $n \geqslant 3$. The telomer with $n = 1$ is not formed under these conditions[34].

Dichloromethylphenylsilane forms with D_3 (molar ratio 1:1) telomers with $n = 1$ (76.2%), $n = 2$ (77.6%), and $n \geq 3$ (13.6%).[34]

When 1,3,5-trimethyl-1,3,5-triphenylcyclotrisiloxane was cleaved by dichlorodimethylsilane, telomers with $n = 1$ (32.9%), $n = 2$ (4.9%), and $n \geq 3$ (63.9%), were obtained. The conversion of siloxane was 88.0% and that of dichlorodimethylsilane 36%.[35] The reaction in an autoclave is accompanied by the dissociation of siloxane bonds in the telomers.

Telomers could not be isolated from the products of the reaction of dichlorodimethylsilane with 1,3,5-trimethyl-1,3,5-trivinylcyclotrisiloxane because of the occurrence of a side process involving polymerisation with participation of the vinyl groups[35].

Hexaethylcyclotrisiloxane is cleaved by dichloromethylsilane with formation of oligomers in which $n = 1$ (64.3%), $n = 2$ (17.6%), and $n \geq 3$ (18.6%).[35] The reaction with dichlorodiethylsilane gives a 61.9% yield of 1,7-dichloro-octaethyltetrasiloxane[37].

1,7-Dichloro-1,3,5,7,7-pentaethyl-1,3,5-tri-n-propyltetrasiloxane (57%) and 1,7-dichloro-1,3,5,7-tetraethyl-1,3,5,7-tetra-n-propyltetrasiloxane (33%) were obtained by the cleavage of *sym*-triethyltri-n-propylcyclotrisiloxane with dichlorodiethylsilane and dichloroethyl-n-propylsilane respectively. 1,3,5,7-Tetra-n-butyl-1,7-dichloro-1,3,5,7-tetraethyltetrasiloxane was synthesised in 42% yield from *sym*-tetra-n-butyltetraethylcyclotrisiloxane and n-butyldichloroethylsilane[38].

D_4 enters into the telomerisation reaction with greater difficulty than D_3. Nevertheless oligomers of the type $ClR(CH_3)Si(OSiR'R'')_nCl$ ($R = R' = R'' = CH_3$; $R = C_6H_5$, $R' = R'' = CH_3$; $R = CH{=}CH_2$, $R' = R'' = CH_3$) have been obtained by the reaction of D_4 with $R(CH_3)SiCl_2$ ($R = CH_3$, C_6H_5, or $CH = CH_2$).[27,39].

When the ratio $D_4 : (CH_3)_2SiCl_2 = 2:1$, telomers with $n = 1$ (16.7%), $n = 2$ (20.0%), and $n = 3$ (7.7%) are formed and when the ratio is 1:1 the products have $n = 1$ (36.9%), $n = 2$ (33.0%), and $n = 3$ (7.5%). The reaction with a 3:1 reactant ratio was also investigated[33]. In all cases a mixture was obtained in which the telomer corresponding to the specified $D_4 : (CH_3)_2SiCl_2$ ratio predominated.

The reaction of equimolar amounts of dichloromethylvinylsilane and D_4 gave telomers with $n = 1$ (18.5%), $n = 2$ (30.8%), $n = 3$ (14.6%), and $n \geq 4$ (36.1%).[39] The reaction of dichloromethylphenylsilane with D_4 under standard conditions (250°C, 3 h) proceeds with the formation of small amounts of telomers (about 10 wt.%). Under more severe conditions (300°C, 5 h, molar ratio 2:1), the overall conversion reaches 18% and telomers with $n = 1$ (7.8%) and $n = 2$ (2.3%) are formed[39].

The synthesis of 1,9- dichlorodecamethylpentasiloxane (yield 34%) by heating a 1:1 mixture of dichlorotrimethylsilane and D_4 in an enamelled autoclave at 270–400°C and 80 atm has been described[40]. At 300°C the yield increases to 50%.

Changes in reactant ratio and temperature affect the yield of reaction products, which is a maximum for a ratio of 1:2–81% at 300°C and 77% at 350°C. At 400°C the yield falls to 42%. In all cases side products of the cleavage of the $-Cl[(CH_3)_2SiO]_nSi(CH_3)_2Cl$ chains with $n = 1$–6, 8, or 12 were obtained. When the reaction was carried out in an autoclave without a glass liner, a low yield of the required telomer was obtained together with a large amount of side products.

1,3-Dichlorotetramethyldisiloxane (22%), 1,5-dichlorohexamethyltrisiloxane (19%), 1,7-dichloro-octamethyltetrasiloxane (15%), higher oligomers (26%), and also D_3 (0.2%) and D_4 (1.0%) were obtained by heating polydimethylsiloxane with dichlorodimethylsilane in a bomb (380–400°C 5 h). In the presence of a catalyst ($FeCl_3$ and HCl or HBr), the reaction takes place also at room temperature[41].

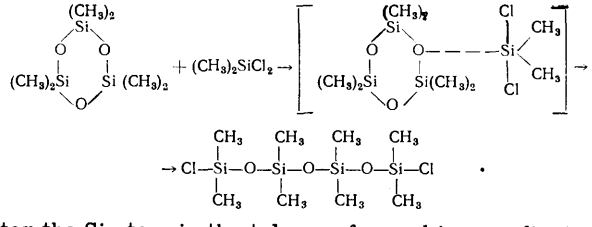
Oligomers containing together with Si–Cl bonds functional groups in the organic substituents were obtained by the reaction of D_3 with alkyl(chloroalkyl)chlorosilanes containing chlorine atoms in the α-, β-, and γ-positions[42] and by the reaction of D_4 with dichloro-(3,3,3-trifluoropropyl)methylsilane[42].

The position of the halogen atom in the hydrocarbon group of dichloro(halogenoalkyl)methylsilanes has a significant influence on the telomerisation reaction[42]. Thus dichloro(chloromethyl)methylsilane reacts with D_3 to form not only the telomers $Cl[(CH_3)_2SiO]_{3n}.SiCH_3(CH_2Cl)Cl$ with $n = 1$ (43.7%) and $n = 2$ and 3 but also their dissociation products containing 2, 3, and 4 silicon atoms in the molecule in yields of 18.3, 16.5, and 12.5% respectively. Dichloro-(2-chloroethyl)methylsilane reacts with D_3 to form telomers in which $n = 1$ (39.1%) and $n = 2$ (10.5%) and dissociation side products. The reaction of dichloro-(3-chloropropyl)methylsilane with D_3 is strictly of the telomerisation type with formation of telomers in which $n = 1$ (63.0%) and $n = 2$ (4.8%). The reactivity of dichloro(chloroalkyl)methylsilanes in the reaction with D_3 falls in the sequence $\beta > \alpha > \gamma$ as the position of the chlorine atom in the alkyl group is varied.

The reaction of D_4 with dichloro-(3,3,3-trifluoropropyl)methylsilane at 250°C involves the formation of a mixture of $Cl[(CH_3)_2SiO]_{4n}SiCH_3.(CF_3CH_2CH_2)Cl$ telomers with $n = 1$ (28.4%), $n = 2$ (7%), and $n = 3$ (10%) for the equimolar reactant ratio and with $n = 1$ (16.2%), $n = 2$ (22%), and $n = 3$ (20%) for the 2:1 ratio. The reaction proceeds mainly as in the case of dialkyldichlorosilanes. The polar and steric effects of the 3,3,3-trifluoropropyl group influence only the yield of the telomers. It proved possible to obtain 1,7-dichloro-octamethyltetrasiloxane and 1,9-dichlorodecamethylpentasiloxane by the cleavage of D_4 with dichlorodimethylsilane (molar ratio 1:4–4:1) in the presence of an equimolar amount of dimethylformamide, its derivatives, or *N*-formylpiperidine at 20°C in 120 h.[44]

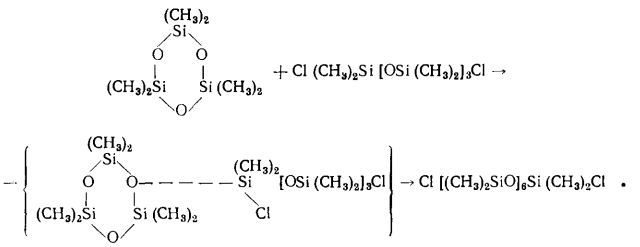
In the presence of a catalyst ($FeCl_3$) the telomerisation reaction is complicated by a side reaction involving the cleavage of telomer ins[36]. The reaction of D_3 with $(CH_3)_2SiCl_2$ results in the formation of the oligomers $Cl[(CH_3)_2SiO]_mSi(CH_3)_2Cl$ in which the number of silicon atoms *m* ranges from 2 to 7. In the presence of $FeCl_3$ linear siloxanes can also enter into the telomerisation reaction with dialkyldihalogenosilanes[45].

The study of the mechanism of the telomerisation reaction[27,32] led to the hypothesis that an intermediate complex of the cyclosiloxane and halogenosilane is formed in the first reaction stage and is subsequently converted into the first member of the homologous series:

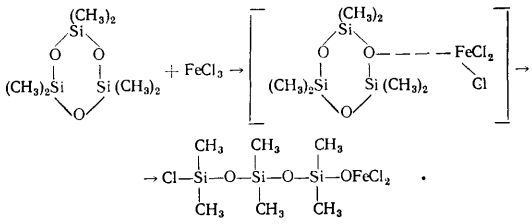


Later the Si atom in the telomer formed is coordinated to the oxygen atom of a new cyclosiloxane molecule as a

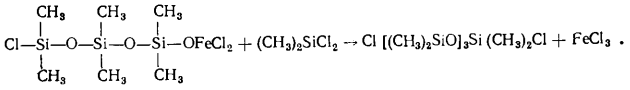
result of which the next member of the homologous series is formed, etc.



In the presence of a catalyst ($FeCl_3$) the reaction becomes reversible[32]. Together with telomers, dissociation products containing 1, 2, 3, and more silicon atoms in the molecule are formed. In this case a molecule of iron(III) chloride is coordinated to the oxygen atom of the cyclosiloxane of the telomer and the resulting complex decomposes via the mechanism



The Si–OFe bond is unstable and under the influence of compounds containing the Si–Cl bond breaks down with liberation of $FeCl_3$ and the formation of the Si–O–Si bond:



3. Cleavage of Cyclosiloxanes by Organic and Inorganic Halogen-containing Compounds

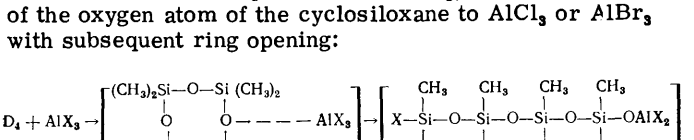
$\alpha\omega$-Dihalogeno-oligodialkylsiloxanes are formed when cyclosiloxanes or linear siloxanes are heated with boron, aluminium, phosphorus, or antimony halides:

$$(RR'SiO)_n + MX_n \rightarrow X(RR'SiO)_mSiRR'X \quad (M=B, Al, P, Sb) .$$

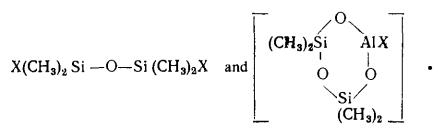
For example, oligomers of the $Cl(RR'SiO)_nSiRR'Cl$ series, where $R = R' = CH_3$,[46] $R = R' = C_2H_5$,[46,47] or $R = CH_3$ and $R' = C_6H_5$,[47] were obtained by the cleavage of the corresponding cyclotrisiloxanes and cyclotetrasiloxanes with aluminium chloride.

Difficult to obtain $\alpha\omega$-dibromo-oligosiloxanes, for example 1,3-dibromotetramethyldisiloxane, 1,5-dibromohexamethyltrisiloxane, and 1,7-dibromo-octamethyltetrasiloxane, have been synthesised by the reaction of D_4 with $AlBr_3$.[48] 1,3-Difluoro- and 1,3-dichlorotetramethyldisiloxanes are formed when cyclosiloxanes are cleaved with BF_3 or BCl_3 respectively[49,50].

It is suggested[48] that the first stage of the reaction of cyclosiloxanes with $AlCl_3$ and $AlBr_3$ is, as in the telomerisation in the presence of $FeCl_3$, the coordination of the oxygen atom of the cyclosiloxane to $AlCl_3$ or $AlBr_3$ with subsequent ring opening:

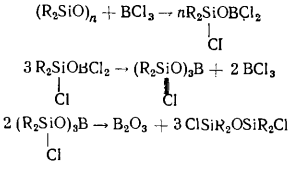


The linear aluminosiloxane formed decomposes into



Under the influence of AlX_3, 1,3-dihalogenotetramethyldisiloxane rearranges to higher $\alpha\omega$-dihalogenopolysiloxanes[48].

It has been suggested[50] that the dialkylchlorosiloxyborates formed initially in the reaction with BCl_3 decompose into the corresponding chlorosiloxanes and B_2O_3:



$\alpha\omega$-Dichloro-oligosiloxanes are also obtained by the distillation of cyclic or linear polysiloxanes with phosphorus oxide halides, antimony halides, or the halides of aromatic acids (benzoyl, phthaloyl, or isophthaloyl chlorides) in the presence of $FeCl_3$.[51]

$\alpha\omega$-Dichloro-oligoalkylmethylsiloxanes, in which the alkyl group contains three and more fluorine atoms, have been obtained by the cleavage with hydrochloric acid (at 30°C and an elevated pressure) of the hydrolysis product of $CH_3(RCH_2CH_2)SiCl_2$ ($R = CF_3$ or C_3F_7).[21]

4. Heterofunctional Condensation Reactions

The heterofunctional condensation reaction, which proceeds according to the general mechanism $\equiv Si-X + RO-Si\equiv \rightarrow \equiv Si-O-Si\equiv$ where X = halogen and R = H, alkyl, or acyl, has been less frequently used to synthesise $\alpha\omega$-difunctional oligomers than the hydrolysis of chlorosilanes with organic substituents and the cleavage of cyclosiloxanes. An advantage of this method over those described above is the possibility of obtaining oligomers with a specified alternation of different substituents at the Si atoms.

When dichloromethylsilane, dichlorodimethylsilane, dichloroethylsilane and dichlorodiethylsilane are heated with chloroethoxydimethylsilane (60–80°C, $FeCl_3$ catalyst), the corresponding $\alpha\omega$-dichloro-oligodialkylsiloxanes containing both identical and mixed alkyl substituents are formed[52]:

$$R_2SiCl_2 + R_2SiCl(OR) \rightarrow Cl(SiR_2O)SiR_2Cl + n\,HCl .$$

The reaction proceeds according to the mechanism

$$ClSiR_2-Cl + C_2H_5O-SiR_2'-Cl \rightarrow ClSiR_2-O-SiR_2'Cl + C_2H_5Cl ,$$

$$ClSiR_2OSiR_2'Cl + C_2H_5O-SiR_2'-Cl \rightarrow ClSiR_2-OSiR_2'-O-SiR_2'Cl + C_2H_5Cl, \text{ etc.}$$

The oligomers $Cl[(CH_3)_2SiO]_nSi(CH_3)_2Cl$ with $n = 1-3$ have been obtained by this method from dichlorodimethylsilane and chloroethoxydimethylsilane (1 : 1 molar ratio) in proportions analogous to those obtained in the partial hydrolysis of dichlorodimethylsilane [$n = 1$ (28%), $n = 2$ (24%), $n = 3$ (15%), and $n = 5$ and 6 (2%)][9,10]; 22% of the initial $(CH_3)_2SiCl_2$ does not react, whereas $(CH_3)_2Si(OC_2H_5)Cl$ reacts completely. The formation of cyclosiloxanes was not observed.

The reaction of dichlorodiethylsilane with chloroethoxydimethylsilane (1 : 1) leads to the corresponding $\alpha\omega$-dichloro-oligodialkylsiloxanes containing preferentially 4 and 5 silicon atoms in the molecule.

When the concentration of $(C_2H_5)_2SiCl_2$ is increased (up to a molar ratio of 2 : 1), the yield of low-molecular-weight $\alpha\omega$-dichloro-oligosiloxanes $Cl[(CH_3)_2SiO]_nSi(C_2H_5)_2Cl$, containing between 2 and 5 silicon atoms [$n = 1$ (14%), $n = 2$ (13.7%), and $n = 3$ (5%)], increases. In the case of dichloromethylsilane and dichloroethylsilane, the main heterofunctional condensation reaction is accompanied by disproportionation [52]:

$$CH_3SiHCl_2 + (CH_3)_2Si(OC_2H_5)Cl \rightarrow CH_3SiH(OC_2H_5)Cl + (CH_3)_2SiCl_2 .$$

The extremely reactive chloroethoxymethylsilane readily reacts with alkyldichlorosilanes [52]:

$$CH_3HSi(OC_2H_5)Cl + CH_3SiHCl_2 \rightarrow Cl(CH_3)SiHOHSi(CH_3)Cl + C_2H_5Cl .$$

Apart from the main products of the heterofunctional condensation of dichloromethylsilane and dichloroethylsilane with chloroethoxydimethylsilane

$Cl[(CH_3)HSiO]_nSi(CH_3)_2Cl$ [$n = 1$ (10%) and $n = 2$ (2.2%)] and $Cl[(C_2H_5)HSiO]_nSi(CH_3)_2Cl$ [$n = 1$ (7.7%) and $n = 2$ (8.8%)], the products $Cl[(CH_3)HSiO]_nSi(CH_3)HCl$ [$n = 1$ (18.3%) and $n = 2$ (6.2%)] and $Cl[(C_2H_5)HSiO]_nSi(C_2H_5)HCl$ [$n = 1$ (8.1%) and $n = 2$ (3.3%)] were also isolated.

Heterofunctional condensation of silanediols containing two organic substituents with dichlorosilanes (1 : 2), also containing two organic substituents, in the presence of aniline yielded the corresponding hexa-alkyl-1,5-dichlorotrisiloxanes [53]:

$$2\,RR'SiCl_2 + R''R'''Si(OH)_2 \rightarrow ClSiRR'OSiR''R'''OSiRR'Cl + 2\,HCl$$

($R = R' = CH_3$, $R'' = C_6H_5$, $R''' = CH_3$; $R = R' = C_6H_5$, $R'' = R''' = CH_3$; $R = R' = C_6H_5$, $R'' = C_6H_5$, $R''' = CH{=}CH_2$; $R = R' = C_6H_5$, $R'' = CH_3$, $R''' = C_2H_5$; $R = R' = C_6H_5$, $R'' = CH_3$, $R''' = CH_2CH(CH_3)C_6H_5$; $R = R' = C_6H_5$, $R'' = CH_3$, $R''' = CH_2CH_2CF_3$).

1,5-Dichloro-1,1,5,5-tetramethyl-3,3-diphenyltrisiloxane is formed in 66% yield on condensation of diphenylsilanediol with dichlorodimethylsilane (1 : 2) in the presence of a solvent and a hydrogen chloride acceptor (pyridine) [54].

5. Other Reactions

Dialkyldihalogenosilanes can react with metal oxides whereby they are converted into $\alpha\omega$-dihalogenosiloxanes. Metal oxides serve as a source of oxygen necessary for the formation of the Si–O–Si bond. Dichlorodimethylsilane reacts with Fe_2O_3 to form 1,3-dichlorotetramethyldisiloxane [55]. However, according to other data [56], anhydrous Fe_2O_3 does not react with $(CH_3)_2SiCl_2$ to form the above compound and therefore its synthesis requires the addition of a small amount of water. Instead of water, one can introduce at the beginning of the reaction a small amount of hydrogen chloride. Evidently chlorodimethylsilanol is formed in the first stage as a result of the hydrolysis of $(CH_3)_2SiCl_2$. Subsequently Fe_2O_3 apparently behaves as an acceptor of hydrogen chloride and a donor of water promoting the heterofunctional condensational reaction:

$$R_2SiCl_2 + H_2O \rightarrow R_2Si(Cl)OH + HCl ,$$
$$3\,R_2Si(Cl)OH + 3\,R_2SiCl_2 + 0.5\,Fe_2O_3 \rightarrow 3\,ClR_2SiOSiR_2Cl + FeCl_3 + 1.5\,H_2O .$$

The reaction of chlorodimethylsilanol with $(CH_3)_2SiCl_2$, which leads to the formation of oligomers, takes place according to the mechanism

$$Cl(CH_3)_2SiOH + (CH_3)_2SiCl_2 \xrightarrow{Fe_2O_3} Cl(CH_3)_2SiOSi(CH_3)_2Cl + HCl ,$$
$$Cl(CH_3)_2SiOH + Cl(CH_3)_2SiOSi(CH_3)_2Cl \rightarrow Cl(CH_3)_2SiOSi(CH_3)_2OSi(CH_3)_2Cl + HCl \text{ etc.}$$

PbO, CaO, MgO, ZnO, CuO, [57,58] BeO, and Ag_2O [58] have also been used as oxygen donors.

Dichlorodimethylsilane reacts with ethanol in the presence of catalytic amounts of $FeCl_3$, forming 1,2-dichlorotetramethyldisiloxane [up to 69% of $(CH_3)_2SiCl_2$ which has reacted] and 1,5-dichlorohexamethyltrisiloxane (21%). [59]

The mechanism of the catalytic effect of iron(III) chloride probably consists of the following steps:

$$3\,C_2H_5OH + FeCl_3 \rightarrow 3\,C_2H_5Cl + Fe(OH)_3 ,$$
$$3\,Fe(OH)_3 + 3\,HCl \rightarrow FeCl_3 + 3H_2O .$$

An interesting method for the preparation of chloro-oligomers is based on the chlorination of hydrosiloxanes containing linkages between H and Si atoms [60,61], for example:

$$H[(CH_3)_3SiO]_2SiO\{SiO[OSi(CH_3)_3]_2\}_nSi[OSi[OSi(CH_3)_3]_2H \quad (n \geqslant 0)$$

or

$$HR(CH_3)Si\{OSi[OSi(CH_3)_3]_2\}_nOSi(CH_3)RH \quad (R = CH_3, C_6H_5 \text{ и } n \geqslant 1) .$$

III. METHODS OF SYNTHESIS OF $\alpha\omega$-DIACYLOXY-OLIGOSILOXANES

1. The Cleavage of Cyclosiloxanes by Carboxylic Acid Anhydrides and Diacetoxydimethylsilane

$\alpha\omega$-Diacyloxyoligosiloxanes have been little investigated compared with other organosilicon oligomers. At the same time $\alpha\omega$-diacyloxysiloxanes containing reactive acyloxy-groups at the end of the chain are very promising and interesting oligomers from which it is possible to obtain a large number of a wide variety of organosilicon compounds.

The most important method of synthesising $\alpha\omega$-diacyloxyoligosiloxanes containing two organic substituents per unit consists in the cleavage of cyclosiloxanes by carboxylic acid anhydrides.

Acetic anhydride cleaves cyclosiloxanes containing two organic substituents (preferably in the presence of catalysts), forming $\alpha\omega$-diacetoxyoligosiloxanes with two organic substituents per unit:

$$(R_2SiO)_n + (CH_3CO)_2O \rightarrow CH_3COO(R_2SiO)_nCOCH_3 .$$

For example, $\alpha\omega$-diacetoxyoligodimethylsiloxanes $CH_3COO[(CH_3)_2SiO]_n.COCH_3$ ($n = 2$ or 3) are formed on catalytic cleavage of D_4 by acetic anhydride (molar ratio about 1 : 5) in the presence of sulfuric acid [62]. A deficiency of this method is the low conversion of D_4 (about 60%), the long duration of the reaction (40 h), and the high yield of diacetoxydimethylsilane, which constitutes about one third of all the reaction products. This reaction is of little interest for the synthesis of diacetoxydimethylsilane, since the latter can be readily obtained directly from dichlorodimethylsilane and acetic anhydride (see, for example, Dolgov et al. [63]).

The use of anhydrous iron(III) chloride or zinc chloride [64–66] as catalysts permits an increase of the conversion of D_4 to 95% and a reduction of the reaction time

to 1.5–4 h. Then oligomers with four and five silicon atoms in the molecule appear in the mixture and the overall yield of oligomers increases [$n = 2$ (20%), $n = 3$ (14%), $n = 4$ (11%), and $n = 5$ (6%); the yields are given relative to the initial reactants]. Diacetoxydimethylsilane is formed in yields up to 5%.

The reaction of D_4 with acetic anhydride involving the formation of $\alpha\omega$-diacetoxyoligodimethylsiloxanes can take place also in the absence of catalysts, provided that it is carried out at 250–260°C under pressure (in an autoclave or a sealed glass tube)[67]. The composition of the oligomers obtained in the autoclave is approximately the same as in the cleavage of D_4 by acetic anhydride in the presence of $FeCl_3$. In the reaction in a sealed glass tube the amount of oligomer with $n = 2$ is lower and that of the oligomer with $n = 5$ somewhat higher [$n = 2$ (14.3%), $n = 3$ (10%), $n = 4$ (9.8%), and $n = 5$ (9.6%)].

$\alpha\omega$-Diacetoxyoligosiloxanes with two organic substituents per unit, containing 3,3,3-trifluoropropyl, ethyl, vinyl, and phenyl groups at the silicon atoms, were obtained similarly from the corresponding cyclosiloxanes $(RR'SiO)_m$ and acetic anhydride[68,69]. The yields of the oligomers are given in Table 1. The conversion of octaethylcyclotetrasiloxane and 1,3,5,7-tetramethyl-1,3,5,7-tetravinylcyclotetrasiloxane is 85–90%. 1,3,5-Trimethyl-1,3,5-triphenylcyclotrisiloxane cannot be isolated from the reaction mixture, since the reaction products begin to decompose on distillation under the influence of the high temperature and the $FeCl_3$ present even before the distillation of the cyclosiloxane begins.

Table 1. Composition of mixtures of $\alpha\omega$-diacetoxysiloxanes with two organic substituents $[CH_3COO(RR'SiO)_nCOCH_3]$ formed when $(RR'SiO)_m$ is cleaved with acetic anhydride[69].

$CH_3COO(RR'SiO)_nCOCH_3$	R=CH₃; R'=CF₃CH₂CH₂		R=CH₃ R'=CH₂=CH	R=R'=C₆H₅	R=CH₃ R'=C₆H₅
	m=3	m=4*	m=4	m=3+4	m=3
n=2	17.7	8.3	11.4	30.3	14.8
n=3	23.0	36.1	12.1	19.7	8.1
n=4	15.2	9.7	10.9	10.9	—
n=5	—	—	2.8	—	—

* The reaction was carried out in an autoclave in the absence of $FeCl_3$.

1,3,5-Tri-(3,3,3-trifluoropropyl)-1,3,5-trimethylcyclotrisiloxane is completely cleaved by acetic anhydride, while 1,3,5,7-tetra-(3,3,3-trifluoropropyl)-1,3,5,7-tetramethylcyclotetrasiloxane is cleaved only to the extent of 30%. When the reaction is carried out in an autoclave (without a catalyst) at 250–260°C, the tetrasiloxane is cleaved almost completely.

When $HClO_4$ is employed as a catalyst, the temperature of the reaction in which cyclosiloxanes are cleaved by acetic anhydride may be reduced[70]. For example, when acetic anhydride is allowed to react with hexaethylcyclotrisiloxane (molar ratio 1 : 1) in the presence of perchloric acid, 1,3-diacetoxyhexaethyltrisiloxane is formed in a yield up to 30% even at room temperature. 1,3-Diacyloxytrisiloxanes with six organic substituents, $R'COO[C_2H_5(R)SiO]_3COR'$, were obtained by the cleavage of the corresponding cyclosiloxanes by carboxylic acid anhydrides in the presence of $ZnCl_2$ at 100°C or without a catalyst at 250°C (in a sealed tube)[70]. The yields of the oligomers are given in Table 2.

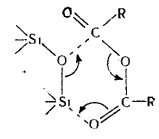
Boron triacetate has also been used as a catalyst of the cleavage of polysiloxanes by carboxylic acid anhydrides[71].

Oligodimethylsiloxanes blocked by perfluoroacyloxy-groups have been obtained by the cleavage of D_4 with perfluorocarboxylic acid anhydrides (in a sealed glass tube)[72]. With a D_4 : heptafluorobutyric acid anhydride molar ratio of 1 : 1, the cleavage products are the oligomers $CF_3CF_2CF_2COO[(CH_3)_2SiO]_nCOCF_2CF_2CF_3$ with $n = 2$ (27%) and $n = 4$ (30%) and also a mixture of oligomers with $n = 5$ and 6. When the ratio of the initial reactants is increased to 9 : 1, a viscous liquid polymer with $\bar{M} = 3840$ is formed. A similar polymer was obtained also in the reaction of D_4 with trifluoroacetic acid anhydride (molar ratio 10 : 1). When D_4 was cleaved with butyric anhydride, a mixture of oligomers with $n = 2$ (25.8%), $n = 3$ (14.8%), and $n \simeq 7$ (57%) was obtained.

Table 2. The yield of $R'COO[C_2H_5(R)SiO]_3COR'$ obtained by the cleavage of $[C_2H_5(R)_3SiO]_3$ with $(R'CO)_2O$.[70]

R	R'	Yield of trisiloxane, %		R	R'	Yield of trisiloxane, %	
		in sealed tube 250°C	in the presence of $ZnCl_2$ at 100°C			in sealed tube 250°C	in the presence of $ZnCl_2$ at 100°C
C_2H_5	CH_3	33.0	63.5	C_2H_5	C_2H_5	22.4	44.8
CH_3	CH_3	—	28.1	C_2H_5	C_4H_9	29.2	41.0
C_3H_7	CH_3	16.8	42.0	C_2H_5	C_6H_{11}	20.7	46.8

The cleavage of cyclosiloxanes by carboxylic acid anhydrides is probably reversible. The composition of the products of the reaction of D_4 with acetic anhydride is independent of the nature of the initial cyclosiloxane (D_3, D_4, D_5, "depolymerisation mixture", and a mixture of cyclic and linear siloxanes) and is determined only by the ratio of the initial reactants[66]. It has been suggested[73] that the cleavage of siloxanes proceeds via the intermediate formation of a six-membered cyclic activated complex involving the Si–O bond and the reactant. As a result of the delocalisation of six electrons in the ring formed, the energy required for the activation of the molecule diminishes, which facilitates cleavage. Similarly, in the cleavage of cyclosiloxanes by acid anhydrides, an intermediate cyclic complex is formed in the first reaction stage (with or without the participation of the catalyst):



which on decomposition gives rise to an $\alpha\omega$-diacyloxysiloxane oligomer with the same number of silicon atoms as in the initial ring:

$$(R_2SiO)_n + (R'CO)_2O \rightarrow R'COO(R_2SiO)_nCOR' .$$

The formation of homologues of this oligomer with a greater or smaller number of silicon atoms in the linear chain takes place via the following reactions.

1. Homofunctional condensation via the acyloxy-groups:

$$2\,R'COO(R_2SiO)_nCOR' \rightarrow R'COO(R_2SiO)_{2n}COR' + (R'CO)_2O .$$

2. Cleavage of the cyclosiloxane by a diacyloxysilane or a diacyloxysiloxane:

$$(R_2SiO)_n + R'COO(R_2SiO)_mCOR' \rightarrow R'COO(R_2SiO)_{n+m}OCOR'.$$

3. Cleavage of the $\alpha\omega$-diacyloxysiloxane by a carboxylic acid anhydride:

$$R'COO(R_2SiO)_nCOR' + (R'CO)_2O \rightarrow R'COO(R_2SiO)_mCOR' + R'COO(R_2SiO)_{n-m}COR'.$$

4. Redistribution of the chains (mutual cleavage) of two molecules of $\alpha\omega$-diacyloxysiloxanes:

$$R'COO(R_2SiO)_nCOR' + R'COO(R_2SiO)_mCOR' \rightarrow R'COO(R_2SiO)_kCOR' + RCOO(R_2SiO)_pCOR'.$$

The possibility of such reactions has been confirmed as follows. When diacetoxymethylphenylsilane is heated at 200–260°C, acetic anhydride and cyclic polymethylphenylsiloxanes are formed[74]. Heating of individual $\alpha\omega$-diacetoxydimethylsiloxanes containing between two and five silicon in the molecule and of diacetoxydimethylsilane, both in the presence of a catalyst and without it, leads to the formation of $\alpha\omega$-diacetoxyoligodimethylsiloxanes both with a smaller and a greater number of silicon atoms compared with the initial oligomer[75,76]. The reaction mixture contains acetic anhydride and a small amount of cyclosiloxanes.

$\alpha\omega$-Diacyloxysiloxanes with two organic substituents are formed from cyclosiloxanes (D_3 and D_4) and acyloxysilanes or acyloxysiloxanes in the presence of catalysts (aprotic Lewis acids)[77]. Thus the reaction of D_3 with diacetoxydimethylsilane in the presence of $ZnCl_2$ yielded 1,7-diacetoxyoctamethyltetrasiloxane and 1,13-diacetoxytetradecamethylheptasiloxane. In the absence of a catalyst, high-molecular-weight polysiloxanes are formed.

2. Cleavage of Cyclosiloxanes by Carboxylic Acid Halides

$\alpha\omega$-Diacetoxyoligodimethylsiloxanes are the main products of the cleavage of D_4 by acetyl halides (acetyl chloride and fluoride)[78,79]. The reaction proceeds both in the presence of a catalyst ($FeCl_3$) and without it (in an autoclave). At the same time the corresponding dihalogenodimethylsilane and 1,3-dihalogenotetramethyldisiloxane are formed:

$$(R_2SiO)_4 + CH_3COX \rightarrow CH_3COO(R_2SiO)_nCOCH_3 + X(R_2SiO)_mSiR_2X,$$

where R = CH_3, X = Cl or F, n = 1–5, and m = 0 or 1.

3. Exchange Reactions of the Terminal Groups and Heterofunctional Condensation

These reactions are less important for the preparation of $\alpha\omega$-diacyloxyoligosiloxanes than those described previously, since they require a preliminary synthesis of oligosiloxanes containing other functional groups at the end of the chain. Nevertheless exchange reactions are employed for the synthesis of specific individual oligomers in high yields.

Reactions involving the substitution of Cl atoms by acyloxy-groups in the corresponding $\alpha\omega$-dichloro-oligosiloxanes by treating the latter with carboxylic acid anhydrides[80–82] or carboxylic acid salts[83,84] are most often used. Thus 1,3-diacetoxytetramethyldisiloxane and 1,5-diacetoxyhexamethyltrisiloxane are formed in yields of 60–75%[80] and 82–86%[81] on heating 1,3-dichlorotetramethyldisiloxane or 1,5-dichlorohexamethyltrisiloxane with acetic anhydride (in proportions of 1 : 2), with simultaneous distillation of the acetyl chloride formed:

$$Cl[(CH_3)_2SiO]_nSi(CH_3)_2Cl + 2(CH_3CO)_2O \rightarrow$$
$$\rightarrow CH_3COO[(CH_3)_2SiO]_nSi(CH_3)_2COCH_3 + 2CH_3COCl.$$

1,7-Diacetoxyoctamethyltetrasiloxane and 1,9-diacetoxydecamethylpentasiloxane were obtained similarly in 86% yield[81].

The products of the reaction of the corresponding $\alpha\omega$-dichloromethylphenylsiloxanes with acetic anhydride are $\alpha\omega$-diacetoxyoligomethylphenylsiloxanes[82]. $\alpha\omega$-Diacetoxydimethylsiloxanes containing at the ends of the chain acryloyloxy- or methacryloyloxy-groups are formed in yields up to 90% when an $\alpha\omega$-dichloro-oligosiloxane containing a sulphate group, $Cl[(CH_3)_2SiO]_{7.4}[(CH_3)_2SiOSO_2O]_{0.17}SiR_2Cl$, reacts with potassium methacrylate or acrylic acid[84].

The reaction of oligosiloxane-$\alpha\omega$-diols with carboxylic acids, their anhydrides, and chlorides has been described[83]:

$$HO(R_2SiO)H + 2R'COX \rightarrow R'COO(R_2SiO)_nCOR' + HX \quad (X=OH,Cl,OCOR').$$

Heterofunctional condensation of dialkyl(aryl)silanediols with dialkyl(aryl)diacetoxysilanes in the presence of a solvent and an acetic acid acceptor (pyridine) makes it possible to obtain diacetoxytrisiloxanes $RR'Si[OSi(R''R''')OCOCH_3]_2$ [53] (R = R' = C_6H_5, R'' = C_6H_5, R''' = CH_3 or R'' = R''' = CH_3; R = CH_3, R' = $CH{=}CH_2$, R'' = R''' = CH_3; R = C_6H_5, R' = CH_3, R'' = R''' = C_6H_5) in yields up to 90%.

High-molecular-weight $\alpha\omega$-diacetoxypolysiloxanes are formed when poly(siloxane-$\alpha\omega$-diols) are condensed with acetic anhydride or with a diacetoxysilane (diacetoxysiloxane) containing two organic substituents in the presence of nitrogenous bases[85].

4. Homofunctional Condensation

On heating, diacetoxydimethylsilane can condense with the formation of $\alpha\omega$-diacetoxyoligosiloxanes[75,76]. Thus, when $(CH_3)_2Si(OCOCH_3)_2$ was heated with $FeCl_3$ at 150°C, diacetoxyoligosiloxanes with n = 2 (27.7%), n = 3 (11.5%), and n = 4 (5%) were obtained.

Since diacetoxydimethylsilane is readily formed from dichlorodimethylsilane, there is a possibility of synthesising oligomers directly from dichlorodimethylsilane. The latter is heated with acetic anhydride until the evolution of the theoretical amount of acetyl chloride, then $FeCl_3$ is added, and, after heating, $\alpha\omega$-diacetoxyoligodimethylsiloxanes are distilled off[75]:

$$(CH_3)_2SiCl_2 + (CH_3CO)_2O \xrightarrow{-CH_3COCl} (CH_3)_2Si(OCOCH_3)_2 \xrightarrow{FeCl_3} \rightarrow$$
$$\rightarrow CH_3COO[(CH_3)_2SiO]_nCOCH_3 + (CH_3CO)_2O.$$

The homofunctional condensation of $\alpha\omega$-diacyloxyoligosiloxanes was mentioned in section III, 1.

IV. METHODS OF SYNTHESIS OF $\alpha\omega$-DIALKOXYOLIGOSILOXANES

1. Cleavage of Cyclosiloxanes by Alcohols and Alkoxysilanes

$\alpha\omega$-Dialkoxyoligosiloxanes with two organic substituents can be obtained directly from cyclosiloxanes by their catalytic cleavage with alcohols: $(R_2SiO)_n + 2R'OH \rightarrow R'O(R_2SiO)_nR' + H_2O$; acids[86–88], alkalis[86], or amines[89,90]

may be employed as catalysts for this reaction. For example, hexamethyl-1,5-di-n-octyloxytrisiloxane and hexaethyl-1,5-di-n-octyloxytrisiloxane were obtained by the cleavage of the corresponding cyclotrisiloxanes and cyclotetrasiloxanes (containing organic substituents) by n-octyl alcohol in the presence of an acid (toluene-*p*-sulphonic acid) or an alkaline (sodium methoxide) catalyst with simultaneous distillation of the water formed[86]. The best yield is achieved when the reaction is stopped after distilling off only 33% of the theoretical amount of water formed in the reaction and removing the catalyst.

When 1,3,5-trimethyl-1,3,5-triphenylcyclotrisiloxane is heated with alcohols in the presence of hydrochloric acid or KIL activated clay, 1,5-dialkoxymethylphenylsiloxanes $RO[CH_3(C_6H_5)SiO]_3R$ ($R = C_2H_5$, n-C_3H_7, or iso-C_3H_7) are formed in yields up to 72–86%[87]. Hydrochloric acid, perchloric acid, or an aluminosilicate may be employed as catalysts[88]. The reaction is significantly influenced by the size of the cyclosiloxane ring, the nature of the substituents at the silicon atoms, and the catalyst. Hexa-alkylcyclotrisiloxanes containing a strained six-membered ring are cleaved more readily than the unstrained octa-alkylcyclotetrasiloxanes.

When $[CH_3(C_6H_5)SiO]_3$ is cleaved with alcohols, individual alkoxy-derivatives are formed, whereas the cleavage of $[CH_3(C_6H_5)SiO]_4$ gives a polydisperse mixture. This is because the rate of cleavage of 1,3,5,7-tetramethyl-1,3,5,7-tetraphenylcyclotetrasiloxane is comparable to the rates of the secondary processes (reactions of the alcohol with the alkoxysiloxanes)[87]. However, the effect of ring size is somewhat reduced when sodium methoxide is employed as a catalyst[86].

In the presence of an acid catalyst, cyclosiloxanes can be arranged in the following sequence in terms of their decreasing reactivity with respect to alcohols: $D_3 > D_4 >$ hexaethylcyclotrisiloxane > octaethylcyclotetrasiloxane > octaphenylcyclotetrasiloxane. In the presence of an alkoxide, the order of the reactivities of cyclosiloxanes alters somewhat: $D_3 = D_4 >$ hexaethylcyclotrisiloxane > octaphenylcyclotetrasiloxane > octaethylcyclotetrasiloxane, i.e. the rate of cleavage of octaphenylcyclotetrasiloxane becomes higher than that of octaethylcyclotetrasiloxane. The explanation is that in acid cleavage the inductive and steric effects of phenyl groups reduce the reactivity of the siloxane bond in relation to the electrophilic agent by decreasing the electron density at the oxygen atom and screening the Si–O bond (by the phenyl groups).

In alkaline cleavage the inductive effect of phenyl groups promotes a nucleophilic attack on the Si atom, while the inductive and steric effects of ethyl groups hinder it[86].

When an excess of alcohol is used, cyclosiloxanes are completely cleaved to the corresponding dialkoxysilanes with two other organic substituents[90]:

$$1/n\,(R_2SiO)_n + 2R'OH \xrightarrow{R'O^-} R_2Si(OR')_2 + H_2O\ .$$

1,3-Dibutoxytetramethyldisiloxane is formed in a yield of up to 40% when D_4 is heated with tetrabutyl orthotitanate at 200°C for 4 h. Dibutoxydimethylsilane and a polymer are formed at the same time[91].

$\alpha\omega$-Alkoxyoligosiloxanes can be obtained also by the reaction of cyclic or linear polydimethylsiloxanes with alkoxysilanes[92]. For example the reaction of a linear polydimethylsiloxane with tri-n-butoxymethylsilane catalysed by KOH yielded tetra-n-butoxy-1,3-dimethyldisiloxane and penta-n-butoxy-1,3,5-trimethyltrisiloxane:

$$[-Si(CH_3)_2OSi(CH_3)_2]_n + CH_3Si(OC_4H_9\text{-}n)_3 \rightarrow (n\text{-}C_4H_9O)_2Si(CH_3)OSi(CH_3)(OC_4H_9\text{-}n)_2 + (n\text{-}C_4H_9O)_2Si(CH_3)OSi(CH_3)(OC_4H_9\text{-}n)OSi(CH_3)(OC_4H_9\text{-}n)_2\ .$$

2. Reactions of Silanes Containing Two organic substituents and Two Functional Groups at the Silicon Atom and Oligosiloxanes with Two Organic Substituents per Unit.

$\alpha\omega$-Dialkoxyoligosiloxanes can be obtained by the partial hydrolysis of dialkoxydialkylsilanes or $\alpha\omega$-dialkoxyoligosiloxanes, by the esterification of $\alpha\omega$-dichlorooligosiloxanes, by homo- and hetero-functional condensation of the corresponding monomers or oligomers, and also by the hydrosilylation of the corresponding unsaturated compounds.

Dialkoxydialkylsilanes are less reactive than the corresponding dialkyldichlorosilanes and are more difficult to hydrolyse. Nevertheless, on heating in aqueous alcohol in the presence or absence of catalysts, they form the corresponding $\alpha\omega$-dialkoxyoligosiloxanes and a certain amount of cyclosiloxanes and polysiloxanes. Thus, when diethoxydiethylsilane was heated (10 h at 90°C) in alcohol with different amounts of water, the oligomers $C_2H_5O[(C_2H_5)_2SiO]_nC_2H_5$ with $n = 4$ (30.3%), $n = 7$ (76.3%), $n = 8$ (74.8%), and $n = 70$ (73.1%) were isolated[93].

$\alpha\omega$-Diethoxyoligo(chloromethyl)methylsiloxanes with $n = 2$, 3, or 4 were obtained by hydrolysing (chloromethyl)diethoxymethylsilane with a small amount of water (in alcohol) or by the esterification of dichloro(chloromethyl)methylsilane (10 h at 75–80°C)[94]. Partial hydrolysis of dibutoxydipentylsilane yields the oligomers $C_4H_9O[(C_5H_{11})_2SiO]_nC_4H_9$ with $n = 1-5$,[95] and that of di-t-butoxymethylphenylsilane gives t-$C_4H_9O[CH_3(C_6H_5)SiO]_nC_4H_9$-t ($n = 1-5$)[96]. 1,3-Dibutoxytetramethyldisiloxane and 1,5-dibutoxyhexamethyltrisiloxane were isolated in very low yields (4.9 and 2.6%) from an alcoholic solution of dibutoxydimethylsilane kept for two days. Only 9.2% of the initial dibutoxydimethylsilane remained[97].

Hydrolysis of $(CH_3)_2Si(OCH_3)_2$ in the presence of a small amount of alkali as a catalyst in 20% aqueous methanol leads to the oligomers $CH_3O[(CH_3)_2SiO]_nCH_3$ ($n = 2-10$)[98], while $C_2H_5O[(CH_3)_2SiO]_nC_2H_5$ ($n = 2-11$) is formed from $(CH_3)_2Si(OC_2H_5)_2$[99–101]. Cyclosiloxanes were isolated together with the above compounds.

$\alpha\omega$-Dialkoxyoligosiloxanes can be obtained directly from dialkyldichlorosilanes. The oligomers $C_2H_5O[(CH_3)_2SiO]_nC_2H_5$ with $n = 2$ (42%), $n = 3$ (39.2%), and $n = 4$ are formed on simultaneous partial hydrolysis and esterification of dichlorodimethylsilane with 97% ethanol[102]. The analogous reaction with isopropyl alcohol gives iso-$C_3H_7O[(CH_3)_2SiO]_nC_3H_7$-iso ($n = 1-5$) in an overall yield of 65–85%,[103] and the reaction with moist n-butyl alcohol gives 1,3-dibutoxytetramethyldisiloxane and 1,5-dibutoxyhexamethyltrisiloxane[92]. The products of the esterification of dichlorodiethylsilane by methanol are the oligomers $CH_3O[(C_2H_5)_2SiO]_nCH_3$ with $n = 1-4$.[104] The reaction of dichlorodiphenylsilane with ethanol leads to 1,3-diethoxytetraphenyldisiloxane[105].

1,3-Di-n-butoxy-1,3-dimethyl-1,3-di-α-naphthyldisiloxane (37.7%) and 1,5-di-n-butoxy-1,3,5-trimethyl-1,3,5-tri-α-naphthyltrisiloxane (26.7%) were obtained by the esterification with n-butyl alcohol of the hydrolysis products of dichloromethyl-α-naphthylsilane[106]. When

the amount of alcohol is reduced by a factor of 4, the yield of disiloxane falls to 25.5% and that of trisiloxane to 4.4%, the main reaction product being $C_4H_9O[CH_3(\alpha\text{-}C_{10}H_7)SiO]_4H$ (53.3%). The corresponding 1,3-dibutoxydisiloxane was also obtained by the reaction of dichloromethyl-α-naphthylsilane with butyl alcohol (yield 11%) or with sodium butoxide (yield 5–6%). In both cases dibutoxymethyl-α-naphthylsilane is formed simultaneously in yields of 60 and 80% respectively[106]. The hydrolysis is sometimes carried out in the presence of hydrogen chloride acceptors.

$\alpha\omega$-Dimethoxyoligodimethylsiloxanes ($n = 2-6$) were isolated in 72–76% yield after partial alcoholysis of dichlorodimethylsilane and the subsequent interaction of the alkoxychlorodimethylsilane formed with $NaHCO_3$. $\alpha\omega$-Diethoxy- and $\alpha\omega$-di-isopropoxy-oligosiloxanes were obtained similarly[107,108]. $\alpha\omega$-Di-t-butoxyoligodimethylsiloxanes with $n = 1-5$ were synthesised directly by the esterification of dichlorodimethylsilane with t-butyl alcohol in the presence of pyridine[109].

$\alpha\omega$-Dialkoxyoligosiloxanes with two organic substituents per unit may be obtained by the exchange of the functional groups in the oligosiloxanes. Thus treatment of $\alpha\omega$-dichloro-oligodialkylsiloxanes with a mixture of anhydrous alcohol and pyridine in benzene leads to 1,7-diethoxyoctaethyltetrasiloxane (70%), 1,7-diethoxytetraethyltetrapropyltetrasiloxane (69%), and tetrabutyl-1,7-diethoxytetraethyltetrasiloxane (73.3%)[38].

If the formation of hydrogen chloride or its salts is undesirable, orthoformic esters may be employed instead of alcohol. The oligomers $R'O(R_2SiO)_nSiR_2OR'$ (R' = alkyl, aryl, or alkylaryl) with $n = 2-1000$ were obtained by this method[110].

$\alpha\omega$-Dialkoxyoligosiloxanes were obtained from $\alpha\omega$-dichloro-oligosiloxanes with trimethylsiloxy-groups in the main chain and CH_3OH, C_2H_5OH, $(CH_3)_2CHOH$, and C_4H_9OH: [60,61]

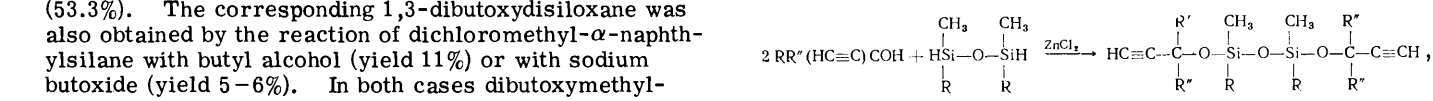
$$RO[(CH_3)_2SiO]_2SiO\{Si[OSi(CH_3)_2]_2O\}_n[OSi(CH_3)_2]_2OR \quad (n = 0,1,2,3,4)$$

and

$$RO(R')CH_3SiO\{Si[OSi(CH_3)_2]_2O\}_nSiCH_3(R')OR \quad (n = 1,2,3 \text{ etc. } R = CH_3 \text{ or } C_6H_5).$$

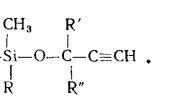
Heterofunctional condensation of dichloromethylphenylsilane with diethoxydimethylsilane, diethoxymethylphenylsilane, and diethoxyethylphenylsilane (in proportions of 1 : 2) in the presence of $FeCl_3$ leads to 1,3-diethoxy-1,1,3-trimethyl-1-phenyldisiloxane, 1,3-diethoxy-1,3-dimethyl-1,3-diphenyldisiloxane, 1,3-diethoxy-3-ethyl-1-methyl-1,3-diphenyldisiloxane, 1,5-diethoxypentamethyl-3-phenyltrisiloxane, 1,5-diethoxy-1,3,5-trimethyl-1,3,5-triphenyltrisiloxane, 1,5-diethoxy-1,5-diethyl-3-methyltriphenyltrisiloxane, 1,7-diethoxyhexamethyl-3,5-diphenyltetrasiloxane, and 1,7-diethoxy-1,3,5,7-tetramethyl-1,3,5,7-tetraphenyltetrasiloxane[111]. The redistribution of functional groups occurring in this process leads to the formation of a mixture of low-molecular-weight and high-molecular-weight condensation products, which hinders the isolation of the pure substances. Therefore the yield of tetrasiloxane does not exceed 47% and sometimes reaches only 13%. $(C_6H_5)_2Si[OSi(CH_3)_2OCH_3]_2$ was obtained by the heterofunctional condensation of diphenylsilanediol with $(CH_3)_2Si(OCH_3)Cl$.[53]

1,3-Dialkoxy-1,3-dialkyl-1,3-dimethyldisiloxanes have been synthesised by the dehydrocondensation of tertiary acetylenic alcohols with 1,3-diethyl-1,3-dimethyl- or 1,3-dimethyl-1,3-dipropyl-1,3-dihydrodisiloxanes in the presence of $ZnCl_2$ according to the mechanism[112]



where (a) R = C_2H_5 and R' = R'' = H, (b) R = C_3H_7 and R' = R'' = H, (c) R = C_2H_5, R' = H, and R'' = C_3H_7, (d) R = C_2H_5 and R' = R'' = CH_3, (e) R = R'' = C_2H_5 and R' = CH_3, (f) R = C_3H_7, R' = CH_3, and R'' = n-C_4H_9.

Under certain reaction conditions and for certain structures of the initial components, monoalkynyloxy-derivatives of tetra-alkyldisiloxanes are also formed:



1,3-Diethoxytetraethyldisiloxane and 1,5-diethoxyhexaethyltrisiloxane were obtained by heating diethoxydiethylsiloxane in an autoclave at about 300°C in the presence of $AlCl_3$ or BCl_3:[113]

$$(C_2H_5)_2Si(OC_2H_5)_2 \xrightarrow{AlCl_3} C_2H_5O[(C_2H_5)_2SiO]_nC_2H_5$$

(n = 2 or 3).

$[CH_3CH = CHOSi(C_2H_5)_2]_2O$ and $[(C_2H_5)_2SiOC(CH_3) = CHCH(CH_3)_2]_2O$ were obtained by the addition of the tetraalkyldisiloxane to acrolein or mesityl oxide[114,115].

V. METHODS OF SYNTHESIS OF $\alpha\omega$-DIAMINO-OLIGOSILOXANES

$\alpha\omega$-Diamino-oligodialkyldisiloxanes are obtained by the reaction of $\alpha\omega$-dichloro-oligodialkylsiloxanes with ammonia or amines:

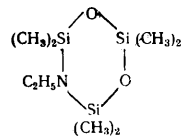
$$Cl(SiR_2O)_nSiR_2Cl + 4R'_2NH \rightarrow R'_2N(SiR_2O)_nSiR_2NR'_2 + 2R_2NH_2Cl,$$

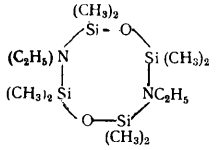
where R' = alkyl or H. Depending on the nature of the substituents at the nitrogen atom, the chain length of $\alpha\omega$-dichloro-oligosiloxanes, and the reaction conditions, $\alpha\omega$-diamino-oligosiloxanes, cyclosiloxazanes, or their mixtures may be obtained.

The initial oligomers containing up to six silicon atoms in the molecule react with an excess of ammonia to form cyclic compounds—cyclosilazanes and cyclosiloxazanes[116]. With increase of the number of silicon atoms in the chain of $\alpha\omega$-dichloro-oligosiloxanes to 7–11, the tendency by the latter towards ring formation falls and linear $\alpha\omega$-diamino-oligodialkylsiloxanes are formed.

When an ethereal solution of an $\alpha\omega$-dichloro-oligosiloxane was added to liquid ammonia, the oligomers $NH_2[(CH_3)_2SiO]_nSi(CH_3)_2-NH_2$ with $n = 6$ (72%), $n = 7$ (58.6%), $n = 8$ (46.4%), $n = 9$ (54.8%), and $n = 10$ (45.4%) were obtained. The analogous reaction with methylamine leads to 1,3-di(methylamino)tetramethyldisiloxane and 1,5-di(methylamino)-hexamethyltrisiloxane[117,118], which, in contrast to the corresponding amino-derivatives, do not cyclise on heating. When gaseous methylamine is passed into a solution of $\alpha\omega$-dichloro-oligodimethylsiloxanes, the cyclisation products $[Si(CH_3)_2OSi(CH_3)_2N(CH_3)]_2$ and $Si(CH_3)_2OSi(CH_3)_2N(CH_3)$ and the linear dimer $(CH_3)N[Si(CH_3)_2OSi(CH_3)_2N(CH_3)_2]_2$ are formed together with 1,3-di(methylamino)tetramethyldisiloxane (yield 40%) and 1,5-di(methylamino)hexamethyltrisiloxane (32%).

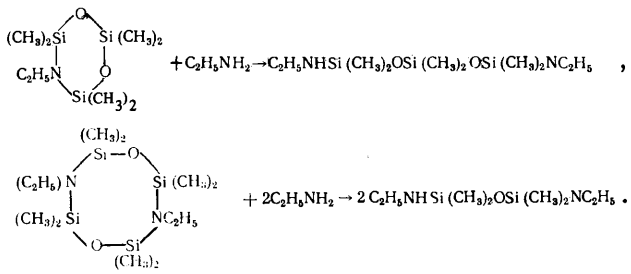
However, when the reaction is carried out at −60°C, the products are αω-di(methylamino)oligodimethylsiloxanes containing between 2 and 10 silicon atoms in yields of 51.8, 65.5, 39.8, 31.4, 21.1, 62.0, 73.3, 74.1, and 37.4% respectively[119]. Depending on the conditions, the products of the analogous reaction of methylamine may be both linear and six- and eight-membered cyclic compounds:





The latter are formed when the process is carried out in a solvent with equimolar proportions of the αω-dichloro-oligosiloxane and the amine. In the absence of a solvent and in the presence of an excess of the amine, the products are the linear oligomers $C_2H_5NH[(CH_3)_2SiO]_nSi(CH_3)_2NHC_2H_5$ with n = 1−4.[120]

It has been suggested that cyclic condensation products are formed in the initial reaction stage and undergo ring opening under the action of the excess of the amine with formation of αω-diamino-oligodimethylsiloxanes[120]:



αω-Dichloro-oligodimethylsiloxanes containing between 5 and 10 silicon atoms in the molecule form linear αω-di(ethylamino)-oligodimethylsiloxanes even in the presence of only the equimolar reactant ratio. The yields of the oligomers are 37.5% for n = 5, 30.5% for n = 6, 36.0% for n = 7, 28.6% for n = 8, 40.8% for n = 9, and 46.5% for n = 10.[121]

The reaction of αω-dichlorodimethylsiloxane with diethylamine yielded the oligomers $(C_2H_5)_2N[(CH_3)_2SiO]_nSi(CH_3)_2N(C_2H_5)_2$ with n = 2−10, which exhibit a high thermal stability. Cyclic compounds are not isolated under these conditions. The yield of the oligomers was between 30 and 60%.[121] With increase in the size of the organic substituent at the nitrogen atom, the capacity for cyclisation diminishes.

The reaction of 1,5-dichlorohexamethyltrisiloxane with n-butylamine gave 1,5-di-(n-butylamino)hexamethyltrisiloxane, which cyclises on heating only in the presence of $CuBr_2$ or $(NH_4)_2SO_4$.[54] αω-Dichloro-oligosiloxanes containing more or less than three silicon atoms in the molecule react with n-butylamine, also forming only linear αω-di(n-butylamino)oligodimethylsiloxanes with n = 1 (70.3%), n = 2 (50.2%), n = 3 (57.7%), n = 4 (50.8%), n = 5 (34.9%), n = 6 (35.8%), n = 7 (43.7%), and n = 8 (51.5%).[122]

VI. SYNTHESIS OF OLIGOSILOXANE-αω-DIOLS

1. Hydrolytic Cleavage of Cyclosiloxanes

The cleavage of oligomeric cyclosiloxanes with two organic substituents by water takes place in the presence of acid[123-125] or alkaline[126,127,129] catalysts: $(R_2SiO)_n + H_2O \xrightarrow{H^+,\ OH^-} HO(R_2SiO)_nH$. In the absence of catalysts cyclosiloxanes are cleaved by water only under severe conditions (at 250°C under pressure), which promote the formation of high-molecular-weight siloxane αω-diols[128].

Acids with a dissociation constant >6.5 × 10^{-2} (HCl, H_2SO_4, p-$CH_3C_6H_4SO_3H$) have been suggested as catalysts for the hydrolytic cleavage of siloxanes and tetrahydrofuran (THF), dimethylformamide, acetonitrile, or acetone have been proposed as solvents[123].

Thus when D_3 is cleaved with 0.05 N HCl in tetrahydrofuran, the products are about 82% of hexamethyltrisiloxane-1,5-diol, about 13% of the initial cyclosiloxane, and about 6% of an unidentified compound. Hexaphenylcyclotrisiloxane is cleaved with 0.5 N HCl in acetone to hexaphenyltrisiloxane-1,5-diol in yields up to 34%.

1,3-Dimethyl-1,3-diphenyldisiloxane-1,3-diol is obtained by the cleavage of 1,3,5-trimethyl-1,3,5-triphenylcyclotrisiloxane with an excess of potassium hydroxide in alcoholic solution with subsequent hydrolysis of the resulting siloxanolate in the presence of KH_2PO_4.[126] The yield of siloxanediol was 87%.

Ammonia and amines are also used as catalysts for the hydrolytic cleavage of cyclotrisiloxanes with six organic substituents[129]. In this case the rearrangement of siloxane bonds, observed in catalysis by strong acids or bases, is ruled out. Such catalysts make it possible to obtain virtually pure linearoligosiloxane-αω-diols with two organic substituents per unit. For example, the cleavage of 1,3,5-tri-(3,3,3-trifluoropropyl)-1,3,5-trimethylcyclotrisiloxane with a mixture of 29% ammonia solution, water, and acetone over a period of 16 h at 20°C gave mainly $HO[CH_3(CF_3CH_2CH_2)SiO]_3H$.

Acid and basic ion-exchange resins are also used as catalysts for the hydrolytic cleavage of cyclosiloxanes[130,131]. Thus in the presence of Amberlite IR-120, D_3 dissolved in acetone is converted into $HO[(CH_3)_2SiO]_nH$ with n = 3 (41%) and n = 6 (11.2%). Basic resins promote the formation of a hexamer[131].

Octamethyltetrasiloxane-1,7-diol was obtained by heating (150°C, 1,5 h) D_4 with 1% of glycerol and 0.5% of bleaching earth containing minerals of the montmorillonite group[132].

Oligosiloxane-αω-diols with two organic substituents per unit are also formed when cyclosiloxanes are cleaved with diphenylsilanediol[133] or with siloxane-αω-diols[126]: $(R_2SiO)_n + HO(R'_2SiO)_mH \rightarrow HO(R_2SiO)_n(R_2SiO)_mH$.

2. Hydrolysis of Silane with two Functional Groups at the Silicon Atom and Two Organic Substituents

A convenient method for the preparation of oligosiloxane-αω-diols is based on the capacity of Si−Cl, Si−OCOR, Si−OR, Si−NRR′, Si−H, Si−SH, Si−SR, etc. bonds in the corresponding disubstituted silanes with two organic groups and in αω-difunctional oligosiloxanes to be readily cleaved by water with formation of Si−OH bonds. Depending on the hydrolysis conditions, the latter can persist or condense further: $nR_2SiX_2 + (n+1)H_2O \rightarrow HO(R_2SiO)_nH + 2nHX$ (X = Cl, OCOR, OR, NRR′, H, SH, or SR).

The reactivity (including the reactivity with respect to water) of Si–X bonds in compounds with functional groups at the silicon atoms falls in the following sequence: Cl > OCOR > OR.[6] Usually the most readily available dichlorosilanes with two organic substituents are hydrolysed. However, during their hydrolysis hydrochloric acid appears in the reaction medium and causes the cyclisation of the siloxanediols. To avoid the formation of a large amount of cyclosiloxanes and high-molecular-weight siloxanediols, the hydrolysis is usually performed under mild conditions (at a low temperature and in the presence of a hydrogen chloride acceptor). The first member of the homologous series of the $HO[(CH_3)_2SiO]_nH$ ($n \geq 2$) oligomers—tetramethyldisiloxane-1,3-diol—was synthesised in a yield of up to 60% by the hydrolysis of dichlorodimethylsilane with a large excess of cold water (2°C) in the presence of NH_4OH (pH ~ 7) [134,135]. When gaseous ammonia is introduced, reproducible results are not always obtained owing to the difficulty of regulating the rate of its supply and the removal of the heat evolved.

Hydrogen chloride can also be neutralised by ammonium sulphate containing magnesium carbonate[136], $NH_4HCO_3(NH_4)_2CO_3$,[138] $NaHCO_3$, $Na_2B_4O_7.10H_2O$,[137] or ammonium bicarbonate carbamate ($NH_4HCO_3.NH_2CO_2NH_4$).[138] In the latter case a pH of 6–8 can be readily attained during the hydrolysis. However, the yield of tetramethyldisiloxane-1,3-diol is only 39%. A decrease of the amount of water leads to a shift of the pH of the reaction medium to the weakly acid region, which makes it possible to obtain higher oligosiloxanediols (hexamethyltrisiloxane-1,5-diol and decamethylpentasiloxane-1,9-diol).

Tetraphenyldisiloxane-1,3-diol (51%) and hexaphenyltrisiloxane-1,5-diol (18%) were obtained by the same method from dichlorodiphenylsilane. The hydrolysis of $(C_6H_5)_2SiCl_2$ with cold water gives low yields of tetraphenyldisiloxane-1,3-diol and hexaphenyltrisiloxane-1,5-diol[139]. Tetraphenyldisiloxane-1,3-diol was also obtained by the hydrolysis of $(C_6H_5)_2SiCl_2$ after which the resulting $(C_6H_5)_2Si(OH)_2$ was allowed to stand in the solvent (benzene–petroleum ether) for three days[140]. Tetramethyldisiloxane-1,3-diol is formed in a very low yield when dichlorodimethylsilane is treated with aqueous t-butyl alcohol[109].

Acid hydrolysis of dichloromethylphenylsilane results in the formation of only cyclotrisiloxanes with *cis*- and *trans*-structures[141]. On the other hand, hydrolysis in dilute ethereal solutions by aqueous alkalis yields ethylphenylsilanediol and 1,3-dimethyl-1,3-diphenyldisiloxane-1,3-diol[142].

Siloxanediols containing complex aromatic and alkyl groups at the silicon atoms have been obtained by the hydrolysis of more complicated dialkyl-, alkylaryl-, or diaryl-chlorosilanes. In this case the hydrolysis of the Si–Cl bond is difficult owing to the steric effect of the substituents at the silicon atoms. The silanediol formed in the first stage of the hydrolysis may be isolated from the reaction mixture. In order to synthesise silanediols, the reaction mixture sometimes has to be heated. Thus in the preparation of deca-*p*-tolylpentasiloxane-1,5-diol, dichlorodi-*p*-tolylsilane is hydrolysed by a mixture of water and ether, after which the ether is removed and the mixture heated to 250°C (at 1 mmHg pressure) and again hydrolysed[143]. The hydrolysis of $(p\text{-}ClC_6H_4)_2SiCl_2$ in toluene, ether, or isopentyl alcohol gives mainly tetra-(*p*-chlorophenyl)disiloxane-1,3-diol. When aqueous alkali or ammonia is employed, a mixture of di-(*p*-chlorophenyl)silanediol and tetra-(*p*-chlorophenyl)disiloxane-1,3-diol is formed. In ethereal solution only the monomeric silanediol is produced and on heating to 110°C is converted into hexa-(*p*-chlorophenyl)trisiloxane-1,5-diol.[144]

Dichloromethyl-α-naphthylsilane is hydrolysed to methyl-α-naphthylsilanediol and its low-molecular-weight condensation products $HO[CH_3-(\alpha-C_{10}H_7)SiO]_nH$.[106] Oligomers with three and four silicon atoms in the molecule have been isolated from the condensation products of ethylphenyl- and benzylethyl-silanediols[145,146].

The study of the effect of bulky alkyl groups (n-hexyl, n-octyl, iso-octyl, and isononyl) at the silicon atoms on the nature of the hydrolysis products of the corresponding dialkyldichlorosilanes[147] showed that in 34.7% hydrochloric acid only cyclic condensation products are formed. In dilute hydrochloric acid a mixture of cyclic and linear siloxanes was obtained, from which 1,3-diethyl-1,3-diiso-octyldisiloxane-1,3-diol (up to 58%), 1,3,5,7-tetraethyl-1,3,5,7-tetraiso-octyltetrasiloxane-1,7-diol (20%), and 1,3,5,7-tetrahexyl-1,3,5,7-tetramethyltetrasiloxane-1,7-diol (12.3%) were isolated.

Prolonged heating of silanediols with two organic substituents, particularly in the presence of dehydrating agents, promotes the successive formation of dimeric, trimeric, and higher oligomeric siloxane-αω-diols. The reaction takes place in steps. By altering the condensation conditions, it is possible to achieve the preferential formation of oligosiloxane-αω-diols, siloxanediols, or cyclosiloxanes[142].

Monomeric compounds R_2SiX_2 containing other functional groups X, for example X = OCOR or OR, are also used for the synthesis of oligosiloxane-α-diols. Thus di(methylvinyl)-, di(allylmethyl)-, di(phenylvinyl), di(chlorophenylvinyl), and di(allylphenyl)-siloxane-1,3-diols have been obtained in yields up to 90–98% by the hydrolysis of the corresponding diacetoxysilanes with two organic substituents[148,149].

Dimethyldi-(1-pentynyl)disiloxane-1,3-diol and di-(1-hexynyl)dimethyldisiloxane-1,3-diol were prepared by the hydrolysis of the corresponding diacetoxydialkynylsilanes with a saturated solution of sodium chloride[150,151]. The cyclosiloxane $[CH_3(CH_2)_3C \equiv CSiO]_4$ is formed at the same time, its yield increasing with temperature and the rate of addition of the acetoxysilane. The hydrolysis of alkoxysilanes with two other organic substituents is usually carried out in the presence of acid catalysts. Thus by hydrolysing diethoxyphenylvinylsilane with 0.1 *N* HCl in ethanol, 1,3-diphenyl-1,3-divinyldisiloxane-1,3-diol was obtained[152], while diethoxydiethylsilane (in 15% HCl) gave tetraethyldisiloxane-1,3-diol (yield up to 88%).[153–155]

Hydrolysis of diethoxydimethylsilane in the presence of traces of sulphuric acid resulted in the formation of tetramethyldisiloxane-1,3-diol (yield up to 66%).[156] The same compound has been obtained by the hydrolysis of dimethoxydimethylsilane[157].

Oligosiloxanediols containing pentafluorophenyl groups at the silicon atoms, $HO[(CH_3(C_6F_5)SiO]_nH$ ($n = 2$ or 4), have been obtained in 80–90% yield by the hydrolysis of dialkoxymethyl(pentafluorophenyl)silane in an alcoholic medium in the presence of acetic acid[158]. Tetramethyldisiloxane-1,3-diol is formed in the hydrolysis of hexamethylcyclotrisilthiane $[(CH_3)_2SiS]_3$ in the presence of sodium hydroxide[159]:

$$2\,[(CH_3)_2SiS]_3 + 12\,NaOH \rightarrow 3HO\,[(CH_3)_2SiO]_2H + 6Na_2S + 3H_2O\ .$$

the same compound has been obtained by the decomposition of an ethereal solution of sodium dimethylsilanediolate

with acetic acid[160,161] or with carbon dioxide[162] and also by keeping a solution of $(CH_3)_2Si(OH)_2$ in 0.001 N aqueous acetic acid[163].

Oligosiloxane-$\alpha\omega$-diols are formed in the hydrolysis of the corresponding hydrosilanes and hydrosiloxanes in the presence of silver, Ag_2O, CuO,[164] and ruthenium on charcoal[165] or when oxygen is passed through a mixture containing a hydrosiloxane, an amine, and a copper(I) salt[166]:

$$H(R_2SiO)_nSiR_2H + H_2O \xrightarrow{Ag,Ag_2O,Ru/C} HO(R_2SiO)_nSiR_2OH + H_2\ (n=0,1\ \text{etc.}),$$

$$H(R_2SiO)_nSiR_2H + O_2 \xrightarrow[CuX]{R_3N} HO(R_2SiO)_nSiR_2OH.$$

3. Hydrolysis of Terminal Functional Groups

The easiest method of synthesising pure oligosiloxane-$\alpha\omega$-diols with two organic substituents is based on the hydrolysis of the terminal functional groups in the corresponding $\alpha\omega$-disubstituted oligosiloxanes with two organic substituents:

$$X(R_2SiO)_{n-1}SiR_2X + 2H_2O \rightarrow HO(R_2SiO)_nH + 2HX\ (X=Cl, OR, OCOR\ \text{etc.}).$$

The disadvantages of the method are the necessity for a preliminary synthesis of the initial oligosiloxane and the possibility (under unfavourable reaction conditions) of side processes involving condensation (primarily cyclisation), cleavage, and rearrangement of the siloxane bonds. The effect of the conditions in the hydrolysis of $\alpha\omega$-dichloro-oligodimethylsiloxanes on the composition of the hydrolysis products has been investigated in fair detail[6,167]. Oligodimethylsiloxane-$\alpha\omega$-diols $HO[(CH_3)_2SiO]_nH$ have been obtained in high yields [$n = 2$ (88%), $n = 3$ (74%), $n = 4$ (76%), and $n = 5$ (55%)] by adding rapidly an approximately 10% etheral solution of the corresponding $\alpha\omega$-dichloro-oligodimethylsiloxane to a 5% solution of sodium hydroxide.

As in the case of dichlorodimethylsilane, hydrolysis in an acid medium leads to a mixture of linear (50%) and cyclic (50%) siloxanes. The only exception is 1,5-dichlorohexamethyltrisiloxane which yields 12% of cyclosiloxanes. By hydrolysing the corresponding $\alpha\omega$-dichloro-oligosiloxanes containing two organic substituents with a 5% solution of alkali in ether, oligodimethylsiloxane-$\alpha\omega$-diols, containing between two and nine silicon atoms in the molecule[168], oligomethylphenylsiloxane-$\alpha\omega$-diols with $n = 2-4$ [169], and also pentaethyltripropyl-, tetraethyltetrapropyl, and tetrabutyltetraethyl-tetrasiloxane-1,7-diols were obtained in yields up to 88%.[38]

When $NaHCO_3$, Na_2CO_3, and NH_4OH were used as neutralising agents, oligodimethylsiloxane-$\alpha\omega$-diols with $n = 9$ (70.9%), $n = 13$ (88.9%), and $n = 53$ (66.5%),[170] siloxanediols containing fluorinated groups at the silicon atoms $HO[CH_3(RCH_2CH_2)SiO]_nH$ (R = perfluoroalkyl containing between one and three carbon atoms; $n = 2$, 3, or 4) [171], and also the siloxanediols $RR'Si[OSi(R''R''')OH]_2$ [$R = R' = CH_3$, $R'' = R''' = C_6H_5$; R = cyclo-C_6H_{11}, $R' = CH_3$, $R'' = CH_2C \equiv CCH_3$, $R''' = CH_3$; $R'' = R''' = CH_3$, $R = C_6H_5$, $R' = CH_3$; $R'' = R''' = CH_3$, $R = C_6H_5$, $R' = CH{=}CH_2$; $R'' = R''' = CH_3$, $R = C_2H_5$, $R' = CH_3$; $R'' = R''' = CH_3$, $R = CH_2CH(CH_3)C_6H_5$, $R' = CH_3$; $R'' = R''' = CH_3$, $R = CH_2CH_2CF_3$, $R' = CH_3$; $R'' = R''' = CH_3$, $R = C_{18}H_{37}$, $R' = CH_3$; $R'' = R''' = CH_3$, R = chlorocyclohexyl, $R' = CH_3$] [53], and oligomers in which the main chain is bounded by trimethylsiloxy-groups were obtained[58,59]:

$$HO[(CH_3)_3SiO]_2SiO\{Si[OSi(CH_3)]_2O\}_nSi[OSi(CH_3)_2]_2OH$$

and

$$HO(R)CH_3SiO\{Si[OSi(CH_3)_3]_2O\}_nSiCH_3(R)OH\ (R=CH_3, C_6H_5;\ n=1, 2, 3, \text{etc.})$$

1-Methyl-1,3,3-triphenyldisiloxane-1,3-diol may be obtained by the hydrolysis of 1,3-dichloro-1-methyl-1,3,3-triphenyldisiloxane in the presence of aniline[16]. Hydrolysis of an ethereal solution of 1,3-dichlorotetraphenyldisiloxane and 1,5-dichlorohexaphenyltrisiloxane in an aqueous dioxan medium (molar ratio dichlorosiloxane: water = 2.1 or 1.5 : 1) yields tetraphenyldisiloxane-1,3-diol (92%) and hexaphenyltrisiloxane-1,5-diol (64%) [19].

Two stereoisomers [meso- and (±)-forms] of 1,3-dimethyl-1,3-diphenyldisiloxane-1,3-diol were obtained by the hydrolysis of a diastereoisomeric mixture of 1,3-dichloro-1,3-dimethyl-1,3-diphenyldisiloxane with 10% aqueous ammonia in ether[15].

Oligosiloxane-$\alpha\omega$-diols with two organic substituents can also be obtained by the hydrolysis of the corresponding $\alpha\omega$-dialkoxyoligosiloxanes with two organic substituents per unit. However, their hydrolysis is much slower than that of the corresponding $\alpha\omega$-dichloro-oligosiloxanes with two organic substituents per unit and in many cases requires the use of acid and basic catalysts. For example, tetraphenyldisiloxane-1,3-diol is formed on hydrolysis of ethoxytetraphenyldisiloxane with 8% hydrochloric acid in toluene or pentyl alcohol[105]. However, oligodimethylsiloxane-$\alpha\omega$-diols with $n = 1-5$ has been obtained by the hydrolysis of $\alpha\omega$-diethoxyoligodimethylsiloxanes in a neutral medium[172].

$\alpha\omega$-Diacetoxyoligosiloxanes with two organic substituents per unit can be used to synthesise siloxanediols[173,174]. They are more reactive than alkoxyoligosiloxanes and form on hydrolysis acetic acid, which does not exhibit a powerful condensing activity like that of hydrogen chloride liberated on hydrolysis of $\alpha\omega$-dichloro-oligosiloxanes. While the hydrolysis of the latter must be carried out under very mild conditions (tenfold dilution of the oligomers with the solvent and the use of a hydrogen chloride acceptor), $\alpha\omega$-diacetoxysiloxanes can be hydrolysed in the absence of solvents and in the absence of an acetic acid acceptor. However, in some cases hydrolysis in the presence of $CaCO_3$ proceeds more smoothly. $HO[(CH_3)_2SiO]_nH$ with $n = 2-5$ (yield 60–90%) and $HO[CH_3(CF_3CH_2CH_2)SiO]_nH$ with $n = 2-4$ (yield 60–80%) have been obtained.

In the hydrolysis of $\alpha\omega$-diacetoxydimethyloligosiloxanes in the presence of CH_3COOH acceptors ($CaCO_3$, NH_4HCO_3, NH_4OH) the highest yields are achieved when $CaCO_3$ is employed. With increase of the basicity of the CH_3COOH acceptor, the cyclosiloxanes D_3 and D_4 appear in the hydrolysis products.

In contrast to $\alpha\omega$-diacetoxydimethylsiloxanes, $\alpha\omega$-diacetoxyoligo-(3,3,3-trifluoropropyl)methylsiloxanes are converted more smoothly into the corresponding siloxanediols when stronger bases, for example sodium hydroxide, are employed as CH_3COOH acceptors. This is evidently associated with the steric effect of the 3,3,3-trifluoropropyl groups, which prevent the condensation of the siloxanediol formed and at the same time hinder the hydrolysis of the acetoxy-groups.

The hydrolysis of $C_6H_5RSi[OSiR'R''(OAc)]_2$ ($R = C_6H_5$, $R' = R'' = CH_3$; $R = CH_3$, $R' = R'' = C_6H_5$; $R = C_6H_5$, $R' = C_6H_5$, $R'' = CH_3$) in ethereal solution in the presence of sodium carbonate has been described[53].

4. The Anhydrocondensation Reaction

Oligosiloxane-$\alpha\omega$-diols with two organic substituents per unit are formed in the anhydrocondensation of silanediols with two organic substituents[175,176]: $n R_2Si(OH)_2 \rightarrow HO(R_2SiO)_nH + (n-1)H_2O$, or in the anhydrocondensation of lower oligodialkylsiloxane-$\alpha\omega$-diols:

$$HO(R_2SiO)_nH + HO(R'_2SiO)_nH \rightarrow HO(R_2SiO)_n(R'_2SiO)H + H_2O.$$

For example, in the thermal condensation of diphenylsilanediol, hexaphenyltrisiloxane-1,5-diol was isolated[175]. On heating to 200°C, hexamethyltrisiloxane-3,3-diol is converted into the corresponding di- and tri-siloxane-$\alpha\omega$-diols in which the silicon atoms in the main chain are linked to trimethylsiloxy-groups[176]:

$$[(CH_3)_3SiO]_2Si(OH)_2 \rightarrow HO\{[(CH_3)_2SiO]_2SiO\}_nH \ (n=2 \text{ or } 3)$$

VII. PREPARATION OF DISODIUM SALTS OF OLIGOSILOXANE-$\alpha\omega$-DIOLS

Disodium (or dipotassium salts) of oligosiloxane-$\alpha\omega$-diols with two organic substituents per unit are readily obtained by the cleavage of siloxanes containing two organic substituents with sodium (or potassium) hydroxide: $(R_2SiO)_n + 2MOH \rightarrow MO(R_2SiO)_nM + H_2O$ (M = Na or K). They are usually formed in as hydrates containing between two and five water molecules, which can be removed by heating in a vacuum.

As early as 1914,[161] salts containing as many silicon atoms in the molecule as the initial cyclosiloxane were obtained by the cleavage of hexaphenylcyclotrisiloxane and octaphenylcyclotetrasiloxane with 3% solutions of sodium hydroxide or potassium hydroxide. When the product of the hydrolysis of dichlorodimethylsilane was cleaved with approximately 50% aqueous sodium hydroxide, disodium salts of tetramethyldisiloxane-1,3-diol and octamethyltetrasiloxane-1,7-diol were obtained[177]. Such reactions are usually carried out in the presence of alcohol. Thus, by cleaving the corresponding cyclosiloxanes with sodium hydroxide in methanol, the salts $NaO[(CH_3)_2SiO]_2Na.5H_2O$, $NaO[CH_3(C_6H_5)SiO]_3Na.4H_2O$,[178] and also the anhydrous salts $NaO[(CH_3)_2SiO]_2Na$, $NaO[CH_3(C_6H_5)SiO]_2Na$,[179] $NaO[CH_3(C_6H_5)SiO]_nNa$ (n = 1, 2, or 3),[180] and $NaO[CH_3(C_6H_5)SiO]_nNa$ (n = 4, 8, 12, etc.)[181] were obtained. The highest yield of the salts of oligomethylphenyl- and oligoethylphenyl-siloxane-$\alpha\omega$-diols was attained by cleaving the corresponding cyclosiloxanes with a solution of sodium hydroxide in 50% aqueous ethanol[182]. The alkali metal hydroxide may be replaced by the metal oxide[182].

The cleavage of cyclosiloxanes with sodium hydroxide is reversible[179]: $(R_2SiO)_3 + NaOH \rightleftharpoons HO(R_2SiO)_3Na \rightleftharpoons NaO(R_2SiO)_3Na + H_2O$; $2HO(R_2SiO)_3Na \rightarrow NaO(R_2SiO)_6Na + H_2O$. Therefore the reaction mixture contains salts with different chain lengths, which, however, largely correspond to the amount of alkali taken and the ring size. Regardless of the proportions of the initial reactants in the alkaline cleavage of cyclosiloxanes one of the products is always the sodium salt of tetramethyldisiloxane-1,3-diol, the yield of which falls as the molar ratio NaOH : cyclosiloxane decreases[183].

Disodium salts of siloxane-$\alpha\omega$-diols with longer chain lengths can be obtained by reducing the amount of sodium hydroxide used to cleave the cyclosiloxane, which leads to the parallel occurrence of the anhydrocondensation process

$$2(R_2SiO)_n + NaOH \rightarrow 2NaO(R_2SiO)_nH \xrightarrow{-H_2O} NaO(R_2SiO)_{2n}Na$$

or the cross-linking of the low-molecular-weight oligomers by dichlorodimethylsilane[184]: $(CH_3)_2SiCl_2 + 2NaO(R_2SiO)_nNa \rightarrow (CH_3)_2Si[O(R_2SiO)_nNa]_2 + 2NaCl$. Salts containing various substituents at the silicon atoms may be obtained by the last method.

Owing to their acid properties, due to the $p_\pi - d_\pi$ interaction between the p electrons of oxygen and the $3d$ orbitals of silicon, siloxanediols can react with alkali metals, forming the corresponding salts: $HO(SiR_2O)_nH + 2M \rightarrow MO(SiR_2O)_nM + H_2$. By allowing tetra-alkyldisiloxane-1,3-diols to react with metallic sodium in xylene[153] or in liquid ammonia[185], the corresponding salts of the diols were synthesised.

The reaction with lithium proceeds similarly[186]. Magnesium and aluminium also react readily with siloxanediols, forming polyalkylmetallosiloxanes[153,187].

The Schmidt Reaction with Ketones

G.I.Koldobskii, G.F.Tereshchenko, E.S.Gerasimova, and L.I.Bagal

The Schmidt reaction with ketones is reviewed. Particular attention has been devoted to the mechanism and kinetics of the interaction of ketones with hydrazoic acid. The side reactions accompanying the main process and the applications of the Schmidt reaction have been indicated.
The bibliography includes 105 references.

CONTENTS

I. Introduction 835

III. Concomitant reactions 843
IV. Applications of the Schmidt reaction 844

I. INTRODUCTION

The Schmidt reaction with ketones belongs to a large group of reactions known as sextet rearrangements. A characteristic feature of these reactions is the formation of an intermediate compound with a sextet of electrons at the nitrogen atom. The reaction is interesting because of its synthetic possibilities. The problems associated with its mechanism include the behaviour of weak bases in strongly acidic media, the characteristics of the reactivity of carbonyl compounds, the capacity of substituents to migrate, and some others. The Schmidt reaction is also a convenient model for the investigation of acid-catalysed processes.

The method is suitable for the preparation of substituted amides, tetrazoles, and ureas which are not otherwise available; some of these compounds exhibit high biological activity and have practical applications[1,2].

Numerous studies have been made on the Schmidt reaction and these have been reviewed by Wolff[3] and Smith[4] who describe the experimental data obtained up to the end of 1962. This review takes into account certain studies which were published later, particularly the recent kinetic investigations, and in this connection the mechanism of the reaction is considered in greater detail.

II. MECHANISM OF THE SCHMIDT REACTION WITH KETONES

1. Overall Characteristics of the Reaction and Its Mechanism according to Smith[4]

The rearrangement of carbonyl compounds under the influence of hydrazoic acid in the presence of acid catalysts was discovered by Schmidt in 1923.[5] It was found that carboxylic acids are converted into amines, ketones into amides, and aldehydes into nitriles and formamides:

$$RCOOH + HN_3 \xrightarrow{H^+} R\,NH_2 + CO_2 + N_2\,, \quad (1)$$

$$RCOR' + HN_3 \xrightarrow{H^+} RNHOCR' + RCONHR' + N_2\,, \quad (2)$$

$$RCHO + HN_3 \xrightarrow{H^+} RCN + RNHOCH + N_2\,. \quad (3)$$

In the presence of an excess of hydrazoic acid, tetrazoles, aminotetrazoles, and ureas are formed from ketones:

$$RCOR + 2HN_3 \rightarrow R{-}N{=}\underset{\underset{N}{\|}}{C}{-}R\,, \quad (4)$$

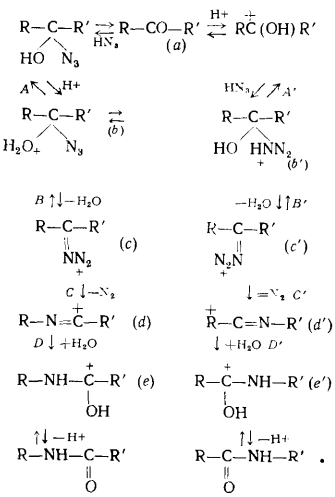
$$RCOR + 3HN_3 \rightarrow R{-}NH{-}\underset{\underset{N}{\|}}{C}{-}N{-}R\,, \quad (5)$$

$$RCOR + 2HN_3 \rightarrow RNHOCNHR\,. \quad (6)$$

Schmidt postulated that the reaction involves the cleavage of hydrazoic acid into an imino-radical [NH] and nitrogen. The imino-radical forms with the carbonyl compound an adduct, which isomerises directly to the reaction products or is converted into an oxime with subsequent Beckmann rearrangement[6]:

$$RCOR + [NH] \rightarrow \left[\begin{array}{c} N \\ | \\ R{-}C{-}R \\ | \\ OH \end{array}\right] \text{ or } \left[\begin{array}{c} R{-}C{-}R \\ \| \\ NOH \end{array}\right] \rightarrow RCONHR\,. \quad (7)$$

However, in later studies by other investigators it was shown that this hypothesis is erroneous. Modern hypotheses concerning the mechanism of the Schmidt reaction have been put forward by Oliveri–Mandala[7], Hurd[8], Sanford et al.[9], and Newman and Gildenhorn[10]. The results of these studies and his own investigations have been reviewed by Smith[11]. Taking into account certain modifications introduced in subsequent years by Smith[4], the mechanism of the Schmidt reaction in ketones can be represented as follows:



(8)

Regardless of the pathway (*A* or *A'*) followed by the rearrangement, the first reaction stage is always the interaction of the carbonyl compound (in a free or protonated form) with hydrazoic acid, which leads to the azidohydrin (*b*). Subsequent dehydration leads to the iminodiazonium ion (*c*).

As a result of the sp^2 hybridisation of the central carbon atom, the iminodiazonium ion can assume two conformations—*syn*- and *anti*-(*c* and *c'*). The assumption of the existence of two conformers of the iminodiazonium ion accounts for the formation of two isomeric amides from asymmetric ketones. The loss of nitrogen by the iminodiazonium ion is accompanied by the migration of the substituent (R or R') in the *anti*-position in relation to the diazo-group. The iminocarbonium ion (*d*) arising under these conditions interacts with water or with any other nucleophilic agent, forming the reaction products.

The mechanism [Eqns. (8)] proposed above explains satisfactorily the principal features of the reactions of ketones with hydrazoic acid although cases are known which do not fit these concepts. A detailed examination of the reaction mechanism is best made by examining the individual stages of the process, beginning with the state of the reactants in the reaction medium.

2. Behaviour of Ketones and Hydrazoic Acid in Strong Acid Solutions

The commonest catalyst of the Schmidt reaction with ketones is sulphuric acid. In most cases sulphuric acid is employed in a 10–20-fold excess in relation to the carbonyl compound and serves also as the reaction medium. In this connection it is desirable to examine the behaviour of ketones and hydrazoic acid in aqueous sulphuric acid solutions.

Ketones are typical weak organic bases which are protonated in strong acid solutions at the oxygen of the carbonyl group[9]:

$$RCOR' + H^+ \rightleftarrows [RCOHR']^+ . \qquad (9)$$

The first quantitative studies on the protonation of ketones were performed by Hammett[12]. Stewart and Yates[13] determined spectrophotometrically the pK_a for a large series of substituted acetophenones and showed that the compounds investigated belong to the series of Hammett bases. However, in a later study[14] it was found that the protonation of acetophenone and certain other conjugated ketones can be satisfactorily described by the amide acidity function H_A. Benzophenones have an individual H_B acidity scale[15]. Reinvestigation of the basicity of the series of aromatic compounds recently showed that the protonation of acetophenone and benzophenone is more satisfactorily described by the H_0 Hammett function than by H_A.[16] It is believed[17] that these discrepancies are associated with the inadequate interpretation of the experimental data by different investigators. The reason for this is the insufficient rigour of the postulates adopted in the development of methods for the calculation of the ionisation ratio of the bases.

The protonation of aliphatic ketones has been less well studied. It has been found that the ionisation constants of their conjugate acids are mainly in the range $pK_a = -6 - 8$.[18,19] The introduction of electronegative substituents into the ketone molecule greatly reduces the basicity of such compounds[20,21]. It has been shown[20,22] that the protonation of acetone, 2-butanone, 2-hexanone, and many nitroketones is satisfactorily described by the Hammett equation.

The interpretation of the protonation of ketones in terms of mechanism (9) is undoubtedly a simplification and does not reflect all the essential features of the process. Hauldna and coworkers[23–25] believe that the following equilibria are characteristic of certain ketones in solutions of strong inorganic acids:

$$S \cdot sH_2O + H^+ xH_2O \rightleftarrows S\cdots H^+ \cdot nH_2O + (s + x - n)\,H_2O ,$$
$$S\cdots H^+ nH_2O \rightleftarrows SH^+ + nH_2O , \qquad (10)$$

where S is the base (ketone). Consequently the results obtained in the study of the protonation of aliphatic ketones refer to equilibrium (10) and not (9).

In many cases there are data confirming these hypotheses. At the same time the results of the study of the activity coefficients of 2-butanone in sulphuric acid obtained by the same investigators[26] are inconsistent with this approach.

Eqn. (9) altogether fails to take into account the effect of the solvent. There is reason to believe[27] that both forms of ketones (S and SH^+) are hydrated and the protonation process may be represented as follows:

$$S \cdot bH_2O + H^+ xH_2O \rightleftarrows SH^+ \cdot mH_2O + (b + x - m)\,H_2O . \qquad (11)$$

Evidently, the final solution of this problem requires combined studies on the protonation of ketones and the kinetics of their acid-catalysed reactions.

Hydrazoic acid is a weak inorganic acid which is protonated in strongly protogenic systems:

$$HN_3 + H^+ \rightleftarrows [H_2N_3]^+ , \qquad (12)$$

$$[H_2N_3]^+ + H^+ \rightleftarrows [H_3N_3]^{2+} . \qquad (13)$$

The basicity of hydrazoic acid has been investigated by partition in sulphuric acid[28] and it has been found that the partition coefficient and hence the activity coefficient of the non-protonated form of hydrazoic acid remain constant as the concentration of sulphuric acid is varied from 25 to 40%. A sharp change in the partition coefficient was observed only in approximately 80% sulphuric acid, which is believed[28] to be due to the protonation of hydrazoic acid. The ionisation constant of $[H_2N_3]^+$ was calculated with the aid of the Hammett equation and proved to be $pK_A = -6.9$†. The anomalous variation of the partition coefficient in sulphuric acid at higher concentrations (>95%) made it impossible to characterise the second protonation process of hydrazoic acid in terms of Eqn. (13). An approximate value $pK_A = -10.9$† was adopted[30] for $[H_3N_3]^{2+}$.

It should be noted that evidence for the applicability of the function H_0 in this case is at present unavailable. Therefore the equilibrium constants obtained may not be the thermodynamic values. Here it would be useful to investigate the kinetics of the acid-catalysed reactions involving hydrazoic acid, for example the Schmidt reaction.

Sometimes hydrochloric, polyphosphoric, trichloroacetic, and trifluoroacetic acids are employed as catalysts of the Schmidt reaction. The reactions of ketones and hydrazoic acid in such media are analogous to those in sulphuric acid. However, here solvation effects play a greater role: in media of low acidity there is a possibility of the formation of a hydrogen-bonded complex of the carbonyl compound with the medium.

When the Schmidt reaction is catalysed by Lewis acids, the reaction species is probably the complex formed by the interaction of the ketone with the aprotic acid[24].

---

† The values of H_0 are based on Vinnik's data[29].

The Schmidt reaction is sometimes carried out in the presence of inert solvents (chloroform, benzene) immiscible with sulphuric acid. Under these conditions, the interaction evidently takes place in an acid layer or at the interface between two phases. These features may have a definite influence on the mode of reaction.

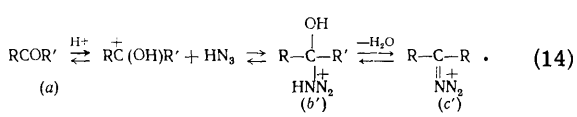
Thus one may suppose that the reactive species in the Schmidt rearrangement is the protonated form of the ketone or its complex with the acid. However, it would be incorrect to rule out completely the involvement in the reaction of the non-protonated form of the carbonyl compound, particularly for ketones with a high reactivity.

3. Addition of Hydrazoic Acid to the Carbonyl Group

The principal characteristics of the addition of nucleophilic reagents to the carbonyl group in the case of acid catalysis have been examined in reviews[31,32]. The available literature data on the Schmidt reaction suggest that these characteristics refer also to the addition of hydrazoic acid to ketones.

As shown above, when ketones are dissolved in aqueous sulphuric acid solutions with a sufficiently high acidity, they are protonated. This leads to an appreciable increase of the polarity of the carbonyl group and promotes the addition of a nucleophilic agent such as hydrazoic acid. In solutions where the carbonyl compound is not protonated, the Schmidt reaction takes place with difficulty.

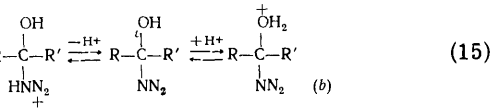
However, in media with a high acidity ($H_0 > -9$) the rearrangement is retarded owing to a decrease of the concentration of the non-protonated form of hydrazoic acid. The interaction of hydrazoic acid with a ketone leads to the iminodiazonium ion (*c'*). The azidohydrin (*b'*) is then formed as an intermediate:



(14)

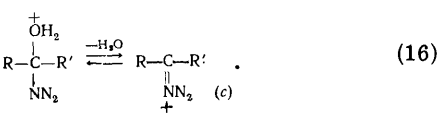
An azidohydrin of type (*b'*) was obtained and identified in the reaction of perfluorocyclobutanone with hydrazoic acid[33].

An azidohydrin with a higher energy content than the initial compound tends to regenerate the double bond. There is then a possibility both of the formation of the initial compounds and of stabilisation as a result of dehydration. Dehydration is promoted by the protolytic equilibrium



(15)

and the consequent formation of the stable iminodiazonium ion (*c*):



(16)

Compared with the hydroxycarbonium ion, the ion *c* has a lower energy content, which promotes a shift of equilibrium (14) to the right. However, dehydration can also take place by a bimolecular mechanism. In this case water or the hydrogen sulphate ion can play the role of the base.

The ease of addition of hydrazoic acid to ketones should depend on the electronic and steric properties of the substituents. Usually substituents with a $+I$- or $+M$-effect lead to an increase of the basicity of the ketone, but lowers its reactivity in relation to the nucleophilic agent. Conversely, substituents with a $-I$- or $-M$-effect reduce the basicity of the ketone, enhancing at the same time its reactivity.

The effect of substituents on the addition of hydrazoic acid to ketones and subsequent dehydration is more complex. Substituents with a $+I$- or $+M$-effect hinder the addition of the acid but facilitate the dehydration of the azidohydrin; substituents with a $-I$- or $-M$-effect have the opposite influence.

The experimental data for the reaction of ketones with hydrazoic acid are in general consistent with the above relations. It is known that aliphatic ketones are more reactive in the Schmidt reaction than alkyl aryl ketones, which are in turn more reactive than diaryl ketones. Since the basicity of the corresponding ketones increases in approximately the same sequence, it has been suggested that the rate of reaction of ketones with hydrazoic acid is determined by their basicity[11]. However, the attempt to account for the observed behaviour only on the basis of differences in the basicity of the ketones must be regarded as insufficiently justified. For example, certain substituted benzophenones are known to be weaker bases than aliphatic ketones[34].

Steric factors play a major role in the reaction of ketones with hydrazoic acid. In this sense, the accessibility of the positively charged carbon atom of the protonated carbonyl group is important. Although there are no systematic quantitative data on the effect of the structure of the carbonyl compound on the rate of the Schmidt reaction, it is known that sterically hindred ketones, such as t-alkyl ketones and *ortho*-substituted benzophenones react more slowly than straight-chain dialkyl ketones and unsubstituted diphenyl ketones[4].

4. Stereochemistry of the Reaction

The iminodiazonium ion formed as a result of the dehydration of the azidohydrin is capable of isomerisation of the same type as that observed in oximes [see mechanism (8)]. The contents of the *syn*- and *anti*-isomers in the equilibrium mixture are determined by the reaction conditions and also by steric and electronic factors. The assumption of the existence of geometrically isomeric forms of the iminodiazonium ion is exceptionally important, since it explains the formation of isomeric amides from asymmetric ketones. The problem has been analysed by Smith and coworkers[35-37]. In 1950 Smith and Horwitz[35] observed that the same ketones give a mixture of amides with the same content of isomers both in the Schmidt reaction and in the Beckmann rearrangement[38]. This enabled them to postulate a similarity of the equilibrium proportions of the isomeric oximes and the stereoisomeric forms of the iminodiazonium ion.

It has been shown for alkyl phenyl ketones and benzophenones[35] that the proportions of the amides formed are greatly influenced not by the electronic but by the steric properties of substituents. Thus in the reaction of alkyl phenyl ketones with hydrazoic acid

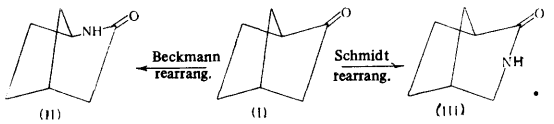
(17)

where R = CH_3, C_2H_5, or $CH(CH_3)_2$, the ratio of the

isomeric forms A/B is 95/5, 85/15, and 50/50 respectively. At the same time isomeric amides in proportions close to 1 : 1 are always formed from the benzophenones p-$RC_6H_4COC_6H_5$, where R = CH_3, C_2H_5, Cl, NO_2, or OCH_3, regardless of the nature of the substituent.

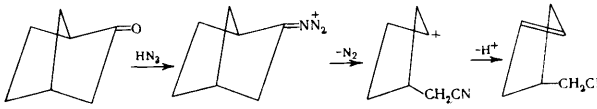
Thus the type of migration of the substituents in asymmetric ketones is in most cases satisfactorily described by an empirical rule according to which the most bulky substituent, occupying the *anti*-position in relation to the diazo-group in the iminodiazonium ion, migrates.

Similar relations hold also for many aliphatic and acyclic ketones. Thus Schechter and Kirk[39] showed for α-substituted cyclohexanones and cycloheptanones that in such ketones the reaction takes place preferentially on the substituted side of the ring. Similar observations have been made for bicyclic ketones[40] and for open-chain ketones[41]. However, in norcamphor and cyclopentanocamphor, migration from the unsubstituted side of the ring is observed[42]. At the same time the Beckmann rearrangement of the oximes of these ketones is accompanied by the formation of lactams with the "normal" structure:



(18)

It should also be noted that the yields of the corresponding amides in the Schmidt reaction are about 30%. Possibly the absence from the reaction products of the lactam (II) is associated with the formation of an unsaturated derivative of acetonitrile according to the mechanism

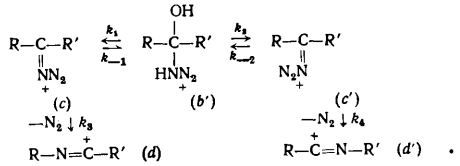


(19)

Remarkable relations have been observed for phenylalkyl ketones $C_6H_5(CH_2)_nCOCH_3$.[10,11] Acetophenone (n = 0) gives a C_6H_5/CH_3 migration ratio of 95/5, phenylacetone (n = 1) gives $C_6H_5CH_2/CH_3$ = 50/50, benzylacetone (n = 2) gives $C_6H_5(CH_2)_2/CH_3$ = 95/5, and 5-phenyl-2-pentanone gives $C_6H_5(CH_2)_3/CH_3$ = 80/20; this type of variation is probably continued with ketones having n = 4 and 5.

In most cases N-substituted acetamides are formed from alkyl methyl and aryl methyl ketones. Two cases are known where preferential migration of the methyl group was observed: N-methylcinnamide and N-methylcyclopropanecarboxamide are formed from benzylideneacetone[43] and cyclopropyl methyl ketone[44]. Extremely interesting results were obtained in a study of the isomeric ratio of the amides formed from *ortho*-substituted benzophenones[37,45] (Table 1). Contrary to expectation, it was found that these compounds do not obey the empirical rule of the preferential migration of the more bulky substituents. Similar deviations have been observed also for 2-substituted fluorononones[46].

According to the mechanism of reaction (8), two isomers of an iminodiazonium ion are formed from a protonated azidohydrin:



(20)

If the energy barrier to the $c \rightarrow d$ rearrangement is lower or comparable to that in the interconversion of the iminodiazonium ions c and c', the ratio of the resulting amides is mainly influenced by the $c \rightleftharpoons c'$ equilibrium. When the energy barrier to the rearrangement is higher, one must expect (according to the Curtin–Hammett principle[47]) that the ratio of the amides will be determined by the difference between the energy barriers to the $c \rightarrow d$ and $c' \rightarrow d'$ rearrangements.

This conclusion follows also from kinetic considerations[47,48]. If the rearrangement (k_3 and k_4) is faster than the interconversion of the isomers c and c', one can write

$$\begin{aligned} d(c)/dt &= k_1(b) - k_3(c)\,, \\ d(c')/dt &= k_2(b) - k_4(c')\,, \\ d(d)/dt &= k_3(c) = k_1(b) - d(c)/dt\,, \\ d(d')/dt &= k_4(c') = k_2(b) - d(c')/dt\,. \end{aligned} \qquad (21)$$

After integration of the last two equations and division of one by the other, we have

$$\frac{(d)}{(d')} = \frac{k_1\int(b)/dt - (c)}{k_2\int(b)/dt - (c')}\,. \qquad (22)$$

This ratio will be equal to k_1/k_2 and k_1k_3/k_2k_4 at $t = \infty$ and $t = 0$ respectively.

Table 1. Ratios of the isomeric amides from *ortho*-substituted benzophenones[45].

Substituent	$C_6H_5NHCOAr/ArNHCOC_6H_5$, %	Substituent	$C_6H_5NHCOAr/ArNHCOC_6H_5$, %
CH_3	78:22	Br	82:18
C_2H_5	78:22	CH_3	50:50
$(CH_3)_2CH$	82:18	NO_2	30:70
Cl	75:25	COOH	3:97

If the slow stage is the rearrangement, the ratio of the amides should be determined by the energy barriers to the $c \rightarrow d$ and $c' \rightarrow d'$ rearrangements and not the thermodynamic stabilities of compounds c and c'. Indeed, according to Eqn. (20) the equilibrium $c \rightleftharpoons c'$ is described by the product k_1k_2/k_2k_1 and the concentration ratio of d/d' is determined as $(k_1k_2/k_2k_1)k_3k_4$. Having denoted the first multiplier by K, we find that the concentration ratio $d/d' = Kk_3/k_4$.

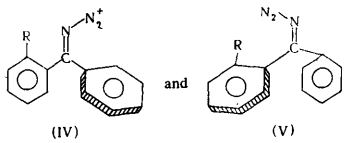
Thus the slower are the rearrangement stages with the constants k_3 and k_4 compared with the rates of interconversion of the iminodiazonium ions (k_1, k_2, k_{-1}, and k_{-2}), the most important will be the electronic factors influencing the tendency of the substituent to migrate. Under these conditions, the thermodynamic equilibrium between c and c' will be correspondingly less important.

However, the extreme cases described will hardly occur in a "pure" form. The ratio of the amides formed is more likely to be affected by all the factors enumerated. Only some of them will of course be decisive. Smith and Antoniades analysed these factors[37].

The difficulty of interpreting the available data consists in the fact that the relations applicable to one series of ketones need not necessarily obtain in another series. This last factor is evidently associated with a possible change in the rates of individual stages as a function of the nature of the ketone and with the competing effect of electronic and steric factors on the structure of the iminodiazonium ion.

As an example, one may refer to the "anomalous" behaviour of *ortho*-substituted benzophenones, in which preferential migration of the unsubstituted phenyl ring has

been observed. At the same time *ortho*-substituted acetophenones give rise to aryl migration products. Smith and Antoniades gave a convincing explanation of this phenomenon.[37] In benzophenones only one phenyl ring is conjugated with the carbonyl group, which leads to the breakdown of the coplanarity of the system. The iminodiazonium ion derived from such compounds can exist as two steric isomers (IV) and (V):



(23)

If the *ortho*-substituent promotes the conjugation of the substituted phenyl group to the carbonyl group, conformation (IV) predominates and preferential migration of the *ortho*-substituted phenyl ring is observed. When the substituent does not have an appreciable effect on the capacity of the phenyl group for conjugation, conformation (V) predominates and the migration of the unsubstituted phenyl ring is significant.

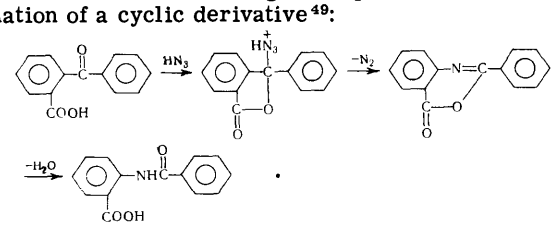
Table 2. Ratios of the isomeric amides (phenyl/substituted phenyl) from benzophenones as a function of the concentration of sulphuric acid[50].

Compound	H_2SO_4	
	88 wt.%	90 wt.%
para-Substituted benzophenones	1:1	1:1
m-Nitrobenzophenone	1:2.16	1:5.02
m-Chlorobenzophenone	1:1.12	1:3.06
m-Methylbenzophenone	0.98:1	7.00:1
p-Methyl-3,5-dinitrobenzophenone*	1.32:1*	0.27:1*

*p-Tolyl/3,5-dinitrophenyl.

The effect of electronic and steric factors on the conjugation of the substituted phenyl group is clearly shown in ketones such as *o*-ethyl- and *o*-methoxy-benzophenones. The ethyl and methoxy-groups are sterically almost equivalent, but the methoxy-group is more effectively conjugated with the phenyl ring. This difference has a marked effect on the migration ratio. The corresponding anilide is mainly formed from *o*-ethylbenzophenone, while *o*-methoxyphenone gives a 1 : 1 mixture of amides[45].

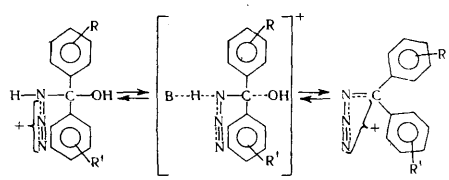
The behaviour of *o*-carboxy-, *o*-nitro-, and *o*-phenylbenzophenones, which exhibit a preferential migration of the substituted aryl group, becomes understandable if it is assumed that the rearrangement proceeds via the formation of a cyclic derivative[49]:



(24)

In many cases the isomeric composition of the mixture of amides formed from asymmetric ketones is influenced significantly by the reaction conditions (temperature and nature of the medium). It has been established that an increase of reaction temperature leads to a change of the ratio of isomeric amides towards an increase of the fraction of the isomer obtained in a smaller amount at a lower temperature[37,39].

Interesting results were obtained by Brackenridge[50] in a study of the effect of the concentration of sulphuric acid on the ratio of isomeric amides in the case of substituted benzophenones and aryl pyridyl ketones (Table 2). The results in Table 2 show that, on increase of the concentration of sulphuric acid from 88 to 99%, there is a sharp change in the migration ratio. Such considerable changes are evidently associated with an increase of the polarity of the medium on passing to more concentrated acid. This assumption may be made on the basis of the following considerations. The dehydration of the azidohydrin *b* proceeds via the transition state in scheme (25):



(25)

where B = H_2O or HSO_4^-. The degree of polarity of the transition state depends on the nature of the substituent and the position of the substituted phenyl ring in relation to the diazo-group. The transition state will be more polar when the *meta*-substituted phenyl ring (with an electronegative substituent) is in the *anti*-position with respect to the diazo-group. The transition state will be less polar when the *meta*-substituted phenyl ring (with an electron-donating substituent) is in the *syn*-position. The rate of dehydration of the azidohydrin depends more on the polarity of the solvent the greater the polarity of the transition state. Consequently, with increase of the polarity of the medium (increase of the concentration of sulphuric acid), the reaction will proceed via a polar transition state. As a result, there is a considerable change in the ratio of the isomeric amides.

Para-substituted benzophenones are almost insensitive to the effect of the medium, since substituents in the *para*-position do not have such a significant influence on the polarity of the transition state. An analogous change in the ratio of isomeric amides was observed by Tomita et al.[51] for 1-indanones and 1-tetralones when sulphuric acid was replaced by trichloroacetic acid.

In general, the problems of the stereochemistry of the Schmidt reaction are fairly complex. The earlier hypothesis of the similarity of the ratio of isomeric amides in the Schmidt reaction and in the Beckmann rearrangement proved to be very approximate when more extensive studies were made. In many cases, particularly for ketones with a complex structure[52,53], it is impossible to predict the mode of reaction. Each year an increasing amount of data accumulates, indicating the breakdown of the rules elaborated previously and further studies are therefore necessary for the solution of this problem.

5. Reaction Kinetics

The kinetics of the Schmidt reaction of ketones have been inadequately investigated. The reason for this is evidently the considerable difficulties of a quantitative study of such complex processes. A systematic investigation of the kinetics of the Schmidt reaction was only undertaken in recent years.

When the rate of reaction of certain ketones with hydrazoic acid was measured in hydrochloric and sulphuric acids, it was shown that the reaction has an overall second order and is of first order with respect to each component[54]. The expression for the rate of the process includes the acidity of the medium: $d(N_2)/dt = kh_0[HN_3]$ [ketone]. Thus the early observations of the dependence of the rate of reaction on the concentration of the acid (catalyst) were confirmed.

It has also been established that the more basic ketones react at a higher rate. On this basis, attempts were made to relate the activity of ketones to their basicity. Fichel et al.[55] studied the kinetics of the reactions of various acetophenones with hydrazoic acid in aqueous sulphuric acid. The data for *meta*- and *para*-substituted acetophenones are inconsistent with the expectations based on the migration capacities of the substituents. Certain *ortho*-substituents (OH, CH_3, OCH_3) retard the reaction, while others (NO_2, Cl) accelerate it.

The changes in the entropies and enthalpies of activation indicate the existence of an isokinetic relation. To some extent these results are consistent with Howell's data[54], but they do not reveal the principal characteristics of the reaction.

The kinetics of the Schmidt reaction involving certain aromatic ketones were studied by Mirek[56,57]. The observed rate of reaction decreases for ketones with electron-donating substituents, which is in general consistent with the effect of these substituents on the position of the carbonyl group band in the infrared spectra. On this basis, the author suggested that the slow reaction stage is the addition of hydrazoic acid to the hydroxycarbonium ion. However, since the reactions investigated are heterogeneous, the results obtained should be treated with caution because the process may be influenced by additional factors.

Quite different data have been reported by Bak[58]. The rate constant for the reaction of phenanthrenequinone with hydrazoic acid decreases appreciably when the concentration of sulphuric acid increases, which is inconsistent with earlier observations. In order to resolve these contradictions, the author suggested that the reaction may involve not only free hydrazoic acid but also its protonated form ($H_2N_3^+$). He made similar assumptions also in a study of the Schmidt reaction with benzoic acid[59].

All the investigations quoted are fragmentary and unsystematic. These and other causes have hitherto precluded an appreciable advance in the understanding in the mechanism of the Schmidt reaction. Certain problems of the formal kinetics of the reaction with ketones can be conveniently examined in the simplest case where only one of the isomeric amides is formed. Here the kinetics of the process based on the suggested reaction mechanism (8) can be represented as follows:

$$A + B^+ \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} C^+ \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} D^+ \xrightarrow{k_3, -N_2} E^+, \qquad (26)$$

(a) (b) (c)

where A is non-protonated hydrazoic acid, B^+ the protonated ketone, C^+ the protonated azidohydrin (I), D^+ the iminodiazonium ion (II), and E^+ the iminocarbonium ion (III).

One of the stages—the rearrangement of the iminodiazonium ion (stage *c*) accompanied by the liberation of N_2—is undoubtedly irreversible. Under these conditions, the occurrence of the rearrangement via a many-centre mechanism or via an intermediate nitrene is kinetically equivalent. In principle, stages (*a*) and (*b*) may be reversible.

It has been shown[60] that the rates of consumption of HN_3 and of liberation of nitrogen in the reaction of 2-hexanone with hydrazoic acid in aqueous sulphuric acid solutions are equal. This implies that the concentrations of the intermediates (I) and (II) are fairly low and may be neglected. The changes in the concentrations of (I) and (II) during the reaction can also be disregarded and therefore in the treatment below the principle of the steady-state has been employed.

If the rate of the process is limited by stage (*c*), the overall rate is

$$\frac{dN_2}{dt} = -\frac{d[A]_{st}}{dt} = k_3 K_2 K_1 [A][B^+]. \qquad (27)$$

On the other hand, if stages (*b*) and (*a*) are rate-limiting, the rate is expressed by Eqn. (28) and (29) respectively:

$$\frac{dN_2}{dt} = -\frac{d[A]_{st}}{dt} = k_2 K_1 [A][B^+], \qquad (28)$$

$$\frac{dN_2}{dt} = -\frac{d[A]_{st}}{dt} = k_1 [A][B^+], \qquad (29)$$

where $[A]_{st}$ is the stoichiometric concentration of HN_3. The variation of the concentration of the protonated ketone and non-protonated hydrazoic acid with their basicity constants and with the acidity of the medium has been omitted. The experimentally observed overall second order of the reaction and the first order with respect to each component are formally consistent with the hypothesis that the slower stage may be any one of the following three: (*a*), (*b*), and (*c*).

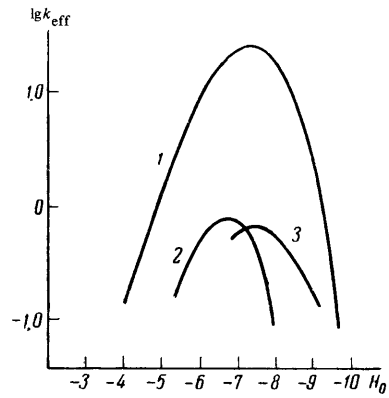


Figure 1. Variation of the logarithm of the observed (effective) rate constant for the Schmidt reaction ($\lg k_{eff}$) in sulphuric acid solutions with acidity: 1) for 2-hexanone; 2) for acetophenone; 3) for *m*-nitroacetophenone[61,62].

Certain characteristics of the mechanism of the reaction of ketones with hydrazoic acid were discovered in a study of the process over a wide range of acidities of the medium. Fig. 1 shows the observed variation of the effective rate constant for the reaction with the acidity function H_0 for 2-hexanone and for acetophenones with substituents in the phenyl ring[61,62]. With increase of the concentration of sulphuric acid, the rate of reaction rises to a maximum

and then falls. It should also be noted that the rate of the Schmidt reaction with carboxylic acids increases continuously with sulphuric acid concentration up to 96.6%,[63] which is evidence of differences in these processes.

Relations of this kind (Fig. 1) in nucleophilic addition to the carbonyl group can be accounted for either by an acid–base equilibrium of the initial reactants or by a change in the rate-limiting stage[31].

If the acid–base equilibrium of the ketone and hydrazoic acid (in the present case in sulphuric acid) is the decisive factor, the effective rate constant for the rate-limiting stage (addition) is[61,63]

$$k_{\text{eff}} = \frac{k' h_0}{K_1\left[1+\frac{h_0}{K_1}\right]\left[1+\frac{h_0}{K_2}+\frac{h_0 h_+}{K_2 K_3}\right]}, \qquad (30)$$

where k' is the true reaction rate constant, h_0 and h^+ are the acidity functions for the neutral bases and singly-charged cations respectively, and K_1, K_2, and K_3 are the basicity constants of the ketone, hydrazoic acid, and monoprotonated hydrazoic acid ($H_2N_3^+$) respectively.

Eqn. (30) is valid only when the ketone and hydrazoic acid behave as Hammett bases. Despite certain difficulties in the solution of this problem, to a first approximation one may postulate that 2-hexanone and acetophenones substituted in the phenyl ring[61,62] satisfy this requirement. The behaviour of hydrazoic acid as a Hammett indicator is assumed.

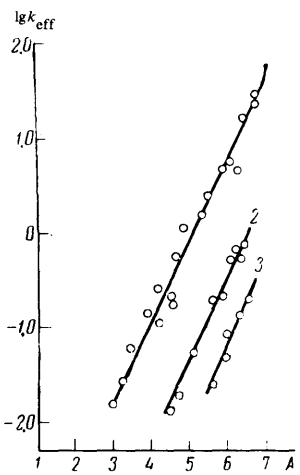

Figure 2. Correlation between $\lg k_{\text{eff}}$ and A in the Schmidt reaction: 1) for 2-hexanone; 2) for acetophenone; 3) for *m*-nitroacetophenone. $A = -H_0 - \lg(1 + h_0/K_1) - \lg(1 + h_0/K_2 + h_0 h_+/K_2 K_3)$, where H_0 is the Hammett acidity function, K_1, K_2, and K_3 are the basicity constants of the ketone, NH_3, and $H_2N_3^+$ respectively, and h_+ is the acidity for singly-charged bases.

Fig. 2 presents the observed correlations between A and k_{eff} determined by Eqn. (30).[61,62] A is the acidity function of the medium corrected for the acid–base equilibrium of the initial reactants.

The linearity of the correlations (Fig. 2) shows that, regardless of which reaction stage is rate-limiting, the reactants are first protonated in sulphuric acid and then the protonated ketone reacts with non-protonated hydrazoic acid.

The satisfactory correlation suggests that the reaction mechanism remains unchanged over a wide range of acidities of the medium. Moreover, one may postulate that the rate constant for the elementary stage does not vary, i.e. is independent of the acidity function.

The experimentally determined ranges of H_0 (Fig. 1) where the effective rate constant is a maximum agree satisfactorily with calculations by the equation

$$h_0^{\max} = \sqrt{K_1 K_2}, \qquad (31)$$

where K_1 and K_2 are the basicity constants of the ketone and hydrazoic acid respectively.

The higher absolute effective reaction rate constants for $h_0^{\max}$ correspond to the more basic ketones. This can be readily explained by the fact that for a more basic ketone, $h_0^{\max}$ is displaced towards lower acidities where the relative concentration of non-protonated hydrazoic acid is higher. The validity of the suggested mechanism (8) has been confirmed by the determination of the basicity of hydrazoic acid using a kinetic method[61]. The value obtained is relatively close to the basicity of hydrazoic acid found by a partition method[28].

The determination of the rate-limiting reaction stage is the most difficult step in the study of the mechanism of multistage processes. This problem has been examined by Smith[4] in relation to the Schmidt reaction with ketones but he did not arrive at a final solution. At the same time, determination of the rate-limiting stage of the process yields exceptionally valuable information about the reaction mechanism as a whole.

Studies on the kinetics of sextet rearrangements, which include the Schmidt reaction, showed that the rate of the process increases on introduction into the molecule of the initial compound (amide, hydroxamic acid, or carboxylic acid) of electron-donating substituents (the value of ρ in the correlation equation is negative). The absolute values of the reaction constants are fairly considerable: 2.58 for the Hoffman reaction[63], 2.51 for the Lossen reaction[64], and 1.76 for the Schmidt reaction[65] (in the last case the reaction series comprises aromatic acids).

A negative value of ρ was obtained also for the reaction of aliphatic acids with hydrazoic acid and it was shown convincingly that the rearrangement stage is rate-limiting[66]. In the absence of stages complicating the process the observed negative sign of the reaction constant ρ may be attributed to the rearrangement itself[67].

A positive reaction constant is observed only when the rate-limiting stage is nucleophilic addition to the carbonyl group[31].

The constant $\rho = +1.79$ has been determined[62] for many substituted acetophenones by correlating the logarithms of the true rate constants with Brown's σ^+ constants (Fig. 3).

The observed positive reaction constant for substituted acetophenones is in general an overall quantity comprising the reaction constants for the rate-determining and preceding stages. However, analysis shows[62] that the slowest stage probably consists in the nucleophilic addition of hydrazoic acid to the carbonyl group. The activation parameters for the Schmidt reaction with ketones are consistent with this hypothesis (Table 3). According to the theory of absolute rates, the enthalpy of a complex reaction, with the exception of cases where intermediates accumulate, may be attributed to the rate-limiting stage.

The observed values of $\Delta H^{\neq}$ are characteristic of the stage involving nucleophilic addition to the carbonyl group. Moreover, it has been shown[60] that the activation energies for the reactions of 2-hexanone with hydrazoic acid in sulphuric acid are similar in different acidity ranges. This yet again confirms that the reaction mechanism does not alter over a wide range of sulphuric acid concentrations.

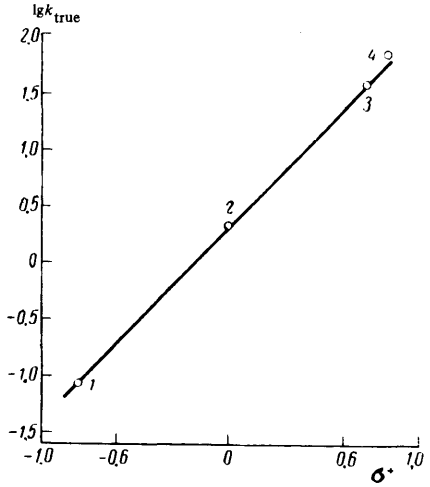

Figure 3. Correlation between the logarithm of the true rate constants for the Schmidt reaction and the electrophilic constants of the substituents:
1) *p*-methoxyacetophenone; 2) acetophenone;
3) *m*-nitroacetophenone; 4) *p*-nitroacetophenone.

The activation entropies for multistage processes are overall quantities, which gives rise to additional difficulties in their interpretation. Therefore it is useful to compare the values of $\Delta S^{\neq}$ for the Schmidt reaction involving ketones and acids. In the latter case the slowest stage is the rearrangement. A small negative value of $\Delta S^{\neq}$ can be explained by a considerable contribution due to the stage involving the liberation of nitrogen and an increase of entropy[66]. For ketones, the activation entropies are more negative, which is satisfactorily consistent with the finding that the experimental $\Delta S^{\neq}$ consist of the entropies of the protonation stage and the stage involving nucleophilic addition to the carbonyl group.

The kinetic isotope effect in the Schmidt reaction involving 2-hexanone and acetophenone has been measured[68]. In both cases the rate increases appreciably when H_2SO_4 is replaced by D_2SO_4 (Table 4). Such acceleration of the reaction is characteristic of processes with a protonation pre-equilibrium[69]. The results obtained by Koldobskii and coworkers[60-62] make it possible to resolve the apparent contradictions between the previous kinetic studies.

In their investigation of the effect of substituents on the rate of the Schmidt reaction with ketones, Fichel et al.[55] and Mirek[57] arrived at opposite results. This is evidently because the authors employed sulphuric acids of different concentrations. Fichel et al.[55] did not indicate which rate constants were employed in the calculations—the effective or true values. Evidently their conclusion is based on the effective rate constants in 67.8% sulphuric acid, which is confirmed by the plot in Fig. 1. Indeed at this concentration of sulphuric acid ($H_0 = -5.6$) the effective rate constants increase when electron-donating substituents are introduced into the ketone molecule. On the other hand, Mirek et al.[57] employed concentrated sulphuric acid (about 93%) and the sign of the effect of substituents was reversed. Correct conclusions can be arrived at only by using the true rate constants, which are independent of the acidity of the medium.

Table 3. Activation parameters and relative rates of the Schmidt reaction for substituted acetophenones[55].

Substituent	Relative rate	$\Delta H^{\neq}$	$\Delta S^{\neq}$
p-CH_3	9.50	8.26	−41.60
m-OH	1.13	—	—
H	1.00	—	—
p-Br	0.69	9.98	−36.22
m-Br	0.58	—	—
p-OCH_3	0.38	—	—
p-NO_2	0.15	14.83	−22.59
m-NO_2	0.10	—	—

The retardation of the reaction of phenanthrenequinone with hydrazoic acid as the acidity of the medium increases can be explained similarly. According to Eqn. (31), the optimum acidity (h_0^{max}) for this ketone ($pK_a = -7.8$) corresponds to $H_0 \simeq -7.4$ and since the process occurs at H_0 between −8 and −9, the rate of reaction falls as the acidity rises.

Table 4. Kinetic isotope effect (k.i.e.) in the Schmidt reaction[68].

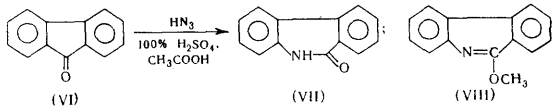
Ketone	k.i.e., litre mole^{-1} s^{-1}, 15°C		$\frac{k_D}{k_H}$
	H_2SO_4 60.5 wt.%	D_2SO_4 60.5 wt.%	
2-Hexanone	0.81	2.50	3.24
Acetophenone	0.02	0.12	6.00

Thus the available kinetic data for the Schmidt reaction involving ketones agree satisfactorily with the reaction mechanism proposed by Smith[4]. However, kinetic methods alone do not yield exhaustive information about the reaction mechanism as a whole. Here it is necessary to employ other physicochemical research techniques.

6. Other Views on the Mechanism of the Reaction of Ketones with Hydrazoic Acid

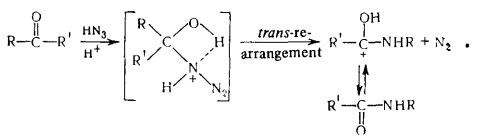
The failure in some cases of the empirical rule that the more bulky substitutent migrates preferentially in the Schmidt reaction with asymmetric ketones[44,45] led some investigators to revise the reaction mechanism proposed by Smith[4,11]. Arcus et al.[46] questioned the possibility of the existence of the iminodiazonium (*c*) and iminocarbonium (*d*) ions [mechanism (8)]. As evidence they quote data

for the Schmidt reaction with fluorenone (VI) in 100% sulphuric acid. They believe that, when an iminocarbonium ion is formed, its hydration is difficult under these conditions and dilution of the reaction mixture with an excess of methanol should lead to 9-methoxyphenanthridine (VIII):



(32)

However, the only reaction product proved to be the phenanthridone (VII). These results were interpreted as unambiguous proof of the absence of an intermediate iminocarbonium ion. As a possible alternative, they proposed a mechanism involving the formation of an intermediate four-membered ring:



(33)

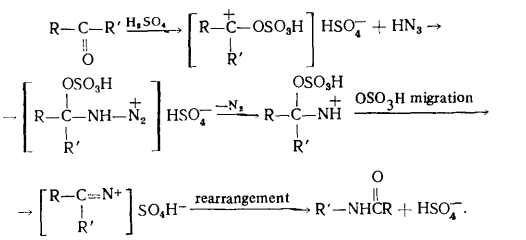
However, in subsequent studies[37,56] it was shown that the arguments put forward by Arcus et al. in favour of the mechanism with a four-membered intermediate are inadequate.

In Schmidt's early studies[70] it was already known that iminoethers are formed when ketones are treated with hydrazoic acid, provided that the reaction is carried out in alcohol. Arcus and coworkers diluted the reaction mass with alcohol only after the process had been completed, when the iminocarbonium ion had already been converted into the protonated amide as a result of hydration.

The fact that the iminocarbonium ion is nevertheless capable of being hydrated under these conditions is confirmed by the well known hydrolysis of nitriles in concentrated sulphuric acid[71,72]. Moreover, if the hydration process were thermodynamically impossible, the formation of iminocarbonium ions from amides should be expected when the latter are dissolved in sulphuric acid. However, the attempts by Newman and Deno to achieve such transformation of amides proved unsuccessful[73]. In addition it is known that, in the presence of an excess of hydrazoic acid, ketones form tetrazoles (see section III). It is not clear how such products could be formed if they were really preceded by the four-membered intermediate shown in mechanism (33).

Finally, it is noteworthy that the hydrogen bond energy is clearly insufficient for the formation of a strained four-membered ring and therefore the existence of such a structure is altogether unlikely.

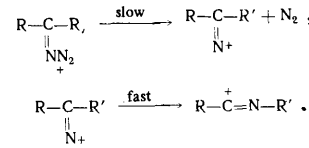
Recently Mirek[56,57] proposed the following mechanism for the Schmidt reaction with ketones:



(34)

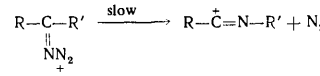
However, this mechanism has no significant advantages over the generally accepted Smith mechanism[4]. Experimental data confirming the validity of this pathway are so far lacking.

In a study of the Schmidt reaction with ketones the problem of the mechanism of the rearrangement proper is exceptionally important. According to mechanism (8), the rearrangement takes place in two stages:



(35)

On the other hand, the process can proceed via a many-centre (push-pull) mechanism with simultaneous elimination of nitrogen and migration of one of the substituents:



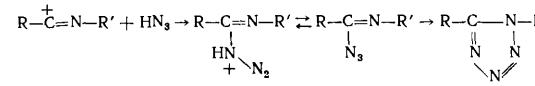
(36)

Since there is no direct proof for a particular mechanism, it is difficult to give preference to any one of them. One can only suppose, by analogy with the related Curtius, Lossen, and Hofmann reactions[74,75], that the synchronous mechanism can also operate in the Schmidt reaction.

III. CONCOMITANT REACTIONS

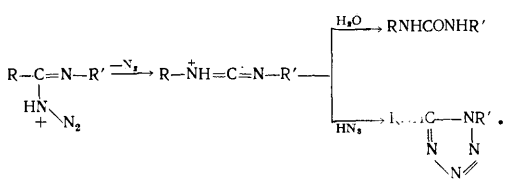
Usually the interaction of ketones with hydrazoic acid leads to the formation of amides. In certain cases, depending on the reaction conditions and the properties of the substrate, tetrazoles, aminotetrazoles, ureas, iminoethers, and certain other compounds may be obtained. Tetrazoles, which exhibit a high biological activity[76] and are used in medical practice as stimulators of cardiac activity[2], are the most important.

Tetrazoles are formed as a result of the reaction of the iminocarbonium ions *d* with an excess of hydrazoic acid:



(37)

The protonated imidoazide is capable of eliminating nitrogen with formation of a carbodi-imide which is converted into an aminotetrazole or urea as a result of secondary reactions with hydrazoic acid or water:



(38)

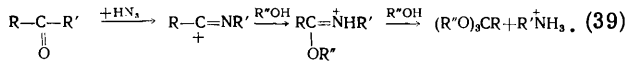
If the reaction is carried out in the presence of water, then, even if there is a large excess of hydrazoic acid, tetrazoles are always obtained in a mixture with amides. Thus benzosuberone was converted into a lactone in 82% yield when sodium azide was added slowly to a solution of the ketone in trichloroacetic acid[77]. When a mixture of the ketone and hydrazoic acid is treated with concentrated sulphuric acid, a tetrazole is formed[78]. Similarly mixtures of the corresponding amides and tetrazoles are formed from di-isobutyl-ketone[79] and cyclohexanone[80].

The formation of aminotetrazoles and urea in the Schmidt reaction takes place extremely rarely and is characteristic only of ketones such as benzophenone[81]. Tetrazoles are formed in a small amount from benzil[82].

Despite the fact that the synthesis of tetrazoles by the Schmidt reaction has found wide application, systematic

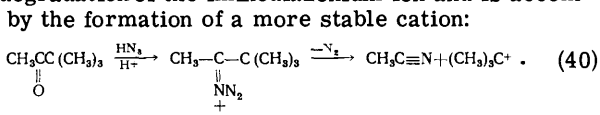
studies have not been made in this field. It is not clear how the structure of the ketone affects its capacity for conversion into a tetrazole, although such a relation undoubtedly exists. One can also suppose that the amide: tetrazole ratio (when a mixture of these products is formed) is determined by the ratio of the activities of hydrazoic acid and water and also by the acidity of the medium. Extensive kinetic studies are required for the solution of this problem.

Alcohols can enter into the reaction with the iminocarbonium ion together with water and hydrazoic acid. In this case there is a possibility of the formation of iminoethers [70]. Since in the presence of acids these substances readily undergo alcoholysis, the rearrangement products are orthoesters and amines [4]:



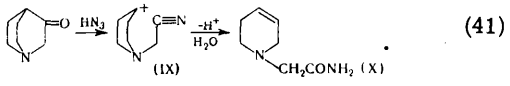
(39)

The composition of the Schmidt reaction products depends to a considerable degree on the structure of the ketone. Ketones such as pinacolone [83], pivalophenone [35], 2-n-butyl-2-phenylbutan-3-one, [84] and certain others [85] react with hydrazoic acid to form the corresponding nitriles. The formation of nitriles takes place as a result of the degradation of the iminodiazonium ion and is accompanied by the formation of a more stable cation:



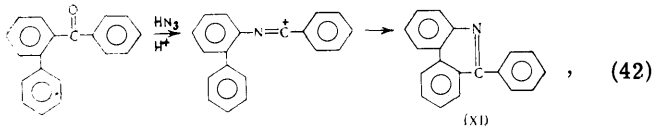
(40)

Even more far-reaching transformations are undergone by 3-quinuclidone [86,87]. In this case the carbonium ion (IX) is stabilised by the removal of a proton, which leads to the formation of an unsaturated amide (X):

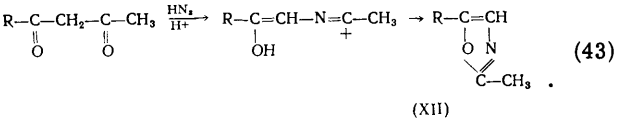


(41)

Certain ketones, for example *o*-phenylbenzophenone [45], acetylacetone, and benzoylacetone [88], give rise to cyclic products (XI–XII) as a result of the Schmidt reaction:



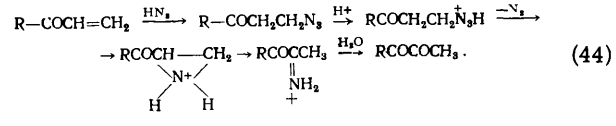
(42)



(43)

Phenylphenanthridine (XI) and oxazole (XII) are formed via an electrophilic attack by the iminocarbonium fragment on the adjacent nucleophilic centres.

The complex reaction involving unsaturated ketones such as methyl vinyl ketone gives rise to diketones [89]:



(44)

IV. APPLICATIONS OF THE SCHMIDT REACTION

The Schmidt reaction with ketones has come to be widely used as a convenient method for the synthesis of *N*-substituted amides with different structures, tetrazoles, and certain other compounds. Compared with other methods, it has the advantage of simplicity, ready availability of the reactants, and mild reaction conditions. The Schmidt reaction may be catalysed by protic and aprotic acids; sulphuric acid is normally employed for this purpose [11,36,90]. In many cases satisfactory results have been obtained using trichloroacetic acid [51,90] and particularly polyphosphoric acid [91,92].

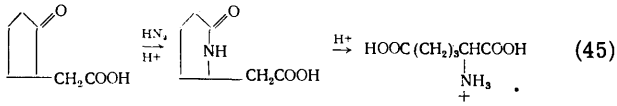
Solutions of hydrazoic acid required for the reaction are prepared beforehand or sodium azide is added directly to the reaction mixture. The use of hydrazoic acid *in situ* makes it possible to avoid direct contact with this explosive and poisonous compound.

Ketones of different structures, ranging from the simplest compounds to alkaloids [93], readily enter into the Schmidt reaction. The few failures reported in the literature can be accounted for by an unsuitable choice of reaction conditions.

The reaction of the carbonyl group of ketones with hydrazoic acid takes place selectively and does not involve functional groups such as the carboxy-, [94] ester [95], nitrile [40], and certain other groups.

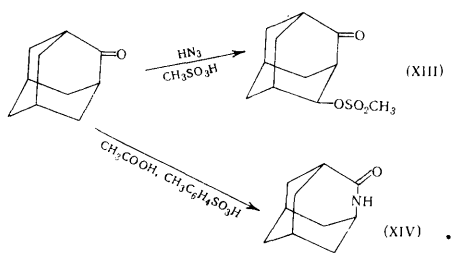
Aliphatic ketones react most readily. The reaction is frequently employed to determine the structure of the ketone or to synthesise the corresponding amide. In some cases amines containing other functional groups are obtained by this procedure. Thus α- and β-aminoacids are formed from acetoacetic or laevulinic acid esters.

The reaction with acyclic ketones takes place with ring expansion and leads to the formation of lactams [39]. Cyclic ketones containing carboxy- or ester groups are converted into lactams, which are hydrolysed under the reaction conditions to dicarboxylic acids [94,95]:



(45)

Depending on the reaction conditions, 4-methylsulphoxyadamantone (XIII) or the corresponding lactam (XIV) are formed from adamantone [96,97]

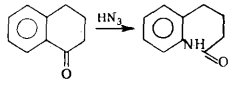


(46)

Alkyl aryl ketones have been investigated in the Schmidt reaction more than other carbonyl compounds. It has been shown that the reaction of substituted acetophenones with hydrazoic acid gives acetanilides in high yields [11,95,98]. This reaction is a convenient method for the preparation of various aromatic amines:

(47)

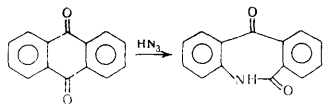
Cyclic alkyl aryl ketones such as tetralone [78] and benzosuberone [77] are converted into lactams under analogous conditions:



(48)

Compared with alkyl aryl ketones and aliphatic ketones, benzophenones are less reactive. However, when sulphuric acid is employed as a catalyst, satisfactory results are obtained[35,45]. Substituted benzophenones are of considerable interest, since the study of these ketones yields valuable information about the migration ratios in the Schmidt reaction.

Aromatic diketones behave somewhat differently in the Schmidt reaction. A complex mixture of products is obtained from benzil[82] and phenanthrenequinone[99] is converted into phenanthridone. Only one carbonyl group in anthraquinone and its amino-derivatives reacts[100]:



(49)

Ketones containing heteroatoms (nitrogen and sulphur) enter into the Schmidt reaction with formation of normal rearrangement products. Thus it has been shown that various carbonyl derivatives of thiophen are converted under the influence of hydrazoic acid in the presence of polyphosphoric acid into the corresponding amides in high yields[92,101]. A similar behaviour has been observed also for other heterocyclic ketones[102-104]. Ketones with a more complex structure, for example certain triterpenoids, give a mixture of amides and tetrazoles under the conditions of the Schmidt reaction[105].

Mechanochemistry of Inorganic Solids

V.V.Boldyrev and E.G.Avvakumov

The chemical consequences of the mechanical treatment of inorganic solids has recently become the subject of detailed studies arising from increasing mechanical loading and the development of a highly effective technology of size reduction. The present review of published data examines the influence of mechanical treatment on the structural and thermodynamic properties of materials, the reactivities of substances, and the rates of physicochemical and chemical processes involving substances subjected to mechanical treatment. The possible mechanisms and characteristic features of mechanochemical processes are discussed, and routes to their practical utilisation are indicated. The bibliography contains 145 references.

I. INTRODUCTION

In the search for new methods of carrying out processes in chemical technology and the development of methods for the directed control of the reactivity of solids, the study of processes taking place during the mechanical treatment of a substance has become extremely important. The mechanical treatment of solids (either beforehand or at the moment when the reaction is carried out), together with the use of heat, light, ionising radiation, electric fields, etc., provides one method for the physical stimulation of chemical processes, the possibilities of which have recently been extended considerably in connection with the development of highly effective techniques of size reduction.

Mechanochemical processes play a unique role in the chemistry of solids. Chemical reactions involving solids take place chiefly on a surface, and the state of the surface plays an important role in these processes. The action of heat on a solid leads to the excitation of all sites in the crystal lattice, whereas by mechanical treatment it is possible to bring only part of it into the excited state. There is another difference between the processes which take place on heating and on mechanical treatment. In thermal decomposition there is a slow increase in temperature, whereas on mechanical treatment there is a rapid pulse-wise increase in temperature at the points of contact between the friction solids, followed by rapid cooling. A consequence of this may be that in contrast to thermal decomposition, secondary processes may not be able to take place during mechanical treatment, and the primary products formed in the initial stages of the process are quenched. This may be one of the reasons for the specific features of the chemistry of mechanochemical reactions.

A number of reviews and monographs on the mechanochemistry of macromolecular organic substances have recently been published in the Soviet and other literature[1-7]. The aim of the present work is to review the mechanochemistry of inorganic solids. We shall therefore not deal here with problems of mechanochemical treatment of organic materials, and we shall not concern ourselves with special problems, such as the mechanochemical corrosion of metals, the study of which has recently undergone extremely intensive development[8-12].

In the examination of mechanochemical phenomena it is necessary to deal with two aspects, which are difficult to separate from one another. The first is the production of new physicochemical properties by the production of finely dispersed particles with increased energy. The second concerns the chemical changes taking place during the treatment of a substance under the influence of the physical processes taking place.

Since the problems of the state of finely dispersed particles have been fairly fully reviewed[13], most attention in the present review is paid to the second aspect, and also to the discussion of the specific features and nature of mechanochemical reactions.

II. PRODUCTION OF NEW PHYSICOCHEMICAL PROPERTIES AS A RESULT OF DISPERSION

1. Change in Free Energy, Solubility, and Thermal Stability

The process of size reduction can be regarded not only as a process of increasing surface area, but also as a process of increasing free energy (chiefly surface free energy). In this sense it can be said that size reduction is also a chemical process, since a change in free energy leads to a displacement of chemical and phase equilibria. The absence of excess free energy in a solid leads to the production of thermodynamically unstable states. A higher concentration of excess free energy corresponds to a higher content of excess internal energy ΔH and an excess entropy ΔS.

When the entropy change is small (the crystalline state is preserved), the change in free energy can be estimated from the change in excess enthalpy by calorimetric methods[14]. According to published work[15,16], the increase in enthalpy, for example, for oxides on going from the single crystal to the finely divided state is 1–3 kcal mole^{-1}. If the entropy change cannot be neglected, the excess free energy can be measured by measuring the equilibrium position of a chemical reaction in which the activated substance reacts with another substance of known activity.

From the relationship

$$\Delta G = -RT \ln \frac{k_2}{k_1} \quad (1)$$

where ΔG is the change in free energy and k_1 and k_2 the rate constants of the forward and back reactions respectively, it can be seen, for example, that a change in ΔG from 0 to 20 kcal mole^{-1} leads to a change in the ratio of k_2 to k_1 from 1 to 1×10^{15}. An example is provided by the reaction [18]

$$Ni + 4CO \rightleftarrows Ni(CO)_4. \quad (2)$$

The equilibrium position of the reaction is displaced to the right with increase in the surface area of the nickel, for example on going from nickel foil to nickel dust. The change in free energy is 1.38 kcal mole^{-1}; the ratio k_2/k_1 changes accordingly by one order of magnitude.

The free energy of finely dispersed particles can be estimated approximately by means of Thomson's equation

$$\Delta G = \frac{2\sigma V}{r}, \quad (3)$$

where σ is the surface tension, r the particle radius, and V the molar volume. Eqn. (3) is approximate, if only because the value of σ must also change when the particle dimensions become very small.

The fine particles exhibiting increased values of the free energy differ from large particles in other properties. In particular, if the particles are sufficiently small, their dissolution may produce concentrations exceeding those corresponding to the usual equilibrium solubility of the substance. Ostwald, and later Freundlich, obtained equations giving the dependence of the solubility on the dimensions of the particles [19]:

$$\ln \frac{C_r}{C^*} = \frac{2\sigma M}{RT\rho r}, \quad (4)$$

where C_r is the solubility of the particles with radius, r, C^* the equilibrium solubility, ρ the density of the solid, and M the molecular weight.

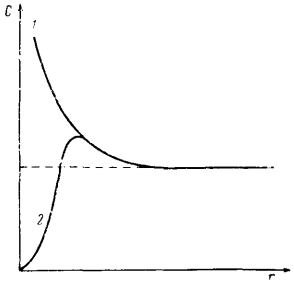

Figure 1. Dependence of solubility on particle size.
1) Freundlich's equation, *2*) Knapp's equation.

The Ostwald–Freundlich equation contains the same assumptions as were made in the derivation of Thomson's equation. For example, it is assumed that the density of the solid and the surface energy are independent of the particle dimensions.

The solubility of finely dispersed particles was examined from another viewpoint by Knapp [20]. He assumed that the particles carry a small surface electric charge, so that the total surface energy is the sum of the surface and electrical energies. On the basis of these assumptions he derived for isolated charged particles the equation

$$C_r = C^* \exp\left(\frac{a}{r} - \frac{b}{r^4}\right), \text{ where } a = \frac{2\sigma M}{RT\rho}, \; b = \frac{QM}{8\pi RT\varepsilon\rho}, \quad (5)$$

Q is the electrical charge of the particle, and ϵ the dielectric constant of the solid. Eqn. (5) gives the curve shown in Fig. 1. The experimental data obtained by Dundon and Mack [21,22] can be regarded as confirming Knapp's conclusions.

A large amount of work has shown that the increase in the surface area of solid particles produced during size reduction leads to an increase in the rates of solid-phase reactions, in particular decomposition [23]. In a number of instances the rates of topochemical reactions pass through a maximum with decrease in the particle dimensions. The reason for this dependence is that with change in the degree of dispersion, the ratio between the rate of formation of the nuclei of the new phase and the rate of their growth changes in such a way that the rate of the process is determined in some instances by nucleous formation, and in other instances by the growth of nuclei [24-26].

2. Kinetics of Size Reduction and the Dissolution of a Finely Divided Substance

Irrespective of the type of apparatus used for size reduction (with the condition that the apparatus is efficient and operates for a sufficiently long time), the change in the particle dimensions on size reduction takes place in three stages [27-30]. The first stage is characterised by a progressive decrease in the particle dimensions with time; the second by the start of aggregation of the particles; and the third by the establishment of equilibrium, in which the particle dimensions remain unchanged with time. The specific surface changes analogously. A characteristic picture of the change in the specific surface and particle dimensions on size reduction is given in Fig. 2.

For the description of the dependence of the particle dimensions on the duration of the size reduction, Schneider [31] proposed the equation

$$\frac{dr}{dt} = -k_0 e^{-\frac{U_B}{U_M}}(r - r_g) + k_r e^{-\frac{U_a}{f\frac{\sigma}{r} + \frac{E}{2}\left(\frac{A}{B + r^n}\right)^2 + U_M}}, \quad (6)$$

where r represents the particle size, r_g the minimal particle size, k_0 the rate constant for the formation of fractures in the lattice, k_r the recrystallisation rate constant, U_B the mean specific energy of fracture, U_M the specific mechanical load, U_a the activation energy of the recrystallisation process, E the modulus of elasticity, and A, B, f, and n constants.

The first term in the right hand side of Eqn. (6) describes the breakdown of the substance, whereas the second term describes the recrystallisation. The quantities appearing in the equation depend on the nature of the substance undergoing size reduction, and in particular on the type of chemical bonding. For ionic compounds the activation energy of recrystallisation is small, whereas for covalent compounds it is much larger (greater energetic interference is required to restore broken

valency bonds). As a consequence, the $dr/dt = \varphi(t)$ curves for ionic compounds pass through a minimum; for covalent compounds the minimum is poorly defined, or completely absent; in the last instance the particle size decreases smoothly with time until the equilibrium value is reached.

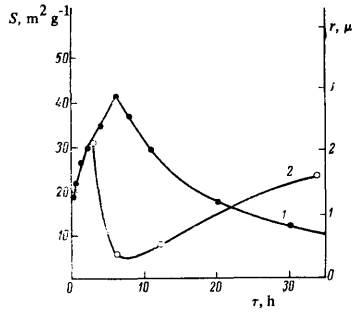

Figure 2. Dependence of specific surface and particle size on duration of size reduction: *1*) specific surface; *2*) particle size.

The specific surface (and the particle size) are influenced to a significant extent by the medium in which the size reduction is carried out. In a study of the mechanical properties of inorganic crystals (galena, calcite, and graphite), Rebinder [32] established that the strength of these crystals is greatly reduced in the presence of surface-active substances. He showed that the changes in the mechanical properties of solids under the influence of surface-active substances results from a decrease in the surface free energy and hence a decrease in the work required to increase the surface area. The decrease in hardness with change in the concentration of surface-active substance takes place in parallel with a change in adsorbability, and is described by an equation analogous to Langmuir's equation

$$\Delta B = \Delta B_\infty \frac{C}{C+\alpha}, \qquad (7)$$

where ΔB is the decrease in hardness, C the concentration of surface-active substance, ΔB_∞ the total decrease in hardness on complete saturation of the absorption layer, and α a constant.

The phenomenon of adsorption decrease in strength under the influence of surface-active substances (the Rebinder effect) provides a basis for the development of methods for controlling the rate of size reduction of solids [33,34]. Despite the fact that with increase in the duration of dispersion the specific surface increases only as far as a certain limit, the breakdown of the crystal lattice continues until the substance is completely converted into the amorphous state [29,30]. Because of the presence of the amorphous state, the solubility increases on size reduction, and the maximal attainable solubility may exceed the normal solubility. Khodakov and Plutsis established that the solubility of quartz in water, after size reduction on a vibro-mill, is given by the equation

$$C = C_\infty(1 - e^{-k\tau}), \qquad (8)$$

where C_∞ is the maximal solubility, τ the duration of size reduction, and k a constant. Eqn. (8) is also applicable to other substances [13,14].

An increase in solubility under the influence of mechanical treatment was also observed for iron oxide [35], copper oxide [16], sodium chloride [16], calcium carbonate [35,36], quartz [29,37,38], bauxite [30], monazite [6], alumina [39], tin(IV) oxide [40], chromite [41], etc.

3. Phase Transformations and Behaviour of Solid Solutions on Size Reduction

Very fine particles with an increased energy content are responsible for the production of metastable states and phases on size reduction. An example is provided by data [42] which show that decrease in particle size is accompanied by an increase in the temperature and enthalpy of solid-phase transformations in quartz, potassium sulphate, and potassium nitrate.

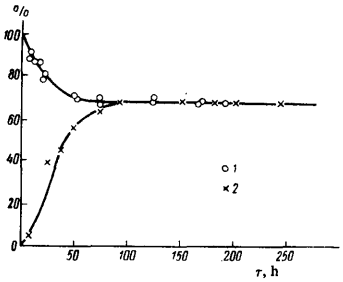

Figure 3. Equilibrium between the two crystalline phases of calcium carbonate under the influence of mechanical treatment [43]. *1*) Aragonite, *2*) calcite.

Under the influence of prolonged size reduction, an equilibrium is established between different modifications of a substance. Thus for example, equilibrium between calcite and aragonite is established after grinding for 80 h in a vibro-mill (Fig. 3) [43]. The high-temperature forms of the substances are also detected during the grinding of zinc sulphide [44], cadmium sulphide and selenide [45,46], barium chromate [47], silicon carbide [47], titanium dioxide [47], silver iodide [48], calcium carbide [49], lead dioxide [50], sulphur [51], selenium [52], quartz [53], nephelite [53], etc.

The establishment of thermodynamic equilibrium between solid phases depends on the rate of diffusion of the components of the mixtures. Since the size reduction of crystals leads to a sharp increase in the number of vacant sites in the lattice [54] and hence to an increase in diffusion and ionic conductivity in ionic crystals, the rate of attainment of thermodynamic equilibrium increases under the influence of size reduction.

The size reduction of a mixture of isomorphous components facilitates solid solution formation. It has been found [55,56] that solid solutions of potassium chloride and bromide can be obtained by grinding them in a mill or by repeated application of pressure to 13 000 atm. If a mixture of two substances is a solid solution of components which mix with difficulty, for example NaCl–TlCl (0.6 mole %) or KCl–AgCl (0.6 mole %), grinding of the solid solution leads to its partial breakdown [57].

III. CHEMICAL REACTIONS DURING THE MECHANICAL TREATMENT OF A SUBSTANCE

1. Decomposition and Preparation of Substances

The possibility of decomposing inorganic substances by grinding was established at an early date. As early as last century it was shown that grinding leads to the decomposition of many solid salts of silver and mercury[58,59]. The mechanochemical decomposition of a large number of inorganic compounds: carbonates, oxalates, nitrates, halates, complexes, etc. has now been studied.

Decomposition to the following extents after grinding for 20 h in a vibro-mill has been reported[60,61]: magnesium carbonate 28.9%, calcium carbonate 13.9%, strontium carbonate 10.8%, barium carbonate 8.4%, sodium carbonate 0.22%, and potassium carbonate 0.16%. Decomposition gives the oxides and oxygen.

Direct mass-spectrometric measurements[62] showed that the average number of monolayers decomposed in the size reduction of crystals of lead, magnesium, and calcium carbonates is 2, 0.37, and 0.09 respectively. The mechanochemical decomposition of calcium carbonate has been studied in detail[43]. The equilibrium thermal dissociation pressure, enthalpy of dissolution, particle size, and specific surface after mechanical activation were determined. The equilibrium pressure of carbon dioxide was used to calculate the values of ΔG, ΔH, and ΔS. Mechanical activation decreases the values of these quantities for thermal decomposition at 625°C: ΔG from 8.1 kcal mole^{-1} to 6.2 kcal mole^{-1}, ΔH from 33.2 kcal mole^{-1} to 14.8 kcal mole^{-1}, and ΔS from 28.0 e.u. to 9.6 e.u.

The decomposition of iron, zinc, and manganese carbonates is analogous. Peters[6] showed that different products may be obtained, depending on the conditions of mechanical treatment. The decomposition of iron carbonate (siderite) in air gives the oxide Fe_2O_3; in the presence of moisture the hydroxide $Fe(OH)_3$ is obtained. When the carbonates are subjected to size reduction in a vacuum, the quantity of carbon dioxide liberated is greater by an order of magnitude than that for decomposition in air. In the size reduction of sulphides (for example cinnabar[63]), decomposition to the metal and sulphur may take place.

A large amount of work has been done on the study of the effect of mechanical action on the decomposition of explosives. The thermal theory of the initiation of explosions by mechanical action has been intensively developed[64]. Criteria by means of which the mechanical sensitivity of explosives might be characterised have not been established, however.

To investigate the characteristic features of mechanochemical decomposition, the properties of the product of the mechanochemical decomposition of silver oxalate were compared with the properties of the product of its thermal decomposition[65]. The results indicated that the activity of "mechanochemical" silver is much less than that of silver obtained by thermal decomposition, but much greater than the activity of photochemical silver.

The mechanochemical decomposition of alkali metal, alkaline earth metal, and rare earth metal nitrates has been studied[66,67]. The degree of decomposition of the alkali metal nitrates was determined from the yield of nitrate, and that of the alkaline earth metal nitrates and anhydrous lanthanum nitrate from the yield of metal oxide. The decomposition curves have the same form as the specific surface curves, that is the degree of decomposition passes through a maximum, after which an equilibrium state is established (Fig. 4). The existence of this correlation may indicate that the mechanochemical reactions are localised on the surface of the substance subjected to size reduction. The decomposition curves before the maximum are described satisfactorily by the equation

$$\alpha = k\tau^n \qquad (9)$$

where α is the degree of decomposition, τ the time, and k and n constants[68]. For the substances studied, $n = 3$.

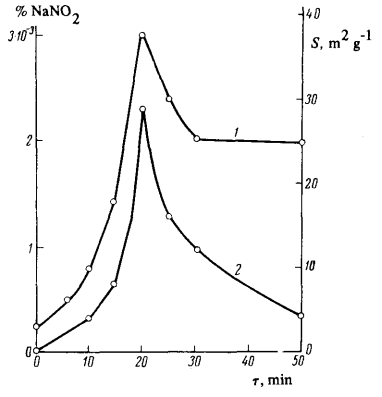

Figure 4. Dependence of the specific surface and yield of the product of the mechanochemical decomposition of nitrate on the duration of size reduction. *1*) Specific surface, *2*) $NaNO_2$ concentration.

With increase in the mechanical energy supplied, the degree of decomposition of the substances increases but the form of the curve is preserved. This can be seen from Fig. 5, which shows curves giving the dependence of the mechanical decomposition of sodium nitrate on the acceleration developed in a centrifugal planetary mill[67]. It follows from published data[66], reproduced in Fig. 6, that in a series of nitrates of the same type, the degree of decomposition increases with decrease in the crystal lattice energy. An analogous dependence is observed for the decomposition of substances under the influence of an explosion[69,70]. The similarity between the decomposition of substances on grinding and decomposition under the influence of an explosion is also shown in the fact that identical decomposition products are formed, for example in the decomposition of copper compounds[69,71].

The rate of mechanochemical decomposition may change in the presence of substances which exhibit redox properties or which act as catalysts. The decomposition of minerals and salts takes place particularly readily in the presence of ammonium salts or their mixtures with one another[72]. The rate of decomposition of substances can be altered by introducing catalysts, such as transition metal oxides. It has been shown[73] that the rates of decomposition of sodium nitrate in the presence of Ni, Fe, Zn, Cu, and Mn oxides show a correlation with the work function of an electron from the oxide.

When a mixture of substances is ground, synthetic and exchange reactions take place between them. The sulphides of Hg, Ag, Mg, Cd, Zn, Sn, Pb, Sb, and Bi are formed in yields of 25–100% when the metals are ground with sulphur, carbides are obtained by grinding with graphite, phosphides by grinding with phosphorus, iodides with iodine, etc.[69,72,74].

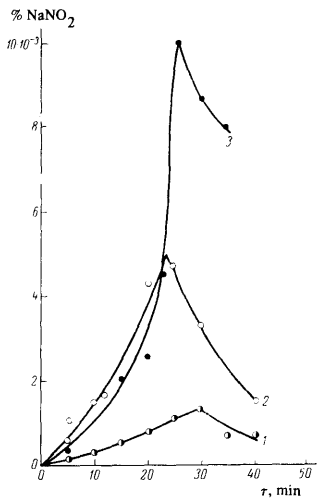

Figure 5. Influence of mechanical load on the degree of mechanochemical decomposition of sodium nitrate. Acceleration:
1) 20g, *2*) 40g, *3*) 60g.

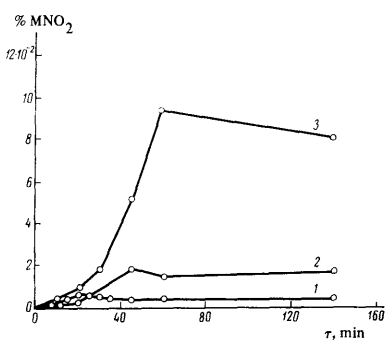

Figure 6. Mechanochemical decomposition of alkali metal nitrates.
1) $NaNO_3$, *2*) KNO_3, *3*) $CsNO_3$.

Oxides are formed when metals are ground in the presence of atmospheric oxygen[4]. The rate of oxidation passes through a maximum, depending on the duration of grinding, and before the maximum it is described by the equation

$$\ln v = k\tau + c \qquad (10)$$

where v is the rate of oxidation, and k and c constants.

Metal carbonyls, in particular Ni, Fe, and Zn carbonyls[75-77], can be obtained by a mechanochemical method. Detailed study of the carbonylation of nickel has established that mechanochemical treatment lowers the activation energy of the formation of nickel carbonyl from 10.2 kcal mole^{-1} to 2.1 kcal mole^{-1} [75]. The rate of formation of nickel carbonyl may be altered by the presence of additives of different types. It has been shown[76,77] that substances such as O_2, $KClO_3$, $K_2Cr_2O_7$, $KMnO_4$, KI_2O_3, Na, Ca, and I_2 decrease the reaction rate, whereas the addition of sulphur and compounds containing sulphur has an activating influence on the formation of carbonyls. It is considered that the catalytic activity of these compounds is due to the formation of the intermediate compound γ-NiS.

Mechanochemical treatment can be used to prepare silicates from silicon dioxide and alkali and alkaline earth metal oxides or carbonates, and to prepare molybdates and tungstates from carbonates and oxides[6]. It has also been possible to carry out preparations which could not be carried out by other methods. Mechanochemical processes have been used to prepare catalysts with high selectivity[78,79], spinels[80], dyes[81], metallates[82], organometallic compounds[83], etc.

A large number of exchange reactions take place on grinding, and these have been used to develop simple methods of qualitative chemical analysis[59,72,84,85].

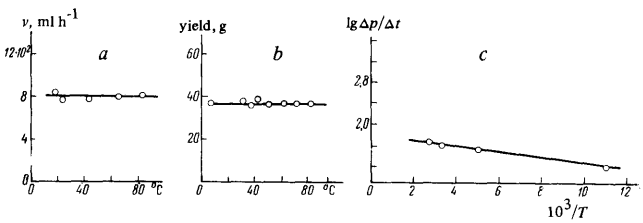

Figure 7. Temperature dependence of the rate of mechanochemical reactions[86-88].
a) $SiC + 2H_2O \rightarrow CH_4 + SiO_2$, *b*) $Sn + 2C_6H_5CH_2Cl \rightarrow (C_6H_5CH_2)_2SnCl_2$, *c*) $2Fe + O_2 \rightarrow Fe_2O_3$.

2. Influence of Temperature on Mechanochemical Reactions

One of the features indicating the specific nature of mechanochemical reactions is the fact that they are independent of temperature. Published data[86-88] on the influence of temperature on the rate of mechanochemical reactions are given in Fig. 7. The reaction rates remain almost unchanged (Fig. 7). Analogous results were obtained in a study of the decomposition of nitrates at room temperature and at the temperature of liquid nitrogen[66].

3. Formation of Free Radicals and Reactions Taking Place on Freshly-formed Surfaces

Measurements made on powders show that in diamagnetic substances after size reduction, paramagnetic centres resulting from the production of free radicals appear in the surface layers to a depth of 20–30 μ.

The regular features of the formation of radicals in the size reduction of quartz and their reaction stability at elevated temperatures have been studied[89-93]. Concentrations of unpaired electrons of the order of 10^{14} to 10^{15} g^{-1} were obtained. With decrease in the size of the particles their concentration increases. According to some authors[94], the paramagnetic centres in quartz are stable at 120°; their concentration decreases linearly in the range 120–360°. According to other data[92], the free radicals produced in quartz are stable as far as 350–400°, so that they can be preserved for a long time at room temperature.

The infrared spectrum of quartz after size reduction[95] showed a peak at 950 cm^{-1} due to the siloxane group SiOH. The production of the peroxo group ≡Si:O:O as a result of the mechanical treatment of quartz has been established[96].

It has been shown[97] that on the surface formed by the size reduction of graphite crystals, the carbon atoms are in two different electronic states—atoms in a bivalent singlet state and atoms forming over-stressed quasi-acetylenic bonds; free radicals containing carbon atoms with broken π- and σ-bonds are also present.

The EPR spectrum of zinc oxide subjected to mechanical treatment has been studied. The spectrum of the original zinc oxide showed two weak signals with $g = 2.006$ and $g = 1.956$, of approximately equal intensity. After the specimen had been ground in a mortar, the EPR spectrum, in place of the singlet with $g = 2.006$, showed a strong unsymmetrical triplet superimposed on a weaker spectrum, from which two components could be seen; with decrease in temperature to −196° these components increased by a factor of 4, whereas the amplitude of the triplet remained almost unchanged. The singlet with $g = 1.956$ decreased by a factor of several times after the substances had been ground. The EPR spectrum produced on grinding remains unchanged when the specimen is exposed to air, on evacuation of 10^{-3} mmHg, on treatment with solvents, or when iodine and quinone are adsorbed on its surface, but it gradually disappears when the specimen is heated above 100° in a vacuum or in air.

The EPR spectra of silicon, germanium, silicon carbides, diamond, the oxides of magnesium, calcium, strontium, and zinc, calcium and zinc sulphides, quartz, and α-alumina have been studied[88,90]. It has been stated[93] that the spectra obtained after mechanical treatment show a similarity to the spectra obtained after the irradiation of substances with fast neutrons. This is observed particularly clearly for magnesium and silicon oxides, for which both mechanical treatment and irradiation with neutrons lead to the formation of an F-centre with identical g-factor for the single signal.

As a consequence of the formation of active centres on the surface, reactions which do not take place under ordinary conditions become possible. An increase in pH and the bonding of atmospheric nitrogen as nitrate and ammonia has been observed on size reduction of sodium chloride. The change in the concentration of hydroxide ions was found to be proportional to the square of the surface area. The authors cited consider that the binding of nitrogen as the compounds on sodium chloride particles produced by the evaporation of sea water is an extremely important source for the accumulation of nitrogen compounds in the atmosphere.

The influence of the mechanical breakdown of crystals (NaCl and $BaSO_4$) on the polymerisation of vinyl monomers has been studied[100]. It has been shown that the initiation of the formation of polymers is brought about by the electron emission arising on breakdown of the crystals (mechano-electrons) and not by static defects in the solid phase (vacancies, colour centres, etc.), obtained by preliminary irradiation of the salts.

IV. MECHANISM OF MECHANOCHEMICAL REACTIONS

1. Physical Phenomena on Grinding

In early work on the mechanochemical reactions of solids[72,101], the chief role was assigned to particles of moisture adsorbed on the surface. It was assumed that there is no fundamental difference between reactions taking place in concentrated solutions and reactions taking place on grinding. It was established[102], however, that there is no relationship between the rate of reaction on grinding and the solubility of a salt. Moreover, it was established that in a number of instances, water decreases the reaction rate. It was found that a more important role in mechanochemical reactions is played by physical processes taking place on contact between solids in friction. The following phenomena are related to these processes.

Liberation of heat. When solids slide together, the greater part of the work done against the forces of friction is liberated in the form of heat. At locally restricted points on the surface, the temperature reaches an extremely high value. Bowden and Tabor[103] showed theoretically and experimentally that in sliding friction the temperature at the points of contact increases as far as the melting point, but never rises above it. For refractory substances, an instantaneous local increase in temperature to 1000°C may be achieved in the surface layer. The main bulk of the substance at this moment remains cold. The duration of existence of these temperature spikes on an area of 10^{-3}–10^{-5} cm is of the order of 10^{-4} s.

Production of high pressures. At the points of contact of friction solids, the production of a high temperature is accompanied by a simultaneous short-lived increase in pressure. The magnitude of this pressure has been estimated[104]. A series of substances for which the pressures (bar) of the phase changes were known were taken: PbO 5500, MnF_2 9500, Sb_2O_3 10 800, SiO_2 13 500, BeF_2 17 500, B_2O_3 18 500, and $BaAsO_4$ 30 000. The substances were ground in a mill, after which the ground products, for all the above substances except $BaAsO_4$, were found to contain the modifications existing at high pressures. On the basis of these data it was concluded that on contact between the solids in the mill, pressures of up to 15 000 bar were developed.

Production of electric charges. On friction between solids, electric charges are produced. The reasons for the production of electric charges on surfaces are varied. According to one view[105], solid dielectrics, because of the presence of structural defects, carry on their surface a charge which is compensated by ions adsorbed from the air. On friction, the compensation of the intrinsic charges is destroyed, and electrification results.

It has been shown[106] that the charges produced on contact between semiconductors and metals are linearly dependent on the difference in the work functions of an electron from the solids in contact.

When the surface of a crystal carries a charge, a space charge with sign opposite to the sign of the charge on the surface is produced in the volume of the crystal in order to preserve its electrical neutrality; this space charge undergoes oscillations (like the oscillation of the charge between the plates of condensers[107]). In large crystals the amplitude of the oscillations of the space charge is small, and the magnitude of the varying potential difference produced on breakdown of the crystal is correspondingly small. As the size of the crystal decreases, the potential difference increases, but for very small crystal dimensions it decreases again. The potential produced on the surface of ionic crystals under the influence of shock or deformation shows a correlation with the plasticity of the crystal[108]. The softer the crystal, the higher the potential, and vice versa.

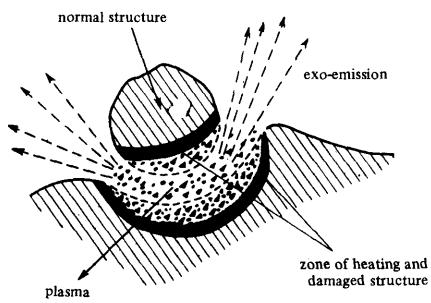

Figure 8. "Magma-plasma" model of mechanochemical processes[4].

Exo-emission and mechano-emission of electrons. In solids at the moment of mechanical treatment and afterwards, mechano-emission and exo-emission of electrons takes place. The electrons of the exo-emission, which is quenched extremely slowly after mechanical treatment, have an energy not greater than 1 eV, [109] whereas the mechano-emission electrons (mechano-electrons) have energies of tens of keV. [110] Exo-electronic emission results from heating, irradiation, chemosorption, etc., that is it is similar to thermal emission with its over-the-barrier removal of electrons. The mechano-electrons obtain their high energy by acceleration in the field of a "micro-condenser", the plates of which are the separated surfaces of the fracture. The electrons tunnel through the barrier, as a consequence of the high electric field.

Triboluminescence. When solids are subjected to size reduction and shock, extremely intense luminescence is produced. Most workers consider that the triboluminescence is associated with electric charges produced between the broken particles[111]. In triboluminescence accompanying the breakdown of ionic crystals in air, the nitrogen spectrum observed is the same as that for an electric discharge.

With allowance for the physical phenomena associated with size reduction, Thiessen and coworkers[4] put forward a "magma-plasma" model of mechanochemical processes (Fig. 8). According to this model, the energy liberated on shock or grinding, as a consequence of the low thermal conductivity of solids, leads not only to a local increase in temperature and sublimation of the substance, but also to the production of a state of the substance in which it exists in the form of ions and electrons (plasma). It was noted above that in the decomposition of substances under the influence of an explosion and on grinding, identical products are obtained. On this basis it may be stated that when a substance is ground, characteristic "micro-explosions" take place on contact between the solids in friction. These results also provide evidence in support of the "magma-plasma" model.

The production of the above phenomena on mechanical treatment brings mechanochemical reactions closer to plasma reactions, and if the treatment is carried out in aqueous medium, conditions are created for hydrothermal reactions.

2. Comparison with Reactions Taking Place Under the Influence of Heat, Light, and Radiation. Mechanochemical Equilibrium

It can be seen from the foregoing that mechanochemical reactions show almost no temperature dependence, whereas the latter is a characteristic feature of reactions taking place under the influence of heat. Another characteristic feature of mechanochemical reactions is that the reactions may take place by a thermodynamically unfavourable route. An example is provided by the decomposition of the alkali metal bromates, which can take place by two reactions:

$$MBrO_3 \rightarrow MBr + {}^3/_2O_2 \ . \qquad (11)$$

$$MBrO_3 \rightarrow {}^1/_2M_2O + {}^1/_2Br_2 + {}^5/_4O_2 \ . \qquad (12)$$

The free energy (T = 298°K) for reaction (11) is negative, and that for reaction (12) is positive. Mechanochemical decomposition, however, takes place almost entirely according to Eqn. (12)[112]. Data for other reactions taking place by a thermodynamically unfavourable route have been published[113].

The tribochemical decomposition of a number of inorganic substances has been studied[64], and a correspondence between the start of the thermal decomposition and the ability to undergo mechanochemical decomposition was not observed. Thus for example, the temperature of the start of decomposition of ammonium chromate is 110°, but it does not decompose on grinding, whereas mercury(I) chromate, for which the temperature of the start of thermal decomposition is 500°, decomposes readily on grinding. A large number of studies[114,115] have shown that the mechanochemical splitting of molecules gives products which have nothing in common with the products of thermal decomposition, and reactions which take place in the opposite direction on heating are possible[6].

In a study of the reaction of copper with water under the influence of mechanochemical activation, it was found that after grinding for 5–6 d, more than 2% of metallic copper reacts with water with the liberation of hydrogen[12]. The equilibrium constants for the reaction of copper with water in the range 298–3000°K are given in Table 1. Calculation shows that even at 3000°K the partial pressure of hydrogen should not exceed 10^{-2} mmHg. The experimental data show that the pressure exceeds the calculated

value by a factor of 1000. It was concluded that the local-heating theory cannot explain the displacement of hydrogen by copper.

Peters[6] showed that the reactions taking place on mechanical treatment are reversible. For example, treatment of zinc oxide in the presence of carbon dioxide leads to the formation of zinc carbonate, whereas dissociation of zinc carbonate takes place on treatment in a vacuum. In recent years, many systems in which mechanochemical reactions take place in both directions have been detected[116]. If the rates of the forward and reverse reactions on mechanical treatment are equal, there is no overall macroscopic change in the system.

Table 1. Thermodynamic calculation of equilibrium constants[12].

Reaction	ΔG, kcal mole^{-1}	k_r, °K			
		298°	1000°	2000°	3000°
$Cu + H_2O_{gas} \rightarrow CuO + H_2$	+24.2	10^{-18}	10^{-17}	10^{-5}	10^{-4}
$2Cu + H_2O_{gas} \rightarrow Cu_2O + H_2$	+19.6	10^{-15}	10^{-5}	10^{-5}	10^{-3}

For purely thermal action, we speak of chemical equilibrium. In contrast to chemical equilibrium, the steady state produced on mechanical treatment is described as mechanochemical equilibrium.

Quantitative data on mechanochemical equilibrium in the system $CdC + CO_2 \rightleftharpoons CdCO_3$ have been obtained[116]. The dependence of the reaction rate on the carbon dioxide pressure and the composition of the solid phase are shown in Fig. 9. A positive value of the ordinate denotes the forward reaction, and a negative value the back reaction. For different compositions of the solid phase, the reaction rate becomes equal to zero at different CO_2 pressures. This steady state can be reached from two directions. Fig. 9 shows that mechanochemical equilibrium differs from chemical equilibrium. The position of chemical equilibrium does not depend on the concentration of carbonate in the solid phase. According to Gibbs' phase rule, in the carbonate system $MCO_3 + MO + CO_2$, each temperature corresponds to a definite CO_2 pressure. Thus the equilibrium pressure for the $CdCO_3 + CdO + CO_2$ system is $p_{CO_2} = 133 \times 10^{-6}$ mmHg at 298°K, whereas for the carbonate subjected to preliminary mechanical treatment $p_{CO_2} = 1.7$ mmHg at 298°K. It can be seen from Fig. 9 that on mechanical treatment the pressure corresponding to mechanochemical equilibrium depends markedly on the composition of the material undergoing size reduction. With change in the concentration of $CdCO_3$ from 50 mole % to 90 mole % the equilibrium pressure of CO_2 increases by approximately two orders of magnitude. For pure cadmium carbonate at mechanochemical equilibrium the CO_2 pressure is $p_{CO_2} =$ 660 mmHg at 298°K.

The next difference between mechanochemical and chemical equilibrium is that its maintenance requires the irreversible introduction of mechanical energy into the system. In this respect, mechanochemical processes are similar to photochemical and radiochemical processes.

As shown above, radical formation is possible when inorganic solids are ground. The first stage in a mechanochemical reaction may therefore be bond rupture and the formation of free radicals, the second stage being the reaction of the free radicals. Thus in some instances the overall picture of mechanochemical transformations shows features in common with radiochemical reactions[117].

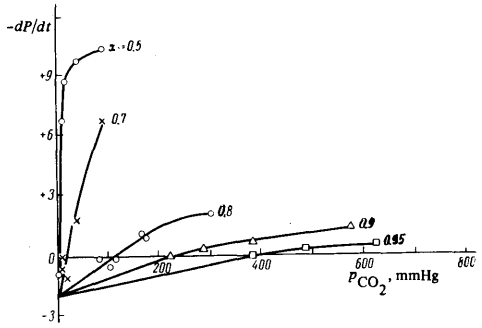

Figure 9. Dependence of the rate of reaction in the $CdO + CO_2 \rightarrow CdCO_3$ system on the pressure of CO_2 and the composition of the solid phase[116] (x is the mole fraction of $CdCO_3$).

The mechanochemical decomposition of alkali and alkaline earth metal nitrates, and the decomposition of sodium nitrate in the presence of heterophase (metal oxides) and homophase (added by cocrystallisation) additives have been studied[66] in order to compare the results with thermal, radiochemical, and photochemical decomposition. The results showed that, as in radiation decomposition, a correlation is observed in mechanochemical decomposition between the degree of decomposition and the free volume. The correlation is less distinct, however, than that for radiation decomposition. A correlation between the degree of mechanochemical decomposition and the order of the thermal stabilities of these compounds is not observed, however. An analogous picture is observed when the action of homophase and heterophase additives is compared.

3. Characteristic Kinetic Features of Mechanochemical Reactions. The Role of Non-equilibrium States

Since the decomposition of molecules on mechanical treatment takes place chiefly in the surface layers and the layers next to the surface, the rate of the mechanochemical decomposition of molecules is determined in the initial stages of size reduction by the rate of increase in the surface area, which depends on the nature of the substance undergoing size reduction and also on the type of size-reducing apparatus. After the particle radius during size reduction has decreased to the thickness of the surface layer, a constant maximal rate of decomposition is established. As a consequence of the recrystallisation which takes place on size reduction, however, a decrease in the rate of mechanochemical decomposition may take place after the maximum rate has been reached. If during size reduction conditions are created for the reverse reaction (for example through the difficulty of removing reaction products from molecularly compact aggregates), a state of mechanochemical equilibrium is established.

To explain the nature of the process of bond rupture in mechanically stressed molecules, Zhurkov[118] suggested that under the influence of stress, the F-energy [dissociation energy? (Ed. of Translation)] of the bond Q decreases by an amount of energy ϵF, and the rate constant for bond rupture k increases according to the equation

$$k = k_0 \exp\left(-\frac{Q-\epsilon F}{RT}\right) \quad (13)$$

where k_0 is a constant, with order of magnitude close to that of the vibrational frequency ($\sim 10^{13}$ s^{-1}).

It was shown above that the rate of mechanochemical processes either is weakly dependent on temperature or is characterised by a negative temperature coefficient[119], so that Eqn. (13) is not applicable in all instances.

To explain the nature of mechanochemical processes, Butyagin[120] introduced the concept of non-equilibrium states of bonds in molecules. This makes it possible to explain why small energies are sufficient to bring about mechanochemical decomposition (this differs from the "magma-plasma" model, according to which mechanochemical decomposition takes place as a consequence of the liberation of large amounts of energy on contact between colliding particles).

On mechanical treatment the energy of deformation of a bond is converted into thermal energy and redistributed between other bonds. This excess energy, the magnitude of which is much smaller than the bond strength, may be sufficient for the rupture of bonds present in a non-equilibrium state. On the basis of this assumption, Butyagin obtained an equation for the rate constant of the mechanochemical reaction, of the following form

$$k = A \exp\left(-\frac{E_M^*}{\Delta E_M}\right) \quad (14)$$

where A is a coefficient which takes account of the rate of redistribution of the mechanical energy in the system, E_M^* is the minimal mechanical energy required for bond rupture, and ΔE_M the average level of the excess energy.

It is assumed that on mechanical treatment of a substance, the rate of absorption of the mechanical energy supplied is to a first approximation proportional to the intensity of its introduction I, and the rate of relaxation of the stresses is proportional to the average level of the excess energy ΔE_M. In the steady state the rates of the two processes are equal, that is

$$\gamma I - k_r \Delta E_M = 0 \quad (15)$$

where γ is a dimensionless coefficient which takes account of the efficiency of absorption of the mechanical energy, and k_r the rate constant for the relaxation of the stresses. With allowance for Eqn. (15), Eqn. (14) becomes

$$k = A \exp\left(-\frac{k_r E_M^*}{\gamma I}\right). \quad (16)$$

If the dependence of the rate constant of a mechanochemical reaction on the quantity of mechanical energy introduced is determined, the values of A, E_M, and k_r can be calculated from Eqn. (16). Experimental data on the mechanochemical decomposition of polymethyl methacrylate and quartz, treated by means of Eqn. (16), give values of A 10^{-3}–10^{3}, $E_M^* \sim 10$–10^2 kcal, $\gamma \sim 1$–10^{-3}, and $k_r \sim 10^{-1}$–10^{-4} s^{-1}. It can be seen that E_M^* is much smaller than the bond energy Q, and A differs from k_0 by several orders of magnitude.

Analogous concepts were used by Bartenev and Razumovskaya[121] to develop the concept of the phonon breakdown of brittle solids. They consider that in the breakdown of solids it is necessary to examine not the thermal vibrations of the atoms but the propagation, interaction, and generation of phonons. The stages in the breakdown of a solid (the first is the formation of defects, and the second the growth of micro-cracks from these defects) can be regarded as independent processes only in the initial period. As the defects develop, the energy liberated on rupture leads to an increase in the density of phonons of definite frequencies (non-equilibrium phonons). This energy source influences both the development of the actual defect generating the phonons, and also the development of neighbouring defects.

There is thus a fundamental difference between the rupture of bonds in a solid and the rupture of bonds between isolated atoms in a molecule. The change to the phonon concept makes it possible, as the authors cited assert, to introduce for each structure a characteristic spectrum, which can be obtained experimentally, and also to use the achievement of the modern quantum theory of solids to develop a theory of breakdown processes.

V. PRACTICAL ASPECTS OF MECHANOCHEMISTRY

It follows from the foregoing that mechanochemical phenomena touch on a wide range of problems of practical interest. The utilisation of mechanochemical processes is proceeding along the following lines.

Intensification of dissolution and leaching processes. The conversion of sparingly soluble substances into a soluble state, usually carried out by heating with concentrated acids or alkali, or by fusion with active components (sodium carbonate, alkali, hydrogen sulphate, etc.) can be accelerated by mechanochemical treatment of the components to be dissolved. An increase in solubility under the influence of mechanochemical treatment is observed for many inorganic substances of practical importance. Data on the increase in solubility under the influence of mechanochemical activation for various substances are given in Table 2.

Increase in the rate of decomposition and synthesis. The problem of increasing the rates of chemical reactions is extremely important, particularly for solid-phase reactions. The reaction product formed at the contact between the granules has a blocking influence on solid-phase reactions. When the reaction is carried out under conditions of intensive mechanical treatment, the reaction product is removed and the surface is renewed, with a consequent significant increase in reaction rate. Moreover, the preliminary mechanochemical treatment of substances not only can provide a means of preparing substances to increase the rate of a reaction, for example with heating, but also can provide an independent and the only possible method of decomposing or preparing substances. Examples of processes which it has been possible to carry out by means of mechanical activation are the preparation of rongalite[126], phosphors[82], metallates[81], organometallic compounds[83], complex compounds[4], catalysts[75,76,127], etc.

Activation of catalysts. On mechanical treatment, the activity of catalysts changes not only as a result of a change in the surface but also as a result of the fact that some of the kinetic energy of the solids in friction is

transferred to the surface. The stresses created in the surface layers are sufficient for breakdown of the structure and rearrangement of the atoms and molecules to form less ordered structures exhibiting a higher potential energy than the ordered crystal structure.

Table 2. Increase in the solubility of inorganic substances under the influence of mechanochemical activation.

Substance	Solvent	Duration of grinding in mill, h	Duration of dissolution, h	Quantity transferred to solution, % of original	Refs.

Study of the catalytic activity of nickel oxide [128] and zinc oxide [129] established that the catalytic activity increases with increase in the degree of subdivision. It was shown that the catalytic activity changes in step with the breakdown of the crystal lattice.

The dependence of the catalytic activity of α-Fe_2O_3 on the duration of mechanical treatment passes through a maximum. According to Schrader [130], the activity of α-Fe_2O_3 at the maximum (grinding for 16 h) in the oxidation of carbon monoxide to carbon dioxide is greater than the activity of the original catalyst by a factor of 5. Analogous data were obtained for catalysts such as copper oxide [131], magnesium oxide [132], alumina [133], etc. [134–137].

The influence of mechanical treatment on the temperature of reduction of oxides has been studied [138]. After treatment for 20 h, the temperature of the start of reduction was decreased by 80 deg for Fe_2O_3, 75 deg for Fe_3O_4, 50 deg for NiO, and 40 deg for CuO.

Mechanical treatment also alters considerably the properties of complex catalysts. It has been shown [139] that prolonged grinding of an aluminosilicate catalyst alters its acidic properties, leading to a decrease in the catalytic activity of the catalyst in the depolymerisation of paraldehyde in benzene solution. Annealing of a catalyst treated in this way leads to the restoration of its activity. Infrared spectroscopic data indicate that water molecules, bonded to the surface by hydrogen bonds, appear on the catalyst surface during size reduction.

The use of mechanochemical treatment for the preparation of new catalysts also appears promising. This method has been used, for example, to prepare a mixed vanadium–molybdenum–aluminium catalyst, used for the oxidation of acrolein, with increased activity and selectivity [75], iron and zinc ferrites [77], etc.

Preparation of substances with new properties. Mechanochemical treatment can be used to solve problems in the modification and improvement of the properties of such substances as adsorbents, zeolites, binding agents, etc. The ability of kaolin to form zeolites on grinding has been studied [140]. It has been established [142] that on dispersion, aluminosilicates are converted into minerals of the kaolinite group. The mechanochemical technology of the production of binding agents from industrial wastes is being developed [143].

Separation of elements with similar properties and the components of complex mixtures. A procedure has been proposed [29] for the extraction of titanium from titanium magnetic ores by mechanical treatment followed by thermal treatment and dissolution in hydrochloric acid. After these operations, TiO_2 passes into solution, and iron(II) oxide is converted into insoluble iron(III) oxide.

A method for separating pyrite and haematite by grinding a mixture of these minerals in the presence of ammonium nitrate has been proposed [72]. On grinding, pyrite is converted into acid-soluble iron sulphate, and haematite remains in the insoluble residue. This operation can be used to separate other substances, for example lead from iron, etc.

Elements with similar properties can also be separated by making use of differences in the rates of their mechanochemical decomposition.

Improvement of existing technological processes. Mechanochemical reactions take place in chemical technology during the size reduction of substances and their mixtures at ordinary temperatures. Little attention has been paid to these reactions until now. For example, before flotation, pyrite is subjected to size reduction in the presence of moisture and atmospheric oxygen. Size reduction is accompanied by the formation of water-soluble oxidation products (sulphates, sulphides, hydroxides, oxides, etc.), and these are lost on flotation [144]. Analogous losses take place in the processing of other mineral products.

Mechanochemical methods of activating a substance in order to increase solubility, separate substances, etc. are also promising in that they make it possible to reduce the consumption of water, a shortage of which has recently been noted. Certain preparations which are usually carried out in aqueous or organic media can be carried out in the solid phase. The reduction of, for example, metals from their sulphides [145] and oxides, etc., can be carried out in this way.

In conclusion it may be noted that despite the fact that the theoretical interpretation of mechanochemical phenomena, because of the complexity of the processes taking place and the restricted nature of the methods for studying them, is extremely far from complete, mechanochemistry has already progressed beyond the trial stage and is providing a means of solving fundamental problems facing chemistry, such as the development of methods for decomposing and preparing substances, and methods for the directed control of chemical reactions.

Influence of Electronic Interactions with the Carrier and of State of Dispersion of the Metal on the Catalytic Activity of Supported Metal Catalysts

A.A.Slinkin and E.A.Fedorovskaya

The application of the metal-semiconductor boundary layer theory to the study of the catalytic properties of supported metal catalysts is discussed. Published work on the structure of very small metal crystals and on anomalous adsorption and catalytic centres in such crystals is discussed with particular reference to the dependence of catalytic activity on the state of dispersion of the metal deposit. 103 references.

I. INTRODUCTION

The chemistry of catalysis has made important advances during the past 15–20 years, and a deeper understanding of the nature of the catalytic act and of catalyst structure has been acquired by applying new theoretical concepts based on recent advances in solid-state theory, as well as new physical methods of investigation.

The electronic theory of catalysis on semiconductors developed by Vol'kenshtein, Hauffe, and others, and Dowden's use of the concept of *d*-band filling to explain the catalytic properties of transition metals and their alloys, have clearly shown the importance of the collective properties of solids in the field of catalysis.

These ideas have been tested by electrical, magnetic, optical, and other methods, and as a result of this work some new and more precise concepts (involving crystal field and ligand field theories) have emerged. In addition to the collective properties of the solid, the local properties of an individual atom or ion in the lattice (determined by its electronic structure and co-ordination) began to attract attention.

These problems were considered in detail at the Fourth International Congress on Catalysis, held in Moscow, and also in the Symposium on Electronic Phenomena in Catalysis.

This review is concerned with both collective and localised interaction problems in supported metal catalysts, which include a large proportion of all modern industrial catalysts.

Relevant theoretical problems include the mechanism of the interaction between the metal and the carrier, the specific properties of small metal crystals, the relationship between the size and the catalytic activity and selectivity of such crystals, the influence of the carrier on the activity and selectivity of the catalyst, etc.

The past decade has witnessed some important advances in the study of metals on carriers [1], resulting from the development of techniques for the direct examination of disperse metal (magnetic measurements, electron microscopy, X-ray and electron microprobe analysis, CO and H_2 chemisorption). The detailed studies of supported platinum [2,3] and nickel [4–8] on various carriers will be discussed below.

No attempt will be made to review the whole of the work on supported catalysts published during the last few years. We shall deal mainly with the more complex studies of catalysts, which throw light on their structure and physical properties as well as on their precise catalytic activity.

II. ELECTRONIC ASPECTS OF METAL–CARRIER INTERACTION

The role of the carrier in mixed (metal–carrier) catalytic systems has long been thought [9] to be merely structural (protection of the dispersed metal from sintering phenomena, preservation of the large surface area and orientation of the crystals). The development of an electronic approach to catalysis, by Roginskii [10], Vol'kenshtein [11], Hauffe [12], Dowden [13], and others, has brought about a reappraisal of the role of the carrier, for which Schwab and his coworkers [14] have been mainly responsible.

Essentially, the electronic theory of catalysis states that a definite (though indirect) relationship exists between the concentration of current carriers and the Fermi level in the solid on the one hand and the catalytic activity of the solid on the other hand. A change in the semiconductor properties of the carrier, according to Schwab, should produce a corresponding change in the electronic properties of the deposited metal in contact with the semiconductor, and hence it should enhance (or inhibit) the catalytic reaction, since both the catalytic act and its precursor stages (chemisorption of reactants) involve a redistribution of the electron density between catalyst and reacting system.

Schwab's hypothesis was tested experimentally by studying a model reaction of a well characterised type (the dehydrogenation of formic acid). Assuming that the reaction involves electron transfer from the formic acid molecule to the metal, the theory predicts that if the Fermi level in the metal is raised by electronic interaction with the semiconductor the activation energy of the dehydrogenation reaction should increase, and conversely that a decrease in the Fermi level should lower the activation energy of the reaction. Experiments of this type were made by Schwab and coworkers [15] with the following catalysts: metallic nickel, cobalt, and silver, deposited on variously doped (2–5 mol.%) Al_2O_3 samples. Aluminium oxide is an *n*-type semiconductor and is inactive towards the dehydrogenation of formic acid when

heated above 900°C. Addition of oxides of lower-valency metals (NiO, BeO) lowers the electrical conductivity of Al_2O_3, whereas oxides of higher-valency metals (GeO_2 and TiO_2) increase the conductivity. The doped carriers were heated at 1050°, and coated with a thin film of nickel, cobalt, or silver by evaporation in a vacuum. As a control, the dehydrogenation of formic acid was also studied on films of these metals deposited on the corresponding massive metals.

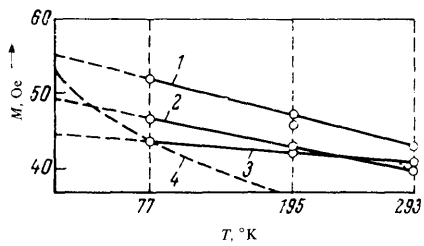

Figure 1. Thermomagnetic curves of Ni on carriers: *1*) Al_2O_3 + NiO; *2*) Al_2O_3; *3*) Al_2O_3 + TiO_2; *4*) shape of the thermomagnetic curve for small nickel particles.

As expected, the activation energy of the reaction was found to be lower than for pure Al_2O_3 on the samples doped with NiO and BeO, and higher on the samples doped with TiO_2 and GeO_2. An attempt was made to demonstrate experimentally the transfer of electrons from TiO_2-doped alumina to the metal by measuring the saturation magnetisation of the nickel and comparing the saturation magnetic moment with that of nickel on pure Al_2O_3. The metal particles were assumed to be very small and in intimate contact with the carrier. The thermomagnetic curves (Fig. 1) of three catalysts were measured: Ni on Al_2O_3, Ni on Al_2O_3 + TiO_2, and Ni on Al_2O_3 + NiO. The curves were measured in the temperature range 77 to 293°K, and extrapolated to 0°K: the magnetic moment was found to be largest on the carrier Al_2O_3 + TiO_2, and smallest on the carrier Al_2O_3 + NiO.

Schwab's next experiment was made with nickel deposited on the *n*-type semiconductor ZnO,[16] doped with Li^+ (which lowers its conductivity) or Ga^{3+} (which increases it). The catalysts were prepared by heating mixtures of the nitrates, and reducing the resulting mixture of oxides to give (according to the authors) very small crystals of nickel in a matrix of ZnO. Another donor reaction was also examined: the hydrogenation of ethylene. The rate of hydrogenation of ethylene (referred to 1 g of nickel) was found to increase when the ZnO contains fewer conduction electrons, i.e. in the presence of Li^+, and to decrease when the concentration of conduction electrons in ZnO is enhanced by adding Ga^{3+}.

Schwab also discusses the ammonia synthesis catalysts[14] from this point of view. He considers that in this case the most important additive is potassium oxide. which has the same effect on Al_2O_3 as BeO,[15] i.e. lowers the concentration of conduction electrons. Since the synthesis of ammonia is a complicated process, the simpler dehydrogenation of formic acid was studied on ammonia synthesis catalysts with and without additions of K_2O. Addition of 1% of K_2O lowers the activation energy from 18 to 13 kcal mole^{-1}, and 2% lowers it to 7 kcal mole^{-1}. Addition of an oxide of higher valency (GeO_2), which increases the conductivity of Al_2O_3, produces the opposite effect: the activation energy increases to 23 kcal mole^{-1}. Thus, Schwab concludes that in the dehydrogenation of formic acid the additives to the Al_2O_3 have an overriding effect both on the electrical conductivity of the alumina and on the catalytic activity of the iron.

Szabo and Solymosi[17] adopted a similar approach to the study of the decomposition of formic acid on Ni–Cr_2O_3 and Ni–TiO_2 catalysts, in which the carriers were doped with ions of different valency (Be, Al, W, Sb, Ni, Cr) in order to alter their conductivity. The pure and the doped carriers were heated at 900°, impregnated with a solution of nickel nitrate, and reduced in hydrogen. Unlike Schwab and his coworkers, these workers determined the extent of reduction of the nickel by measuring the hydrogen evolved on dissolving the catalyst in dilute perchloric acid. The activity was again measured by the activation energy of the dehydrogenation of formic acid. On a pure TiO_2 catalyst the reaction proceeds with an activation energy of 31 kcal mole^{-1}, and on pure Ni the activation energy is 24.6 kcal mole^{-1}. When the Ni is deposited on TiO_2 (in 0.2–3% amounts) the activation energy falls to 22.0 kcal mole^{-1}. Addition of 2% Sb_2O_3 to the carrier raises its electrical conductivity, and the activation energy correspondingly rises by 2 kcal mole^{-1}; addition of 1–5% BeO lowers both the conductivity and the activation energy. Doping the carrier with chromium oxide produced an anomalous result: according to Hauffe Cr_2O_3 increases the conductivity of TiO_2, but Szabo and Solymosi found that the activation energy is lowered. They explain the anomaly by pointing out that the conductivity in this system is affected by the atmosphere in which the measurements are made, and that in a reducing atmosphere the conductivity of titanium dioxide is decreased by doping with chromium oxide, i.e. the Cr^{3+} ions behave like typical lower-valency ions. With Ni–Cr_2O_3 catalysts, on the other hand, addition of titanium dioxide (0.5–5%) to the chromium oxide increases the activation energy and addition of nickel oxide (0.5–5%) lowers the activation energy, with corresponding effects on the electrical conductivity of the carrier. The authors also studied the effect of temperature (400 and 500°) and of time of reduction (1–10 h) on the activation energy of the decomposition of formic acid. In both cases the activation energy increased at 500° and on extending the duration of the reduction. Szabo and Solymosi explain this finding by suggesting that the amount of Ni/NiO in the catalysts decreases as the extent of reduction increases: as previous workers had shown[18], this couple is more active than pure nickel towards the decomposition of formic acid. In the case of Ni–Cr_2O_3 catalysts the resulting spinel is a better carrier for Ni than pure chromium oxide, and the activation energy for the reaction falls to 7 kcal mole^{-1} (for a catalyst containing 5% of NiO) on raising the temperature.

Langenbeck and coworkers[19] studied the effect of *n*-type metal oxides on the catalytic properties of nickel towards the reactions of cyclohexane. They found that the *n*-type oxides ZnO, CdO, TiO_2, and ThO_2 alter the selectivity of the reaction in favour of dehydrogenation to benzene. Several series of preparations were investigated. Initially, zinc oxide was introduced as the third component in Ni–MgO and Ni–Al_2O_3 catalysts at the oxalate or hydroxide coprecipitation stage. The ternary catalysts gave a much higher yield of benzene than the binary catalysts without ZnO. It was subsequently found that a high dehydrogenation activity can be obtained with simple mechanical mixtures of ZnO and the binary catalysts, or by adding zinc powder to the binary catalysts.

Additions of CdO, ThO_2, and TiO_2 were also examined. CdO was very effective at low concentrations, but it was reduced by hydrogen to metallic cadmium at temperatures just above 300°: the cadmium was lost from the bulk of the catalyst by evaporation, and the selectivity reverted to its original value. Addition of TiO_2 and ThO_2 has an appreciable effect only on the $Ni-Al_2O_3$ catalyst, and addition of oxides which are not *n*-type semiconductors (BaO, MgO) has no effect on the properties of nickel. Langenbeck and coworkers, like Schwab, explain these effects by postulating transfer of electrons from the *n*-type oxides to the 3*d* shell of nickel, with the following results: 1) the activation of hydrogen with electron transfer to the nickel, a necessary condition for the degradative hydrogenation of cyclohexane to methane, is prevented by the filling of the 3*d* band of the nickel; 2) the possibility of electron transfer from the cyclohexane molecule to the nickel, with consequent deformation of the chemisorbed molecule and breaking of the C–C bonds, is also excluded. In practice, the observed dehydrogenation (as opposed to degradation to methane) may be due to a combination of these two factors. Another important aspect should be stressed. All promoters are oxides which are partly reduced to metals capable of forming alloys with nickel [20] under the conditions of the reaction: this effect also tends to fill the 3*d* band of the nickel. No clear-cut distinction can be drawn between the electronic effect of the *n*-type semiconductor oxide and the effect of alloying. The main conclusion from this work is that the enhanced selectivity afforded by zinc oxide is due to a change in the electronic properties of the nickel.

Nehring and Dreyer [21] extended this work by studying the reactions of cyclohexane in the presence of a $Ni-Al_2O_3$ catalyst in which the Al_2O_3 was doped with TiO_2 and ThO_2.

They tried to explain the observed dependence of the dehydrogenating activity of the catalyst on the composition of the oxide carrier in terms of the accompanying changes in the electrical conductivity of the carrier. The additions of ThO_2 and TiO_2 were made at the hydroxide coprecipitation stage. The electrical conductivity of the carriers was measured after heat treatment at 1200° (for ThO_2) and 1050° (for TiO_2) because the results obtained after heat treatment at 900° were not reproducible. Measurements of electrical conductivity were carried out in a stream of hydrogen. The conductivity of Al_2O_3 doped with ThO_2 went through a sharp maximum at 1–2% ThO_2, whereas in the $Al_2O_3-TiO_2$ system the conductivity increased continuously with TiO_2 concentration, rapidly at first (up to ~5%) and more slowly up to 100% TiO_2. The nickel was introduced by impregnating the carrier with nickel formate and reducing in a stream of hydrogen (5 wt.%). The decomposition of cyclohexane was studied at 400°: with $Al_2O_3-ThO_2$ catalysts the maximum concentration of benzene in the condensate was obtained with the catalyst containing 10% of ThO_2, and with $Al_2O_3-TiO_2$ catalysts the optimum composition was 1% of TiO_2. Neither of these compositions corresponds to an extremum in the electrical conductivity. The changes in catalytic activity were correlated also with changes in the total surface area of the catalysts. In both systems, the surface area is decreased drastically by small additions of the second oxide, but in the case of TiO_2 the decrease in area occurs in the region of composition corresponding to the maximum yield of the dehydrogenation reaction, whilst in the case of ThO_2 no correlation is found. The lack of correspondence between the maxima in conductivity and in activity is not understood. The results are discussed from the conventional standpoint of changes in the electronic properties of the carrier. It is assumed that the high dehydrogenation activity of Zelinskii and Komarevskii's [22] $Ni-Al_2O_3$ catalyst arises from a modification of the properties of nickel by the conduction electrons of the weakly *n*-type aluminium oxide. Since the addition of higher-valency oxides raises the conductivity of *n*-type semiconductor oxides, the increased selectivity of alumina produced by additions of ThO_2 and TiO_2 is ascribed entirely to this effect.

We have discussed a group of papers characterised by a common approach to the catalytic properties of metals supported on a carrier. Schwab's paper [15], in particular, played a pioneering role in this work and stimulated further research. However, the present writers believe that both the original and the subsequent work contains serious errors.

Firstly, an intimate contact between the phases (i.e. a high degree of dispersion of the deposited metal) is a necessary condition for the postulated, reversible electron transfer between the carrier and the metal. But, as Block pointed out in the discussion of Szabo's paper at the Second Congress on Catalysis [23], even if the metal particles contain as few as 10^3-10^4 atoms the influence of charge transfer on the concentration of electrons and on the position of the Fermi level in the metal is negligibly small. We may consider whether the above condition is fulfilled in the published work. In every case the carrier was heat treated at temperatures of the order of 1000° and, therefore, its surface area was not very great. Hence it is difficult to believe that under these conditions the nickel particles were small enough. Schwab and coworkers [15], assuming their nickel to be very finely divided, quote the effect of additives on the saturation magnetic moment of the nickel as their main evidence for electron transfer from the carrier to the metal. However, the thermomagnetic curves reproduced in Fig. 1 are typical of coarsely divided nickel, and the small difference in the magnetisation of the three catalysts at 77°K (the lowest measurement temperature) is probably due to small differences in the extent of reduction of the metal, which the authors assumed to be 100% without proof. Correct extrapolation to 0°K, with due allowance for the variable extent of reduction, should lead to a single value for the saturation magnetisation, and not three different values as found by the authors. Schwab and Mutzbauer [16] assume that the nickel in their catalysts is present as small particles in a ZnO matrix, but they do not substantiate their claim, which is inconsistent with a recent report [24] that nickel crystals of 360–400 Å diameter are the most stable in a ZnO matrix.

Secondly, all the work discussed attempts to correlate electrical conductivities measured at 900° with activation energies for a chemical reaction at 250–400°. There can be no doubt that the electronic properties of the carrier may be altogether different at the temperature of the catalytic reaction.

Thirdly, the activation energy is not necessarily the best measure of catalytic activity, because of the possibility of compensation which Schwab himself points out [15] without proving that the same kinetic equation applies to all the catalysts used in his experiments. Szabo and Solymosi [17] ascribe significance to changes in E_{act} of 2 kcal $mole^{-1}$, which lie within experimental error, and Langenbeck [19] estimates activity from the percentage conversion of cyclohexane into benzene. Much more reliable means of comparing catalytic activities are needed in order to characterise the more subtle physical effects [25].

Fourthly, no one has considered the direction of electron transfer, i.e. whether the electrons are donated to the conduction band of the metal (where they would have no effect on the magnetic properties), or whether they populate the narrow d_e band (where they would alter the saturation magnetic moment of the Ni atom). Although we do not know whether d electrons (which determine the magnetic properties of ferromagnetic materials) take part in electrical conduction[26], it is important to establish the direction of electron transfer when discussing catalytic activity. If the electron transfer produces a change in the magnetic moment (i.e. an effect analogous to the addition of diamagnetic metals to the nickel), Dowden's theory predicts a decrease in catalytic activity. However, if the electron enters the conduction band there should be no change in the catalytic properties of the nickel, because the resulting contribution to the total number of conduction electrons in the nickel is negligibly small.

In order to understand the physical nature of the charge transfer effect a more detailed consideration of the metal–semiconductor interface is required. We shall assume that an n-type semiconductor (work function φ_S) is in contact with a metal (work function φ_m), where $\varphi_m > \varphi_S$ (see Fig. 2).

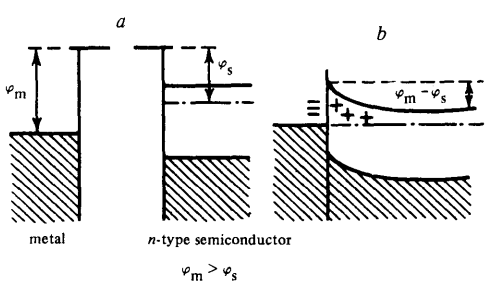

Figure 2. Energy levels at the contact between a metal and an n-type semiconductor: *a*) before contact; *b*) after contact

Since $\varphi_S < \varphi_m$, electrons will pass from the semiconductor into the metal until their chemical potentials (Fermi levels) in the two phases are equal. As a result, the layer of semiconductor immediately adjacent to the metal is depleted of current carriers and becomes positively charged, and the metal becomes negatively charged. The barrier (called a Schottky barrier) which appears at the interface is responsible for contact rectification phenomena.

It is evident from the above that the most important parameter in contact phenomena is not the concentration of current carriers in the semiconductor but the ratio of the work functions in the metal and the semiconductor. Yet, all the published work attempts to correlate catalytic activity with electrical conductivity, and work functions are completely ignored. It certainly cannot be assumed (e.g., in the case of an n-type semiconductor) that the electrical conductivity and the work function must vary in the same sense as a result of doping.

Thus, there are two prerequisites to a correct evaluation of the potential jump which appears at the boundary between the two solid phases: 1) the system must be capable of being described in terms of Schottky's theory[27]†, and 2) the ratio of the work functions in the two phases must be unaffected by interactions with the reacting system. However, even these conditions are necessary but not sufficient. The theory of surface and contact rectification, developed as a branch of semiconductor physics[28], states that the potential barrier at the interface can be modified by the presence of extraneous, poorly conducting layers between the metal and the semiconductor, such as oxide layers (which are termed chemical barrier layers), and also by chemical impurities or lattice defects at the surface (which are termed surface states). Furthermore, doping can have uncontrolled side effects on the catalytic activity by altering the structure type of the lattice, the porosity, and the grain size (i.e. the specific surface area, see Ref. 21). It is clear, therefore, that the state and the properties of the boundary layer in the metal–carrier system are controlled by many factors, and that *a priori* conclusions on the transfer of electrons from the carrier to the metal based only on measurements of the electrical conductivity of the carrier can be of little value. For this reason, attempts are being made to modify the electronic properties of semiconductor catalysts by methods other than doping, e.g. by irradiation with visible and u.v. light during the reaction[29]. Recent data are reviewed by Steinbach[30].

The carriers used by Schwab, Szabo, and Nehring were sintered oxides showing only weak semiconductivity. In the whole of their work the electronic effect of the carrier on the catalytic properties of nickel was only qualitatively assessed. Baddour and Deibert's attempt[31] to demonstrate in a quantitative way the promoting effect of electronic interactions between the carrier and the metal on the decomposition of formic acid is therefore particularly interesting. Germanium, both pure and doped with 0.01% of Zn, Sb, and As, was used as the carrier, to enable the concentration and mobility of the current carriers to be measured by the Hall effect in single crystals of the same composition. Zn-doped germanium becomes a p-type semiconductor, and germanium doped with Sb or As becomes an n-type semiconductor with a known concentration of conduction electrons. The carriers were prepared by grinding Ge single crystals in a vacuum (to avoid atmospheric oxidation). The nickel catalyst was deposited on the carriers by quantitative decomposition of nickel carbonyl. The surface area of the samples was measured (658–1143 $cm^2\ g^{-1}$), and the number of Ni monolayers was calculated (1–18.5). The potential difference at the Ni/Ge interface was calculated by Schottky's theory[27] of contact phenomena at a metal–semiconductor boundary. (A similar calculation[32] for various metals in contact with silicon had given good agreement with experiment). Using the known work functions of Ni (4.96 eV) and Ge (4.78 eV), the authors evaluated the concentration of electrons in the boundary layer of germanium at 240° (the reaction temperature) as 1.4×10^{15}, and also the extent of electron transfer from Ge to Ni for all three dopings. The results are summarised in Table 1.

The activity of pure Ni and Ni/Ge catalysts towards the dehydrogenation of formic acid was studied in a flow reactor at 240 ± 30°, and it was found to decrease with time (particularly in the case of pure nickel). The activity was therefore identified with the initial rate of reaction.

†This condition requires an intimate contact between the two phases and a large area of contact, which are achieved by preparing the metal catalyst in a highly disperse state (see above).

The kinetic order of the reaction (with respect to formic acid) is close to unity on Ni/Ge catalysts and close to zero on pure Ni. As well as the specific reaction rates (per 1 m^2 of total surface area), the authors measured the activation energies and the pre-exponential factors. As the number of Ni layers on the carrier decreases, the activation energy was found to increase sharply from 10 kcal $mole^{-1}$ (for 13–18 layers) to 18–34 kcal $mole^{-1}$ (for 6 and 4 layers respectively). However, due to the compensation effect, the specific reaction rates differed by less than an order of magnitude and increased with the number of atomic layers (for example, for Ni/Ge(Sb) catalysts, from 4×10^{-4} to 22×10^{-4} mole h^{-1} m^{-2} as the number of layers increases from 1 to 18). It is interesting to note that the specific rate of dehydrogenation of formic acid on pure Ni is 3–4 orders of magnitude higher than on supported nickel. The authors compared the specific activities of the three types of Ni/Ge catalyst (doped with Zn, Sb, and As), allowing for the number of layers of deposited nickel (i.e. for the thickness of the metal deposit). Over the thickness range 4–13 layers, the ratio of the activities remained constant (Zn : Sb : As = 1 : 3 : 4). As Table 1 shows, the extent of electron transfer increases in the same order by a factor of 100. The transfer of one electron from the carrier for every 10^5 nickel atoms is found to increase the activity of the metal towards the dehydrogenation of formic acid by a factor of 1.33–3. According to the authors, this indicates that the limiting step in the decomposition of formic acid is dissociative chemisorption, with formation of a negatively charged formate group on the surface (step *1*):

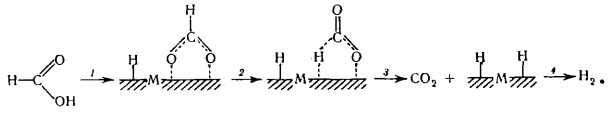

Table 1.

Carrier	Electronic properties	
	Concentration of conduction electrons at 240°, n_s, cm^{-3}	Equilibrium charge transfer at Ni–Ge interface, σ, cm^{-3}
p-type semiconductor		
Zn doped	3×10^{16}	7.3×10^{10}
n-type semiconductor		
Sb doped	3.4×10^{17}	5.3×10^{11}
As doped	2.4×10^{19}	3.7×10^{12}

An electron is transferred from the catalyst to the formic acid molecule. Of course, an increase in the concentration of electrons in the catalyst should assist this step of the reaction. Thus, according to the authors, electron transfer from the carrier to the metal is a very important factor in catalysis. Although their paper describes a well conceived and original physicochemical investigation, an analysis of their results reveals a number of weaknesses. First of all, as the authors themselves point out, effective electronic interaction at the metal–carrier interface requires a large interface area (i.e. a very small metal particle size). This condition does not appear to be fulfilled in their experimental conditions, since the germanium particles have only a moderate surface area (600 to 1100 cm^2 g^{-1}) and it is difficult to believe that the nickel can exist on these coarse particles as very fine crystals. The catalytic activity is related to 1 m^2 of total surface area rather than 1 m^2 of active surface area. The latter, apparently, decreases as the thickness of the deposited layer increases, and therefore the authors' conclusion that the activity increases with the number of layers is not convincing. Furthermore, an increase in catalytic activity by only a factor of 3 is usually interpreted as a constant activity [33,34]. It is also well known that the bulk properties of germanium can differ very substantially from the properties of its surface [35,36], which can be treated as "quasi-isolated". Therefore, Hall measurements of the electronic properties of germanium single crystals [37,38], both pure and doped, may be entirely irrelevant to the electronic properties of the surface of the germanium carrier. Furthermore, the work function of *n*- and *p*-type doped germanium is the same [39]. In any case, the characteristics of the electronic properties of the carriers had been determined before the materials were powdered and coated with nickel. It is well known that fracture can introduce various defects and dislocations in the crystal lattice, leading to the formation of large numbers of surface states which can have a profound effect on the electronic properties of the carrier surface. Lastly, the main conclusion that the transfer of one conduction electron from the carrier per 10^5 nickel atoms can have a significant effect on the catalytic activity is difficult to accept.

As regards the assessment of the catalytic activity, this work is a considerable step forward in comparison with the work of Schwab and Szabo, since the specific reaction rate (rather than the activation energy) is taken as a measure of the activity. But the observed time-dependence of the catalytic activity, and the need to extrapolate the measured rate to zero time, make the comparison of the catalytic and the physical properties of the various materials less than convincing.

Equally unconvincing is the assumption that electron transfer from the semiconducting carrier to the metal (where the concentration of intrinsic conduction electrons is higher by several orders of magnitude) can have a significant effect on the catalytic properties of the metal. Perhaps for this reason, Schwab has recently begun to develop a new approach to the problem: he has used semiconductor catalysts deposited on catalytically inert metals. Thus, the oxidation of CO has been studied on a nickel oxide catalyst deposited on silver [40], and the oxidation of SO_2 on iron oxide deposited on silver alloyed with palladium and mercury [41]. A study has also been reported [35] of the oxidation of methanol in the presence of a ZnO.Ag mixture and of separate samples of ZnO and Ag in various proportions by weight, which show a synergistic effect even when located in different parts of the reactor. In the presence of a metallic carrier the active phase (the semiconductor) is enriched or depleted of current carriers, and this effect controls its catalytic activity. Physical evidence for this hypothesis is provided by the observation, by Schwab and Kritikos [36], that the electrical conductivity of ZnO, NiO, and Cu_2O is affected by the addition of a small percentage of Ag. The latest paper in this series was published in 1969, [42] but a detailed analysis of its results lies beyond the scope of this review.

III. INFLUENCE OF STATE OF DISPERSION AND OF CARRIER ON THE CATALYTIC ACTIVITY OF SUPPORTED METAL CATALYSTS

The relationship between the catalytic activity and the degree of dispersion of the active component is one of the

basic problems of heterogeneous catalysis. In the case of metallic catalysts supported on a carrier, the following questions need to be answered first: whether the catalytic activity depends on the particle size of the deposited metal, whether the formation of a crystal lattice having the properties of the massive metal is a necessary condition for catalytic action, and lastly whether there is an optimum crystallite size giving the maximum catalytic activity. During the 1930's Dankov and Kochetkov [43] studied the hydrogenation of ethylene and the decomposition of H_2O_2 on platinum, and noted a maximum in the activity for a crystal size of 40–50 Å, followed by a rapid fall to zero activity for a diameter of 20 Å. Rubinshtein [44] found the optimum crystal size of nickel on Al_2O_3 for the dehydrogenation of alcohol in the region 60–80 Å. But only recently has a full appreciation of these problems been made possible by careful measurements of the specific catalytic activity per unit area of metal surface, combined with various physical methods of measuring the dispersenes of the metal (electron microscopy, X-ray line broadening, magnetic methods, H_2 and CO chemisorption, etc.). In spite of these advances, the problems are still controversial.

1. Platinum on Carriers

In 1953 Boreskov formulated the hypothesis [33] of constant specific catalytic activity in catalysts of constant chemical composition. He considered the specific activity to be determined mainly by factors such as the chemical composition and the chemical structure of the catalyst. The hypothesis was confirmed by the results obtained by his research team, who found that the specific activity of Pt towards the oxidation of SO_2 [45] and of hydrogen [46] varies by less than an order of magnitude as the specific surface area of the catalyst is varied by 4 orders of magnitude (Pt/SiO_2, and massive platinum in the form of sponge, wire, and foil).

However, the work of Boreskov ignores the influence of the surface structure of the platinum crystals on the catalytic activity. The problem was first formulated by Poltorak, who proposed the "mitohedric method" [47] to deal with it. The method, which is based on a crystallographic description of the co-ordination numbers of the atoms and of the fraction of the atoms in various states within the lattice, involves the following steps. Atoms of three types are considered: 1) atoms associated with microdefects on the surface of large crystals, 2) atoms on crystal edges, and 3) atoms on crystal faces. In order to distinguish their effects, we must compare the specific activities of equilibrium crystals in three regions of crystal size: 10–20 Å (average co-ordination number $\bar{x} < 6$; the atoms are equivalent to microdefects), 20–40 Å ($\bar{x} = 7$, edge elements), and 100–∞ ($\bar{x} = 9$, as on the perfect faces of an infinite crystal). Metal catalysts covering the desired range of crystal size were prepared in the form of platinised silica gels, and the Pt surface area was measured by the hydrogen chemisorption method. Somewhat later, the authors developed the "absolute adsorption isotherm" method [48] of measuring surface area. Many different hydrogenation and dehydrogenation reactions were studied: the hydrogenation of hex-1-ene, cyclohexene, and allyl alcohol [47], the dehydrogenation of cyclohexene [49] and isopropanol [50], the hydrogenolysis of pentane [50], etc. As a result, it was shown that the specific activity of faces, edges, and crystal defects in platinum is approximately constant. Anomalies in the activity were found to be associated not with surface structure, but with changes in the chemical composition of the adsorption layer (oxygen effect, varying degrees of deactivation of the catalyst as a result of secondary reactions, etc.). Poltorak's results appear to confirm Boreskov's hypothesis of constant specific activity [33], with the single exception that Poltorak's experiments dealt with the range of crystal sizes in which the effect of structure on catalytic activity should be apparent (10–50 Å), whereas Boreskov looked for this effect in a region of particle size (> 50 Å) where, according to Poltorak, the effect is normally absent.

In contrast to the results for hydrogenation and dehydrogenation catalysis, studies of the oxidation of ethanol on platinised silica gel revealed a 100-fold decrease in specific activity on changing from a particle size of ~40 Å to 11 Å particles [51]. With particles greater than 40 Å the activity remained constant, and equal to that of platinum black. Thus, crystal faces are the most active elements towards oxidation. It is interesting to note that Poltorak and coworkers did not find a single instance of enhanced activity at edges or crystal defects: this experimental fact is in direct conflict with the widely held belief that co-ordinationally unsaturated atoms in the platinum lattice have a high specific activity.

Boudart and coworkers [34] extended Boreskov's studies of the specific activity of Pt on carriers. They examined a new system—Pt on Al_2O_3, both γ and η forms—in which the platinum is very highly dispersed and the metal particle size can be accurately controlled by raising the temperature at which the catalyst is formed. They showed that the specific activity of their catalysts towards the hydrogenation of cyclopropane was independent of the amount of platinum on the catalyst, of the crystalline form of the alumina, and of the nature of the carrier (Al_2O_3 or SiO_2). By covering the range from highly disperse platinum, in which practically every atom is on the surface, to platinum foil, the specific activity varied by a factor of two whilst the specific surface area varied by 4 orders of magnitude. Thus, in this work, also, we obtain the surprising result that the catalytic activity is "insensitive" to the crystal size, the nature of the carrier, and the method of preparation.

The next paper by Boudart and coworkers [52] was devoted to a study of the catalytic activity of platinum in another reaction: the transformation of neopentane, which in the presence of Pt undergoes isomerisation to isopentane and hydrogenolysis to isobutane and methane. SiO_2, carbon, and η- and γ-Al_2O_3 were used as carriers. The disperseness of the Pt, defined as the ratio of the number of surface metal atoms to the total number of metal atoms, was varied from 3×10^{-2} (for Pt powders) to over 70 (for supported metal). The authors measured the specific activity of the catalysts for both reactions, and obtained the selectivity coefficient s, equal to the ratio of the specific activities for the isomerisation and the hydrogenolysis reaction respectively. The parameter s varied by a factor of 100 for the catalysts examined, the most selective catalysts being Pt on carbon and Pt powder. The selectivity of supported platinum increased with the forming temperature of the catalyst (from 425° to 900°). Following Anderson and Avery [53], the authors explained their results by suggesting that isomerisation occurs through a three-point adsorption of neopentane on the platinum surface, whereas hydrogenolysis involves a transition state showing two-point adsorption. The greater the number of three-atom groupings ("triplets") on the surface, the more predominant isomerisation

becomes as opposed to hydrogenolysis. A geometrical and thermodynamic treatment of the structure and stability of various crystallographic planes of the Pt lattice led the authors to conclude that the greatest number of triplets should be found on a {111} surface, which is the most stable up to 1500°, and also on face edges. Thus, the selectivity should be directly dependent on the disperseness of the platinum and on the heat treatment of the catalyst before the reaction. For example, Pt powder which has been activated in an oxygen atmosphere before being reduced in hydrogen can be expected to have a "rough" surface with a high concentration of triplets: this explains its high selectivity.

Boudart's results on the hydrogenation of cyclopropane are confirmed by the work of Dorling and Moss [3], who studied the hydrogenation of benzene in the presence of a series of Pt/SiO_2 catalysts and observed only a twofold change in the activity of catalysts covering a range of dispersion of two orders of magnitude. Zaidman and coworkers [54-56] studied the specific activity of Pt on Al_2O_3 (as a function of concentration and disperseness of the platinum) towards the dehydrogenation of cyclohexane, and they also found that the activity of the catalyst is unaffected by the disperseness of the platinum.

Other workers (e.g. Sinfelt and coworkers [57] state that the specific catalytic activity of Pt in the dehydrogenation of cyclohexane depends on the nature of the carrier and on the state of dispersion of the metal. Thus, Pt crystals of 10 Å average size (estimated by H_2 chemisorption) were obtained by depositing the metal on Al_2O_3, and 85 Å crystals on alumina–silica. The specific catalytic activity of the highly disperse platinum was the higher by a factor of 6.

Results conflicting with those of Boudart and coworkers [52] were reported also by McKee [58], who showed that the specific activity of platinum black in the propane cracking reaction decreases as the catalyst is sintered.

2. Nickel on Carriers

The effect of state of dispersion on the specific catalytic activity of nickel has been studied in detail by Sinfelt and Carter, and their coworkers: the results have been summarised by Sinfelt [59]. The assumption underlying the whole of this work is that there is no *a priori* reason to expect constant specific activity when the degree of dispersion of the metal is varied over wide limits. Since the proportion of co-ordinationally unsaturated surface atoms in very small particles is large, it is assumed that the electronic properties of small metal particles must differ from those of large crystallites and the massive metals. Furthermore, since the catalytic properties of a supported metal must be largely determined by the electronic properties of its particles, a direct relationship can be expected between the catalytic activity and the particle size of supported metals. Similar views are expressed in the magnetochemical papers of Michel [60], Selwood [61], and others, who state that the Curie temperature of a ferromagnetic metal must be a function of degree of dispersion, and that the exchange interaction parameter in small crystals must be very different from the bulk value: this explains the special electronic properties of small crystals [62]. The theory of ferromagnetism in metals and alloys cannot give an unequivocal answer to the question of the relationship between electronic properties and disperseness, and experimental data on the subject are contradictory. Thus, it is stated in a recent paper [63] that the Curie temperature and the saturation magnetisation of small Ni particles are not significantly different from the values for the massive metal. However, Carter and Sinfelt [64] have shown experimentally that Ni in Ni/SiO_2 catalysts with a low Ni content (1–7%) has a low (paramagnetic) magnetic moment as compared with the massive metal: this observation formed the physical basis of their hypothesis. Sinfelt and his coworkers made a detailed study of the catalytic activity of all the Group VIII metals on various carriers (SiO_2, Al_2O_3, Al_2O_3–SiO_2), using the hydrogenolysis of ethane as a model reaction [4-8,65-68]. Nickel was studied in greatest detail [4-8,65]. An interesting fact was discovered in one of the earliest studies [5]: varying the roasting temperature of NiO/SiO_2 catalysts containing ~10 wt.% of Ni from 100° to 760° has no effect on the specific catalytic activity, although the surface area of the reduced nickel is thereby reduced by a factor of 3. However, the activity could be varied by a factor of 50 by depositing the Ni on different carriers (the highest activity being found with SiO_2, the lowest with alumina–silica) [4], in spite of the fact that the surface of the Ni on the different catalysts varied only by a factor of 2.

A study [7] of the effect of crystal size on the catalytic activity of Ni deposited on silica–alumina showed that the specific activity of the metal is decreased 20-fold by a 3-fold increase in the size of the Ni particles (~30–90 Å).

The same team [6-8] studied also a series of catalysts containing between 1 and 5% of Ni in a highly disperse form on SiO_2 and Al_2O_3–SiO_2. The surface area of the metal was measured by the magnetic method when the hydrogen chemisorption method could not be used (at very low adsorptions) [8]. The catalytic activities and crystallite sizes of the Ni on different carriers are compared in Table 2.

Table 2.

Catalyst	Size of Ni crystals, Å	Specific activity towards hydrogenolysis of ethane
1) Ni on SiO_2		
1% Ni	12	11
10% Ni	24	500
2) Ni on Al_2O_3		
10% Ni	23	260
3) Ni on Al_2O_3—SiO_2		
1% Ni	26	>0.08
10% Ni	29	9.5

The authors stress that the differences in activity are not due to differences in the extent of reduction of the metal, and they suggest that the difference in particle size may itself be the cause of the phenomenon (see above). They put forward the view that small particles have a special activity, irrespective of their large surface area, since the comparison is between specific activities. As Table 2 shows, the enhanced activity of Ni on SiO_2 (as compared with Ni on Al_2O_3–SiO_2) can be ascribed to the higher degree of dispersion of the former catalyst. However, increasing the amount of metal on any one carrier causes both the crystal size and the catalytic activity to increase. The authors conclude that a consideration of crystal size alone is not sufficient to explain their results. The influence of the carrier on the catalytic properties of the metal is a complicated problem, which cannot be formulated exclusively in terms of state of dispersion.

An alternative explanation of Sinfelt's results (Table 2) has recently been put forward by Shephard [69], who suggests that measurements of the active surface of the metal by hydrogen chemisorption may result in misleading values of the specific activity. If the catalyst contains "blocked" pores, accessible to hydrogen but not to the reacting molecule (ethane), too high a value will be obtained for the surface area available for the reaction. But this explanation is tenable only when the specific activity decreases with increase of forming temperature, as in Ref. 7: in this case it is easy to see how the true specific activity can remain constant, or even increase, while the apparent value decreases for the reason given. However, if the specific activity increases [8] (see case 1 of Table 2), the negative correction to the surface area of the metal (to allow for the inaccessibility of narrow pores to the ethane molecule) can only lead to a still higher value of the specific activity. These views are by no means new: a method of measuring effective surface areas by the adsorption of molecules of size comparable to that of the reactant was proposed [70] in 1951.

Yates and Sinfelt [67] obtained interesting results in their study of the catalytic activity of rhodium on SiO_2 towards the hydrogenolysis of ethane as a function of degree of dispersion. The catalysts, containing 0.1–10% of Rh with 11–40 Å particle size, differed in specific activity by no more than a factor of 4, but the most highly dispersed catalysts (0.1–0.3% Rh) had the lowest activity. In contrast to Boudart's results, the activity of massive rhodium and of the samples heated to the highest temperatures (particle size greater than 120 Å) was 20–40 times lower than the activity of the dispersed catalysts. The authors conclude that the region of highest catalytic activity occurs at intermediate degrees of dispersion of the metal.

Catalysts containing nickel on SiO_2 and on alumina–silica have been studied also in the hydrogenation of cyclopropane [71] and of benzene [72]. In the former reaction, as in the hydrogenolysis of ethane, the carrier has a strong influence on the activity and selectivity of the nickel (the reaction can follow two paths: hydrogenation to propane and hydrogenolysis to ethane and methane). Thus, the specific activity of Ni on SiO_2 was 16 times higher than the activity of Ni on Al_2O_3–SiO_2 towards the hydrogenation reaction, and 44 times higher towards the hydrogenolysis reaction. In the latter system, the samples which had been used to study the hydrogenolysis of ethane were examined also for their catalytic activity towards the hydrogenation of benzene. The specific activities of catalysts containing 1 and 10% of Ni on SiO_2 had been found (see Table 2) to be approximately the same, while their particle sizes differed by a factor of 2. This work led the authors to conclude that the activity of Ni/SiO_2 catalysts is independent of the degree of dispersion of the nickel also in the hydrogenation of benzene. The behaviour of Ni/Al_2O_3–SiO_2 catalysts was entirely different. The size of the Ni crystals was practically the same in the two samples (26 and 29 Å, see Table 2), and the activity for benzene hydrogenation decreased sharply as the Ni concentration was lowered to 1%, showing (according to the authors) that the carrier can influence these catalysts. These results confirm the earlier work of Hill and Selwood [73], according to whom the specific activity of Ni/Al_2O_3 catalysts in the same reaction decreases sharply with decrease of Ni concentration in the region of ~ 8%, and preparations containing < 3% Ni are completely inactive (i.e., the finer particles are less active). Conversely, the activity of Ni–SiO_2 catalysts in the region of 1% Ni is indistinguishable, as already stated, from that of the catalysts containing 10% Ni.

We shall consider some other examples of studies of the state of dispersion and catalytic properties of Ni from the standpoint of possible effects of the carrier. Thus, Lyubarskii [74] found that the specific activity of nickel towards the hydrogenation of benzene is constant for the carriers Al_2O_3, Cr_2O_3, and MgO, and also for the catalyst prepared by decomposition of the oxalate or formate.

Nikolaenko and coworkers [75] studied the specific activity of Ni–MgO catalysts prepared by thermal decomposition of the mixed oxalates towards the hydrogenation of benzene, and found a constant activity as the particle size decreased from 3000 Å to less than 17 Å.

Aben and coworkers [76] studied the effect of metal particle size and of the nature of the carrier on the specific catalytic activity (towards the hydrogenation of benzene) of platinum, palladium, and nickel catalysts deposited on SiO_2, Al_2O_3, Al_2O_3–SiO_2, and MgO–SiO_2. The activity, referred to a single surface atom of the metal, was found to be independent of particle size and of the type of carrier.

Dixon and Singh [77] showed, for the same reaction on Ni–Al_2O_3 catalysts covering the wide range of Ni concentrations from 5 to 75%, that the specific activity calculated for 1 m^2 of nickel surface was constant and independent of degree of dispersion.

On the other hand, Swift and coworkers [78], who studied the physical and catalytic properties towards the dehydrogenation of cyclohexane of Ni and Pt deposited by impregnation on η- and γ-Al_2O_3, point out that the activity of Ni (though not of Pt) is affected by the nature of the carrier. These results can be criticised on the grounds that the percentage conversions per unit weight of catalyst and per unit area of catalyst surface were both taken as a measure of the activity. Thus, the Ni–γ-Al_2O_3 catalyst, which had almost twice the area of active phase of the Ni–η-Al_2O_3 catalyst and had a greater activity as judged by the percentage conversion, was found to be the less active when the results were recalculated for 1 m^2 of catalyst area.

Van Hardeveld and Hartog [79] studied Ni catalysts on Aerosil with different mean particle size and size distribution. By measuring the intensity of the i.r. absorption bands of adsorbed N_2, CO, and CO_2 molecules they were able to evaluate the proportion of active centres (defined below) on the nickel surface, and to compare this quantity with the activity and selectivity of the catalyst in the exchange and deuteration reactions of benzene. These workers showed that the ratio of the exchange and deuteration rates and the initial isotopic composition of the benzene are very sensitive to the type of catalyst. High activity in exchange reactions results from the presence of large crystallites, and is most probably associated with defects in such particles. This effect almost exactly balances the decrease in the number of surface atoms with decreasing crystal size, and as a result the Ni surface remains uniform towards the deuteration reaction. Thus, the size of the crystals is found to be of fundamental importance in determining the activity and selectivity of the catalysts.

As the above examples show, in most comparative studies of catalytic activity and selectivity the specific surface area of the metal is treated as a simple parameter, and the distribution of particle sizes is ignored. More latterly, as a result of the growing interest in the properties of small particles, more detailed discussions of the nature of active centres in catalysts containing very

finely divided metals on a carrier have been published [80-82]. A basic investigation by van Hardeveld and van Montfoort[80] deals with the influence of crystal size on the adsorption of molecular nitrogen on Ni, Pd, and Pt. It is shown that the stretching vibration of the nitrogen molecule is active in the infrared spectrum only when the N_2 is adsorbed at some special sites on the surface. These centres are present in significant numbers only in small crystals ($20 < d < 70$ Å), and have a co-ordination number of 5 (B_5 centres): an atom adsorbed on such a centre is in contact with 5 Ni atoms. The particle size of the Ni–SiO_2 catalysts was measured by electron microscopy. The authors examined models of particles with different numbers of atoms, in the form of perfect or incomplete cubo-octahedra. The former are bounded exclusively by {111} and {100} surface planes: B_5 centres are absent, and the co-ordination number of adsorbed atoms is 3 or 4 for the two planes respectively.

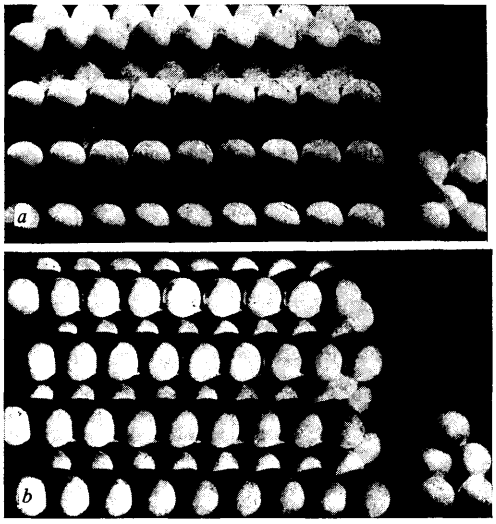

Figure 3. Models of defect planes containing B_5 centres: *a*) {110} plane; *b*) {113} plane. The configurations of the two types of B_5 centre are shown on the right.

In the second model, the less densely packed {113} and {110} planes are present as well as the {100} and {111}; these introduce two geometrically distinct types of B_5 centre (Fig. 3). The authors used a mathematical method of calculating the maximum number of B_5 (and also B_3 and B_4) centres as a function of crystal diameter, and they obtained distribution curves for the three types. B_5 centres are absent in very small particles ($d < 10$ Å), and also in particles with $d > 40$–50 Å, and their probability of occurrence is a maximum in the region 18–25 Å. The adsorption of molecular nitrogen on Ni, Pt, and Pd, first observed by Eischens and Jacknow[83], is discussed in detail in the same paper. Although the relatively high heat of adsorption (12 kcal $mole^{-1}$) suggests that we are dealing with chemisorption, the authors conclude from the lack of specificity of the phenomenon that adsorption on noble metals is physical. The main conclusion of the work is the following. Before making any statement as to the influence of current carriers on the catalytic and chemisorption properties of a metal, as revealed for example by changes in the spectra of adsorbed molecules (cf. the work of O'Neil and Yates[84] on nickel catalysts and of Eishens[85] on platinum), we must examine the distribution of particle size, which is determined first and foremost by the nature of the carrier. The number of B_5 centres, and hence the relative contribution of "defect" planes to the total metal surface, can be evaluated from the intensity of the absorption bands of adsorbed nitrogen. This approach was mentioned above when discussing the work of van Hardefeld and Hartog[79] on the deuteration and exchange reactions of benzene on a nickel catalyst.

Schlösser[81] extended the work of van Hardeveld and van Montfoort[80] on the number of B_5 centres in various cubo-octahedral models. He considered models of cubo-octahedra having different symmetries and defect structures, and he discussed in particular the forms obtained by cutting the corners and edges of a simple cubo-octahedron in various proportions and which can be expected to exist in real catalysts. He showed that the appearance of new low-index planes such as {311}, {210}, etc. increases the number of active B_5 centres, and he compared the number of B_5 centres and the catalytic activity for a number of systems described in the literature.

The paper presented by Bond to the Fourth International Congress on Catalysis[82-85] discusses the same problem from the standpoint of the influence of B_5 centres on the mechanism of various catalytic reactions.

When comparing the activity of a series of catalysts with their degree of disperseness it is important to note that the particle size of the metal can change in the course of the reaction, because of the increased mobility of certain atoms. For example, the size of the Pd crystals varied from 65 Å to 1300 Å, even at 40°, during the hydroisomerisation of but-1-ene on a Pd–graphite catalyst[86]. Obviously, the number of active (e.g. B_5) centres measured prior to the catalytic reaction may also be affected by the exposure of the catalyst to the reaction system. It is very important, therefore, to study the physical properties of the catalyst after, as well as before, the reaction as in the work of Rubinshtein and coworkers[24].

---o0o---

In spite of the variety of apparently contradictory information on the influence of state of dispersion, and type of carrier, on the catalytic activity of metals, there is a general trend which allows us to systematise the existing knowledge and to formulate profitable objectives for future investigations. The first explicit statement of the correct approach to the problem was made by Boudart and coworkers[34], whose results are discussed on p. 865. It is proposed that all catalytic reactions be divided into two classes: "unhindered" [facile] and "hindered" [demanding]. In the former the active centres have approximately the same activity, and the specific activity is independent of particle size and of the method of preparation of the catalyst (as in Ref. 34). The second class includes reactions which require special configurations of surface atoms, produced by optimising the catalyst preparation procedure. Hindered reactions are invariably sensitive to the size of the metal particles, to heterogeneity of the catalyst surface, and to the type of carrier. Boudart's classification of catalytic reactions shows some obvious similarities with Balandin's views on

the role of the geometric factor in catalysis. As Boudart himself points out, similar ideas were put forward much earlier by Taylor [87], who stated that the catalytically active fraction of the surface is determined by the catalytic reaction in progress. Boudart stresses that the model reactions chosen for systematic studies of catalysts must not be of the hindered type. Reliable correlations between the activity and the structure of the catalyst can be expected only for reactions known to be free from structural complications. In addition to the reactions of neopentane on platinum [52], Boudart discusses other examples of reactions of both types which had been previously studied by Kemball and coworkers [88] on nickel catalysts and by Kral [89] on palladium deposited on carbon.

Table 3. Dependence of activity on state of dispersion for supported metal catalysts.

Reaction	Catalyst	Dependence on		Refs
		state of dispersion of metal	nature of carrier	
Oxidation of SO_2	Pt, Pt/SiO_2	no	no	45
Oxidation of H_2	Pt, Pt/SiO_2	no	no	46
Hydrogenation of benzene	Ni, Ni/Cr_2O_3, Ni/MgO	no	no	79
	Ni/SiO_2, Ni/Al_2O_3, Ni/C, $Ni/Al_2O_3 \cdot SiO_2$, $Ni/MgO \cdot SiO_2$			74–76, 90–92
	Co/SiO_2, Co/Al_2O_3, Co/C $Co/Al_2O_3 \cdot SO_2$	no	no	93
	Pt/SiO_2, Pt/Al_2O_3, $Pt/Al_2O_3 \cdot SiO_2$, $Pt/MgO \cdot SiO_2$	no	no	3, 76
	Pd/SiO_2, Pd/Al_2O_3, $Pd/Al_2O_3 \cdot SiO_2$, $Pd/MgO \cdot SiO_2$	no	no	76
Dehydrogenation of cyclohexane	Ni/SiO_2, Ni/Al_2O_3, $Ni/Al_2O_3 \cdot SiO_2$	no	no	78, 93
	Pt/Al_2O_3, $Pt/Al_2O_3 \cdot SiO_2$	no	no	54–57, 94, 95
Hydrogenation of phenol	Ni, Ni/Al_2O_3, Ni/ZnO, Ni/NiO	no	no	96
Hydrogenation or hydrogenolysis of cyclopropane	Ni/SiO_2, $Ni/Al_2O_3 \cdot SiO_2$	no	yes	72
	Pt/SiO_2, Pt/Al_2O_3	no	yes	34
Hydrogenolysis of ethane	Ni/SiO_2, Ni/Al_2O_3	no, or positive effect*	yes	4, 5, 7
	$Ni/Al_2O_3 \cdot SiO_2$		yes	
H–D exchange in $C_6H_6 + D_2$ mixture	Co/SO_2, Co/Al_2O_3, $Co/Al_2O_3 \cdot SiO_2$		yes	97
	Ni/SiO_2	negative effect		80
Hydrogenation of CO_2	Ni/Cr_2O_3	no		98, 99
Dehydrogenation of n-hexane	Pt/Al_2O_3	no		100
Isomerisation of n-hexane	Pt/Al_2O_3	no		
Hydro-cracking of n-heptane	Pt/Al_2O_3	transition from positive to negative effect	yes	95, 101
Dehydrocyclisation of n-heptane	Pt/Al_2O_3	no		
Isomerisation of n-heptane	Pt/Al_2O_3	negative effect		
Hydrogenation of heavy oil	Pt/Al_2O_3	no	yes	102
Hydro-cracking of heavy oil	Pt/Al_2O_3	transition from positive to negative effect		
Hydrocyclisation of methylcyclopentane	Pt/Al_2O_3	negative effect		103

*The terms "positive" or "negative" effect are used in the meaning of the classification proposed by Bond to the Fourth International Congress on Catalysis, Moscow, 1968.

For example, the deuteration of ethylene on nickel is unhindered, in contrast to the deuterium exchange of alkylbenzenes. As stated above, the hydrogenation of benzene [75–77] is an unhindered reaction (unexpectedly so, in the light of the sextet mechanism of the reaction). However, Bond has pointed out [82] that the formation of olefins by the partial hydrogenation of aromatic compounds was reported at the Third International Congress on Catalysis: this suggests the possibility of a doublet mechanism. Van Hardeveld and Hartog [79] had generally assumed that adsorbed molecules of benzene are attached to a single nickel atom, with formation of a surface compound of the π-complex type. This view is consistent with the experimental fact that the hydrogenation of benzene is unhindered. On the other hand, reactions involving linear molecules such as paraffin hydrocarbons (e.g. the hydrogenation of ethane, studied by Sinfelt and coworkers) are of the hindered type. Schlösser [81] has published a detailed analysis of the available data, summarised in Table 3, in the light of Boudart's classification. In the present state of knowledge if is not yet possible to account for all the known facts, or to predict whether the specific activity of the supported catalyst in various types of reaction should be a function of particle size or of the nature of the carrier. However, the present approach, based on the conformation of the reacting molecules and on the geometry of the assumed active centres, is much more successful than the earlier "electronic" concepts on the influence of the carrier on the properties of the metal.

Therefore, we conclude that the most important problem facing experimentalists at the moment is to compare catalytic activities (preferably, in various types of reaction) with the average particle size and also with the particle size distribution of the catalyst. Reliable information of this type must be made available before further progress can be made towards a full understanding of the nature of the catalytic action of supported metals.

Quantitative Aspects of the Mechanism of Reactions Involving Hydrocarbons

A.I.Vitvitskii

This review attempts to generalise a method of evaluating the contributions to the heat of formation of hydrocarbons and their halogen derivatives based on modern views on the structure of the carbon atom. This approach throws new light on the mechanism of a number of reactions, and on the nature of the activation energy of these processes. 88 references.

1. INTRODUCTION

The mathematical difficulty of exact calculations based on quantum theory[1-6], the complexity of atomic structures, and the wide variety of organic compound have given rise to a great deal of pessimism on the prospect of obtaining exact information useful to experimental chemists, in spite of the advent of electronic computer techniques. However, there is little doubt (in view of the many experimentally observed correlations) that relatively simple methods of solving these problems must exist. The need for simple computational methods arises on the one hand because of the large number of such computations envisaged, and on the other hand from the fact that many of the problems are only of passing interest. For this reason, semi-empirical methods are being applied on an increasing scale in various branches of chemistry[7-13], including quantum chemistry[14-17]. Descriptive (though not strictly accurate) concepts are often more useful to the practical worker than complicated and fully developed physical models. For example, the electronegativity concept[18-22] has played an important role in the development of chemical thinking in spite of the many criticisms which have been levelled at it.

This article aims to review the ideas which enable the heats of formation of hydrocarbons and their halogen derivatives to be correlated with structural parameters[23-26]. The proposed semi-empirical method for calculating heats of formation differs from alternative approaches[7-9,27,28] in its basic principles, and it allows calculation of the heats of formation not only of hydrocarbon molecules but also of their gaseous radicals and their halogen derivatives of practically any structure. Thus, the method is of value in the quantitative discussion of reaction mechanisms[29-32].

2. CONTRIBUTIONS TO THE HEAT OF FORMATION OF HYDROCARBONS

We shall make the following assumptions: 1) the energy of a covalent bond between two atoms is a constant, depending only on the chemical nature of the atoms involved; 2) the energy evolved when electrons become hybridised is determined by the form of the hybridisation of the orbitals; 3) hydrogen (or halogen) atoms combined with carbon atoms develop a constant charge, and the charge on the carbon atom is equal and opposite to the sum of the charges on these atoms. If these assumptions are true, the heat of formation (ΔH) of any gas-phase molecule or radical C_nH_p is given by the expression

$$\Delta H_{C_nH_p} = n_1\Delta H_{C'} + (n - n_1)\,\Delta H_C + p\Delta H_H - pE_{C-H} - wE_{p^3} - fE_{sp^3} - gE_{sp^2} - hE_{sp} - sE_{C-C} - tE_{C=C} - uE_{C\equiv C} - m\sum_{i=1}^{n} a_i^2 \quad (1)$$

where $\Delta H_{C'}$, ΔH_C, and ΔH_H are respectively the heats of formation of a bivalent and a quadrivalent carbon atom from graphite, and of a hydrogen atom from its molecule; n_1 and p are the numbers of bivalent carbon atoms and hydrogen atoms respectively; E_{C-H}, E_{C-C}, $E_{C=C}$, and $E_{C\equiv C}$ are the energies of the covalent C–H, C–C, C=C, and C≡C bonds; s, t, and u are the numbers of C–C, C=C, and C≡C bonds; E_{p^2}, E_{sp^3}, E_{sp^2} and E_{sp} are the energies involved in p^2, sp^3, sp^2, snd sp hybridisation of the electrons; w, f, g, and h are the number of carbon atoms in p^2, sp^3, sp^2, and sp states of orbital hybridisation; $\sum_{i=1}^{n}$ denotes summation over values of i from 1 to n; a is the number of hydrogen atoms on the i-th carbon atom; m is the energy of the electrostatic attraction between a hydrogen atom and a carbon atom with an equal and opposite charge.

The last term of Eqn. (1) relates exclusively to the electrostatic interaction of the carbon atoms with the hydrogen atoms directly attached to them.

Applying Eqn. (1) to the heats of formation of methane, ethane, ethylene, and acetylene, and using these values to calculate the enthalpy of formation of a hydrocarbon molecule without conjugated double bonds, for which $n - n_1 = f + g + h = s + t + u + 1$, we obtain

$$\Delta H_{C_nH_p} = s\Delta H_{C_2H_6} + (f - 2s)\,\Delta H_{CH_4} + t\Delta H_{C_2H_4} + u\Delta H_{C_2H_2} + m\,(16f - 14s + 8t + 2u - \sum_{i=1}^{n} a_i^2). \quad (2)$$

This equation makes no allowance for possible conjugation of double bonds, which produces additional stabilisation energy, or for bond strain resulting from distortion of the bonds from their normal directions [24].

For the special case of gaseous paraffin hydrocarbons with an unbranched chain (C_nH_{2n+2}), Eqn. (2) takes the simpler form

$$\Delta H_{C_nH_{2n+2}} = (n-1)\,\Delta H_{C_2H_6} + (2-n)\,\Delta H_{CH_4} + (2-n)\,2m\,. \qquad (3)$$

Table 1. Heats of formation of gaseous hydrocarbons under standard conditions.

Formula	Compound	ΔH, kcal mole^{-1} corrected (Refs.9,28, 33,34)	ΔH, kcal mole^{-1} calculated by Eqn.(2)	$\Delta H_{calc} - \Delta H_{corr}$ kcal mole^{-1}

* The carbon atoms of the cyclohexane molecule are not coplanar [35,36]; as a result, the bonds are unstrained.
** The carbon atoms in the cyclooctatetraene molecule lie in different planes [35,38]. This may explain the absence of a conjugation effect.

By inserting known values [9,28,33,34] of ΔH into Eqn. (3) it can be shown that $m = 1.291$ kcal mole^{-1}. Knowing m, Eqn. (2) can be used to calculate the enthalpies of formation of various gaseous hydrocarbons [23,24], saturated or unsaturated, aliphatic or cyclic. The precision of some of these calculations is illustrated in Table 1: evidently, there is a loss of precision when the carbon chain is branched. Eqn. (2) can be used to calculate approximate enthalpies of formation not only at the standard temperature [26]. It can be used also to evaluate [24] the effect of strain in cyclic molecules due to distortion of the bonds from their normal tetrahedral angles [35-37], and the energy of conjugated double bonds due to π-bond delocalisation [5,6,35-37].

3. QUANTITATIVE EXPRESSIONS FOR THE CONTRIBUTIONS TO THE HEATS OF FORMATION

It is experimentally known [27,34] that an expenditure of 80 kcal mole^{-1} is needed to abstract the hydrogen atom from a diatomic CH particle in which the carbon atom is bivalent and the electrons are not in any way hybridised. Since the electrostatic attraction energy between the C and H atoms in this case is m, it follows that the energy of the covalent C−H bond is $E_{C-H} = 78.71$ kcal mole^{-1}.

Also, applying Eqn. (1) to the experimental values for the heats of formation of methane, methyl, and allene (−17.889 kcal mole^{-1} [33,34], +31.5 kcal mole^{-1} [33,39], and +45.92 kcal mole^{-1} [33,34] respectively), we can easily show that

$$\Delta H_C - E_{sp^3} = 109.25 \text{ kcal mole}^{-1}\,, \qquad (4)$$

$$\Delta H_C - E_{sp^2} = 122.98 \text{ kcal mole}^{-1}\,, \qquad (5)$$

$$\Delta H_C - E_{sp} = 150.04 \text{ kcal mole}^{-1}\,. \qquad (6)$$

Since the heat of formation of a gaseous carbon atom in the ground state (C′) from graphite is $\Delta H_{C'} = 171.698$ kcal mole^{-1} [34], we obtain the value $E_{p^2} = 47.3$ kcal mole^{-1} [24] for the p^2-hybridisation energy by taking the heat of formation of methylene as 66 kcal mole^{-1} [27,40]. Using Eqns. (4)−(6) and the enthalpies of formation of ethane, ethylene, and acetylene we arrive at $E_{C-C} = 55.9$ kcal mole^{-1}, $E_{C=C} = 116.6$ kcal mole^{-1}, and $E_{C\equiv C} = 190.1$ kcal mole^{-1}. Eqns. (4)−(6) also show that the energy of sp^3-hybridisation of the orbitals of a quadrivalent carbon atom is greater than the energy of sp^2-hybridisation by 13.7 kcal and is greater than the energy of sp-hybridisation by 40.8 kcal.

Thus, since $n - n_1 = f + g + h$, all the quantities which appear in Eqn. (1) are known, and they can be used in principle for approximate calculations of the heats of formation of gaseous hydrocarbon molecules or radicals free from conjugation or strain effects. However, simpler and more accurate methods [7-9,27,28,34] are available for calculating the heat of formation of molecules, including our Eqn. (2). Hence, Eqn. (1) is most effectively used, in conjunction with Hess's law, to calculate the thermochemistry of reactions involving hydrocarbon radicals, and also to evaluate the heats of formation of the radicals.

4. HEATS OF SOME REACTIONS BETWEEN HYDROCARBON MOLECULES AND RADICALS

a. Hydrogen Atom Removal Reactions

All the carbon atoms in paraffin hydrocarbon molecules are in the sp^3 state of orbital hybridisation. When a combined hydrogen atom is removed, the carbon atom passes from the sp^3 to the sp^2 form of electron hybridisation, and at the same time the electrostatic contribution to the C−H bond energy of the carbon atom changes. The heat of this reaction (Q_1) is given by Eqn. (1) and Hess's law in the form

$$Q_1 = E_{C-H} + E_{sp^3} - E_{sp^2} + m\,(2a-1) \qquad (7)$$

where a is the number of hydrogen atoms bound to the original carbon atom [30].

Similarly, when a hydrogen atom is removed from an unsaturated molecule containing a double bond, the reacting

carbon atom passes from the sp^2 to the sp hybridisation form, and the heat of the reaction (Q_2) is given by

$$Q_2 = E_{C-H} + E_{sp^3} - E_{sp} + m(2a - 1) . \quad (8)$$

The heats of a number of reactions in which hydrogen atoms are removed from hydrocarbon molecules and radicals, calculated in this way, are listed in Table 2. Where experimental values exist, the agreement is satisfactory.

Table 2. Heats of hydrogen atom removal from hydrocarbon molecules and radicals.

No.	Reaction	State of carbon atom: initial V	initial H	final V	final H	Q, kcal mole^{-1}: calc.	exper. (Ref.41)
	Removal of H from molecules						
1	$CH_4 \rightarrow CH_3 + H$	4	sp^3	4	sp^3	101.5	103±2
2	$-CH_3 \rightarrow -CH_2 + H$	4	sp^3	4	sp^3	98.9	97±1
3	$>CH_2 \rightarrow >CH + H$	4	sp^3	4	sp^3	96.3	94±2

6	$\diagdown\!\!>CH \rightarrow \diagdown\!\!>C + H$	4	sp^2	4	sp	107.0	—
	Removal of H from radicals						
7	$CH_3 \rightarrow CH_2 + H$	4	sp^2	4	sp	112.2	—
8	$CH_3 \rightarrow CH_2 + H$	4	sp^2	2	p^2	86.6	85±7
9	$-CH_2 \rightarrow -CH + H$	4	sp^2	4	sp	109.6	—
10	$-CH_2 \rightarrow -CH + H$	4	sp^2	2	p^2	84.0	—
11	$>CH \rightarrow >C + H$	4	sp	4	sp	107.0	—
12	$>CH \rightarrow >C + H$	4	sp^2	2	p^2	81.4	—
13	$=CH \rightarrow =C + H$	4	sp	2	—	101.7	—
14	$CH_2 \rightarrow CH + H$	2	p^2	2	—	129.9	128±6
15	$-CH \rightarrow -C + H$	2	p^2	2	—	127.3	—

Note. V = valency, H = hybridisation.

Tatevskii has pointed out[42] that the distinction between molecules and radicals is to some extent arbitrary. Therefore, the following reasoning may be justified. Reactions 7, 9, and 11 (Table 2) give rise to "hot" particles, containing an excess of energy as compared with the bivalent state of the carbon atom with p^2 hybridisation (reactions 8, 10, and 12 of Table 2). However, since the rate of collisions between gas-phase particles can be as high as 10^{28} per second[43,44] [sic!, 10^{10} at one atm. is more reasonable, (Ed. of Translation)], the excess of energy is quickly dissipated[45], and these "hot" particles have no practical existence.

b. Hydrogen Atom Exchange Reactions Involving Radicals

Using Eqn. (1) and Hess's law, we obtain the following expression for the heat (Q_3) of hydrogen atom exchange reactions involving radicals, in which the reacting carbon atoms are in the sp^3 hybridisation and the sp^2 hybridisation in the initial molecule and radical respectively (Table 3, reactions 1–4, 7–9, 12, 13, 16):

$$Q_3 = 2m(a - a_1 - 1) \quad (9)$$

where a and a_1 are the numbers of hydrogen atoms on the reacting carbon atoms of the original molecule and radical respectively.

When the reacting carbon atoms in the radical and the molecule have the same (sp^3) hybridisation, as in reactions 5, 6, 10, 11, 15, 17, 18 of Table 3, the heat of the reaction (Q_4) is given by

$$Q_4 = 2E_{sp^3} - E_{sp^3} - E_{sp} + 2m(a - a_1 - 1) \quad (10)$$

Table 3. Heats of radical reactions involving hydrogen exchange and biradical formation.

38	$CH\equiv CH \rightarrow CH_2=C$	65.5

When a hydrogen atom reacts with a molecule in which the reacting carbon atom is held by saturated σ bonds (reactions 19–22 of Table 3), the heat change (Q_5) is

$$Q_5 = E_{C-H} - 2\Delta H_H + E_{sp^3} - E_{sp^2} + m(2a - 1) \quad (11)$$

c. Biradical Formation Reactions

Table 3 includes the heats of some biradical formation reactions, which may be involved in the intermediate steps of a number of processes[46-52]. The active carbon atom in the biradical is assumed to be in the bivalent ground state with p^2 hybridisation of the orbitals. The heat (Q_6) of formation of such a biradical by the removal of a hydrogen molecule from the saturated hydrocarbon (reactions 25–27 of Table 3) is given by the expression

$$Q_6 = \Delta H_{C'} - E_{p^2} - \Delta H_C + E_{sp^3} - 2\Delta H_H + 2E_{C-H} + 4m(a-1). \quad (12)$$

The heats of the other reactions listed in Table 3 may be obtained in a similar way. The ability to calculate the heats of even hypothetical reactions is a useful feature of Eqn. (1), since it enables us to select the correct mechanism of various processes.

5. HALOGEN DERIVATIVES OF HYDROCARBONS

The ideas discussed above can be extended to halogen derivatives of hydrocarbons[25,29]. In this case, the contributions to the heat of formation of the gaseous halogenated hydrocarbon molecules and radicals of composition $C_nH_pX_v$ are given by the expression

$$\Delta H_{C_nH_pX_v} = n_1\Delta H_{C'} + (n-n_1)\,\Delta H_C + p\Delta H_H + v\Delta H_X - pE_{C-H} - vE_{C-X} - wE_{p^2} - fE_{sp^3} - gE_{sp^3} - hE_{sp} - sE_{C-C} - tE_{C=C} - uE_{C\equiv C} - m\sum_{i=1}^{n}(a+dk)\left(a+dk\frac{l_{CH}}{l_{CX}}\right), \quad (13)$$

where E_{C-X} is the energy of the covalent C–X bond, d is the number of halogen atoms on the i-th carbon atom, k is the proportionality coefficient[25] between the charge on the halogen atom and the charge on the hydrogen atom, l_{CH} and l_{CX} are the mean lengths of the CH and CX bonds.

Table 4. Characteristics of hydrogen and halogen atoms in hydrocarbons and their derivatives.

X	k	E_{C-X}, kcal mole^{-1}	l_{C-X}, Å (Ref.34)
H	1	78.71	1.09
F	−0.54	98.52	1.35
Cl	+0.27	63.89	1.75
Br	+0.43	50.47	1.93
I	+0.68	34.06	2.12

For the case of gaseous halogenated hydrocarbons of composition $C_nH_pX_v$ without conjugated double bonds, Eqn. (14) can be obtained from Eqn. (13) by transformations similar to those used in the derivation of Eqn. (2):

$$\Delta H_{C_nH_pX_v} = s\Delta H_{C_nH_4} + (f-2s)\,\Delta H_{CH_4} + t\Delta H_{C_nH_4} + u\Delta H_{C_nH_2} + v\,(\Delta H_X - \Delta H_H + E_{C-H} - E_{C-X}) + m\left[16f - 14s + 8t + 2u - \sum_{i=1}^{n}(a+dk)\left(a+dk\frac{l_{CH}}{l_{CX}}\right)\right]. \quad (14)$$

The quantities E_{C-X} and k are evaluated[25] by substituting into Eqn. (14) the known values of $\Delta H C_nHpX_v$ [33,34] listed in Table 4.

The following expression for the heat (Q_7) of removal of a halogen atom from halogenated alkanes (reactions 1–10 of Table 5) is readily obtained by using Hess's law and Eqn. (13):

$$Q_7 = E_{C-X} + E_{sp^3} - E_{sp^2} + m\left[ak\left(1+\frac{l_{CH}}{l_{CX}}\right) + (2d-1)\,k^2\frac{l_{CH}}{l_{CX}}\right]. \quad (15)$$

The heat of formation of biradicals from halogenated methane molecules by dehydrohalogenation (reactions 15, 17, 19 of Table 5) is given by the equation

$$Q_8 = \Delta H_{C'} - E_{p^2} - \Delta H_C + E_{sp^3} + \Delta H_{HX} - \Delta H_H - \Delta H_X + E_{C-H} + E_{C-X} - m\left[2a - 1 + (a+d-1)\,k\left(1+\frac{l_{CH}}{l_{CX}}\right) + (2d-1)\,k^2\frac{l_{CH}}{l_{CX}}\right] \quad (16)$$

where ΔH_{HX} is the heat of formation of a molecule of HX from its elements.

Table 5. Heats of formation of radicals from halogenated hydrocarbons.

* Values used in the calculations: ΔH_{CF_2} = −39.7 kcal mole^{-1} [57], $\Delta H_{CH_2F_2}$ = −105.5 kcal mole^{-1} [33], ΔH_{CF_4} = −220.0 kcal mole^{-1} [27].

The heats of the other reactions listed in Table 5 can be obtained by means of expressions derived in a similar way.

It is evident from Table 5 that the biradical mechanism, involving removal of a molecule of hydrogen fluoride, is energetically more favourable than the formation of monoradicals by removal of a fluorine atom in the thermal decomposition of fluorinated methane derivatives. The biradical mechanism was confirmed experimentally in the pyrolysis of methyl fluoride[59] and trifluoromethane[58,60]. A similar mechanism also applies to the decomposition of chloroalkanes with removal of an HCl

molecule[61-64]. Furthermore, the heats of formation of mono- and biradicals from bromo derivatives are very similar, suggesting that the two processes can occur in parallel[65,66], whereas with the iodo derivatives the mechanism involving breaking a C–I bond or the removal of an I_2 molecule is energetically more favourable. The decomposition of methyl or ethyl iodide is a well known method of producing alkyl monoradicals[67,68].

6. DISCUSSION OF SOME REACTIONS IN THE LIGHT OF THE PROPOSED APPROACH

A knowledge of the contributions to the heat of formation of hydrocarbons allows us to re-examine the mechanism of a number of reactions, and also to speculate on the nature of the activation energy attending various processes[30-32].

* Q values are listed in Table 3.

Thus, we can assume that in hydrogen atom exchange radical reactions, in which the reacting carbon atom of the original molecule is in the sp^3 hybridisation and that of the original radical is in the sp^2 hybridisation, the necessary condition is conversion of the sp^3 hybridisation of the carbon atom of the molecule into the sp^2 form, which requires an expenditure of 13.7 kcal mole^{-1} of energy. But since the heat of the reaction is altered by the interaction of the molecule and the radical, the activation energy barrier (E) which the system must overcome is given by the sum of 13.7 kcal mole^{-1} and the heat of the reaction, i.e.

$$E = 13{,}7 + Q \ . \qquad (17)$$

If the activated state of the hydrocarbon molecules for reactions 11–14 of Table 6 is similar to that for reactions 1–10, the activation energy can be calculated in a similar way from formula (17).

Leaving aside the nature of the active state of the hydrogen molecule, it is reasonable to assume that the same state is involved in reactions 16–19 of Table 6 as in the reaction between a hydrogen molecule and a hydrogen atom, for which the activation (or excitation) energy of the hydrogen molecule is approximately[39,43,76] 7.3 kcal mole^{-1}. Hence, the activation energy of reactions 16 to 19 can be obtained from the expression

$$E \approx 7.3 + Q \qquad (17a)$$

Reactions 2, 3, 4 of Table 6 differ from 5, 9, 10, and reactions 11–14 differ from 16–19, in being the reverse of the other process. The intermediate state of the system must be different in the two cases, as the difference between the activation energies for the forward and the reverse reaction is not equal to the heat of the reaction[31].

It is interesting to compare the activation energies for the cracking reactions of various saturated hydrocarbons with the heats of formation of the hydrocarbons from their biradicals. Thus, a biradical is formed from a methane molecule by reaction 25 of Table 3 with a heat absorption of 83.9 kcal mole^{-1}, and the activation energy for the cracking of methane is variously given[77,78] as 79–90 kcal mole^{-1}. On cracking ethane, biradicals are formed by reactions 26 and 28 (Table 3) with absorption of 78.7 and 68.4 kcal mole^{-1} respectively. The experimental values of the activation energy for this process lie in the range 68.7–79.5 kcal mole^{-1} [78,79]. In the pyrolysis of trifluoromethane the activation energy corresponds to the heat of formation of the biradical CF_2 [58]. It is a plausible assumption that a biradical is formed by reaction 34 of Table 3, with a heat of 45.9 kcal mole^{-1}, as an intermediate in the gas-phase hydrogenation of ethylene. This value is close to the experimentally observed[80,81] activation energy of the process (43–44.8 kcal mole^{-1}).

Unless the numerical agreement between these quantities is fortuitous, it suggests some definite conclusions as to the origin of the activation energy of these reactions, and in particular it suggests the widespread occurrence of a biradical mechanism. A comparison of the properties of mono- and biradicals leads to the same conclusion. Thus, monoradicals can recombine only as a result of mutual collisions, not by collisions with molecules[39,43,72]. Biradicals can be studied both in addition reactions and following internal electronic rearrangements to give a double bond[82-84]. Recombination of monoradicals occurs with a negligibly small activation energy[39,43,72]. Presumably, the same is true of biradicals[82,83,85]. There is evidence[46,86,87] that chain reactions account for a very small fraction of the total number of alkane molecules decomposed in cracking reactions: this confirms the likelihood of a biradical mechanism in reactions of this type.

In conclusion, we shall consider specifically the reactions

$$CH{\equiv}CH \rightarrow CH{\equiv}C + H \qquad (18)$$

and

$$CH{\equiv}CH \rightarrow C{\equiv}C + 2\,H \ . \qquad (19)$$

Reaction (18) requires the expenditure of ~121 kcal mole^{-1} [39,88], and reaction (19) requires 246 kcal mole^{-1} [40]. Since the reacting quadrivalent carbon atom is converted from sp hybridisation to a valency state without any hybridisation of the orbitals, we can use the heats of these reactions to calculate the energy evolved as a result of sp hybridisation. The mean value of E_{sp} is ~42 kcal mole^{-1} (41 kcal mole^{-1} by reaction (18) and 43 kcal mole^{-1} by reaction (19)). Hence, according to Eqn. (6), the heat of formation of a quadrivalent carbon atom from graphite is approximately $\Delta H_C = 192$ kcal g-atom^{-1}. But since the heat of formation of gaseous carbon in the ground state is 171.7 kcal g-atom^{-1}, it follows that the transition of a $2s$ electron to a $2p$ orbital requires ~20 kcal g-atom^{-1}. Using the above value of ΔH_C and Eqns. (4) and (5), the energy evolved during sp^3 and sp^2 hybridisation can be calculated: $E_{sp^3} = 83$ kcal g-atom^{-1} and $E_{sp^2} = 69$ kcal g-atom^{-1}. Thus, the ideas discussed in this review allow quantitative evaluation of a number of important parameters in the chemistry of hydrocarbons.

Complexing Adsorption Chromatography and Its Prospects

T.B.Gapon, L.S.Aleksandrova, and K.V.Chmutov

Investigations on complexing adsorption chromatography during its period of existence (1954-1970) are reviewed, and possible ways for its future development are considered.
The method was developed originally for preparing the extremely pure salts used in the production of phosphors, and then grew to be a general method of separating substances, enabling the most selective processes to be accomplished by simple procedures. However, widespread introduction of the method is hindered by the absence of published summaries covering technique, theory, and fields of application. The present review covers these aspects, and will enable research workers to apply the method correctly and to extend its field of use in the laboratory and in industry. A list of 80 references is included.

CONTENTS

IV. Fields of application of complexing adsorption chromatography 883

I. INTRODUCTION

The problem of the selective extraction of substances from complicated mixtures has recently become especially important, as a consequence of the development of many branches of chemistry and technology which require the use of pure and ultrapure materials. Establishment of the most effective and economical methods for isolating, separating, and purifying substances is necessary to meet the demands of the development of nuclear energy, the manufacture of semiconductors, phosphors, and single crystals, the rational exploitation of combined ores, and many other branches of industry and fields of science.

Chromatography has played a considerable part in solving these problems, enabling pure substances to be obtained in various areas of chemical science and industry, including the selective extraction of substances from complicated mixtures.

The greatest difficulties arise in the development of procedures for obtaining pure and ultrapure materials and separating elements of closely similar properties. The practical solution of this problem requires the use of especially delicate and effective methods, since the usual chromatographic methods, based on the use of general-purpose sorbents (including ion exchangers), often prove ineffective. In this connection research workers have recently directed their efforts towards producing selective sorbents characterised not only by group but also by individual specificity towards particular elements. The development of such sorbents is extremely promising, since their practical use will enable the best separation to be obtained. Efforts to obtain such sorbents have been made for a long time, a particularly large number of papers having been published during recent years (see the reviews[1-3]).

It is well known that ordinary general-purpose ion exchangers possess some measure of selectivity, which is responsible for the sequential sorption of ions in so called "adsorption series". Selective exchangers, however, exhibit a more clearly pronounced selectivity, as a consequence of the presence in the polymer matrix of specific active groups, most often complex-forming.

General-purpose exchangers also often exhibit complexing properties, leading to a decrease in the degree of dissociation of ionogenic groups and hence an increase in selectivity. For example, cation-exchange resins containing carboxylate and phosphate groups, and also anion-exchange resins of low and medium basicity, absorb metal ions as a result of complex formation. Specially prepared selective exchangers usually contain ionogenic groups capable of forming inner complexes with metal cations. They are prepared by introducing an appropriate chelating agent into the polymer matrix. However, existing methods do not yet allow us to obtain selective exchangers having specified properties or with any active group, in spite of the varied range of specific reagents available to the modern analytical chemist. This explains the hitherto insignificant use which selective exchangers have found[1-10].

However, other opportunities for highly selective chromatographic separations can be realised by creating special conditions under which a rich variety of specific reagents of different kinds can be used for these processes.

The origin of this line of development was the use of precipitation chromatography[11-14] for many complicated separations by the simplest procedures. An almost unlimited number of chemical reagents can be used as precipitants in the columns. However, the broadest opportunities for selective separations are to be expected from the application of complexing agents by the method of complexing adsorption chromatography[15-20]. A great part in establishing this method and working out its physicochemical principles was played by Gurvich[15-20].

In contrast to precipitation chromatography, in which an inert support is used and the precipitates are frequently not attached to the carrier, but more along the column with the stream of solution, complexing adsorption chromatography uses as carrier a sorbent capable of retaining both the complexing agent and the products of its reaction with metal cations, which vary in solubility.

The complexing adsorption column consists of a sorbent carrier, which retains the complexing reagent sorbed on its surface. The term "modified" has recently been applied to such sorbents. When the solution of a mixture of substances is filtered through the column, separation occurs as a consequence of the differences in their capacity

for complex formation with the given reagent, in the stability of the complexes which are formed, and also in their sorbability on the given sorbent carrier. Separation is intensified also by the chromatographic method itself, a distinguishing feature of which is a multiplicity of elementary acts of separation. The reaction products are retained on the sorbent carrier in the column as sparingly soluble complex compounds (sometimes as soluble complexes). At the same time substances which do not react with the given complexing agent pass freely through the column into the filtrate.

Thus a selective process of separation can be realised most fully in the complexing adsorption method, the main factor in the present case being the selectivity of the complexing agent. Advances in the preparation of a large variety of such reagents opens up wide prospects for developing the method and extending its fields of application. Successful separation requires that the appropriate complexing agent and carrier should be matched, the properties of the modified sorbent studied, and also optimum conditions chosen. The conditions of separation include the most varied procedures used in chromatography—use of particular masking complexing agents, variation in solution pH, temperature, and rate of filtration—together with other procedures which may in some measure enhance the specificity of the reagent and the selectivity of the method. By this means columns possessing exceptional selectivity can be prepared by simple procedures using ordinary chemical reagents together with cheap and readily available sorbents.

The separation of substances by complexing adsorption chromatography is accomplished in several cases with only one filtration of the mixture through the column, whereas even complexing elution requires two stages—production of the primary chromatogram, followed by displacement by the eluent.

The procedures of complexing adsorption chromatography closely resemble those of precipitation chromatography, from which the method arose historically as a consequence of improving the latter by replacing the inert carrier by a sorbent actively involved in the process of separation[18]. The method was originally termed "adsorption–precipitation chromatography", but since in most cases sorbable reagents were used, which formed complexes with the separable substances, also sorbed to some extent on the carrier, the term "complexing adsorption chromatographic method" was adopted later[17,18].

Adsorption phenomena are secondary in precipitation chromatography; they always accompany separation to some extent. In the complexing adsorption method, however, adsorption phenomena are a factor determining the possibility of separation[19].

Since substances are more easily adsorbed from a given solvent the less soluble they are in it, the present method is applied most frequently to the separation of substances which react with the reagent to form products of limited solubility. It is interesting that sometimes, where several reactions are possible between a given substance and the complexing agent, reaction which leads to the formation of the most easily adsorbed product is accelerated under the conditions of a column. In this connection complex formation quite often involves different reaction mechanisms under static conditions and in the column[18,19]. Precipitation chromatography can be regarded as the limiting case of the adsorption—precipitation method in which, in view of the sparing solubility and the "tenacity" of all the compounds formed in the column, the adsorbent can be replaced by an inert support.

II. PHYSICOCHEMICAL PRINCIPLES OF COMPLEXING ADSORPTION CHROMATOGRAPHY

Detailed investigation of the processes accompanying the complexing adsorption of metals has revealed several specific features of this method[19]. It is distinguished from other methods of chromatographic analysis mainly by the conditions of application of complex formation, a reaction which is widely used for the separation of substances in both static and dynamic processes. Opportunities for the application of complex formation were especially broadened by the development of chromatography. Complexing processes became an important factor in separation both in ion-exchange and adsorption and in partition and precipitation chromatography.

The method of applying complexing agents most widely used in classical adsorption chromatography is development of the primary chromatogram. In this case the developer reacts with already separated substances, without taking part in their separation. Metals can be separated also by chromatographing mixtures of their soluble complexes on molecular sorbents, e.g. on aluminium oxide[21–23].

In ion-exchange chromatography a very widely used method for developing the primary chromatogram of the ions is the use of solutions of organic reagents which form readily soluble complexes with the separable cations. This procedure is especially valuable for the separation of rare-earth elements[24]. An analogous method is employed in partition chromatography[25]. In some cases the use of ion-exchange columns to separate complex ions obtained in solution or to segregate them from other substances is effective[26,27].

In isolated cases precipitation chromatography also makes use of sparingly soluble complexing agents in the form of chemisorbents together with carriers which are inert towards reactants and reaction products[11,27]. The fundamental process in precipitation chromatography is the formation of sparingly soluble compounds as a new phase, while adsorption processes, as already stated above, are secondary and may exert different and opposite effects on the separation.

In the method under review complex formation is invariably combined with sorption processes: no new solid phase is formed. The complexing agent is first attached to the sorbent carrier by sorption interaction, and then a solution of the mixture is introduced into the column. Separation in such a column is determined by the difference in the instability constants of the complexes formed by the cations with the complexing agent, these latter also being in some measure retained on the sorbent carrier by sorption forces. Under the most favourable conditions for separation some elements form complexes and are attached to the column, while others do not form such compounds and pass into the filtrate. One of the components can then be isolated in pure form, as has been achieved, for instance, in the thorough purification of salts used in the production of phosphors [15,16,19]. Thus in this method the possibility of separation is governed by the sorption interaction of the complexes with the sorbent carrier.

In this connection it is important to note also that, in the limiting case, the formation of sparingly soluble complexes takes place in the complexing adsorption method without isolation of a new solid phase: they are attached by van der Waals forces to the surface of the sorbent carrier at the instant of their formation, i.e. bypassing the precipitation stage, apparently becuase the bonding between

molecules of the complex and the surface of the sorbent is stronger than that between molecules of the complex in its crystals. It should be noted that the complexes which are formed may vary in solubility.

One condition for use of the complexing elution of chromatographic columns is that the reagent should be more or less soluble. This is a second stage, following formation of the primary chromatogram, and the ion forming the most stable compound is the first to pass into the filtrate. In contrast to this, the condition for application of the complexing adsorption method is that the reagent should be relatively sparingly soluble but readily adsorbed on the sorbent carrier, so that the reagent remains in the column and does not contaminate the solution of separable cations. Separation is accomplished by the application of only one process—filtration of the solution of separable substances through the column—and the cation forming the least stable complex is the first to pass through into the filtrate. This fact is responsible for the high selectivity of complexing adsorption columns and the possibility of using them to purify large quantities of substances, which do not react with the complexing agent, from impurities which form with the latter complex compounds that are sorbed on the carrier.

It is an extraordinarily complicated task to reveal the main laws and the mechanism of complexing adsorption, especially in view of the multiplicity of combinations in the preparation of modified sorbents, where both the properties of the carrier itself and of the complexing agent and also qualitatively new characteristics of the modified sorbent and those of the separable system may develop and influence the process.

One of the most important factors determining the mechanism of complexing adsorption is the nature of the sorbent carrier. The demands made on the latter by the essential nature of the method reduce basically to the following: the carrier should be insoluble in water or other solvent and possess a sufficiently large surface, the ability to sorb molecularly the complexing agents and their reaction products with the separable substances, good filtering ability, mechanical and chemical stability, and optimum kinetic characteristics. Existing sorbents may only partly satisfy these main requirements.

If the sorbent carrier contains any soluble components, they may be extracted during the process and further contaminate the solution of separable substances. The sorbents sometimes contain soluble components and mineral impurities, which are easily removed by careful preliminary washing.

The advisability of using a particular sorbent carrier depends in large measure on its adsorption capacity. In this connection sorbents having a maximum surface area, because of the presence either of pores or of a network structure, should be preferred. It is important that molecules of the modifier (i.e. of the already sorbed complexing agent) should be accessible for subsequent reaction with the separable ions.

The main type of sorption in the present method would be molecular sorption on to the carriers both of the complexing agents and of the metal complexes formed in the process of separation. Most sorbents contain various functional groups and energetically non-uniform centres, and one mechanism or another may predominate depending on the conditions of sorption. A study of the mechanism of sorption is therefore of great value in choosing the most suitable carrier–modifier system for a particular process.

The good filtering power, mechanical durability, and chemical resistance demanded of a sorbent carrier are governed by its operating conditions. Filtering power depends on the grain size of the sorbent, which is selected within optimum limits for a given size of column and a given rate of filtration of the solution. Adequate mechanical durability of the sorbent is important on prolonged operations, especially if it is desirable to regenerate the sorbent and use it many times. Various corrosive media may be employed during separation or sorbent regeneration, so that the chemical resistance of the sorbent is also quite important. Changes in the sorbent resulting from chemical reactions may lead not only to contamination of the solution but also to mechanical disintegration and loss of sorption capacity.

Modifying the surface of a sorbent carrier by the sorption of various complexing agents yields a qualitatively new sorbent: not only the chemical but also the physical properties of its surface have changed. The pore size and hence the total surface vary depending on the quantity of complexing agent sorbed by the carrier. The absorption of metal ions takes place on a modified sorbent, as a consequence of their chemical reaction with the complexing agent and the formation of new complexes. Other types of sorption, characteristic of the unmodified carrier, may be either partly or completely suppressed.

It must be borne in mind that the chemical reactions occurring in a complexing adsorption column may differ from those in solution[19]. For example, compounds which are unstable in solution under ordinary conditions are often formed in a column and exist for a long time[12–14]; in other cases certain reactions, which are not feasible under static conditions, may go to completion in a column[19]. These aspects of the accomplishment of reactions directly in columns may find the widest practical application, from the separation of different modifications of chemical compounds to reactions which occur with difficulty under static conditions, including catalytic processes for organic and for inorganic substances.

We have investigated the mechanism of the sorption of complexing agents and inorganic ions on active carbon[28,29], and shown that the former (e.g. dimethylglyoxime, 1-nitroso-2-naphthol, 8-hydroxyquinoline, tannin, xanthates, dithizone, diethyldithiocarbamates, derivatives of hydroxamic acids, phenylarsonic acid, thionalide, thiourea, etc.) undergo sorption of molecular type. Carbon is able to retain firmly 10–20% of the complexing agent, about 1.0–3.0 mg-equiv.g^{-1}, while the ion-exchange sorption of inorganic ions on active carbon is only 0.05 to 0.07 mg-equiv.g^{-1}. These results are consistent with those obtained by other workers[19,30]. It was established also that the sorption of the complexes formed with metal ions is molecular in character[28,29].

The fact that sorption can occur on active carbon by two mechanisms—molecular and ion-exchange—does not prevent its use as a carrier in the complexing adsorption method. Ion-exchange sorption has been shown[28,29] to predominate at low (up to 1%) surface coverage by the modifier. Above 1% coverage this is suppressed by sorption of the complexing agent, and the metal is absorbed by the complexing adsorption mechanism. We can therefore regard modified active carbon as monofunctional, corresponding in its action to the complexing modifier sorbed on it.

The optimum quantity of modifier on the carrier should be found empirically in each individual case. The total absorption capacity of the metal increases with increase in the coverage of carbon by the modifier[28,29], while the degree of utilisation of the complexing agent diminishes. However, the most complete exploitation of the modifier,

in some cases even ~100%, can be attained by selecting experimental conditions under which the metal ion is complexed to the maximum extent. This is usually achieved by choosing the optimum pH for the given system[22,28,29].

The temperature conditions are very important for separations by the complexing adsorption method. Rise in temperature tends to increase the rate of absorption of a metal cation. A considerable temperature effect can be used for intensifying complexing adsorption, since it tends to increase the productivity of the columns and permits higher rates of filtration.

All the above factors, influencing in some measure the separation of substances by complexing adsorption, must obviously be taken into account in determining optimum procedures for the chromatographic processes.

III. CONDITIONS OF APPLICATION OF SORBENT CARRIERS AND COMPLEXING AGENTS IN COMPLEXING ADSORPTION CHROMATOGRAPHY

Very few sorbent carriers at present available for complexing adsorption satisfy the above requirements. The most widely used for these purposes is active carbon, which was first employed by the originators of this method[15,17]. Subsequently technical conditions were developed for "active wood charcoal for chromatography" (DAUKh) [19], which was used in industry for obtaining high-purity salts employed in the manufacture of phosphors. In contrast to other carriers, charcoal, like most carbon sorbents, is a readily available and cheap material, possessing adequate sorption capacity, mechanical and thermal durability, and structural stability. The oblong grains of DAUKh charcoal have a cross-section of 0.2–0.6 mm. Carbon of such grain-size ensures a satisfactory rate of filtration when used in fairly large columns[19]. Complexing adsorption processes have been accomplished also on other brands of carbon[31–35].

Other sorbents, e.g. Wofatit E[36], whose capacity is several times greater than that of active carbon, have been used as carriers. Our investigations indicate that Wofatit E is useful as a sorbent carrier in processes where strong selective absorption is required. This resin is unsuitable for very fine separations, since with strong absorption substances of similar properties exhibit no differences in behaviour.

Among Soviet synthetic materials it is only recently that macroporous resins have been synthesised which are capable of both molecular and ion-exchange sorption. Such resins may be supposed to be good sorbent carriers for complexing agents.

Experience in the application of various complexing agents has enabled us to recommend several general and special procedures for modifying carbon in order to prepare selective sorbents. Charcoal can conveniently be freed from mineral impurities by pretreatment with 5–10% hydrochloric (or sulphuric) acid heated to 60–70°C.[16] The completeness of extraction of mineral impurities—mainly iron, copper, and potassium—must be checked by application of the most sensitive analytical methods to the filtrate. After treatment the excess acid must be washed out of the charcoal with distilled water until the washings are neutral to Methyl Orange, and the carbon brought to an air-dry state.

The method used to prepare the modified carbon may vary with the properties of the complexing agent. Sorption of sparingly soluble, non-volatile reagents (e.g. dimethylglyoxime, *N*-hydroxy-*N*-phenylbenzamide) is best accomplished by heating an aqueous suspension with carbon on a water-bath at 70°C. Heating is advisable to accelerate dissolution of the reagent and to remove air. As reagent is absorbed, fresh portions gradually dissolve and pass into the sorbed state. Soluble reagents (e.g. diethyldithiocarbamate, tannin, phenylarsonic acid) may be sorbed from aqueous suspension on shaking. It is advisable to preheat the suspension at 70°C for 5–10 min to remove air bubbles. Heating is inadvisable for the sorption of reagents which are volatile in steam (e.g. hydroxyquinoline). In this case saturation must be accomplished at ordinary temperatures, by shaking an aqueous suspension of carbon with the reagent. It is advisable to preheat an aqueous suspension of the carbon (without the reagent) at 70°C, and then cool it. Completion of sorption is assessed by disappearance of the corresponding colour from the solution when a sensitive qualitative test is applied for the given reagent.

The quantity of complexing reagent which can be retained in the sorbed state on DAUKh charcoal is usually 10–20% based on the weight of carbon.

Most complexing agents are firmly sorbed on the carbon surface, and hardly any desorption occurs on washing with water or on the passage of considerable volumes of solution. But in some cases, e.g. in the sorption of tannin, the reagent is not firmly retained on the carbon surface, and is gradually washed out of the column. In order to secure better attachment of such reagents, it is advisable after sorption to dry the modified carbon without washing it with water[29,37].

Some sorbents absorb well from solutions in organic solvents, e.g. dithizone from chloroform solution on to carbon[31]. The modified sorbent obtained sorbs heavy metals well from aqueous solutions.

An interesting method is to impregnate active carbons and other inert carriers with liquid organic reagents. McClaine and Noble[32,33] extracted uranium selectively on carbon treated with organophosphorus acid derivatives, which give stable chelate complexes with several metals, in particular uranium. Such sorbents have been employed in industry to extract rare metals.

In some cases a modifier is deposited from the vapour phase on to a carrier[38,39]. A carbon–titanium sorbent, which absorbs uranium selectively, has been obtained in this way.

The application of modified sorbents under dynamic conditions—in complexing adsorption chromatographic columns—is most effective, and we shall be concerned here mainly with this method.

Independently of column size (from laboratory to industrial dimensions) the modified sorbent is introduced as a suspension in an appropriate solvent (aqueous suspensions are mostly used). If the modified sorbent required is in a dry form, its aqueous suspension is first heated at 70°C. This is especially important in cases in which separation is effected at high temperatures, since dissolved air would be evolved from an unheated suspension, and might cause swelling of the sorbent layer.

If substances which do not react with the modifier are to be thoroughly freed from impurities that react with it to form stable sorbable compounds, it is advisable to place a layer of the pure sorbent carrier below the layer of modified sorbent, in order to prevent contamination of the filtrate with compounds that may be partly desorbed from the modified sorbent layer. The pure carrier is introduced into the column by the same procedures as the modified sorbent.

In the preparation of modified sorbents it must be borne in mind that the reactions of complexing agents on sorbent carriers with metal ions often occur differently from in a homogeneous medium. The special features of the process are exploited to intensify the separation effect (e.g. with dimethylglyoxime, 1-nitro-2-naphthol, xanthates, etc.). Sometimes, however, reactions in columns do not produce the expected separation, owing to the occurrence of undesired reactions.

An example of the complicating effect of the sorbent carrier is provided by columns containing carbon modified with sodium tetraphenylborate, a selective reagent for precipitation of the univalent ions K^+, Rb^+, Cs^+, NH_4^+, Ag^+, Hg_2^{2+}, and Tl^+. The solubility products of compounds of these metals with tetraphenylborate lie in the range 2×10^{-8}–5×10^{-10}. It would therefore appear promising to use such columns for the selective absorption of these ions from solutions of salts of other metals, especially for the thorough purification of sodium salts. However, our investigations of the sorption of potassium from aqueous salt solutions has revealed certain anomalies in this process. Potassium is completely absorbed on a carbon–tetraphenylborate column provided that sodium is absent from the solution: in the presence of sodium salts, however, the sorption of potassium is considerably weaker. Potassium absorbed by a column is displaced by sodium salts. A precipitate of potassium tetraphenylborate obtained in the absence of carbon is decomposed on addition of the latter to the system, with the liberation of K^+ and BO_3^{3-} ions. We explain this by the following decomposition of tetraphenylborate in the presence of carbon

$$(C_6H_5)_4BK + 4H_2O \rightleftarrows H_3BO_3 + KOH + 4C_6H_6 . \quad (1)$$

The decomposition of sodium tetraphenylborate occurs according to the equation[40]

$$(C_6H_5)_4BNa + 3H_2O \rightleftarrows C_6H_5B(OH)_2 + 3C_6H_6 + NaOH . \quad (2)$$

Detection of the BO_3^{3-} ion in solution indicates that reaction (1) takes place in the presence of carbon. It is interesting that displacement of the reaction to the right-hand side, i.e. liberation of the K^+ ion, does not take place from a precipitate of potassium tetraphenylborate in sodium iodide solution. Carbon evidently catalyses the decomposition of tetraphenylborate. For this reason sodium salts cannot be completely freed from contamination by potassium using a carbon–tetraphenylborate column. The maximum degree of purification achievable by this method does not exceed 0.0016%.

In some cases the sorption capacity is diminished when a sorbent is modified, owing to blocking of the active groups of the modifier. An example is provided by Dzhelassi and Egorov[41], who investigated the sorption of germanium on BAU carbon, alumina, and EDE-10P anion exchanger, all treated with dimethylaminophenylfluorone. It was found that after such treatment the sorption of germanium increased on the anion exchanger, but diminished on carbon and on alumina. The explanation offered[41] was that, when the modifier is sorbed on carbon and alumina, the *ortho*-dihydroxy-groups capable of reacting with germanium lose their activity.

The above examples show that a favourable effect cannot always be expected after modification of a sorbent. When the expected effect is not achieved, the reasons must be ascertained, and if possible another modifier–carrier system chosen.

Experience in the application of several complexing agents has shown that most selective isolations can be conducted more efficiently in complexing adsorption columns than in solution. The development of the theory of complex formation during recent years has revealed new opportunities for accomplishing many specific separations which can be successfully used in the complexing adsorption method. Complexes of the chelate type—hydroxyquinoline, dithizone, *N*-hydroxy-*N*-phenylbenzamide, diethyldithiocarbamate, pyridylazoresorcinol, pyridylazonaphthol, dimethylglyoxime, etc.—should play a special part here. If masking agents are used, chelate compounds provide the widest possibilities for the isolation and separation of pure elements. The number of chelate compounds studied is continually increasing, with an accompanying increase in the possibility of choosing systems having the maximum selectivity for extracting rare, trace, and other impurity elements[80].

IV. FIELDS OF APPLICATION OF COMPLEXING ADSORPTION CHROMATOGRAPHY

1. Production of Pure Salts

Complexing adsorption chromatography was developed during 1954–1957 in solving purely manufacturing problems[15,16,19,28]. The first field of application of this method was the production of high-purity salts used in the manufacture of phosphors. This problem was successfully solved for the purpose of purifying metals, which do not react with the complexing agent in the column, from impurity metals which form stable and firmly adsorbed compounds with it (e.g. the purification of zinc and cadmium sulphates from traces of copper, iron, nickel, and cobalt)[16,19]. The columns used consisted of two layers: the lower layer contained active carbon; the upper layer comprised active carbon and a complexing agent (e.g. dimethylglyoxime or 1-nitroso-2-naphthol) to react with impurities, in the proportions 10 : 1. The purpose of the lower layer was to prevent the partly water-soluble organic reagent from breaking through into the filtrate. The complex compounds formed in the column were firmly retained on the surface of the carbon. Purification of dissolved salts of zinc, cadmium, alkali metals, and alkaline-earth metals in the presence of hydrogen peroxide at pH 5.8–7.2 on such carbon–dimethylglyoxime and carbon–1-nitroso-2-naphthol columns lowered the concentration of copper, iron, nickel, and cobalt to 1×10^{-9}–4×10^{-8} g ml^{-1}.[16,19,28]

The fact that in this case the complexing agent does not react with the cations of the salts to be purified is responsible for the selective sorption of impurities by the columns, the lack of an effect of the initial impurity concentration on the degree of purification of the solutions (this can be assessed from colorimetric and luminescence analyses), and the extremely high operating capacity of such columns. In the purification of reagent salts with impurity contents exceeding the standard level by factors of 10–1000 the capacity of the column is measured in tons of solution for kilograms of sorbent. The use of carbon–dimethylglyoxime columns to purify the raw materials for the production of phosphors has been adopted by industry, and is applied successfully in both works and laboratory[15–18,20,42–44]. Carbon–*o*-hydroxyquinoline columns can be used to purify alkali-metal salts from heavy metals[15].

Cations which react with the complexing agent can also be separated by means of a complexing adsorption column. As in other applications of chromatography, it is important that there should be a sufficiently large difference in properties (stability constants of the complexes).

For example, a carbon–dimethylglyoxime column can be used to free cobalt salts from contamination by nickel[20]. Cobalt is the first to pass into the filtrate, as it forms a less stable compound with dimethylglyoxime in the column than does nickel. Chemical analysis does not detect nickel in the filtrate, and during purification the cobalt salt does not become contaminated with any substances which it did not contain before purification. In this case the lower layer of the column, which retains the cobalt dimethylglyoximine desorbed from the upper layer, should not be too small.

When the solutions to be purified contain cobalt, it is advisable to use carbon–1-nitroso-2-naphthol columns. These have some advantage over carbon–dimethylglyoxime columns, since they are able to free from cobalt more concentrated (20–25%) zinc sulphate solutions[17]. Furthermore, cobalt dimethylglyoximine begins to be desorbed relatively rapidly from the column, which is not observed when 1-nitroso-2-naphthol is used. In cases in which it is desirable to recover the absorbed nickel and cobalt, however, it is advisable to use dimethylglyoxime columns, since the reaction between dimethylglyoxime and metal cations is reversible in a column (unlike the reaction under static conditions), and the absorbed nickel and cobalt can be extracted with a small volume of aqueous hydrochloric acid[17].

Modified sorbents which bind the main substance but do not react with impurities can also be used to obtain high-purity products. We proposed a method of purifying radioactive niobium-95 from microquantities of antimony-125 on a carbon–*N*-hydroxy-*N*-phenylbenzamide column[29,44] from tartrate solutions buffered to pH 4.5–5.5 with ammoniacal ammonium acetate at 90°C. The column had first been washed with the same buffer mixture. The niobium complex of the modifier formed on filtration was retained in the column, whereas at this pH the antimony passed freely into the filtrate. The niobium sorbed in the column was then washed out with the buffer mixture at the same temperature. Analysis of the filtrates by means of a γ-ray spectrometer showed that the first portions of the filtrate contained the pure radioactive isotope ^{125}Sb, and subsequent fractions contained the pure radioactive isotope ^{95}Nb.

2. Group Separation or Isolation of One Component from a Mixture

The complexing adsorption method has recently become widely used for the separation of metals into groups and for the isolation of one component from a mixture. The application of modified sorbents is especially important when other methods prove ineffective (e.g. in the separation of rare-earth, rare, and trace elements).

We have recommended carbon–xanthate columns for the segregation of alkali and alkaline-earth metals from heavy metals and for the separation of metals which react with xanthates to form sparingly soluble compounds (e.g. Cu^{2+} from Zn^{2+}, Ni^{2+}, etc.)[43].

Conditions have been described for the separation and purification of metals by means of dithizone[31,43,45–47], sodium diethyldithiocarbamate[43,48], zinc and cadmium diethyldithiocarbamates[49], and several other complexing agents[50]. Aleksovskii[51,52] proposed a specially prepared zinc aluminosilicate as sorbent carrier for sodium diethyldithiocarbamate: after modification with a 1% solution of this salt a sorbent which is selective towards copper is obtained. Pierce and Peck[53] recommend that dithizone should be sorbed on acetylated cellulose, and the modified sorbent was used for the selective extraction of zinc, shown to be absorbed by the reaction $Zn^{2+} + 2HDz = ZnDz_2 + 2H^+$.

Hesford[54] recommends that active carbon should be saturated with bases—aqueous ammonia, methylamine, diethylamine, alkylamines, hexamines, pyridine, etc.—having different dissociation constants. Strong bases were used to segregate most cations, which form insoluble hydroxides, from alkali and alkaline-earth metals. Weak or complexing bases were used to isolate or separate certain cations.

Andreev et al.[31] applied the method for the selective isolation and concentration of lead, iron, copper, manganese, cobalt, and cadmium present in microconcentrations in natural waters. Active carbon of KAD and BAU brands was used as sorbent carrier. The dithizone modifier was sorbed from chloroform solution, and subsequently removed by the solvent. Carbon–dithizone columns containing an underlayer of pure carbon possess considerable capacity for the above elements, and are capable of multiple extraction and concentration of metals. The absorbed metals can be isolated into the filtrate with a small volume of weak hydrochloric acid, after which the column is ready for further use without additional regeneration.

3. Concentration of Metals

The complexing adsorption method makes it possible not only to isolate but also to concentrate metals from very dilute solutions ($\leq$ 0.2–0.3 mg litre^{-1}). The metal extracted by the column from a salt solution in which it occurred at a low concentration can be desorbed by decomposing the complex formed in the column and can be concentrated into a small volume of solution. For example, nickel can be segregated on a carbon–dimethylglyoxime column from excess of such a salt as zinc sulphate or sodium sulphate, and then extracted from the column with a small quantity of dilute hydrochloric acid; this increases the nickel concentration a hundredfold[17]. Similarly the reversibility of the reaction between cobalt and dimethylglyoxime in a column, in contrast to the reaction under static conditions, can be used to recover the cobalt removed in the purification of zinc sulphate solution.

4. Qualitative Analysis of Ions

The complexing adsorption method is no less effective for the qualitative analysis of mixtures of ions. Visual observation on colourless adsorbents is most suitable for this purpose. For example, aluminium oxide "for chromatography", after it has been wetted with water, is able to adsorb from aqueous solution metal complexes of dimethylglyoxime. The adsorption properties of aluminium oxide can be exploited by using water-saturated columns of the oxide mixed with dimethylglyoxime, e.g. in the proportions 10 : 1, for the qualitative determination of nickel and cobalt when present together[20]. In such a column nickel forms a pinkish-red zone, and cobalt forms a yellow zone below the nickel zone. It is possible in this way to detect 0.4 μg of nickel at a dilution of 250 000 : 1 in a 3700-fold excess of cobalt, and 2.9 μg cobalt at a dilution of 34 500 : 1 in a 500-fold excess of nickel. Mixtures of Co^{2+}, Ni^{2+}, and Fe^{2+} can also be separated on such columns[55].

The wide possibilities of combining various complexing agents with sorbent carriers has enabled a systematic qualitative analysis of ions to be based on this method[56,57]. It gives entirely reliable detection of micro-quantities of ions.

5. Study of Complex Formation under Dynamic Conditions

Gurvich showed the great possibilities of the method for investigating complex formation in a column[42,55]. Using as example a carbon–dimethylglyoxime column, he obtained new information on the properties of organic reagents, the structure and stability of their compounds with metals, the formation of compounds whose existence had not previously been detected, etc. Thus it has been established that in a carbon–dimethylglyoxime column bivalent nickel, cobalt, copper, and iron form compounds of general formula $M(HDm)_2$, and their relative stabilities have been determined. On such a column these cations form the sequence—$Cu^{2+} > Ni^{2+}$, $Co^{2+} > Fe^{2+}$—in order of diminishing sorbability. This coincides with the order of decreasing stability of their dimethylglyoximines of type $M(HDm)_2$. The order of diminishing stability—$Cu^{2+} > Ni^{2+} > Fe^{2+}$—has been found similarly for the 1-nitroso-2-naphtholates.

Study of the order of sorbability of Cu^{2+} and Fe^{3+} on a carbon–dimethylglyoxime column indicated[42] the existence of compounds—iron(III) copper dimethylglyoximines—in which dimethylglyoxime was combined with both metals. In fact, these compounds were subsequently detected when the reactions were conducted under static conditions. Iron(III) dimethylglyoximine was detected on a column formed by a mixture of aluminium oxide and dimethylglyoxime. This was later confirmed by conducting the reaction between an iron(III) salt and an aqueous solution of dimethylglyoxime under static conditions[55].

6. Extraction of Rare and Trace Elements

Complexing adsorption chromatography has a great future for the incidental extraction of rare and trace elements in the combined exploitation of ores. Appropriate choice of the sorbent carrier and also of the complexing agent will make it possible to extract completely valuable impurities present in minute quantities in the original raw material, and then to obtain them as concentrates. An example of such application is the industrial extraction of germanium from copper schists on columns of Wofatit E saturated with tannin[36]. Germanium was sorbed from 0.1 *N* sulphuric acid having a germanium content of 15 to 200 mg litre^{-1} and with a minimum ratio of germanium to the other elements in the lye of 1 : 10 000. Germanium was sorbed selectively, and the quantity remaining in the mixture did not exceed 0.1 mg litre^{-1}. It was desorbed by means of 9–10 *N* hydrochloric acid: the quantity of tannin thus extracted was so minute that only after 6–8 cycles did some diminution in the capacity of the column for germanium become appreciable. The amount of tannin required to regenerate the column was only 25% of the original quantity.

Other modified sorbents have been examined for the selective extraction of germanium[34,41,58–62]. Matveeva and Press[34] sorbed tannin on KAD–iodide carbon and on AN-1 anion exchanger. The sorption of germanium has been investigated also on KAD–ground carbon and on ASM silica gel modified with catechol, quinalizarin, and phenylfluorone[59], on EDE-10P anion exchanger modified with Tiron [disodium 4,5-dihydroxy benzene-1,3-disulphonate][58], and on BAU carbon modified with 8-hydroxyquinoline, tartaric and citric acids, and iron hydroxide[60–63]. In all cases modification of the sorbent led to increased sorption of germanium. However, the best results were obtained by Ziegenbalg and Scheffler on the Macroporous resin Wofatit E.[36] The use of macroporus resins as sorbent carriers is undoubtedly extremely promising for such processes. Further searches for optimum modified sorbents must be directed not only at new complexing agents but also at producing the best sorbent carriers.

Modified sorbents based on active carbons have been used to isolate uranium. A large-scale countercurrent scheme was proposed for the selective extraction of uranium from ore slurries and sulphuric-acid concentrates by walnut, coconut, and almond shell charcoals modified with di-2-ethylhexyl pyrophosphate and other organophosphorus compounds capable of chelating uranium[32,33]. These workers established also that the capacity of the modified sorbent depends on the nature of the complexing agent, its surface concentration, and the nature of the sorbent carrier.

The selective sorption of uranium from nitrate solutions containing zinc, thorium, iron, and vanadium has been accomplished[64] on BAU carbon modified with tributyl phosphate, and a method has been suggested[65] for separating uranium and iron on KAD carbon modified with 1-nitroso-2-naphthol. In the presence of trilon B at pH 4.5 to 5.5 and ratios of uranium to iron of 1 : 1–100, uranium undergoes almost complete absorption with insignificant sorption of iron. Variation in the ratio of uranium to iron within wide limits has no effect on the results of the separation.

"Alkaline A" carbon treated with phenylarsonic acid, and also arsenazo III and alkylphosphoric acids, was used for the quantitative isolation of protactinium from 1 M sulphuric acid in the presence of tin, titanium, chromium, aluminium, iron, thorium, zirconium, and uranium[35]. These sorbents were used to concentrate protactinium from uranium ores and from the products of their processing, and also to isolate protactinium from neutron-irradiated thorium.

Acetylcellulose and the vinyl chloride–acetate copolymer Corvic have been successfully used as supporting sorbents[66–68]. Microquantities of indium have been extracted on an acetylcellulose column modified with dithizone[66], and the Corvic copolymer modified with di-2-ethylhexyl hydrogen orthophosphate has been used to separate the rare-earth metals from lanthanum to lutetium. The separation was conducted from dilute perchloric acid at 60°C. Elements absorbed by the column were eluted separately in order of increasing atomic weight by perchloric acid of gradually increasing concentration[67,68].

The complexing adsorption method has been recommended also for the overall segregation of rare-earth elements from heavy metals[69,70].

7. Separation of Elements with Similar Properties

We have shown[29,43,44,71–73] that complexing adsorption chromatography offers the greatest opportunities for effecting highly selective processes in the separation of elements with closely similar properties. Niobium and tantalum, which possess similar chemical and physical

properties, were taken as the most difficult pair of elements to separate. The difficulty of separation is aggravated by the interaction of the elements, since they partly lose their individual properties when present in admixture. Aqueous solutions of their tartrate or oxalate complexes were used, with DAUKh charcoal as supporting sorbent. We find it useful to divide methods of separating niobium and tantalum into two groups, according to the complexing agents employed.

1. The modified sorbent binds mainly niobium, which is retained by the column, while tantalum passes into the filtrate with the stream of buffered solution. This enables spectroscopically pure tantalum to be isolated. Such separations have been developed by using sorbents modified with 8-hydrozyquinoline and *N*-hydroxy-*N*-phenylbenzamide. Quantitative separation of the elements can be achieved from tartrate solutions of pH 5.2–5.4 on a carbon–hydroxyquinoline sorbent at ~95°C. With a carbon–*N*-hydroxy-*N*-phenylbenzamide sorbent the best results are obtained from tartrate solutions of pH 4.5 at 95°C; a tantalum fraction free from niobium can be obtained in only ~80% yield.

2. The modified sorbent binds tantalum preferentially, while niobium passes into the filtrate with the stream of buffered solution. The niobium fraction contains the spectroscopically pure element. These results have been obtained on sorbents modified with phenylarsonic acid and tannin. Quantitative separation of the elements was obtained on both sorbents. On a carbon–phenylarsonic sorbent separation is achieved at ~95°C from oxalate media containing 0.65–1.0 *N* hydrochloric acid. On a carbon–tannin sorbent niobium and tantalum are separated from oxalate solutions of pH 2–3 at 95°C.

Complexing adsorption chromatography can be used to concentrate dilute solutions of niobium and tantalum and also for isolating these elements from a mixture. Such processes can be accomplished, for example, on a carbon–diethyldithiocarbamate sorbent, when the columns can be used many times without further regeneration.

The methods which we have proposed for isolating and separating niobium and tantalum have defined advantages over existing methods, mainly in their simplicity, the elimination of injurious and flammable organic solvents, of toxic and chemically corrosive fluorides, plus the possibility of obtaining spectroscopically pure components.

8. Separating Organic Substances and Effecting Chemical Reactions

The principle underlying complexing adsorption chromatography can obviously be used not only for the separation of inorganic substances but also in organic chemistry to accomplish certain chemical reactions and to separate organic compounds.

Forster and Rogers[74] separated amines on columns comprising silica gel or aluminium oxide treated with inorganic salts. Modification was shown to improve the selectivity and increase the capacity of the sorbents. As in the separation of inorganic products, sorption is described by the Langmuir equation. Balint[75] separated the aromatic components of solar distillates on an aluminosilicate treated with picric acid.

9. Use of Modified Sorbents under Static Conditions

We have been discussing the chief ways in which modified sorbents can be used chromatographically, i.e. on columns under dynamic conditions. Sometimes, however, it is desirable to apply them under static conditions, e.g. at the enrichment stage in the selective sorption of elements from slurries and lyes and in some other cases.

Lodeishchikov and Panchenko showed[76] that the isolation of gold and silver from the difficultly filterable slurries formed in the processing of an argillaceous ore can be suitably and economically accomplished by stirring the slurry vigorously with a suspension of carbon in the presence of thiourea. With gold and silver contents in the slurry of 7.8 and 3.2 g t^{-1} respectively the total content of noble metals after isolation on carbon was given as 240 to 250 kg t^{-1}.

Kuzin et al.[77] investigated the sorption of uranium, cerium, thorium, iron, and magnesium on SKT active carbon from acetic-acid solutions, and found that under these conditions uranium is sorbed selectively and can be separated from the other components of the mixture. Desorption of the uranium with 1 *N* hydrochloric acid enables a high degree of concentration to be achieved.

Similar results were obtained by Kogan and Evdokimov[78,79] for the sorption of germanium from oxalate solution on BAU active carbon. They found that the molecular proportions of germanium and oxalic acid sorbed approximated to the ratio in the complex $H_2[Ge(C_2O_4)_3]$.

It must be borne in mind, however, that in the static variant we lose the advantages of the chromatographic method, i.e. the possibility of separating sorbable substances on a column and maximum utilisation of the capacity of the sorbent.

---o0o---

Study of the mechanism of the complexing adsorption of metals enables paths for its further development to be mapped out, and possible limits to and the advisability of its application for practical purposes to be assessed.

We have investigated the mechanism and the kinetics of the absorption of metal ions on modified sorbents in which the carrier was DAUKh charcoal[28,29]. Several regularities which were then established—the molecular character of the sorption of complexing agents and their reaction products with metal ions, the inner-diffusion kinetic mechanism, and the occurrence of a second-order chemical reaction—can be regarded as general features of the method, as is shown by the kinetics of the process. At the same time there are also specific features of the mechanism resulting from the properties of active carbon as a carrier—the simultaneous occurrence of two sorption mechanisms (ion exchange and molecular) and the effect of the character of the pores on the sorption processes, as evident in the dependence of the degree of utilisation of the complexing agent on coverage of the sorbent carrier by the agent, on the retention time of the modified sorbent, and on the temperature.

Investigations of the mechanism and the kinetics of absorption on other sorbents, which can subsequently be used as supports for complexing agents, should be of considerable interest for the development of complexing adsorption chromatography. A promising field is the application of the recently synthesised macroporous and isoporous resins, which are capable of the molecular sorption of organic compounds. Perhaps these carriers will yield modified sorbents with better kinetic characteristics and greater utilisation of the modifier than in the case of sorbents based on active carbon. However, the application of active carbon in the complexing adsorption

method is not yet exhausted, and continued examination of the properties of this extremely interesting sorbent is required, so that all its inherent possibilities can be more fully exploited.

Active carbon is most convenient in industrial and semi-industrial preparations because of its cheapness, mechanical durability, and chemical resistance. The radiation resistance of carbon enables it to be used to separate radioactive preparations at various stages in the processing of ores. For example, Davydov et al.[35] used active carbon saturated with phenylarsonic and alkylphosphoric acids to concentrate protactinium from uranium ores and their products, and also for isolating protactinium from neutron-irradiated thorium. The yield of protactinium exceeded 90%. Modified carbon can be used[44] to purify radioactive isotopes.

The complexing adsorption method should play a quite important part in the isolation of rare and trace elements and in the separation of elements having closely similar properties[29,43,44,71-73].

Study of a series of complexing adsorption systems has shown that an unlimited range of highly selective sorbents having specified properties can be prepared by the simplest methods, by exploiting for this purpose the rich opportunities provided by the different kinds of complexing agents available to the chemist[80]. Some ways of preparing such modified sorbents have been discussed above.

Even at this stage in the development of complexing adsorption chromatography the analytical chemist is already able to select a modified sorbent for the overwhelming majority of separation processes, by skilfully exploiting the properties of separable and complexing substances.

The practical application of complexing adsorption chromatography has shown that it is most suitably employed for purifying substances which are not sorbed in the column from impurities present in minute concentrations and retained by the modified sorbent. With other concentration relations of the elements to be separated the advisability of using this method would be determined by economic considerations taking into account the possibility of regenerating the modified sorbent.

The broad development of the complexing adsorption method and its introduction into industry require the production of special sorbent carriers possessing mechanical, chemical, and radiation stability, a high capacity for various kinds of organic compounds, good kinetic and hydrodynamic characteristics, and a structure which would ensure full utilisation of the modifier independently of its amount on the carrier.

Oxygen Fluorides and Dioxygenyl Compounds

I.V.Nikitin and V.Ya.Rosolovskii

The review considers the methods of preparation, structures, and properties of oxygen fluorides and dioxygenyl compounds which are genetically related to them.
The bibliography includes 124 references.

I. INTRODUCTION

The oxygen compounds of the halogens constitute one of the groups of compounds of the most electronegative elements. Substances of this kind are oxidants with a high energy store, which are capable of releasing their chemical energy under certain conditions either instantaneously or at a controlled rate. Compounds of fluorine and oxygen are of special interest in this sense, since they comprise light electronegative atoms.

The chemical bond between oxygen and the halogens is covalent. The names adopted for the binary compounds of oxygen and halogens—"oxygen fluorides" and "chlorine, bromine, and iodine oxides"—reflect the electronegativity of the elements and are consistent with the rules of the International Union of Pure and Applied Chemistry (IUPAC).

This review deals with oxygen fluorides, the methods for their preparation, and their physical properties, structures, and reactions. The existing reviews[1-3] no longer embrace the entire accumulated experimental data. The authors of the present review do not claim an exhaustive presentation of the subject, their aim being to examine mainly studies published after the extensive review by Streng[1].

One of the most important properties of oxygen fluorides is their capacity to react with fluorine-containing Lewis acids forming dioxygenyl salts. Dioxygenyl hexafluoroplatinate, the first compound of the O_2^+ cation (obtained by Hartlett[4]), preceded and simulated the synthesis of valence compounds of xenon[5]. These studies had a significant influence on the development of modern refined inorganic syntheses. Dioxygenyl compounds are considered in a separate section of the present review.

II. OXYGEN FLUORIDES

1. Oxygen Difluoride

Oxygen difluoride has been known since 1927.[6] A widely employed method for the separation of OF_2 is based on the reaction of gaseous fluorine with a dilute aqueous solution of alkali[1,7]:

$$2F_2 + 2NaOH\ (KOH) \rightarrow OF_2 + 2NaF\ (KF) + H_2O\ .$$

Oxygen difluoride is also obtained by the electrolysis of hydrogen fluoride containing added water and an alkali metal fluoride[1,8]. Recently the reaction of fluorine with water in the presence of an alkali metal (Na, K, and Cs) fluoride was proposed as a method for the preparation of OF_2.[9] The synthesis is carried out in a glass apparatus where the HF and SiF_4 formed combine with the metal fluoride and do not contaminate the desired product, the yield of which reaches 80%.

Oxygen difluoride is thermally stable up to 200–250°C. It melts at −224°C, the yellow liquid boiling at −145°C; the vapour pressure of OF_2 is 1 mmHg at −196°C and 11 mmHg at −183°C.[1] Probably the most reliable value of the standard enthalpy of formation, $\Delta H^\circ_{f298}[OF_{2(gas)}] = 5.86 \pm 0.38$ kcal mole^{-1}, has been obtained[10] by measuring the heat of combustion of hydrogen in OF_2. The average thermochemical energy of the O–F bond in the OF_2 molecule is 45.7 kcal mole^{-1}.[10] The dissociation energy of the first O–F bond is less than the dissociation energy of the second bond; for example, $D(F-OF) \simeq 42.7$ and $D(OF) \simeq 48.3$ kcal mole^{-1} have been quoted[11].

The geometrical parameters of the OF_2 molecule have been determined by microwave spectroscopy[12]: $r(O-F) = 1.390$ Å and $\angle FOF = 104°16'$, differing somewhat from $r(O-F) = 1.412$ Å and $\angle FOF = 103°10'$ obtained by Pierce et al.[13] The infrared spectrum of gaseous OF_2 contains three intense bands corresponding to three normal vibrations: 928 (symmetrical stretching), 461 (deformation), and 831 cm^{-1} (antisymmetric stretching) and a number of weak absorptions—overtones and compound frequencies: 1281, 1648, 1728, 1740, 1840, 2188, 2455, 2643 cm^{-1}.

Oxygen difluoride is an effective fluorinating agent, somewhat inferior in reactivity to elemental fluorine[15]. In systems subjected to the action of an electric discharge or radiation, oxygen difluoride both fluorinates and oxidises. The reaction of OF_2 with unsaturated nitrogen fluorides in an electric discharge results in the formation of nitrogen trifluoride, oxide fluorides, and oxide[16]. By exposing oxygen difluoride and NF_3 to an electric discharge, it is possible to obtain trifluoroamine oxide[17,18]. A photochemical reaction of OF_2 with chlorine trifluoride has been used to synthesise chlorine oxide trifluoride $ClOF_3$.[19] When ionising radiation acts[20] on a mixture of NF_3 and OF_2 at −196°C, O_2F_2 and N_2O_4 are formed. XeF_2 and KrF_2 have been obtained by the photochemical fluorination of xenon[21] and krypton[22]. By heating a mixture of xenon and oxygen difluoride to 400°C or passing a mixture of the reactions through a discharge, XeF_4 and xenon oxide fluorides have been synthesised[1]. Oxygen difluoride does not react with liquid chlorine, or with gaseous chlorine at a moderate temperature, but in an electric discharge at low temperatures a reaction leading to the formation of ClF, ClO_2, and ClO_2F takes place[16].

The primary stage in the thermal reactions of oxygen difluoride with nitrogen dioxide[23] and tetrafluorohydrazine[24] is the abstraction of a fluorine atom from the OF_2 molecule:

$$(N_2O_4 \rightleftarrows 2NO_2)\ NO_2 + FOF = FNO_2 + OF,$$
$$(N_2F_4 \rightleftarrows 2NF_2)\ NF_2 + FOF = NF_3 + OF\ . \qquad (*)$$

The activation energy for reaction (*) is 22.5 kcal mole^{-1}. We may note for comparison that the activation energy for the reaction

$$NF_2 + F_2 = NF_3 + F$$

is only 9.7 kcal mole^{-1}.[25] The reaction of oxygen difluoride with tetrafluorohydrazine,

$$2N_2F_4 + OF_2 = FNO + 3NF_3\ ,$$

gives rise to nitrosyl fluoride, which does not react with oxygen difluoride below 170°C.[24]

Certain reactions involving oxygen difluoride may be regarded as addition to the second reactant of a fluorine atom and an OF radical—fragments derived from OF_2. When radiation at a wavelength of 3650 Å was allowed to act on a mixture of OF_2 and SO_3 at room temperature, fluoroperoxy-sulphuryl fluoride FSO_2OOF was obtained[26,27]. If the radiation includes quanta the energy of which is sufficient for the excitation of sulphur trioxide, then FSO_2OOF is formed in trace amounts and the main reaction products are pyrosulphuryl fluoride and sulphuryl fluoride[28]. The fact that the OF group in fluoroperoxysulphuryl fluoride originates from oxygen difluoride was demonstrated[29] in a study of the reaction of OF_2 and SO_3 by a tracer atom method, the products being analysed by ^{17}O NMR. The photochemical reaction of oxygen difluoride with peroxydisulphuryl difluoride[28] yields FSO_2OOF and FSO_3F. The reaction probably takes place as follows:

$$(1)\ F_2S_2O_6 \rightleftarrows FSO_3 + FSO_3,\ (2)\ OF_2 \rightarrow F + OF,$$
$$(3)\ FSO_3 + F = FSO_3F, \qquad (4)\ FSO_3 + OF = FSO_2OOF\ .$$

The photochemical reaction of OF_2 with sulphur dioxide gave pyrosulphuryl fluoride and sulphuryl fluoride[28], whereas on heating OF_2 and SO_2 to 300–500°C sulphuryl and thionyl fluorides are formed[30].

The reaction of oxygen difluoride with primary amines[31] leads to the formation of nitroso-compounds or oximes, for example nitrosocyclopropane has been obtained by the oxidation of cyclopropylamine at −42°C. It is believed that the interaction of OF_2 with amines can be described in terms of the following mechanism[31]:

$$RNH_2 + OF_2 \rightarrow [\overset{(+)}{R}NH_2{-}OF]\overset{(-)}{F} \longrightarrow RN{=}O + 2HF$$
$$\underset{\text{or}}{\downarrow} [RNH{-}OF] + HF \longrightarrow \uparrow\ .$$

One of the intermediate stages in the low-temperature (−78° or −40°C) oxidation of olefins and alkynes by oxygen difluoride probably involves the addition of F–OF to the double or triple bond[32]. Perfluoroethylene, perfluoropropene, perfluorobut-2-ene, and perfluorocyclobutene are less reactive with respect to oxygen difluoride: the reactions of these compounds with OF_2 require thermal or photochemical activation[33]. It is believed that in this case the OF_2 molecule adds to the double bond, but the resulting hypofluorites undergo further reactions, as in the reaction between OF_2 and unsaturated hydrocarbons. When OF_2 reacts with tetramethylallene, the hypofluorite (I) may be formed as an intermediate, which is converted further into compounds (II) and (III):[34]

$$Me_2C{=}C{=}CMe_2 \xrightarrow[-78°]{OF_2} \left[Me_2C{=}\underset{\underset{FO\ \ F}{|\ \ \ |}}{C}{-}CMe_2\right] \rightarrow Me_2\underset{\underset{F\ O\ F}{|\ \ \|\ \ |}}{C}{-}CMe_2 +$$
(I) (II)
$$+ Me_2\underset{\underset{F\ \ O}{|\ \ \|}}{C}{-}C(Me){=}CH_2 + HF\ ,$$
(III) (Me=CH$_3$)

The thermal (at 50–90°C) or photochemical (λ = 3660 Å; 0°C) reaction of oxygen difluoride with carbonyl sulphide[35], $OF_2 + S = CO \rightarrow F_2SO + CO$, may be regarded as yet another example of the addition of OF_2.

The reaction of oxygen difluoride with carbonyl fluoride in the presence of a catalyst (CsF for RbF) at 25°C gave bis(trifluoromethyl) trioxide[36]: $OF_2 + 2F_2CO = CF_3OOOCF_3$. CF_3OOOCF_3 is formed in low yields when sodium trifluoroacetate is fluorinated[37]. CF_3OOOCF_3 is quite stable at room temperature, decomposing slowly at

70°C with formation of CF_3OOCF_3 and oxygen. The catalytic synthesis of CF_3OOOCF_3 proceeds via several stages[36,38]:

$$(1)\ COF_2 + MF \rightarrow M^+OCF_3^-, \qquad (2)\ OF_2 + CF_3O^- \rightarrow CF_3OOF + F^-,$$
$$(3)\ CF_3OOF + CF_3O^- \rightarrow CF_3OOOCF_3 + F^-, (4)\ CF_3OOF + COF_2 \rightarrow CF_3OOOCF_3.$$

Yet another method for the preparation of bis(trifluoromethyl) trioxide was described recently[39]: it involves the reaction of carbonyl fluoride with di(fluoroxy)difluoromethane in the presence of CsF. Simultaneously with the work of Anderson and Fox[39], a method was described for the preparation of CF_3OOOCF_3 by the reaction of $F_2C(OF)_2$ with caesium trifluoromethoxide in the presence of CsF.[40] In addition to bis(trifluoromethyl) trioxide, CF_3OF, $CF_3OOC(O)F$, and $CF_3OOOCF_2OOCF_3$ are formed by this reaction. The last compound is much less stable than CF_3OOOCF_3 or $CF_3OOOC_2F_5$ and decomposes explosively at 40°C.

The hypothesis postulating oxygen difluoride as a source of OF radicals in reactions involving it appears fairly reasonable. The possibility of the stabilisation of the OF group as a cation must be viewed with restrained optimism: even one of the most probable compounds in which OF^+ might exist, namely $[FO]^+[SbF_6]^-$, could not be obtained by the reaction of OF_2 and SbF_5,[16,41] although the OF_2 molecule, which has the same electronic structure as the OF^+ cation, exists and is quite stable.

In connection with the search for methods of synthesising OF radicals, the behaviour of oxygen difluoride was studied in recent years under conditions leading to its dissociation. The photochemical decomposition of OF_2 in the temperature range 15–45°C has the following mechanism[42]:

$$OF_2 \xrightarrow{h\nu,3650\ Å} F + OF,$$
$$F + F + M = F_2 + M,$$
$$OF = {}^1/_2F_2 + {}^1/_2O_2 .$$

The slow reaction $F + OF_2 = F_2 + OF$, the activation energy of which exceeds 15 kcal mole^{-1},[42] is also possible.

The thermal decomposition of OF_2 into fluorine and oxygen has been investigated[43] in a nickel flow reactor at temperatures in the range 500–700°C. The OF radicals were not detected mass-spectrometrically in the samples removed from the reactor: the ratio of the peak intensities for $m/e = 35$ (OF) and 54 (OF_2) did not differ from the ratio usually observed in the mass spectrum of OF_2. Nor were OF radicals detected in a study of the pyrolysis of OF_2 on heated metallic filaments[44]. The attempt at a mass-spectrometric detection of OF radicals in a stream of oxygen difluoride passed through a microwave discharge also proved unsuccessful[44]. OF radicals were not found to accumulate in an OF_2 specimen subjected to ionising radiation at −196°C.[20]

The mechanism of the decomposition of OF_2 in a shock wave (590–1030°C) and in a static reactor (290–360°C) has been discussed[45,46]. The decomposition of OF_2, which begins after a short induction period, proceeds for a time as a first-order reaction[46], but the overall kinetics of the thermal composition of OF_2 are not consistent with a unimolecular reaction[43,46]. The addition of oxygen does not influence the rate of the thermal decomposition of OF_2 and the addition of fluorine inhibits it. It is suggested[11] that the inhibiting effect of fluorine can be accounted for by the reaction $F_2 + OF = OF_2 + F$. Analysis of the literature data[43,45–47] and the results obtained in a study of the decomposition of OF_2 in a shock wave tube (500–1120°C) enabled Lin and Bauer[11] to suggest a mechanism for the thermal decomposition of OF_2 similar to that for the photochemical decomposition:

$$OF_2 + M \overset{a}{\rightleftarrows} F + OF + M,$$
$$2\,OF \xrightarrow{b} 2F + O_2,$$
$$2F + M \rightleftarrows F_2 + M .$$

Reaction (a) determines the rate of decomposition, its activation energy being 30–40 kcal mole^{-1} according to a number of data[11,43,45–47]. In the temperature range 500–960°C, $k_a = 10^{16.7}\exp(-45\,500/RT)$ cm^3 mole^{-1} s^{-1}.[48] The following mechanism has been postulated for reaction (b):

$$FO + OF \rightarrow (F{-}O{-}O)^* + F + 30\ \text{kcal (fast)},$$
$$(FO_2)^* \rightarrow F + O_2\ \text{(very fast)}.$$

The existence of OF radicals could be demonstrated only with the aid of the matrix isolation technique combined with infrared spectroscopy[49]. The radicals were obtained by the photolysis of OF_2–N_2 or OF_2–Ar mixtures deposited on caesium bromide with the ratio of the number of moles of the matrix to the number of moles of the reactant $M/R = 40$. The absorption band at 1028 cm^{-1} in an argon matrix and a doublet at 1025 and 1030 cm^{-1} in a nitrogen matrix arose after the photolysis of the mixtures deposited at 4°K and disappeared on heating the matrix to 40–45°K. The frequency shift observed in the spectra on photolysis of $^{18}OF_2$ agrees with the calculation on the assumption that the absorption is due to the OF radical. The vibration frequency of the OF radical is 1028 cm^{-1}—the maximum frequency of the OF stretching vibrations in the compounds, including OF_2. Special experiments with the addition of nitrous oxide to the mixture of gases deposited for photolysis revealed the cause of the appearance of a doublet in the nitrogen matrix. The 1025 cm^{-1} band is due to OF radicals in matrix cages containing N_2O and the 1030 cm^{-1} band is due to OF radicals in cages without N_2O. Nitrous oxide is formed as an impurity in the isolating matrix by the reaction of atomic oxygen with N_2 molecules. The low efficiency of the emission at a wavelength of 3650 Å in relation to the generation of OF radicals, compared with gas-phase reactions[26,42], indicates an appreciable role of the cage effect in the matrix photolysis of OF_2.

The yield of OF radicals increases appreciably in the photolysis of OF_2 in a nitrogen matrix in the presence of nitrous oxide or carbon dioxide[50]. One of the pathways for the destruction of radicals is the recombination reaction $F + OF = OF_2$. In the presence of nitrous oxide fluorine atoms are consumed in the reaction

$$F + N_2O \rightarrow OF + N_2 \qquad (**)$$

which constitutes an additional source of OF radicals. According to reaction (**), the lower limit of the bond energy in the OF radical may be estimated as about 40 kcal. An increase of the yield of OF radicals was achieved also in experiments with added CO_2, but the mechanisms of the action of the CO_2 and N_2O additives are different. Fluorine atoms do not react with carbon dioxide under the conditions of matrix photolysis:

$$F + CO_2 \not\rightarrow OF + CO .$$

Probably the following reactions take place in the photolysis of an OF_2–CO_2 mixture:

$$O + CO_2 \rightarrow CO_3,$$
$$F + CO_3 \rightarrow OF + CO_2 .$$

It is also possible that the presence of CO_2 in the matrix and the reaction

$$O + CO_2 \overset{h\nu}{\rightleftarrows} CO_3$$

extend the migration region of O atoms and increase thereby the probability of the reaction $O + F \rightarrow OF$.

The strength of the bonds in the OF radical is sufficiently high for the radicals to exist as stable entities, for example at room temperature. The numerous unsuccessful attempts to detect OF radicals in the gas phase are evidence of their extremely high reactivity. The stabilisation of OF is possible only in an inert matrix over a very narrow temperature range.

2. The Reaction of Fluorine with Oxygen

The term "polyoxygen difluorides" embraces oxygen fluorides the molecules of which contain more than one oxygen atom. Polyoxygen difluorides are very unstable compounds, which decompose considerably below room temperature. They cannot be obtained simply by heating a mixture of fluorine and oxygen. Nevertheless at an elevated temperature fluorine interacts with oxygen and if provision is made for the stabilisation of the reaction products, the fluorine–oxygen compound formed may be isolated. When fluorine and oxygen are passed through a quartz reactor heated to 240–500°C with subsequent quenching of the gases by contact with a surface cooled to −196°C, it is possible to obtain O_2F radicals in an amount sufficient to record their ESR spectrum [51]. In the synthesis of dioxygenyl compounds by heating fluorine, oxygen, and arsenic or antimony pentafluorides to 130–200°C, [41] O_2F radicals are probably formed initially:

$$F_2 \rightleftarrows 2F,\ O_2 + F \rightarrow O_2F,$$

and then react further with the Lewis acid:

$$O_2F + AsF_5\ (SbF_5) = O_2AsF_6\ (O_2SbF_6).$$

The stabilisation of unstable species with the aid of a powerful Lewis acid is a procedure widely employed in inorganic synthesis.

Polyoxygen difluorides are synthesised from the elements in a glow discharge where the reaction of fluorine with oxygen under optimum conditions goes almost to completion. The reaction is carried out in a quartz or pyrex discharge tube, the walls of which are maintained at a low temperature. In experiments at a low current, the electrodes consist of copper or nickel plates inserted into the tube with the aid of Teflon stoppers or in some other way. If the experiments are performed at a discharge current exceeding about 50 mA, the electrode shells are cooled with tap water. A stream of a fluorine–oxygen mixture is passed through the discharge at a reduced pressure. The residual pressure in the apparatus is unimportant when polyoxygen difluorides are obtained in a glow discharge. The pressure is maintained in the range from a few tenths to several mmHg. The Table summarises certain data for the reaction of O_2 and F_2 in a glow discharge. The synthesis of O_2F_2, O_3F_2, and O_4F_2 in an electric discharge from oxygen difluoride and fluorine [52] is analogous to the syntheses of the above compounds from the elements and is of no preparative interest, since oxygen difluoride is less readily available as a starting material than oxygen.

Apart from the flow discharge, the silent and arc discharges are sometimes employed for the synthesis of organic compounds. The reaction of fluorine with oxygen in discharges of this type has not been investigated in sufficient detail. The authors of a study [57] published in 1909 did not obtain oxygen fluoride by passing fluorine and oxygen through an arc discharge and a tap cooled with liquid air. In subsequent years the synthesis of oxygen fluorides in an electric arc was apparently not investigated. The synthesis of O_2F_2 and O_4F_2 in a silent discharge cannot compete as regards the yield of products per unit time and the energy yield with the synthesis of these compounds in a glow discharge and is of interest only within the framework of the study of the mechanism of the reaction of fluorine and oxygen in electric discharges.

Preparation of polyoxygen difluorides.

Reaction equation	Refs	Typical conditions of synthesis			
		compn. of initial mixt. (F_2:O_2 by volume)	flow rate, litre h^{-1}*	Current, mA	Temp. of cooling bath, °C

Dioxygen difluoride with an admixture of other polyoxygen difluorides was obtained by the action of ionising radiation on a mixture of fluorine and oxygen at −196°C. [58] The apparatus used in this method of synthesis is more complex than the apparatus necessary to synthesise dioxygen difluoride in a discharge. The radiolysis of oxygen difluoride at −196°C leads to the decomposition of OF_2 into the elements with formation of a certain amount of dioxygen difluoride [20].

The available literature data suggest that a gas-phase photochemical reaction can occur between fluorine and oxygen. By keeping a mixture of fluorine, oxygen, and AsF_5 or SnF_5 in the light, the dioxygenyl salts O_2AsF_6 and O_2SbF_6 were obtained [59]. Probably the O_2F radical formed initially reacts with the Lewis acid ($O_2F + EF_5 = O_2EF_6$) as in the thermal reaction [41]. When a mixture of fluorine and oxygen was irradiated by light from a mercury lamp, the formation of dioxygen difluoride was noted [60]. Bearing in mind that appreciable decomposition of O_2F_2 begins at a temperature as low as −100°C, [61] it is very remarkable that the experiments of Levy and Copeland were carried out at −42°C.

As a result of the irradiation of a mixture of fluorine and ozone with ultraviolet light in a reaction vessel thermostatted at −153°C, [62] O_2F_2 and OF_2 were formed. It is suggested that the reaction proceeds as follows:

$$F_2 \xrightarrow{h\nu,\,3650\,Å} 2F,\ F + O_3 \rightarrow O_2 + OF,$$

$$OF + OF = O_2F_2,\ OF + F = OF_2,\ OF + F_2 = OF_2 + F.$$

In analogous experiments at −78°C only oxygen difluoride was obtained [62]. If the photochemical reaction of fluorine with oxygen is carried out at a still higher temperature (0°C and 20°C), the decomposition of ozone without the formation of oxygen fluorides is observed [63]:

$$F_2 + O_3 \xrightarrow{h\nu,\,3650\,Å} F_2 + {}^3/_2O_2.$$

Among all the reactions enumerated and leading to the formation of dioxygen difluoride and other polyoxygen

difluorides, only the reaction of fluorine with oxygen in a glow discharge can be regarded as a simple and readily available method of synthesis of polyoxygen difluorides.

The most probable mechanism of the synthesis of polyoxygen difluorides from the elements includes as the primary step the reaction of atomic fluorine with molecular oxygen:

$$F + O_2 = O_2F$$

and further stages involving O_2F radicals, for example:

$$O_2F + F = O_2F_2,$$
$$O_2F + O_2F = O_4F_2,$$
$$O_2F + O_2 \rightarrow O_4F \xrightarrow{+O_2F} O_6F_2 .$$

In this mechanism the dissociation of O_2 molecules is not regarded as an essential stage of the synthesis. Possibly, in general any activation of oxygen is superfluous. Irradiation of F_2–O_2 mixtures under matrix conditions at 4° or 20°K by ultraviolet light, which dissociates only fluorine molecules, leads to the formation of O_2F radicals[64,65]. Atomic oxygen is probably formed when F_2–O_2 mixtures are passed through a glow discharge, but in this case too there is no need to include in the mechanism for the synthesis of polyoxygen difluorides reactions involving atomic oxygen. An equimolar fluorine–oxygen mixture is almost completely converted into O_2F_2 with a low energy expenditure per unit volume of the reacting gases with a negligibly low degree of dissociation of oxygen[66]. With increase of energy expenditure, the dissociation of O_2 molecules becomes more pronounced and the synthesis of O_2F_2 is accompanied by the formation of ozone as a side reaction.

The preparation of unstable polyoxygen difluorides has been fairly thoroughly investigated, but a method for the synthesis of the thermally stable oxygen difluoride from the elements is unknown. The formation of trace amounts of OF_2 in the synthesis of O_2F_2 has been noted[44] but the possibility of obtaining OF_2 in an appreciable yield in a glow discharge is doubtful. The formation of O_2F_2 or another polyoxygen difluoride, which does not require the dissociation of O_2 molecules, has a clear advantage over the synthesis of OF_2. Under the conditions where the degree of dissociation of O_2 becomes appreciable, the formation of OF_2 may be hindered by the consumption of O atoms in the synthesis and decomposition of oxone: $O + O_2 = O_3$ and $O_3 + O = 2O_2$. One must also assume the possibility of the recombination of OF radicals with formation of O_2F_2:

$$OF + OF = O_2F_2 (S),$$

where (S) is a cold wall. Finally it is extremely likely that the absence of OF_2 from the product of the reaction of fluorine with oxygen in a glow discharge is simply due to the high vapour pressure of OF_2, which is about 1 mmHg at −196°C. It is difficult to freeze a substance with such a vapour pressure on the cold wall of the discharge tube and thereby prevent its decomposition in the hot reaction zone.

3. Dioxygen Difluoride

In order to prepare dioxygen difluoride, an equimolar mixture of fluorine and oxygen or one containing a slight excess of fluorine is passed through a glow discharge[53,67,68]. Dilution of the initial equimolar mixture with argon hardly alters the degree of its conversion into dioxygen difluoride[66]. When fluorine, oxygen, and nitrogen are passed through a glow discharge in a low-temperature reactor, dioxygen difluoride is also formed but in this case a certain amount of oxygen also enters into the reaction as a result of which trifluoroamine oxide is formed[69].

The dioxygen difluoride obtained in the glow discharge is sometimes contaminated by one or several substances, for example SiF_4 and O_4F_2. The decomposition of the less stable oxygen fluorides present in the freshly prepared O_2F_2 specimen can probably account for the increase of pressure in a closed system observed when O_2F_2 is heated to a temperature close to −160°C. Usually the impurity content is small and does not affect appreciably the results of the chemical analysis of O_2F_2 and does not prevent its further employment. Brief heating above −78°C causes partial decomposition of O_2F_2 and therefore O_2F_2 can be distilled from one compartment of a closed system to another, without removing by the vacuum pump a "cushion" of fluorine and oxygen, only with the aid of liquid helium.

Dioxygen difluoride melts at −163.5°C [53] (−154°C according to later data[70]) and decomposes below the boiling point; the normal boiling point found by extrapolating the the temperature variation of the vapour pressure is −57°C.[61] Solid O_2F_2 is orange-yellow in colour (yellow according to some observations[58,70]), turning into an oily bright-red liquid on fusion. With increase of temperature, the molar extinction coefficient of O_2F_2 rises[71]. The density of O_2F_2 decreases from 1.912 g cm^{-3} at −165°C to about 1.44 g cm^{-3} at −57°C.[61] The vapour pressure of O_2F_2 in the temperature range between −132° and −100°C is described by the equation[61] $\lg p$ (mmHg) = 7.515 − $1000/T$, the decomposition of O_2F_2 beginning above −100°C. The vapour pressure of O_2F_2 is (in mmHg) 0.01 at −168°C,[1] 0.05 at −163°C,[72] 1 at −143°C,[72] 3 at −132°C,[61] and 257 at −79.5°C.[61] $\Delta H^{\circ}_{f_{298}}[O_2F_2(gas)]$ found in a study of the decomposition of dioxygen difluoride is 4.73 kcal mole^{-1}.[73]

It has been established by microwave spectroscopy[74] that the O_2F_2 molecule consists of an F–O–O–F atomic chain bent in space and characterised by the following parameters: r(O–O) = 1.217 Å, r(O–F) = 1.575 Å, ∠ OOF = 109°30′, a dihedral angle of 87°30′, and a dipole moment of 1.44 D. Quantum-mechanical calculation shows[75] that the configuration of the O_2F_2 molecule with a dihedral angle of 85°C is separated from the *cis*- and *trans*-configurations by energy barriers of 16.62 and 20.83 kcal mole^{-1} respectively. The spectrum of $^{16}O_2F_2$ recorded at −196°C contains absorption bands at 1306 cm^{-1} (O–O stretching vibration), 621 cm^{-1} (O–F symmetrical stretching vibration), 615 cm^{-1} (O–F antisymmetric stretching vibration), 457 cm^{-1} (O–O–F antisymmetric deformation vibration), 369 cm^{-1} (O–O–F symmetrical deformation vibration), and 205 cm^{-1} (torsional vibration)[70,76]†.

The dioxygen difluoride molecule is diamagnetic. Pure O_2F_2 molecules do not give rise to an ESR signal[58]. The paramagnetic centres in dioxygen difluoride are the O_2F radicals[77,78] the presence of which can be accounted for by the partial decomposition of the compound.

An unusually low ^{19}F chemical shift (−865 p.p.m.) has been found[79] in O_2F_2 (10% solution of O_2F_2 in CF_3Cl), which is evidence of very weak screening of the fluorine nuclei. Subsequent studies[80–82] confirmed this report[79]. δ = −865 p.p.m. was found for liquid O_2F_2 at −128°C using $CFCl_3$ as an external standard[81]. Extrapolation to

† After this paper had been sent to the Editors, D. J. Gardiner, N. J. Lawrence, and J. J. Turner published the results of a study of the vibrational spectra of O_2F_2 [J. Chem. Soc., A, 400 (1971)].

infinite dilution of O_2F_2 in CF_3Cl at −83°C gave δ = −825 p.p.m.[82] The ^{17}O shift in the $^{17}O_2F_2$ molecule is[80,83] −647 p.p.m. relative to $H_2{}^{17}O$.

The O–O distance in the O_2F_2 molecule is close to the interatomic distance in the oxygen molecule (1.207 Å), r(O–F) in O_2F_2 considerably exceeds r(O–F) in the OF_2 molecule (1.39–1.41 Å). With these interatomic distances, there should be a strong O–O bond and a weak O–F bond in O_2F_2. The following dissociation energies have been found mass spectrometrically[72]: D(FO–OF) = 103.5 ± 5 kcal mole^{-1} and $D(F-O_2F) \simeq D(O_2-F) \simeq 18$ kcal mole^{-1}. The fluorine atoms weakly bound to oxygen are readily split off as a result of which O_2F_2 is extremely reactive even at a low temperature.

The kinetics of the thermal decomposition of dioxygen difluoride have been investigated as early as the 1930's.[67,84,85] In the temperature range between −60° and −25°C the decomposition reaction is homogeneous and unimolecular with an activation energy of about 17 kcal mole^{-1}. As was to be expected, the activation energy for the decomposition is almost identical with the O–F bond dissociation energy. Addition of fluorine activates the decomposition of O_2F_2.[85] The most probable decomposition mechanism[11] involves O_2F radicals:

$$O_2F_2 + M \rightarrow F + O_2F + M,$$
$$O_2F + M \rightarrow F + O_2 + M,$$
$$F + O_2F_2 \rightarrow F_2 + O_2F,$$
$$F + F + M \rightarrow F_2 + M\ .$$

The decomposition mechanism[86] the initial stage of which is the formation of OF radicals,

$$O_2F_2 \rightarrow OF + OF\ ,$$

is unlikely, since it requires a considerable activation energy[11]. The method of chemical analysis of dioxygen difluoride is based on the determination of the amount of fluorine and oxygen obtained after the decomposition of O_2F_2.

The O_2F radical, detected by infrared spectroscopy in the photolysis of OF_2–O_2 or F_2–O_2 mixtures under matrix isolation conditions[64,65,87], plays an important role in the chemistry of low-temperature oxygen fluorides. It has also been noted[64] that O_2F radicals are generated when oxygen difluoride is exposed to an ultrahigh frequency glow discharge. When the matrix isolating the radicals (oxygen, nitrogen, or argon) becomes softened, recombination takes place[64]:

$$O_2F + F = O_3F_2,$$
$$O_2F + O_3F = O_4F_2\ .$$

The dioxygen monofluoride radical consists of the atomic chain O–O–F. Quantum-mechanical calculation[88] shows that the asymmetric OOF structure is energetically more favourable to the extent of almost 100 kcal mole^{-1} compared with the symmetrical structure OFO. The vibration frequencies in the infrared spectrum of $^{16}O_2F$ are[87] 1495 (ν_1), 585 (ν_2), and 376 cm^{-1} (ν_3). The force constant k_{O-O} for O_2F is close to the value in the oxygen molecule and lies in the range 8–12 mdyn Å^{-1} characteristic of double bonds:

	k_{O-O}, mdyn Å^{-1}		
O_2F	10.45[64]	10.47[65]	10.50[87]
O_2	11.43[89]		

The dissociation energy of the O–O bond in O_2F is 110 kcal according to mass-spectrometric data[72,90], i.e. the addition of the F atom to the O_2 molecule does not result in an appreciable loss of strength by the O–O bond. The average lifetime of dioxygen monofluoride depends on the surrounding medium and at temperatures between −180° and −160°C amounts to minutes[91]. Generally speaking the dioxygen monofluoride radical resembles stable molecular radicals more than unstable radicals such as OF. If the interpretation[92] of the results obtained in the study of the decomposition of O_2BF_4 is correct, the radicals O_2F may exist for a long time in the gas phase at room temperature. In this connection, it is interesting to note that NF_2, an electronic (but not structural) analogue of O_2F, is stable at temperatures considerably exceeding room temperature, while the radical OOCl, which has the same structure, is unstable in the gas phase.

Exhaustive compilations of the reactions of O_2F_2 investigated up to 1963 have been published[1,93]. This review presents certain data taken from Streng[1,93] and also from later sources.

Dioxygen difluoride does not react with Pyrex glass and quartz. In the recording of the infrared spectrum of O_2F_2, silver chloride and high-pressure polyethylene were employed[70]. Polytetrafluoroethylene apparently reacts with O_2F_2.[74] In contact with platinum, O_2F_2 explodes[1]. The effect of atomic hydrogen at −196°C leads to the substitution of F by H atoms and to the dissociation of the O–O bond in dioxygen difluoride[93]:

$$2\,O_2F_2 + 10\,H = 4\,HF + H_2O_2 + 2\,H_2O\ .$$

At −140°C O_2F_2 does not react with N_2O, oxidises NO to NO_2 and FNO_3 at temperatures between −160°C and −70°C, and forms with nitrogen dioxide an unidentified unstable white solid compound[16]. It converts N_2F_4 into NF_3 at −100°C but at −150°C it does not react with N_2F_4 and N_2F_2.[1] The reaction of O_2F_2 with phosphorus trifluoride[93] at −148°C yields phosphorus pentafluoride and a substance to which the formula $(POF_3)_n$ was attributed. It is quite possible that the postulated polymer $(POF_3)_n$ contained dioxygenyl hexafluorophosphate. Sulphur tetrafluoride reacts vigorously with O_2F_2 at about −140°C:

$$SF_4 + O_2F_2 \rightarrow SF_6 + O_2\ .$$

In the presence of perchloryl fluoride as a solvent, it is possible to obtain an extremely unstable product of the addition of O_2F_2 to sulphur tetrafluoride[93]:

$$O_2F_2 + SF_4 \rightarrow O_2SF_6\ .$$

The reactions of O_2F_2 with chlorine and bromine fluorides have been investigated in detail. In the temperature range between −154°C and −143°C, chlorine monofluoride forms with O_2F_2 a violet compound $(O_2ClF_3)_n$:[93,94]

$$n\,O_2F_2 + n\,ClF \rightarrow (O_2ClF_3)_n\ .$$

Chlorine dioxide trifluoride can be stored for a long time at −78°C. This compound does not contain ions and does not dissociate in hydrogen fluoride solution[95]. Other pathways for the formation of chlorine dioxide trifluoride involve the reaction of O_2F_2 with HCl:[93,95]

$$O_2F_2 + 2\,HCl \rightarrow 2\,HF + O_2 + Cl_2,$$
$$O_2F_2 + Cl_2 \rightarrow 2\,ClF + O_2,$$
$$O_2F_2 + ClF \rightarrow O_2ClF_3,$$

or the photochemical reaction of ClF_3 with oxygen at −78°C:[95,96]

$$ClF_3 + O_2 \xrightarrow{h\nu,\,2537\,Å} O_2ClF_3\ .$$

The unstable compound O_2BrF_5, which decomposes completely into O_2 and BrF_5 at −100°C, was obtained by the reaction of O_2F_2 with bromine trifluoride[93,97]. At about −140°C hydrogen bromide reacts with an excess of O_2F_2:

$$3O_2F_2 + HBr \rightarrow O_2BrF_5 + HF + 2O_2 .$$

At low temperatures iodine pentafluoride does not react with O_2F_2 but at elevated temperatures it is converted into the heptafluoride[93].

XeF_2 has been obtained by the reaction of dioxygen difluoride with xenon at −118°C,[98,99] while elemental fluorine does not react with xenon at room temperatures and above. Some of the reactions of dioxygen difluoride enumerated above constitute the usual type of fluorination; the addition of O_2F_2 molecules to another reactant takes place in the reaction with ClF, BrF_3, or SF_4. The possibility of reactions involving O_2F radicals under mild conditions, where a rapid and uncontrollable decomposition of radicals such as O_2F as well as dioxygen difluoride itself is ruled out, is of considerable interest for preparative inorganic chemistry. The transfer of O_2F radicals is also implied in the reactions of O_2F_2 with Lewis acids—fluoride ion acceptors. Such reactions result in the formation of the O_2^+ cation, which, when combined with the anion of a complex fluorine acid, forms a dioxygenyl salt.

At −183° or −160°C dioxygen difluoride fluorinates sulphur dioxide:

$$SO_2 + O_2F_2 \rightarrow F_2SO_2 + O_2 .$$

Apart from the main product (sulphuryl fluoride), smaller amounts of FSO_2OSO_2F and fluoroperoxysulphuryl fluoride FSO_2OOF are also formed[100,101]. Experiments with the oxygen-17 isotope and by the ^{17}O NMR method showed that the synthesis of FSO_2OOF constitutes a reaction of O_2F_2 with transfer of an O_2F radical. Another example of the transfer of O_2F is the reaction of O_2F_2 with hexafluoropropene[102], which takes place smoothly at −183°C in chlorotrifluoromethane. The reaction results in the formation of a high yield of a mixture of isomers: $CF_3CF(OOF)CF_3$ and $CF_3CF_2CF_2OOF$.

4. Other Oxygen Fluorides: O_3F_2, O_4F_2, O_5F_2, and O_6F_2

a. Trioxygen difluoride. The report[103] of the synthesis of O_3F_2 when a liquid mixture of F_2 and O_2 is irradiated with ultraviolet light was treated sceptically and the possibility of the existence of trioxygen difluoride was not taken seriously until the publication in 1959 of the work of Kirshenbaum and Grosse[54]. The name "ozone fluoride"[54] proposed for O_3F_2 did not become established. Trioxygen difluoride melts at about −189°C and can be supercooled to −196°C. On heating to room temperature, O_3F_2 decomposes completely to fluorine and oxygen, probably with formation of dioxygen difluoride as an intermediate in the thermal decomposition. The activation energy for the decomposition of O_3F_2 in the temperature range between −196° and −157°C was found to be 3.7 kcal mole^{-1}.[54]

The conditions for the synthesis of O_3F_2 and O_2F_2 in an electric discharge differ only by the composition of the initial gas mixture: the $F_2:O_2$ ratio is 2:3 for O_3F_2 compared with 1:1 for O_2F_2. According to Kirshenbaum and Grosse[54], a mixture of two volumes of fluorine and three volumes of oxygen is quantitatively converted into O_3F_2 in a glow discharge, the yield reaching 3–4 g h^{-1}. We may note that the desired product can be by no means always synthesised. As a rule, O_2F_2 is formed in the synthesis of O_3F_2 and the oxygen present in excess of the amount required for the synthesis of O_2F_2 either does not react at all or is converted into ozone.

The ESR spectra of O_2F_2 and O_3F_2 have been found to be identical[77]. The paramagnetic centres in both fluorides are the O_2F radicals. The concentration of free radicals in O_3F_2 specimens is higher by two powers of ten than in dioxygen difluoride specimens and reaches 5–10 mole %. It is believed[77] that such a high concentration of O_2F is caused by the thermal decomposition of O_3F_2.

Investigation of the properties of O_3F_2 by spectroscopic methods gave rise to doubts concerning the individuality of trioxygen difluoride. Different models have been proposed[44,80,81,83] whereby it might be possible to account for the characteristics of the ^{19}F and ^{17}O NMR spectra and the mass spectrum of O_3F_2. Probably it is most correct to regard trioxygen difluoride as a mixture of dioxygen difluoride and tetraoxygen difluoride in equilibrium with O_2F radicals; this has been demonstrated by Solomon and coworkers[80,83].

O_2F_2 has been obtained by the reaction of fluorine activated in a discharge (atomic fluorine) with O_3F_2 at −196°C, i.e. F atoms add to the O_2F radicals present in trioxygen difluoride. O_3F_2 does not react with molecular fluorine at −196°C.[54] The reaction of O_3F_2 with boron trifluoride yields O_2BF_4 with evolution of fluorine[83]. The stoichiometry of the reaction

$$4O_3F_2 + 6BF_3 = 6O_2BF_4 + F_2$$

is consistent with the hypothesis that trioxygen difluoride is a mixture of O_2F_2 and O_4F_2.

b. Tetraoxygen difluoride. O_4F_2 has been obtained in a gas discharge reaction of fluorine and oxygen under mild conditions[55,104]. This compound is probably formed as a result of the recombination of O_2F radicals:

$$FO_2 + O_2F = O_4F_2 ,$$

but other reactions cannot be ruled out[58,64]:

$$O_2F + O_2 \rightarrow O_4F \xrightarrow{+F} O_4F_2,$$
$$F + O_4 \rightarrow O_4F \xrightarrow{+F} O_4F_2 .$$

The O_4F_2 molecule probably consists of the atomic chain F–O–O–O–O–F, where the O–O bonds adjoining the fluorine atoms are equivalent and close in strength to double bonds[64]. The dissociation energy of the central O–O bond hardly exceeds about 3 kcal mole^{-1}.[58] The ESR spectrum of O_4F_2 is determined[105], as for O_2F_2 and O_3F_2, by O_2F radicals. The red-brown solid O_4F_2 melts at −191° ± 2°C and explodes on being heated rapidly. The O_4F_2 vapour pressure is 0.25 mmHg at −183°C.[104] The half life of O_4F_2 at −183°C is 16 days but at −196°C the compound or its solutions in carbon tetrafluoride can be stored for several weeks[104]. The final products of the thermal decomposition of O_4F_2 are fluorine and oxygen. Like O_2F_2, tetraoxygen difluoride forms a dioxygenyl salt with boron trifluoride[83,92]. At −196°C O_4F_2 reacts with tetrafluorohydrazine, forming nitrogen trifluoride[104].

c. Higher representatives of the polyoxygendifluoride family. In 1966 the preparation of oxygen fluorides with the empirical formulae O_5F_2 and O_6F_2 was described[56]. The first compound decomposes slowly at −196°C and rapidly at −183°C, the final decomposition products of O_5F_2 being fluorine and oxygen. The second compound decomposes slowly on heating from −213° to −183°C with evolution of ozone, while rapid heating from −183°C results in an explosion of O_6F_2.

The solubility of O_5F_2 and O_6F_2 in liquid oxygen difluoride is about 5 wt.% at −208° and −213°C respectively. The structures of O_5F_2 and O_6F_2 are unknown. The attempts to obtain fluorides with a higher oxygen content from an initial $5O_2-F_2$ mixture by the method described for the synthesis of O_5F_2 and O_6F_2 were unsuccessful[56]. The preparation of a mixture of oxygen fluorides, one of the components of which might have been O_6F_2, was reported in 1969.[58]

The thermal stability of polyoxygen difluorides decreases with increasing number of oxygen atoms in the O_nF_2 molecule: for $n > 2$, the compounds are extremely unstable or their very existence is debatable. However, CF_3OOF, CF_3OOCF_3, and CF_3OOOCF_3 (and possibly $CF_3OOOOCF_3$), i.e. perfluoroalkyl derivatives of polyoxygen difluorides, exist and are much more stable than the corresponding oxygen fluorides[2]. The increase of the stability of the chain of oxygen atoms is an extremely interesting result of the substitution of fluorine atoms by perfluoroalkyl radicals and merits a more detailed investigation.

III. DIOXYGENYL COMPOUNDS

The existing methods for the synthesis of dioxygenyl compounds consist in the oxidation of molecular oxygen:

$$O_2 + PtF_6 \rightarrow O_2^+PtF_6^-$$

and the reaction of oxygen fluorides (O_2F radicals) with the corresponding Lewis acids:

$$O_2F + BF_3 \rightarrow O_2F \cdot BF_3 \rightarrow O_2^+BF_4^-$$

or

$$O_2F + EF_5 \rightarrow O_2F \cdot EF_5 \rightarrow O_2^+EF_6^- \ (E=P, As, Sb, Bi)$$

1. Dioxygenyl Hexafluoroplatinate

Dioxygenyl hexafluoroplatinate was described in 1962.[4,106] It is formed in the fluorination of platinum or its salts in glass and quartz vessels. The oxygen required for the synthesis of O_2PtF_6 is evolved in this case when fluorine acts on the walls of the reaction vessel. Treatment of platinum sponge with a mixture of fluorine and oxygen at 450°C or heating of platinum sponge in an atmosphere of OF_2 also leads to the synthesis of O_2PtF_6. At room temperature O_2PtF_6 was obtained by tensimetric titration of oxygen with platinum hexafluoride.

The crystal lattice energy of $O_2^+PtF_6^-$ calculated from the Kapustinskii equation is −125 kcal mole^{-1} and the electron affinity of platinum hexafluoride has been estimated as not less than 7 eV. Platinum hexafluoride is a powerful oxidising agent capable of forming crystalline compounds on reaction with molecular oxygen or xenon. However, the attempts to carry out the reaction between PtF_6 and krypton, nitrogen, or nitrogen trifluoride were unsuccessful[107,108].

Dioxygenyl hexafluoroplatinate is a red solid which sublimes above 90°C in a vacuum and melts with decomposition at 219°C.[106] Two modifications of O_2PtF_6 have been established by X-ray diffraction: a rhombohedral low-temperature modification and a high-temperature cubic modification with a unit cell parameter $a = 10.032$ Å and $z = 8$. The $r(O-O) = 1.13$ Å distance obtained in an X-ray diffraction study[106] is not entirely reliable owing to the difficulty of determining the positions of the light O atoms in the presence of the heavy Pt atoms. In a neutron diffraction study[109] of O_2PtF_6 powder, only the limits of $r(O-O)$ were found: 0.9–1.4 Å. The magnetic susceptibility of this compound in the range 88–294°K obeys the Curie–Weiss law. The magnetic moment $\mu_{eff} = 2.57$ Bohr magnetons[106] is close to the pure spin moment for two unpaired electrons (2.83 Bohr magnetons); one unpaired electron belongs to the O_2^+ and the other to the octahedral PtF_6^- ion. The magnetic moment $\mu_{eff}(O_2^+) = 1.57$ Bohr magnetons at room temperature[110]. In the Raman spectrum of O_2PtF_6 the O_2^+ vibration frequency is 1837 cm^{-1}.[108]

Dioxygenyl hexafluoroplatinate reacts vigorously with water, evolving oxygen and a small amount of ozone. The solution formed on hydrolysis contains PtF_6^{2-} ions and the residue consists of hydrated PtO_2. The hydrolysis of O_2PtF_6 by water vapour takes place similarly[4]. The reaction of O_2PtF_6 vapour with heated potassium fluoride or the reaction of potassium fluoride with O_2PtF_6 in iodine pentafluoride leads to the substitution of the O_2^+ cation by K^+. The reactions of O_2PtF_6 with bromine trifluoride and selenium tetrafluoride proceed as follows:

$$O_2PtF_6 + 3BrF_3 \rightarrow (BrF_3)_2PtF_4 + BrF_5 + O_2,$$
$$O_2PtF_6 + 3SeF_4 \rightarrow (SeF_4)_2PtF_4 + SeF_6 + O_2.$$

The reactions of O_2PtF_6 with ClF_3 and IF_5 yielded difluorochlorinium and tetrafluoroiodinium hexafluoroplatinates[4,106]. Dioxygenyl hexafluoroplatinate reacts vigorously with benzene, cyclohexane, and pyridine but not with carbon tetrachloride.

2. Dioxygenyl Compounds of Group V Elements

The synthesis of salts with the general formula O_2EF_6 (E = P, As, or Sb) was reported in 1964.[111,112] In addition a patent[113] taken out by Young et al.[111] reports the bismuth compound O_2BiF_6. The method of synthesis of the compound O_2EF_6 is based on the reaction of dioxygen difluoride with fluorine-containing Lewis acids—the pentafluorides of Group V elements. The synthesis is carried out at a low temperature by bringing dioxygen difluoride and the condensed pentafluoride into contact, either directly in a discharge reactor where O_2F_2 is obtained or O_2F_2 is distilled into a separate trap containing the other reactant. The end of reaction is indicated by the disappearance of the orange colour of dioxygen difluoride. The solid reaction products are kept for several hours in a vacuum to remove the excess pentafluoride. The dioxygenyl salts of arsenic and antimony are also obtained when daylight is allowed to act on a mixture of oxygen, fluorine, and arsenic or antimony pentafluoride[59]. A thermal synthesis of dioxygenyl compounds was described in 1969.[41] When mixtures of OF_2 and AsF_5 are heated to 200°C and a pressure of 200 atm, dioxygenyl hexafluoroarsenate is formed in a yield up to 80%: $4OF_2 + 2AsF_5 = 2O_2AsF_6 + 3F_2$. A mixture of fluorine and oxygen may be used instead of oxygen difluoride. O_2AsF_6 has been obtained in almost quantitative yield by heating the starting materials in the proportions $F_2 : O_2 : AsF_5 = 1 : 2 : 2$ at 130°C or 200°C and 150 atm for 5–7 days. Similar results were achieved in experiments using antimony pentafluoride as the Lewis acid. The attempts to obtain dioxygenyl salts by this method from BF_3, PF_5, SiF_4, BrF_3, BrF_5, and IF_5 were unsuccessful[41].

a. Dioxygenyl hexafluorophosphate. When O_2PF_6 is prepared by the reaction

$$O_2F_2 + PF_5 \xrightarrow{-126 \text{ or } -100^\circ} O_2PF_6 + {}^1/_2F_2,$$

a certain amount of POF_3 is formed. The solid white dioxygenyl hexafluorophosphate is a very unstable compound which decomposes slowly at −80°C.[111-113]. At room temperature O_2PF_6 decomposes rapidly:

$$O_2PF_6 \rightarrow O_2 + {}^1/_2F_2 + PF_5.$$

Owing to its low thermal stability, O_2PF_6 is not formed when fluorine, oxygen, and PF_5 are heated together[41].

The reaction of O_2PF_6 with water leads to the evolution of oxygen; O_2PF_6 reacts with nitrogen dioxide according to the equation[111]

$$O_2PF_6 + NO_2 = O_2 + NO_2PF_6.$$

b. Dioxygenyl hexafluoroarsenate. Apart from the methods for the preparation of O_2PF_6 enumerated above, the reaction of fluorodiazonium hexafluoroarsenate with oxygen has been mentioned[16]:

$$N_2FAsF_6 + O_2 \xrightarrow{2 \text{ atm}} O_2AsF_6 + N_2 + {}^1/_2F_2.$$

Dioxygenyl hexafluoroarsenate is stable below 100°C but decomposes rapidly at 130–180°C:[111]

$$O_2AsF_6 = O_2 + {}^1/_2F_2 + AsF_5.$$

The O_2^+ peak has been recorded in the mass spectrum of the vapour over a specimen of pure O_2AsF_6 at a pressure of the order of 10^{-6} mmHg and room temperature[111]. X-Ray powder diffraction patterns of O_2AsF_6 and $NOAsF_6$ show that these compounds are isomorphous, which confirms the ionic structure $O_2^+AsF_6^-$. The unit cell parameter of the cubic O_2AsF_6 lattice is $a = 8.00$ Å [111] or 8.10 Å.[59] The infrared spectrum of dioxygenyl hexafluoroarsenate contains a single absorption band at 705 cm^{-1}, which is characteristic of the AsF_6^- ion[41,59,111]. The vibrations of the octahedral AsF_6^- ion at 688, 574, and 375 cm^{-1} and the vibration of the O_2^+ ion at 1858 cm^{-1} are active in the Raman spectrum[114] of O_2AsF_6. A singlet line with a g-factor of 1.9980 has been observed in the ESR spectrum of dioxygenyl hexafluoroarsenate.

The hydrolysis of O_2AsF_6 is described by the equation

$$2\,O_2AsF_6 + H_2O = O_2 + O_3 + HAsF_6,$$

and its reaction with nitrogen dioxide yields a nitronium salt[111].

b. Dioxygenyl fluoroantimonates. In general the reaction between dioxygen difluoride and SbF_5 cannot be described by the equation $O_2F_2 + EF_5 = O_2EF_6 + \frac{1}{2}F_2$ (E = Sb), which is valid for phosphorus and antimony pentafluorides. In contrast to arsenic pentafluoride, SbF_5 is considerably associated and contains fluorine bridge bonds. The existence of polymeric (dimeric and trimeric) fluoroantimonate anions is well known, for example in the compounds $N_2F_3^+Sb_2F_{11}^-$ [115] and $ClO_2^+Sb_3F_{16}^-$ [116] (incidentally, arsenic pentafluoride also forms the dimeric ions $As_2F_{11}^-$)[117]. SbF_5 probably reacts in the monomeric form at an elevated temperature[41]. The composition of the product of the low-temperature reaction of dioxygen difluoride and antimony pentafluoride corresponds more closely to the compound $O_2Sb_2F_{11}$ than to O_2SbF_6.[118] The authors of an early investigation[111] probably synthesised $O_2Sb_2F_{11}$ from dioxygen difluoride and antimony pentafluoride. Little is known about the interaction of antimony trifluoride with dioxygen difluoride; it has only been reported that O_2SbF_6 could not be obtained by the reaction of SbF_3 with O_2F_2.[16]

The face-centred cubic unit cell of O_2SbF_6 is a = 10.13 Å [41] or a = 10.30 Å.[59] Nikitina and Rosolovskii[118] found a = 5.07 Å (z = 1) for the cubic O_2SbF_6 lattice. The compound $O_2Sb_2F_{11}$ is usually amorphous to X-rays; certain specimens give rise to an X-ray diffraction pattern with two intense lines (d = 3.95 and 3.59 Å), the number of lines increasing after fusion of the salt[118]. The infrared spectrum of O_2SbF_6 contains the ~669 cm^{-1} band of the SbF_6^- anion[41,118]. The fluoroantimonate $O_2Sb_2F_{11}$ absorbs at 492 and 665–715 cm^{-1}; it is suggested that the absorption at 492 cm^{-1} is caused by the vibrations of the Sb–F–Sb bridge bond[118]. The O_2^+ vibration is observed in the Raman spectrum of solid O_2SbF_6 at 1862 cm^{-1} or at 1860 cm^{-1} for an O_2SbF_6 solution in SbF_5.[114] The magnetic susceptibility of O_2SbF_6 has been measured in the range 80–333°K.[119] The effective magnetic moment at room temperature is 1.65 Bohr magnetons.

Dioxygenyl fluoroantimonates have been investigated by differential thermal analysis[118]. The endothermic effect in the thermogram of $O_2Sb_2F_{11}$ at 180–185°C corresponds to its fusion, rapid decomposition beginning above 260°C. The thermogram of O_2SbF_6 shows three endothermic effects: at 160–165°C (polymorphic transformation), 240–245°C (decomposition), and about 280°C. The two-stage decomposition process of O_2SbF_6 involves the mechanism

$$2\,O_2SbF_6 \xrightarrow{\sim 240^\circ} O_2 + {}^1/_2F_2 + O_2Sb_2F_{11},$$

$$O_2Sb_2F_{11} \xrightarrow{\sim 280^\circ} O_2 + {}^1/_2F_2 + 2SbF_5.$$

Thus dioxygenyl fluoroantimonates are much more stable to heat than dioxygenyl fluorophosphate and fluoroarsenate. On heating in a vacuum above 130°C, $O_2Sb_2F_{11}$ is converted into O_2SbF_6:

$$O_2Sb_2F_{11} \rightarrow O_2SbF_6 + SbF_5.$$

By heating a mixture of $O_2Sb_2F_6$ and antimony pentafluoride at 180–200°C, it is possible to obtain $O_2Sb_2F_{11}$, i.e. we have the equilibrium

$$O_2Sb_2F_{11} \rightleftharpoons O_2SbF_6 + SbF_5.$$

which is almost completely displaced to the left at room temperature[118].

3. Dioxygenyl Tetrafluoroborate

Dioxygenyl tetrafluoroborate was apparently obtained in 1960 from boron trifluoride, oxygen, and fluorine in a glow discharge[16]. In 1964 the synthesis of O_2BF_4 by the reaction of dioxygen difluoride with boron trifluoride at −126°C was reported[112]. Subsequently[83,92] the reaction of O_4F_2 with BF_3 was investigated: $\frac{1}{2}O_4F_2 + BF_3 = O_2BF_4$. It was established[92] that at −138°C O_4F_2 reacts with BF_3 much more vigorously than does O_2F_2 at −126°C. The difference between the reaction rates can be readily accounted for: O_4F_2 apparently dissociates more readily into O_2F radicals than does O_2F_2, but this difference is not fundamental since it has been shown[58] that the reaction of several millimoles of BF_3 with dioxygen difluoride at −126°C terminates in 10 min, which is comparable to the rate of reaction between O_4F_2 and BF_3.[92] It is known[58] that O_2BF_4 is formed when bremsstrahlung with an energy of 3 MeV acts upon a mixture of BF_3, O_2, and F_2 in a sapphire reactor.

X-Ray powder diffraction patterns of O_2BF_4 and $NOBF_4$ show that these compounds are isomorphous. The orthorhombic unit cell of O_2BF_4 has the parameters a = 8.77 Å, b = 5.58 Å, and c = 7.05 Å.[58] The effective

magnetic moment of O_2BF_4 is 1.7 Bohr magnetons[120]. The unpaired electron of the cation has been detected by ESR spectroscopy[58,112]. The vibrations of the BF_4^- ion have been found in the infrared spectrum[121] of O_2BF_4 recorded at −196°C at the following frequencies (cm^{-1}): 769 (ν_1), 374, 362 (ν_2), a broad band at 1200–900 (ν_3), 532, 518 (ν_4). The ν_1 and ν_2 vibrations of the free tetrahedral (T_d) BF_4^- ion are inactive in the infrared spectrum. The appearance of these frequencies in the O_2BF_4 spectrum can be explained by a decrease of the symmetry of the BF_4^- ion. The O_2^+ vibration gives rise to a weak doublet in the infrared spectrum of O_2BF_4 at 1868 and 1866 cm^{-1}. The substitution of the oxygen-16 isotope by oxygen-18 leads to a shift of the doublet to 1764 and 1762 cm^{-1}. The splitting of the O_2^+ band is caused by interionic interactions in the unit cell of the crystal. The vibration frequencies of the O_2^+ ions and dioxygenyl compounds are close to that of the free ion at 1876 cm^{-1}, which confirms the existence of O_2^+ in the salts.

Reactions involving the formation and decomposition of O_2BF_4 have been investigated by the tracer atom method[92] using radioactive fluorine-18. The salt decomposes slowly at 0°C and comparatively rapidly at room temperature. O_2BF_4 specimens decompose completely in several hours in a "dynamic" vacuum but in a sealed vessel the decomposition is only partial over a period of several weeks[92]. This behaviour can be accounted for by the equilibrium

$$O_2BF_4(\text{solid}) \rightleftharpoons O_2F(\text{gas}) + BF_3(\text{gas}). \qquad (***)$$

Boron trifluoride suppresses the dissociation of O_2BF_4. Fluorine and oxygen are formed in the decomposition of O_2BF_4 by the dimolecular reaction

$$O_2F + O_2F \xrightarrow{k} F_2 + 2O_2.$$

In the experimental temperature range 0–32°C the decomposition of O_2BF_4 is described by the equation[92]

$$dp_{BF_3}/dt = kK^2/p^2_{BF_3},$$

where K is the equilibrium constant of reaction (***).

Like the dioxygenyl salts already examined, O_2BF_4 reacts with nitrogen dioxide and is hydrolysed with evolution of ozone[112]. Dioxygenyl tetrafluoroborate reacts vigorously with organic solvents but dissolves in cyanogen without reaction at −25°C.[58] Certain chemical properties of O_2BF_4 have been described by Goetschel et al.[122] When O_2BF_4 reacts with substances the ionisation potential of which is lower than that of oxygen, O_2^+ is reduced and a fluoroborate with another cation is formed. If the resulting fluoroborate is unstable, BF_3 and fluorine are evolved, i.e. O_2BF_4 can behave as a fluorinating agent. For example, O_2BF_4 reacts smoothly at −25°C with carbon tetrachloride, forming $CFCl_3$ and CF_2Cl_2. The reaction of O_2BF_4 with hexafluorobenzene yields a mixture of fluorocarbons; saturated fluorocarbons do not react with O_2BF_4. The reaction of O_2BF_4 with xenon, accompanied by evolution of O_2, takes place rapidly at −96°C and it is believed that it involves the formation of $XeBF_4$. Oxygen is evolved in the reaction of O_2BF_4 with ClO_4, Cl_2, and ClF_3. Chloryl tetrafluoroborate has been obtained by the reaction of O_2BF_4 with ClO_2.

The reaction of BF_3 with a mixture of oxygen fluorides obtained by the radiolysis of F_2 and O_2 probably results in the formation of the unstable O_6BF_4 and O_4BF_4 in addition to O_2BF_4:[58]

$$O_6F + BF_3 = O_6BF_4 \text{ (decomposes at } -140°),$$
$$O_4F + BF_3 = O_4BF_4 \text{ (decomposes at } -33°).$$

However, reliable evidence for the existence of these interesting compounds has not so far been obtained.

---o0o---

Dioxygenyl fluoro-complexes are formed by a few higher fluorides of the elements: BF_3, PF_5, AsF_5, SbF_5, BiF_5, PtF_6, and possibly SnF_4,[123] and also VF_5.[124] The stabilisation of the O_2^+ cation, i.e. the shift of the equilibrium $O_2 + X \rightleftharpoons O_2^+ + X^-$ to the right, depends significantly on the nature of X. Platinum hexafluoride, the most powerful electron acceptor, readily oxidises molecular oxygen. The Lewis acids BF_3 and EF_5 do not react with molecular oxygen but do react with O_2F radicals, which constitute a kind of "precursor" containing "almost" molecular oxygen, i.e. two oxygen atoms linked almost as strongly as in the O_2 molecule:

$$O_2F + EF_5(BF_3) \rightarrow O_2F \cdot EF_5(BF_3).$$

In this stage of the reaction, the polarisation of the O–F bond probably increases and the tendency towards the formation of a stable tetrahedral or octahedral anion induces a transfer of F^- to the environment of the central atom in the Lewis acid:

$$O_2F \cdot EF_5(BF_3) \rightarrow O_2^+EF_6^-(BF_4^-).$$

All the known dioxygenyl salts are oxidising agents, the chemical properties of which have not been investigated in sufficient detail.

Kinetics and Nature of Mechanochemical Reactions

P.Yu.Butyagin

Certain general characteristics of the kinetics, mechanism, and nature of the primary step in chemical reactions initiated by mechanical action in various low- and high-molecular-weight substances have been examined. The formal kinetics of mechanochemical reactions occurring in constant and variable mechanical fields have been analysed in Section II. In constant fields the rate of the process is determined by the rate of the primary chemical stage and in variable fields the rate-limiting stage may be the supply and absorption of elastic energy. Section III deals with the mechanisms of the conversion of elastic into chemical energy. The chemical changes in a substance are associated either with the elastic deformation of the electron shells of the reacting species or with the generation of non-equilibrium vibrationally excited states in the process of dissipation of elastic energy as heat. Under certain conditions, local short-lived regions of intense absorption of elastic energy may play a major role. Data concerning the nature of the primary active species in mechanochemical reactions —free radicals in various charged states—are discussed in the last section.
The bibliography includes 153 references.

I. INTRODUCTION

The studies in various fields of mechanochemistry are widely scattered. The mechanochemistry of polymers [1-9] is separated from studies on mechanochemical reactions in solids (the German term is tribochemical reactions)[10-16]; reactions initiated by ultrasonic waves [17-22], chemical reactions in solids at high pressures with shear stress[23-27], reactions in shock waves [28,29], the phenomenon of detonation on impact [30,31], corrosion under stress [32-34], cryogenic processes [35-37], etc. occupy a special place. All these fields have not been combined into a single discipline and one can only hope that ten years hence mechanochemistry, the science of the initiation and acceleration of chemical reactions in gases, liquids, and solids under the action of elastic energy, will be treated uniformly as part of the field of non-thermal chemical reactions together with radiation chemistry, photochemistry, and other processes.

One may suppose that, despite the historic separation of individual branches of mechanochemistry and despite the differences in the methods used to create mechanical fields and the differences in physicomechanical properties of low- and high-molecular-weight substances in various phase states, there exist common characteristics in the thermodynamics, kinetics, and the nature of the primary step in many classes of mechanochemical reactions. In this review an attempt has been made to isolate, using the simplest and most thoroughly investigated reactions, certain characteristic features of the kinetics and mechanisms of mechanochemical reactions. The main examples have been taken from the mechanochemistry of polymers: in linear macromolecular systems it is simpler to analyse the specific features of the phenomenon; extension to three-dimensional systems probably does not involve fundamental changes in the mechanism of the processes.

II. FORMAL KINETICS OF MECHANOCHEMICAL REACTIONS

Usually the primary data on the mechanisms of chemical reactions are obtained in kinetic studies, for example, in measurement of the variation of the reaction rate constant with temperature, concentration, and other parameters. In radiation chemistry the rate of reaction is not understood as the change of concentration per unit time but as the change of concentration as the result of the absorption of a specified energy dose (the energy yield G is the number of species which have reacted after absorption of 100 eV of energy) and the principal parameters are the dose and the dose rate of the radiation. Similarly in photochemistry the quantum yield of the reaction is primarily determined.

Unfortunately in mechanochemistry an equally clear-cut energy approach has not been developed and energy estimates are encountered extremely rarely. This is associated in the first place with methodological difficulties in measuring the amount of mechanical energy absorbed and also with the indeterminacy of the stresses which actually operate and in the second place with the lack of clear concepts concerning the nature of mechanochemical reactions. As a rule, the appearance of hypotheses about the mechanism of a particular process is accompanied by the simultaneous development of an energy approach in the analysis of its kinetics (a good example of this is ultrasonic chemistry) [38-40].

Mechanochemical reactions constitute a complex multistage process, which include stages involving mechanical deformation of a substance (the supply and absorption of mechanical energy), the primary chemical reaction proper, and various secondary processes. In the kinetics of mechanochemical reactions it is possible to isolate two limiting cases: the first corresponds to conditions under which the rate of the entire process is determined by the rate of the primary mechanochemical stage and in the second the rate-limiting stage is the supply or absorption of mechanical energy. Thus the ratio of the rates of absorption of elastic energy and of the mechanochemical reaction proper constitutes a criterion for the subdivision of mechanochemical processes into two types (based on their kinetics).

1. Kinetics in Constant Mechanical Fields

The first case may obtain under conditions where the substance is in a constant field of mechanical stresses.

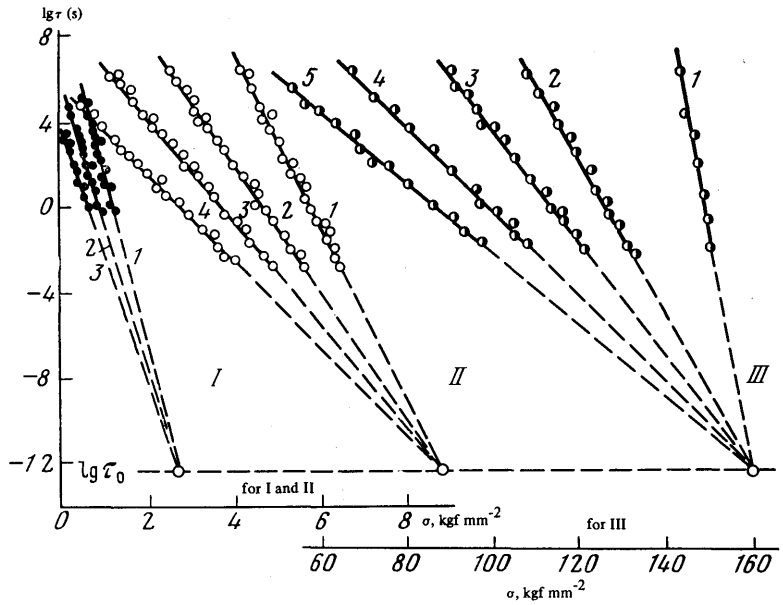

Figure 1. Temperature and time variation of tensile strength: I) rock salt [1) 400°C; 2) 500°C; 3) 600°C]; II) polycrystalline aluminium [1) 18°C; 2) 100°C; 3) 200°C; 4) 300°C]; III) Kapron fibre [1) −180°C; 2) −120°C; 3) −75°C; 4) +20°C; 5) +80°C].

When a constant load is applied, elastic energy is absorbed rapidly and the stage involving elastic deformation may be resolved in time from subsequent slower chemical reactions. Under such conditions, the rate of the mechanochemical process should be determined by the rate of the primary chemical reaction initiated by elastic stresses and the variation of the rate constant with external parameters should reflect the characteristics of this primary reaction.

An example of a process of this type may be degradation of macromolecules on monoaxial extension of polymeric films or fibres by the application of a constant stress. According to the kinetic concept of strength[8], the breakdown of the specimen occurs as a result of the dissociation of mechanically strained macromolecules.

In the idealised case of a uniform distribution of stresses throughout the specimen (under the condition σ = const.), the number of chains bearing the load will decrease with time according to the law

$$N \simeq N_0 \exp(-k_{\text{mech}}\tau). \qquad (1)$$

Here it is assumed that the rate of dissociation of the strained bonds is described by an equation for first-order kinetics (see, for example, Tobolsky and Eyring[41]) and k_{mech} is the rate constant for the mechanical dissociation of polymeric chains. Catastrophic breakdown of the specimen begins when $k_{\text{mech}}\tau = 1$, i.e. the time up to the rupture or, what amounts to the same thing, the lifetime of the specimen τ_{life} is inversely proportional to the rate constant k_{mech}. In other words, the time up to the rupture of the specimen coincides with the characteristic time of the reaction involving the breakdown of the strained polymeric chains and measurements of the lifetime under various stress conditions (medium, temperature, the stress itself, etc.) should in principle throw light on the nature of the primary mechanochemical step.

The formulation of Eqn. (1) only reveals the possibility of a relation between the lifetime and the rate constant for the mechanical dissociation of bonds. A rigorous kinetic theory, which is now being developed, should take into account many aspects of the phenomenon: the structural inhomogeneity of the material and the form of the distribution functions for the stresses throughout its bulk, the variation of the rate constant with the degree of polymerisation and with the magnitude of the effective stresses, secondary free-radical reactions, and the probability of a chain propagation of degradation, etc.

Fig. 1 presents[8] the results of measurements of the variation of the lifetime ($\tau_{\text{life}} \propto 1/k_{\text{mech}}$) of three materials—rock salt, polycrystalline aluminium, and Kapron† fibre with stress (monoaxial extension at σ = const.) at different temperatures. For each material, the $\tau_{\text{life}} = f(T, \sigma)$ relation obeys the Zhurkov equation[42] over a fairly wide range of temperatures T and stresses σ:

$$\tau_{\text{life}} = \tau_0 \exp\left(\frac{U_0 - \gamma\sigma}{RT}\right). \qquad (2)$$

where R is the gas constant and τ_0, U_0, and γ are constants for the given material; γ depends on the nature and history of the specimen and is called the structural factor. The constant τ_0 is always close to magnitude to the vibration period of the atoms in the crystals (about 10^{-13} s). Table 1 presents[8] the results of the calculation of the constant U_0 from measurements of the lifetime at σ = const. and includes for comparison the corresponding values of E—the heats of sublimation of metals or the

†A type of nylon produced in the USSR (Ed. of Translation).

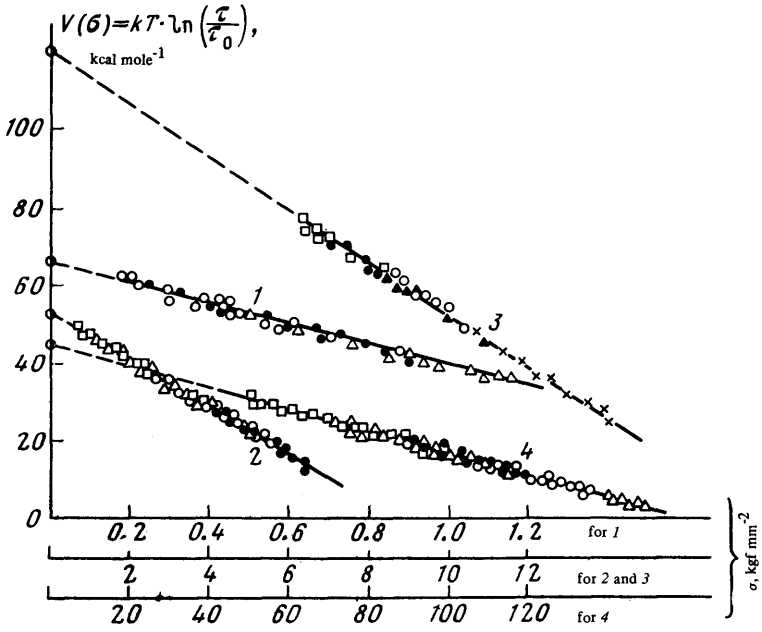

Figure 2. Variation of the effective energy barrier $U = RT\ln(\tau_{life}/\tau_0)$ with tensile stress σ: 1) rock salt; 2) polycrystalline aluminium; 3) polycrystalline platinum; 4) Kapron fibre.

activation energies for the thermal degradation of polymers. A graphical determination of the constant U_0 is illustrated by the data in Fig. 2. [8] To a first approximation, U_0 does not differ markedly from the energy of interatomic bonds.

Table 1. Comparison of the constants U_0 with the heats of sublimation of metals and the activation energies for the thermal degradation of polymers [8].

Substance	U_0, kcal mole^{-1}	E, kcal mole^{-1}
Platinum	120	127
Iron	100	97
Copper	81	80
Aluminium	53	55
Zinc	30	31
Rock salt	68	–
Polytetrafluoroethylene	75	76
Polypropylene	56	58
Kapron	45	43
Poly(vinyl chloride)	35	32

The agreement of τ_0 and U_0 with molecular constants confirms the hypothesis that the kinetic behaviour of mechanochemical processes in constant mechanical fields are indeed determined by the characteristics of the primary chemical reaction stage.

Reactions in constant mechanical fields include also the electrochemical dissolution of metals under the simultaneous influence of mechanical stresses (corrosion under stress) [32-34,43-45]. In this case measurements are made of the so called polarisation diagrams: the variation of the anodic (or cathodic) current i with the electrical potential φ. [43] In the absence of mechanical stresses, these values are related as follows:

$$i = K_{el}\exp\left(\frac{\alpha\varphi - \varphi^0}{b}\right), \qquad (3)$$

where K_{el} is a constant, φ^0 the standard electrode potential of the metal, $b = RT/zF$, z is the valency of the ion, and F the Faraday.

Line *1* in Fig. 3*a* illustrates [43] this relation in terms of a plot of φ against $\lg i$. In a mechanically deformed metal the linear relation between φ and $\lg i$ persists, but, over a certain range of stresses, the corresponding straight lines are displaced upwards to an extent which is greater for increasing relative deformation. The data in Fig. 3*b* illustrate [44] the relation between the mechanochemical effect (the variation of the corrosion current—curve *2*) with increase in strength on deformation. Evidently, in the stage involving an intense increase in strength on deformation (region *E*), the effect increases and in the concluding stage, when the planar accumulations of dislocations break down, the effect diminishes [34].

Thus, in the stage involving an increase in strength (region *E*), the metal "becomes less noble" under the influence of mechanical stresses—the standard potential φ^0 diminishes by an amount $\Delta\varphi^0$, which depends on the degree of increase in strength $\Delta\sigma$ due to deformation ($\Delta\sigma$ is the amount by which the stress applied to the material exceeds the microscopic yield point). According to the literature [34,35],

$$\Delta\varphi^0 = -\frac{nR}{\bar{\alpha}R'ZF}\Delta\sigma,$$

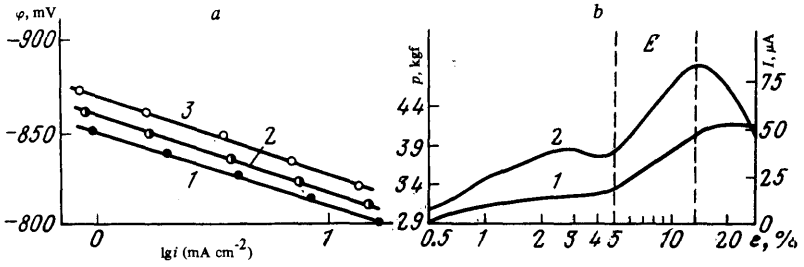

Figure 3. Kinetics of corrosion under stress: *a*) variation of the anodic current with electrical potential for steel 20 in 1.1 *N* sulphuric acid at 20 (°C ?) [degree of deformation (%): 1) 0; 2) 10; 3) 30]; *b*) variation of the corrosion current (curve *2*) and the extending force (curve *1*) with the degree of deformation; 08SV steel in 7 *N* sulphuric acid solution; rate of extension 34% per minute.

where n is the number of coplanar dislocations in planar accumulations, $\bar{\alpha}$ the coefficient in the equation relating the density of dislocations to the degree of deformation of the metal, $R' = kN_{max}$, k is the Boltzmann constant, and N_{max} the maximum possible density of dislocations (in metals $N_{max} \simeq 10^{12}$ cm^{-2}). The general equation for the kinetics of electrochemical or chemical dissolution of a metal under the simultaneous influence of mechanical stresses is of the form

$$i = K_{\text{electrochem}} \exp\left(\frac{A}{RT} + \frac{n\Delta\sigma}{\bar{\alpha}R'T}\right), \qquad (4)$$

where A is chemical or electrochemical affinity. The second term in the exponent reflects the effect of mechanical stresses on the chemical potential of the metal, which determines the rate of the process in a constant mechanical field.

2. Reactions in Variable Mechanical Fields

The second limiting case of the kinetics of mechanochemical processes [9,46] corresponds to conditions under which the rate of supply or absorption of elastic energy is much less than the rate of reaction initiated as a result of the absorption of this energy. Such conditions may obtain, for example, under the influence of periodic stress application at frequencies in the range of the intrinsic mechanical losses of the material. This may occur in various types of fatigue tests, under the influence of ultrasonic waves on polymer solutions, in the comminution of solids in mills, in the breakdown of the surface layer of materials on friction, etc.

When the material is acted upon in cyclic processes under steady-state conditions, the time-average mechanical power supplied to the specimen remains constant. In each single stress-application cycle part of the mechanical energy is absorbed by the material and after a certain number of cycles an average steady-state degree of deformation of the material and a corresponding average level of absorbed energy ΔE_{def} are established. The rate of absorption of energy is directly proportional to the power supplied W and the rate of dissipation is equal to the average level ΔE_{def}. Under steady-state conditions,

$$\alpha W = \frac{1}{\tau_r}\Delta E_{def} \quad \text{or} \quad \Delta E_{def} = \alpha\tau_r W \qquad (5)$$

where α is a coefficient the value of which is close to the mechanochemical efficiency of the process (efficiency $< \alpha < 1$) and τ_r is the relaxation time of the stresses.

Real materials are inhomogeneous and the deformation energy is non-uniformly distributed among the system of bonds: the form of the distribution function is in general unknown. To make the treatment concrete, one may suppose that the distribution is fairly steep and is described by an exponential law, i.e. the fraction of bonds characterised by a deformation energy E_{def} and above is proportional to $\exp(-E_{def}/\Delta E_{def})$. Moreover, since the stresses operate periodically, there is a constant redistribution of energy in the system with a characteristic time $1/A$, which depends both on the frequency of application of mechanical action and on the intrinsic relaxation time of the material.

When the rate of the mechanochemical process is limited by the redistribution of mechanical energy in the system, the rate constant should be proportional to the rate of redistribution of deformation energy among the bonds (A, s^{-1}) and the probability of the accumulation at a given bond of a certain critical deformation energy E^*_{def} sufficient to initiate the mechanical reaction. Therefore, considering Eqn. (5), [46] we then have

$$k_{\text{mech}} \simeq A \exp\left(-\frac{E^*_{def}}{\alpha\tau_r W}\right), \qquad (6)$$

Outwardly Eqn. (6) resembles the Arrhenius equation for the variation of the unimolecular decomposition rate constant with temperature, but the significance of the constants is in this case quite different. The pre-exponential factor in Eqn. (6) should be close in magnitude to the rates of relaxation of stresses and not to the vibration frequencies of atoms (10^{12}–10^{13} s^{-1}). The temperature in the exponent in Eqn. (6) is replaced by the rate of supply of mechanical energy. One must stipulate that the distribution function of stresses may also have a different form with a corresponding change in the form of Eqn. (6).

The variation of the rate constant for a mechanochemical reaction with the rate of supply of mechanical energy in variable fields has been measured (Fig. 4) [40,46] in several cases: in ultrasonic degradation of polystyrene in dilute solutions [40], in the comminution of poly(methyl methacrylate) in a vibration mill [46], and in dynamic tests on vulcanised rubbers [47]. In the first two cases the range of rates is very wide (W changes by a factor of 20,

which is much more than usually happens in measurements of the activation energies for thermal reactions where the temperature changes at most by a factor of 2–3).

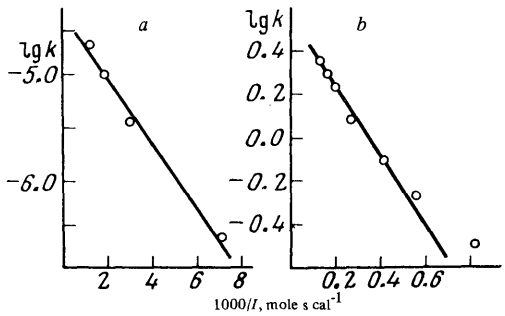

Figure 4. Variation of the rate constant for mechanical degradation with the rate of supply of mechanical energy (lg k plotted against $1000/I$): *a*) comminution of poly(methyl methacrylate) in a vibration mill; *b*) ultrasonic degradation of polystyrene.

Very low values of the pre-exponential factor (10^1–10^{-4} s^{-1}) were obtained throughout (Table 2). This confirms the hypothesis that the rate of the process is indeed limited by the rate of redistribution of elastic energy in the system, i.e. by the physicomechanical properties of the material. Unfortunately the constants α and τ_r are unknown and therefore E^*_{def}, i.e. the minimum deformation energy necessary to initiate the reaction, cannot be determined. To estimate the order of magnitude of the constant τ_r, one may suppose that $\alpha \simeq 10^{-2}$ (this is confirmed by the energy yields for degradation) and $10^4 < E^*_{def} < 10^5$ cal mole^{-1}. Then we have for poly(methyl methacrylate):

$$\frac{E^*_{def}}{\alpha\tau_r} = 700 \text{ or } \tau_r = \frac{10^4 - 10^5}{700 \cdot 10^{-2}} \simeq 10^3 - 10^4 \text{ s}^{-1}.$$

As was to be expected, the relaxation time τ_r and the constant $1/A$ are of a similar order of magnitude.

Table 2. The constants A and $E^*_{def}/\alpha\tau_r$ in Eqn. (6) for various materials.

Material	Conditions of measurements	A, s^{-1}	$E^*_{def}/\alpha\tau_r$	Refs.
Poly(methyl methacrylate)	Dispersion in vibration mill	10^{-4}	70	46
Polystyrene	Ultrasonic degradation in solution	3÷5	3700	40
Vulcanised rubber	Dynamic tests	10^{-2}	—	48

Eqn. (6) has several important consequences. Firstly, in variable mechanical fields the efficiency of the mechanochemical process should increase sharply with the intensity of mechanical action, the conditions of maximum concentration of mechanical energy per unit volume of the substance and per unit time being the most favourable. When the intensity is low, the characteristic effects associated with the contribution by non-relaxed stresses (the ΔE_{def} level) may not appear at all.

Secondly, in mechanochemical processes in variable fields, the frequency of application of mechanical action plays a major role. Thus in the mechanical degradation of poly(methyl methacrylate) in a vibration mill, $\tau_r \simeq 10^3$ to 10^4 s. Consequently, when the process is interrupted for a period of this duration, the rate of the mechanochemical reaction should fall appreciably. Fig. 5 presents [46] results of the measurements of the rate of degradation of poly(methyl methacrylate) under two types of conditions: continuous and periodic (duration of interruption 300 s). In degradation with interruptions the rate of bond dissociation fell almost by a factor of 2.

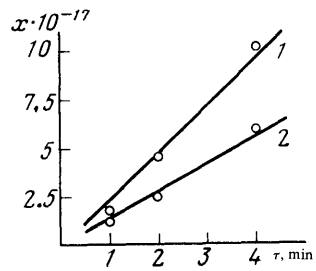

Figure 5. Mechanical degradation of poly(methyl methacrylate) in a vibration mill (x = number of bonds dissociated; temperature 100°K): 1) continuous conditions; 2) periodic conditions (5 min interruptions).

In solids the frequency of application of mechanical action should probably fall within the limits of the frequency spectrum of mechanical losses, including the low-frequency region (see, for example, Fitzgerald [49]). For mechanochemical reactions in gases, it is important that the frequency should correspond to the relaxation time for the transmission of energy from translational to vibrational degrees of freedom of molecules (the phenomenon of the dispersion of sound in gases [17]).

The temperature variation of the rate of a mechanochemical reaction is not explicitly included in Eqn. (6), but the constants of this equation, related to the relaxation times of the stresses, depend on temperature. For example, in polymers they should change sharply in the region of structural transitions, primarily near the glass temperature T_g. Therefore one may expect that, for degradation in variable mechanical fields, the form of the temperature variation of the rate of degradation will alter as T_g is approached. We may note for comparison that under static conditions (constant mechanical fields), when the rate constant for degradation is determined by the molecular constants τ_0 and U_0, the temperature variation of the rate of degradation of polymers does not change near T_g (see, for example, Fig. 1).

Polukhina and Baramboim [51] measured simultaneously the rate of mechanical degradation (comminution of polymers in a vibration mill) and the modulus of elasticity (the rate of propagation of longitudinal sonic waves C_e).

The relation between k_{mech} and C_e for polystyrene, poly(methyl methacrylate), and poly(vinyl acetate) in the temperature range 223–303°K is presented in Fig. 6.[51] Below T_g ($10^{-6}C_e$ cm $s^{-1} > 15$), the points corresponding to the three different polymers fit satisfactorily on a common section of line A. Above the glass temperature ($10^{-6}C_e$ cm^{-1} $s^{-1} < 10$) the nature of this relation changes sharply (straight line *B*). These data confirm yet again the hypothesis that in variable mechanical fields the rate of a mechanochemical reaction and the temperature variation of k_{mech} are closely related to the physicomechanical properties of the substance, i.e. the rate-limiting stage is the redistribution of elastic energy.

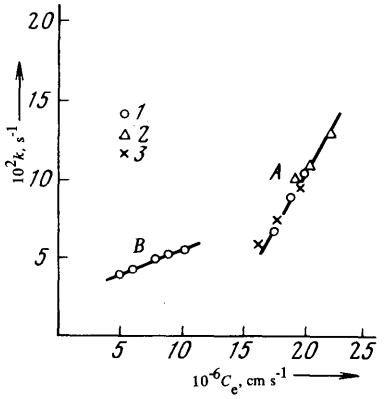

Figure 6. Relation between the rate constant for the mechanical degradation of polymers and the rate of propagation of longitudinal sonic waves C_e in the temperature range 223–303°K; polymer: 1) poly(vinyl acetate); 2) polystyrene; 3) poly(methyl methacrylate).

3. Characteristics of the Kinetics of Reactions in Polydisperse Systems

The conclusions concerning the rate-limiting stages in the kinetics of mechanochemical reactions are probably valid for a wide range of processes in both low- and high-molecular-weight systems. Eqns. (2), (4), and (6) explain the nature of the rate constant. However, frequently the rate constant for a mechanochemical reaction does not remain constant during the mechanical treatment of the substance. Its variation may be due to changes in the properties of the material: in the type of distribution of stresses and structural defects, degree of dispersion, etc. Below we consider the characteristics of the kinetics of mechanochemical reactions which are typical for polydisperse systems. Examples of such reactions are those in polymers (distribution with respect to chain length) and comminution of solids (distribution with respect to particle size). The kinetics of reactions in polydisperse systems have been analysed in greater detail for the mechanical degradation of macromolecules[52].

The absorption of mechanical energy by macromolecules and at the same time the rate of the mechanochemical reaction depend on the length of the macromolecule—the degree of polymerisation. As a result of the dissociation of bonds, the degree of polymerisation falls and therefore, under steady-state conditions of mechanical treatment, the rate of bond dissociation will not be constant: its variation will be caused by changes in the molecular weight distribution of the polymeric substance during the reaction. Other conditions being equal, the kinetic equation for the degradation is determined by the form of the variation of the elementary rate constant with the length of the polymer chain. The formal kinetics of such reactions have been developed by Palov[52] and the subsequent treatment has been taken from his paper.

We shall denote the rate constant for the decomposition of molecules with a length equivalent to z units by $k(z)$. Then the following relation holds for the rate of increase of the number of molecules in the system:

$$\frac{dn}{d\tau} = \sum_1^\infty k(z) n_z, \tag{7}$$

where n is the total concentration of molecules and n_z the concentration of molecules with a length z. After dividing both parts of Eqn. (7) by $n = \sum_1^\infty n_z$, we obtain

$$\frac{d\ln n}{d\tau} = \frac{d\ln n/n_0}{d\tau} = \frac{\sum_1^\infty k(z) n_z}{\sum_1^\infty n_z} = [\overline{k(z)}], \tag{8}$$

where n_0 is the initial concentration of the species and $[\overline{k(z)}]$ is by definition the number average of $k(z)$. Bearing in mind that $n/n_0 = P_0/P$, where P_0 and P are the initial and actual number-average degrees of polymerisation, we finally obtain

$$\frac{d\ln(P_0/P)}{d\tau} = [\overline{k(z)}]. \tag{9}$$

This equation describes the rate of degradation as characterised by the left-hand side in terms of the average rate constant for the decomposition of the macromolecules. Since it is impossible to predict beforehand the type of variation of $k(z)$, in the general case Eqn. (9) cannot be given a concrete form. If it is assumed that the degradation rate constant is independent of the length of the macromolecule [$k(z) = k$], then

$$\frac{d\ln(P_0/P)}{d\tau} = k \text{ and } P = P_0\exp(-k\tau). \tag{10}$$

When the rate constant is directly proportional to the length of the polymeric molecule $k(z) = k_1 z$, the kinetic equation $d\ln(P_0/P)/d\tau = k_1 P$ assumes the following form after solution:

$$\frac{1}{P} - \frac{1}{P_0} = k_1\tau \tag{11}$$

which is characteristic of the so called random degradation.

Random degradation occurs on ultrasonic treatment of polymers in cavitation fields when chains are actually ruptured by active radicals formed when the cavities are flooded and not as a result of the direct action of shear stresses. The characteristic changes in the molecular weight distribution have been examined by Jellinek and White[53].

Using Eqn. (9), it is also possible to solve the converse problem, the determination of the form of the variation of the elementary rate constant with chain length from data on the decrease of the degree of polymerisation in the degradation process. We shall postulate that $k(z) = \delta k(P)$, where δ is a coefficient which depends on the variance in

the distribution of molecules with respect to length; then the variation of $d\ln(P_0/P)/d\tau$ with P is the same as the variation of $k(z)$ to within the coefficient δ. Figs. 7*a* and 7*b* show [52] the variation of $k(z)$ plotted by graphical differentiation for the ultrasonic degradation of polystyrene in solution. The kinetic curves analysed were taken from different studies [40,50] with markedly differing conditions (concentration, frequency, and ultrasonic power). Although the form of the $k(z)$ curves is different, they both show clearly the existence of the so called degradation limit—the minimum chain length on reaching which the degradation rate constant falls almost to zero. Thus under the specified conditions mechanical degradation is possible only for macromolecules with lengths above a specific limit.

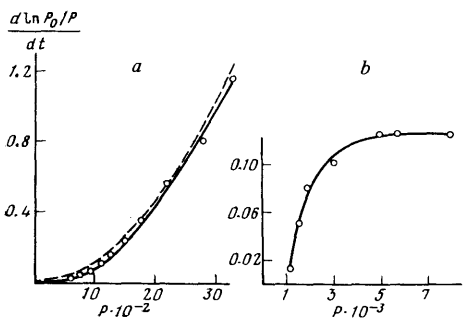

Figure 7. Variation of the rate constant with the degree of polymerisation in the ultrasonic treatment of polystyrene solutions: *a*) Schmid's data [54]; *b*) data of Berlin and El'tsefon [40].

The existence of the limit, associated with a sharp decrease of the rate of the mechanochemical process when the particle size diminishes, is the most characteristic feature of reactions in polydisperse systems. The limiting particle size enters into almost all the kinetic equations: the empirical Schmid equation [54], the Baramboim equation [1] corresponding to the degradation of macromolecules at "weak" bonds, the Schrader equation for the comminution of solids, and others. With increase in particle size, the rate constant rises sharply. Under these conditions, the quadratic relation $k(z) = k_2z^2$ is comparatively common. In the kinetics of the mechanical degradation of macromolecules, the Schmid equation [52] corresponds to the quadratic law. A relation of the type $k(z) = k_2z^2$ was observed also in the comminution of solids in surface-active media [55].

Rigorous analysis of kinetic data combined with the derivation of a relation for $k(z)$ is apparently possible only for mechanochemical processes in liquid media (degradation of polymers in solution, dispersion of solids in an aqueous medium, etc.) when the individual species are fairly well stabilised.

---o0o---

The above very brief discussion of the formal kinetics of mechanochemical reactions shows that the rate of the process may be related to various parameters which depend on external conditions: to the inhomogeneity of the distribution of mechanical stresses throughout the bulk of the substance, the relaxation times of the stresses, and the characteristics for the absorption of mechanical energy by species of different size; finally, when the rate-limiting stage is the primary chemical step, the bond strength and vibration frequency enter into the kinetic equation.

Other factors with a marked influence on the rate of mechanochemical reactions undoubtedly exist. These include primarily the effect of mechanical stresses on the rate of diffusion of species in the condensed phase. This problem is not considered in the present review.

III. POSSIBLE MECHANISMS OF MECHANOCHEMICAL REACTIONS

Mechanochemical reactions differ from other chemical reactions initiated by physical methods in that they can develop with a comparatively low average level of elastic energy per unit volume of the substance. In photochemistry the energy quanta are comparable to the excitation energies for the electronic levels of the molecules. In radiation chemistry the energy of the particles acting upon the substance greatly exceeds the energies of the chemical bonds and one of the tasks in investigations of this kind is to follow the pathways in the dissipation of the excess energy. In the analysis of a mechanochemical process an attempt is made in the first place to deduce the mechanisms of the concentration of energy at individual bonds or in small local volumes in the substance.

Apparently there exist two direct mechanisms for the conversion of elastic into chemical energy which are specific to mechanochemistry: the first of these is associated with the deformation of the electron clouds of the reacting species (a change in the interatomic distances, valence angles, etc.) and the second with the vibrational excitation of the bonds during the dissipation of elastic energy as heat. The first mechanism may be referred to as the equilibrium mechanism, since the equilibrium Maxwell–Boltzmann distribution of energy among the degrees of freedom persists in the system, while the second is a non-equilibrium mechanism.

1. The Equilibrium Process

When a chemical bond is extended, its energy diminishes. At equilibrium, the deformation energy is

$$U_{\text{def}} = \int_{r_0}^{r} f_U dr \quad \text{or} \quad U_{\text{def}} = \int_{V_0^*}^{V^*} \sigma_U dV^*, \tag{12}$$

where f_U and σ_U are the force and the stress acting on the bond, r_0 and r are the length of the initial and the deformed bond, and V_0^* and V^* are the corresponding activation volumes; $V^* = rs^*$ and s^* is the effective cross-section of the molecule (bond) is relation to the applied stress.

In calculations of the deformation energy and the activation energy for bond dissociation when a force f_U operates, one usually employs the Morse potential function. The variation of the activation energy for decomposition with the force f_U is [56]

$$\frac{U}{U_0} = \sqrt{1-\frac{f_U}{F_0}} - \frac{f_U}{2F_0}\ln\frac{1+\sqrt{1-\frac{f_U}{F_0}}}{1-\sqrt{1-\frac{f_U}{F_0}}}, \tag{13}$$

where F_0 is the ultimate strength of the bond. A plot of the function $L(f_U)$ is presented in Fig. 8 (curve *1*). Under real conditions, a specific group of bonds are deformed; the characteristic features of the energy relations of the process in this case have been analysed [57]. The functions $U(f_U)$ corresponding to the extension of sections of the macromolecule with lengths equivalent to 10, 20, 50, and 100 bonds are compared in Fig. 8 (curves *2–5*) [57].

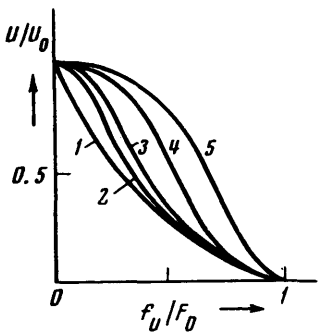

Figure 8. Plot of the function $U(f_U)$; number of bonds in deformed section of chain: 1) ∞; 2) 100; 3) 50; 4) 20; 5) 10.

Eqn. (13) in fact describes the simplest case of the conversion of mechanical into chemical energy and is used to account for the dissociation of mechanically strained bonds. Eqn. (13) is approximate: in complex molecules account must be taken of the deformation of valence angles, angles of internal rotation, and the interaction between atoms not linked by valence bonds [58].

The activation energy for thermal decomposition reactions in the Arrhenius equation is the same as the bond energy U_0:

$$k = k_0 \exp\left(-\frac{U_0}{RT}\right), \qquad (14)$$

where k is the decomposition rate constant (s^{-1}) and k_0 the pre-exponential factor, close to 10^{12}–10^{13} s^{-1} in order of magnitude. When the bonds are mechanically strained, U_0 may be replaced by the expression for the strength of an elastically deformed bond [$U(f_U)$, see Fig. 8]:

$$k_M = k_{0,M} \exp\left(-\frac{U(f_U)}{RT}\right). \qquad (15)$$

An analogous approach based on estimates of the decrease of the energy barrier to purely thermal transitions under the influence of "weak" factors is frequently employed in the analysis of the kinetics or thermodynamics of various processes (diffusion processes, migration of dislocations, effect of the medium on the equilibrium position, etc.). Thus in an equilibrium process the role of mechanical stresses reduces to a decrease of the energy barrier in the thermal reaction. A direct purely mechanical dissociation of bonds without the involvement of thermal fluctuations is possible only when stresses exceeding the bond strength F_0 are applied during a time less than the vibration period (10^{-12}–10^{-13} s). This implies that, for a bond length of the order of 10^{-10} m the rate of propagation of stresses

$$w \simeq \frac{10^{-10}}{10^{-12}-10^{-13}} \simeq 10^{2}-10^{3} \text{ m s}^{-1},$$

must be comparable to the velocity of sound. Probably this limiting case of a purely mechanical rupture occurs under the conditions of a severe stress, for example under the action of shock waves.

The most striking example of a mechanochemical process with an equilibrium mechanism is the degradation of molecules on deformation (monoaxial extension) of polymeric films or fibres. Here all the consecutive stages of the process have been investigated experimentally.

The existence of strained bonds in the main valence chain in polymeric materials subjected to mechanical deformation has been recently demonstrated by infrared spectroscopy [59–61]. Fig. 9*a* shows [61] the variation of the form of the 975 cm^{-1} band corresponding to the skeletal vibrations in oriented polypropylene on monoaxial extension of the specimen. Under load, the position of the maximum shifts insignificantly but the line contour becomes greatly extended towards longer wavelengths, which reflects the existence of a continuous distribution of bonds overstrained to different extents. The frequency $\nu \simeq 940$–950 cm^{-1} corresponds to the bonds deformed to the maximum extent. The distribution function of external stresses with respect to the chemical bonds of the specimen, obtained by analysing the form of the line contour for $\sigma = 84$ kgf mm^{-2}, is plotted in Fig. 9*b*. [61] The distribution is extremely inhomogeneous and extends far into the region of high stresses. According to the first estimates, the maximum stresses reach $\sigma_{max} \simeq 1000$ kgf mm^{-2}; since the decomposition rate constant increases exponentially with increase of the true stress [Eqn. (15)], the degradation process should be virtually confined to bonds subjected to maximum stress.

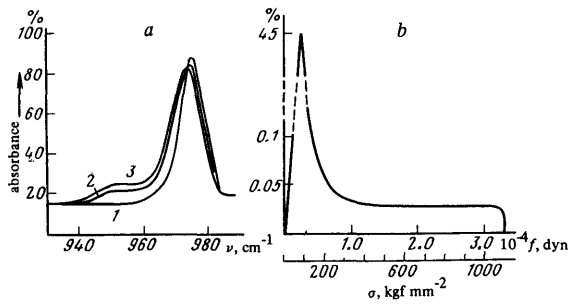

Figure 9. *a*) Variation of the absorption band contour at 975 cm^{-1} in oriented polypropylene under load [applied load (σ, kgf mm^{-2}): 1) 0; 2) 65; 3) 80]; *b*) distribution of stresses with respect to bonds.

The decomposition of the strained parts of the chains is confirmed by the formation of free radicals as a result of the dissociation of chemical bonds. Free radicals have been detected in monoaxial extension processes in various polymers directly in the resonator of an ESR spectrometer and also in cold-drawn specimens [62–71].

Under the conditions where σ = const., the rate of formation of radicals, which is proportional to the rate of dissociation of overstrained bonds, depends on the stress according to the law [64]

$$\frac{d[R^{\cdot}]}{d\tau} = B\exp(\beta\sigma),$$

where B and β are constants.

Over a wide range of variation of external parameters (σ and T), $d[R^{\cdot}]/d\tau$ agrees well with the rate of decomposition of the specimens. The logarithms of the rates of formation of radicals (corresponding to the steady-state sections of the kinetic curves) are plotted in Fig. 10 against the lifetimes of the specimens [64]; all the points are located on a single straight line with a slope of unity. The kinetics of the accumulation of radicals and the formation of submicrocracks—the primary breaks in the continuity of the material—likewise proved to be similar in polymers [71].

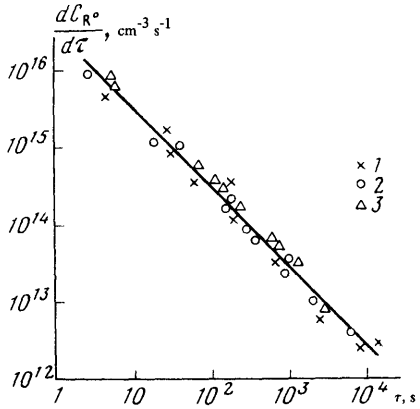

Figure 10. Relation between the rate of formation of radicals and their lifetime in oriented Kapron: 1) −50°C; 2) +18°C; 3) +50°C.

All these data and also the results of many other investigations (see, for example, Pozdnyakov and Regel' [72]) convincingly confirm the reality of the equilibrium mechanism of dissociation of deformed bonds and also the thermal-fluctuation concept of the strength of solids based on this mechanism [8].

The equilibrium processes include the corrosion of metals under stress. A theory has been developed which takes into account the effect of the perturbations of the electronic levels in metals, associated with the generation of dislocations, on the standard electrode potential [73].

2. The Non-equilibrium Process

Mechanochemical reactions can develop not only under stress but also during the removal of stresses or during their redistribution in the substance when elastic energy is transformed into thermal energy [9,46]. In a material subjected to elastic stress, the bonds of the framework of the substance which withstand the mechanical stress are mainly deformed and when the stresses are removed, thermal (vibrational) energy is liberated at these bonds. For example, at the instant of contraction of the macromolecule one may expect vibrational excitation of the bonds in the main chain. Subsequently the vibrational excitation energy is redistributed among all the degrees of freedom of the system. In other words, since the entire flux of elastic energy dissipated as heat passes through the bonds of the main chain, it follows that, for a certain definite period τ^*, these bonds are in a vibrationally excited state.

The conversion of the elastic energy of the deformed bonds (U_{def}) into thermal energy (Q_{therm}) can be represented schematically as follows:

$$U_{def} \rightarrow \Delta U_{vibr} \rightarrow Q_{therm}$$

where ΔU_{vibr} is the vibrational excitational energy of the deformed bonds.

Under steady-state conditions the concentration of the vibrationally excited bonds $[A^*]$ is defined by the relation

$$[A^*] \simeq \tau^* \frac{dU_{def}}{d\tau} . \qquad (16)$$

The lifetime of the vibrationally excited states in solids is short and hardly exceeds 10^{-10} s (i.e. corresponds to 10^2–10^3 vibration periods). During the time τ^*, the excitation energy can either pass to other degrees of freedom of the system or can give rise to a mechanochemical reaction; if τ_{chem} is the characteristic reaction time, the ratio τ^*/τ_{chem} defines the probability of reaction during the lifetime of the vibrationally excited state. When $\tau^*/\tau_{chem} \geq 1$, excitation always leads to reaction.

In order to estimate qualitatively τ_{chem}, one may postulate that, during the dissipation of elastic energy, excitation extends over a region sufficiently large to employ the concept of the vibrational temperature T^*. To a very rough approximation, $RT^* \simeq \Delta U^*_{vibr}$; then, for example for the bond dissociation energy [46] (with $\Delta U_{vibr} \gg RT$),

$$\tau_{chem} \simeq \tau_0 \exp\left(\frac{U_0}{\Delta U_{vibr}}\right) \qquad (17)$$

or in the general case

$$\tau_{chem} \simeq \tau_0 \exp\left\{\frac{U(f_U)}{\Delta U_{vibr}}\right\} .$$

For the inequality $\tau^*/\tau_{chem} \geq 1$ to hold, it is necessary that

$$\Delta U^*_{vibr} \geqslant \frac{U(f_U)}{\ln\frac{\tau^*}{\tau_0}} , \qquad (18)$$

i.e. the dissipation of energy greater than ΔU^*_{vibr} will always lead to bond dissociation. The critical energy ΔU^*_{vibr}, necessary for the dissociation of the bond during the period τ^*, is appreciably less than the bond energy U_0; when $\tau^* = 10^2\tau_0$, $\Delta U^*_{vibr} \simeq 0.2U$.

The rate of the mechanochemical reaction is proportional to the concentration of the vibrationally excited bonds $[A^*]$ and consequently [16] the rate of dissipation of elastic energy as heat is

$$\frac{dC}{d\tau} \simeq \tau^* \frac{dU_{def}}{d\tau} , \qquad (19)$$

Thus the principal feature of the non-equilibrium mechanism is that the rate of the mechanochemical reaction is determined by the rate of relaxation of the elastic energy in the system.

The non-equilibrium mechanism of mechanochemical reactions can be confirmed either by direct spectroscopic measurements or on the basis of a series of indirect chemical characteristics. There are so far no spectroscopic data in the literature, but the first chemical measurements have already been made [46]. In polymers the dissociations of the vibrationally excited sections of the chains should lead to the formation of hot macroradicals capable of further chemical reactions at low temperatures where the usual thermal reactions are retarded. The most probable reaction of hot radicals is decomposition with formation of low-molecular-weight compounds. Fig. 11 presents the results of measurements of the amount of low-molecular-weight products formed on mechanical breakdown of polyisobutylene and polyformaldehyde powders in a mill at −78°C. [46] At the same time measurements were made of the concentration of radicals by ESR. In all the experiments the amount of low-molecular-weight decomposition products (mainly monomeric compounds—isobutene and formaldehyde) exceeds by severalfold the concentration of the radicals formed, i.e. the excess vibrational energy is sufficient for the ejection of several monomeric units.

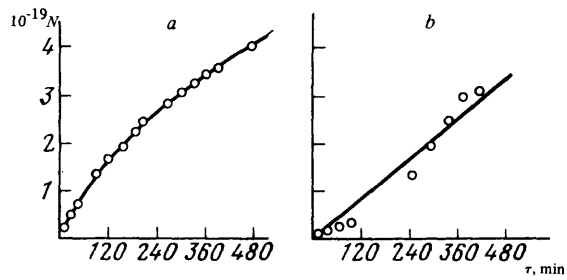

Figure 11. Formation of low-molecular-weight products in the mechanochemical disintegration of polyisobutylene (*a*) and polyformaldehyde (*b*) powders at −78°C.

The data in Fig. 11 and also the measurements of the amount and composition of volatile products evolved during the extension and after the rupture of polymeric films [72, 74,75] at higher temperatures confirm the occurrence of chemical decomposition reactions during the dissipation of elastic energy.

The possibility of the dissipation of energy after the dissociation of macromolecules [76] or after "ejection" of energy on breakdown of a solid subjected to an elastic stress [77] are usually discussed in an examination of the correspnding processes. As already pointed out, elastic deformation and non-equilibrium excitation are consecutive stages of the same process. The essential feature of the non-equilibrium mechanism [46] consists in the fact that the dissipation of an amount of the elastic energy stored by the system less than is required for its breakdown leads to the generation of non-equilibrium excited states, resulting in chemical reactions including bond dissociations and degradation of the macromolecules.

The generation of non-equilibrium vibrationally excited states was recently postulated in connection with the explanation of the kinetics of the photochemical degradation of mechanically strained macromolecules [78].

3. Local Regions of the Absorption of Elastic Energy

The direct pathways for the conversion of elastic into chemical energy discussed above do not cover all the hypotheses which have been put forward concerning the nature of mechanochemical reactions. In ultrasonic chemistry [19,79,80,81], in tribochemistry [10,82], in the theory of impact detonation of explosives [30,31], and in the chemistry of shock-waves [28], models explaining the occurrence of mechanochemical reactions as a result of the generation of local regions where elastic energy is concentrated and absorbed in the bulk or in the surface layer of the substance are widely used. The duration of the existence of such local regions is short and in various hypotheses is estimated as 10^{-3}–10^{-6} s and less, their radius being 10^{-3}–10^{-7} cm. The high pressures and the intense heating in the local regions initiate chemical reactions.

Among the existing theories of the conversion of elastic energy in small volumes within the substance, only the theories of the propagation of shock waves and cavitation have been comparatively thoroughly developed.

In ultrasonic fields and in turbulent flow, the local absorption of elastic energy is associated with the phenomenon of cavitation. Cavitation—local, point disruption of the liquid with the appearance of cavities filled by the dissolved gas and the saturated vapour of the liquid—constitutes an unusually effective mechanism of the absorption of the energy of elastic vibrations in liquids. Chemical reactions begin when the cavities collapse during the contraction phase of the sonic wave. The high pressures (10^4 atm) and temperatures (thousands of degrees) developed in the stage of the adiabatic compression of the bubble [19] lead to the excitation and dissociation of the molecules filling it; after collapse, the active species [83] (in aqueous solutions H atoms, OH radicals, hydrated electrons [84,85], etc.) pass into solution where they can initiate various oxidation reactions, polymerisation, and many other processes. Adiabatic compression of gas bubbles is among the processes involved in the initiation of the detonation of explosives by impact [86].

The brief existence of local regions with high pressures and temperatures (the shock wave front, the "hot spots" in the friction of solids, the magma–plasma model, etc.) has been confirmed by various model experiments. However, the specific features of mechanochemical reactions, the direction of the process, its rate, etc. cannot always be accounted for by purely thermal effects or the simultaneous action of heat and pressure.

The chemical and physicochemical reactions in shock waves are unusually rapid ($\tau \ll 10^{-6}$ s) [88], much more rapid than would be expected on the basis of the existing hypotheses concerning the growth of the nuclei of a new phase or the mechanisms of diffusion in a condensed phase [28]. For such ultrafast processes, the term "diffusion-free" reactions has been proposed. It has been suggested [87] that, at the pressures developed in the shock-wave front, the substance passes into the state of a single activated complex, close to the metallic state characteristic of high degrees of compression. On releasing the pressure after the passage of the shock wave, the form of matter stable when the degree of expansion corresponds to the instant of decomposition of the single activated complex becomes stabilised (this is because electronic transitions are much faster than the rearrangement of atoms). This hypothesis has been put forward to account for the polymorphic transformations of the graphite–diamond type in powerful shock waves. Outwardly similar hypotheses concerning the rapid "quenching" of different

forms of a substance, corresponding to the instant when "hot spots" exist, have been used in the mechanochemistry of solids.

The specific features of mechanochemical processes are also associated with plastic deformation and the nature of the strained state of the substance. Pressure and temperature can supply sufficient energy for the reaction to occur (they can create a "thermodynamic background" [28]), but it is also necessary that mechanical stresses should act in the same direction as the reaction. Thus, in the mechanical degradation of macromolecules, sheer or tensile stresses not only dissociate the bonds in the main chain but they also liberate from the "cages" the radicals formed and prevent their recombination. In polymerisation it is not sufficient to set up a pressure at which the density of the monomer becomes comparable to that of the polymer; it is also necessary to consider the possibility of chain propagation, which is achieved by plastic deformation of the material with simultaneous application of pressure and sheer deformation [26,27].

IV. PRIMARY ACTIVE CENTRES IN MECHANOCHEMICAL REACTIONS

In the analysis of the elementary mechanisms of various mechanochemical reactions, it is important to know the nature of the primary active species or surface centres formed as a result of the transformations of elastic energy. Information about the nature of the primary centres has been obtained mainly in studies on the mechanical degradation of macromolecules, certain organic reactions, chemical reactions in ultrasonic fields, and, to a lesser extent, in processes involving the disruption of solids.

According to the most general considerations, in the ideal case of the dissociation in vacuo of chemical bonds of different types (ranging from homopolar to purely ionic), the formation of electrically neutral decomposition products is more favourable on energy grounds. In principle, two cases are possible:

$$\sim A-B\sim \begin{cases} \longrightarrow \sim A^{\cdot} + {}^{\cdot}B\sim \text{ (I)} & U_{A-B} \\ \longrightarrow \sim A^{+} + {}^{-}B\sim \text{ (II)} & U_{A-B}+(I_A-A_B). \end{cases}$$

In the first case the energy expenditure is equal to the strength of the A–B bond, while in the second case it is necessary to supply additional energy equal to the difference between the ionisation potential of the fragment $\sim A(I_A)$ and the electron affinity of the species $B\sim(A_B)$. In the dissociation of bonds in compounds of the alkane series this difference approaches

$$I_{C_2H_7} - A_{C_2H_7} = 8.7-1.0 = 7.7 \text{ eV} \simeq 170 \text{ kcal mole}^{-1}.$$

In the majority of organic reactions, the difference $I - A$ in the dissociation of bonds is somewhat less, but nevertheless remains considerable; thus the electron affinities of certain radicals may reach 1.5–2.0 eV, but the ionisation potentials of molecules or their fragments are rarely less than 6 eV; therefore the difference $I - A$ can hardly be less than 4–5 eV.

In exactly the same way, when the typically ionic compound NaCl decomposes in a vacuum,

$$I_{Na} - A_{Cl} = 5.14-3.81 = 1.33 \text{ eV} \simeq 30 \text{ kcal mole}^{-1},$$

i.e. even in this limiting case of an ionic bond the formation of electrically neutral Na and Cl atoms remains more favourable than the formation of Na^+ and Cl^- ions. Recently it was established that, in the mechanical disruption of NaCl crystals, sodium (it was referred to as the amalgam) and gaseous chlorine are evolved in considerable amounts[89].

In polar media, where there is a possibility of an energy gain owing to the solvation or polarisation of the species formed, the situation may alter significantly. One may expect that in the majority of organic substances the main pathway for bond dissociation in mechanical disruption (and also in thermal degradation) is radical or molecular but not ionic. All the experimental data accumulated hitherto are consistent with these general considerations: in the mechanical disruption of carbon chain and heterochain organic polymers, free radicals are formed. Initially they were detected by the acceptor method[1–5], but in the last decade vigorous investigations of the free-radical products of the mechanical degradation of polymers by ESR began [90,91].

The dissociation of linear macromolecules with formation of radicals has been observed in solutions under the influence of sheer and ultrasonic gradients and in polymeric substances in the rubber-elastic, vitreous, and crystalline states.

Table 3. The structure of the primary free radicals formed in the mechanical rupture of polymer chains.

Substance	Structure of radicals	References
Polyethylene	$\sim CH_2\dot{C}H_2 + \dot{C}H_2CH_2\sim$	92,93
Polytetrafluoroethylene	$\sim CF_2\dot{C}F_2 + \dot{C}F_2CF_2\sim$	94
Polystyrene	$\sim CH(C_6H_5)\dot{C}H_2 + \dot{C}H(C_6H_5)CH_2\sim$	95
Polyamides	$\sim CH_2\dot{C}H_2 + \dot{C}H_2(NHCO)\sim$	93
Poly(ethylene oxide), poly(ethylene sulphide) (X = O or S)	$\sim X\dot{C}H_2 + \dot{C}H_2X\sim$	96,97

The structure of the primary radicals has been elucidated by ESR, i.e. the sites of the preferential mechanical rupture of polymer chains have been established (Table 3), quantitative measurements of the rates of bond dissociation under various conditions of disruption of polymeric materials have been begun (monoaxial extension [62–64,69], comminution [46], etc.), and the direction and kinetics of secondary free-radical reactions are being investigated, i.e. the further fate of radicals is being traced [92,98–103].

Active species capable of initiating various chemical reactions, including chain processes have been detected also when low-molecular-weight substances are subjected to mechanical action.

In ultrasonic fields (cavitation conditions) chemical reactions are initiated by the free-radical decomposition products of water [83]. The decomposition of H_2O can occur either as a result of a sharp adiabatic compression of the cavity [19,79] or under the influence of microdischarges (electrical breakdown of the cavity) in the stage of its formation [80] or its collapse [81]. None of these mechanisms can so far be rejected. Hydrated electrons were recently detected [84] in water decomposition products:

$$H_2O \xrightarrow{u.s.} OH^{\cdot}, H^{\cdot}, H_2O_2, e^-_{aq.} \text{ etc.}$$

The probabilities of various elementary processes leading to the formation of excited species, radicals, and ions in the cavity have been compared in a review [85]. The chemical effect of ultrasonic cavitation resembles in broadest outline the indirect effect of radiation on aqueous solutions.

One of the most sensitive methods for demonstrating the existence of active species in various systems is the

initiation of chemical chain reactions. Chain polymerisation was observed in ultrasonic cavitation fields [104,105] (in the absence of traces of water there is no polymerisation [106]), in shock waves [107-109], under the influence of high pressures with shear [26,27,110], and finally in the mechanical dispersion of solids [111-114]. In the last two systems the reaction mechanism was established by measuring the copolymerisation rate constants: when high pressures with shear operate, the reaction is propagated by free radicals [110] and in the comminution of the monomer together with various solids, polymerisation is caused by the effect of charged species [114,115] and possibly of emission electrons [115].

The problem of the analysis of the nature of the primary centres is much more complex in the mechanochemistry of solids where it is necessary to take into account not only the dissociation of various bonds but also the behaviour of the entire crystal and its surface. The primary active states in solids are investigated by adsorption, low-temperature electron emission, luminescence, ESR methods, etc. The results of studies on the nature of paramagnetic centres detected by ESR in solids of different types are compiled in Table 4. Analysis and interpretation of the ESR spectra in polycrystalline solids constitutes a fairly complex problem and as a rule the nature of the centres has been established indirectly by the analysis of their physical and chemical properties.

As already mentioned, in complex organic reactions free radicals are formed. When the two-dimensional networks of graphite are broken, free radical centres are formed on the basal planes, their concentration reaching 10^{14} cm^{-2}. There is at present no unanimous view concerning the nature of the paramagnetic centres in silicon. Judging from chemical characteristics, a considerable proportion of the centres detected in SiO_2 are of a free-radical type, but this has not been demonstrated convincingly.

Table 4. The nature of the paramagnetic centres detected in the mechanical disintegration of certain materials.

Charged states (electrons in shallow traps) stable only at a low temperature have been detected in both GeO_2 and $BaSO_4$. One may suppose that the formation of charged centres is part of the range of mechano-emission phenomena accompanying the mechanical disruption of solids and reflected in static electrification [140], luminescence [10], electron emission [141,142], etc. There is so far no general theory of emission phenomena. In the electrical theory of adhesion [143,144] the emission of high-energy electrons is explained by the formation of an electrical double layer at the surfaces in contact. When the adhesion contact is broken, a powerful electric field abstracts electrons from the surface and disperses them. Electrical excitation of matter can occur as a result of the interaction of elastic waves with current carriers (the electroacoustic effect) [145-147]; the polarisation of substances in shock waves is apparently associated with this mechanism [148,149]. The emission and luminesence on friction and on impact by solids has also been explained within the framework of the magma–plasma model [10].

Electro-emission phenomena are of great importance for mechanochemistry, since an electrical discharge between solid surfaces or a planar surface discharge [150] can lead to the formation of active species, including electrons, which initiate various chemical reactions [115].

---o0o---

Mechanochemical phenomena occur widely in nature and are of considerable importance for many branches of science and engineering; these are the problems of the strength of solids and of the physicochemical mechanics of materials, certain branches of colloidal chemistry, the physics and physical chemistry of polymers, geochemistry, biophysics, the technology of inorganic substances, and chemical kinetics, the theories of the reactivity of molecules and molecular acoustics, and problems of friction and wear, heterogeneous catalysis and adsorption, detonation and propagation of shock waves, metal corrosion, etc. Mechanochemical reactions are of a wide variety of types and at first sight it is difficult to compare processes involving the absorption of sound in gases with chemical changes in the friction of solids or reactions in shock waves with corrosion of a mechanically strained metal. However, the chemical reactions are throughout induced by the absorption of elastic energy and these widely differing processes have common features reflected in the nature of the primary steps and their kinetics. In the present review particular attention has been devoted to these problems in the analysis and classification of published data. Many no less important aspects of mechanochemical reactions have not been mentioned or only touched upon: the process energetics and thermodynamics, the relation between mechanochemistry on the one hand and physicochemical mechanics and processes involving the disruption of materials on the other [77], mechano-emission phenomena, processes in which a substance is subjected to the simultaneous action of various types of energy [78,151] (for example elastic and emission energies), the characteristics of reactions in inorganic substances [152], the generation of luminescence and the occurrence of gas-discharge processes [153], etc.

The Chemistry of Acyl Radicals in Solution

M.G.Vinogradov and G.I.Nikishin

The available methods for the generation of acyl radicals and their reactions in solutions are reviewed. The effect of stabilising and polar factors on the reactivity of acyl radicals and the mode of their addition to unsaturated molecules are discussed. The characteristics of the reactions involving acyl radicals, initiated by various methods (by peroxides, ultraviolet light, γ-irradiation, etc.) have been examined. Much attention has been devoted to the role of acyl radicals in chain processes constituting the basis of new methods for the synthesis of carbonyl compounds.
The bibliography includes 266 references.

I. INTRODUCTION

Acyl radicals are some of the simplest carbonium radicals. In 1949 Kharasch et al.[1] proposed a method for their preparation from aldehydes with the aid of peroxides and ultraviolet light. In the next 20 years numerous studies were made on the reactivity of acyl radicals and their role in liquid-phase homolytic processes was investigated. Owing to the ease of formation of acyl radicals in solution, they are finding increasing application in organic synthesis.

At the present time there are six main methods for the generation of acyl radicals in solution:

1. Homolytic removal of hydrogen from aldehydes:

$$R-C\begin{matrix}H\\ \diagup\\ \diagdown\\ O\end{matrix} + A\cdot \rightarrow R-\dot{C}=O+AH\,.$$

2. Homolytic removal of a halogen from acid halides:

$$R-C\begin{matrix}X\\ \diagup\\ \diagdown\\ O\end{matrix} + A\cdot \rightarrow R-\dot{C}=O+AX\,.$$

3. Thermal, photolytic, or radiolytic dissociation of ketones and carboxylic acid derivatives:

$$R-C\begin{matrix}Y\\ \diagup\\ \diagdown\\ O\end{matrix} \rightarrow R-\dot{C}=O+Y$$

(Y = alkyl or a functional group).

4. One-electron oxidation of aldehydes:

$$R-C\begin{matrix}H\\ \diagup\\ \diagdown\\ O\end{matrix} + M^n \rightarrow R-\dot{C}=O+M^{n-1}+H^+ \quad (M\text{—metal})\,.$$

5. Addition of carbon monoxide to alkyl radicals:

$$R^\cdot + CO \rightarrow R-\dot{C}=O\quad .$$

6. Decomposition of more complex radicals, for example:

$$R-\underset{\displaystyle R'}{\overset{\displaystyle \dot{O}}{\underset{|}{C}}}-\overset{\displaystyle O}{\overset{\|}{C}}-R'' \rightarrow R''\dot{C}=O + R-\overset{\displaystyle O}{\overset{\|}{C}}-R'\,.$$

The radicals R–Ċ=O readily add to multiple carbon–carbon bonds and also to the bonds >C=O, >C=N–, –N=N–, etc. At elevated temperatures they lose carbon monoxide and are converted into alkyl radicals. Many photochemical rearrangements and decompositions of aldehydes, ketones, and carboxylic acid derivatives involve acyl radicals.

The radicals R–Ċ=O generated in solution are usually identified on the basis of the products of their further reactions. Owing to the short lifetime of acyl radicals in the liquid phase, their ESR spectra[2–5] can be obtained only at low temperatures (in the frozen state).

The present review deals with studies on the methods of generation and reactions of acyl radicals published up to 1970.

II. METHODS OF GENERATION OF ACYL RADICALS

1. FORMATION OF ACYL RADICALS FROM ALDEHYDES

In the generation of acyl radicals from aldehydes, compounds which readily undergo thermal dissociation (organic peroxides, azo-compounds, etc.), oxygen, and variable-valence metal salts are most often employed. Acyl radicals are also obtained by allowing ultraviolet light or γ-rays to act directly on aldehydes.

The relative reactivities of various aldehydes in reactions involving the removal of a hydrogen atom by t-butoxy-radicals have been investigated[6–8]. The t-butoxy radicals were obtained from t-butyl hypochlorite. The reaction has a chain mechanism, the chain being probably initiated as a result of the trimolecular reaction

$$2\,(CH_3)_3COCl + RCHO \rightarrow 2\,(CH_3)_3C-O\cdot + HCl + RCOCl\,.$$

The removal of a hydrogen atom by the $(CH_3)_3CO\cdot$ radical from CH_3CHO and from C_6H_5CHO is faster by a factor of 4.3 and 3.4 respectively than from cyclohexane[6]. *m* and *p*-Nitrobenzaldehydes do not react with $(CH_3)_3COCl$[7] owing to the electrophilic properties of t-butoxy-radicals. In this case the polar factor promotes an increase of activation energy, which hinders the removal of a hydrogen atom[6]. Probably this is why the removal of hydrogen from n-butyraldehyde by perbenzoate radicals is much easier than from benzaldehyde[9].

The relative reactivities of substituted benzaldehydes in the reaction with sulphuryl chloride initiated by benzoyl peroxide have been investigated by the method of competing reactions. Aroyl radicals are generated as a result of an attack on the aldehyde by the $\cdot SO_2Cl$ radical[10-12]. The values obtained are correlated in terms of the Hammett equation ($\rho = -0.48$). The effect of substituents is determined by the role of polar factors in the transition state[12]:

$$RC\overset{O}{\underset{H}{\diagup}} + \cdot SO_2Cl \rightarrow RC\overset{\delta+}{\underset{O}{\cdots}}H\cdots\overset{\delta-}{SO_2Cl} \rightarrow R-\dot{C}=O + SO_2 + HCl\,.$$

The relative reactivities of substituted benzaldehydes in the reaction with $\cdot CCl_3$ radicals were determined by Lee[13]. In this case $\rho = -0.74$. When C_6H_5CHO is replaced by C_6H_5CDO, the kinetic isotope effect is 2.4 at 80°C. $BrCCl_3$ was used as a source of $\cdot CCl_3$ radicals. The reactivities of C_6H_5CHO and other hydrogen donors with respect to the trichloromethyl ($\cdot CCl_3$)[14] and phenyl ($\cdot C_6H_5$)[15] radicals have been compared[14,15]. Table 1 lists the reactivities of C–H bonds in reactions involving the removal of hydrogen by certain radicals.

Table 1. Relative reactivities of various C–H bonds in reactions involving the abstraction of a hydrogen atom.

Radical	Compound				References
	$C_6H_5CH_3$	C_6H_5CHO	CH_3CHO	cyclohexane	
$(CH_3)_3C-O\cdot$	1	12.8	16.1	0.16	6
$\cdot SO_2Cl$	1	9.7	—	2.9	11
$\cdot CCl_3$	1	58	—	—	14

$\alpha\alpha'$-Azobisisobutyrate, a widely used initiator of many homolytic processes, has proved relatively ineffective for the generation of acyl radicals from aliphatic aldehyde[16]: only 15–20% of the total amount of $\cdot C(CH_3)_2-COO-CH_3$ radicals formed in the decomposition of the azo-compound removed hydrogen from the aldehyde, while the remainder recombined or added to the azo-group of the initiator.

When acrolein is attacked by t-butoxy-radicals, the reaction involving the removal of hydrogen from the aldehyde group predominates ($K_{rem}/K_{add} \geqslant 18$):[8]

$$(CH_3)_3COCl \xrightarrow{h\nu} (CH_3)_3C-O\cdot + Cl\cdot$$

$$(CH_3)_3C-O\cdot + CH_2=CHCHO \begin{cases} \xrightarrow{K_{rem}} CH_2=CH-\dot{C}=O + (CH_3)_3COH \\ \xrightarrow{K_{add}} (CH_3)_3COCH_2-\dot{C}H-CHO\,. \end{cases}$$

Acetyl radicals are generated in the catalytic chain oxidation of acetaldehyde by oxygen (catalysed by a cobalt salt)[17-19]. At an advanced stage of the reaction, the following elementary steps play a decisive role in chain initiation[19]:

$$CH_3CHO + Co^{III} \rightarrow CH_3-\dot{C}=O + Co^{II} + H^+\,,$$

$$CH_3\overset{O}{\overset{\|}{C}}-OO-\overset{OH}{\overset{|}{C}}HCH_3 + Co^{II} \rightarrow CH_3COO^- + Co^{III} + \cdot O-\overset{OH}{\overset{|}{C}}HCH_3\,.$$

Subsequently the $CH_3CH(OH)O\cdot$ radical removes hydrogen from the aldehyde, as a result of which $CH_3-\dot{C}=O$ is formed.

From a study of the kinetics of the oxidation of aromatic aldehydes by hydrated cobalt ions in aqueous acetonitrile, a mechanism was proposed for this reaction with intermediate formation of aroyl radicals[20]:

$$ArCHO + Co^{III} \rightarrow Ar-\dot{C}=O + Co^{II} + H^+\,.$$

A kinetic isotope effect of 2.3 at 10°C was observed in the oxidation of ArCDO. Consequently the rate-limiting stage of the process is the dissociation of the C–H(D) bond in the aldehyde group[20].

The $C_6H_5-\dot{C}=O$ radicals were obtained by the oxidation of C_6H_5CHO with cerium(IV) perchlorate in 85% acetic acid[21]. Acrylonitrile was used as the $C_6H_5-\dot{C}=O$ acceptor. Each molecule of polyacrylonitrile formed contained one benzoyl group.

Free radicals, most probably $C_6H_5-\dot{C}=O$, are generated in the oxidation of benzaldehyde by chromic acid[22] and chromyl acetate[23]. In the first case the radicals arise only after the appearance in the solution of chromium(IV), which is evidently responsible for their formation.

In contrast to aromatic aldehydes, aliphatic aldehydes are oxidised by transition metal ions in an aqueous medium in the hydrated[24,25] or enolic[26] forms. One may expect that alkoxy-radicals are generated in such cases. Recently a method has been proposed for the preparation of acyl radicals by the reaction of aliphatic aldehydes with manganese triacetate in the absence of a solvent of in glacial acetic acid[27]. The authors believe that this reaction proceeds via a stage involving the intermediate formation of a radical-cation[28]:

$$RCHO + Mn(OAc)_3 \rightarrow R-\overset{+}{\underset{H}{\overset{O}{\diagup}}}C\,[Mn(OAc)_3]^- \rightarrow R-\dot{C}=O + AcOH + Mn(OAc)_2\,.$$

When aldehydes are irradiated with ultraviolet light, acyl radicals are generated as a result of the secondary reactions of the excited molecules. The primary processes occurring in the photolysis of aldehydes have been fairly thoroughly investigated[29]. For the majority of aldehydes, the lowest excited state corresponds to an $n-\pi^*$ transition (i.e. the transition of one of the non-bonding $2p$ electrons of the oxygen atom to an antibonding π^* orbital of the carbonyl group). Since in the $n-\pi^*$ excited state aldehydes, like ketones, exhibit the properties of free radicals with an unpaired electron at the oxygen atom[30], they can remove hydrogen from other aldehyde molecules with formation of acyl free radicals:

$$RCHO \xrightarrow{h\nu} RCHO^*\,,$$

$$RCHO^* + RCHO \rightarrow R-\dot{C}H-OH + R-\dot{C}=O\,.$$

Although the decomposition of excited aldehyde molecules into $R-\dot{C}=O$ and a hydrogen atom has been observed under the condition of flash photolysis, nevertheless it does not play a significant role in photolytic reactions[29].

It is noteworthy that the use of ultraviolet light for the generation of $R-\dot{C}=O$ radicals from aldehydes frequently involves undesirable side processes, for example the cleavage of the aldehyde molecule with formation of an olefin (a Norrish type II cleavage)[29] or the polymerisation of the aldehyde to a cyclic trimer[31,32].

γ-Irradiation has been used to generate acyl radicals in free-radical reactions involving the addition of aldehydes to alk-1-enes (Section III). The study of γ-radiolysis of propionaldehyde showed that this process has a chain mechanism[33].

2. Formation of Acyl Radicals from Ketones

The most widely used method of generation of acyl radicals from ketones involves ultraviolet irradiation. Many studies have been made on the photolysis of ketones [29,34-38]. The mode of photolytic decomposition of ketones, like that of aldehydes, is greatly influenced by their structure. n-Alkyl methyl ketones, such as methyl propyl ketone and butyl methyl ketone undergo exclusively a type II decomposition on ultraviolet irradiation in the liquid phase, i.e. they decompose into acetone and an olefin (ethylene and propene respectively) [39]. Such decomposition (via a cyclic transition state) is readily undergone also by other ketones with hydrogen atoms in the γ-position. Acyl radicals are formed preferentially on ultravilet irradiation of aliphatic ketones without hydrogen atoms in the γ-position, for example, alkyl t-butyl ketones [39,40]. They are cleaved in accordance with the rule governing the formation of the most stable alkyl radical (in this case the t-butyl radical):

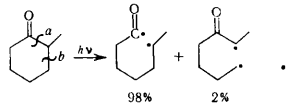
$$(CH_3)_3C-\overset{O}{\overset{\|}{C}}-R \xrightarrow{h\nu} (CH_3)_3C\cdot + O=\dot{C}-R.$$

Cis-trans isomerisation of hex-4-en-2-one also takes place with homolytic dissociation of the C–C bond adjoining the carbonyl group [41]. The $CH_3-\dot{C}=O$ radicals generated in this process add to the multiple bond (if the photolysis is carried out in the presence of an alkene) and butenyl radicals recombine to isomeric octadienes.

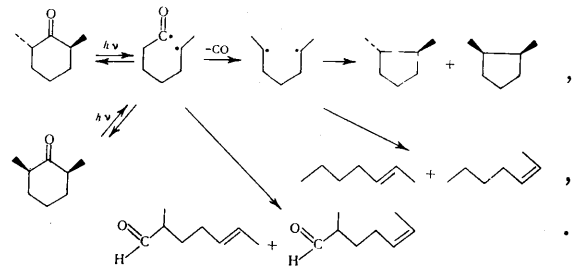
It has been shown that acyl radicals are obtained together with hydrogen and alkyl and α-oxoalkyl radicals in the liquid-phase radiolysis of simple aliphatic ketones (acetone [42], ethyl methyl ketone [43], and diethyl ketone [43]).

Many reactions are known in which cyclic ketones are photochemically cleaved with formation of an unsaturated aldehyde or ketone, which are formally products of an intramolecular disproportionation of intermediate acyl–alkyl biradicals. Nevertheless the problem of whether or not free radicals are really formed in the photolysis of cyclic ketones was regarded as controversial until recently [29]. In contrast to the free-radical mechanism, a hypothesis was put forward according to which the C–C bond of the cyclic ketone is dissociated and new bonds are formed by a synchronous mechanism, i.e. without the involvement of the radical pair [36,44].

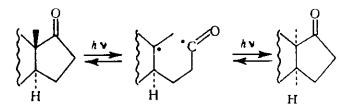
Nowadays the formation of an acyl–alkyl biradical on ultraviolet radiation should probably be regarded as proved, at least for simple cyclic ketones. Important studies designed to confirm this view have been made by Pritchard, Rickdorn, and others [45,46]. They found that the opening of the 2-methylcyclohexanone ring takes place to the extent of 98% at *a* and only to the extent of 2% at *b*. Such high process selectivity is due to the greater stability of a secondary alkyl radical compared with a primary radical:



As a result of the intramolecular disproportionation of the intermediate acyl–alkyl biradical, a mixture of *cis*- and *trans*-isomers of 5-heptenal is obtained (under the reaction conditions, these isomers are not interconverted) [49]. The photochemical cleavage of 2,6-dimethylcyclohexanone takes place similarly [45]. Ultraviolet irradiation of both the *cis*- and *trans*-isomer of this ketone leads to the same mixture of *cis*- and *trans*-1,2-dimethylcyclopentanones, *cis*- and *trans*-hept-2-enes, and *cis*- and *trans*-2-methylhept-5-enals with the same component ratio, which unambiguously demonstrates a free-radical mechanism:



2,3-Dimethylcyclopentanone is also cleaved by ultraviolet light with formation of an acyl-alkyl biradical, because the reaction products are a mixture of *cis*- and *trans*-1,2-dimethylcyclobutanes [47]. Homolytic dissociation of the C–C bond takes place also in the photolysis of bicyclic ketones, since examples of their photochemical epimerisation are known [48]:



Section V deals with examples of the migration of acyl groups, which confirm the free-radical mechanism of the photochemical cleavage of cyclic ketones. It should be noted that in some cases steric factors can favour the preferential occurrence of the reaction involving a molecular (synchronous) mechanism [49].

Radiolysis of cyclopentanone [50] leads to ring opening, probably via the same mechanism as in the photolysis of cyclic ketones, i.e. with intermediate formation of an acyl–alkyl biradical, but in this process side hydrogenation–dehydrogenation reactions play a significant role (the radiolysis products contain appreciable amounts of cyclopenten-2-one and cyclopentanol).

α-Diketones can also be used for the generation of acyl radicals. Thus diacetyl undergoes thermal dissociation into acetyl radicals with a 50% decomposition time of about 17 h at 145 °C [21]. Acetyl radicals are obtained from diacetyl also under milder conditions—when it is attacked by the alkyl radicals generated from the solvent by peroxides or ultraviolet irradiation [52,53]. In both cases intermediate α-oxoalkoxy-radicals are formed and are readily decomposed:

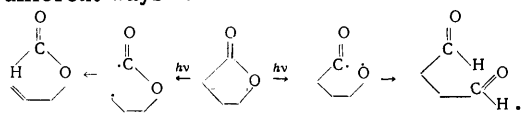
$$R\cdot + CH_3-\overset{O}{\overset{\|}{C}}-\overset{O}{\overset{\|}{C}}-CH_3 \rightleftarrows CH_3-\overset{\dot{O}}{\underset{R}{\overset{|}{C}}}-\overset{O}{\overset{\|}{C}}-CH_3 \rightarrow$$

$$\rightarrow CH_3-\overset{O}{\overset{\|}{C}}-R + CH_3-\dot{C}=O.$$

Photolysis of dibenzoyl leads to $C_6H_5-\dot{C}=O$ with a quantum yield of 0.25 on irradiation with light at a wavelength of 366 nm. [64] The photochemical cleavage of other α-diketones has also been investigated [55].

3. Formation of Acyl Radicals from Carboxylic Acid Derivatives

Irradiation of α-butyrolactone with light at a wavelength of 253.7 nm leads to the cleavage of the lactone ring in two different ways [56]:



The quantum yields of succinaldehyde and allyl formate are respectively 0.06 and 0.23 at 25°C. As a result of the photolysis of carboxylic α-ketoacids, carbon monoxide is evolved with formation of acyl and alkoxy-radicals [57].

A convenient method for the preparation of acyl radicals is based on the photolysis of *S*-acyl and *O*-alkyl xanthates [58]:

$$R-\overset{O}{\overset{\|}{C}}-S-\overset{S}{\overset{\|}{C}}OC_2H_5 \xrightarrow{h\nu} R-\dot{C}=O + \cdot S-\overset{S}{\overset{\|}{C}}OC_2H_5 .$$

Mixed benzoic and dithiocarbamic acid anhydrides can serve as a source of benzoyl radicals [59]:

$$R_2NC\overset{S}{\overset{\|}{S}}C\overset{O}{\overset{\|}{C}}C_6H_5 \xrightarrow[\lambda>3000\,Å]{h\nu} R_2N\overset{S}{\overset{\|}{C}}-S\cdot + O=\dot{C}C_6H_5 .$$

In contrast to *N*-disubstituted anhydrides, *N*-monosubstituted mixed anhydrides undergo photochemical dissociation in two ways [60]: with the scission of both $C_6H_5-\dot{C}=O$ and $C_6H_5C(O)\dot{S}$.

There are preliminary data [61] showing the formation of $R-\dot{C}=O$ on heating acid anhydrides with activated charcoal above 200°C. Schmidt [3,4,62,63] showed that acyl radicals are generated on ultraviolet irradiation of aliphatic and aromatic carboxylic acid halides:

$$R-C\overset{O}{\underset{X}{<}} \xrightarrow[2540\,Å]{h\nu} R-\dot{C}=O + X\cdot ,$$

where X = Br or Cl.

In contrast to the above reaction, when carboxylic acid halides react with peroxides, only the hydrogen atoms linked to the α-carbon atom of the acid halide are attacked; acyl radicals are not then formed [63,94].

Metal hydrides or carbonyls can be used successfully for the generation of acyl radicals from acid halides. For example, trialkyl- and triphenyl-tin hydrides readily react with acyl halides according to the mechanism [65]:

$$RCOCl + R'_3SnH \rightarrow R-\dot{C}=O + R'_3Sn\cdot + HCl ,$$

$$R'_3Sn\cdot + RCOCl \rightarrow R'_3SnCl + R-\dot{C}=O .$$

The relative reactivities of substituted aroyl halides in the reaction with tributyltin hydride have been determined [65]. The observed effect of substituents on the rate of removal of chlorine from the acid chloride is evidence of the important role of polar factors in the transition state

$$\left[ArC\overset{O}{\overset{\|}{}}\cdots Cl\cdots Sn \right]^{\cdot} .$$

C_2H_5COCl is approximately 5.6 times more reactive in the above reaction than C_6H_5COCl.

When perfluoroacyl chlorides react with nickel carbonyl, perfluoroacyl radicals are obtained [66]:

$$2\,R_FCOCl + Ni(CO)_4 \rightarrow 2\,R_F-\dot{C}=O + NiCl_2 + 4\,CO .$$

The reaction is catalysed by benzonitrile, the use of which as a solvent makes it possible to lower the temperature from 150° to 20°C.

Carboxylic acid chlorides are readily reduced to the corresponding aldehydes in the presence of palladium (Rosenmund reaction). Although the mechanism of this catalytic process is not altogether clear, it is quite likely that acyl radicals are formed in the first stage [67]:

$$2\,RCOCl + Pd \rightarrow 2R-\dot{C}=O + PdCl_2 .$$

4. Formation of Acyl Radicals from Other Compounds

Acyl radicals can be obtained by the addition of carbon monoxide to alkyl radicals generated by the usual methods from saturated and unsaturated hydrocarbons [68-72] or from tetra-alkyl-lead [73]:

$$R\cdot + CO \rightleftarrows R-\dot{C}=O .$$

Since the reaction is reversible, the process is usually carried out under a pressure in excess of 500 atm in order to displace the equilibrium towards the formation of $R-\dot{C}=O$ and also to suppose the side reaction of R· with the solvent.

Thermolysis of α-acyl-t-alkyl hypochlorites leads to unstable α-acyl-t-alkoxy-radicals which are readily decomposed with elimination of $R-\dot{C}=O$:

$$R-\overset{O}{\overset{\|}{C}}-\overset{OCl}{\overset{|}{CR'_2}} \xrightarrow{(CCl_4)} R-\overset{O}{\overset{\|}{C}}-\overset{O\,\dot{}}{\overset{|}{CR'_2}} \rightarrow R-\dot{C}=O + R'COR' .$$

Subsequently the reaction develops as a chain process. The decomposition of α-acetyl-s-butyl hypochlorite results in a quantitative yield of 2-butanone and acetyl chloride [74].

Acyl radicals are obtained by the reaction of di-t-butyl peroxide with three-five-membered cyclic ethers, for example tetrahydrofuran (THF). [75] The reaction is remarkable because acyl radicals are generated as a result of an intramolecular rearrangement of the alkyl radicals formed initially [75]:

Attempts have been made to generate $R-\dot{C}=O$ radicals by the thermal decomposition of acyl and aroyl di-imides (RCO–N=N–COR). However, this process apparently has a complex mechanism, since propionyl di-imide initiates the polymerisation of olefins (acrylonitrile, styrene, etc.) only very slightly [73] and the thermal decomposition products of benzoyl di-imide contain only an insignificant amount of dibenzoyl [76]. More definite data supporting the formation of $C_6H_5-\dot{C}=O$ from benzoyl di-imide were obtained in a study of its photolytic cleavage [76].

III. ADDITION OF ACYL RADICALS TO MULTIPLE BONDS

1. GENERAL RELATIONS

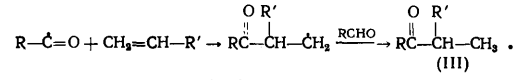
The free-radical addition of aldehydes to α-olefins was described for the first time by Kharasch et al. [1] The process has a chain mechanism:

$$RCHO \xrightarrow[(h\nu)]{peroxide} R-\dot{C}=O ,$$

$$R-\dot{C}=O + CH_2=CHR' \rightarrow \underset{(I)}{R\overset{O}{\overset{\|}{C}}CH_2-\dot{C}H-R'} + RCHO ,$$

$$I + RCHO \rightarrow \underset{(II)}{R\overset{O}{\overset{\|}{C}}CH_2CH_2R'} + R-\dot{C}=O \quad \text{etc.}$$

A detailed study of the products of the reaction initiated by peroxides [32,77], ultraviolet light [32], and γ-radiation [78,79] showed that acyl radicals attack not only the terminal but partly also the β-carbon atom of the vinyl group in the α-olefin:

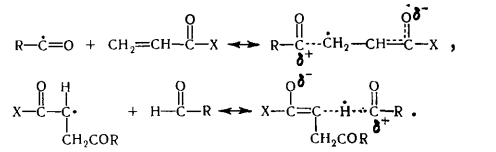


The content of compound (III) in a mixture of compounds (II) and (III) is 5–10%. The composition of the mixture of isomeric ketones is independent of the method of initiation of the reaction and of the reactant ratio [32].

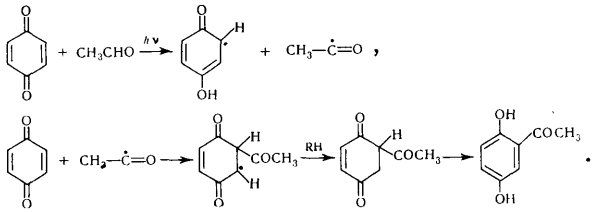
As in other free-radical reactions, the mode of addition of R–Ċ=O to olefins is determined in the first place by the degree of stabilisation of the intermediate alkyl radical. The addition to isobutene [32] and 2-methylbut-2-ene [80] takes place almost exclusively at the least substituted carbon atom of the C=C group and the addition to straight-chain alk-2-enes takes place approximately equally at both carbon atoms linked by the double bond [80].

The radical additionof aldehydes to norbornene and camphene takes place stereoselectively with formation of ketones having the *exo*- and *endo*-configurations respectively [81,82]. When acyl radicals react with $\alpha\beta$-unsaturated acids, their esters, and nitriles, the β-carbon atom of the above compounds is also attacked preferentially. The reaction of aliphatic aldehydes with asymmetric dichlorodifluoroethylene gives only one isomer [83]:

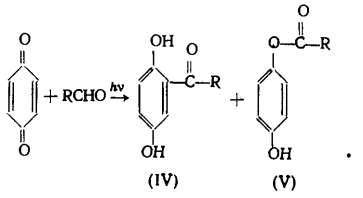
Although the reactivities of acyl radicals with respect to different types of double bond have not been estimated quantitatively, it has been shown in many cases that they add most readily to >C=C< or >C=O bonds with a reduced electron density. The radical addition of aldehydes to $\alpha\beta$-unsaturated carbonyl compounds and nitriles, perfluoro-olefins, and hexafluoroacetone takes place with a high yield and without the formation of an appreciable amount of telomers. According to Walling's hypothesis [84], the nucleophilic properties of acyl radicals are due to the effect of their electron-donating properties in the transition state in stages involving addition and chain transfer:



The role of polar factors in the attack by acyl radicals on multiple bonds is shown most strikingly in the photoinitiated reaction of aldehydes with quinones. When a solution of 1,4-benzoquinone in acetaldehyde is illuminated, hydroquinone (15%), acetylhydroquinone (67%), and an insignificant amount (0.6%) of *p*-hydroxyphenyl acetate are obtained [85]. The mechanism of the formation of acetylhydroquinone may be as follows:

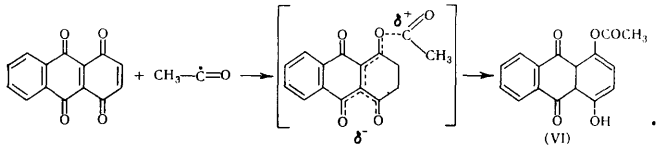


The products of the addition of benzaldehyde to benzoquinone contain benzoylhydroquinone (49%) and hydroquinone monobenzoate (15%), i.e. benzoyl radicals add not only to the carbon–carbon double bond but also attack to an appreciable extent the carbonyl group of the quinone [86]. The lower selectivity of the addition of benzaldehyde compared with acetaldehyde is probably associated with the fact that C_6H_5–Ċ=O is less nucleophilic than CH_3–Ċ=O owing to the conjugation of the unpaired electron with the benzene ring. The ratio of the products of the addition of substituted benzaldehydes to the >C=C< and >C=O bonds of benzoquinone depends greatly on the nature of the substituent:



The (V) : (IV) ratio increases as the R–Ċ=O radical becomes less nucleophilic, *p*-nitrobenzaldehyde and cinnamaldehyde adding exclusively to the carbonyl group of benzoquinone [86].

When a solution of quinizarinquinone in acetaldehyde is illuminated, only the monoester is obtained [86], which can be explained by the ease of formation of the transitional dipolar structure promoting attack on the oxygen atom of the carbonyl group by the acetyl radical:



In contrast to the reaction of acetaldehyde with unsubstituted *p*-benzoquinone, its addition to chloranil takes place almost exclusively at the carbonyl group [87], owing to steric hindrance in the attack on the C=C bond of chloranil.

The reactivities of chloroperfluoro-olefins in the homolytic reaction with aldehydes decrease in the sequence $CFCl{=}CCl_2 > CF_2{=}CCl_2 > CFCl{=}CFCl$. [88]

The relative reactivities of cyclic olefins in their radical reaction with acetaldehydes initiated by γ-radiation have been determined [89]: cyclo-octene > cyclopentene > cycloheptene > cyclohexene.

2. ADDITION TO THE CARBON–CARBON DOUBLE BOND

In recent years the addition of aldehydes to olefins has come to be very widely used, since it permits the ready synthesis of a wide variety of organic compounds containing the keto-group [18,90,91]. It is usually initiated by organic peroxides, ultraviolet light, or γ-radiation. It has been shown recently that oxygen and variable-valence metal salts can also be employed as initiators. Each of the above methods of initiation has its characteristics, which have a specific effect on the process. Therefore the examples of the addition of R–Ċ=O to the carbon–carbon double bond will be classified on the basis of the methods of initiation of the reaction.

a. Reactions Initiated by Peroxides

The addition of aldehydes to olefins is usually initiated by benzoyl and acetyl peroxides, which undergo thermal decomposition at 80–100°C. It is undesirable to carry out the reaction above 100°C since decarbonylation of acyl radicals begins to play an important role under these conditions (Section IV). In order to suppress the telomerisation side reaction, a three–five-fold excess of the aldehyde is employed.

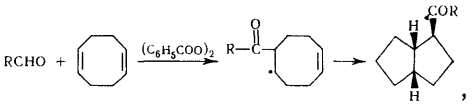
The free-radical addition of aldehydes to ethylene [92], alk-1-enes [1,32,77,93–95], α-pinene [97], β-pinene [77,97], camphene [81,97], norbornene [81,82], (+)-limonene [97], cyclohexene [93], crotonic [98] and substituted acrylic [99] acids and their esters [98,100] and nitriles [99,101], the nitrile of cinnamic acid [98,102], the esters of maleic [98,100,103–105], fumaric [103], itaconic [103], aconitic [108], and undeconoic [100,106–108] acids, αβ-unsaturated ketones [109,110], allyl acetate [111,112], and other esters of allyl alcohols [112,113], allyl ethers [112], acetals of acrolein [112,114], dichlorodifluoroethylenes [83], perfluoro-olefins [115,116], and unsaturated silicon-containing compounds [117–119] has been described.

The radical addition of butyraldehyde to 3,3-diphenylbut-1-ene is accompanied by a rearrangement with migration of the phenyl group [120]:

$$R\dot{C}{=}O + CH_3C(C_6H_5)_2CH{=}CH_2 \longrightarrow$$

$$CH_3C(C_6H_5)_2\dot{C}HCH_2COR \xrightarrow{O} CH_3\dot{C}(C_6H_5)CH(C_6H_5)CH_2COR$$

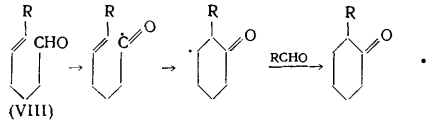
In the presence of benzoyl peroxide a bicyclic ketone is formed from aliphatic aldehydes and *cis-cis*-cyclo-octa-1,5-diene by an intramolecular interaction in the intermediate cycloalkyl radical with the second double bond [121]:



where R = CH_3 or C_3H_7.

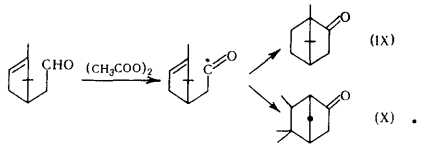
According to patent data, acetaldehyde adds to hexa-1,5-diene [93] and isoprene [122] (in both cases to one double bond).

The acyl radicals generated from unsaturated aldehydes of type (VIII) add intramolecularly to the double bond, forming a six-membered cyclic ketone (yield 40 to 50%):[123]



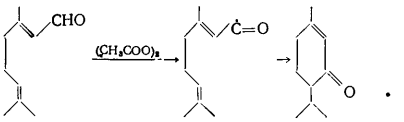
(VIII)

The free-radical cyclisation of α-campholenic aldehyde [124] takes place in two ways:



The reaction products consist of a mixture of 95% of camphor (IX) and 5% of dihydrocamphenone (X).

Similar results were obtained in a study of the radical cyclisation of apocampholenic aldehyde, citronellal, and citral [125]. For the last aldehyde, the reaction is complicated by the simultaneously occurring thermal isomerisation processes, but on rapid decomposition of acetyl peroxide in citral an αβ-unsaturated cyclic ketone is the main product:

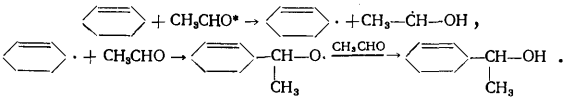


In contrast to the reactions described above, the interaction of 4-formylcyclohexene and *endo*-5-formylbicyclo-[2,2,2]oct-2-ene with di-t-butyl peroxide leads to dimeric products [126].

b. Reactions Initiated by Ultraviolet Light, γ-Radiation, and β-Radiation

The radiation and photochemical methods for the initiation of the reactions of aldehydes with olefins have been fairly well investigated. The addition of aldehydes to ethylene [127,128], propene [78,127], isobutene [127,129], alk-1-enes [79,80,127], alk-2-enes [80,127], cyclohexene [79,130,131], other cyclic mono-olefins [85], chlorotrifluoroethylenes [84,132], perfluorocyclobutene [116], and dimethyl esters of maleic and fumaric acids [133] has been achieved under the influence of γ-radiation.

In the reaction of aldehydes with olefins initiated by ultraviolet light the main process is often accompanied by side reactions, which as a rule play a significant role. Thus the photochemical addition of butyraldehyde to hept-1-ene proved to be relatively ineffective owing to the formation of a considerable amount of parabutyraldehyde [32]. The photochemical reaction of aliphatic aldehydes with cycloalkenes also does not take place unambiguously [130]: a considerable amount of acetoin was obtained together with cyclohexyl methyl ketone from a mixture of acetaldehyde and cyclohexane. According to the data of other workers [134], cyclohexylmethylmethanol is also formed in the above reaction, probably according to the following mechanism:



Illumination of an equimolar mixture of methylenecyclohexane and n-butyraldehyde gives four products, one of which is cyclohexylmethyl ethyl ketone [135].

A preparative method of synthesising γ-silylketones by the photochemical addition of aldehydes to vinylsilanes has been proposed [136]:

$$R_3SiCH{=}CH_2 + R'CHO \xrightarrow{h\nu} R_3SiCH_2CH_2\overset{O}{\overset{\|}{C}}R' ,$$

where R = CH_3, C_2H_5, or OC_2H_5 and R′ = CH_3, C_2H_5, iso-C_4H_9, etc. Benzaldehyde does not react with vinylsilanes [136].

Only one example of the initiation of the addition reaction by a beam of electrons has been described. When a mixture of acetaldehyde and cyclohexene was exposed to β-radiation, cyclohexyl methyl ketone and a considerable amount of side products—acetoin and 1-acetyl-2-(2′-cyclohexenyl)cyclohexene—were obtained [130].

c. Reactions Initiated by Oxygen and (or) Variable-valence Metal Salts

The effectiveness of oxygen as an initiator of the addition of aldehydes to a multiple bond depends on the structure of the olefin. The reaction takes place most readily with olefins having an electrophilic multiple bond. Thus the ester of butyrylsuccinic acid was obtained from butyraldehyde and dimethyl maleate in a quantitative yield [137]. The process is interesting because acyl radicals are generated directly in the reaction between the aldehyde and oxygen (the intermediate peroxides do not play a significant role in this case):

$$RCHO + O_2 \rightarrow R-\dot{C}=O + HO\dot{O} \text{ or}$$

$$2\,RCHO + O_2 \rightarrow 2R-\dot{C}=O + H_2O_2\ ,$$

$$R-\dot{C}=O + CH_3OOCCH=CHCOOCH_3 \xrightarrow{RCHO} H_3COOC\underset{\displaystyle COR}{\underset{|}{C}}HCH_2COOCH_3\ .$$

In contrast to this reaction, the oxygen-initiated addition of aldehydes to alk-1-enes leads to the formation of large amounts of acids [32]. However, the process selectivity increases sharply when acetic anhydride is introduced into the system [138,139]. Its role consists in the binding of the peracid, arising in the oxidation of the aldehyde, into a diacyl peroxide. The peroxide obtained *in situ* subsequently undergoes thermal decomposition into free radicals and thus initiates the reaction [139]

$$RCHO \xrightarrow{O_2} R-\overset{\displaystyle O}{\overset{\|}{C}}-OOH\ ,$$

$$R-\overset{\displaystyle O}{\overset{\|}{C}}-OOH + (CH_3CO)_2O \rightarrow R-\overset{\displaystyle O}{\overset{\|}{C}}-O-O-\overset{\displaystyle O}{\overset{\|}{C}}-CH_3 + CH_3COOH$$

$$\downarrow$$

$$R\cdot + 2\,CO_2 + \cdot CH_3\ .$$

The products of the addition of aldehydes to olefins initiated by oxygen in the presence of acetic anhydride are formed in yields up to 90% with a comparatively low degree of oxidation of the aldehyde to the acid (5–10%).

The use of oxygen in the presence of catalytic amounts of cobalt salts proved to be even more effective [96,137]. The method of oxidative catalytic initiation has been used to synthesise various ketones and their functional derivatives [96,137,140,141]. The preparation in a single stage of γ-acetylpropyl acetate [141]—one of the starting materials in the manufacture of vitamin B_1—may be of particular practical interest [141]:

$$CH_3CHO + CH_2=CHCH_2OOCCH_3 \xrightarrow[Co(OOCCH_3)_2]{O_2} CH_3\overset{\displaystyle O}{\overset{\|}{C}}CH_2CH_2CH_2OOCCH_3\ .$$

This and other similar reactions take place readily at room temperature.

The oxidation of aldehydes by oxygen is a complex chain process. In order to determine at which stages acyl radicals are generated, the structures of the intermediate peroxides [142] and the kinetics and mechanisms of their thermal [143] and catalytic [19] decomposition were investigated.

Variable-valence metal salts, for example manganese(III) triacetate, can initiate the addition of aldehydes to a multiple bond also in the absence of oxygen [27,28].

3. ADDITION TO A CARBON–CARBON TRIPLE BOND

Only a few examples of the addition of acyl radicals to a C≡C bond are known [133,144]. The reaction of acetaldehyde with acetylene in the presence of benzoyl peroxide takes place in steps according to the mechanism [144]:

$$CH_3CHO \rightarrow CH_3-\dot{C}=O \xrightarrow{CH\equiv CH} CH_3COCH=\dot{C}H \xrightarrow{CH_3CHO} CH_3COCH=CH_2 \xrightarrow{CH_3\dot{C}=O} \rightarrow$$

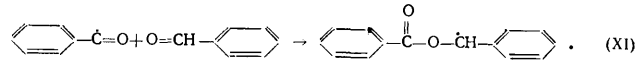
$$\rightarrow CH_3CO\dot{C}HCH_2COCH_3 \xrightarrow{CH_3CHO} CH_3COCH_2CH_2COCH_3\ .$$

γ-Diketones are formed also as a result of the radical addition of aldehydes to butylacetylene [144] and acetylenedicarboxylic acid [133].

4. ADDITION TO A $\rangle C=O$ BOND

Addition to a carbonyl group is less typical for acyl radicals than addition to a carbon–carbon double bond. On the basis of the available data, it is impossible to arrive at any general conclusions concerning the factors which determine the capacity of acyl radicals to attack the $\rangle C=O$ group in each specific case. The activity of the $R-\dot{C}=O$ radicals depends most on the nature of R and the structure of the carbonyl compound (see above).

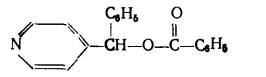
When organic peroxides are decomposed in benzaldehyde, the intermediate benzoyl radicals readily add to the carbonyl group of the aldehyde [145,146]:



(XI)

The radicals (XI) subsequently recombine. A similar reaction occurs also with *o*-methylbenzoyl radicals generated from *o*-methylbenzaldehyde [147].

The interaction of benzaldehyde with a peroxide in the presence of pyridine yields compound (XII), which is formally a product of the addition of radical (XI) to pyridine [148]:



(XII)

The decomposition of di-t-butyl peroxide in 2,3-dimethyl-3-phenylbutanal gives preferentially an ester owing to the addition of an acyl radical to the carbonyl group of the aldehyde with subsequent chain transfer [149]:

$$R-\dot{C}=O + RCHO \rightarrow RCOO-\dot{C}H-R \xrightarrow{RCHO} RCOOCH_2R\ .$$

The free-radical addition of benzaldehyde and aliphatic aldehydes to hexafluoroacetone and chlorofluoro-derivatives of acetone takes place very readily [150]:

$$RCHO \xrightarrow{\text{initiator}} R-\dot{C}=O$$

$$R-\dot{C}=O + O=\overset{\displaystyle CX_3}{\overset{|}{C}}-\underset{\displaystyle CX_3}{\underset{|}{}} \rightarrow RCO-\overset{\displaystyle O}{\overset{\|}{C}}-\overset{\displaystyle CX_3}{\overset{|}{C}}\cdot \xrightarrow{RCHO} RCO-\overset{\displaystyle O}{\overset{\|}{C}}-\overset{\displaystyle CX_3}{\overset{|}{C}}H\ ,$$

$$\qquad\qquad\qquad

of tributyltin hydride was proposed recently. The reaction takes place at room temperature via a chain mechanism:

$$RCOCl \xrightarrow{Bu_3SnH} R-\dot{C}=O\,,$$

$$R-\dot{C}=O + R'R''C=O \rightarrow RCOO-\dot{C}R'-R''\,,$$

$$RCOO-\dot{C}R'-R'' + Bu_3SnH \rightarrow RCOOCHR'R'' + Bu_3Sn\cdot\,,$$

$$Bu_3Sn\cdot + RCOCl \rightarrow Bu_3SnCl + R-\dot{C}=O \quad \text{etc.}\,.$$

The relative reactivities of various aldehydes and ketones with respect to the propionyl radical have been determined. It was found that n-heptanal is more reactive than benzaldehyde and the rate of addition of $CH_3CH_2-\dot{C}=O$ to cyclohexanone is about 20 times faster than the rate of addition of cyclopentanone [151].

The relative reactivities of substituted benzaldehydes in the above reaction are correlated with the σ^+ constants [151]. Electron-accepting substituents accelerate and electron-donating substituents retard the reaction (ρ = 0.43), which is consistent with the hypothesis that acyl radicals have nucleophilic properties.

An ester can be synthesised also by the direct interaction of an acid chloride or bromide with a substituted tin hydride [151,153]. Benzyl benzoate was obtained by this method in 87% yield from benzoyl chloride and triphenyltin hydride at room temperature in the absence of a solvent [153]:

$$2\,C_6H_5COCl + 2\,(C_6H_5)_3SnH \rightarrow C_6H_5COOCH_2C_6H_5 + 2\,(C_6H_5)_3SnCl\,.$$

It has been suggested that in this case an aldehyde formed as an intermediate in the reduction of the acid chloride is acylated [151]. This explanation is consistent with the finding that an aldehyde is present in the reaction product and the aldehyde : ester ratio varies from 9 to 0.25, depending on the nature of the reactants and the experimental conditions [151]. The ester is probably formed by the radical-chain mechanism described above, since the reaction is sensitive to inhibitors and is accelerated by azobisisobutyronitrile [153].

Esters of enediols have been synthesised by the reaction of perfluoroacyl chlorides with nickel carbonyl in benzonitrile:

$$R_FCOCl \xrightarrow{Ni(CO)_4} 2\,R_F-\dot{C}=O \rightarrow R_F-\overset{O}{\overset{\|}{C}}-\overset{O}{\overset{\|}{C}}-R_F;$$

$$R_F-\overset{O}{\overset{\|}{C}}-\overset{O}{\overset{\|}{C}}-R_F + R_F-\dot{C}=O \rightarrow R_F\overset{O}{\overset{\|}{C}}O-\overset{R_F}{\overset{|}{C}}=\overset{R_F}{\overset{|}{C}}-O\cdot \xrightarrow{R_F-\dot{C}=O} R_F\overset{O}{\overset{\|}{C}}O\overset{R_F}{\overset{|}{C}}=\overset{R_F}{\overset{|}{C}}\overset{O}{\overset{\|}{C}}O-R_F.$$

The addition of an acyl radical to the carbonyl group probably takes place as one of the stages in the original method for the preparation of substituted propiolactones by the condensation of aldehydes with keten under the influence of benzoyl peroxide [154]:

$$R-\dot{C}=O + CH_2=C=O \rightarrow \overset{R-C=O}{\overset{|}{CH_2}}-\dot{C}=O \rightarrow \overset{\dot{R}-C-O}{\overset{|}{CH_2}}-C=O \xrightarrow{RCHO} \overset{R-CH-O}{\overset{|}{CH_2}}-C=O.$$

9-Benzoyloxy-10-hydroxyphenanthrene was obtained by a photochemical reaction of benzaldehyde with phenanthrenequinone [155]:

$$C_{14}H_8\langle{}^{O}_{O} \xrightarrow{h\nu} C_{14}H_8\langle{}^{O\cdot}_{O\cdot}\,,$$

$$C_{14}H_8\langle{}^{O\cdot}_{O\cdot} + C_6H_5CHO \rightarrow C_{14}H_8\langle{}^{OH}_{O\cdot} + C_6H_5-\dot{C}=O\,,$$

$$C_6H_5\dot{C}=O + C_{14}H_8\langle{}^{O}_{O} \rightarrow C_{14}H_8\langle{}^{O\cdot}_{OCOC_6H_5} \xrightarrow{C_6H_5CHO} C_{14}H_8\langle{}^{OH}_{OCOC_6H_5}\,.$$

5. Addition to N=O and N=N Bonds

The addition of acyl radicals to N=O and N=N bonds has been much less investigated than the addition to C=C and C=O bonds.

The reaction of acyl radicals with nitroso-compounds [156] is of interest as a convenient method for the synthesis of stable nitroxy-radicals:

$$R-\dot{C}=O + O=N-R' \rightarrow R-\overset{O}{\overset{\|}{C}}-\overset{R'}{\overset{|}{N}}-O\,.$$

t-Butyl peroxide and also nitrosoalkanes, which readily decompose into NO and alkyl radicals under the influence of heat or ultraviolet light, were used to generate $R-\dot{C}=O$ radicals in this process. Stable acylnitroxy-radicals were obtained also by another method [156]—by decomposing alkyl nitrites in hydrocarbons. The aldehydes and nitroso-compounds formed as intermediates react further with one another as described above.

A radical-chain addition of aldehydes to certain azo-compounds (azobenzene, azodibenzoyl, and azodicarboxylic acid esters) has been described:

$$RCHO + R'-N=N-R' \rightarrow R-\overset{O}{\overset{\|}{C}}-\overset{R'}{\overset{|}{N}}-NH-R'\,,$$

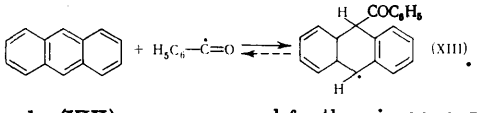
where R = C_6H_5CO, CH_3CO, etc. and R′ = C_6H_5, C_6H_5CO, or R″OCO. Di-t-butyl peroxide [157], azobisisobutyronitrile [158], and atmospheric oxygen [159,160] were used as initiators. The reaction is of preparative interest for the synthesis of acylated hydrazine derivatives (yields up to 90%).

In its thermal and photolytic decomposition in organic solvents, azodibenzoyl undergoes radical benzoylation [79], which leads to tribenzoylhydrazine and diphenyloxadiazole. The same compounds were isolated in the oxidation of benzoylhydrazine by silver oxide [76]. Both reactions probably have similar mechanisms. It has been suggested [76] that in the latter case benzoyl radicals add to the benzoylhydrazine formed.

Benzoyl radicals can also attack the azo-group of azobisisobutyronitrile [157].

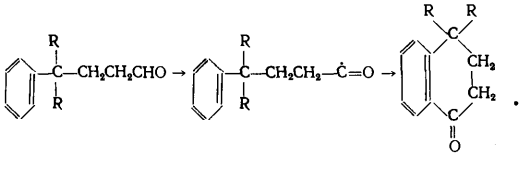
6. ADDITION TO AROMATIC SYSTEMS

Very little is still known about the addition of acyl radicals to aromatic systems. The addition of the benzoyl radical to anthracene has been investigated [161]. The first stage of this process is probably reversible:



The radicals (XIII) are consumed further in several ways: they recombine with one another or with $C_6H_5-\dot{C}=O$; also they lose hydrogen atoms and are converted into benzoylanthracene.

When a peroxide is allowed to react with aliphatic aldehydes containing a phenyl substituent in the γ-position, the benzene ring undergoes intramolecular acylation [149]:



The oxidation of benzoylhydrazine by silver(II) oxide in the presence of ferrocene leads to benzoylferrocene. It is most likely that ferrocene is acylated by a free-radical mechanism [161,162].

The possibility of the free-radical acylation of heterocyclic bases (pyridine, acridine, isoquinoline, etc.) by aldehydes in an acid aqueous medium has been demonstrated [163]. The reaction is initiated by redox systems. Owing to the nucleophilic properties of acyl radicals, they readily attack the electrophilic centres in the rings of the above bases.

IV. DECARBONYLATION

Decarbonylation is the reverse process in relation to the addition of carbon monoxide to alkyl radicals described in Section II:

$$R-\dot{C}=O \rightleftarrows R' + CO.$$

At a pressure close to atmospheric R–Ċ=O decomposes almost irreversibly and therefore such decomposition is often used as a method for the generation of free alkyl radicals [26]. Acyl radicals are usually obtained from aldehydes. The decarbonylation of aldehydes is a chain process:

$$RCHO + Z\cdot \rightarrow R-\dot{C}=O+ZH,$$

$$R-\dot{C}=O \rightarrow R' + CO,$$

$$RCHO + R\cdot \rightarrow RH + R-\dot{C}=O \text{ etc.}$$

The ease of removal of CO from R–Ċ=O depends significantly on the nature of R· (Table 2). It has been firmly established in a number of cases that the decomposition of R–Ċ=O takes place more readily the more stable is R. [16,126,164,165] However, this rule is valid only for aliphatic and alicyclic acyl radicals (benzoyl radicals do not show any capacity for the removal of CO) [4,16,58].

Table 2. Relative reactivities of certain aldehydes in the decarbonylation reaction [164].

R in RCHO	Reactivity	R in RCHO	Reactivity
$CH_3CH_2CH_2$	1	1-norbornyl	0.6
$(CH_3)_2CH$	8.3	1-bicyclo[2,2,2]octyl	110
$(CH_3)_3C$	90	1-adamantyl	175

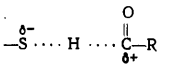
The rate of decarbonylation of the first three aldehydes depends linearly on the R–H bond energy in the hydrocarbon formed. The C–H bond energies in norbornane, bicyclo[2,2,2]octane, and adamantane have been estimated by extrapolation on the basis of the above relation [164].

The stability of the intermediate alkyl radical evidently plays a decisive role also in the decarbonylation of cyclopropanealdehyde [165] (Table 3).

The decarbonylation of the optically active bicyclo[2,2,2]octanealdehyde gave a racemic mixture of bicyclooctanes [166].

In a series of bicyclic aldehydes with similar structures, *endo*-bicyclo[2,2,2]oct-2-ene-5-aldehyde is decarbonylated most readily owing to the formation, following the removal of CO, of a stable non-classical alkyl radical [126]. The reactivities of alicyclic [167,168] and bicyclic [126] aldehydes are in many cases significantly influenced by steric factors.

The dependence of the decarbonylation chain length on the proportions of the aldehyde and di-t-butyl peroxide [169], usually employed as an initiator, has been investigated. In the presence of small amounts of mercaptans the chain length increases appreciably [170–172]. The explanation is that the formation of the transition state S...H...C requires a lower activation energy than the formation of the transition state C...H...C, owing to the ease of formation of the acylated complex



Thus mercaptans play the role of chain-transfer agents in the decarbonylation of aldehydes.

Table 3.

Aldehyde			
Yield of CO, %	traces	50	90

The decomposition of acyl radicals is widely used for the investigation of various reactions of the radicals produced in this process. The following types of rearrangement of alkyl radicals have been observed in the decarbonylation of aldehydes: 1,2-C,C- [166,173–182] and 1,3-C,C-migration [149] of aryl groups, 1,2-C,C-migration of the acetoxy-group [183], allyl rearrangement [184], ring opening [182], and ring expansion [185,186]. Attempts have also been made to observe the 1,2-C,C-migration of methyl [187], benzyl [188], and phenoxy-groups [178] and 1,2-S,C-migration of the phenyl group [189], but these were unsuccessful.

The alkyl radicals formed in the decarbonylation of aldehydes are not only capable of removing hydrogen atoms but some can also add to the aldehyde groups:

$$RCHO \xrightarrow{-H\cdot} R-\dot{C}=O \xrightarrow{-CO} R,$$

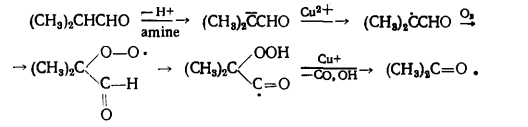
$$R\cdot + RCHO \rightarrow R_2CH-O,$$

$$R_2CH-O\cdot + RCHO \rightarrow R_2CHOH + R-\dot{C}=O \text{ etc.}$$

The decomposition of di-t-butyl peroxide in n-butyraldehyde yields propane and dipropylmethanol in proportions of about 10 : 1. [190]

In the decarbonylation of aldehydes in the presence of olefins (alk-1-enes [191], chloropolyfluoroethylenes [83], and diethylmaleate [192]), the addition of alkyl radicals to the multiple bond was observed.

A convenient method has been proposed for the synthesis of ketones [193] by the oxidation of α-branched aldehydes with oxygen in a polar solvent (dimethylformamide, t-butyl alcohol). The ketone is formed as a result of the decomposition of the intermediate α-hydroperoxyacyl radical:

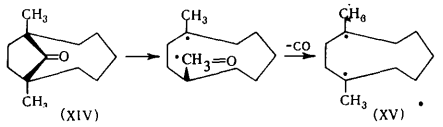


The reaction is catalysed by copper salts and tertiary amines {amines with a sterically hindered electron pair

at the nitrogen atom, for example 1,4-diazabicyclo-[2,2,2]octane, are the most effective}.

The mechanism of the decarbonylation reactions of aldehydes and ketones initiated by ultraviolet radiation is frequently not susceptible to unambiguous interpretation, since the homolytic dissociation of the C–C bond and the removal of CO can occur as two consecutive stages or in a single photochemical step without the intermediate formation of an acyl radical. However, since the decarbonylation processes initiated by peroxides and ultraviolet radiation have many features in common, in many cases preference is given to the mechanism involving the R–Ċ=O radical. This hypothesis is valid at least for photochemical reactions of acyclic and simple cyclic ketones.

Since photolytic reactions in solution are usually carried out under mild conditions, only the least stable acyl radicals readily undergo photochemical decarbonylation. For example, acyl radicals with a quaternary α-carbon atom readily lose carbon monoxide [194,195]. Photolysis of the bicyclic ketone (XIV) [194] leads to three isomeric olefins as a result of an intramolecular disproportionation of the intermediate biradical (XV):



(XIV) (XV)

In the photolysis of dibenzyl ketone [196], carbon monoxide is split off and the benzyl radicals recombine quantitatively:

$$C_6H_5CH_2\overset{O}{\overset{\|}{C}}CH_2C_6H_5 \xrightarrow{h\nu} 2C_6H_5CH_2\cdot + CO,$$
$$2\,C_6H_5CH_2\cdot \rightarrow C_6H_5CH_2CH_2C_6H_5.$$

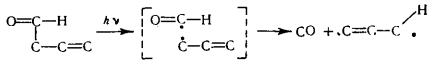
The free-radical mechanism of this reaction is confirmed by the fact that, when a mixture of dibenzyl ketone and 1,1,3,3-tetraphenylacetone is irradiated, two symmetrical and one asymmetric hydrocarbon are formed as a result of the recombination of the corresponding arylalkyl radicals.

In contrast to acetone, which hardly undergoes photolysis in the liquid phase [40,197], monochloropentafluoroacetone decomposes under the influence of ultraviolet light with liberation of carbon monoxide [198]. This is evidence of the instability of the CF_3–Ċ=O and CF_2Cl–Ċ=O radicals.

The liquid-phase photolysis of aldehydes, particularly those branched at the α-carbon atom, also gives rise to the elimination of carbon monoxide. Photochemical decarbonylation is inhibited by hydroquinone, which is evidence of a chain mechanism of the process [199]. The primary step in the photochemical decomposition of unsaturated aldehydes with a quaternary α-carbon atom yields formyl and alkyl radicals. The latter remove a hydrogen atom from the solvent and H–Ċ=O undergoes further decomposition [200]:

$$RCHO \xrightarrow{h\nu} RCHO^* \rightarrow R\cdot + H\text{–}\dot{C}{=}O$$
$$\text{solvent} \rightarrow RH \qquad \rightarrow CO.$$

The mechanism of the decarbonylation of $\beta\gamma$-unsaturated aldehydes differs from that described above. Hydrogen transfer in such aldehydes takes place intramolecularly via a stage involving the formation of a radical pair or via a synchronous mechanism [200,201]:



In the photolysis of benzaldehyde a certain amount of carbon monoxide is given off; however, this is not due to the decomposition of C_6H_5–Ċ=O, but is probably a result of the decomposition of the intermediate keten [4].

The irradiation of *O*-alkyl and *S*-acyl xanthates with visible or ultraviolet light [58] also leads to the liberation of carbon monoxide, which is believed to be caused by the decomposition of acyl radicals:

$$R\text{–}\overset{O}{\overset{\|}{C}}\text{–}S\text{–}\overset{S}{\overset{\|}{C}}\text{–}OC_2H_5 \xrightarrow{h\nu} R\text{–}\overset{S}{\overset{\|}{\dot{C}}}{=}O + \cdot S\text{–}\overset{S}{\overset{\|}{C}}\text{–}OC_2H_5,$$
$$R\text{–}\overset{S}{\overset{\|}{\dot{C}}}{=}O \xrightarrow{-CO} R\cdot;\ R\cdot + \cdot S\text{–}\overset{S}{\overset{\|}{C}}\text{–}OC_2H_5 \rightarrow R\text{–}S\text{–}\overset{S}{\overset{\|}{C}}\text{–}OC_2H_5.$$

The reaction takes place smoothly when R = benzyl, s-alkyl, or t-alkyl, is more difficult with acyl xanthates where R is a primary alkyl, and does not occur in the photolysis of *S*-benzoyl xanthate.

Trimethylacetaldehyde undergoes a radical-chain decarbonylation in oxidation by manganese(III) acetate [27], as under the influence of peroxides or ultraviolet light. The intermediate t-butyl radicals remove hydrogen from the aldehyde and are also oxidised by the manganese(III) salt to isobutene:

$$(CH_3)_3CCHO \xrightarrow{Mn(OOCCH_3)_3} (CH_3)_3C\text{–}\dot{C}{=}O \rightarrow (CH_3)_3C\cdot + CO$$
$$\text{aldehyde} \rightarrow (CH_3)_3CH \qquad Mn^{III} \rightarrow CH_2{=}C(CH_3)_2.$$

In the oxidation of triphenylacetaldehyde with chromic acid [202], the evolution of carbon monoxide was also observed:

$$(C_6H_5)_3CCHO + Cr^{IV} \rightarrow (C_6H_5)_3C\text{–}\dot{C}{=}O + Cr^{III} + H^+,$$
$$(C_6H_5)_3C\text{–}\dot{C}{=}O \xrightarrow[H_2O]{Cr^{IV}(Cr^{VI})} (C_6H_5)_3COH + CO.$$

The reaction products contain (apart from triphenylmethanol) triphenylacetic acid, which may be formed as a result of the oxidation of the intermediate acyl radical with electron transfer or as a result of two-electron oxidation of the initial aldehyde. A more selective decarbonylation of $(C_6H_5)_3CCHO$ was observed when chromyl acetate or cerium(IV) salts were used as oxidising agents (in these cases the reaction products did not contain triphenylacetic acid) [202].

The decarbonylation of β-phylisovaleraldehyde catalysed by palladium [203] results in the formation of only an insignificant amount of the neophyl rearrangement products of this aldehyde. The authors believe that the decarbonylation may have a radical mechanism, but, as a result of the fixation of the radicals on the surface of the catalyst, the migration of the phenyl group in the 2-methyl-2-phenylpropyl radical is difficult.

V. PHOTOCHEMICAL ACYL RADICAL MIGRATION PROCESSES

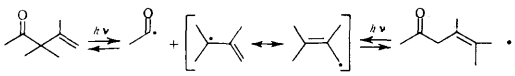
Many photochemical rearrangements of ketones, esters, and carboxylic acid amides involve the migration of acyl radicals. The rearrangements of ketones with

different structures (aliphatic, mono-, bi-, and polycyclic, $\beta\gamma$-unsaturated, etc.) have been thoroughly investigated.

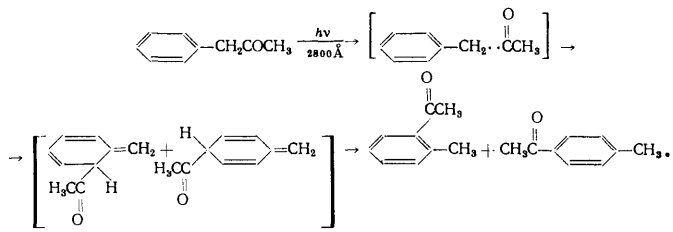
1. C,C-MIGRATION

a. Rearrangement of $\beta\gamma$-Unsaturated Acyclic Ketones

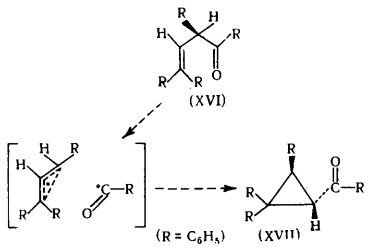
Kiefer and Carlson[204] observed the allyl rearrangement of 2,3,3-trimethylpent-1-en-4-one via a free-radical mechanism:



Irradiation of benzyl methyl ketone in t-butyl alcohol or n-hexane causes the formation of a mixture of *o*- and *p*-methylacetophenones[205]. The photolysis products also contain dibenzyl. The ratio of methylacetophenone and dibenzyl increases as the concentration of the ketone falls. The following mechanism has been proposed for this reaction:



When the ketone (XVI) is irradiated with ultraviolet light in benzene, the benzoyl group migrates with formation of the cyclopropane ring[206]. The reaction is stereospecific. However, cyclisation is not the main process in the photolysis of compound (XVI): it largely undergoes fragmentation to phenylallyl radicals, which then recombine, and benzoyl radicals, which probably behave as precursors of biphenyl. Compound (XVII) can be formally regarded as a product of the recombination of $C_6H_5-\dot{C}=O$ with the mesomeric cyclopropyl radical, but, in view of the stereospecificity of the process, the concerted mechanism involving the dissociation of compound (XVI) and the formation of a new bond must be regarded as more likely:

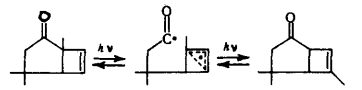


(XVI) (R = C_6H_5) (XVII)

b. Rearrangement of $\beta\gamma$-Unsaturated Cyclic Ketones

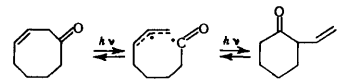
The allyl rearrangements of $\beta\gamma$-unsaturated cyclic ketones can take place with retention of the original number of carbon atoms in the ring (the position of the double bond or of substituents is altered) and with ring contraction or expansion. A characteristic feature of allyl rearrangements is their reversibility, i.e. the ratio of the isomeric ketones is independent of the isomer employed as the initial compound.

In 1960 Büchi and Burgess[207] described the rearrangement of a bicyclic $\beta\gamma$-unsaturated ketone, the mechanism of which can be represented as follows[208,209]:



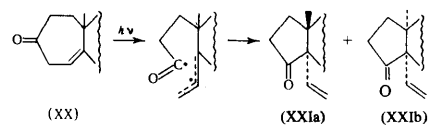
Subsequently a similar isomerisation was observed for other $\beta\gamma$-unsaturated bicyclic[208-210] and tricyclic[211] ketones.

One of the most typical examples of a rearrangement with a change in the number of carbon atoms in the ring is the conversion of cyclo-oct-3-en-1-one into 2-vinylcyclohexanone[212,213]:



(XVIII) (XIX)

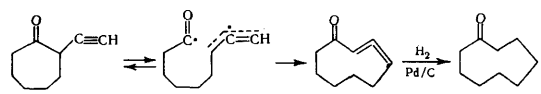
The ratio of compounds (XVIII) and (XIX) under the conditions of photoequilibrium is 7 : 40.[213] Ultraviolet irradiation of cyclodec-3-enone leads to a mixture of 2-vinylcyclo-octanone and the initial ketone in proportions of 2 : 5.[214] Similarly 2-isobutenylcyclopentanone was obtained from 2,2-dimethylcyclohepten-3-one[215]. A mixture of *cis*- and *trans*-isomers (XXI, a and b) was formed in the photolysis of the ketosteroid (XX), which is evidence of the intermediate formation of an acyl alkyl biradical[216]:



(XX) (XXIa) (XXIb)

Examples of the isomerisation of bicyclic ketones containing five-membered[217,218] and six-membered[210] rings to ketones with four-membered rings have been described.

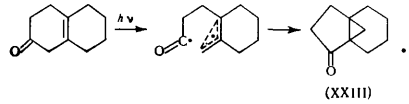
Acetylene—allene rearrangement. Carlson and Henton[219] described an interesting rearrangement of 2-ethnylcycloheptanone to a cyclic allene:



(XXII)

Compound (XXII) could not be isolated in a pure state, but its reduction gave a high yield of cyclononanone.

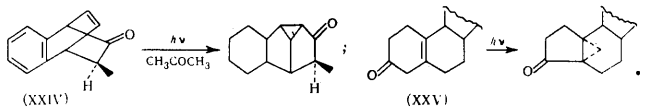
Rearrangements with formation and opening of rings are photochemical processes in which cyclopropane rings are mainly formed or cleaved. Ultraviolet irradiation of a solution of 2-oxo-1,2,3,4,5,6,7,8-octahydronaphthalene in t-butyl alcohol[220,221] gives the tricyclic ketone (XIII) in 60% yield:



(XXIII)

Cyclopropane hydrocarbons are obtained by the photolysis of six-membered $\beta\gamma$-unsaturated ketones only[220,221-224]. The solvent has a significant influence on the mode of photolysis. For example, when the ketone (XXIV)

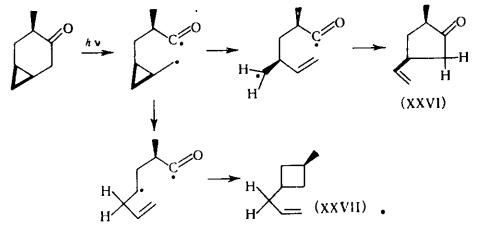
was irradiated in acetone, an isomeric ketone was obtained in 70% yield. In cyclohexanone solution only keten and naphthalene were obtained from compound (XXIV) [223]:



(XXIV) (XXV)

The photolysis of the $\beta\gamma$-unsaturated 3-oxosteroid (XXV), like that of compound (XXIV), is stereospecific and irreversible [221,222]. This is probably evidence that the dissociation of the C–C bond and the migration of the acyl group take place synchronously—a hypothesis which is consistent with conformation (XXV).

Irradiation of (–)-*cis*-4-caranone gives rise to C,C-migration of the acyl group and the opening of the cyclopropane ring [225]:

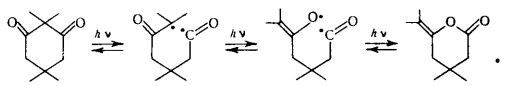


(XXVI) (XXVII)

The reaction is irreversible with (XXVI) : (XXVII) ≃ 3 : 1.

2. C,O-MIGRATION

Photolysis of compound (XXVIII) leads to the establishment in the solution of a photoequilibrium between compounds (XXVIII) and (XXIX) [229] with (XXIX) : (XXVIII) = 92 : 3.6:

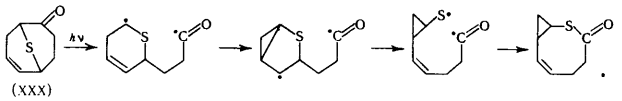


(XXVIII) (XXIX)

The rearrangement of other cyclic ketones containing two [227] or three [228] carbonyl groups in the β-positions relative to one another takes place similarly.

3. C,S-MIGRATION

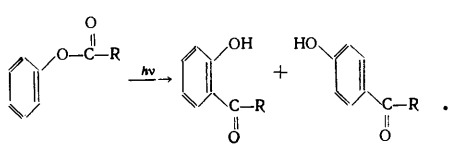
The recently described rearrangement of the thiaketone (XXX) belongs to this type of photochemical reactions [229]. One of the most likely mechanisms is



(XXX)

4. O,C-MIGRATION

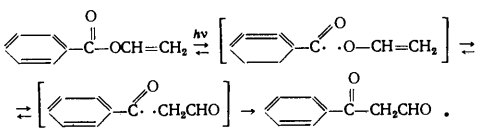
O,C-Migration of acyl groups has been observed in the photolysis of esters. The Fries photochemical rearrangement is best known:



Kobsa [230] proposed a free-radical mechanism for this reaction, according to which the bond between the carbonyl group and the ester oxygen atom is dissociated initially. The radical mechanism of the photochemical rearrangement of aryl esters has been fairly widely adopted, mainly because the reaction mixture always contains a phenol together with alkyl hydroxyphenyl ketones.

However, it has recently been shown [231] that the quantum yield of ketones is independent of the solvent, while the yield of the phenol decreases sharply as the viscosity of the medium increases. Consequently the formation of ketones takes place preferentially via a molecular mechanism and that of phenols via a free-radical mechanism.

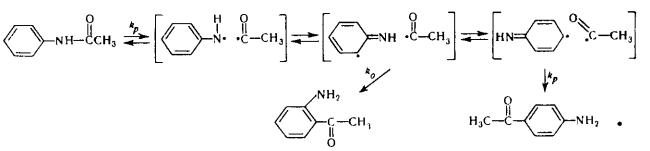
Ultraviolet irradiation of vinyl benzoate initiates the rearrangement according to the following probable mechanism [232]:



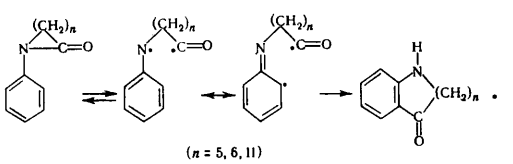
The intermediate formation of benzoyl radicals is also postulated in the photolysis of 1-cyclohexenyl benzoates [233].

5. N,C-MIGRATION

On ultraviolet irradiation, *N*-acylanilides isomerise in a manner similar to the rearrangement of aryl esters described above, with formation of a mixture of *o*- and *p*-acetanilides [234]. Shizuka [235] proposed a radical mechanism for this reaction:



The ratios of the rate constants for the recombination of the radicals $k_N : k_o : k_p = 1 : 0.35 : 0.6$ were calculated on the basis of the quantum yields of *o*- and *p*-acetanilides. The ratios are satisfactorily correlated with the "additional" π-electron density at the nitrogen atom and the carbon atoms of the benzene ring in the *o*- and *p*-positions: $\rho_N : \rho_o : \rho_p = 1 : 0.46 : 0.66$ (calculated ratios). The presence of an alkyl substituent at the nitrogen atom in acetanilide does not prevent the migration of the acyl group to the ring [236]. Consideration of the Fischer reaction [236] led to the development of a preparative synthesis of macrocyclic heterocycles:



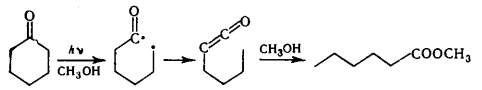
(n = 5, 6, 11)

VI. PHOTO-INITIATED DISPROPORTIONATION REACTIONS

1. REACTIONS WITH FORMATION OF UNSATURATED ALDEHYDES AND KETENS

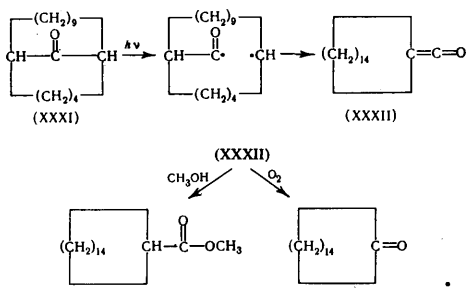
Many examples of the formation of unsaturated aldehydes in the photolysis of ketones in solution involving free radicals disproportionating in a solvent cage (Section II) are known. The reaction has been thoroughly described in monographs [29,34,35] and therefore will not be considered in detail in the present review.

The disproportionation of acylalkyl biradicals generated in the photolysis of cyclic ketones can result in the formation of a keten in addition to the unsaturated aldehyde. If the reaction is performed in the presence of water, an alcohol, or an amine, the keten is converted into an acid, an ester, or an amide [48,237]. For example, the main product of the photolysis of cyclohexanone in methanol is methyl caproate [237]:



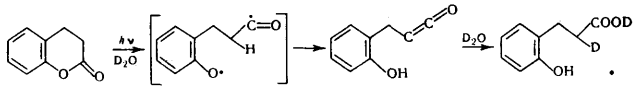
In contrast to cyclohexanone, in the photolysis of an alcoholic solution of cyclopentanone [237] only an insignificant amount of methyl valerate is obtained: in this case the second type of disproportionation of the acylalkyl biradical, leading to an unsaturated aldehyde, plays the main role.

Ketens are also formed when polycyclic ketones are irradiated with ultraviolet light [48,49,194,238-241]. Depending on the conditions, macrocyclic esters or ketones can be synthesised from bicyclic ketones of type (XXXI):



An ester is formed when the reaction is carried out in a carbon tetrachloride–methanol mixture and ketones are formed in carbon tetrachloride in the presence of oxygen [241].

An interesting rearrangement with ring opening was observed [231] when a cyclic lactone was irradiated in an aqueous dioxan solution:

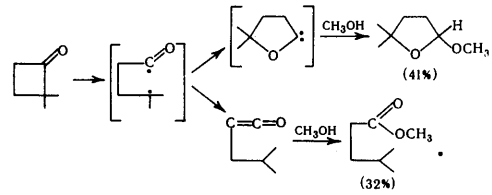


The intermediate formation of a keten was established by an isotope method [231-252].

2. REACTIONS WITH FORMATION OF OXACARBENES

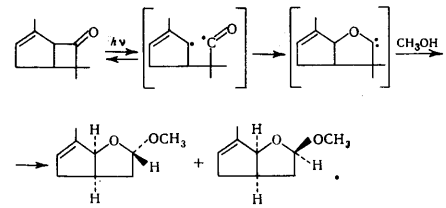
In a number of studies published in recent years [237,243-252] a new type of photochemical decomposition of cyclic ketones via a stage involving the generation of α-oxacarbenes was reported. The reaction takes place as a rule in the photolysis of alcoholic solutions of strained cyclic ketones [237]:

cyclobutanones [244,245,248,250], cyclobutanediones [246,247], camphor [252], and cyclocamphanone [243].



The photochemical reaction of *o*-phthalaldehyde probably also involves a carbene [251]. An oxacarbene is readily formed in the photolysis of aliphatic [249] and six-membered cyclic silaketones [237] in which the silicon atom is linked to the carbonyl group.

The involvement of acylalkyl biradicals in the formation of the oxacarbene was proved by Erman [253] by analysing the products of the photolysis of a bicyclic ketone:

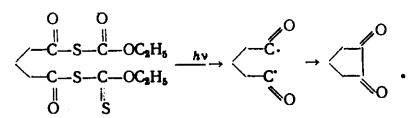


Identification in the reaction product of two epimeric bicyclic acetals is evidence that the dissociation of the carbon–carbon bond adjoining the carbonyl group precedes the formation of the oxacarbene.

Examples are known in which photolysis reactions of ketones involving a carbene take place stereospecifically [244,248,249]. In such cases the C–C bond probably dissociates via a concerted mechanism with formation of a carbene.

VII. OTHER REACTIONS

Acyl radicals are capable of dimerising to α-diketones. This reaction has been observed on ultraviolet irradiation of acetaldehyde [1], propionaldehyde [254], and isovaleraldehyde [254], on oxidation of acetaldehyde with oxygen [255] and manganese triacetate [27], on reaction of perfluoroacyl chlorides with nickel carbonyl [66], and on radiolysis of acetone [42]. An interesting example of an intramolecular recombination of acyl radicals as a result of the photochemical decomposition of a *cis*-*S*-acyl xanthate has been described [58]:



In the presence of hydrogen donors acyl radicals are converted into aldehydes [54,63,65].

When acyl radicals react with sulphuryl chloride [10-12,256], t-butyl hypochlorite [6-8], α-acyl-n-alkyl hypochlorites [74], carbon tetrachloride [16,63,69,173], bromotrichloromethane [13,14], and *N*-bromosuccinimide [14], they abstract a halogen atom forming acid halides. The preparation of acyl halides

from aldehydes using the above halogenating agents has a chain mechanism:

$$\left.\begin{matrix}\mathrm{RCHO}\\ \mathrm{XCl}\end{matrix}\right\} \xrightarrow[\text{(peroxide)}]{\Delta} \mathrm{R{-}\dot{C}{=}O} + \mathrm{X},$$

$$\mathrm{RCHO} + \mathrm{X}\cdot \rightarrow \mathrm{R{-}\dot{C}{=}O} + \mathrm{HX},$$

$$\mathrm{R{-}\dot{C}{=}O} + \mathrm{XCl} \rightarrow \mathrm{RCOCl} + \mathrm{X},$$

where $X\cdot = t\text{-}BuO\cdot$, $\cdot SO_2Cl$, $\cdot CCl_3$, etc.

Acyl radicals readily combine with oxygen and become converted into peroxy-radicals [257]:

$$\mathrm{R{-}\dot{C}{=}O} + \mathrm{O_2} \rightarrow \mathrm{R{-}\overset{\overset{\mathrm{O}}{\|}}{\mathrm{C}}{-}OO}\cdot$$

This reaction constitutes the basis of the industrial syntheses of acetic acid and acetic anhydride by the oxidation of acetaldehyde [255].

When di-t-butyl peroxide is decomposed in alcoholic or phenolic solutions of aldehydes in the presence of catalytic amounts (about 10^{-3} M) of variable-valence metal salts (Cu, Co, Fe, Mn), alkyl or phenyl benzoates are formed [258]. The formation of esters results from the one-electron oxidation of acyl radicals by the catalyst in the oxide form:

$$(\mathrm{CH_3})_3\mathrm{COC}(\mathrm{CH_3})_3 + \mathrm{Cu^I} \rightarrow (\mathrm{CH_3})_3\mathrm{COCu^{II}} + (\mathrm{CH_3})_3\mathrm{C{-}O},$$

$$(\mathrm{CH_3})_3\mathrm{C{-}O}\cdot + \mathrm{RCHO} \rightarrow (\mathrm{CH_3})_3\mathrm{COH} + \mathrm{R{-}\dot{C}{=}O},$$

$$(\mathrm{CH_3})_3\mathrm{COCu^{II}} + \mathrm{R'OH} \rightleftarrows \mathrm{R'OCu^{II}} + (\mathrm{CH_3})_3\mathrm{COH},$$

$$\mathrm{R{-}\dot{C}{=}O} + \mathrm{Cu^{II}OR'} \rightarrow \mathrm{RCOOR'} + \mathrm{Cu^I}.$$

Acyl radicals give up an electron most readily in reactions with copper(II) and cobalt(III) salts.

Decomposition of aqueous hydrogen peroxide in the presence of carbon monoxide, iron salts, and various organic compounds leads to the formation of carboxylic acids [70]. It has been suggested that [70] the intermediate acyl radicals are converted in this process into acylium cations [70].

The oxidation of $CH_3{-}\dot{C}{=}O$ with electron transfer is postulated as one of the stages in the decarboxylation of pyruvic acid by manganese(III) [259] and cobalt(III) [260] ions.

One-electron oxidation of acyl radicals probably occurs also in the following processes catalysed by copper salts: decomposition of t-butyl perbenzoate in aldehydes [261,262], photolysis of diacetyl [263,264], radiolysis of acetone [265], and oxidation of aldehydes by Fenton's reagent [266].

Thus, owing to the simplicity of their preparation and the wide variety of their chemical properties, acyl radicals are finding increasing application in organic chemistry.

Structural Analysis of Natural Triglycerides

A.G.Vereshchagin

An account is given of modern views on the structural analysis of triglycerides of natural fats by transesterification, lipase hydrolysis, determination of stereoisomerism, and establishment of polymorphism in their crystals. The possibilities of the practical application of these methods in fat analysis are shown. A list of 172 references is included.

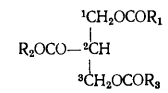
V. Polymorphism of triglycerides 945

I. INTRODUCTION

It was assumed for a long time that natural fats were mixtures of simple monacid triglycerides (I) in which the alkyl groups R were identical ($R_{(1)} = R_{(2)} = R_{(3)}$).



(I)

At the beginning of the twentieth century, however, mixed-acid triglycerides based on (I: $R_{(1)} \neq R_{(2)} \neq R_{(3)}$, $R_{(1)} \neq R_{(3)}$) were isolated from several fats. The problem of the structure of triglycerides arose. The hypothesis of a statistical distribution of acyl residues RCO in triglycerides, according to which the probability of formation of a particular individual triglyceride was determined solely by the molar concentration of its component fatty acids in the given fat and by the frequency of occurrence of these acids in the given triglyceride was soon abandoned, and the search for the laws governing the glyceride structure of natural fats has continued to the present time.

The present Review makes a systematic survey of the development of work on the positional distribution of acyl groups in triglycerides—from the original discovery by transesterification of the non-statistical character of the structure of natural fats to the establishment by lipase hydrolysis of the non-equivalence of the 1,3- and the 2-positions in the glycerides, and finally to the recent discovery of the stereospecificity of the structure of animal and plant triglycerides. The last section of the Review deals with the polymorphism of glycerides, which, in combination with their chemical synthesis (Section II, 3), is also used to establish the structure of individual triglycerides in natural fats.

II. ESTABLISHMENT BY TRANSESTERIFICATION OF THE NON-STATISTICAL DISTRIBUTION OF ACYL RESIDUES IN NATURAL TRIGLYCERIDES

1. Transesterification of Triglycerides

Transesterification is the free redistribution (randomisation) of acyl groups among glycerides under the influence of certain physical and chemical factors, as a consequence of which the structure of the glycerides becomes statistical instead of oriented. It is the oldest method in the structural chemistry of natural triglycerides, for the discovery of marked changes in melting point and other properties of fats after randomisation was the immediate reason for posing the problem of their structure. During actual transesterification the initial and final products are triglycerides: depending on whether the acyls migrate within a single glyceride or between different triglycerides, we can distinguish intramolecular and intermolecular transesterification. Glycerolysis—the transesterification of a fat with excess of glycerol—results in the appearance of a large quantity of mono- and di-glycerides. Transesterification is of great practical as well as theoretical value: the changes in polymorphism, melting point, texture, plastic range, and other properties of a fat accompanying randomisation and glycerolysis greatly influence its digestibility and its suitability for the manufacture of margarines, monoglyceride emulsifiers, and other technical products having specified properties [1-6].

Transesterification can be accomplished [6-31] by treating a fat free from moisture, free acids, and peroxides in several ways—(1) in the absence of a catalyst at 300°C, (2) with alkaline catalysts at 100–140°C with 0.03–0.3% of sodium methoxide, at 30°C with 0.6% of sodium methoxide for 1 h (for a 3 : 2 mixture of an oil and hexane), or at 20°C with 0.005% of lithium t-butoxide for 12–15 h (for a 1 : 10 mixture of a fat and dimethylformamide), (3) with naphthalene-2-sulphonic acid as catalyst, or (4) with tin and its salts or dihydroxide at 225°C [2,3,6,9,10]—after which the catalyst is neutralised, and the glycerides are purified [11]. The most effective catalyst is sodium methoxide, but at high temperatures complete randomisation of the composition cannot be obtained, though under milder conditions a purely statistical mixture of glycerides is produced [13]. A statistical mixture of triglycerides can also be obtained by transesterification of the methyl esters of fatty acids with triacetin (Ac_3), [8] but the transesterification of cocoa-butter with ^{14}C-tristearin and tritium palmitate yields uniformly labelled ^{14}C- and ^{3}H-triglycerides [12]. Lagrange's rule of multipliers for a system of any two fatty acids A and B shows that the maximum content [A_2B] of a glyceride A_2B is reached when [A] = 2[B]; we then have the contents 44.4%, 29.7%, 22.2%, and 3.7% for [A_2B], [A_3], [AB_2], and [B_3] respectively. These calculations are used in selecting the acid concentrations for the preparation of a mixture of glycerides of a specified composition [4,7].

As already mentioned, the properties, composition, and structure of triglycerides are greatly changed by transesterification. The changes in the Bömer number and in the melting point depend on departures from the random values in the concentrations in a given fat of glycerides containing only saturated acyls [Sat_3].[2] Appreciable changes occur also in the phase structure of the triglycerides (Section V, 3). When molten pork fat, containing 25% of 2-palmito-oleostearin (2-PalOlSt), is chilled rapidly, coarse crystals of the β'-3-polymorphous form of this glyceride are produced, and prevent the use of this fat in the confectionary industry. After transesterification the 2-PalOlSt content falls to the statistical value (3.4%), and readily fusible Sat_2Unsat glycerides of vegetable type appear; these crystallise in the β'-2-form, the granularity of the product disappears, and its emulsifying power improves [4,14]. It is possible also to change the properties of a fat in the required direction by controlled transesterification, in which the randomisation of liquid fats such as cottonseed oil is combined with low-temperature crystallisation, which removes saturated acids from the mixture as a Sat_3 precipitate [4,7].

The transesterification of natural and artificial fats usually increases the total number of individual triglycerides of differing polarity [15-18]. Olive oil yields the new glycerides OlPalLinoleoyl and OlStLinoleoyl, and a mixture of St_3 and Ol_3 is converted into the more complicated statistical mixture of StStSt, OlStSt, StOlSt, StOlOl, OlStOl, and OlOlOl [11,19]. The structure of transesterified fats is usually close to the statistical structure, independently of the presence of a solvent in the reaction mixture.

However, selective physicochemical reaction parameters (preferential re-esterification of acids having a longer chain, differences in reactivity between 1- and 2-hydroxy-groups of glycerol, etc.) often divert the distribution of acyls in the randomised oil from the calculated distribution [2,19,21]. Such deviations have been found, in particular, in the composition of transesterified fats rich in volatile acids, such as coconut oil and especially randomised milk fat, which differs appreciably from the original fat (Fig. 1A) in its content of triglycerides in which the total number of carbon atoms in all the acyls is $m = 50-54$) (Fig. 1B) [13,19]. The equilibrium mixtures obtained by transesterifying St_3, Ol_3, and Ela_3 (where Ela = elaidate) or a mixture of the methyl esters of the fatty acids with Ac_3, have the statistical composition [8,17,22]. The content of fractions of different polarity does not vary so greatly in the transesterification of liquid oils (safflower and olive) as in the randomisation of solid cocoa butter [12, 18,21]. The transesterification of sunflower and cottonseed oils produced statistical distributions of unsaturated acyls in individual groups of triglycerides [23]. The composition of milk fat, pork fat, soya-bean oil, and olive oil after transesterification corresponded to the statistical distribution [10,15]. If the content of saturated acyls at position 2 of the glycerides [$Sat_{(2)}$] is lower after randomisation of a vegetable oil, contamination of the oil with fats obtained by esterification is indicated [20].

2. Glycerolysis of Triglycerides

A fat is subjected to glycerolysis by heating it with excess of glycerol in 0.1% caustic soda in a stream of an inert gas. Cessation of reaction and the establishment

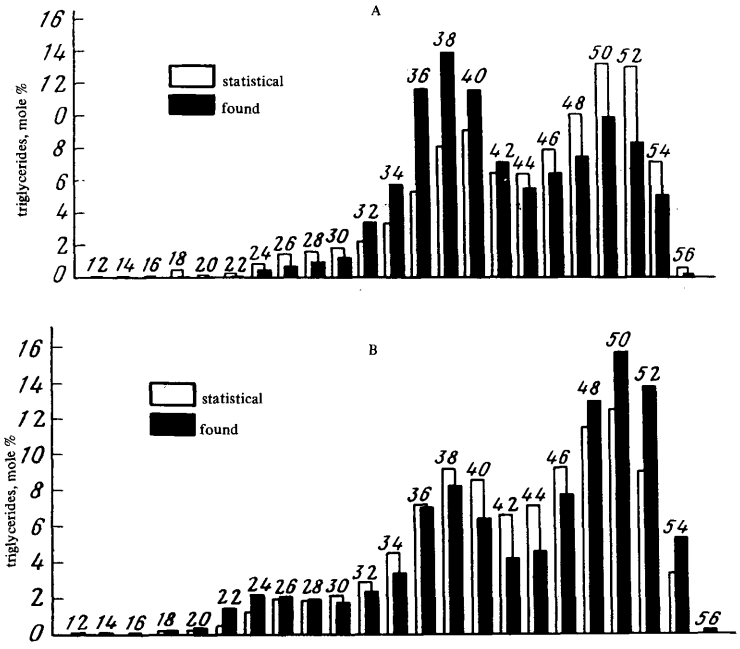


Figure 1. Composition of triglycerides of milk fat [13]: A) native; B) transesterified. The numerals 12-56 indicate the numbers of carbon atoms in individual fractions.

of dynamic equilibrium are assessed from the solubility of the mixture in 2–5 parts of methanol. The equilibrium constant K_e of glycerolysis is calculated from the contents in the mixture of glycerol, 1(3)- and 2-monoglycerides, 1,3- and 1,2(2,3)-diglycerides, and triglycerides determined by adsorption chromatography, measurement of the hydroxyl, acid, and saponification numbers, and also periodate oxidation [16,24]. Such calculation established a fundamental fact in triglyceride chemistry: positions 1 and 2 are not equivalent with respect to acylation [25–29].

Table 1. Composition (wt. %) of equilibrium mixture of glycerolysis* products [24].

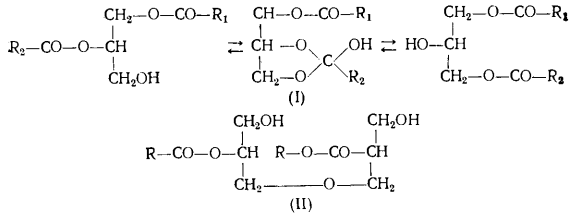
Components	Found	Calculated for	
		$K_e=3.4$	$K_e=1$
Glycerol	6.5	6.5	6.5
1(3)-Monoglycerides	36.5	39.5	28.3
2-Monoglycerides	4.4	5.1	14.2
1,2(2,3)-Diglycerides	15.6	14.1	27.0
1,3-Diglycerides	32.7	26.9	13.5
Triglycerides	4.3	7.9	10.5

*Linseed oil (1 mole) and glycerol (1.85 mole) were heated with 0.1% trisodium orthophosphate at 240°C for 2 h.

If glycerolysis occurred strictly quantitatively, and the probability of esterification was the same for glycerol derivatives containing free primary and secondary hydroxy-groups (R^POH and R^SOH), the molar contents of esterified (a) and free (b) hydroxyl in the mixture could have been used to calculate the statistical concentrations of tri-, di-, and mono-glycerides and of free glycerol as ($\times 10^{-4}$) respectively a^3, $3a^2b$, $3ab^2$, and b^3. [4,26] In this case the relative molar concentrations of positional isomers in the monoglycerides and diglycerides at the equilibrium $R^POH + R^SOOCR \rightleftharpoons R^SOH + R^POOCR$ would have been [1(3)-MGl] = 2[2-MGl] and [1,2(2,3)-DGl] = 2[1,3-DGl], while the equations K_e = [1(3)-MGl]/2[2-MGl] = [1,2(2,3)-DGl]/2[1,3-DGl] would give a calculated value of $K_e = 1$. However, the equilibrium concentrations obtained by the usual glycerolysis (at 175–180°C) were [1(3)-MGl]/[2-MGl] = 88 : 12 and [1,2(2,3)-DGl]/[1,3-DGl] = 40–60, from which $K_e = 3.0 \pm 0.6$. Hence the free energy of a primary hydroxy-group of glycerol on esterification $\Delta F = -RT \ln K_e$ exceeds the free energy of the secondary group by 1.2 kcal mole^{-1}, and the probability of esterification of a primary hydroxyl is treble that of the secondary group [26,27]. The composition of the equilibrium mixture calculated with $K_e = 3.4$ agrees well with the experimental results, but those calculated with $K_e = 1$ show marked discrepancies (Table 1) [24]. Increase in the number of carbon atoms m and decrease in the number of double bonds e in the acyl residue diminishes the rate of acyl migration, but does not affect the value of K_e. [25] Substitution of one primary hydroxyl does not affect the rate of esterification of the other primary group. With fall in the temperature of the reaction K_e increases [28].

Little work has yet been done on the mechanism of transesterification and glycerolysis [30–32]. Transesterification itself may be a particular case of glycerolysis, in which, under the influence of the catalyst and of the free hydroxyls of water as initiators of the reaction, traces of glycerol, monoglycerides, and diglycerides continually appear in and disappear from the mixture, with a consequent dynamic equilibrium (randomisation) of the acid radicals [4]. A cyclic orthoester (I, Scheme 1) may be an intermediate product in the acyl migration [31].

Scheme 1



Study of the migration of the acyl groups in mono- and di-glycerides in ethereal hydrogen-chloride solution has shown that this reaction requires the presence of traces of water. The mixture formed by the transesterification of a 2-monoglyceride contains a 1,7-dihydroxy-4-oxa-heptane-2,6-diyl dicarboxylate (II) (a dimerised ether), and corresponding derivatives are formed by the transesterification of 1(3)-monoglycerides and 1,3-diglycerides. According to one view an equilibrium mixture of the 2-monoglyceride and (II) is produced in the solution, after which rupture of the ether bond occurs with simultaneous intramolecular migration of the acyl group and formation of a 1(3)-monoglyceride [30]. According to another author (II) is not an intermediate but a secondary product of the reaction, which is synthesised by the combination of a monoglyceride or a diglyceride with the corresponding acid chlorides formed by the action of hydrogen chloride on these glycerides [32].

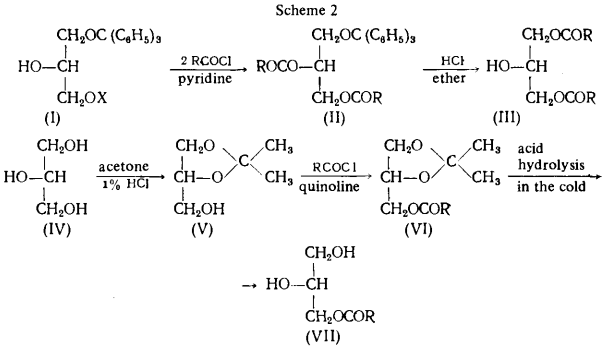
3. Chemical Preparation of Triglycerides of Definite Structure

Together with transesterification, the preparation of specified triglycerides (of a mixture of stereoisomers—see Section IV, 8) for comparison with natural triglycerides (melting point, polymorphism, etc.), in order to identify the latter, was one of the earliest methods of investigating fats [33–37]. Monacid triglycerides (AAA) are prepared by the single-stage direct esterification of excess of the fatty acid with glycerol in the presence of toluene-p-sulphonic acid. The preparation of diacid and triacid triglycerides is a multistage process with protection of particular hydroxy-groups at individual stages, and also the isolation, purification, and identification of intermediate products [5,34].

Symmetrical triglycerides ABA are obtained by combining 1,3-diglycerides of acid A, which are easily segregated from the more easily fusible 1,2(2,3)-diglycerides by crystallising the equilibrium mixture, with excess of the chloride of acid B by heating in chloroform–pyridine solution [36]. Migration of acyl groups, which is very considerable when toluene-p-sulphonic acid is used as catalyst, is absent from this reaction. A statistical mixture of the 1,3-diglycerides of palmitic and stearic acids on reaction with oleoyl chloride gave a mixture of triglycerides similar to cocoa butter [12].

Scheme 2 shows the reactions involved in the preparation of 1,3-diglycerides of polyunsaturated acids (I–III) and 1(3)-monoglycerides (IV–VII). 1,3-Diglycerides of polyunsaturated acids (III) which crystallise with difficulty are prepared by acylating the 1(3)-monotrityl ether of glycerol (I: X = H) and then detritylating with quantitative migration of the 2-acyl to the outer position. Unsymmetrical diacid triglycerides AAB are obtained by using the chloride of acid A to acylate 1(3)-monoglycerides of acid B (VII: R = B), prepared by Fischer's method with 1,2(2,3)-isopropylidene protection subsequently removed by acid hydrolysis [29,38].

Scheme 2



Finally, the preparation of a triacid triglyceride (ABC) involves first obtaining the 1(3)-monoglyceride of acid A (VII: R = A) by the mechanism (IV) → (VII), and then converting it into the 3(1)-monotrityl ether (I: X = COA), which is esterified in the 2-position by the chloride of acid C with subsequent acyl migration by the mechanism (I) → (III) to give the 1,3-diglyceride of acids A and C (III: R = A or C); this is substituted at position 2 by the chloride of acid B. If C is an unsaturated acid, the trityl protection in (II) is removed by hydrogenolysis without acyl migration, and the resulting 1,2(2,3)-diglyceride is acylated at the last stage by the chloride of another unsaturated acid to form a triacid triglyceride of type $SatUnsat_2$. [4,35]

III. STRUCTURAL ANALYSIS OF TRIGLYCERIDES BY LIPASE HYDROLYSIS

1. Lipase Hydrolysis of Triglycerides

It was discovered as early as 1945 that the lipase hydrolysis of fats in the intestine ceased long before all the ester bonds had been cleaved [1,35,39–45]. Subsequent experiments with synthetic triglycerides of known structure showed that 1,2(2,3)-isomers predominated among the diglycerides present in the products of incomplete hydrolysis [39,44]. The preferential detachment by pancreas lipase *in vivo* and *in vitro* of the outer acyls in triglycerides of saturated and unsaturated acids having $m = 12–18$ is indicated also by the incorporation of ^{14}C-labelled free fatty acids, in the presence of lipase and a fat, only in the 1,3-positions of triglycerides, and by the formation of the 2-isomers of monoglycerides on lipase hydrolysis, as demonstrated by their isomerisation with perchloric acid and periodate oxidation [40 46–51]. On the basis of these discoveries a method was proposed in 1956 for determining the composition of acyl groups in the 1,3- and 2-positions of triglycerides in natural fats from the composition of the free fatty acids and of 2-monoglycerides resulting from its enzymic cleavage [48]. Lipase hydrolysis is now the principal method for the structural analysis of triglycerides [42,47].

In contrast to esterases, which hydrolyse water-soluble substrates, lipase (glycerol ester hydrolase, EC 3.1.1.3) is almost completely specific to 1,3-esters of glycerol which have limited solubility in water [52,55]. In oil of ergot, for example, it does not cleave the ester bonds between the ricinoleate residues and the glycerol [56]. Furthermore, lipase possesses no stereoselectivity (Section IV, 1). [39] The simplified lipase reaction can be divided into two stages:

$$\text{TGI} \xrightarrow{k_1} \text{1,2(2,3)-DGI} \xrightarrow{k_2} \text{2-MGI} \quad .$$

Each stage has its own rate constant: for the oil from *Madhuca longifolia* the constants are $k_1 = 0.35$ and $k_2 = 0.36$; but the corresponding values for pork fat are 0.31 and 0.36. From the equation for the reaction we find that (where e is the base of natural logarithms and t the time of reaction) [52]

$$[\text{TGI}]_t = [\text{TGI}]_0 \cdot e^{-k_1 t};$$

$$[\text{DGI}]_t = [\text{DGI}]_0 + [\text{TGI}]_0 \cdot [k_1/(k_2 - k_1)]\,(e^{-k_1 t} - e^{-k_2 t});$$

$$[\text{MGI}]_t = [\text{MGI}]_0 + [\text{TGI}]_0\{1 - [1/(k_2 - k_1)]\} \cdot (k_2 e^{-k_1 t} - k_1 e^{-k_2 t}) \quad .$$

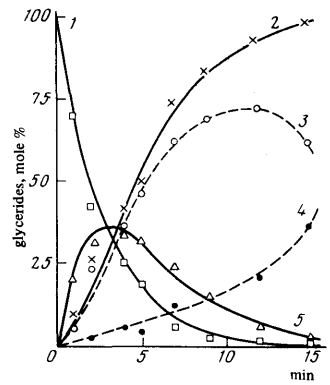


Figure 2. Dependence of lipase hydrolysis of oil of the plant Madhuca longifolia on time of reaction [52]: 1) triglycerides; 2) monoglycerides + glycerol; 3) monoglycerides; 4) glycerol; 5) diglycerides. The full curves represent calculated concentrations (Section III, 1), and the broken curves the experimental values.

Before hydrolysis the protein of the enzyme is absorbed on the surface of the fat micelles, and therefore the reaction velocity depends on the degree of emulsification of the substrate in the aqueous solution, which determines the area of this surface, and also on the relative quantities of enzyme and fat [57]. The free fatty acids and monoglycerides formed by hydrolysis are desorbed into the aqueous phase [55]. The rate of the reaction gradually decreases, since triglycerides, 1,2(2,3)-diglycerides, and

2-monoglycerides release 2, 1, and 0 mole respectively of acids per mole of glycerol [53]. Maximum contents of diglycerides and monoglycerides are observed after 40% and 70% hydrolysis respectively (Fig. 2). Free glycerol may appear in the medium after 25–40% hydrolysis, as a consequence of acyl migration (Section III, 3) [47,52]. Several reviews have been published on the properties, kinetics, and mechanism of the reaction of pancreatic lipase [1,41,43,44,54].

Table 2. Reaction conditions (per 1 g of fat) in studying the structure of triglycerides by lipase hydrolysis (data in parentheses relate to the micromodification of the method) [1,10,35,47,55,56,58–64].

Parameter of reaction medium and units of measurement	Numerical value
Composition and concentration of buffer solution	1.2 M or 1 M NH_4OH-NH_4Cl
Quantity of buffer solution	18–23 (160–1050)
Optimum pH of buffer solution	8.0–8.5
Sodium taurocholate, mg	5–20 (250–500)
Calcium chloride, mg	350–440 (2000–8000)
Enzyme, mg	70–400
Temperature of medium, °C	37–40
Duration of incubation, min	10–90 (2–30)
Degree of hydrolysis of ester bonds, %	50–70
pH of medium after addition of 1–6 *N* HCl	1–3
Atmosphere	nitrogen or air
Rate of stirring of mixture, rev/min	120–3000

2. Conditions of Lipase Hydrolysis

The conditions under which lipase hydrolysis is conducted are summarised in Table 2. The source of the enzyme is usually the secretion or a preparation of pig pancreas—pancreatin, steapsin, etc.—which may vary greatly in activity and in positional specificity [15,42,56,59]. The quantity of lipase is chosen to give a 65–70% yield on hydrolysis for the minimum time, and its specificity is checked by its action on synthetic triglycerides of known structure [44,47,49,58,64]. The activity of the enzyme increases by a factor of 135 on purification, which includes removal of fat, extraction with water, adsorption on aluminium hydroxide, precipitation with ammonium sulphate, dialysis, and chromatography on DEAE cellulose. However, purification does not improve positional specificity, and for the study of glycerides, therefore, it is usually restricted to Desnuelle's stage (II). [40,43,65,66] It is important to remove endogenous lipids from the preparation, and to eliminate any esterase activity (if glycerides of acids having $m < 12$ are under investigation) and non-specific "lipase" activity, which sometimes amounts to 2–10% of the total lipase activity, is promoted by a taurocholate, and is inhibited after 2 h at pH 9 and 40°C. [62,63,67,68]

The substrate—natural or synthetic triglycerides—and other reactants are also freed from any contamination with mono- and di-glycerides [44,69]. Unsaturated glycerides are hydrolysed in an atmosphere of nitrogen (Table 2). Only a liquid and well emulsified substrate undergoes cleavage [15–39], and therefore the mixture with the emulsifier is homogenised by heating before addition of the lipase. As acyl migration and inactivation of the enzyme increase above 40°C, homogeneity of the medium is best created by rapid mechanical stirring [40,43,47]. The usual emulsifier is sodium taurocholate, which, however, activates the foreign "lipase" (see above) and exerts a still not altogether clear promoting effect on the pancreatic lipase itself [41,59]; polymers—polyvinyl alcohol, gum arabic, etc.—are also used [42,61]. However, the emulsifiers are often inadequate for the production of good emulsions from solid Sat_3 glycerides (chain length of each acyl $m_S > 12$); in that case they are mixed, before emulsification, with liquid carrier lipids, which do not influence the specificity of hydrolysis of saturated substrates [70,71]. Mixing an Sat_3 glyceride with triolein (1 : 1 or 4 : 1) contaminated the reaction mixture with hydrolysis products of the latter, and therefore it is now replaced by methyl esters—methyl oleate, methyl pentadecanoate, etc. [55,63,69]

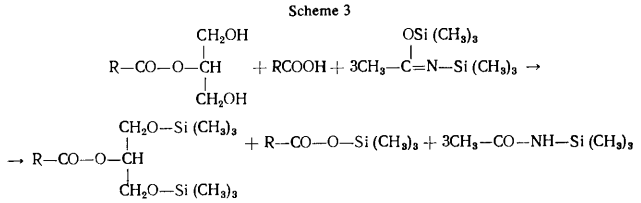
With hydrolysis on a macro-scale, when the molar ratio of fat (0.2–2 g) to buffer is ~ 1.5, the pH falls rapidly below the optimum value (Table 2). [10,47,59,61,63] To avoid inactivation of the lipase the optimum pH must be maintained by adding ammonium hydroxide or 0.5–1 *N* caustic soda either manually or by means of a recording pH-stat, which enables the point of maximum content of monoglycerides in the medium to be detected (Fig. 2). [42,56,59,63,72] In the micro-method (1–50 mg of fat) the existing buffer solution usually ensures maintenance of the optimum pH [47,65]. Calcium ions (Table 2) bind free fatty acids, and therefore hydrolysis proceeds to the monoglycerides; in the absence of the calcium ion, or in the presence of a phosphate buffer to combine with it, only diglycerides are produced, and free fatty acids accumulate and inactivate the enzyme [43,44,55]. If time t elapses between addition of the lipase and the appearance of turbidity due to insoluble calcium salts, time $2t$ corresponds to the maximum content of monoglycerides [41,54]. Reaction is terminated by excess of hydrochloric acid, and the total lipids are extracted [40,57,61,73].

The structure of natural triglycerides is determined from the composition of the products of lipase hydrolysis. The composition of the mono- and di-glycerides can be established by gas chromatography of their acetates: monoglycerides could be separated as far as monoarachin, and diglycerides as far as palmitomyristin. Acetates of 1-monoglycerides and of 1,3-diglycerides were eluted more slowly than the derivatives of 2-monoglycerides and 1,2-diglycerides respectively [74]. A mixture of 1- and 2-monoglycerides was analysed by treatment with methanesulphonyl chloride and an acetone solution of sodium iodide: 2-monoglycerides pass into the 1-isomers, and the resulting allyl esters of fatty acids are separated on the non-polar liquid phase at 240°C for 60 min [75,76]. Quantitative determination of the hydrolysis products of glycerides containing acid-labile groups in the chain of the fatty-acid residues was accomplished by gas chromatography of the unchanged triglycerides and the trimethylsilyl derivatives of monoglycerides, diglycerides, and free aliphatic acids, which were obtained in a 20% solution of bistrimethylsilylacetamide in pyridine (Scheme 3). The trimethylsilyl ethers of monoglycerides and diglycerides and the trimethylsilyl esters of fatty acids were immediately separated by temperature programming. This method was used for the positional analysis of glycerides of *cis*-12,13-epoxyoleic, 10-hydroxyoctadeca-*trans*-9,*trans*-12-dienoic, and octadeca-*cis*-9,*trans*-11,*trans*-13-trienoic acids; decomposition products obtained by other methods of silylation were absent here [77].

The products of lipase hydrolysis—unchanged tri-, di-, and mono-glycerides, free fatty acids, and glycerol—are usually isolated by thin-layer or column adsorption chromatography [40,78–89]. If the adsorbent is impreg-

nated with boric acid, diglycerides and monoglycerides are separated into symmetrical 1,3- and 2-isomers and into unsymmetrical 1,2(2,3)- and 1(3)-isomers respectively [65,79]. Each class of lipids is considered quantitatively, and the composition of their acids is determined by gas chromatography [60,78,84,85]. From the content of a fatty acid in the original fat [A] and for one position in the triglycerides, the composition of another position is calculated by means of the formula $3[A] = 2[A_{(1,3)}] + [A]_{(2)}$, and the content of A in the 2-position is $H = 100[A_{(2)}]/3[A]$. [17, 44,80,82,90-92] Acyl migration (Section III, 3) is assessed by decomposition 1(3)-monoglycerides with periodate, and reisolating the 2-monoglycerides [64,83,87,90]. The structure of diglycerides and monoglycerides is determined also by esterifying them with chlorides of fatty acids not present in the given fat, subjecting the artificial triglycerides obtained to further lipase hydrolysis, and examining the cleavage products of the latter [46,68].

Scheme 3



3. Determination of Reliability of Enzymic Analysis of Triglycerides

In order to assess the reliability of the results of lipase hydrolysis it is necessary firstly to ascertain whether the rates of elimination of different fatty acids are the same and whether it is a random process, and secondly to know whether positional specificity of hydrolysis is maintained and how it is affected by possible migration of acyl groups [43,60,68,73,93-101].

No great changes in composition of the acids of each class of lipids (Section III, 2) were observed with different times of hydrolysis of ordinary fats having $[Sat_{(2)}] < 10\%$ and $m = 12-18$ carbon atoms in saturated and unsaturated acids; the unchanged triglycerides and combined fraction of free fatty acids and 2-monoglycerides were similar in acid composition to the original fat (provided that the diglyceride content of the mixture was low). Thus there is little fatty-acid specificity in the reaction, while the hydrolysis of 1,3-acyl groups is itself a random process [1, 40,44,52,57,71,99-107].

Acids having $m:e = 20:5$ and $22:6$ in the fats of marine animals, owing to the proximity of their carboxyls to the first double bond and the terminal methyl group (as a consequence of bending of the chain), are detached more slowly than ordinary acids by factors 5–10, and therefore accumulate in the diglycerides and triglycerides of the reaction mixture. The 22:5 acyls, which do not exhibit these steric features, are hydrolysed normally. Lipase hydrolysis has now been replaced by use of a Grignard reagent—methylmagnesium bromide—for the structural analysis of "marine" fats [80,95,107].

On the other hand, short-chain acyls ($m < 12$), owing to the ease of their migration from the 2-position to the 1,3-position in 2-monoglycerides and 1,2(2,3)-diglycerides, are hydrolysed at three times the rate for ordinary acids, so that they accumulate in the monoglycerides. Therefore the results of lipase hydrolysis for milk fat, the fat of Cuphea llavia, the oil of Irvingia gabonensis, and other fats rich in volatile acids are unreliable. The degree of migration of lauric acid, which occupies a position intermediate between volatile and non-volatile acids, has not yet been determined [16,39,53,82,87,93,94, 96,97,100,102-104,106].

Chain branching inhibits the detachment of acyl groups, but the introduction of a hydroxy-group has no effect on the rate of hydrolysis. The dibasic acyls in triglycerides containing azelaic acid were hydrolysed like ordinary acyl groups. Unsaturated acyl groups in pork fat ($[Sat_{(2)}] \simeq 75\%$) were eliminated preferentially, which increased the saturation of the remaining triglycerides and diglycerides. The composition of 2-monoglycerides $[Sat_{(2)}]$ remained unchanged, and therefore calculation of $[A_{(1,3)}]$ (Section III, 2) and the structure of glycerides from $[A_{(2)}]$ and [A] is more correct than the previous calculation of $[A_{(2)}]$ from the variable composition of free fatty acids. Results for the effect of *cis–trans* isomerism on the rate of hydrolysis are contradictory [41,46,47,54,59,98,105].

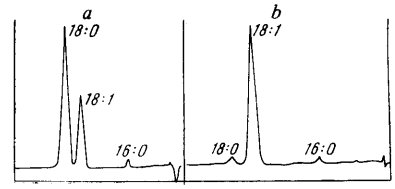


Figure 3. Gas–liquid chromatograms of fatty acids: *a*) 1,3-distearo-2-olein; *b*) 2-monoglycerides obtained by lipase hydrolysis of (*a*) [55].

The hydrolysis of synthetic and natural glycerides in the intestine and on a micro-scale *in vitro* for 1–2 min (Fig. 3) corresponds to the chemical equation (Section III, 1) [42,52,57,83]. With increase in the time of reaction the monoglycerides isomerise: they are usually found to contain 10–30% and more of 1(3)-monoglycerides formed by the migration of acyl groups in an aqueous medium at pH 8, and easily converted into glycerol (up to 30–40% by the end of the reaction) [39,66,71]. Isomerisation can be partly eliminated by adding free fatty acids or by using microbial lipases with an acid optimum pH (section III, 4) [41,49,108]. The migration of acyl groups is directed thermodynamically to the 1,3-positions, and its rate is lower than that of detachment. Therefore 2-monoglycerides are free from acyl groups present in the 1,3-positions of the initial triglycerides, and the composition of their acids corresponds to that of the 2-position of these triglycerides [46,47,82].

The positional specificity of lipase is almost absolute [44, 55,105]. Thus hydrolysis of the acylation products of 1(3)- and 2-monoglycerides (Section III, 2) resulted in the elimination of 98% and 2–10% respectively of the original acid, but the composition of the hydrolysis products from derivatives of 1,2(2,3)- and 1,3-diglycerides corresponded to the theoretical value within 5%. Similar results have been obtained in experiments with 1,3-benzylidene-2-oleoylglycerol and 1,3-dihexadecyl-2-oleoylglycerol, where migration of oleate is excluded, while foreign "lipase" (Section III, 2) is inhibited [62,68].

Quantitative estimate were made of migration and specificity of hydrolysis by subjecting 2-[9′,10′-$^3H_2$]oleoyl-1,3-dipalmitoyl-*sn*-glycerol to cleavage at the constant pH = 8 (Table 3 and Fig. 4). The acid composition of the reaction products diverged from the theoretical only as a consequence of the isomerisation of 1,2(2,3)-diglycerides and especially 2-monoglycerides, which increased during incubation; the content of 1-monoglycerides and free oleate in the hydrolysis products did not exceed 3–5%.

Table 3. Hydrolysis of 1,3-dipalmitoyl-2-[9′,10′-$^3H_2$]-oleoylglycerol by pancreatic lipase (mole %).[65]

Time, min	Free fatty acids in products	Content of ^3H (%) in				1,3-PalOl × 100 / 1,2-PalOl	Moles per 100 moles of 2-MGl		
		TGl	DGl	MGl	FFA		all 1-MGl	1-MOl	1-MPal
19	31	26	34	37	3	2	23	20	3
22	50	17	27	52	4	3	23	20	3
30	60	6	15	74	5	4	38	35	3
45	60	11	15	66	8	6	43	38	5

The radioactivity of the triglycerides, diglycerides, and monoglycerides obtained from the tritiated triglyceride by hydrolysis with the lipase of the mould Rhizopus arrhizus was respectively 60, 59.9, and 55.5 (in 10^3 d.p.m. μ mole^{-1}), which indicates slight migration of the tritiated oleoyl from the 2-position[65].

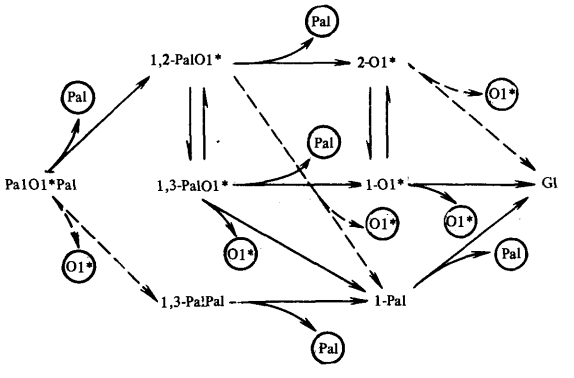

Figure 4. Possible transformations of PalTOlPal on lipase hydrolysis[65], Full lines represent normal hydrolysis of 1,3-acyl groups, and broken lines abnormal hydrolysis of 2-acyl groups. The symbol ⇌ denotes spontaneous acyl migration.

Lipase was used originally for the hydrolysis either of synthetic individual triglycerides or of natural fats of complicated glyceride composition[40,42,44,50]. The results were expressed as the acid composition at 2- and 1,3-positions. The calculation was also based on values of H (Section III, 2), other parameters of the positional distribution of individual acids, and the composition of the fat glycerides from the appropriate equations[64,68,93,105]. When $H \simeq 33\%$, a purely statistical distribution of the given acyl group is present[71,82,106]. However, this seldom occurs[63]: the structure of most animal and vegetable fats diverges greatly from the statistical[43,45,83]. The differences in composition between the 1,3- and 2-positions led to the hypothesis that two enzymes, differing in fatty-acid and positional specificity, were responsible for the synthesis of glycerides[35,49,73]. It has now been shown that the best method for the structural analysis of glycerides is a combination of a micromethod of lipase hydrolysis with preliminary chromatography of the fats[1,41,47,54,72,87].

The defects of lipase hydrolysis are the sometimes poor reproducibility of the effects of different lipase preparations containing various impurities, the migration of acyl groups, the re-esterification of free fatty acids due to the transferase activity of lipase on prolonged incubation in the absence of calcium ions, and the absence of stereospecificity of hydrolysis[1,39–42,47,54,67,109–111].

4. Use of Other Lipases for the Analysis of Triglycerides

Besides the pancreatic lipase of the pig, the corresponding enzymes from other mammals, and also the lipases of cod, skate, and lobster, which have the same positional specificity, are used in the analysis of fats[39,43,79,112–114]. Lipases of milk and of the fungus Pseudomonas fragi are also specific to the 1,3-positions. The optimum pH for their functioning is 5.6, and therefore acyl migration is less pronounced than with pancreatic lipases[1,44,100,115]. The lipase of Vernonia anthelmintica seeds attacks the 2-position to give 1,3-diglycerides. The enzyme of the fungus Geotrichum candidum is specific, although not absolutely so, to *cis*-9-unsaturated acids, especially to oleic acid, independently of their position (Section IV, 8). The enzyme hardly detaches elaidic acid at all, which demonstrates the stereoselectivity of formation of the enzyme–substrate complex[101,112,116]. The non-specific lipases of the castor-oil plant and of Streptococcus aureus are not used in the analysis of glycerides[54,105]. Hypotheses assuming the participation of plant lipases in the synthesis of triglycerides have now been abandoned[41].

5. Structural Analysis of Triglycerides by Mass Spectrometry

Non-enzymic methods for the structural analysis of triglycerides include mass spectrometry (Fig. 5) and also the determination of polymorphism, nuclear magnetic resonance spectroscopy, and infrared spectroscopy (Section V).

The mass spectrum of synthetic 1-myristoyl-3-palmitoyl-2-stearoyl-*sn*-glycerol, obtained on an MS-9 instrument at 170–200°C, exhibited the following peaks: (1) a peak due to the molecular ion M^+ at $m/e = 804$; (2) peaks at 523, 551, and 579 formed by the elimination of RCOO groups from M^+ (where R = St, Pal, or Myr); (3) peaks due to the ions of these acyl groups at 267, 239, and 211; and (4) peaks due to ions formed by elimination of the fragment CH_2OCOR from M^+ (at 509, 537, and 565 respectively). Fig. 5 shows that the intensity due to the ion (peak with $m/e = 509$) resulting from the elimination of $CH_2OCOC_{17}H_{35}$ (the fragment containing the 2-stearate residue from the initial triglyceride) from the M^+ ion was

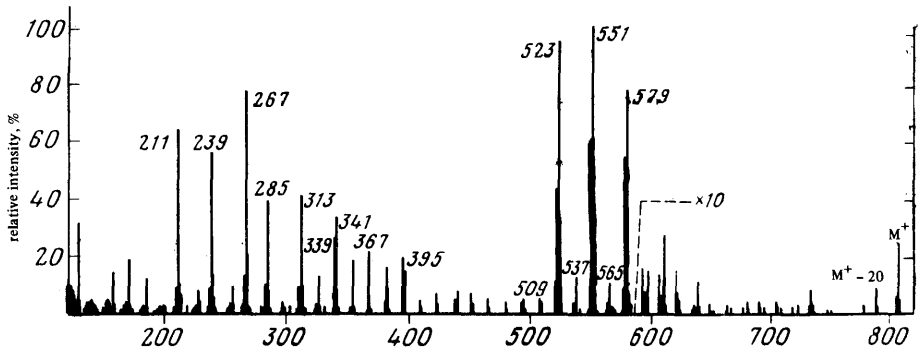

Figure 5. Mass spectrum of 1-myristo-2-stearo-3-palmitin [117].

$CH_2OCO_{13}H_{27}$
|
$CHOCOC_{17}H_{35}$
|
$CH_2OCOC_{15}H_{31}$
$M = 804$

one-third of the intensities of ions with peaks at 537 and 565. Hence the position of an acyl radical in the triglyceride molecule can be established from the relative intensities of the peaks due to $M^+ - CH_2OCOR$. Thus the synthetic triglycerides 2-OlStSt and 1-OlStSt gave different mass spectra. With compounds of molecular weight below 1058 decomposition under the influence of electron impact is not accompanied by thermal decomposition. The mass-spectrometric method is an improvement on lipase hydrolysis with respect to speed and sensitivity of analysis, but as yet it is applicable only to purified individual triglycerides [41,117].

The natural glycerides which have been investigated by mass spectrometry include the optically active triacid triglyceride from the polar fraction of the Chinese oil from Sapium sebiferum, which yields on methanolysis esters of linoleic, linolenic, and deca-2,4-dienoic (10:2) acids. The molecular weight of this glyceride, determined by mass spectrometry, is 920, not the 778 which might have been expected from its fatty-acid composition. The difference of 142 indicates that this compound contains also a residue of a C_8 hydroxy-acid. Since the spectrum did not contain a peak due to $M^+ - CH_2OCOR$ (R = 10:2), it could be assumed that the 10:2 acid was not attached directly to the glycerol. These results helped to establish the structure of the optically active triglyceride, as described in detail below (Section IV, 4).

IV. DETERMINATION OF ABSOLUTE CONFIGURATION OF TRIGLYCERIDES

1. Present-day Position of the Problem of the Absolute Configuration of Fats

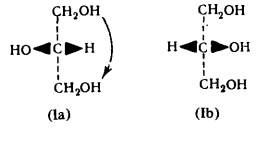
Most of the naturally occurring asymmetric compounds —amino-acids, carbohydrates, terpenes, alkaloids, etc.—are usually enantiomers [35,118]. The structural analysis of triglycerides is often confined to lipase hydrolysis [119], and the stereoisomerism of triglycerides, in contrast to their composition, has been little studied as yet, owing to the difficulty of isolation in a pure form, insufficient development of the preparation of their stereoisomers, and also the fact that modern methods do not usually detect optical activity in the stereoisomers of triglycerides [118].

Optical activity may be expected in asymmetric triglycerides of the type ABC (A = B and A ≠ B) [41], which have now been detected in all natural fats [120]. A racemic mixture of equal quantities of the enantiomers of such glycerides does not possess optical activity. If, however, one enantiomer is completely or partly absent from the mixture, experimental detection of the asymmetric $C_{(2)}$ atom of the glycerol residue is in principle possible [121]. The equivalence or non-equivalence of composition of the acyl groups in positions 1 and 3 in mixtures of optically active glycerides is important for a complete description of the fat and for assessing the reliability of theories of the structure of triglycerides, since many of these theories are based on the hypothesis of a statistical distribution of acyl groups in the 1,3-positions. This problem can also be solved independently of any structural theory [118,121-123].

2. Nomenclature of Stereoisomers of Glycerol Derivatives

The glycerol molecule, which is devoid of optical activity, is usually regarded as symmetrical. The problem arises of how to distinguish between carbon atoms 1 and 3, which are differentiated in the exchange reactions of lipids. The Fischer projection formula of glycerol (Ia) in Scheme 4 (where the solid triangles denote bonds directed towards the reader, and the broken lines those directed away from the reader) shows that the halves formed by the plane through the $C_{(2)}$ atom and the HO–H line are not identical, since they cannot be superimposed.

Scheme 4

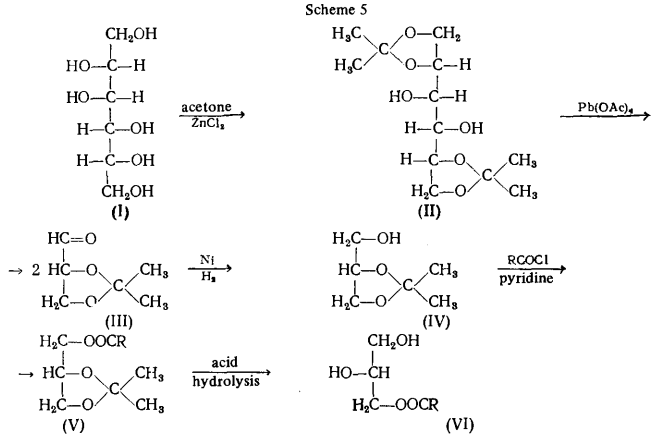


Thus $C_{(2)}$ in glycerol is a *meso*-atom, and glycerol itself has a *meso*-structure, so that it is devoid of rotational symmetry. Indeed, on rotating (Ia) through 180° about an axis perpendicular to the plane of the paper, we obtain (Ib) for glycerol, which cannot be superimposed on (Ia).

The *meso*-structure and the absence of rotational symmetry suggest that the two hydroxymethyl groups will have different fates during exchange reactions with asymmetric reactants (which include all biological reactions), and that they can be distinguished from each other. Thus the biosynthetic replacement of active hydrogen in one of these groups by phosphate, alkyl, acyl, etc. will give a glycerophosphate, batyl alcohol, a 1-monoglyceride, etc. exhibiting optical activity. The steric nomenclature of the carbon atoms of glycerol is therefore important for studying the structure and the biosynthesis of fats [124].

Until recently the Baer–Fischer system was used for denoting the absolute configuration of optically active derivatives of glycerol. In this system a given derivative is assigned to the *D*- or the *L*-series according to which of the two stereoisomers of glyceraldehyde (*D* or *L*) it can be converted into by the least number of reactions. In particular, one stage in such conversion for unsymmetrical mono- and di-glycerides is oxidation of the free primary hydroxymethyl group to an aldehyde group without change in position of the substituents. A non-acylated, phosphate-substituted, radioactively labelled, etc. hydroxymethyl group is always denoted by the Greek letter α and the secondary $CH.OR_{(2)}$ group by the letter β. This system has several drawbacks for structural and biochemical purposes, since it remains obscure whether α denotes the 1- or the 3-position. Baer and Fischer's nomenclature was modified to the so called "conventional" *D*/*L* system.

Scheme 5



This still used the prefixes *D* and *L*, but the positions of substituents were denoted by the numerals 1, 2, and 3, where "1" denotes acylation of a hydroxymethyl group. This system also has defects: for example, according to this nomenclature the phosphorylation product of an *L*-1,2-diacylglycerol (a phosphatidic acid) can be termed either an *L*-1,2-diacylglycero-3-phosphate or a *D*-2,3-diacylglycero-1-phosphate. Therefore this system has now been replaced by others [124-126].

The more complete (*R*)/(*S*) system is based on the sequence in which radicals of different ranks are arranged about the centre of asymmetry [118]. The rank of a given group depends on its position in the arbitrary hierarchy—OH > COOH > ketone > aldehyde > hydroxymethyl > CH_3 > > H, etc. [126] In glycerides longer acyls have priority before shorter acyls, unsaturated before saturated, branched before straight-chain, *cis* before *trans*, etc. A hydroxymethyl group substituted by an acyl of lower rank is numbered "1". In a triglyceride the sequence begins with a group of higher rank—OR at $C_{(2)}$—containing oxygen, and it terminates with the radical of lowest rank—the hydrogen atom at $C_{(2)}$. If the radicals in order of diminishing rank are arranged clockwise in a plane above the $C_{(2)}$ atom viewed from the side opposite to the substituent of lowest rank (the hydrogen atom), the triglyceride belongs to the right-hand or (*R*) configuration; if the opposite is true, it belongs to the left-hand or (*S*) configuration. Thus the optical enantiomers of α-laurodipalmitin (Section IV, 3) are denoted in the (*R*)/(*S*) nomenclature as (*S*)-1-laurodipalmitin (I) and (*R*)-1-laurodipalmitin (II) [118]. The advantages of this system are universality and the absence of any ambiguity in the notation. However, the reactions of glycerol derivatives mostly involve only the 1- and 3-ester bonds. As a consequence, the configurational prefixes (*R*) and (*S*) are often interchanged: thus the product of the phosphorylation of an (*S*)-1,2-diacylglycerol is termed an (*R*)-phosphatidic acid. Little use of the (*R*)/(*S*) system is now made in the nomenclature of lipids [124].

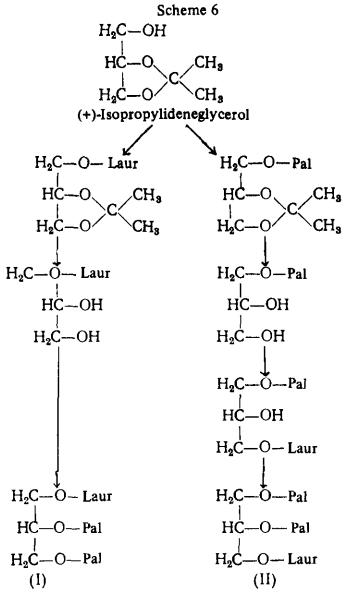
Hirschmann proposed for glycerol derivatives a system of stereospecific numbering with a fixed position of substituents (the *sn*-system), which is now the most widely used for denoting the stereospecificity of triglycerides [124, 126]. If was stipulated that the carbon atoms in the projection formula of glycerol (Ia), in which the substituent of higher rank (the hydroxyl on the *meso*-carbon atom) is always turned to the left, and the hydrogen to the right, should be numbered in the same way as the carbon atoms in *L*-glyceraldehyde, i.e. downwards (I). Thus each primary hydroxymethyl group of glycerol has a definite number in the *sn*-system, and can sometimes be numbered "1" and sometimes "3". Here a triglyceride is termed a 1,2,3-triacyl-*sn*-glycerol, and Baer and Fischer's *D*- and *L*-$\alpha\beta$-diglycerides become 1,2- and 2,3-diacyl-*L*-glycerols respectively. An equilibrium mixture of two enantiomers is denoted in the *sn*-system by the prefix *rac*, e.g. *rac*-1-oleodipalmitoglycerol; if the configuration is unknown the prefix X is used, e.g. X-1-palmitodioleoglycerol. The Commission on Biochemical Nomenclature of the International Union of Pure and Applied Chemistry has now recommended the *sn*-system for general application in denoting the absolute configuration of lipids [124,126].

3. Stereospecific Chemical Synthesis of Triglycerides

Owing to the difficulty of isolating stereoisomers from natural fats for the comparison of synthetic with natural enantiomers, methods have been worked out for the stereospecific chemical synthesis of triglycerides [4,120]. Early syntheses were based on the resolution of racemates of intermediate products by means of *D*-tartaric acid, saccharic acid, or strychnine into enantiomers, which were converted into glycerides without racemisation [4]. Nowadays the preparation starts from the optically active natural compound *D*- or *L*-mannitol. In Fischer and Baer's method for the preparation of an *L*-monoglyceride (Scheme 5) 1,2:5,6-di-isopropylidene-*D*-mannitol (II), obtained by treating *D*-mannitol (I) with acetone in the presence of zinc chloride, is converted by oxidative cleavage at the 3,4-hydroxyls with lead tetra-acetate into two molecules of isopropylidene-*D*-glyceraldehyde (III), which is reduced to *D*(+)-isopropylideneglycerol (IV), and this is esterified in the 1-position with an acid chloride to yield the 3-acyl-*L*-glycerol (VI) after the acetone residue

in (V) has been removed by hydrolysis. The 1-acyl-*L*-glycerol is prepared similarly from *L*-mannitol[4]. The stereoisomeric monoglycerides are converted into triglycerides (Section II, 3).

Scheme 6



Scheme 6 shows the synthesis of 1-lauroyl-2,3-dipalmitoyl-*L*-glycerol ((−)(*S*)-1-laurodipalmitin) (I) and 1,2-dipalmitoyl-3-lauroyl-*L*-glycerol ((+)(*R*)-1-laurodipalmitin) (II). Physical methods proved that the products were indeed optical enantiomers[118]. In the stereospecific synthesis of 1,2-dipalmitoyl-3-sorbin the free hydroxyl in (IV) was protected with benzyl, which was removed by hydrogenolysis; the triglyceride obtained was compared with the naturally occurring compound from the oil of S. sebiferum. For the measurement of optical rotation under conditions excluding acyl migration, the 1,2- and 2,3-diglycerides obtained by lipase hydrolysis of the asymmetric triglycerides were acylated with sorboyl chloride or converted into the trimethylsilyl derivatives[120,123]. Triglycerides are synthesised not only from synthetic monoglyceride enantiomers but also from 1,2-diacyl-*L*-glycerols obtained by the action of phospholipase C on egg lecithin[125,127].

4. Physical Methods for Determination of Absolute Configuration of Triglycerides

The primary physical method is polarimetry, since many glycerol derivatives—glycerophosphates, batyl alcohol, monoglycerides, diglycerides, trityldiglycerides—exhibit appreciable optical rotation[4,35,118,123]. Among triglycerides only those containing one or two residues of aromatic acids or volatile aliphatic acids have shown rotation: the *L*-forms of these glycerides are laevorotatory, and the *D*-forms dextrorotatory. This coincidence of the configuration and the sign of the rotation is probably fortuitous: the corresponding 1,3-diglycerides do not exhibit such coincidence[118]. The higher fatty acyls, which differ little in chain length and structure, give rise to such weak optical activity in the enantiomeric triglycerides that it cannot be detected by polarimetry even in the ultraviolet. Acylation of optically active *D*(+)-1,2-diolein ($[\alpha]_D^{20} = +1.73°$) in the 3-position at once removes the optical activity[4,34,35,118,120,121,123]. The dispersion of optical rotation at 300–600 nm in synthetic 1,2-dipalmito-3-laurin is 4% of the value in 1-monopalmitin and is opposite in sign of rotation[118]. Thus the absence of rotation in an unsymmetrical triglyceride still does not suggest that it is racemic in composition. Enantiomeric triglycerides, which do not directly exhibit optical rotation even in ultraviolet radiation, are said to be "cryptoactive"[4,34,35,118].

The strong rotation of dolphin fat and of the oils of the plants S. sebiferum and Sebastiana lingustrina (Euphorbiaceae family) is due to the presence of a centre of asymmetry not in the glycerol residue but in the acyl groups[118,120,128]. The polar fraction of the oil from S. sebiferum is an optically active triglyceride ($[\alpha]_D^{20} = -21.9°$). Treatment with lithium tetrahydroaluminate followed by acetic anhydride with the formation of triacetin and the acetates of the aliphatic alcohols shows that this glyceride contains equal quantities of linoleate and linolenate together with 31.5% of deca-2,4-dienoic acid. The optical activity of the glyceride disappeared after hydrogenation, and ethyl decadienoate was inactive. The first paper on this topic attributed the optical activity to the presence of decadienoic acid in the 1- or 3-position of the glyceride, near the potential centre of asymmetry, the $C_{(2)}$ atom of glycerol[128]. However, the value of $[\alpha]_{546}^{20}$ for the synthetic analogue—the 1,2-dipalmitate 3-hexa-2′,4′-dienoate of *sn*-glycerol—was only −3.60°. A later investigation of the glyceride of S. sebiferum by infrared and nuclear magnetic resonance spectroscopy together with mass spectrometry established[129] its true structure as

Linolenoyl.O.CH_2.CH(O.Linoleoyl).CH_2.O.CO.$[CH_2]_3$.CH:CH*:CH.CH_2.O.CO.CH:CH.CH:CH.$[CH_2]_4$.CH_3.

The decadienoic acid residue was proved to be attached not to the glycerol residue but to the acyl of an optically active C_8 hydroxy-allenic acid. Thus the centre of asymmetry C* of the triglyceride occurs not in the glycerol residue but in the aliphatic chain of a C_8 acid[128,129].

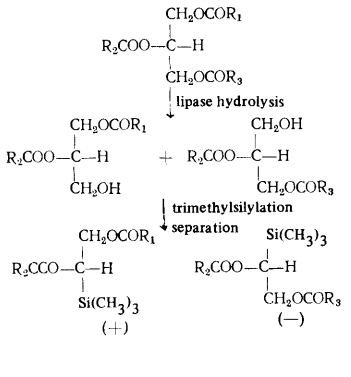
Among natural triglycerides only the *L*-1,2-diacyl-3-acetins—the main components of the seed oils of Euonymus verrucosus, Impatiens edgeworthii, and other plants of the families Celastraceae, Rosaceae, Balsaminaceae, Lardizabalaceae, and Ranunculaceae—have shown measureable optical activity due to asymmetry of the glycerol residue. After hydrogenation the oil contained *L*-1,2-palmitostearo-3-acetin and *L*-1,2-distearo-3-acetin; their mixture had $[\alpha]_{350}^{25°} = 1.9°$, and the main infrared band was located at 8.1 μm, indicating the presence of an acetate group. The optical activity of the stereoisomeric glycerides does not vanish on hydrogenation, storage under ordinary conditions for 6–7 years, or heating to 170°C with the exclusion of acyl migration and oxidation. However, the optical activity was lost after randomisation, which proves that the centre of asymmetry is situated in the glycerol residue of these triglycerides[130–132].

The identification of enantiomers and racemates and establishment of the configuration of cryptoactive triglycerides by physical methods requires the isolation and careful purification of individual glycerides, and these should be examined in the form of crystals. Study of the

piezoelectric excitability of three synthetic triglycerides between electrodes at the a.c. frequency showed that a piezoelectric effect occurred only with enantiomers, but was absent in a racemate. Differences in melting point between the racemate and enantiomers are too small for identification of the latter, and it is therefore necessary to obtain phase diagrams of mixtures of a triglyceride of unknown configuration with each of the corresponding enantiomers [34,118].

It is more convenient to determine the stereoisomerism of triglycerides by X-ray examination. Stereoisomers give the same diffraction pattern, which differs from that due to the racemate. To determine the configuration of 2-OlPalSt of cocoa butter, therefore, the X-ray photographs of a synthetic racemate and of the natural glyceride were compared: the identity of the patterns showed that the natural product was a racemate. If such coincidence had not occurred, it would have been necessary to obtain the X-ray diagram of a mixture of the natural glyceride with one of the synthetic stereoisomers: if the pattern remained unchanged, the cocoa glyceride was idential with this stereoisomer; if not, it was identical with the other stereoisomer [118].

Scheme 7



5. Qualitative Detection of Optical Activity of Triglycerides by Chemical Methods

The detection of optical activity e.g. in vegetable SatUnsatUnsat triglycerides, requires their conversion by lipase hydrolysis into a mixture of the 1,2- and 2,3-diglycerides; the diglyceride acetates obtained by acetylation can be oxidised at the double bonds with a solution of potassium permanganate and periodate to give a mixture of AcAzSat and $AcAz_2$ triglycerides. The presence of rotation in this mixture will suggest non-equivalence in the composition of the acids at positions 1 and 3 in the original SatUnsatUnsat glycerides [41].

Appreciable rotation ($[\alpha]_{546}^{20°} = +3.7°$) was observed in synthetic 1,2-dipalmitoyl-3-sorboyl-*L*-glycerol. It was therefore suggested that polarimetry of appropriate derivatives of 1,2- and 2,3-diglycerides—products of the lipase hydrolysis of the fat—could be used to establish the presence of stereoisomers in a fat [41,120]. Polarimetry was applied to the trimethylsilyl ethers of the diglycerides, since they surpassed both sorbic esters and the diglycerides themselves in angle of rotation $[\alpha]$; furthermore, migration of acyl groups was excluded by their use. The standard was the trimethylsilyl ether of *L*-1,2-dipalmitoylglycerol, with $[\alpha] = +4.7°$. The SatSatUnsat and UnsatUnsatSat glycerides of several natural fats were split with lipase, and measurements of the angle of rotation $[\alpha]$ were made on the stereoisomers of trimethylsilyl-sn-1,2- and -2,3-diglycerides of different acid composition obtained by thin-layer chromatography of the silver complexes (Scheme 7). All the triglycerides studied were active, the angles of rotation of enantiomers being opposite in sign; however, all fractions had lower values than the synthetic standard (Scheme 8). In this way we can first establish the absolute configuration of a glyceride or its predominant stereoisomer [123].

Scheme 8

Fat	Triglycerides	[α] of trimethylsilyl derivative of 1,2-diglycerides		[α] of trimethylsilyl derivative of 2,3-diglycerides		Absolute configuration *sn*-system	Absolute configuration Ingold
Pork fat	SatSat Unsat	SatSat	+1.6°	UnsatSat	-1.3°	Sat—{Sat, Unsat}	(*R*)

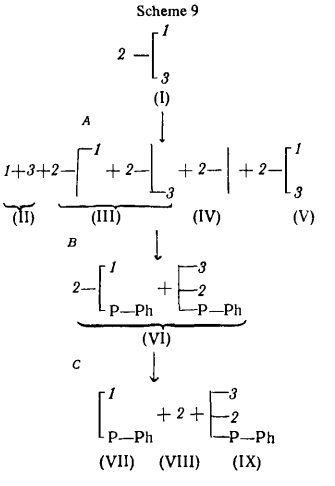
Scheme 9



6. Quantitative Determination with Phospholipase A of the Stereoisomerism of a Natural Mixture of Triglycerides

Brockerhoff's method [125] is based on the steric and positional specificity of lipolytic enzymes (Scheme 9, where *1–3* are acyl groups of fatty acids). Lipase hydrolysis (*A*) of the triglyceride (I) gives the free fatty acids (II), a racemic mixture of *sn*-1,2- and *sn*-2,3-diglycerides (III), a monoglyceride (IV), and unchanged triglyceride (V). The mixture (III) is phosphorylated (*B*) with phenyl phosphorodichloridate to give a mixture of *L*- and *D*-phosphatidylphenols (VI), which is hydrolysed at the 2-position (*C*) by means of stereospecific phospholipase A

(EC 3.1.1.4), to yield *L*-lysophosphatidylphenol (VII), a free fatty acid (VIII), and an unhydrolysed 2,3-diacyl-*L*-glycerol 1-phosphate (IX) (*D*-phosphatidylphenol in Fischer's nomenclature). The composition of the acyls in the 1,2- and 3-positions of the triglycerides can be calculated independently from the acid composition of the initial, intermediate, and final products.

If acyl migration occurs and hydrolysis is specific with respect to fatty acids, the acid composition of the 1,3-positions in the diglycerides will not be identical with that of the original fat [41]. Hydrolysis of *D*-, *L*-, and *DL*-dipalmito-olein by lipase showed that acyl groups *1* and *3* were detached simultaneously and at the same rate, and the diglycerides obtained were optically inactive. The [Pal]/[Ol] ratio in the free fatty acids and in the diglycerides in the reaction mixture (1 : 1 and 3 : 1 respectively) corresponded to the theoretical value [133]. During hydrolysis on a macro-scale stearate was split off more slowly than other acyl groups [68]. To ensure statistical hydrolysis hexane was added to the medium (Section III, 2); this weakened the van der Waals forces that retained selectively the longer and less curved acyl groups on the surface of the fat micelle [9,125]. The detachment of polyunsaturated acids having $m = 20–22$ lagged behind even with hexane, so that they accumulated in the diglycerides. Therefore "marine" fats and also pork fat and maize oil were deactivated with a Grignard reagent (0.06–0.12 M CH_3MgBr in ether): symmetrical monoglycerides and diglycerides showed considerable changes in composition owing to migration of the acyl groups, but 1,2(2,3)-diglycerides corresponded in composition to the original fat, and could be used for stereospecific analysis [9,41,107,134–136]. The composition of the acids of 1,2(2,3)-diglycerides, obtained by hydrolysis on a macro-scale [125,137], differed markedly, by an increased content of saturated acyl groups, from that calculated theoretically. A micro-method of hydrolysis gave better agreement [47,134]. It is possible that statistical hydrolysis is ensured by a diminished calcium-ion level and an increased enzyme content in the reaction mixture [41].

In Brockerhoff's method the diglycerides obtained by hydrolysis (yield 20–30%) were separated into 1,2(2,3)- and 1,3-diglycerides by chromatography on silica gel impregnated with boric acid; in the presence of phenyl phosphorodichloridate, ether, and pyridine at 0°C the 1,2(2,3)-diglycerides were converted into phosphatidylphenols, whose triethylammonium salts were hydrolysed with phospholipase A in ether at pH 7.5 in the presence of calcium chloride. The reaction products were separated by chromatography on an adsorbent impregnated with boric acid, and the acid composition of each fraction was determined by gas chromatography [9,125,135,136]. The compositions of positions 1, 2, and 3 are reliable only if the analytical results show the following equalities: (I) = (V), (III) = (VI), and (IV) = (VIII) (Scheme 9); these indicate that hydrolysis by lipase and by phospholipase has occurred statistically and without isomerisation. The compositions of positions 1 (VII) and 2 (IV) and (VIII) are determined directly; the acid content in the 3-position is calculated in two ways, as either 3[(I) – (IV) – (VII)] or 2[(IX) – (IV)]. An absolute divergence of 4% is acceptable when [A] ≥ 40%, not more than 3% with 10–35%, and at most 2% when [A] < 10%; the error in the calculation does not usually exceed ±2%, and only with difficultly hydrolysable saturated fats does it increase to 8%. [9,10,119,125,136] However, if the results show good reproducibility, only fractions (I), (IV), (VII), and (IX) are analysed [9]. Brockerhoff's method has been tested on synthetic and semi-synthetic triglycerides [125].

Direct analysis of the composition at the 3-position was accomplished by converting the 1,3-diglycerides, obtained by deacylating the fat by means of a Grignard reagent, into *L*-2-phosphatidylphenols and splitting the latter at position 1 with phospholipase A. The resulting lysophosphatides corresponded in acid composition to the 3-position of the initial fat [135].

7. Determination of Absolute Configuration of Individual Triglycerides

In all the fats studied, positions 1 and 3 differ in composition. This proves indirectly the presence of stereoisomeric triglycerides, but does not indicate their nature [123]. However, even identity of composition at positions 1 and 3 in a mixture of triglycerides would not necessarily prove that all the glycerides in the fat were racemates. Thus the ratio of palmitoyl to stearoyl at positions 1 and 3 is unity for the equimolecular mixture—(*R*)-PalOlSt + (*S*)-PalPalSt + (*R*)-PalOlSt + (*S*)-PalPalSt + (*S*)-PalOlSt + (*R*)-PalPalSt—although this mixture contains one-third of the racemate 2-OlPalSt plus one-third of the racemate 2-PalPalSt plus one-sixth of the enantiomer (*R*)-PalOlSt plus one-sixth of the enantiomer (*S*)-PalPalSt. Therefore the absolute configuration can be assessed only by analysing individual glycerides or simple mixtures in which a certain acyl group (e.g. palmitoyl in (*S*)-PalOlSt + StOlSt) is present only in one of the outer positions in one of the glycerides [118].

The problem of analysing the configuration of mixtures and individual types of diacid (A_2B) triglycerides has now been solved, at least in principle: metamers having the same m and e but different numbers of saturated acyls (e.g. StStLinoleoyl and StOlOl) can be separated; the proportions of stereoisomers in A_2B are easily found from the content of the acid B at positions 1, 2, and 3 in the mixture AAB + ABA + BAA. Establishment of the configuration of triacid glycerides—i.e. the proportions of the six possible stereoisomers ABC, ACB, BAC, BCA, CAB, and CBA—is a more complicated matter. From the composition of the acids at positions 1, 2, and 3 it is possible to find the proportions of any pairs of isomers, e.g. pairs with respect to the content of acid A:[122]

(I)				(II)		
AA	BC	BC		AB	AC	BC
BC	AA	CB		BA	CA	CB
CB	CB	AA		PP	PP	PP
				x	y	z

An additional parameter is necessary for calculation of the quantity of each stereoisomer in the mixture (I), and can be obtained by separating the intermediate products in the analysis according to the acid composition: the glyceride ABC is hydrolysed with lipase, and 1,2(2,3)-diglycerides are isolated; the 1,2-diglycerides are converted into phosphatidic acids by means of stereospecific diglyceride kinase, and the acid composition of each position is found by Brockerhoff's method modified by first separating the phosphatidic acids into pairs of stereoisomers according to acid composition (II). The proportions of the pairs x, y, and z are equal to the proportions of the acids C, B, and A respectively in the 3-position. The proportions of isomers within a pair are determined by hydrolysis with phospholipase A [138].

8. Use of Other Enzymes than Phospholipase A for Analysis of Stereoisomerism of Triglycerides

If the glyceride ABC contains oleate, the additional parameter for estimating the stereoisomers can be obtained by means of the lipase of G. candidum (Section III, 4) together with Brockerhoff analysis; the 1,2(2,3)-diglycerides obtained by the elimination of oleate from the 1(3)-positions are converted into phosphatidylphenols, and the ratio of stereoisomers in a pair is determined by hydrolysis with phospholipase A[139].

Other stereospecific enzymes of lipid metabolism are suitable for the analysis of stereoisomerism. A racemic mixture of phosphatidylphenols can be resolved by hydrolysis with phospholipase C, which is specific to the L-isomer[9]. The triglycerides of rat liver have been analysed by means of the diglyceride kinase of Escherichia coli, which converts 1,2-diglycerides, obtained by lipase hydrolysis, 25 times as rapidly as 2,3-diglycerides into phosphatidic acids[137,140,141]. The contents of each acid at positions 1, 2, and 3 were calculated by means of the formulae

$$[A]_1 = (2[A]_{Phtd} - [A]_{MGl}) : 3;$$
$$[A]_2 = ([A]_{MGl}) : 3;$$
$$[A]_3 = [A]_{TGl} - (2[A]_{Phtd}) : 3,$$

where $[A]_{TGL}$, $[A]_{MGl}$, and $[A]_{Phtd}$ are the contents of acid A in the initial triglycerides and in the 2-monoglycerides and phosphatidic acids obtained from them. These equations hold only if the fatty-acid composition of the 1,2(2,3)-diglycerides obtained by lipase hydrolysis corresponds to the calculated composition (Section IV, 6) and substitution of $[A]_{1,2(2,3)}$ for $[A]_{1,2}$ in the equation gives the same acid composition in 1- and 3-positions. The differences observed indicate the minimum error of the method. These differences are often considerable, which is evidence of the fatty-acid selectivity of lipase hydrolysis. It is therefore necessary in each experiment to ensure agreement between experimental and theoretical acid compositions[134].

V. POLYMORPHISM OF TRIGLYCERIDES

1. Lattice Structure and Phase Transitions of Triglycerides

The phenomenon of polymorphism was discovered as early as 1821 by Mitscherlich. The various forms of a given compound differ appreciably in crystal structure, lattice parameters, melting point, density, and other properties, but have the same composition and chemical structure and, unlike position isomers, give an identical liquid or gaseous phase. The crystalline modifications of carbon—graphite and diamond—provide an inorganic example of polymorphic forms. Organic compounds also exhibit polymorphism, especially long-chain aliphatic compounds, including natural glycerides. Before the 1930s the triple melting points of a triglyceride, discovered more than a century earlier, were attributed to the presence of a series of position isomers; only Malkin proved that the melting anomalies were due to differences in the crystal lattice. When a solidified melt (the polymorphic α-form) of a simple Sat_3 glyceride is heated slowly, it melts, and then solidifies again with the evolution of heat, to form the stable β-form or an intermediate β'-form; the latter appears when the melt is maintained at 1–2 deg above the melting point of the α-form. The direction of these transitions, which may not be accompanied by fusion, is from less stable modifications, whose formation requires a minimum change in free energy of the lattice, to thermodynamically more stable polymorphic forms having little free energy. The principal α-, β-, and β'-forms of triglycerides differing in composition and structure have similar properties, since the acyl chains play the decisive part in the polymorphism. However, new, additional polymorphic forms are continually being found in the huge variety of natural fats, and therefore a classification and a nomenclature have not yet been established for the latter. The direction and the products of polymorphic transitions depend on the purity of the material, the presence and nature of a crystal seed, the solvent, the pressure, the temperature, its rate of change, etc. Thus the crystalline, thermal, X-ray diffraction, and other properties of a triglyceride under given environmental conditions can be assessed only after establishment of the polymorphic form in which the compound is then present. Several reviews have appeared on the polymorphism of triglycerides[4,142-154].

X-Ray diffraction indicates that aliphatic chains are zigzag structures with rectilinear axes, in which the angle between the carbon–carbon bonds is 109°28', and the increase in the length of an acyl residue accompanying expansion of the latter by a methylene group is $a = 1.28$ Å.[4] If the temperature is not sufficiently low, close approach of chains to one another is difficult, and the triglycerides remain liquid, without an ordered structure. As the acyls come closer together on cooling, van der Waals forces of attraction become effective between carbon atoms of adjacent chains: i.e. the triglycerides crystallise[146,147].

Crystals formed by identical aliphatic molecules, whose ends differ in polarity, contain a mainly parallel arrangement of chains forming a kind of "palisade" and usually a crystalline double layer by means of the hydrogen bonds of the polar groups. A vivid model of this arrangement would be two bundles of very large numbers of matches, where the heads represent methyl groups and the free ends the polar groups: one bundle is placed with the heads in a plane, and the other with the free ends on the first bundle. Thus the double layers of molecules are bounded by non-polar "methyl" planes, the distance between which is termed the long spacing L (in Å). The value of L found from X-ray examination enables us to determine the number of chains constituting the long spacing[4].

If the double layers $2m$ long are perpendicular to the methyl planes, $L = 2m$. Layers having L which are multiples of $3m$ or $4m$ occur in crystals of mixed glycerides. Mostly, however, $m < L < 2m$, and the angle of tilt between the axes of the chains and the planes $\beta_X < 90°$. The variation in β_X between different crystalline forms is a principal cause of the polymorphism of triglycerides: decrease in β_X strengthens contact between their more polar ester groups, and hence improves the stability of the polymorphic forms[143,146,149]. The value of L for a given form varies with the acid composition of the triglycerides. The hypothesis that decrease in L is due, not to tilting of the chains, but to erratic secondary bends[149], has not yet been proved experimentally.

The parallel chains in triglycerides form a unit cell—a right prism or an oblique prism—whose width, termed the short spacing S, is determined by the mode of packing of chains in the crystal lattice. This is the other main reason for the polymorphism of glycerides. In contrast

to L, values of S for a given form are almost constant and independent of m.[143,147,154]

Fig. 6 shows a model consisting of two pairs of chains in the unit cell of stearic acid[4]. A triglyceride unit cell containing two molecules is more complicated: since the axis of one acyl forms an angle of 180° with those of the other two acyl groups (Fig. 6), each chain in the lattice coincides with the long axis of the four-sided prism formed by the other four chains (Fig. 7)[149].

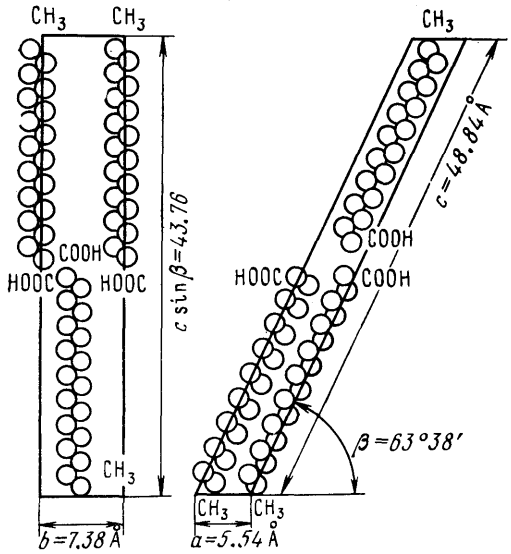


Figure 6. Unit cell of crystal of polymorphic β-form of stearic acid[4]: a and b are short interplanar spacings; $c \sin \beta_X$ is the long interplanar spacing.

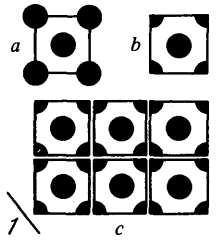

Figure 7. Unit cell of triglycerides[149]: *a*) cross-section; *b*) cross-section with two molecules (or double molecules) belonging to the cell; *c*) cross-section through crystal.

Fig. 8 illustrates possible configurations of the molecules in triglyceride crystals. It was assumed initially that the fork configuration predominates, and later that a chair configuration will give denser packing. X-Ray examination of a single crystal of the β-form of trilaurin has now shown (Fig. 9) that a rod configuration gives the most economical packing with the smallest free energy, without contradicting the principles of symmetry[143,144].

The crystal is seen to consist of $2m$ layers of rodlike molecules in triclinic packing: two acyl groups are located in a straight line, while the third (it is not yet known which—whether the middle or one of the outer acyl groups) is located at their side and parallel to them. Good agreement is evident between values of the angle β_X found from the X-ray photograph and calculated from L (62°7′ and 61°35′ respectively). The rod form ensures also the formation of $3m$ and $4m$ layers in the crystal (Fig. 8)[143,149]. The shape of the molecules in the other main modifications (α and β') has not yet been ascertained[151].

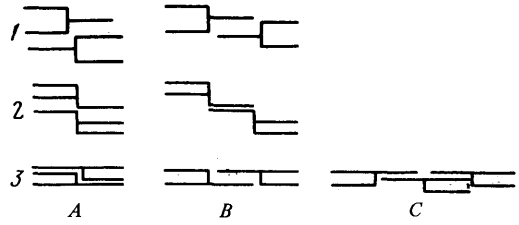

Figure 8. Possible configurations of triglycerides in crystals: 1) fork; 2) chair; 3) rod. Long spacing multiple of: *A*) $2m$; *B*) $3m$; *C*) $4m$.

Phase transitions in heterogeneous systems may be either enantiotropic, i.e. occur reversibly in both directions without melting as the temperature is varied, or monotropic, these being irreversible processes accompanied by loss of free energy in the direction of greater stability, and regeneration of the unstable from the stable form requires intermediate fusion. The phase transitions of triglycerides are mainly monotropic[143].

Pure triglyceride preparations, uncontaminated by homologues of closely similar composition or structure, are necessary in order to obtain sharp polymorphic transitions and forms having definite properties. Thus low-resolution nuclear magnetic resonance spectra indicate the absence of a liquid phase below the melting point in pure specimens of trilaurin and tristearin, but this phase appeared long before melting in contaminated crystals of the β-forms of OlPalPal, PalOlPal, PalOlOl, and StOlSt.[152,161]

In supercooled melts the dependence of the logarithm of the viscosity on the reciprocal of the absolute temperature usually shows a break in the curves immediately below the melting point of the β-form, indicating intensification of aggregation of the glycerides by parallel packing. On the other hand, the crystalline structure of a triglyceride is partly preserved immediately after melting: on rapid cooling, this melt immediately crystallises. After the partly ordered structure of the liquid phase has been destroyed by being kept at a temperature 20 deg above the melting point for 30 min, crystals form slowly[153,160,164]. When tripalmitin is crystallised from a solvent, the properties of the resulting crystals of the β-form depend on the nature of the latter[157].

Table 4 indicates the conditions under which the main polymorphic forms of simple Sat_3 triglycerides are obtained[143,146], together with several methods for investigating the polymorphism. The early methods involved determining melting points in capillary and differential

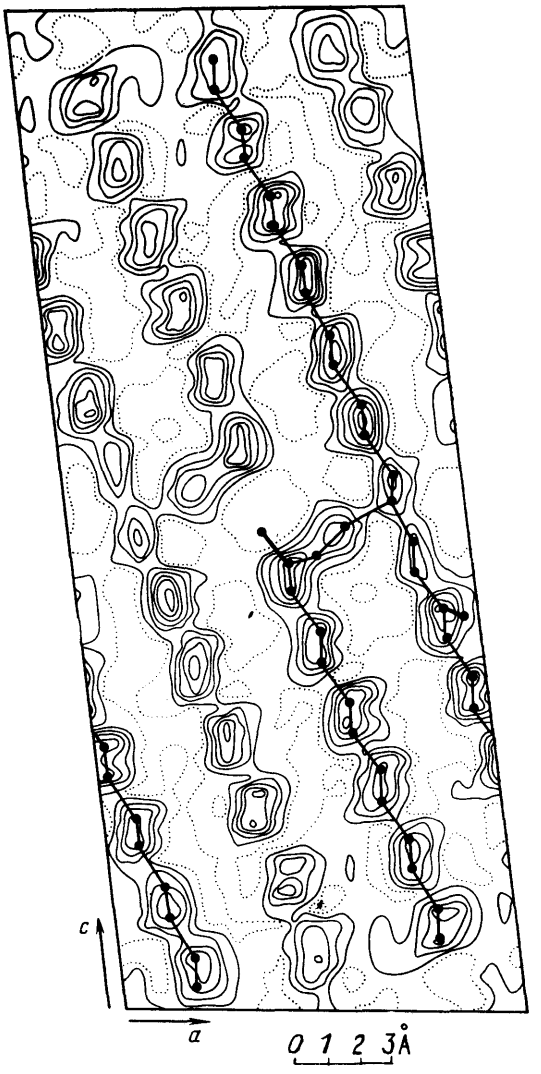

Figure 9. X-ray electron density diagram of polymorphic β_L form of trilaurin[143].

thermal analysis, consisting in recording continuously the evolution of heat during solidification, or its absorption during fusion, from the curves for the difference in temperature between the surrounding medium and a sample of the triglyceride during cooling or heating respectively[4,5,33,155-163]. Dilatometry records the increase in specific volume V_S (in ml g^{-1}) of the triglyceride at a phase transition point—the melting point—and also the equal but opposite change (contraction) at the freezing point. Both processes are recorded as functions of temperature[148,156,158]. Heating the α- and β-forms of tripalmitin in a microdilatometer at a rate of 6.4 deg min^{-1} (Fig. 10) led to the discovery that the differences between initial and final specific volumes when the β-form melts are due to the formation of an intermediate β'-form when the melt sets. The setting of trilaurin and tristearin melts led directly to the metastable α-form, whose stability increased with increase in m; heating the latter resulted in appearance of the β-form[157].

Polymorphic transitions governed by temperature can be detected by periodic determination of the number and magnitude of L and S characteristic of particular forms of a given glyceride, and also from the X-ray diffraction diagrams of the powdered crystals or a large single crystal (Fig. 9)[154,159,164,165]. Changes in the packing of chains on passing from an unstable to a stable polymorphic form can be detected by infrared spectroscopy (Fig. 11) from the characteristic skeletal vibrations at 2–15 μm (5000–600 cm^{-1}).[147,149,155,159,162] Finally, low-resolution nuclear magnetic resonance spectroscopy evaluates the rotational mobility of the acyls in a triglyceride lattice, detects the thermal $\alpha \rightarrow \beta$ transition in tristearin, and enables small quantities of liquid phase in triglyceride crystals to be determined to ±2%. This method is more effective than dilatometry, which gives only the relative content of the solid phase[161,164].

2. Polymorphic Forms of Trisaturated Triglycerides

The polymorphic forms and several of their properties are given in Table 4;[143,146] fuller information will be found in Markley's monograph[4]. There is as yet no generally

accepted nomenclature for the forms (Table 4). Malkin's early nomenclature, which distinguishes four forms of a given glyceride—vitreous, α, β', and β—in order of rising melting point, is defective, since different forms differing in crystalline structure may have closely similar or even identical melting points [4,145,149]. According to Lutton no vitreous form devoid of crystalline structure actually exists, and there are only three main forms—α, β', and β-characterised by the spacing S (Table 4). [147,154,165,166] To avoid confusion the nomenclature used for a given form is denoted by a subscript indicating the author (α_M, α_L, β'_L, etc.), and the number of chains in L is denoted by a numeral following the subscript (β'_L-2, β'_L-3, etc.). [144,146,151,159]

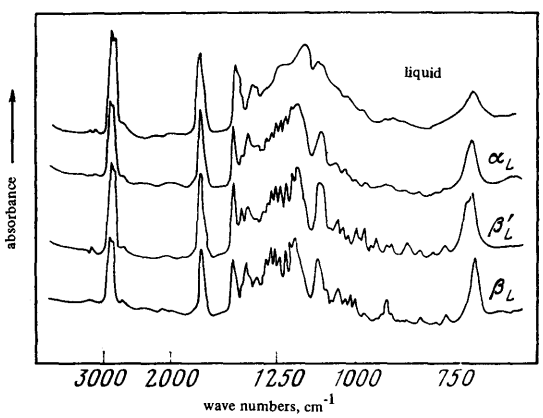

Figure 11. Infrared spectra of polymorphic forms of tristearin [143].

The number and the properties of individual polymorphic forms of triglycerides have been determined also by infrared spectroscopy. The characteristics of the infrared spectra of melts or solutions of simple Sat_3 glycerides are given in Table 5. [33,142,155,159] Solid glycerides are characterised by the intensity and the number of vibrational bands in group V; three types of infrared spectra, corresponding to Lutton's principal modifications, have been found from these sets of bands (Table 4).

In the α_L modification (Table 4), which is formed from the melt, the chains are 5 Å apart, and rotate freely about their vertical axis. The numerous bands due to the α_L form at 1250 cm^{-1} prove that it is crystalline, not vitreous as assumed by Malkin. In the glycerides trilaurin and above, which have a stable α_L form, the number of these bands is $\frac{1}{2}m$, which enables the length of the acyls in the glycerides to be determined from the infrared spectrum [143].

The properties of the β'_L form (Table 4) indicate the usual orthorhombic packing of two types of tilted chains, in mutually perpendicular planes. Formation of this modification of tristearin has been observed on crystallisation from paraffin oil [143,152].

Finally, the β_L form (Table 4) corresponds to triclinic packing, in which all planes of the zigzag aliphatic chains are mutually parallel. The chains themselves are more stable and are packed more densely than in the α_L form. In tristearin the amplitude of rotational oscillations of the chains about the vertical axis does not exceed 17°. [143]

The nomenclatures of Malkin and of Lutton do not enable triglycerides to be compared with other aliphatic compounds with respect to the properties of their polymorphic forms. In Gunstone's nomenclature [146] the polymorphic forms of long-chain saturated compounds are divided into five groups according to the angle β_X, triglycerides occurring in the first three groups V, U, and T (Table 4). The value of L in crystals of mono-, di-, and tri-acid Sat_3 triglycerides ABC (the acyl group B always occupies the 2-position), being a linear function of the chain length m, can be calculated by means of the equation $L = 1.28 \sin \beta_X (m_A + mB + mC) + c$, where m_A, mB, and mC are the numbers of carbon atoms in the acyls A, B, and C, while c is the constant increment in L (in Å) representing the length of a glycerol residue and the zone of contact of the ester groups. Table 4 gives values of c for $2m$ and $3m$ layers of simple and mixed triglycerides containing acyl groups A, B, and C of different lengths. For a double ($2m$) layer m_A in Gunstone's equation is regarded as zero. Good agreement was found between calculated values of L and those obtained from X-ray data [146].

Table 5. Main absorption bands in the infrared spectrum of simple trisaturated triglycerides.

Group of vibrations	I	II	III	IV	V
Absorption bands, cm^{-1}	3030—2967	1751—1733	1464—1453, 1383—1361	1179—1166	1261—1250, 730—717
Vibrating group	C—H	C=O in COOR	CH_2	C—O	CH_2
Mode of vibration	stretching	stretching	scissor deformation	stretching	rocking deformation

Gunstone's numenclature showed for the first time that each polymorphic form is characterised by a definite angle of tilt, but it is unsuitable for calculations on unsaturated glycerides and does not allow for additional polymorphic forms of simple Sat_3 glycerides having the same value of β_X as the principal modifications [151]. The sub-α_L form is one such additional modification: it is produced without fusion from the α_L form of tristearin at −50°C, is converted reversibly into the α_L form, and is identical with the β'_L form in all properties other than the angle $\beta_X = 90°$. Crystallisation from a solvent or heating of the α_L form sometimes results in the appearance of a series of stable β_L forms, identical in diffraction pattern but differing in β_X. In contrast to "even" triglycerides, "odd" acids are stable not in the β_L but in the β'_L form [142,143,152,159].

Attempts to allow for the additional forms were made by Hoerr and by Larsson. Hoerr's nomenclature allows for four modifications—α, β', intermediate, and β—in order of rising melting point. The intermediate modification, which appears when the α form is heated, has since proved to be a mixture of equal quantities of orthorhombic and triclinic forms [146,148]. According to Larsson, (1) forms having a single value of $S = 4.15$ Å are denoted α; (2) forms having two values of S (4.2 and 3.8 Å) and a doublet at 720 cm^{-1} are denoted β'; and the symbol β is applied to all forms which do not correspond to criteria (1) and (2), the presence of several such forms of a given glyceride being indicated by β_1, β_2, etc. in order of decreasing melting point. According to Larsson all planes of the zigzag chains are parallel in β forms, mutually perpendicular in β' forms, and show no definite regularity of arrangement in α forms [151].

Lutton's nomenclature, in spite of its defects, has remained the most acceptable up to the present. It comprises three main forms of simple Sat_3 glycerides—unstable α_L, intermediate β'_L, and stable β_L—which must be regarded as sets of crystalline modifications that have closely similar properties but are not identical. Further research is required to achieve a complete classification [143].

Table 6. Polymorphic forms of some di- and tri-acid saturated triglycerides.

TGl	Δm	Principal forms			Additional forms	Infrared spectrum resembles	Remarks
		α_L-2	β'_L-2	β_L-2			
PalStSt	+2	+	+	+	β_L-3	StStSt	(*a*)
StPalPal	+2	+	+	+	ditto	PalPalPal	
StPalSt	−2	+	−	+	»	StStSt	(*b*)
PalMyrPal	−2	+	−	+	»	PalPalPal	(*b*)
PalStPal	+2	+	+	−	»	PalPalPal	(*c*)
MyrPalMyr	+2	+	+	−	»	MyrMyrMyr	(*c*)
StMyrSt	−4	+	+	+	β'_L-4	StStSt	(*d*)
StLaurLaur	−6	+	+	−	β'_L-3, β_L-3		

(*a*) β'_L and β_L forms equally stable.
(*b*) β_L form the most stable.
(*c*) β'_L form the most stable; β_L form difficult to detect.
(*d*) β_L and β'_L forms have similar values of L.

The polymorphism of diacid and triacid Sat_3 glycerides (Table 6) is extremely individual, depending on the difference Δm between the lengths of the acyls in the 1,3- and 2-positions, the symmetry of the structure, and the presence of an acyl of a lower fatty acid in the 2-position. Sets of polymorphic forms are analogous in homologous series of triglycerides having a certain value of $+\Delta m$ or $-\Delta m$, while symmetrical and unsymmetrical triglycerides of the same composition have identical values of L for $2m$ and $3m$ layers, in good agreement with Gunstone's calculated value (Table 4). In different triglycerides the β_L, β'_L, or α_L form is the most stable. Thus in the glycerides of behenic acid the β'_L forms, not the β_L forms, are stable. Those which are difficult to detect are formed only in the presence of crystals of succinic acid. Mixed glycerides containing two acyls of any acid are almost identical with simple glycerides of the same acid in the number of infrared bands of the α_L form in the region of 1250 cm^{-1}. [142,143,159,166,167] The complexity of the polymorphism increases with the absolute magnitude of Δm (Table 6). An important part in the polymorphism of mixed glycerides containing acyls of volatile acids is played by the carbonyl groups of the latter, with the formation of unique polymorphic forms [4,146,154].

3. Polymorphic Forms of Other Types of Triglycerides

The less studied simple $UnSat_3$ triglycerides in general resemble one another and the corresponding Sat_3 glycerides in the set of polymorphic forms and their properties. Sometimes additional forms occur, e.g. β_L-3 in *cis*-unsaturated triglycerides, which are characterised by bands at 690 and 1660 cm^{-1} due to scissor vibrations of the hydrogen atoms in the *cis*-bond. Triolein resembles tristearin in the main infrared absorption bands of the polymorphic forms at 723 (α_L), 729 and 722 (β'_L), and 722 (β_L) cm^{-1}. When the *cis*-bond is replaced by a *trans*-bond, a band appears at 963 cm^{-1} in all the modifications, and the similarity of the polymorphism with that of Sat_3 glycerides of the same length is still more pronounced. The number of $Unsat_3$ bands at 1250 cm^{-1} is $\frac{1}{2}m$, as with Sat_3 (Section V, 2) [142,144]. Thus unsaturation in simple triglycerides has little effect on polymorphism [4].

Table 7. Properties of polymorphic forms of triglycerides of cocoa butter, 2-OlPalSt and 2-OlStSt.

Form	sub-α_L-3	α_L-2	β'_L-2	β_L-3 (V)	β_L-3 (VI)
Melting point, °C	17	23	27	33	36
Short spacing, A	3.8and4.2	4.2	3.8and4.2	4.6	4.6

Triglycerides of the type SatUnsatSat, constituting ~ 80% of the economically important oil of cocoa beans, have a large set of polymorphic forms. The polymorphism of this oil has been well studied, since it was the chief method of determining the structure of glycerides before the appearance of lipase hydrolysis [168-171]. Crystalline fractions of the oil are identical with a mixture of synthetic PalOlSt, StOlSt, and PalOlPal, while the PalOlSt isolated from the oil coincides with the synthetic triglyceride in melting point, heating curves, dilatometry, diffraction patterns, and infrared spectra of their individual polymorphic forms before and after hydrogenation (Table 7) [33,142]. A mixture of PalOlSt and StOlSt gives three polymorphic forms and differs from either component in rate of conversion of unstable forms, whereas a mixture of StOlSt and StStOl (1 : 3) may give a new crystalline form not present in the initial components [150, 162,165]. Comparison of the polymorphism of StOlSt and StStOl showed no parallelism with the corresponding saturated isomers (Table 6). [168] In homologous series PalPalOl is analogous to StStOl in its polymorphism, and PalOlPal is analogous to StOlSt; in the unsymmetrical $SatUnsat_2$ glycerides StOlOl and PalOlOl, as also with StStOl and PalPalOl, the β'_L-3 form is stable [170]. Nuclear magnetic resonance spectroscopy indicates that the oleate chains in StStOl are less densely packed than are the saturated acyls, and rotate more freely about the axis [4,5, 143,144].

Polymorphism has been most thoroughly studied, apart from StStOl, on the SatSatUnsat glycerides of pork fat [89]. The main component is identical in the properties of its polymorphic forms with OlPalSt [33,150]. Coarse-grained crystals of the β'_L-3 form of this triglyceride appear when pork fat is stored at 27°C, and impair the appearance of the product [172], a phenomenon which is eliminated by transesterification (Section II, 1). [163] In contrast to OlPalSt, StStOl, and PalOlOl, the symmetrical glycerides of pork fat OlStOl and OlPalOl give the forms α_L, β'_L-2, and β_L-3, the last of which is stable [170].

The β_L form is stable in native, hydrogenated, and transesterified beef and mutton fats and in their Sat_3 glycerides [5,163], but the β'_L form, obtained by crystallisation from hexane in the presence of succinic acid, in hydrogenated cottonseed oil, where PalStPal predominates

(Table 6).[172] Transition to the stable polymorphic composition is accelerated by mixing fats rich in SatSatUnsat with fats containing much SatUnsatSat[150,168], and also by keeping at a constant temperature[154]. Thus several vegetable oils acquire a grainy texture during winter storage, owing to the direct transition of the α_L form of the Sat_3 glycerides into the β_L form[4,170].

Study of the polymorphism of natural fats has made progress, and has shown in particular that their structure is not statistical. Further investigations should give a more complete picture of the polymorphic forms of triglycerides, especially the unsaturated compounds, which constitute the major part of the world production of fats, although their polymorphism has been little studied as yet[146]. Determination of the totality of properties of all crystalline modifications of corresponding synthetic and natural triglycerides is important for identification of the latter with respect to composition and structure[5]. The polymorphic properties of a fat are important also for its technical appraisal[164] with respect to consistency, plasticity, graininess, and other properties[142,143].

The Application of Electrophysical Effects to the Study of the Thermal Decomposition of Solids

A.A.Kabanov

A critical review is presented of work on the thermal decomposition of solid inorganic compounds, based on electrophysical phenomena (electrical conductivity, photoconductivity, contact phenomena, thermo-e.m.f., Hall voltage, and dielectric characteristics). It is shown that electrophysical methods offer an effective approach to the study of the thermal decomposition of solids. The need for further developments in the experimental procedures available, and for comprehensive analysis of the results, is stressed. 156 references.

1. INTRODUCTION

Studies of the mechanism of chemical reactions in the solid phase have both theoretical and practical importance, because many of the reactions used in industrial practice involve solid compounds. Thermal decomposition reactions occur in the metallurgical industry, in the production of catalysts, in the synthesis of new semiconductor materials and phosphors, in the preparation of ferrites, and in the decomposition of explosives. The solution of the problems presented by the control of all these processes is tightly bound up with an understanding of their mechanisms and their kinetics.

Even as recently as 10 years ago, very little attention was paid to the physical aspects of thermal decomposition reactions, but there is no longer any doubt that a sound understanding of the correlation between the kinetics and the electrophysical characteristics of decomposition reactions involving solid inorganic compounds is essential to further progress. The predominant role of ionic and electronic crystal defects in determining decomposition mechanisms and various electrophysical properties has been convincingly demonstrated[1,2]. Electrical conductivity, photoconductivity, contact phenomena, thermo-e.m.f., Hall voltage, and dielectric effects are among the electrophysical phenomena which have been most widely studied. A systematic appraisal of the electrophysical methods of investigation of thermal decomposition reactions, and an analysis of the results, are now needed.

2. STUDIES OF THERMAL DECOMPOSITION BY MEASUREMENTS OF ELECTRICAL CONDUCTIVITY

McDonald and Sandison[3] tried to determine the form of the nuclei of the new phase produced during the thermal decomposition of silver oxalate by combining measurements of electrical conductivity with kinetic studies of the decomposition reaction. For the case of two-dimensional (planar) nuclei, a sudden increase in electrical conductivity was expected when the nuclei began to coalesce (10–25% decomposition). However, the jump in conductivity was observed experimentally at 60% decomposition. The authors concluded[3] that three-dimensional (spherical) nuclei are formed in this reaction. Bel'kevich and Osinovik[4] repeated this work, and arrived at the opposite conclusion. Coalescence of the silver nuclei was observed at 17–30% decomposition of the silver oxalate, suggesting the formation of two-dimensional nuclei. Thus, entirely different results were obtained in nominally similar experiments. One possible explanation is that detailed differences in technique were responsible for the discrepancy, including sample preparation before pressing (drying, ageing, grinding), during pressing (temperature, pressure, duration), choice of electrode material and method of deposition, and, lastly, strength and frequency of the electric field used in the measurement and duration of the electrical stress applied to the sample. No special mention of these experimental details is made in the published papers[3,4], and therefore it is difficult to comment meaningfully. McDonald and Sandison did not describe their measurements of electrical conductivity. Bel'kevich and Osinovik's only comment is that electrical conductivity was measured with pressed samples, using a constant applied d.c. voltage of 1.3 V. The present writer has made a special study[5] of the influence of a d.c. electric field of 80 V cm^{-1} on the electrical conductivity and on the decomposition kinetics of pressed samples of silver oxalate. The field was applied continuously, or intermittently. Bel'kevich and Osinovik[4] have shown that the rate of decomposition of the sample goes through a maximum at the instant when the flash is observed: we have used this observation in our measurements. In the absence of an electric field the sample flashed at 143 ± 4°; with a periodically applied field (5 s, at 10 min intervals) the flash took place at 130 ± 2°, and when the field was applied continuously the sample flashed at 122°. In all cases, the extent of decomposition at the moment of the flash was the same, and a sudden increase in conductivity was observed. Hence it was concluded that a steady electric field accelerates the thermal decomposition of the oxalate, but has no effect on the shape of the silver nuclei. Savel'ev and Greben'[6] placed silver oxalate between condenser plates with a field of 6–10 kV cm^{-1}, and they also observed an accelerated vacuum thermolysis of the oxalate. Similar effects were found with silver and barium azide. The influence of a constant magnetic field (1100 Oe) on the decomposition of these compounds was also examined: both types of field were found to accelerate the thermal decomposition of

barium azide, and to lower the rate of decomposition of silver oxalate. Since transverse electric and magnetic fields can influence only electronic processes, it follows that these processes must play an important role in the thermolysis of barium azide and silver oxalate. These facts give valuable insight into the development of methods for studying electronic processes, and also into the nature of the electronic steps in the thermal decomposition of solids. Sviridov and Branitskii[7] showed that silver oxalate is readily decomposed by grinding: 35% decomposition of the oxalate can be achieved by grinding the material for 20 min. During this treatment the colour of the material changes from white, through grey, to black. We have noted a colour change in silver oxalate during cold pressing. Thus, the grinding and pressing operations used in the prepatation of the samples can lead to the mechanochemical decomposition of the oxalate, with formation of a solid product (colloidal silver) which acts as a catalyst during the subsequent thermal decomposition[8]. But what is the shape of the growing silver nuclei during thermolysis of the oxalate? Assuming that the shape of the silver nuclei is unaffected by the partial decomposition during pressing of the samples and by other artefacts during sample preparation and measurement of the electrical conductivity, and taking into account Griffith's observation[9] of a layered structure in the silver nuclei, Bel'kevich and Osinovik's hypothesis seems the more credible.

Garner and Heycock[10,11] monitored electrical conductivity in their study of the induction period attending the thermal decomposition of lithium aluminium hydride at 100°, and observed parallel changes in conductivity and in pressure of hydrogen evolved. The electrical conductivity increased by a factor of 2 (from 3×10^{-8} to 6×10^{-8} ohm^{-1}) in the first 35 min, reaching a maximum. After 45 min the conductivity had reverted to its original value, and after 160 min a minimum in conductivity was observed. After 500 min the conductivity rose sharply, as a result of the coalescence of the aluminium nuclei. The maximum and the minimum in electrical conductivity correspond roughly to points of inflection in the kinetic curves describing the thermolysis of the material. After the first point of inflection the rate of decomposition decreases by approximately 13%, and after the second point of inflection (corresponding to the conductivity minimum) the rate increases to a value 9% higher than the initial rate. Thus, a clear correlation exists between the rate of decomposition and the electrical conductivity of $LiAlH_4$. The authors showed that lithium aluminium hydride is a semiconductor, and suggested that its electrical conductivity at 100° is due to the presence of F'-centres. They further suggested that the formation and growth of aluminium nuclei proceeds by the association of F'-centres along dislocations and internal surfaces. The initial increase in conductivity is ascribed to an increase in the concentration of F'-centres (due to the desorption of hydrogen from the surface) and diffusion of the new F'-centres into the bulk, and the decrease in conductivity is identified with the association of F'-centres to give aluminium nuclei. This work provided one of the first unambiguous correlations between decomposition kinetics and changes in electrical conductivity.

Following the work of Garner and Heycock, Weidenthaler also reported a correlation[12,13] between conductivity and extent of decomposition as a result of his study of the thermolysis of silver oxide (in the form of pressed disks). The surface of the samples was found to be covered with a layer of Ag_2O_3, and the silver oxide behaved like an n-type semiconductor. Weidenthaler interpreted the proportionality between the extent of decomposition and the electrical conductivity of Ag_2O as evidence for the reaction

$$O^{2-} \rightarrow \square^{-} + 2\bar{e} + {}^1/_2O_2,$$

where $\square^-$ is an anion vacancy and $\bar{e}$ is a quasi-free electron.

However, other workers[14,15] found that silver oxide behaves like a typical p-type semiconductor. Garner and Reeves[16] measured the resistance of silver oxide samples undergoing thermolysis under "equilibrium" conditions (i.e. heated in an oxygen atmosphere), and observed a constant electrical conductivity and an activation energy (for the thermal decomposition of Ag_2O) approximately 6 times higher than Weidenthaler's value.

Torkar and coworkers[17,18] discussed the mechanism of thermal decomposition of silver azide in terms of their measurements of electrical conductivity. They observed a number of singularities in the temperature dependence of conductivity of silver azide samples heated at a uniform rate. The low-temperature electrical conductivity is ascribed to cation conduction by vacancies, and the high-temperature region (with a higher activation energy) to cation conduction by interstitials. In the high-temperature region sodium azide decomposes, and its electrical conductivity decreases because some of the interstitial ions are removed by the decomposition process. Further decomposition leads to an increase in conductivity, associated with the coalescence of the nuclei of the new phase. Under vacuum conditions the rise in conductivity is followed by full interlocking of the nuclei, and the electrical conductivity becomes independent of temperature over an appreciable temperature range. This stage is followed by flash decomposition. When the measurements are made in the air, the temperature coefficient of conductivity at first decreases, but eventually the activation energy adopts the same value as before the formation of nuclei, which is explained by the break-up of nuclei at the surface. These results were used to confirm the Mott mechanism of formation and growth of nuclei, involving alternate capture of electrons and interstitial cations. It would be interesting to devise an experiment to determine directly the nature of the current carriers. Conduction by vacancies can easily be distinguished from conduction by interstitials by the sign of the thermo-e.m.f., since these carriers stand in the same relationship as electrons and postive holes[19].

The writer has observed[20] anomalies in the temperature dependence of the electrical conductivity of silver sulphite, similar to the behaviour of silver azide. Above 156° the rate of thermal decomposition of silver sulphite begins to increase rapidly, and the electrical conductivity decreases and passes through a minimum. This effect is not observed[20,21] if the pressure used in the preparation of the samples is kept below 4 tonnes cm^{-2}, probably because conditions in low-density samples are not conducive to the development of ionic processes,[22] or because the partial mechanochemical decomposition of the sulphite does not take place at low pressures. The decrease in electrical conductivity was explained (as in the work of Torkar) by postulating association of interstitial cations, in keeping with currently held views on the mechanism of thermal decomposition of silver sulphite[23]. The sign of the thermo-e.m.f. confirms that interstitial cations are responsible for the fall in conductivity; the lack of dependence of the effect on the composition of the atmosphere leads to the same conclusion.

In ammonium perchlorate, heated in the temperature range 230–270°C, the rate of thermal decomposition[24] goes through a maximum (238°) and a minimum (251°). We find[25] that the thermal conductivity of the perchlorate (in contrast to that of silver sulphite) varies in the same sense as the rate of decomposition. This is evidently due to the generation of intrinsic current carriers during the decomposition of the perchlorate. Adopting Boldyrev's interpretation[26] of the initial stages of the thermolysis of ammonium perchlorate, and taking electrophysical data into account[25], it is easy to account for these anomalies. The native current carriers in ammonium perchlorate must be proton vacancies, since their concentration increases during decomposition of the perchlorate.

Zhuravlev and coworkers[27] studied the decomposition of silver oxalate, and observed a minimum and a maximum in electrical conductivity 60 and 120 min respectively after the crystals had been heated to the decomposition temperature. Conductivity was measured on crystals $2 \times 0.1 \times 0.1$ mm^3 in dimensions by a contactless method. The fall in conductivity during the initial stages of decomposition was ascribed to the loss of weakly held interstitial cations, with formation of silver nuclei. A special study of the desorption of water molecules in relation to this effect showed that desorption of water does occur, but its contribution to the loss of electrical conductivity by a factor of 6 during the early stages of decomposition is far from predominant. The subsequent increase in conductivity is due to the accumulation of metallic product. Although the authors did not specifically attempt to investigate the mechanism of thermal decomposition, their experimental methods are undoubtedly interesting.

Young[22] studied the electrophysical properties of silver azide before and during decomposition, and concluded that the best method for studying the sintering of solids is to measure electrical conductivity with a d.c. applied potential, using powdered samples held between metallised glass plates. Detonation of the silver azide was observed in d.c. fields in excess of 250 V cm^{-1}. Young stresses the importance of the method of sample preparation and of the rate of heating and cooling in controlling the reproducibility of conductivity measurements. However, we cannot accept his conclusion that ionic conduction is more developed in the denser samples. Thus, Gladkovskii and Meiklyar[28] concluded from their electrical measurements that single crystals of silver bromide are electronic semiconductors, whereas polycrystalline samples show mainly ionic conductivity. Andrievskii and coworkers[29] observed faster diffusion of various ions (in isotopic form) in polycrystalline cuprous oxide than in single crystals of the same oxide. The conditions which favour the ionic or the electronic component of the conductivity are probably best discussed in the light of the structural and defect parameters of the samples.

It has been shown[30–36] that potassium permanganate and its solid decomposition products are electronic semiconductors, and the elementary mechanism of the thermolysis of this compound has been discussed[37]. The formation of potassium manganate (one of the decomposition products) in solid solution raises the conductivity of potassium permanganate in the structure-sensitive region and lowers the activation energy for conduction. Similar effects were observed in measurements of the conductivity of partly decomposed samples. It was concluded that the manganate formed by thermal decomposition of potassium permanganate is initially present in solid solution, in agreement with the report[38] that the crystal lattices of potassium manganate and permanganate are isomorphous, and with Glemser and Buthenuth's work on the decomposition of potassium permanganate in the beam of an electron microscope.[39] The writer has pointed out[36] that the β and γ modifications of manganese dioxide can be distinguished by the temperature dependence of their electrical conductivity, and hence that the manganese dioxide obtained as the end product of the thermal decomposition of potassium permanganate is not in the β modification. These results have shed new light on the differences of opinion[40–43] regarding the catalytic effect of manganese dioxide on the thermolysis of potassium permanganate: the discrepancies were due to failure to take account of the crystalline modification of the dioxide.

The method of homo-phase additives is widely used in studies of the influence of microdefects on the thermal decomposition of ionic salts. By artificially varying the concentration of a given kind of point defects in a crystal—usually Schottky or Frenkel' defects—the role of various defects in the thermal decomposition of the crystal can be clarified and suggested intermediate steps can be confirmed. Furthermore, the homo-phase additive method gives an indication of the presence of ions of different valency in the lattice of a solid electrolyte. Measurements of electrical conductivity are most commonly used for this purpose, since they offer a quick and simple test for substitutional solid solutions. When solid solutions are formed, the plot of electrical conductivity against concentration of additive has a characteristic V-shape[44–48]. The method enables the ionic defects which act as the main charge carriers to be identified (cations, anions, cation vacancies, anion vacancies), and it allows their concentration and mobility to be calculated by the Koch–Wagner method[49,50]. However, the homo-phase additive method has also a number of shortcomings. As a rule, only the change in concentration of ionic defects is considered, even though several other changes may occur in the crystal at the same time. The additive can affect the mobility of the ionic defects, the lattice parameters, and the concentration of electronic defects. High concentrations of additives can deform the crystal, thus perturbing the crystal field, and generating localised stresses in the crystal which can influence the electronic steps in the thermal decomposition reaction. Radically different conclusions can result if all the relevant factors are taken into consideration in the discussion of the effect of additives on the rate of a solid-phase reaction[47]: hence, it is important to give due weight to all such factors. The problem is by no means new. For example, lattice deformation and a change in the lattice parameters of silver oxalate were detected by X-ray diffraction[46] when bivalent lead ions were added in concentrations above 1 mol.%. Solov'eva and coworkers[51] stressed the need to allow for the effect of impurities on the mobility of ionic defects in studies of solid-state reactions. Brenet[52] observed that either the β or the γ modification of manganese dioxide can be obtained as the decomposition product of manganese nitrate by adding different homo-phase impurities, and that these modifications have different catalytic properties[53]. Lastly, a common weakness of many investigations by the method of additives is the lack of firm evidence on the amount of impurity which has entered the lattice. In this respect, the recent application of ESR by Boldyrev and coworkers[47,54] to the quantitative determination of impurity in the lattice is noteworthy.

Thus, relatively few papers have been published on the rational application of electrical conductivity measurements to the study of thermal decomposition mechanisms in solids, but the results obtained so far offer conclusive

evidence that these measurements give valuable information when interpreted in the light of recent advances in solid-state physics. Thus, the further application, development, and refinement of these methods is to be welcomed.

3. USE OF PHOTOCONDUCTIVITY PHENOMENA

Maclaren and Rogers[55] observed photoconductivity in the region of the long-wave intrinsic absorption edge of undecomposed silver azide. With a partially decomposed sample the photoconductivity maximum is shifted towards longer waves, as a result of the photoeffect in the silver nuclei. The authors concluded, from the existence of photoconductivity at the decomposition temperatures of silver and lead azides, that the first decomposition step consists in the transfer of an electron to the conduction band, followed by trapping of the electron at an interstitial cation: the latter condition is favourable to the decomposition of the N_3 radical. These results suggest the possibility of applying photoconductivity measurements to the study of the nucleation of metals in azides, and to the interpretation of the autocatalytic effect of the solid decomposition product in azides. The catalytic effect of electron-acceptor impurities, predicted by this mechanism, was demonstrated by Mitchell.[56] Young's more careful measurements showed[22] that photoconductivity is absent in freshly prepared silver azide, and becomes significant only after partial decomposition of the material. This worker suggested that all the specimens used by Maclaren were partly decomposed by irradiation or by spontaneous ageing.

Forty and coworkers[57] studied nucleation in lead iodide undergoing thermal decomposition from the accompanying photoconductivity changes. The photoconductivity decreases as soon as lead nuclei appear: this effect is ascribed to the acceptor properties of the nuclei. The nucleation of lead in lead iodide is very fast at 180° because of the ready association of F-centres at this temperature, with trapping of free electrons. However, the nucleation of a new phase and loss of photoconductivity may result, also, from free electron trapping at interstitial cations. Dedman and Lewis[58] studied photoconductivity in lead azide with the aim of correlating the electrophysical properties and the decomposition kinetics of the compounds. Measurements of dark conductivity and photoconductivity in polycrystalline and single-crystal samples of lead azide gave different results. Heat treatment increased both the dark conductivity and the photoconductivity of the material, possibly as a result of incipient decomposition. The photocurrent was ascribed to exciton dissociation with formation of free electrons and positive holes. The dissociation energy of the excitons was calculated from the temperature dependence of the photoconductivity. The increased photoconduction in partially decomposed crystals was explained by postulating an increase in the mobility of the electrons.

Boldyrev and Skorik[59] studied the gamma- and photoconductivity of silver and barium azides under thermal decomposition conditions. In the decomposition of barium azide the electrical conductivity was significantly increased by irradiation with X-rays (using a dose rate of 110 rad min^{-1}). In the thermal decomposition of silver azide neither gamma- nor photoconduction was observed. The authors suggest that the decomposition of barium and silver azides proceeds through the formation of free electrons followed by electron capture at interstitial cations, and they conclude that the rate of thermal decomposition of the azides should be proportional to the concentration of free electrons as long as this concentrarion is smaller than the concentration of electron traps. It is suggested that this condition obtains in barium azide, since its rate of decomposition increases during irradiation with X-rays. The rate-limiting step in the thermal decomposition of barium azide is thought to be, on the basis of the above results, the transfer of an electron from an anion to the conduction band. In silver azide, on the other hand, the rate of thermolysis is unaffected by irradiation. It follows that the excitation of electrons to the conduction band is not rate-limiting in the decomposition of silver azide, in spite of statements to the contrary[49,55].

Zakharov and Savel'ev[23,49] concluded, from the absence of photoconductivity in pressed samples of silver sulphite and oxalate, that the thermal decomposition of these compounds involves the excitation of electrons from the valence band to exciton levels, and not to the conduction band. The absence of photoconductivity was used as an argument for classifying silver sulphite and oxalate among ionic conductors. Photoconductivity (like the Hall effect[60]) is one of the most accurate and unambiguous methods for the detection of electronic conduction in ionic compounds, but even when these effects are vanishingly small it cannot be argued that significant (or even predominant) electron or hole conduction must be absent[61]. This situation may arise through the dependence of the photoconductivity and the Hall e.m.f. on the mobility of the charge carriers: thus, the method is severely restricted by the limitations of the existing apparatus and experimental techniques for measuring these characteristics. It has been shown[62] that the Hall e.m.f. becomes very difficult to measure when the electron (or hole) mobility is lower than 0.04 $cm^2 V^{-1} s^{-1}$. Photoconductivity is difficult to measure[63] in semiconductors with a carrier lifetime below 10^{-4} s. Thus, arguments on the exciton mechanism of the initial stages of thermal decomposition of solids should be accepted with caution if they are based solely on the absence of photoconductivity or Hall effect.

4. APPLICATION OF ELECTROPHYSICAL PHENOMENA AT THE BOUNDARY BETWEEN TWO SOLIDS

Electronic effects[64-66] at the interface between two solids have been used with success[67-73] to discuss catalytic and autocatalytic mechanisms in the thermal decomposition of ionic salts. Because of differences in work function between the host material and impurities, the region of the crystals adjacent to the contact may become enriched or depleted in electrons. According to recent views[1,2,74], the thermal decomposition of ionic salts involves both electronic and ionic steps. Any change in concentration of the free electrons in the reaction zone can affect (directly or indirectly) the rate of thermal decomposition of the material[68,75]. Electrons near the contact always tend to pass into the medium with the higher work function. By suitable choice of dopants, this effect can be used to bring about a redistribution of the electron density near the surface in the desired sense. The effectiveness of catalytically active impurities is determined by the thickness of the depleted layer, which is proportional to the contact potential difference.

Contact phenomena were first invoked by Erofeev[67] to explain the mechanism of thermal decomposition. As the contact potential difference between an ionic compound

and the metal increases, the number of anions in the surface layer increases, and so does also the rate of thermal decomposition of the material. Using this approach, Erofeev postulated a proportionality between the rate of decomposition and the work function of the solid product of the reaction (for the case of solids with a common anion and cations of similar electronic structure). He quotes as an example the azides of barium, strontium, and calcium, in which the activation energy of thermal decomposition is found to be inversely proportional to the work function of the corresponding metals (which are also the decomposition products of the azides).

The realisation of the important role played by contact potential in thermal decomposition reactions has already produced useful results, but in many cases the available data are not sufficiently reliable. Thus, it is difficult to compare the electronic work functions of barium, strontium, and calcium[67] from results obtained under different conditions and by different methods because the scatter of the data is excessive. Fomenko[76], by averaging the results of 10–18 investigations, concludes that the work function of strontium is lower than that of barium. Thus, there is little justification for the statement that the rates of decomposition of barium, strontium, and calcium azides vary in the same sense as the work functions of the corresponding metals. Equally unjustified is the assumption that azides with different crystal lattices[77] and different physical properties[2,56] can have the same work function simply because they have a common anion and cations from the same group of the Periodic Table. To prove Erofeev's hypothesis we require a knowledge of the relative work functions of the contacting pairs of materials under the conditions which apply during the thermal decomposition of the azides: in particular, suitable allowance has to be made for the influence of a number of factors on the work function of metals and ionic crystals.

The method most commonly used to determine the thermodynamic work function is the vibrating condenser method[78–81], in which the key element is a vibrating metal plate whose work function is taken as standard. Allowance must be made for any change in the work function of the standard metal under the conditions used in the thermal decomposition of the experimental material. The electronic work function of metals usually decreases with increase of temperature[82,83] (if other complicating factors are excluded), and depends on the nature of any adsorbed gas[76,84,85]. The work function of compounds is even more sensitive to temperature[76,86,87], composition of the atmosphere[76,88–91], state of the surface, and intensity of illumination[92–94]. The electronic work function is a surface electronic characteristic of solids[95,96]. It is determined by the properties of a few monolayers of the material, since the surface of a crystal can be defined[97] as a layer of thickness equal to the mean free path of electrons, and therefore proportional[98] to the electron mobility and effective mass. Hence, the work function is affected by surface contamination (whether accidental of deliberate), and by the lapping and polishing treatments applied to the surface. If the decomposition product is a metal, we must allow also for the geometric factor[99,100] (an increase in work function with decreasing particle size). For example, Sviridov and Branitskii[8] found that the autocatalytic effect of silver nuclei in the thermolysis of silver oxalate disappears when the nuclei reach a certain critical size: one explanation of this effect could be the influence of the geometric factor.

Zakharov and Savel'ev[68,69] analysed published data on the effect of various oxides on the rate of thermolysis of potassium permanganate, ammonium perchlorate, and potassium chlorate, and noted a clear correlation between the catalytic effect of the oxides and their work function. Oxides with the highest work function had the strongest catalytic effect on the thermolysis of all three compounds. The thermal decomposition of silver oxalate was found[68] to be accelerated by additions of nickel oxide or cuprous oxide. On the other hand, zinc oxide or silver sulphide additions inhibit the decomposition of silver oxalate. In these experiments, too, the catalytic effect of the oxides was proportional to their work function, even when the work function values used in the calculation had been obtained under conditions far removed from those of the decomposition reaction. In a more recent paper[70], Zakharov and coworkers quote their own measurements of work function for silver azide and various additives under conditions close to those used in the thermal decomposition of silver azide. A more exact proportionality between the catalytic effect and the work function of the additives was observed, in spite of the failure to allow for oxygen evolution from the oxides at the decomposition temperature of the azide, and for the effect of the evolved oxygen on the work function of the standard gold electrode. A similar experiment is needed also to characterise the effect of the nitrogen (evolved from the silver azide) on the work function of the additives and of the standard. The experiment could take the form of a measurement of the contact potential difference between two gold plates under conditions leading to the decomposition of the appropriate substances.

Boldyrev and coworkers[71] confirmed the presence of electron-acceptor autocatalysis by manganese dioxide in potassium permanganate by measuring the work function of both materials at room temperature in an atmosphere of air, using the vibrating condenser method. The electronic work function of manganese dioxide was found to be 5.48 eV, that of potassium permanganate 4.76 eV. Hence, electron-acceptor catalysis is a possibility.

However, a number of criticisms must be levelled at this work, if only in order to highlight the complexity of the problem. The direction of electron transfer at the $KMnO_4$–MnO_2 boundary was determined from work function measurements made under conditions far from those which exist during the decomposition of potassium permanganate. Furthermore, the form of the manganese dioxide used in these experiments is not stated: the compound can exist in two stable modifications[101,102] as well as in an amorphous form. It is known[64–66] that the electronic work function of a semiconductor is equal to the sum of the work done against the electrical image forces and one-half of the width of the forbidden gap. Assuming that the work done against the electrical image forces remains the same for crystalline and amorphous forms of a compound as long as the short-range order is preserved[74,103–105], the work function difference between the two forms can be estimated from the difference in the forbidden gap. The γ modification of manganese dioxide has a greater activation energy for electrical conduction than the β modification.[53] Hence, we can expect the work function of γ-MnO_2 to be greater than that of β-MnO_2. When a compound is converted into the amorphous state the width of the forbidden gap usually increases because of the decrease in density[64,106]. For example, iodine (which is known to be a semiconductor[107]) has a work function of 2.8 eV in the monoclinic form and 6.8 eV in the amorphous state.[76] Hence, the most marked effects on the thermal decomposition of the original solid will be observed when the decomposition product (or the additive) is in the amorphous state if the catalysis is of the electron-

acceptor type. However, the production of manganese dioxide in an amorphous state during the thermolysis of potassium permanganate is highly unlikely[41].

In addition to the contact potential difference measured by the vibrating condenser method, the contact resistance can be used to compare the work functions of semiconductors, since it is associated[64-66] with the contact p.d. of the metal–semiconductor pair. The contact resistance is measured by the exponential portion of the current–voltage characteristic of the pair. By using different metal electrodes it is possible to evaluate[108] the work function of a semiconductor of a given conductivity type. The writer has used this method[73] to study the thermal decomposition of silver permanganate at 115°, catalysed by metal oxides. ZnO and ThO_2 were found to accelerate the thermolysis of silver permanganate, Co_3O_4 and NiO had no effect, and TiO_2 inhibited the process. No definite correlation was observed between the catalytic activity of the oxides and their published work functions. To explain the results, an electron exchange process between the additive and the undecomposed material through a layer of products was postulated. The current–voltage characteristics obtained at a number of temperatures for ZnO, $AgMnO_4$, and its solid decomposition product against platinum and gold electrodes were used to give a comparative assessment of the work functions of all these materials. The work function of zinc oxide was found to increase with temperature, whereas the work function of the decomposition products decreased and that of silver permanganate showed a barely significant increase. It was concluded from these results that under the conditions leading to decomposition of silver permanganate the electrons in the ZnO–product–$AgMnO_4$ system are transferred from the decomposition product towards both the zinc oxide and the silver permanganate. Mechanical admixture of the decomposition product or of its separate components (manganese dioxide and silver oxide) was found to inhibit the thermolysis of silver permanganate very markedly. Electron transfer from the decomposition product to the zinc oxide appears to minimise the inhibiting effect of the former and to accelerate the decomposition of the permanganate.

All the authors whose work has been discussed so far have considered only one effect at the contact: the transfer of electrons towards the material with the highest work function. This is by no means the only manifestation of contact phenomena at the solid–solid interface in catalysis and autocatalysis. Firstly, no account had been taken of the possible effect of the electric field at the contact. For the electrical conductivities and work functions of the materials most commonly investigated in solid-state chemistry, the voltage drop across the electron-deficient ("depletion") layer at the interface is of the order of 1 volt. Assuming a normal electron mobility and effective mass for ionic crystals, the thickness of the contact layer works out[98] to 10^{-4}–10^{-6} cm. Thus, the contact region of materials undergoing decomposition may experience electric fields of the order of 10^4–10^6 V cm^{-1}, i.e. field intensities sufficient to bring about decomposition. Furthermore, contact electric fields and electron transfer phenomena may occur not only at the contact between two different substances but also at the contact between crystals of the same material. The effect may arise from work function differences between different crystal faces: it has been observed in crystals of metals[76] (manganese, copper, silver, tungsten) and of semiconductors. The difference in work function between different faces in cadmium and lead sulphides[94] lies in the range 0.1 to 0.3 eV. Assuming an average depletion layer thickness of 10^{-5} cm, we obtain a contact surface field of the order of 10^4 V cm^{-1}. We cannot exclude the possibility that this effect may influence the rate of thermolysis of solids; the effect may also be responsible for the maximum observed in the plot of rate of thermolysis against degree of dispersion for a number of substances[109,110].

5. POTENTIAL APPLICATIONS OF THERMO-E.M.F. AND HALL VOLTAGE PHENOMENA

Although the well known thermo-e.m.f. phenomena can be measured simply[25,78,107,111] and without costly and cumbersome apparatus, it has not so far been used to any significant extent in studies of the mechanism of solid-state reactions. Even a cursory study of published work on the thermo-e.m.f. of ionic crystals reveals a number of questions of great importance to solid-state chemistry[1,2,74] and which could in principle be answered by measurements of thermo-e.m.f.

The existence of solid solutions in crystals can be recognised from anomalies in the differential thermo-e.m.f. isotherms[112-114]. Electron conduction in semiconductors can be distinguished from hole conduction by the sign of the thermo-e.m.f., even when alternative methods fail, as in polaron semiconductors[61,115,116] (oxides with partly filled 3*d* shells). In solid electrolytes, ionic conduction by interstitials can be distinguished from ionic conduction by vacancies according to the sign of the thermo-e.m.f. The differential thermo-e.m.f. (or thermoelectric power) in solid electrolytes can be used to calculate[44,117] the activation energy attending the formation and the motion of ionic defects. The concentration of current carriers in semiconductors of the band[118] and the polaron[119] types can be calculated from the thermo-e.m.f., and changes in carrier concentration due to various effects can be monitored.

The thermo-e.m.f. has one important "drawback" in comparison with the Hall effect, the photo-e.m.f., and photoconductivity. The former can be induced by charge carriers of any kind, whereas the latter three effects are specific to electronic and positive hole process. However, the ionic thermo-e.m.f. becomes significant only at high temperatures (most commonly, in the region of intrinsic ionic conduction), because ionic mobilities are extremely low. Under these conditions the concentration of ions involved in the conduction process, and their mobility, become high enough to support a significant thermoelectric current. However, with mixed (electronic–ionic) conductors, or when the conduction type is unknown, the characteristics of both ions and electrons can be calculated by combining the measurements of thermo-e.m.f. with other methods of measuring the kinetic parameters of charge carriers (Hall voltage, transport numbers, photo-e.m.f., and photoconductivity). Very little has been published[44,117,120] on the ionic thermo-e.m.f.: the phenomenon is much less well documented than the electron (or hole) thermo-e.m.f. But even among the few available results, some are difficult to accept (particularly those relating to thermionic currents). For example, the report by Reingold[120] of an ionic thermo-e.m.f. in silver sulphide, selenide, and telluride is unconvincing since these compounds are known to be electronic semiconductors[19,61,121,122]. However, in spite of the rare occurrence of ionic thermo-e.m.f.s, the contribution of ions to the total thermo-e.m.f. should always be treated as a possibility.

There is little published information on the thermo-e.m.f. (or other electrophysical properties) of the complex systems of interest in studies of solid-state reactions. The early work of Lashof[123] on the electrophysical properties of lead chromate is noteworthy. In spite of the low conductivity of lead chromate (of the order of 10^{-9} ohm^{-1} cm^{-1} at 100°), measurements of transport numbers and of thermo-e.m.f. showed that the compound is an electronic semiconductor. Lashof was among the first to point out the importance of colloidal metal particles (formed by thermal or photochemical decomposition) in the development of electronic conduction in ionic salts. The Hall effect of lead chromate could not be measured because of the high resistance of the samples. The sign of the thermo-e.m.f. was taken as evidence that the conductivity is by electrons (and not by holes). Good agreement was obtained between the measured thermo-e.m.f. and the value calculated from the free electron model: this was quoted as additional evidence that $PbCrO_4$ is an n-type semiconductor. Lashof's work is interesting for the methods used, but it failed to characterise satisfactorily the mechanism of electronic conduction, since the author[123] ignored the possibility of electron transfer between chromium ions of different valencies, which is frequently found in systems of this type[124-127] and accounts for most of their electronic conduction.

The writer[20] has used the thermo-e.m.f. to demonstrate cation transport through interstitials of the silver sulphite lattice, and hence to confirm the growth of nuclei by the Mott mechanism. The sign of the thermo-e.m.f. was one of the arguments[25] in favour of a proton conduction mechanism through vacancies in the cation sublattice of ammonium perchlorate, in agreement with the onset of thermal decomposition[26]. Measurements of thermo-e.m.f. have been used[31,36,73] to confirm the n-type conduction of univalent metal permanganates, in which photoconductivity and Hall effect could not be measured.

Young[2,22] applied the thermo-e.m.f. phenomenon in his studies of electronic and ionic processes in pure and in partially decomposed silver azide. By combining these measurements with optical spectra, Hall e.m.f., electrical conductivity, and photoconductivity studies he concluded that undecomposed silver azide is a cation conductor, whereas the same compound partly decomposed by heating or illumination is an electronic conductor. He suggested that the optimum conditions for electronic conduction occur in powdered samples, and the optimum conditions for ionic conduction occur in monolithic samples. Colloidal silver particles, formed during irradiation or heating, are responsible for the electronic conduction of these samples.

Young[22] quotes his measurements of thermo-e.m.f. in support of these conclusions. The differential thermo-e.m.f. of partially decomposed (up to 180°) silver azide remains negative but decreases in absolute value. Beyond this temperature the coefficient changes sign, reaching a maximum at 185°, and at 187° it falls almost vertically, changes sign, and goes through a sharp peak at 190°. At 192–193° the thermo-e.m.f. of the azide decreases very rapidly, changes sign, and returns to the previous maximum value. The final value remains unchanged on cooling the sample. This complicated and unusual variation of thermo-e.m.f. with temperature is consistent with the conclusions reached by Young from his measurements of the other electrophysical properties of the material. The first change of sign of the thermo-e.m.f. is due to sintering of the particles, and "displacement" of electronic conduction by cationic conduction. The anomalies in the region of the transition at 190° are explained by alternate enhancement and interaction of electronic and cationic conduction as a result of the collapse and re-growth of crystals during heat treatment. According to both electrical conductivity and thermo-e.m.f. measurements, this transition in silver azide is irreversible. However, the temperature difference used by Young (2–3°) may have been too low[118] to give reliable values of the differential thermo-e.m.f.: a temperature difference of the order of 10° across the sample is preferred[128,129] for the measurement of differential thermo-e.m.f.

The Hall e.m.f. is a reliable method[60,61,64] for separating the electronic component of the conductivity and at the same time determining the concentration of the charge carriers. The method can be used to monitor changes in the concentration of free electrons and holes during various types of treatment of solids (including decomposition). However, the sensitivity of existing apparatus is inadequate to identify the mechanism of solid-state reactions in the majority of solid inorganic compounds. So far, the Hall effect has been used to study electronic processes in solids having a resistivity not greater than 10^8 ohm[130-132]. A more promising method of studying reactions in solids is the photo-Hall effect[133-136], in which the Hall e.m.f. is generated by light-induced electrons, since many of the compounds used in research on solid-state reactions are ionic conductors[1,2]. For example, in silver azide the Hall e.m.f. appears only after partial decomposition[22], showing that the undecomposed azide is an ionic conductor and confirming Young's hypothesis on the donor properties of colloidal silver particles.

6. USE OF DIELECTRIC CHARACTERISTICS

The dielectric constant and the tangent of the dielectric loss angle are the most important electrophysical characteristics of a material. The variation of these characteristics with temperature, frequency, atmosphere composition, illumination, and pre-treatment (heating, irradiation, grinding, etc.) gives valuable information[64,137-143] on the mechanism of thermal decomposition of solids. The variation of ϵ and $\tan\delta$ with frequency reflects changes in physicochemical properties such as mobility and concentration of charge carriers, decomposition of neutral associations of ionic defects, effective mass of electrons and holes, and phase transitions[144-146], which may accompany the thermal decomposition of ionic salts. The rate of thermal decomposition usually changes rapidly at temperatures close to the modification transition[20,21,24,25], and so does also the electrical conductivity. Measurements of ϵ and $\tan\delta$ can be expected to give additional information on changes affecting electronic and ionic processes in the temperature region of the modification transition.

Very little has been published on the application of ϵ and $\tan\delta$ measurements specifically to the study of reaction mechanisms in the solid state. This is due, at least in part, to the experimental difficulties and to the difficulty of interpreting the results. In addition to the detection of modification transitions, two applications of ϵ and $\tan\delta$ in solid-state chemistry should be mentioned. They are the detection of solid solution formation from dielectric characteristics[45,46,147] and the calculation of the activation energy of thermally excited electrons[2,55-58] from the dielectric constant and the optical excitation energy of the electrons to the conduction band. The well known Mott formula[148] is used in the latter calculation. Having determined the width of the forbidden gap, and converted the optical

excitation energy into the thermal excitation energy by the Mott formula, this latter value is compared with the experimentally observed activation energy of the thermolysis reaction. Close agreement between theory and experiment is taken as evidence that electronic excitation is the rate-limiting step of the thermolysis reaction. However, Mott's formula is known to be only an approximation in calculations of this type.[75] A number of experimental findings are inconsistent with Mott's formula[61,107,148-152]. Alkali-metal halides with *F*-centres, barium and zinc oxides, and zinc and cadmium sulphides are semiconductors for which the activation energy differs very substantially from the expected value. Alkali halide crystals become semiconductors when colour centres are induced in them. By analogy with Sikorskii's results[153] for sodium chloride, the influence of *F*-centre polarisation on the static dielectric constant can be ignored. Thus, energy calculations by Mott's formula can be misleading.

Suzuki and Kotera[154] studied the kinetics of the anatase–rutile phase transformation by a dielectric method. The ϵ values of these modifications of titanium dioxide differ by a factor of 3.5. Hence, the presence of a new phase could be detected by the dielectric method even at concentrations below 10%. The method is particularly attractive, since the variation of ϵ with the concentration of the new phase is almost linear.

Ellis and Hall[155] used the dielectric method to monitor changes in the defect structure of sodium azide during thermal decomposition. The decomposition kinetics were studied, in parallel with ϵ and $\tan\delta$, from the pressure changes in the vacuum system. No change of ϵ was noted during the early stages of decomposition, but both ϵ and $\tan\delta$ showed a sharp maximum near the point of inflection in the decomposition curve. With further decomposition, the low-frequency values of ϵ and $\tan\delta$ continued to increase, whereas the high-frequency values did not change significantly. The authors ascribe these changes in the dielectric characteristics to the lattice defects produced during decomposition, rather than to the decomposition products. Since the predominant ionic defects in sodium azide are believed to be of the Schottky type, defect pairs consisting of an *F*-centre and an anion vacancy are likely to be formed during thermolysis. The *F*-centres may be formed by the reaction

$$2N_3^- \rightarrow 3N_2 + 2\bar{e} .$$

Zhuravlev[156] made a detailed study of the dielectric properties of silver oxalate and silver nitrite before and during thermolysis. The dielectric properties before decomposition had to be studied in order to establish the nature of the dielectric losses and of the polarisation. It was concluded that electrical polarisation in these compounds consists mainly of electronic, ionic, and migrational polarisation, and these processes were invoked in the discussion of the decomposition mechanism. A sharp decrease in $\tan\delta$ and in electrical conductivity was noted[156] during the early stages of the thermal decomposition of silver oxalate and nitrite. It was shown that the reaction kinetics during this period can be followed from the changes in $\tan\delta$, and that the rate of disappearance of defect ions (with formation of a metallic phase) can be assessed in the same way. The dielectric constant does not change at first, but after some time it begins to rise very rapidly, suggesting the coalescence of fine silver nuclei into coarser structures. The overall conclusion was that the decomposition kinetics of compounds of this type can be studied by using changes in dielectric properties to monitor the amount of metallic phase produced.

Thus, a comprehensive and objective study of electrophysical properties is a powerful means of characterising the electronic and the ionic steps in the thermal decomposition of solids.

Present State of the Oscillopolarographic Method of Analysis

G.K.Budnikov

This review considers the main achievements of oscillographic polarography with a given form of polarisation voltage. Methods for increasing the sensitivity and resolving power of this analytical method and its use as a method for studying the mechanism of electrochemical processes are discussed. The influence of various factors determined by the composition of the solution in the cell and by the nature of the substances being studied on the form of the oscillopolarographic curves, and the characteristic features of the use of the method in the analysis of inorganic and organic compounds are examined. The bibliography contains 238 references.

III. Analytical applications of oscillographic polarography 974

I. INTRODUCTION

Recent years have been characterised by further development of the oscillopolarographic method of analysis. A number of new papers have been published, in which considerable attention has been paid to the theory of the method and to its various practical applications; papers demonstrating the advantages of oscillopolarography as a highly sensitive method of analysis over other electrochemical methods have been published. Oscillographic polarography is at present used in organic, bio-organic[1], analytical, and physical chemistry, pharmacology and medicine, clinical studies and therapy, geochemistry, oceanography, and botany. Thus the materials studied include not only synthetic laboratory mixtures, but also natural materials such as minerals, petroleum, living tissue, plant materials, etc.

Recently, however, the accepted description of the method as "oscillographic polarography" has often been replaced in non-Soviet literature by other descriptions; this introduces certain difficulties, and sometimes even confusion. To standardise terminology and facilitate the classification of electrochemical (particularly polarographic) methods, and to permit generalisation of the results of studies by different workers using essentially the same method under different descriptions, the term "oscillographic polarography" should be preserved, although it may be noted that this description does not fully reflect the essential features of the method. In this method, in which the rapid change in the electrode potential brings about a rapid change in current strength, the polarisation curves are recorded with an inertia-free instrument—a cathode-ray oscillograph; hence the name of the method. The oscillograph, however, is also used, together with a string galvanometer, to record the current–time curves at constant potential, and also to record curves in chronopotentiometry[2] and other relaxation electrochemical methods[3] used to study the kinetics and mechanism of electrode processes. On the other hand, in oscillographic polarographs the rate of increase in potential can be varied within certain limits, and it can be made relatively small, comparable with the rate in classical polarography. Thus there is no sharp distinction between these methods[1,4].

The present state of oscillographic polarography is characterised by considerable variety in the versions of the method and the associated techniques of oscillopolarographic measurement[5-9]. These versions are classified according to four familiar features[6], of which the chief is the form of the polarising voltage. The latter determines to a considerable extent the electrical circuit and the oscillopolarographic assembly. Depending on the form of polarising voltage, it is possible to distinguish methods involving a linear polarising pulse—saw-tooth, symmetrical triangular, etc.—and methods involving a potential which changes non-linearly, for example according to a sinusoidal law.

The method involving the recording of the plot of $I = f(E)$ with a linearly changing voltage is called Randles–Sevcik oscillographic polarography; other names encountered in the literature are: voltammetry with continuously changing potential, voltammetry with change in potential or with scanning of the potential, and chrono-amperometry with scanning of the potential (particularly in the American literature[9]). Another method of oscillographic polarography—with a given sinusoidal current[7]—makes it possible to obtain oscillopolarograms in the form of the plots of dE/dt against E (these curves give the dependence of the rate of change of potential at the polarised electrode on its potential).

The method involving the recording of the $dE/dt = f(E)$ curves has been developed chiefly by the Prague school of polarographers. Regular symposia on oscillopolarography, and special courses for the training of specialists have helped the development and extensive application of this method of analysis in Europe[10-12], and papers have recently been published by South American workers[13]. The method involving the recording of $I = f(E)$ curves has also developed considerably in recent years, and there has been a marked increase in the volume of factual material obtained by this method.

In the Soviet Union this has been assisted by the mass production of the Soviet OP-1-61 oscillopolarograph and more particularly the PO-5122 01-02 and 02A oscillopolarographs.

The fact that recent work has not been reviewed makes it somewhat difficult to evaluate the main achievements of oscillographic polarography. In the present

review an attempt is made to fill this gap and to give a picture of the present state of this physicochemical method of analysis.

Most attention has been paid to the method involving the recording of $I = f(E)$ curves, since the other method mentioned above has been dealt with fairly fully in an earlier review[1]. Where necessary for comparison, however, data from papers dealing with the method involving the recording of $dE/dt = f(E)$ curves are introduced.

II. SOME THEORETICAL ASPECTS OF THE STATE OF THE OSCILLOPOLAROGRAPHIC METHOD OF ANALYSIS

1. Sensitivity and Resolving Power, and Methods for Increasing Them

The analytical applicability of classical and oscillographic polarography is usually estimated on the basis of the sensitivity and resolving power of the method. The sensitivity is characterised by the magnitude of the minimum concentration which can be reliably determined from the oscillopolarogram, and the resolving power is determined by the possibility of carrying out the simultaneous polarographic study of two substances. Resolving power with respect to potentials and resolving power with respect to concentrations are distinguished. If a single polarographic cell is used for the polarographic study, that is if the difference method, discussed below, is not used, and if the method involving build-up at the electrode is not used, the minimal concentration of a substance, undergoing reversible reduction, which can be determined in the solution is 5×10^{-7} M [4], with a resolving power with respect to potentials equal to ~40 mV [14] (for a polarising voltage of linear form).

The chief factor limiting the sensitivity of modern oscillographic polarographs is the capacity current. The total current for electrolytic reduction, recorded by the oscillograph, consists of the Faraday current I_e of the electrochemical reaction, associated with the transfer of electrons, and the capacity current I_c, which appears as a consequence of the existence of the electrical double layer. The sensitivity of the oscillopolarographic method is determined not by the magnitude of the total current but by the ratio of the "useful" current I_e to the current I_c, which represents an interference in analytical determinations. The rate of change in the polarisation potential V at low concentrations of the substance being studied can be decreased, in order to increase the ratio I_e/I_c, only to a certain limit. At low values of V, even without this, the small value of I_e decreases to such an extent that it becomes commensurate with background in the apparatus, and at high values of V the value of I_e is lost against a background which is many times greater than I_c. Thus decrease in the capacity current without change in I_e would mean an increase in the sensitivity of the method. For this reason, the developers of new apparatus have sought new methods of eliminating or decreasing the interference from I_c. For a long time, however, the solution to this problem in oscillopolarography was unsatisfactory. For example, in the slightly more sensitive electrochemical method of alternating-current polarography, the capacity current is eliminated by a variety of methods which make use of a special form of polarising voltage and special apparatus[3], whereas in oscillographic polarography, until recently the capacity current was eliminated only by linear compensation, which is insufficiently effective, however, since the capacity of the double layer shows a non-linear dependence on potential.

The earliest oscillographic polarographs had a comparatively low sensitivity, and the values of the parameters mentioned above were not achieved immediately. Comparatively recently, the difference method of oscillographic polarography has made possible the reliable determination of cadmium, lead, and zinc ions at concentrations down to 10^{-6} M, so that ordinary (not difference) oscillopolarography had an even lower sensitivity.

Subsequent work improved the electronic systems and the design of the individual blocks of oscillographic polarographs[16-18], and developed a circuit for the partial compensation of the capacity current[17]. One method for eliminating the capacity component and other interfering components of the current passing through the cell was the method of difference oscillographic polarography, developed by Pozdeev[19]. This makes it possible to increase both the sensitivity and resolving power of the analysis[5,15], since it gives a significant increase in the ratio I_e/I_c by presenting an oscillographic curve from simultaneous electrolysis of solutions in two identical cells. For example, this method can be used to eliminate the undesirable components of the current, associated with contamination of the electrolyte, the presence of large concentrations of other substances, and charging of the capacity of the double layer.

This method has been used to solve other problems[4], but it has several disadvantages. In addition to the fact that its use requires two cells, with a consequent increase in the complexity of the apparatus, the efficiency of this method of polarographic study is limited by the error in the subtracting assembly, and also by the difficulty of selecting two identical dropping mercury electrodes[9]. Thus the sensitivity of the difference method[14] achieved at present is 1.5×10^{-7} M, which is much greater than that of modern oscillographic polarographs operating with one cell (5×10^{-7} M) [20,21].

The theoretical and practical development of an oscillopolarographic method with a much lower level of capacity current than existing methods was achieved by Vyaselev[22]. The method was based on the principle of time selection, which makes it possible to separate the capacity and Faraday currents. In accordance with this principle, when a sudden change in potential is applied to a polarographic cell, the capacity current is damped more rapidly than the Faraday current. The current of the electrochemical reactions proportional to $t^{-1/2}$, whereas the capacity current is proportional to $e^{-t/RC}$, where R is the ohmic resistance of the cell and C the capacity of the double layer. Thus after a certain time interval from the moment when the sudden change in potential is applied, the current passing through the cell will be determined chiefly by the Faraday component. The idea of the possibility of using a step-like form of polarising voltage in oscillographic polarography was first put forward by Barker[23,24]. For a long time before Vyaselev's work[22], however, the idea was not realised, either theoretically or in practice. The theoretical study of the dependence of the diffusion current on the step-like polarising voltage showed that for step-like voltage, the measured values of the capacity current are in fact much smaller than those for a linear voltage[25,26]. This led to the development of an oscillopolarographic method in which the polarising voltage is applied in the form of sudden exponential increases[27]. Theoretical problems of oscillographic polarography with stepwise change in the polarising voltage were solved by

Vyaselev and Nigmatullin [25,26] and by Lingane and Christie [28,29]. The sensitivity of the method with step-like voltage (with respect to cadmium chloride solution) is 5×10^{-8} M, which is greater by an order of magnitude than that of the method using a linearly-changing voltage [26].

In addition to the difference method [19], differentiation of the oscillopolarographic curve [6,14,16,17] has been used to increase the resolving power. The analytical expression for the first derivative of the curve $I = f(E)$ was determined by Shekun [30], who showed by calculation that the height of the peak on the first-order differential oscillopolarogram $dI/dE = f(E)$ is a linear function of the concentration of depolariser; this makes it possible to use the relationship for quantitative analysis, as in classical polarography.

Unlike the first derivative of the classical integral polarogram, the oscillographic differential polarogram shows a negative peak as a consequence of a decrease in the current on the original curve, and the potential of its maximum does not coincide with $E_{1/2}$. This form of oscillopolarogram with negative peak makes the interpretation difficult, particularly in the study of multicomponent systems, and it is not convenient for analytical purposes.

Nigmatullin [31] was the first to show that for a reversible electrode reaction, the oscillopolarographic relationship $I = f(E)$ is a fractional derivative, of half-order, of the classical integral polarisation curve. On this basis, it was suggested that not ordinary differentiation, but half-order differentiation, that is so-called fractional differentiation, of the oscillographic curve be used to improve the resolving power of the method. The fractionally-differentiated oscillopolarogram obtained in this way corresponds in appearance to the first derivative of the classical integral polarogram, that is it does not have a negative peak and can be used for analytical purposes.

By combining the methods of difference oscillopolarography [19] and differentiation of the oscillopolarograms [6], Davis and Rooney [14] were able to obtain the second derivative of the oscillopolarogram, which gives good qualitative resolution with respect to potentials, but which is inconvenient for quantitative treatment.

Because of the mutual influence of different depolarisers, present simultaneously in the solution, on the shape of the peaks on the oscillopolarograms, quantitative calculations do not always have sufficient accuracy and reproducibility. To increase the accuracy of the measurement, Gokhshtein and Gokhshtein [32] proposed a method for extending the descending branch of the oscillopolarogram when the wave of another component was superimposed on it. The method gives satisfactory results if there is no appreciable capacity current; it can therefore be used successfully only at comparatively high concentrations of the substances being studied, when the capacity current is satisfactorily compensated by a linear method.

In oscillographic polarography with a polarising voltage of linear form, the relationships for the height and position of the peak on the oscillopolarogram are derived with the condition that the potential of the micro-electrode is a linear function of time [33,34]. As a consequence of the decrease in voltage across the ohmic resistances of the electrolytic cell and the elements of its circuit, however, this relationship is not observed for the change in potential under the conditions of the experiment. As a result, the oscillographic wave is extended, its height decreases, and the peak is displaced towards more negative potentials and becomes less sharp, so that the sensitivity of the measurements decreases. With very high ohmic resistances, the wave is completely "flattened", and the study becomes impossible. These phenomena have been observed experimentally, and in particular have been reproduced in an electric model [35-38] and have been the subject of discussion [39]. A special assembly has been designed [40] to compensate the cell resistance and obtain an oscillographic curve suitable for treatment, and also to increase the accuracy of the measurements. It successfully combines automatic compensation of the volume resistance with manual control, proposed by Valenta and Vogel [41]. The automatic compensation of the volume resistance is achieved by the oscillographic polarograph together with a three-electrode cell of special design. The method used for the controlled compensation of the volume resistance involves in practice a gradual increase in the feedback signal until the polarogram on the oscillograph screen corresponds to the theoretical. This form of compensation is less convenient, since in each specific case it requires the selection of the feedback signal in relation to the magnitude of the cell resistance. This method can be used, however, to estimate the magnitude of the compensated resistance.

Oscillographic polarography has recently become one of the highly sensitive methods which can be used for the analysis of traces of elements [42]. Despite the fact that data on the accuracy, sensitivity, and resolving power of this method have been published, it cannot be considered that these problems have been sufficiently fully studied from the methodological viewpoint.

It may be assumed that the dependence of the error in the measurement on the concentration of the substance being determined is of the form typical of micro-determinations [43], when the error increases close to the limit of the determination, since at this level of concentrations, the useful signal and the signal of the background (or blank experiment) are of comparable magnitude. The reliable measurement of signals at the level of the limit of the determination of substances and the "noise" of the oscillographic apparatus are metrological problems, and constitute one of the most important topics in measuring technology [44]. If the methods known as amalgam polarography with build-up (APB) [45] and film polarography are used, the sensitivity can be increased; these methods are examined in considerable detail in the literature.

Another method for increasing the sensitivity of polarographic determinations is based on the adsorption of the molecules of the depolariser on the electrode surface. Many reactions at an electrode take place with the participation of adsorbed species [46]. The concentration of these species at the electrode surface may be many times greater than their concentration in the volume of the solution. Thus when the polarographic voltage is applied to the cell, the reduction current in the first moments of time should be much greater than the value which might have been reached in the absence of adsorption; this makes it possible in principle to alter considerably the magnitude of the concentration minimum being determined.

The possibility of the practical realisation of this experiment was first demonstrated by Kalvoda and the present author [47,48] for the example of various organic substances (benzophenone, dibenzylmercury, etc.) sparingly soluble in aqueous alcohol, and thiosemicarbazones [49].

For the effective utilisation of the phenomenon of adsorption to increase sensitivity, the following conditions are obviously necessary [50]: 1) for significant "enrichment" of the electrode surface in adsorbed molecules, sufficient time is required for the establishment of adsorption equi-

librium at the micro-electrode in dilute solution; in some instances about 1 h has been necessary[46]; 2) since the quantity of adsorbed molecules at the surface of the micro-electrode is comparatively small, the oscillopolarogram must be recorded in a short time interval, that is it is necessary to select a suitable rate of polarisation; 3) the oscillopolarograms should be recorded with improved apparatus which makes it possible to eliminate the charging current of the double layer capacity, for example an oscillographic polarograph with step-like voltage[26,27,50].

The use of the phenomenon of adsorption to increase sensitivity opens up extensive possibilities in the analysis of organic substances by oscillographic polarography. Although the method of APB can be used successfully to determine traces of ions in solution, this is impossible for organic compounds, for reasons which are well understood. For some classes of organic compound containing groups which are active with respect to the electrode material, such as aldehydes, ketones, derivatives of urea and thiourea, thiosemicarbazones, organic compounds of sulphur, etc., which react with mercury at positive potentials[1] with the formation of the corresponding organomercury compounds or mercury sulphide[51,52], however, it is possible to use the principles of film polarography. This involves essentially preliminary electrolysis of the solution being studied at the potential of the initial level of recording of the $I = f(E)$ curve, as a result of which the compounds mentioned above are formed on the electrode surface in the form of a film; with cathodic polarisation of the electrode they are revealed as sharp peaks corresponding to the reduction of the corresponding substances, and this is used for analytical purposes. For thiourea, the minimal concentration which can be determined by this method is 10^{-7} M [52].

The sensitivity of the oscillopolarographic method can also be increased by making use of the formation of sparingly soluble substances, with low degrees of dissociation, in the solution[53-56]. Decrease in the activity of a substance leads to a decrease in the extent to which it is adsorbed on an electrode surface[53]. Since for sparingly soluble substances the activity is inversely proportional to the change in solubility, decrease in solubility will lead to an increase in the degree of covering of the electrode surface, that is adsorption.

The mechanism leading to the increase in the depth of the peaks under the influence of anions is still insufficiently clear. It is probable that in addition to a change in the Ψ'-potential in solutions containing anions which are readily adsorbed on the electrode, some contribution is made by adsorption-chemical interaction of the anions with the atoms of the reduced metal. From this it follows that when the sensitivity of an oscillographic polarograph is established with respect to a given substance (cadmium salts are usually employed for this purpose), it is necessary to indicate the composition of the background. An increase in sensitivity is facilitated by the formation not only of sparingly soluble substances, but also of complexes of the ions being determined with organic ligands, with a low degree of dissociation[13,57,58]. Thus cobalt is readily determined in plant materials, from the oscillopolarograms of its inner-complex compounds with dimethylglyoxime[58].

An example of a process similar to this mechanism of concentration is apparently provided by the extraction of various ions of uranium, zirconium, mercury, and the rare earth elements from aqueous solutions by organophosphorus compounds present in the adsorbed state on the surface of a stationary electrode[59]. In this instance it is assumed that coordinate bonds are formed between the metal and the organophosphorus compound in the surface layer[60], leading to the accumulation of the substance and hence to an increase in sensitivity. This method of increasing sensitivity has essentially not yet been used in oscillographic polarography.

Finally, mention must be made of another way of increasing the sensitivity of the oscillopolarographic analysis of organic substances—the use of the salting-out effect. In early work on oscillographic polarography, concentrated base electrolytes (1 M or more) were generally used to decrease the resistance in the polarographic cell. For a number of organic compounds, increase in the concentration of the background is not without an effect, since the organic compound is usually salted-out from solution. The salting-out of organic substances from concentrated solutions of electrolytes leads to an increase in their surface concentration[61]. Thus if the last effect is observed, the heights of the peaks or teeth on the oscillopolarograms will increase with increased concentration of the background electrolyte, and this leads to an increase in sensitivity. Thus Kalvoda[62] showed for derivatives of benzoic acid that with increase in the KF concentration to 10 M, the determination of these compounds becomes possible, whereas in a background of the usual neutral buffer, almost no capacity effects are observed on the oscillopolarograms of solutions of these derivatives.

2. Form of Oscillopolarographic Curves and the Mechanism of Electrode Reactions

A source of information on the nature of an electrode process and the composition of a solution being analysed is provided by the oscillographic curve, the form of which depends on a number of factors.

Firstly, the form of the curve, and in particular the position of the peak with change in V depends on the type of electrode process and its characteristic features[1]. In earlier work[51,52,63,64], conclusions regarding the nature of the electrode reaction were generally reached on the basis of the rate coefficient, or the so-called "Semerano criterion"[1,65]. Recently, various diagnostic criteria have been derived for the investigation of the nature of the various stages of an electrochemical process, associated with the transfer of electrons and involving conjugated chemical reactions. For this purpose, Nicholson and Shain[66] proposed the use of not only the form of the change in current at the peak I_p with change in V, but also the dependence of such parameters as the potential E_p, the half-peak potential $E_{p/2}$ (when the peak is "flattened" over several millivolts along the axis of potentials), the width of the oscillopolarogram (the extent of the curve along the axis of potentials between the abscissae E_p and $E_{p/2}$), the ratio of the heights of the anodic and cathodic peaks I_{pa}/I_{pk} with change in V, and also the dependence of the current function Ψ (the current function Ψ is defined by the expression $I_p/nFAC_0\sqrt{Da}$, where I_p is the current at the peak, A the area of the electrode, C_0 the volume concentration of the depolariser, a a kinetic parameter $a = nFV/RT$, and the other symbols have their usual significance) on V. These criteria were derived for the usual conditions of oscillographic polarography with an electrode, the surface of which does not change during the recording of the curve. It should, however, be noted that the form of the oscillopolarogram for a definite form of polarising voltage depends on the type of electrode

used[4,67,68], that is on whether the electrode is liquid or solid, spherical, flat, or film, etc., on the dimensions of the space next to the electrode[69], on the ohmic factors of the cell[39,70], which depend on the concentration of the background electrolyte, and apparently on the nature of the solvent[4]. If the oscillopolarograms are obtained as the plots of I against E at a mercury electrode with a very short dropping period of ~0.008 s, the form of the curves is identical to that of the usual classical curves[67]. If the surface of the mercury electrode changes during the recording of the oscillopolarograms, the most suitable criterion for the calculation of I_p for different V and arrests of the polarisation pulse is the moment when the curve reaches E_p [71]. In principle the method of oscillographic polarography makes it possible to determine a number of parameters characterising the electrode process, such as a, the transfer coefficient; D, the coefficient for the diffusion of the substance towards the electrode; n, the number of electrons taking part in the electrode reaction; k_s, the reaction rate constant; and ΔG, the standard free energy of activation of the discharge process. Moreover, it is possible to establish the nature of the separate electrochemical stages, complicated by chemical reactions, the reaction rate constants, and the orders of the reactions, and to detect the formation of intermediate species during electrolytic reduction or oxidation. Usually, the relationships for the calculation of the parameters have been derived without allowance for the adsorption of depolariser species on the electrode surface, as for example in Ref. 66, or with the assumption that the contribution of adsorption is slight. For organic compounds this is only a particular case. The use of oscillographic polarography to study adsorption phenomena will be examined below.

If an electrode process is controlled by the rate of diffusion and the electron transfer stage is reversible or almost reversible and is not complicated by chemical reactions, the corresponding oscillopolarograms have a sharp maximum. E_p in this instance is independent of the depolariser concentration. The value of I_p is determined by the familiar equations of Sevcik or Randles[33,34,72,73], is independent of the pressure on the dropping mercury[74], and is directly proportional to $V^{1/2}$. For reversible processes, the following relationships are applicable[66,75]:

$$E_{p/2} - E_p = \frac{0.057}{n}(1) \quad \text{and} \quad E_p = E_{1/2} - (1.109 \pm 0.002)\frac{RT}{nF} \qquad (2)$$

or for an indistinct peak $E_{p/2} = E_{1/2} + 1.09\,RT/nF$, where $E_{1/2}$ is the polarographic half-wave potential, and R, T, and F are familiar constants. From the descending branch of the oscillopolarograms at potentials 0.2 V more negative than E_p, it is possible to determine n from the equation

$$I_p/I = n^{1/2} \cdot \text{const} \qquad (3)$$

derived theoretically[76] and later found empirically[77], and also the diffusion coefficient of the depolariser D[76]:

$$I_{0.2} = 1.43 \cdot 10^5 \cdot n \cdot A \cdot C_0 \cdot V^{1/2} \cdot D^{1/2} \qquad (4)$$

where $I_{0.2}$ is the current for a potential of $(E_p + 0.2)$ V. For reversible processes with diffusion control, moreover, the quantity $\Delta E_{p/2}/\Delta \lg V$ is independent of V [66]. If the electrode is polarised by a triangular voltage pulse, for a reversible process, an anodic peak is observed in addition to a cathodic peak, the ratio I_{pa}/I_{pk} is equal to unity[66], and ΔE_{pak} is $0.057/n$ V[78]. Study of the dependence of ΔE_{pak} on V makes it possible to find comparatively simply the value of k_s—the heterogeneous rate constant for the electrode reaction[78]. The chief source of error in this determination is the non-compensated quantity IR, which depends on C_0, V, and the concentration of the background in the cell. With increase in I, the ohmic potential drop will be commensurate with ΔE_{pak} so that it is necessary to take precautions to eliminate it or to make allowance for this effect in the calculations.

For an irreversible electrode reaction with diffusion control, I_p is determined by Delahay's equation[79]:

$$I_p = 2.99 \cdot 10^{-5} \cdot n \cdot A(\alpha n_a)^{1/2} \cdot C_0 \cdot D^{1/2}V^{1/2} \qquad (5)$$

where n_a is the number of electrons taking part in the potential-determining stage ($0 < n_a < 1$). The form of the curve for an irreversible process depends on αn_a, whereas the heterogeneous rate constant k_s defines only the position of this curve on the axis of potentials, that is it depends on E_p. Since $\alpha < 1$, and $n_a < n$, it follows that I_p for an irreversible process is less than I_p for a reversible process. To determine n it is possible to use Eqns. (3) and (4), which are also applicable for an irreversible reaction with allowance for the coefficient α. The transfer coefficient is found from Matsuda's relationships[75]:

$$\alpha = \frac{0.048}{n(E_{p/2} - E_p)} \qquad (6)$$

Comparison of the experimentally observed value of I_p for an irreversible process with that calculated theoretically from Randles' equation[73] also makes it possible to estimate α from the equation[75]

$$\alpha = \left(0.9\,\frac{I_p^{\text{exptl}}}{I_p^{\text{theor}}}\right)^2 \qquad (7)$$

On going to irreversible processes, for example with increase in V [76], the sharp form of the maximum on the oscillopolarogram is smoothed out, and the curve extends further along the potential axis than that for a reversible reaction, and the slope of its central section is given by the expression[66]:

$$E_p - E_{p/2} = -1{,}857 \cdot \left(\frac{RT}{\alpha n_a F}\right). \qquad (8)$$

The anodic peak for irreversible processes is absent, or else its potential is much greater than the theoretically permissible difference ΔE_{pak}. It has been shown that for an irreversible reaction the current passing in the initial section of the oscillopolarogram is independent of V [66,80]. E_p and $E_{p/2}$, however, are functions of V [66]:

$$(E_{p/2})'' - (E_{p/2})' = (E_p)'' - (E_p)' = \frac{RT}{\alpha n_a F} \ln \sqrt{\frac{V'}{V''}} \qquad (9)$$

that is with an irreversible process a cathodic shift of the peak or half-peak potentials by about $0.03/\alpha n_a$ is observed for each tenfold increase in the rate of polarisation. From the relationship for the current and potential of the electrode for irreversible reduction[66], as for Gokhshtein's equation[76], it follows that the plots of $\lg I_p$ against $(E_p - E_0)$, where E_0 is the formal electrode potential, for different V are given by straight lines with slope equal to αn_a, and with distance between them proportional to k_e°—the rate constant for direct electron transfer. This relationship is convenient for finding the kinetic parameters of an electrode reaction, although this requires

a change in V by several orders of magnitude. The value of k'_e can also be found from Matsuda's equation[75]:

$$\lg k'_e = 1.1339 - \lg f/\sqrt{D} + {}^1/_2 \lg(\alpha n_a) V + \frac{\alpha n_a E_p}{0.0591} \qquad (10)$$

where E_p is given relative to the potential of the hydrogen electrode, and f is the activity coefficient. This equation also shows that k'_e depends on E_p and V. The standard free energy of activation ΔG is given by the equation derived[81] from the equation of Delahay[79] and the Gokhshteins[32]:

$$\Delta G = F[\alpha n_a(E_a - E_p) - 0.0591 \lg I_p/nAC_0 + 0.54 + 0.0591 \lg 10^8 \cdot \rho] \qquad (11)$$

where E_a is the potential of the reference electrode, and ρ the distance to which the depolariser species approaches the electrode. Fig. 1 gives some of the graphs which

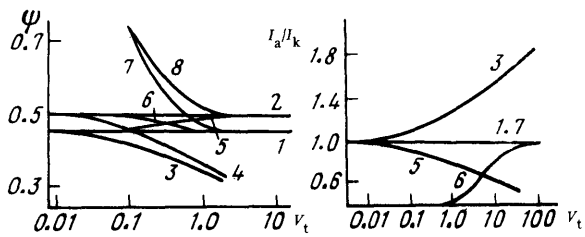

Figure 1. Dependence of the current function Ψ and the ratio I_a/I_k on the rate of polarisation[66]: *1*) reversible and *2*) irreversible charge transfer; *3*) reversible and *4*) irreversible charge transfer preceded by chemical reaction; *5*) reversible electron transfer, followed by a reversible chemical reaction; *6*) reversible charge transfer, followed by irreversible chemical reaction; *7*) catalytic reaction with reversible and *8*) irreversible electron transfer.

serve as diagnostic criteria for the main types of reaction mechanism[66]. It should be noted that Eqns. (5)–(11) are applicable with the condition that αn_a is independent of potential. Methods for finding the rate constants of the chemical reactions preceding, taking place in parallel with, or following the transfer of electrons have been examined by a number of authors[66,82-95]. Compared with classical polarography, oscillographic polarography makes it possible to extend the range for the determination of these quantities by four orders of magnitude. From the theory of kinetic currents in polarography it follows that for an electrode process taking place according to the scheme $L \underset{k_B}{\overset{k_f}{\rightleftharpoons}} O \overset{n_e}{\rightleftharpoons} B$, the upper limit is given by the expression $k_B = 200\ \tau^{-1}K^{-2}$ [46,82], where τ is the duration of electrolysis or the dropping period of the electrode, and $K = k_f/k_B$ the equilibrium constant for the chemical reaction. It follows from the last expression that in order to find the constants for very fast chemical reactions it is necessary to decrease the duration of electrolysis. In oscillopolarography, τ depends on the rate of polarisation. If it is assumed that $V = 500$ V s^{-1}, and that the polarisation pulse varies in the region of 1 V, then the duration of electrolysis is less than 2×10^{-3} s, and this makes it possible to study extremely fast chemical reactions taking place at the electrode. The practical restrictions here are that at such high values of V, there is a marked increase in I_C, as mentioned above. If the methods of difference oscillopolarography[19] or a stepped polarising voltage[26-28] are used, however, this restriction can be eliminated to a considerable extent. Essentially, for each chemical reaction preceding electron transfer, it is possible to find a range of V for which the $I = f(E)$ curves become independent of the rate of the chemical reaction. In this case the current recorded will be controlled by the diffusion of the substance O to the electrode and will correspond to a state of equilibrium between L and O. The value of K in this case is determined independently of the values for the rate constants of the chemical reaction. This method was used to determine the equilibrium constant for the hydration of formaldehyde[85] and the isomeric pyridine aldehydes[86].

The case where the reversible transfer of electrons is preceded by a chemical reaction of first order was examined by Saveant and Vianello[82]. Using the method of dimensionless parameters, they derived relationships characterising the dependence of the current function on the electrode potential for different values of K and k ($k = k_f + k_B$). The change in the parameter $\lambda = \frac{RT}{nF}\frac{k_f + k_B}{V} = \frac{kTk}{nFV}$ within certain limits makes it possible to change from pure diffusion current to currents controlled by a preceding chemical reaction. For $K > 20$ the current–potential curves have the usual form characteristic of diffusion-controlled processes. At smaller values of K the curves show kinetic limitation. For $K < 0.5$ the range of existence of kinetic currents is determined by the value of λ in the range

$$0.025 < \lambda < \frac{100}{K^2} \qquad (12)$$

For $\lambda < 0.025$ the rate of the chemical reaction is so low compared with V that during the polarisation pulse, significant formation of the substance O from L does not take place, and the current is controlled by the diffusion of O, the concentration of which is determined by the equilibrium $L \rightleftharpoons O$. For very low values of K the diffusion currents are very low and difficult to measure. However, since I_p is proportional to $V^{1/2}$, the measurement can be made at suitable values of V. For $\lambda > 100/K^2$ the rate of the chemical reaction is so great compared with V that the equilibrium at the electrode is established almost instantaneously, so that I_p is determined by the volume concentration of the depolariser. The $I = f(E)$ curves then show a cathodic displacement by an amount $\frac{RT}{nF}\ln\frac{K}{1+K}$ with increase in V by one order of magnitude. For intermediate values of λ, given by Eqn. (12), the currents are limited by the kinetics of the chemical reaction. If V changes in the range 0.1–500 V s^{-1}, the measured kinetic currents are determined by the range $0.1\ s^{-1} < k < 2 \times 10^6/K^2\ s^{-1}$ (for 25°). The form of the anodic peak on the oscillopolarograms obtained with a triangular voltage pulse is influenced by a preceding chemical reaction to a much smaller extent than the form of the cathodic peak[66]. In the work cited[66], a change in the quantities I_a/I_k, $\Delta E_{p/2}/\Delta \lg V$ and I_k with change in V was also detected, and it was recommended that these be used as diagnostic criteria. A particular case of reversible electron transfer with a preceding chemical reaction,

considered above, is a process of the type $L \underset{k_B}{\overset{k_f}{\rightleftharpoons}} 2\,O$; $O \overset{ne}{\rightleftharpoons} B$ [83]. For this the form of the oscillopolarogram depends on the value of a certain dimensionless parameter θ, proportional to the product $\frac{(k_B)^{1/2}}{V^{1/2}} \cdot K^{3/4} \cdot C_0^{-1/4}$ [83]. For very small values of θ the $I = f(E)$ curves have the form of integral polarograms, for which $E_{1/2}$ is given by the equation (for 25°):

$$E_{p/2} = E_{1/2} + \frac{0.041}{n} + \frac{0.03}{n}\lg n - \frac{0.03}{n}\lg k_B - \frac{0.015}{n}\lg K + \frac{0.03}{n}\lg V + \frac{0.015}{n}\lg C_0 \qquad (13)$$

For high values of θ the reduction current is diffusion controlled, and $E_{p/2}$ is not now dependent on V

$$E_{p/2} = E_0 + 0.01 + \frac{0.03}{n}\lg K - \frac{0.03}{n}\lg C_0 \qquad (14)$$

(with the condition that the diffusion coefficients of O and B have similar values) where E_0 is the normal redox potential of the O/B complex.

Irreversible transfer of an electron with a *preceding* chemical reaction of first order was examined in detail by Nicholson and Shain[66], who give the dependence of the calculated values of the current function on the parameters of the chemical reaction (K, $k_f + k_B$) for which equilibrium is established slowly, compared with discharge. Voloshin[84] used these calculations in a study of electrochemical processes with a preceding reversible chemical reaction of higher order $L + mz \rightleftharpoons B$ and found that a change in the concentration of z displaces the potential of the peak in the same way as $E_{1/2}$ changes with the pH of the solution for processes preceded by protonisation[46]. For this type of electrode reaction it is useful to study the dependence of I_p and $\Delta E_{p/2}/\Delta \lg V$ on V.

A paper already cited[66] discussed for the first time the case where the *rapid transfer* of electrons according to a reaction $L + ne \rightleftharpoons O$ is followed by a *reversible chemical* reaction $O \underset{k_B}{\overset{k_f}{\rightleftharpoons}} B$ (if the electron-transfer stage is retarded, the subsequent chemical reaction does not influence the form of the oscillopolarogram). A change in the value of the parameter $\xi = K\sqrt{\frac{nFV}{RT(k_f + k_B)}}$ by almost three orders of magnitude has little influence on the magnitude of the current function, so that to study the subsequent chemical reactions it is convenient to use the displacement of E_p with V. With change in the parameter ξ by one order of magnitude, E_p undergoes a cathodic displacement of almost $60/n$ mV, and tabulated data[66] can be used to estimate the parameters of the chemical reaction. The subsequent reversible chemical reaction has a marked influence on the anodic peak. It should, however, be noted that in this instance the depth of the anodic peak depends on the amplitude of the polarisation. Thus the dependence of the ratio I_a/I_k on ξ for the electrode reaction being considered must be obtained for some selected amplitude of polarisation.

If the *reversible transfer* of electrons is followed by an irreversible chemical reaction, taking place at a low rate, it has almost no influence on the form of the oscillopolarogram. For high values of the parameter RTk/nFV, however, the displacement of the potential of the cathodic peak with V can be used for a kinetic analysis[66]:

$$E_p = E_{1/2} - \frac{RT}{nF}\left(0.78 - \ln\sqrt{\frac{RTk_f}{nFV}}\right) \qquad (15)$$

It follows from Eqn. (15) that increase in the expression under the square root sign leads to an anodic displacement of E_p, whereas for the previous example a displacement of E_p towards cathodic potentials was noted. When the electrode is polarised by a triangular voltage pulse, useful information on the chemical reaction is obtained from the dependence of the quantity I_a/I_k on V, if allowance is made for the amplitude of the polarisation (or the time taken for E for the electrode to change from $E_{1/2}$ to the final polarisation potential)[66]. Saveant and Vianello[87] derived an expression for the dependence of E_p on C_0 for the depolariser and V for the case where the deactivation of the electrode products takes place as a result of their bimolecular interaction. From these equations it follows that the value of E_p should be displaced with increase in V, and $\frac{\Delta E_p}{\Delta \lg V} = \frac{RT}{nF}\left(\frac{1}{m+1}\right)$; with increase in C_0 the quantity E_p becomes more positive and $\frac{\Delta E_p}{\Delta \lg C_0} = \frac{m-1}{m+1}\cdot\frac{RT}{nF}$, where m is the order of the reaction with respect to the electrode products (for dimerisation, $m = 2$). The authors cited[87] point out that from the nature of the dependence of E_p on $\lg C_0$ it is possible to distinguish a process with retarded electron transfer from a process in which reversible electron transfer is followed by rapid dimerisation of the electrode products.

Electrode reactions with order greater than unity have been studied[88]. The $I = f(E)$ curves for polarisation of the electrode by triangular pulses were calculated by the published method[66] for processes $mO + ne \rightleftharpoons qL$ ($m > 1$), controlled by diffusion. It was found that for $m = 2$ and 3, the peaks are lower and broader than the peaks corresponding to a first-order reaction, examined above[66]. The theoretical calculations were verified experimentally for the example of the dissolution of mercury in potassium cyanide solutions ($m = 2$ or 3, depending on the cyanide concentration).

The catalytic reaction, in which the reversible transfer of electrons to the molecule of the depolariser O is accompanied by its parallel regeneration under the influence of the catalyst Z,

$$O + ne \rightleftarrows B, \quad B + Z \xrightarrow{k_f'} O$$

was discussed in detail by Saveant and Vianello[89], and later by Nicholson and Shain[66]. For a given value of k_f' and concentration of the catalyst, change in V gives a family of curves with a common asymptote, the ordinate of which is independent of V and is determined by the expression

$$I_{lim} = nFA\sqrt{C_Z D k_f'} \qquad (16)$$

Eqn. (16) can be used to find k_f'. The parameters of the catalytic reaction can be studied by means of triangular voltage pulses, for which the form of the oscillopolarograms depends on the magnitude of RTk_f'/nFV [66],

and also from the dependence of $\Delta E_p/\Delta \lg V$ on V. For a catalytic system of this type the ratio I_a/I_k is equal to unity and is independent of V, as in the case of reversible transfer of electrons, not complicated by chemical reactions[66].

For a system in which *the electrochemical and chemical stage* of catalysis are *irreversible*, the results obtained are analogous to the previous example, but the peaks in this instance will have a smaller height and will be slightly more extended along the axis of potentials. The form of the wave depends on the parameter $\frac{RTk'_f}{\alpha n_a FV}$. Saveant and Vianello[90] recommend for the determination of k'_f the measurement of the dependence of the ratio of the limiting catalytic current to the current for a given rate of polarisation on V.

An interesting type of electrode reaction is that corresponding to processes which take place by the so-called ECE mechanism, that is when there is a chemical reaction $L \overset{n_1 e}{\rightleftharpoons} O \overset{k_f}{\rightarrow} B \overset{n_2 e}{\rightleftharpoons} Z$ between the electrochemical stages. The oscillopolarograms may have different forms, depending on the relative ease of reduction of the depolariser species L and B, and also on the extent to which the chemical reaction and the electron transfer stage are reversible. In general, the study of its dependence on the parameters of the electrode reaction is very complex. Examples where the chemical stage is irreversible[92-94], and the transfer of electrons takes place rapidly[92-94] or is retarded[92], have been examined. If both transfers of n_1 and n_2 electrons are reversible, and the difference in the ease of reduction of the species L and B (that is their $\Delta E_{1/2}$ values), is sufficiently large and it is more difficult to reduce B than L, then the curves contain two peaks, the form of which is determined by the parameter RTk_f/nFV and the ratio n_2/n_1. At low values of this parameter the second peak is not observed, and with increase in the parameter the peak height increases. The form of the anodic peaks depends to a considerable extent on k_f and the extent of polarisation of the electrode, so that it is difficult to obtain information on the process from it. The calculated values of the current function for the reversible and irreversible transfer of electrons for different values of the kinetic parameter n_2/n_1 and $E_{1/2}$ [92] make it possible to determine k_f for the chemical reaction included. For example, a detailed study was made of the reduction of *p*-nitrosophenol, which takes place by an ECE mechanism[93]. The values obtained for k_f show good agreement with results obtained by other electrochemical methods. For cases analogous to *p*-nitrosophenol (for $n_1 = n_2$), it is convenient to determine k_f by means of the equation

$$I_k/I_d = \frac{0.4 + \frac{RTk_f}{nFV}}{0.396 + \frac{RTk_f}{nFV} \cdot 0.469} \qquad (17)$$

where I_k is the height of the kinetic peak, measured at a certain value of V, and I_d is the magnitude of the current, calculated with the assumption that there is no chemical reaction, or measured at high values of V.

Despite the extensive possibilities provided by oscillographic polarography for the study of the mechanism of electrode reactions, the number of papers in which the theory of the method has actually been used for this purpose is small. Thus the value of k_s for the reduction of the cadmium ion in 1 M KCl has been determined[78], and values of α, n, k_s, D, and the free energy of activation for reduction at a dropping mercury electrode (d.m.e.) have been found for the ions of europium[96], indium and antimony[97], and silver in alkali metal nitrate solutions[98], and of silver, cadmium, lead, copper, and indium in a eutectic mixture of sodium and potassium nitrates at 245° at a platinum electrode. In the last work cited, it was established in which of the systems the reduction product is oxidised to the oxide by nitrate, or the metal forms an alloy with the electrode material. The reversible discharge of a substance with constant activity, accompanied by irreversible combination of the reaction product at the electrode has been studied in detail for the example of the anodic dissolution of mercury in sodium sulphide solutions[100].

Study of the mechanism of the reduction of sulphur dioxide in acid media at a mercury electrode showed that under these conditions, hydrogen sulphide and elementary sulphur may be formed[101].

The method of oscillopolarography with triangular scanning of the voltage has been used to study the stability and ligand exchange of mixed porphyrin complexes of Fe^{III} with cyanide and pyridine in solution at a platinum electrode[102] and ligand exchange in the product of the reduction of Fe^{III} acetylacetonate in acetonitrile[103], and to study the kinetics of an electrode process involving ionic complexes of zinc with hydroxide ions and ammonia at a stationary mercury film electrode[104]. The method was used to study the kinetic parameters and the nature of the reduction of the nitriles of acrylic, vinylacrylic, and cinnamic acids[105] at a mercury electrode, Cupferron at a carbon paste electrode[106] and a d.m.e. [107] in aqueous alcohol, diphenylpicrylhydrazyl in tetrahydrofuran at a platinum electrode[108], and isomeric cyanopyridines[109]. Study of the dependence of E_p for the peak on V and C_0 for the tropylium cation showed that in its one-electron reduction at a d.m.e., dimerisation of the radicals takes place[110]. In the reduction of benzanthrone in acidic aqueous alcoholic solutions, however, in addition to the peak corresponding to the transfer of one electron with subsequent dimerisation of the product, at high rates of polarisation a second peak produced by further reduction of the radical is detected[111]. From the nature of the I_p and V relationships observed in a study of the catalytic currents of cystine, cysteine, and albumin in the presence of cobalt ions, it was found that the magnitude of the catalytic effect is determined not only by the rate of the catalytic reaction but also by the rate of decomposition of the active complex[112].

It was noted above that the ohmic potential drop in the cell distorts the shape of the oscillopolarograms, that is it influences I_p, E_p, and their dependence on V, so that the determination of the kinetic parameters of the electrode reaction from these curves is impossible. Moreover, the non-compensated capacity current makes it impossible to use experimentally the high rates of change of potential which are often necessary for kinetic measurements. This is the reason for the comparatively small extent to which oscillopolarography is used in the study of the mechanism of electrode processes. A considerable restriction in the use of Eqns. (1)–(17) is caused by the phenomenon of adsorbability (particularly of organic depolarisers), which was not taken into account in the theoretical derivation of Eqns. (1)–(17). Oscillographic polarography can be used, however, to make a special study of the adsorption of organic compounds on

an electrode surface[1,113] and in some instances to estimate the contribution which it makes to an electrochemical process.

For substances which are not depolarisers, the method is based on the study of the change in I_C when these substances are added to the polarographic solution at different values of V. The principles of the method have been discussed[1,113]. Delahay believes[114] that the method gives erroneous results if allowance is not made, where necessary, for the fact that the adsorption is controlled by diffusion. Moreover, the method is restricted to the range of comparatively concentrated solutions of background electrolyte (greater than 0.1 M), since it does not allow for the resistance of the solution in the cell. The analytical application of this method is well known[1]. In addition to the quantitative determination of adsorbed substances from appropriate calibration curves, which generally have the form of the Langmuir isotherm, the method makes it possible to reach conclusions regarding the nature of the surface-active substances and some of their properties. The adsorption peaks with the form of a sharp maximum are characterised by a ratio $\lg I_p/\lg V$ equal to 1 (the so-called "Semerano coefficient"[65]). The situation is more complicated when the substance exhibiting surface activity is a depolariser. In this instance oscillographic polarography makes it possible to determine the adsorbed quantity of reacting substance by integration of the oscillopolarogram[115]. The integration is carried out in different ranges of potential, and for each range of integration, graphs are constructed giving the dependence of Q the quantity of electricity passed on $V^{-1/2}$. For reversible processes with only one electrochemical stage and with depolariser supplied by diffusion, this dependence is given by a straight line passing through the origin of coordinates. If reduction of the adsorbed depolariser takes place at the electrode, the straight line obtained by plotting Q against $V^{-1/2}$ has an intercept on the ordinate axis (that is as $V \to \infty$) corresponding to the quantity of electricity Q consumes in the reduction of the depolariser on the electrode surface. This method of extrapolating the values of Q to $V \to \infty$ is based on the fact that for volt-ampere oscillopolarograms of reversible processes, the current at each point of the curve is proportional to $V^{1/2}$. Comparatively recently, it was shown[116] that for irreversible processes, the area of the initial sections under the current–potential curves is independent of V (since in these regions I is determined by the rate of the actual irreversible electrochemical reaction), so that in these instances the observed dependence of Q on V is more complex, and this makes the correct extrapolation to $V \to \infty$ difficult. This method was used to study the reversible reduction of adsorbed chloranilic acid[117]. One can agree with the view[118] that this method has no advantage over the charging-curves method. To achieve the accuracy given by the recording of the charging curves, volt-ampere polarography makes more rigorous demands on the apparatus and the conduct of the experiment than the charging-curves method.

The theoretical influence of various factors on the form of the oscillopolarograms for processes involving an adsorbed depolariser has been studied by a number of workers.

When depolariser species are adsorbed, the potential–current curves after the maximum show a current drop which is much sharper than that for diffusion-limited processes, and the transfer coefficient, according to Semerano[65], is greater than 0.5. In actual fact, for diffusion limitation the current decreases comparatively slowly with time, as the diffusion layer becomes broader, in proportion to $t^{-1/2}$. On reduction of a substance in the adsorbed state, however, higher values of the currents are observed at the peak, and this is followed by a sharp decrease in the current as a result of the exhaustion of the adsorbed depolariser to a level corresponding to its rate of supply by diffusion from the depth of the solution.

Wopschall and Shain[119,120] recently studied the form of the volt-ampere curves for the reversible reduction of a depolariser with strong and weak adsorption of the depolariser on the electrode surface in accordance with Henry's or Langmuir's relationships. The curves obtained with a linearly-polarising voltage of triangular form were studied. The theoretical curves for the system without complication by adsorption are compared with those with adsorption of the depolariser or the product of its reduction in Fig. 2. Weak adsorption of the depolariser leads to a slight increase in the height of the cathodic peak relative to the system without complication, and to a smaller increase in I_a on the anodic branch of the curve.

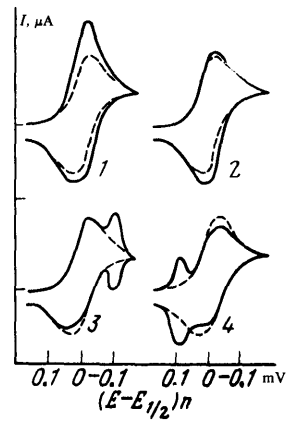

Figure 2. Theoretical forms of the oscillopolarograms for reversible electron transfer, complicated by adsorption[119]: *1*) weak adsorption of depolariser; *2*) weak adsorption of reduction product; *3*) strong adsorption of depolariser; and *4*) strong adsorption of its reduction product. The broken lines correspond to the systems not complicated by adsorption.

It is suggested that the dependence of the currents I_k and I_a on V and C_0 be used as diagnostic criteria. For high values of V the quantity of substance diffusing is small compared with the quantity of adsorbed substance reacting on the electrode surface, and for high values of V the opposite applies. Thus with increase in V the current increases relative to the value characteristic of the diffusion process for a given V. Fig. 3 gives a graph showing the dependence of the ratio of the current function Ψ (with adsorption of the depolariser) to the value 0.446 (for the process with complication by adsorption) on V. Change in the rate of polarisation also influences the magnitude of the reversible anodic peak, although its increase relative to the peak without complication by adsorption is slightly smaller than that for the cathodic peak (because of partial diffusion of the reduction product into the depth of the solution during the scanning of the polarisation pulse).

Increase in V, however, leads to a decrease in this loss of substance from the electrode surface, and the current also increases more rapidly relative to the process not complicated by adsorption. The graph giving the dependence of the ratio I_a/I_k on V has the form shown in Fig. 4, from which it can be seen that at low values of V the fraction of the current depending on adsorption becomes insignificant, and the ratio $I_a/I_k = 1$, as for the simple process. The observation that adsorption has a smaller influence on the form of the curves and the height of the peak at low values of V is a general feature of oscillopolarography, so that to decrease the effect of adsorption it is necessary to use low values of V. For weak adsorption, the fraction of the current corresponding to the adsorbed depolariser decreases with increase in C_0, and at high values of C_0 the current function Ψ takes values which are the same as those for the process without the adsorption of depolariser: this is illustrated in Fig. 5. To observe these effects, however, it is necessary to change C_0 by three orders of magnitude, and this is not always possible.

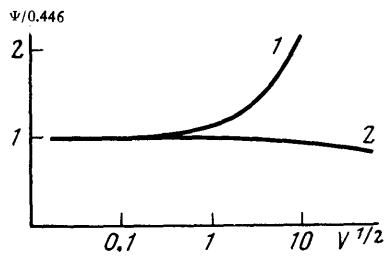

Figure 3. Dependence of the function $\Psi/0.446$ for the cathodic peak on V for weak adsorption of depolariser (*1*) and its reduction product (*2*) [119].

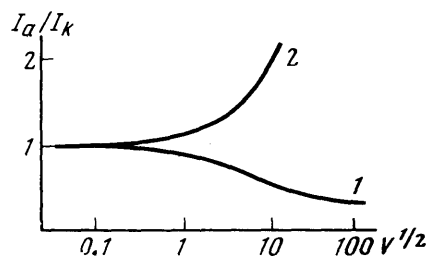

Figure 4. Dependence of the ratio I_a/I_k on V for weak adsorption of depolariser (*1*) and the product of its electrode reaction (*2*); duration of polarisation pulse after the half-wave potential $180/n$ mV [119].

An increase in the height of the anodic peak for an adsorbed reduction product relative to the peak in the absence of adsorption is usually observed when the product of the electrode reaction has been unable to diffuse into the volume of the solution during the scanning of the polarisation pulse. If the rate of polarisation is low, part of the substance is lost from the electrode surface during the passage of the pulse between the cathodic peak and the start of the anodic process, and this influences the depth of the anodic peak. This time depends on the amplitude of the pulse, so that the magnitude of the latter must be taken into account in measurements of this kind. For weak adsorption of a reducing agent, according to Wopschall and Shain[119], the cathodic peak, is only slightly displaced towards more positive potentials with increase in V, whereas the depth of the anodic peak increases appreciably and the ratio I_a/I_k also increases (see Fig. 4).

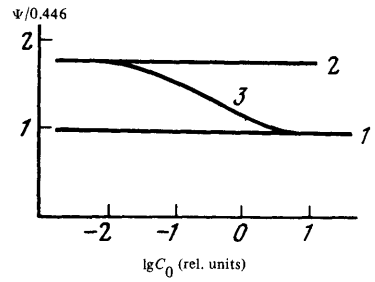

Figure 5. Dependence of the cathodic function $\Psi/0.446$ on C_0 for a system not complicated by adsorption (*1*) and for adsorption of the depolariser according to Henry's law (*2*) and Langmuir's law (*3*) [119].

At the same time, Wopschall and Shain[119] examined the case of *strong adsorption* of the depolariser or the product of its reversible electrode reaction, obeying the Langmuir isotherm.

If the product of the electrolytic reduction is strongly adsorbed on the electrode surface, the oscillopolarograms show two peaks. The first peak is an adsorption peak (its current is I_{ads}), and the second is associated with the supply of depolariser species to the electrode by diffusion (I_d) (see Fig. 2). The difference in the potentials of these peaks ΔE depends on C_0 and to some extent on V, but is determined chiefly by the nature of the adsorbed species. For low values of C_0, the ratio I_{ads}/I_d is less than 1, and the adsorption parameters are found from the half-width of the adsorption peak, ΔE for the peaks, and the dependence of I_{ads}/I_d on V and C_0. For high values of V, the preliminary adsorption peak may have diffusion character, and the diffusion peak, that is I_d, may be absent. A more detailed treatment of this example of adsorption can be found in the original paper[119].

Independently, Laviron[121] examined the influence of the adsorption of depolariser on the form of the oscillopolarograms for the reversible transfer of electrons for the example of the reduction of Methylene Blue. For $C_0 < C_{max}$, where C_{max} is the depolariser concentration at which saturation of the electrode surface takes place and the current at the peak is no longer dependent on the concentration, I_p is given by the expression

$$I_p = 6.96 \cdot 10^5 \cdot A \cdot n^2 \cdot V \cdot C_0 D^{1/2} \cdot t_1^{1/2} \qquad (18)$$

where t_1 is the time, given by the arrest before the polarisation pulse and the duration of its scanning before the peak. For $C_0 > C_{max}$, that is when the current at the

peak corresponds to the limit of the Langmuir isotherm, the value of I_p is given by the equation

$$I_p = 9.4 \cdot 10^5 \cdot A \cdot n^2 \cdot V \cdot \Gamma_{max} \quad (19)$$

where Γ_{max} is the quantity of substance adsorbed on the electrode surface. Laviron's equations, derived theoretically[121], make it possible in a number of instances to calculate the adsorption characteristics from the magnitude of the currents at the oscillographic peak.

A theoretical and experimental study of the influence of adsorption on the form of the curves for compounds undergoing irreversible reduction was made for the example of 1,2-dipyridylethylene[122]. Laviron based this study on the same premises and the assumptions[121] that the adsorption equilibrium at the electrode is displaced towards the adsorbed form of the depolariser, that is that the rate of adsorption is high and is not limited by the rate of formation of the film (at all concentrations). In this instance the current at the peak is given by the expression

$$I_p = 1.38 \cdot 10^6 \cdot n(\alpha n_a) \cdot A \cdot \Gamma_{(t_1)} V \quad (20)$$

where $\Gamma_{(t_1)}$ is the quantity of substance adsorbed in time t_1 (see above). The potential at the peak is displaced by an amount $0.059/\alpha n_a$ (at 25°) with change in V by one order of magnitude. Laviron's relationships[122] can be used to determine various parameters of the electrochemical reaction from the form of the peak.

It has been found for *m*-substituted nitrobenzenes that the current at the peak and the rate coefficient for the nitro-group depends on the nature of the substituent in the nitrobenzene molecule[64]: the higher the observed peak, the sharper the decrease in the current after the maximum (sometimes as far as the background current) and the greater the Semerano coefficient. The wave for the nitro-group appears on the curves in a range of potentials extremely favourable for adsorption. The changes in I_p, the form of the curves, and $\lg I_p/\lg V$ take place in parallel with the change in the depression of the differential capacity of the electrode in the presence of various nitro-compounds. The difference in the adsorbability of *m*-substituted nitrobenzenes is attributed to structural factors, and also to differences in the solubilities of the substances. The series studied show a tendency for I_p and $\lg I_p/\lg V$ to increase with decrease in the solubility. Analogous relationships were observed for various hydrazones[64], for which the irreversible four-electron wave appears on the curves in a wide range of potentials from −0.4 V to −1.4 V, depending on the nature of the substituent. As the reduction potential approached the point of maximal adsorption with the introduction of substituents facilitating discharge at the electrode, the peak mm on the oscillopolarogram became sharper, and the current at the peak increased, but $\lg I_p/\lg V$ exceeded 0.5, and this took place in parallel with the increase in the depression of the differential capacity. The form of the peak and the rate coefficient are also influenced by the concentration of depolariser[64,117]. In some instances the curves for a given depolariser may show two reduction current components: a surface component—a sharp peak, and a volume component—with a diffusion drop. Each of these components of the current has its own characteristic Semerano coefficient[64,117]. These phenomena on the oscillopolarograms agree with the theoretical ideas of Wopschall and Shain[119].

The adsorbability of substances on the electrode surface also explains the slight increase in the current at the peak with increased duration of the arrest before the application of the polarisation pulse, and the displacement of the initial level of recording of the curve away from the peak; this is particularly noticeable at low values of C_0. It should be noted that volt-ampere oscillopolarograms are generally recorded under conditions in which adsorption equilibrium at the electrode is not established. Adsorption with control by diffusion is retarded for strongly adsorbed substances at low volume concentrations. Convection, that is mixing of the solution, increases the rate of this process. A considerable time is sometimes necessary for equilibrium to be established (up to tens of minutes, for example in Ref. 50). Slow attainment of equilibrium at the electrode is apparently the reason for the production of hysteresis loops on current–potential curves[64]. Recently, Kalvoda[123] also emphasised that is it necessary, in the analysis of solutions with low concentrations of substances, to take account of the possibility that the establishment of adsorption equilibrium at the electrode is slow. Adsorption phenomena have also been discussed by Hale and Greef[124].

III. ANALYTICAL APPLICATIONS OF OSCILLOGRAPHIC POLAROGRAPHY

Modern forms of oscillographic polarography have developed towards an increase in sensitivity and resolving power in the study of chiefly inorganic materials. In the practical application of oscillopolarography in the last twenty years the greatest emphasis has been on the study of various ions in solution. As a result of the development of APB, oscillographic polarography has had to give some ground in inorganic analysis, since the APB method is more sensitive, and the apparatus is simpler. As already noted, however, the APB method has only a limited range of practical applications in the analysis of organic compounds, and in this field, among various electrochemical methods for the determination of small concentrations of organic substances, oscillographic polarography has recently found some applications.

1. Inorganic Analysis

The largest number of papers deal with the study of oscillopolarographic behaviour and the development of methods of determination in solution for ions undergoing reversible reduction at a d.m.e. Thus the influence of various factors on the nature of the electrochemical reduction of cadmium ions has been studied. The influence of the nature of the background electrolyte on the height of the peak for cadmium[125,126] in neutral solutions has been established. In the presence of halide anions and a trace of oxygen, the $I = f(E)$ oscillopolarogram in the potential region for the reduction of Cd^{2+} contains two peaks instead of one[125]. The explanation for the production of the peak at more negative potentials is that some of the Cd^{2+} ions at the electrode combine with OH^- ions (formed by the reduction of O_2) to form the sparingly soluble hydroxide, which is adsorbed by the electrode and subsequently reduced. The addition of gelatin or methylcellulose leads to a decrease in the height of this peak, until it disappears completely. The peak is also eliminated by acidification of the solution. This peak has been described as an oxygen peak[126], and it was later shown that its production requires a reaction taking place in parallel with the discharge of cadmium ions and bringing

about the electrochemical generation of OH^- ions. Study of the simultaneous reduction of cadmium ions and bromate anions at a d.m.e. by means of multi-cycle oscillographic polarography with a linearly changing potential[126] showed that the discharge of bromate ions can provide a source of hydroxide ions. Subsequently, a direct proportionality was established[127] between the height of the cadmium peak and the pH of the solution in the pH range 4–6.4. Thus in the presence of O_2 the sensitivity of the determination of Cd^{2+} depends on pH. Cadmium, lead, and thallium, which react reversibly at the electrode, have been the objects of a large number of studies by volt-ampere oscillopolarography. The chief results are summarised in the Table.

Oscillopolarographic study of inorganic ions at a mercury electrode.

Ion	Materials studied and conditions of polarography study	Results obtained	Refs.
1	2	3	4
Cadmium	Ammonia–ammonium salt buffer	Influence of V on reduction	128
	Halide solution	Influence of the nature of the background ion on the rate coefficient, the role of adsorption, and the mechanism of reduction	63
Cadmium and zinc	1 M NH_4Cl, 4 M NH_4OH in the presence of atmospheric oxygen	Selection of optimal conditions for analysis	129
Cadmium, thallium, and zinc	1 M KNO_3 and 0.9 M ammonia–ammonium salt buffer	Influence of V on an assembly with sinusoidal voltage in the range 100–200 V s^{-1}	130
Cadmium, thallium, copper and zinc	1 M CH_3COONH_4, 1 M acetate and ammonia–ammonium salt buffer	Study of the form of the reduction curves at an amalgamated silver electrode	131
Cadmium	1 M ammonia–ammonium salt buffer and Na_2SO_3	Rapid determination in the presence of copper	132
	Present together with lead and zinc in a 5000-fold excess of copper	Determination by differential oscillopolarography, resolving power ~30 mV	133
	Pure salts KCl, NH_4Cl, K_2SO_4, KI, KNO_3, KSCN, and $K_2C_2O_4$	Determination by an oscillopolarographic version of amalgam polarography with build-up	134
	Zinc electrolyte	Simultaneous determination of cadmium and nickel	135
Cadmium, lead, and zinc	4 M ammonia–ammonium salt buffer	Amperometric titration with Complexone III on an oscillopolarograph	136
Lead	1 M NH_4Cl	Selection of optimal conditions for analysis	129
Lead	1 M KNO_3 in the presence of atmospheric oxygen, buffer solutions	Influence of V on ΔE_{pak}; change to irreversible reaction with increase in pH; two forms of ion in solution $PbOH^+$ and $HPbO_2^-$	130
	Lead in bismuth without removal of O_2	Bismuth does not interfere in the determination of lead as far as a ratio Pb : Bi = 1 : 300	137
Bismuth and lead	Lead and bismuth in copper-based alloys	Determination of small quantities	138
Lead	In sea water and the basic rocks of the Pacific volcanic belt	Determination of small quantities	139,140
	In titanozirconate ceramic	Determination of small quantities	141
	In water, petrol, and biological materials	Determination by differential oscillopolarography	142
Lead	In blood	To 0.1 γ in 20 ml solution	143

Table cont'd.

Ion	Materials studied and conditions of polarography study	Results obtained	Refs
1	2	3	4
Thallium	In the presence of atmospheric oxygen, cobalt, and manganese	Quantitative determination	144
Fe^{3+}/Fe^{2+}	0.4 M H_2SO_4	Influence of V on the form of the curves at a Pt electrode	145
	Pyrophosphates in the presence of titanium and copper	Quantitative determination	146
Fe^{2+}	Mixed complexes with bipyridyl and phenanthroline and acetonitrile	Determination of adsorption-kinetic factors in electrolytic reduction	147
	Sulphuric acid medium	New method of coulometric study at Pt and Au electrodes down to ~10^{-7} M	148
Copper and antimony	In the presence of bismuth, cadmium, lead and zinc	Determination of down to 10^{-6} M by difference oscillopolarography	15
Zinc	In the presence of a 290-fold excess of nickel, 690-fold excess of cadmium, and 3580-fold excess of copper	Determination of down to ~3×10^{-6} M by difference oscillopolarography	15
Antimony	1 M HCl	Oscillopolarographic characteristics of the reduction	87
	In cast iron, 6 M HCl	Quantitative determination	149
	6 M HCl	Traces down to 0.1 γ in 1 ml	150
Bismuth	Semiconducting alloys, potassium chloride and oxalic acid in the presence of a 100-fold excess of tin	Quantitative determination	151
Copper and lead	In the presence of sulphonic acid derivatives of 8-quinolinol	Determination of down to 0.013 γ and 0.2 γ in 1 ml respectively	152
Cobalt and nickel	In nickel and cobalt	Quantitative determination	153
Nickel	In cobalt salts, saturated $CaCl_2$ solution without removal of O_2	Quantitative determination	154
Nickel, cobalt, zinc	Pyrophosphate background	Selection of conditions for analysis	155,156
Aluminium	In thorium compounds, in the complex with 2,2,4-trihydroxyazobenzene-5-sulphonic acid	Quantitative determination of down to fractions of 1 γ	157
	In solutions of complex-forming salts	Oscillographic behaviour	158,159
Copper, silver, gold	In the presence of chlorides, thiocyanates, ammonia, pyridine, ethylamine, 2-aminoethanol, 2,2'-2"-nitrilotri(ethanol), piperidine and ethylenediamine	Study of complex formation and selection of conditions of analysis	160
Palladium, copper, gold	In alloys	Quantitative determination	160
Gold, silver	In gold coatings on molybdenum and tungsten, in plant ash, in pure antimony	Determination of ultra-small quantities with preliminary concentration at a carbon paste electrode	161,163
Palladium	In the presence of a 70-fold excess of copper	Quantitative determination	162
Ruthenium, rhodium, palladium, osmium, iridium	In solutions of chloride, thiocyanates, cyanides, ammonia, and pyridine	Study of the electrolytic reduction of complexes, selection of conditions for the analysis of ruthenium, rhodium, and palladium in alloys	164
Niobium	In titanozirconate ceramic, in titanium–niobium and tantalum–niobium alloys, 23 N H_2SO_4	Quantitative determination	141,165, 166
Titanium	In titanozirconate ceramic, in sodium pyrophosphate solution, in the presence of uranium, in phosphoric acid media	Quantitative determination	141,167, 56,168

Table cont'd.

Ion	Materials studied and conditions of polarographic study	Results obtained	Refs
1	2	3	4
Uranium, molybdenum	In the presence of a 10-fold excess of Ferron (7-iodo-8-quinolinol-5-sulphonic acid)	Simultaneous quantitative determination	169
Vanadium	Mineral acids, ammonia-ammonium salt buffer	Study of the multi-stage nature of the reduction $V^{V} \rightarrow V^{II}$; separate stages almost reversible	130,170
Tungsten	7 M hydrochloric acid	Selection of conditions for analysis, use of second peak for reduction of tungstate anion	171
ReO_4^-, $ReCl_6^{2-}$	1-11 M hydrochloric acid	Study of stepwise reduction	172-174
Europium, ytterbium	Monazite sand, background containing ammonium salts and hydrazine	Study of the influence of the composition of the background on the form of the curves, quantitative determination	175
Samarium, dysprosium, ytterbium, lutetium, lanthanum, praseodymium, terbium	Various mineral acids, lithium chloride	Determination of the pH of the start of precipitation of the hydroxides, oscillopolarographic characteristics of the reduction, quantitative determination in phosphors	176-185
Scandium	Lithium chloride acidified with hydrochloric acid	Irreversible reduction at Au, Ag, Ni electrodes, scandium discharge peak follows hydrogen ion discharge	186
Germanium	In solutions of halides, sulphates, carbonates, phosphates	Quantitative determination of Ge^{IV} in 1 M NH_4Cl in the presence of Complexone III	188
	Semiconducting materials, in the presence of selenium, tin, and zinc, alkali solutions with pH ~12 in the presence of oxalate anions	Quantitative determination	189-191
Gallium	Semiconducting alloy, 0.2 M alcoholic solution of tetraethylammonium iodide	Quantitative determination of tenths of 1% gallium	192
Tellurium	Hydrochloric and sulphuric acids	Oscillopolarographic characteristics of reduction, second peak used for analysis, 100 times greater than first	193
Uranium	Concentrated phosphoric acid	Determination of down to $\sim 4 \times 10^{-7}$ M	194
Oxygen	In aqueous solutions, in petrol	Study of oscillopolarographic behaviour, quantitative determination	195,196
Boron	B-Si-C alloys, in a solution of orthoboric acid, sodium sulphite, and mannitol	Determination as mannitol-boric acid	197
Sulphur	In petroleum products, background of 0.04 M sulphuric acid in ethanol	Quantitative determination of aggressive sulphur (S and H_2S) at flowing mercury and Ag electrodes	198
Halogens	In solutions of potassium halides and nitrate	Quantitative determination at an Ag electrode	199
Sulphur, arsenic, and phosphorus anions	Neutral salts and alkaline solutions	Study of oscillographic behaviour, selection of conditions for direct and indirect determination	200-203

The material presented has dealt with the study of various elements in solution. In combination with solid electrodes, however, the method of oscillographic polarography has also been used to study salt melts [204-207]. Silver, lead, and cadmium chlorides have been studied in an equimolar mixture of potassium and sodium chlorides in the range 700-900° [207]; the results confirmed the earlier conclusion [205] that oscillographic polarography can be used for rapid quantitative analysis in molten salts.

The reduction of silver ions in an LiCl-KCl eutectic melt at 500° at low rates of application of the voltage at a platinum cathode [205], and the behaviour of cadmium, lead, tin, and copper ions in an $AlCl_3$-NaCl melt in the range 150-230° at a d.m.e. [208] have also been studied. The behaviour of halide anions was studied in a molten sodium nitrate-potassium nitrate eutectic with stationary and dropping mercury electrodes in the range 230-270° [209]. It was shown that in spite of the fact that the products of the oxidation of these anions at the electrode react with nitrates, distorting the form of the oscillopolarograms, their quantitative determination in the melts is possible.

2. Analysis of Organic Compounds

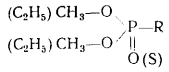
By means of classical polarography it is possible in principle to determine ~10% of all organic substances containing a polarographically active group in the molecule, whereas by means of oscillographic polarography it is possible to analyse not only these compounds but also those which in solution alter the capacity of the electrode double layer. As with inorganic materials, most papers on organic oscillopolarography have been devoted to the study of the behaviour of compounds under different conditions, the influence of the latter on the form of the oscillopolarograms, and the development, on the basis of these results, of specific methods of analysis.

Among organic compounds containing a nitrogen atom in the molecule, detailed studies have been made of the irreversible oxidation of a number of primary, secondary, and tertiary aliphatic amines at a platinum electrode in acetonitrile in a background of $NaClO_4$ [210]. The difficulty of oxidation increases on going from tertiary to secondary and primary amines. Oscillographic studies at a d.m.e. have also been made for hydrazine and hydroxylamine in alkali solutions [211]; the results, however, did not make it possible to reach an unambiguous conclusion regarding the nature of their anodic peaks; they are associated either with oxidation of the substance at the electrode or with reaction with mercury.

Detailed studies have been made of organic compounds containing sulphur, in particular thiourea and its derivatives [52,212], and various thiols [53,213]. The oscillograms for thioacetamide, thiourea, diphenylthiourea, thiosemicarbazide, and dithizone give a sharp cathodic peak, with adsorption characteristics, over a wide pH range. Its height depends not only on the concentration of depolariser, but also on the initial potential of polarisation of the mercury electrode, since it is associated with the formation of a film of an intermediate compound of thiourea or its derivative with mercury. This intermediate compound is capable of undergoing hydrolysis with the formation of mercury sulphide, corresponding to the same cathodic peak on the oscillopolarograms. A peak with analogous form and properties was also observed on the oscillopolarograms of thiols: thioglycollic and thioacetic acids, sodium thioglycollate, cysteine, etc. [53,213,214]. Various S-methyl-substituted thioureas in alkaline solution also gave a cathodic peak similar to the thiol peak [52]. The latter is due to the reduction of mercury thiolate, produced by the reaction of the thiols with mercury on the electrode surface. The works cited [213,214] also describe the oscillopolarographic behaviour of substances containing thiol and thione groups simultaneously in the molecule, such as sodium diethyldithiocarbamate, K ethyl xanthate, and di-isopropyl xanthate disulphide. Their behaviour in alkaline and acidic media resembles that of thiourea and its N-substituted derivatives. Almost no differences are observed in the form of the curves for K ethyl xanthate

and sodium diethyldithiocarbamate in acid solutions, since under these conditions the compounds decompose with the formation of carbon disulphide, which is responsible for the electrochemical activity of the polarographic solution. The works cited[52,53,212-214] consider the possibility of using oscillographic polarography to determine the following organic compounds in their mixtures with one another: thioglycollic acid and thiourea, K ethyl xanthate and sodium diethyldithiocarbamate, and K ethyl xanthate and carbon disulphide, in strongly alkaline or acidic solutions.

As noted above, many organic substances are not reduced or oxidised, but nevertheless give sharp peaks on the oscillopolarograms, due to a sharp change in the capacity of the electrode. Peaks of this kind were found to be characteristic of most organophosphorus compounds used as insecticides, and can be used for quantitative determinations at concentrations of 3×10^{-7} M [215]. The work cited[215] describes a study of dimethyl and diethyl esters of phosphoric and thiophosphoric acids with the general formula



where R represents various alkyl, aryl, or mixed substituents, in a medium of water and organic solvent (CH_3OH, C_2H_5OH, and CH_3COCH_3) in the ratio 1 : 1, with 0.2 M HCl, KCl, or NaOH solutions as background. It was noted that the peaks on the curves are more stable with time for the thio-analogues than for the phosphates and more stable in HCl or KCl than in alkali.

The behaviour under the conditions of oscillographic polarography has been studied for the semicarbazones and thiosemicarbazones of carbonyl compounds[216], the phenylhydrazones of pyruvic aldehyde and ethyl diketobutyrate[217], 5-nitromucic acid and its methyl ester[218], various compounds containing nitro and azomethine groups in the molecule[64], the azo dye Eriochrome Black[219], nitro- and aminoterephthalates[220], the nitriles of acrylic, vinylacrylic, and cinnamic acids[105], the organic analytical reagents 1-nitroso-2-naphthol[221], disodium 1-nitroso-2-naphthol-3,6-disulphonate[222], Cupferron[107], and various heterocyclic compounds: indolizines[223], aminobenzothiazoles[224-226], pyrazine[227], derivatives of 4,4-bis(triansylamino)stilbene-2,2-disulphonic acid[228], and pyrimidones[229].

The study of the behaviour of organic substances under the conditions of oscillographic polarography, described in Refs. 216, 218, and 227, and more particularly Ref. 64, has shown that the form of the curves for organic depolarisers in general depends on their concentration, the pH of the solution, the nature of the solvent, and the concentration of the background electrolyte. The fact that the form of the oscillopolarograms depends on the conditions of the polarographic study and the concentration of the depolariser, which is not always known in analysis, casts doubt on the effectiveness of the use of the so-called oscillopolarographic atlas for the identification of organic substances. This atlas[230] was based on the assumption that the form of the oscillopolarogram is specific for a given substance or series of structurally related substances, and has been proposed for the qualitative detection of organic depolarisers.

Oscillographic polarography has also been used for quantitative determinations in the analysis of α,β-unsaturated ketones present in technical methyl isobutyl ketone[231], various substances exhibiting the properties of photographic developers, such as hydroquinone, *p*-aminophenol[232,233], phenidone[233], substances acting as sensitisers[234,235], and tetraethylthiuram disulphide in the presence of elementary sulphur in organic extracts[236]. Various versions of the use of one-pulse and multi-pulse oscillographic polarography for the analysis of developers, stabilisers, and colour developer components in photography, and polyethylene glycols, which are chemical stabilisers in the production of cinephotographic materials, have been discussed[234]. In the last example an empirical relationship was established between the surface activity of the substance, and hence the height of the adsorption–desorption peaks on the oscillopolarograms, and the molecular weight of the polyethylene glycols.

A study of the oscillographic behaviour of various organic dibasic acids with the general formula $HOOC-(CH_2)n-COOH$, where $n = 0, 1, 2, 3$, or 4, showed that acids such as oxalic, malonic, succinic, and adipic in a background of $NaClO_4$ in the presence of Ge ions give distinct reduction peaks on the oscillopolarograms. Germanium itself is inactive in weakly acidic media, and its presence does not interfere in the analysis, but on the contrary increases the height of the peak for the dicarboxylic acid as a consequence of its catalytic action on discharge at the electrode.

The heights of the peaks depend on the concentration of catalyst depolarisers, the buffer capacity and acidity of the solution, and the nature of the indifferent electrolyte. It was found that with increase in the number of CH_2 groups in the organic acid molecule in the series malonic–succinic–adipic there is a gradual decrease in the catalytic peak and its potential is displaced towards more negative values[237].

Oscillographic polarography has been used successfully for the quantitative analysis of the three stereoisomeric forms of 1,4-distyrylbenzene in the presence of one another[238]. On classical polarograms these stereoisomers give waves with similar values for the half-wave potentials. If the differential oscillopolarograms are recorded, however, the selective determination of the *cis-cis* and *cis-trans* isomers in the mixture becomes possible (the *trans-trans* isomer is separated as a consequence of its low solubility in the polarographic medium) with the condition that the relative concentration of the *cis-cis* form does not exceed 75–80%.

It should be noted that the analysis of organic compounds by oscillographic polarography exhibits a number of specific features, which have been partly discussed above. The adsorbability of the depolariser species on the electrode surface explains the production of two components of the reduction current—the surface component (sharp peak) and the volume component (with a diffusion loop)[64,117]. Since oscillographic polarography exhibits a fairly high resolving power with respect to potentials (this increases for processes involving the adsorption of depolariser species), the form of the curves in the last instance can lead to the erroneous conclusion that the solution contains two electro-active substances. These characteristic features of the behaviour of organic substances under the conditions of oscillographic polarography must be taken into account in the development of analytical methods involving its use.

---o0o---

The development of modern radioelectronics has made it possible to create a wide range of new techniques

in oscillographic polarography, and these have greatly extended the range of practical applications of the method.

It should be noted, however, that each of the methods has its disadvantages and limitations[4]. Those methods which provide promising possibilities in analytical chemistry are particularly noteworthy. These are primarily the method involving fractional differentiation of the oscillopolarographic curve, which makes it possible to eliminate intermediate diffusion components, and hence to alter its form in appropriate fashion; the method involving automatic and controlled compensation of the volume resistance of the solution, which makes possible the polarographic study of non-aqueous solutions; and the method involving a stepped polarising voltage, which eliminates the influence of the background current. It should be noted that oscillographic polarography with triangular scanning of the voltage has a definite advantage over the method involving a saw-toothed form of polarising voltage, since it makes it possible to obtain information on the cathodic and anodic processes simultaneously.

The main achievements of oscillographic polarography are associated not only with the development of new methods of measurement. The development of methods for increasing the sensitivity, based on the adsorption of depolariser species, the action of various salting-out agents, or other means of concentrating the substance being determined on the electrode surface shows that the possibilities provided by oscillopolarography are not yet exhausted. The importance of studying the various factors which determine the form of the oscillographic polarograms and which must be taken into account in the qualitative and quantitative analysis of solutions should also be noted.

Review of published work shows that oscillographic polarography can be used successfully to study electrochemical processes complicated by fast chemical reactions taking place together with transfer of electrons to the depolariser. The interpretation of the oscillopolarograms obtained for this purpose for organic compounds which can be adsorbed on the electrode surface is complicated, however, and further work in this direction is required.

Nature of Carbon-Halogen Bonds

B.M.Mikhailov

This paper is a critical review of the literature on the problem of the nature of carbon-halogen bonds. It examines the various physical properties of halogen-containing organic compounds which are useful in discussing the problem of the chemical bond (infrared spectra, dipole moments, interatomic distances, nuclear quadrupole interaction constants, nuclear magnetic resonance). Special attention is paid to results from nuclear magnetic resonance, which show the uselessness of treating the properties of organohalogen compounds from the position of mesomerism-resonance theory. The correlation between the chemical shifts of nuclear magnetic resonance and the σ-constants of the substituents in various organohalogen compounds is considered. Attention is paid to the hybridisation of the orbitals of the carbon and halogen atoms and to the associated electronic displacements in unsaturated and aromatic systems. 85 references.

7. Nuclear magnetic resonance and correlation of the chemical shifts with the σ-constants of the substituents 987

I. INTRODUCTION

In the interpretation of the properties of molecules contemporary theories of organic chemistry employ ideas about the displacement of valence electrons by induction and conjugation mechanisms. Initially it was thought that the conjugative displacement of electrons, that is, their displacement from one bond to another, can occur in a molecule under the influence of a reagent (Robinson, Lowry, 1922–1923). It was proposed to represent graphically the effect of polarisation according to this mechanism by using curved arrows, symbolising the transfer of electrons from the octet of one atom to the octet of another. It was subsequently postulated that a state of constant polarisation by the conjugative mechanism also occurs in a non-reacting molecule (Arndt, 1924; Ingold, 1926). This conception, now known under the name of the theory of mesomerism, was subsequently used, mostly by Ingold, to explain a large number of problems in the reactivity of organic compounds. The use of quantum-mechanical calculations on unsaturated and aromatic systems using the π-electron approximation (Hückel, Pauling, 1932) was a further development of ideas on the delocalisation of valence electrons in organic molecules. To describe the electronic displacements in complex molecules which contain, in particular, hetero-atoms, the theory of resonance employs a set of structures corresponding to the limiting states of electron displacement

according to the conjugative mechanism. In this approach to the description of the electronic structure of a molecule the resonance theory becomes an adequate theory of mesomerism, differing only from the latter in the manner of representation of the electronic displacements that can be postulated.

The theory of mesomerism–resonance, or, as it is still called, the theory of conjugation (translated into Russian as teoriya sopryazheniya) has now received almost universal acknowledgement and is widely employed in dealing with the physical and chemical properties of organic compounds. Nevertheless, detailed examination shows the mesomerism–resonance theory to be in conflict with many experimental results. The most striking and convincing deficiency of this theory is in its application to organohalogen compounds, the properties of which have been thoroughly studied by physical and chemical methods and which also are the subject of detailed consideration from the standpoint of the theory of mesomerism.

We will consider below some physical properties of halogen derivatives of hydrocarbons—infrared spectra, dipole moments, interatomic distances, nuclear quadrupole resonance (NQR) constants—which are usually produced in support of the carbon–halogen bond's having partial double bond character. As will become evident from what is stated below, to explain some of the physical properties of the halogen derivatives of unsaturated and aromatic hydrocarbons it is unnecessary to have resort to mesomerism–resonance theory, since these properties can be substantially explained by the theory of the hybridisation of the orbitals of the carbon and halogen atoms and other physical criteria of the chemical bond, namely the NQR constants, are direct proof that the halogen atoms exhibit hardly any mesomeric effect. From the experimental results on the NQR constants it can be shown that the bonding orbitals of the halogen atoms in various types of halogen derivatives of hydrocarbons differ in their degree of hybridisation.

The increased strength of the carbon–halogen bond and the lower chemical lability of the halogen in a halogenobenzene as compared with an alkyl halide is explained by the greater overlap of the single-electron orbitals of the carbon and halogen exhibited in the aromatic compound with a higher *s*-character, and not by a greater number of electrons localised on the C–Hal bond in the aromatic compound (as is assumed in the mesomerism–resonance theory). The concept of the mesomerism theory of the participation of a conjugation mechanism in the transmission of the influence of the halogen atoms on the distribution of electronic charges in unsaturated and aromatic systems and the treatment (based upon this mechanism) of the reactivity of halogen-containing organic compounds are worthless.

2. ENERGETICS OF THE MESOMERIC STATE

Ingold originally assumed[1] that "in the halogen series, iodine, being the most capable of deformation, should exhibit the greatest tendency towards an increase in its covalency" and arranged the halogens in the following series according to decreasing mesomeric effect:

$$I > Br > Cl > F. \qquad (1)$$

Such a sequence of intensities in the displacement of electrons under the influence of the +M effect agrees with the order of the halogens according to their decreasing ability to withdraw electrons under the influence of the inductive (*I*) effect and hence leads solely to an increase in the difference between the electronegativities of the halogen atoms. Naturally, the attraction of ideas about the mesomeric effect for halogens, in the stated succession of its appearance, could not prove to be helpful for the interpretation of the physical and chemical properties of halogen-containing organic compounds. Progress in this respect would necessitate a system of effects opposite in their action, a system which would allow the difference between the atoms to be obliterated to the extent to which this is necessary for the interpretation of the experimental facts. Consequently, Ingold subsequently arranged the halogens according to their ability to increase the covalency in the reverse order:

$$F > Cl > Br > I, \qquad (2)$$

in which the mesomeric effect appears most strongly with fluorine and least with iodine. However, there is no physical basis for this series of decreasing mesomeric effects for the halogens, since it does not agree with the ionisation potentials, which increase from iodine to fluorine and not in the opposite direction.

To explain this contradiction it was assumed that the tendency towards an increase in covalency is determined not by the ionisation potentials of lone pairs but by the degree of overlap of the atomic orbitals which is the greater the less the atoms which form the double bond differ in size[2,3]. The worthlessness of this explanation becomes clear on examining actual data. The difference between the energies of double bonds formed by different atoms is ~ 10–50 kcal mole^{-1}.[4] Furthermore, the ionisation potentials of the electrons in the $tr^2tr^2tr\pi^2$ valence state of the halogens (as follows from the results on the energies of the ground states and the energies for promoting to the valence states[5,6]) for F, Cl, Br, and I are 18.24, 13.73, 12.37, and 10.88 eV respectively, that is, the difference in the ionisation potentials of the π-electrons of fluorine and chlorine is 104 kcal mole^{-1} and of fluorine and iodine is 170 kcal mole^{-1}. From energetic considerations, clearly if halogen atoms are capable of showing a mesomeric effect it should decrease in the order I > Br > Cl > F, but then its role as a working instrument in the treatment of the physical parameters of carbon–halogen bonds and of the chemical properties of halogen-containing organic compounds is lost.

3. INFRARED SPECTRA

Results on the vibrational frequencies of the C=C bond in halogenoethylenes will be examined for proof that a mesomeric effect is produced by halogen atoms. The position of the vibrations for this bond in chloroethylene (1608 cm^{-1}), bromoethylene (1598 cm^{-1}), and iodoethylene (1581 cm^{-1}) compared with that of the frequency of the vibration in ethylene (1621 cm^{-1}) is explained by the influence of resonance structure $\bar{C}H_2-CH=\overset{+}{X}$ with an ordinary C–C bond[7].

If the reduction in the vibrational frequencies were connected with the influence of the mesomeric effect of the halogens, then a reduction in the frequency of the vibrations of the C=C bond in fluoroethylene would also be expected, but for this compound the wavenumber is 1650 cm^{-1},[8] that is, higher than for ethylene. Undoubtedly the reduction in the vibrational frequencies for chloro-, bromo-, and iodo-ethylene is due to mechanical reasons—the replacement of hydrogen atoms by the heavy halogen atoms. When the alkene molecule is sufficiently large, the introduction of a chlorine atom has no effect on the vibrational

frequency of the C=C bond. Thus the wavenumbers for tetraethylmethylene [2,3-dimethylbut-2-ene] and trimethylchloroethylene [2-chloro-3-methylbut-2-ene] are the same (1672 cm^{-1}).

4. DIPOLE MOMENTS

There is a body of opinion that results on dipole moments provide experimental proof of the mesomeric effect of halogens [2,3,9]. That the dipole moments of the halogenobenzenes are lower than those of the methyl halides is explained by the effect of the mesomeric structures:

in that the difference in the dipole moments of the aliphatic and aromatic series $\mu CH_3X - \mu C_6H_5X$, is regarded as a measure of the mesomeric effect. This is illustrated by Table 1 (columns 2, 3, and 4), data taken from Coulson's book [9].

Table 1.

x	F	Cl	Br	F	Cl	Br
1	2	3	4	5	6	7
μ (CH_3X)	1.81	1.87	1.80	1.79	1.87	1.80

$CH_2{=}CHI$	0.82	0.332	8.84	0.16	9.31	0.02	20.36	

However, the dipole moments cannot serve as confirmation of the existence of a mesomeric effect for the halogens. The lower dipole moments of the halogenobenzenes is explained by the carbon atoms in the trigonal valence state (sp^2) exhibiting a higher electronegativity owing to which the polarisation of the C_{sp^2}–Hal bond is less than that of the C_{sp^3}–Hal bond. The effect of the hybridisation of the carbon orbitals on the moments of the C–Hal bond was examined by Petro [10]. Thus, the moment of the C_{sp^3}–F bond is 1.50 D, that of the C_{sp^2}–F bond is 0.95 D, that of the C_{sp^3}–Cl, C_{sp^2}–Cl, and C_{sp}–Cl bonds are 1.56, 1.07, and 0.61 D respectively, and those of the C_{sp^3}–Br and C_{sp^2}–Br bonds 1.49 and 1.01 D. The dipole moments of the halogenohydrocarbons also show the effect of the orbital hybridisation of the halogen atoms which is reflected by the electronegativities of their bonding orbitals (see Table 2). As regards the values of $\mu(CH_3X) - \mu(C_6H_5X)$, on selecting the most reliable values of the dipole moments [11] this difference disappears (Table 1, columns 5, 6, and 7).

In the CH_3X and $CH_2{=}CHX$ series the differences in the dipole moments for the fluoro-, chloro-, and bromo-derivatives are 0.36, 0.42, and 0.41 D respectively; for CH_3X and $CH{\equiv}CX$ this difference increases from fluorine to bromine (1.04, 1.43, and 1.80 D respectively) [11].

5. HYBRIDISATION OF THE ORBITALS OF HALOGEN ATOMS AND LENGTHS OF THE CARBON–HALOGEN BONDS

One of the main arguments in support of the halogen atoms exerting a mesomeric effect was the lengths of the carbon–halogen bonds in halogenohydrocarbons. Thus the shortening of the C–Cl bond in chlorobenzene and the chloroethylenes by 0.06–0.08 Å in comparison with the length of this bond in the halogenomethanes was explained by the presence of 15–18% double-bond character [12]; in the halogenoacetylenes, where the shortening of the carbon–halogen bond reaches ~ 0.15 Å, the degree of double-bond character is estimated at 30–36%. [13]

In the light of the theory of hybridisation, variations in the lengths of the carbon–halogen bonds are explained by orbital effects—the sizes of the covalent radii of carbon and the halogens in various valence states, realisable in one molecule or another [14]. The hybridisation of the orbitals of carbon atoms is determined simply from results on the geometry of the molecules [15]. Information about the hybridisation of the bonding orbitals of halogen atoms is underlined by the nuclear quadrupole interaction constants. The use of the latter for determining the degree of hybridisation of the orbitals of halogen atoms was hindered by the fact that they are functions of both the degree of hybridisation (s) and the ionicity of the bond (i). Both these parameters have a definite relation with a single experimental quantity, the number of non-bonded p-electrons [sic]:

$$U_p = -\frac{eQq_{mol}}{eQq_p},$$

in accordance with Eqn. (5):

$$U_p = (1-s)(1-i). \qquad (5)$$

Various attempts [16,17] were made earlier to find a relation between the ionic nature of a bond and the difference in electronegativities of the bound atoms, in order to substitute the ionicity of the bond in Eqn. (5) to determine the degree of hybridisation of the halogen orbitals. In this, however, no account was taken of the extremely important fact that a change in the hybridisation of the orbitals of the halogen atom is accompanied by a change in its electronegativity. After Hinze and Jaffe [5,6] had found a relation between these two parameters it was possible to determine the s-nature of the halogen orbitals and to show its effect on the length of the carbon–halogen bonds [14].

The ionic nature of a bond i is determined on the basis of the concept of bond electronegativity with the aid of Eqn. (6):[18]

$$i = |nAj - 1| = \left| \frac{\Delta\chi}{2(C_A + C_B)} \right|, \quad (6)$$

where nAj is the number of electrons in the jth orbital of atom A, $\Delta\chi$ the difference between the electronegativities of atoms A and B, eV; C_A and C_B the half-differences between the ionisation potential and the electron affinity for the orbitals of atoms A and B respectively, $C = \frac{1}{2}(I_V - E_V)$. The electronegativity of the carbon and halogen atoms depends linearly on the s-character of the bonding orbital[5], as does the ionisation potential I_V and the electron affinity E_V for the halogens. The ionisation potentials and electron affinities of the carbon atoms in a state of non-integral hybridisation are found from curves constructed from available information for sp^3, sp^2, and sp states. The valence states of the carbon atoms (s-nature) are found from results on molecular structure with the aid of the relation derived by Coulson[19]. Subsequently by selecting the values of i which satisfy the experimental results about the number of non-bonded p-electrons (5) the s-nature of the halogen bonding orbitals was calculated. To determine the degree of hybridisation of the halogen orbitals in bromo(methyl)acetylene and iodo(methyl)acetylene [1-bromo- and 1-iodo-propyne], in which the electronegativity of the halogen is less than for carbon in the sp state, Eqn. (7) is used[16]:

$$U_p = (1 - s)[1 + i(1 + 2C)] \quad (7)$$

where C is a screening constant, 0.13 for bromine and 0.12 for iodine.

The calculated values of the s-nature of the halogen orbitals in various types of halogenohydrocarbons are given in Table 2, which shows that the bonding orbitals of chlorine are 19–26% hybridised, those of bromine 14–21%, and those of iodine 10–16%.

In the analysis of results on the interatomic distances it is noteworthy that in different types of halogenohydrocarbons the carbon atoms in different valence states have different covalent radii[14,15]. A significant part is also played by the change in the covalent nature of the halogen with change in the covalent radii of the carbon and halogen in one or another valence state depending on the ionicity of the bond. Conclusions about the degree of double-bond character can only be drawn from the lengths of the carbon–halogen bonds if all these factors are taken into account.

The covalent radii of carbon, as a function of the s-nature of its orbital (r_C^{cov}), and their change with the ionicity of the bond (Δr_C) are determined by the relations (8) and (9) derived earlier[15]:

$$r_C^{cov} = (0.854 - 0.328)\,\text{Å}, \quad (8)$$

$$\Delta r_C = 0.88\,|n_C - 1|\,\text{Å}, \quad (9)$$

where n_C is the number of localised electrons in the carbon orbital.

The variation of the covalent radius of chlorine with the s-nature of its bonding orbitals and its change with the ionicity of the bond are determined by starting from results for chlorotrifluoromethane and dichloromethane, in which the s-nature of the chlorine orbitals is the same (0.19) (see Table 2). By using the results on the s-nature of the carbon orbitals and the bond ionicity i in these halogenomethanes (Table 2), by use of Eqns. (8) and (9) the covalent radii $r_C^{*\delta}$ can be found, and subtraction of these from the interatomic distances gives the covalent radii of chlorine $r_{Cl}^{-\delta}$ for CF_3Cl and CH_2Cl_2 (Table 3). From the values of $r_{Cl}^{-\delta}$ and i for these molecules can be found the covalent radius of chlorine for its hybridisation (0.934 Å) and ΔrCl, Eqn. (10), and then by bearing in mind that for the chlorine molecule the s-character is 0.01 and r_{Cl}^{cov} = 0.994 Å, the relation between the covalent radius of chlorine and the degree of hybridisation of its orbital, (11), can be found:

$$\Delta r_{Cl} = 1.30\,|n_{Cl} - 1|\,\text{Å}, \quad (10)$$

$$r_{Cl}^{cov} = (0.997 - 0.33\,s)\,\text{Å}. \quad (11)$$

[There is no Eqn. (12) in this paper (Ed. of Translation)].

The calculated lengths in CH_3Cl, chlorobenzene, and chloroacetylene, obtained with Eqns. (8)–(11) and the data of Table 2, agree well with experimental values (Table 3). The calculated length of the C–Cl bond in vinyl chloride differs from some of the experimental results[28] but agrees with others[20]; the differences between the calculated and experimental lengths of the C–Cl bond for 1-chloropropene, *cis*-1,2-dichloroethylene, and *cis*-2-chloro-1-fluoroethylene vary between +0.01 and −0.01 Å, attributable to the uncertainty in the structural parameters of these molecules.

The dependence of the covalent radius of bromine on the s-character of its orbitals, Eqn. (13), and the change in the orbital radius with the number of electrons localised on it, Eqn. (14) were calculated from results on CH_3Br, bromo(methyl)acetylene [1-bromopropyne] (with equal s-character of the halogen orbitals), and Br_2.

$$r_{Br}^{cov} = (1.144 - 0.23\,s)\,\text{Å}, \quad (13)$$

$$\Delta r_{Br} = 1.28 \cdot |n_{Br} - 1|\,\text{Å}. \quad (14)$$

The length of the C–Br bond in bromobenzene was calculated with the aid of Eqns. (8), (9), (13), and (14) and the data of Table 2, and differed from the experimental value by 0.002 Å. For CF_3Br the difference was 0.015 Å, which shows that the C–F bonds in this compound are of the "banana" type. The calculated value of the length of the C–Br bond in bromoethylene differs from the

experimental values (which show considerable variation) obtained from microwave spectra (1.853 and 1.891 Å).

The following relations for r_I^{cov}, Eqn. (15), and Δr_I Eqn. (16), were found from the results for CH_3I, iodomethyl)acetylene, and I_2.

$$r_I^{cov} = (1.342 - 0.15\,s)\,\text{Å}, \quad (15)$$

$$\Delta r_I = 1.25\,|n_I - 1|\,\text{Å}. \quad (16)$$

Starting from the parameters of the molecular structure adopted in work on iodoethylene [36] ($\angle C_2C_1I = 122.4°$, $\angle C_2C_1H = 120°$), the calculated length of the C–I bond is 0.019 Å shorter than that found. It is noteworthy that to calculate the length of the C–Hal bond in halogenoethylenes it is necessary to know $\angle C_2C_1H$, which was taken as 120° in work on bromoethylene and iodoethylene, The agreement of the calculated lengths of the C–I bond in iodoethylene with published data is obtained if $\angle C_2C_1H = 124°$.

Correlation equations (10) and (11) were derived from results for molecules (CF_3Cl and CH_2Cl_2) in which the mesomeric effect for chlorine should not appear. In chlorobenzene and chloroacetylene, where a mesomeric effect is theoretically possible the C–Cl interatomic distances would not obey Eqns. (10) and (11), should this effect appear, and the departure of the calculated values of the C–Cl bond lengths from the experimental ones would serve as a measure of the mesomeric effect of chlorine in aromatic and acetylene compounds.

At 5% double-bond character the length of the C–Cl bond in chlorobenzene would be shorter than that calculated by 0.021 Å, as follows from Eqn. (17):[12]

$$R = R_1 - (R_1 - R_2)\frac{3x}{2x+1}, \quad (17)$$

where R is the interatomic distance in a bond of intermediate type, R_1 the length of an ordinary bond, R_2 the length of a double bond, and x the degree of double-bond nature.

Actually the difference between the calculated and experimental lengths of the C–Cl bond in chlorobenzene is 0.001 Å.

Correlations establishing a relation between interatomic distances in carbon–halogen bonds and the hybridisation of the orbitals of the carbon and halogen atoms serves as proof of either the absence of a mesomeric effect for the halogen atoms or of its appearance to such a slight extent that it does not have any appreciable effect on the lengths of the carbon–halogen bonds.

6. NUCLEAR QUADRUPOLE RESONANCE

A most important and independent criterion of the ability of halogen atoms to show a mesomeric effect is provided by results on the nuclear quadrupole interaction, obtainable with the aid of microwave spectroscopy.

According to Goldstein and Bragg [37,38], a measure of the influence of the mesomeric effect in vinyl halides is provided by the asymmetry parameter, given by the expression:

$$\eta = \frac{\chi_{xx} - \chi_{yy}}{\chi_{zz}} \quad (18)$$

where χ_{xx}, χ_{yy}, and χ_{zz} are the quadrupole interaction constants along the corresponding coordinate axes x, y, and z, with χ_{zz} (eQq_{mol}) being the quadrupole coupling constant along the carbon–halogen bond. The degree of double-bond character of the carbon–halogen bond is determined by the quantity:

$$\delta = \frac{\eta \cdot eQq_{mol}}{^3/_2 eQq_{atom.}}, \quad (19)$$

and the percentage double-bond character = $100\,x\,\delta$.

The degree of double bond character has been calculated for various vinyl halides: 4–6% in vinyl chloride [28,38,39], 4% in *cis*-1,2-dichloroethylene [31], 4% in vinyl bromide [35], and 3% in vinyl iodide [36,39,40]. In evaluating the asymmetry parameter in the vinyl halides which are molecules of the asymmetric tap type, in which the principal axis of inertia does not lie along the direction of the carbon–halogen bond, a series of assumptions are made concerned with the impossibility of transforming the quadrupole interaction constants relative to the principal axes of the molecule a, b, and c into the new axes x, y, and z. In addition the values of the bond constants are very sensitive in relation to assumed parameters. Thus the experimental results are not inconsistent with the presence in vinyl chloride of only 2% double-bond character [28]. The difficulties in the calculation of χ_{xx} and χ_{zz} are due in particular to the insufficiently precise data about the molecular structure of the vinyl halides obtainable by electron diffraction.

The available information about the NQR in the halogen derivatives of benzene relates (except for bromobenzene) to the solid state. The quadrupole effects observed in these compounds, although distorted by the influence of the crystal field, show a very low degree of double-bond character in the carbon–halogen bond. Thus, in *p*-dichlorobenzene the double-bond character is 2.7 ± 0.7%, in *p*-chlorobenzyl chloride 2.4 ± 0.7%, in *p*-chloroaniline 2.0 ± 1%, [41] and in iodo-substituted benzenes the degree of double-bond character amounts to 1.6–2.8% (*m*-iodonitrobenzene 1.6%, *p*-iodoaniline 1.6%, *p*-di-iodobenzene 2.1%, 4-iodobenzoic acid 2.1%, 3-iodobenzoic acid 2.7%, *p*-iodonitrobenzene 2.8%) [42]. To obtain more reliable information about the degree of double-bond character of C_{sp^2}–halogen, Rosenthal and Dailey [33] made a fundamental investigation of the quadrupole effects in *gaseous* bromobenzene, in which (unlike the halogenoethylenes) the principal axis of inertia coincides with the direction of the carbon–halogen bond. It appeared that the quadrupole constants in the isotopic modification $C_6H_5{}^{79}Br$ agree with 1–2% double-bond character in the C–Br bond, and in the isotopic modification $C_6H_5{}^{81}Br$ there is no double-bond character, within the limits of accuracy of the measurements. The authors concluded that the explanation for the peculiarities of the C–Br bond in aromatic compounds in terms of the conjugation theory is implausible.

Hence modern results on the NQR spectra show either the complete absence of mesomeric effect for halogen atoms, or its appearance to such a slight extent that its influence should hardly be reflected in the physical parameters of the carbon–halogen bond and in the chemical properties of halogen-containing organic compounds.

7. NUCLEAR MAGNETIC RESONANCE AND CORRELATION OF THE CHEMICAL SHIFTS WITH THE σ-CONSTANTS OF THE SUBSTITUENTS

A discussion of the electronic structure of molecules often is based on a joint examination of NQR spectroscopic and chemical results and is greatly subject to the establishment and analysis of correlations between the ^{13}C, ^{1}H, and ^{19}F chemical shifts and the σ-constants of the substituents. This is quite regular, since the system of

inductive and mesomeric effects of the substituents, including halogen atoms, was developed on the basis of an examination of chemical properties. The dissociation constants of halogen-substituted phenylboric and benzoic acids, phenol, and aniline were the experimental material which stimulated Ingold to examine the problem of the relative intensity of the mesomeric effect at the halogens. As follows from the positive values of the substituent constants [43,44], the replacement of hydrogen in any position of the benzene ring hy a halogen atom leads to an increase in the strength of the substituted acid, but not in the same order as would be expected on the basis of the relative electronegativities of the halogen atoms. To explain the experimental facts required not only that the halogens have the ability to show a mesomeric effect but also their arrangement according to decreasing mesomeric effect in the same order (F > Cl > Br > I) as would give a fluorine atom attached to an aromatic system the least electronegativity and an iodine atom the greatest.

If the concepts of the quantitative theory of the reactivity of organic compounds are followed and the σ-constant of a substituent is regarded as the sum of inductive and mesomeric constituents ($\sigma = \sigma_I + \sigma_R$), the mesomeric influence of halogen atoms on the strength of, for example, *p*-halogenobenzoic acids is very pronounced. Thus in *p*-fluorobenzoic acid the aliphatic constant of the substituent (σ_I), which is 0.52, is reduced to 0.48, and in *p*-chloro-, *p*-bromo-, and *p*-iodo-benzoic acids the aliphatic constants of the substituents (0.47, 0.45, and 0.38) are reduced to 0.24, 0.22, and 0.10 respectively. Hence the mesomeric effect, if it appears in the aromatic system, reduces the aliphatic constant of the substituent by 30–90%.

Table 4. Chemical shifts of ^{13}C in monosubstituted benzenes (in magnetic units in relation to benzene).

Substituent	C–X	*ortho-*	*meta-*	*para-*

CHO	—9.0	—1.2	—1.2	—6.0
NO_2	—19.6	5.3	—0.8	—6.0
$COCH_3$	—9.3	—0.2	—0.2	—4.2

Let us examine to what extent the information about the distribution of electronic density in substituted benzenes based on the chemical properties reflects the electronic structure of the molecules in their ground state, by comparing the chemical results with those on the magnetic resonance of ^{13}C, ^{1}H, and ^{19}F nuclei, and also let us attempt to discover certain features of the effect of the substituent (halogens and alkyl groups) on their introduction into unsaturated and aromatic systems.

As Table 4 shows, the ^{13}C chemical shifts in the meta-position in all the monosubstituted benzenes investigated are found at weaker fields relative to benzene, and with the halogens the screening decreases steadily from fluorine to iodine [45].

The chemical shifts of ^{13}C in the para-position for all the substituents without multiple bonds, including halogens and CH_3, are located at higher fields. Among the halogens the strongest screening effect is exerted by fluorine, the least by iodine. The methyl group has less influence than fluorine on the chemical shift, but more than chlorine, bromine, and iodine. In the theory of electronic displacements it is assumed that the inductive effect of the substituents is transmitted along the aromatic system of bonds to the same extent in both the meta- and the para-positions but the mesomeric effect of the substituent appears only in the ortho- and para-positions. If the relative electron densities at the carbon atoms in the meta-position were determined solely by the inductive effect then their screening under the influence of the halogens should be reduced from iodine to fluorine and not in the opposite direction, as is actually observed; under the influence of the methyl group (which is regarded theoretically as electron-repulsive) the electron density at the meta-carbon atom should be increased: in reality it is decreased in comparison with benzene. The same contradiction arose in the theory of the reactivity of organic compounds when explaining the relative strength of the *m*-halogeno-substituted benzoic acids with the aid of the inductive effect. Since, according to the theory of mesomerism the mesomeric effect can be transmitted to the reaction centre solely from the para- and ortho-position, the strength of the *m*-halogenobenzoic acids should be determined by *I*, the inductive effect of the substituent and their acidity should increase steadily from *m*-iodobenzoic to *m*-fluorobenzoic acid as occurs in the series of halogenoacetic acids. However, *m*-fluorobenzoic acid ($\sigma_m = 0.34$) is weaker than *m*-chlorobenzoic acid ($\sigma_m = 0.37$) and the latter is weaker than *m*-bromobenzoic acid ($\sigma_m = 0.39$) (see Table 5). The same sequence in the degree of dissociation is observed in the series of *m*-halogenophenols. To explain this phenomenon it was suggested [46] that the halogens (and also other similar substituents) in the meta-position bring about a mesomeric shift of π-electrons into the other-position, from which they are transmitted to the reaction centre by an *induction mechanism* as is shown by the following resonance structure (A):

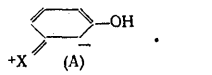

Table 5. Values of the constants δ_m, δ_m^0, δ_R^m, δ_p, δ_p^0, δ_R^0, and δ_I for the substituents.

Substituents	δ_m after Brown and Danielo	δ_p after Taft	δ_R^m	δ_p after Brown and Danielo	δ_p^0	δ_R^0	δ_I

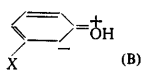
NH_2	—0.16	—0.14	—0.24	—0.66	—0.38	—0.48	0.10
$N(CH_3)_2$	—0.21	—0.15	—0.25	—0.83	—0.44	—0.54	0.10
CHO	0.36	—	—	0.22	—	—	—
NO_2	0.71	0.70	0.07	0.78	0.82	0.19	0.63
$COCH_3$	0.38	0.34	0.06	0.50	0.46	0.18	0.28

The displacement of π-electrons towards the reaction centre by this mechanism should proceed to such an extent that the usual series of relative electronegativity of the

halogens (F > Cl > Br > I) is reversed (F < Cl < Br < I). From the energetic point of view the assumption about the displacement of negative charge from the ortho-carbon in structure (A) to the electronegative (oxygen) and not to the electropositive centre ($X^+=$) is quite unfounded.

In connection with the problem, already discussed, of the delocalisation of π-electrons within the framework of the localised pairs method, mention must be made of the effect of resonance structure (B):



(B)

with an additional stabilising localisation of charge at the ortho-carbon.

On the basis of a procedure of partitioning the substituent constants into inductive and mesomeric constituents, Taft and Lewis quantitatively estimated the capability of meta-substituents to show a mesomeric effect (σ_R^m), by assuming that it is one-third [47] or one-half [48] the mesomeric effect of the substituents in the para-position (σ_R^0). Actually, however, the ratio σ_R^m/σ_R^0 is not constant and varies (Table 5) from 0.2 (for CH_3) to 0.5 (F, Cl, and other substituents). It is still not clear why even in a series of monotypical substituents (halogens) the transmission of the m-effect from the meta-position takes place with different intensity (for example, for Cl $\sigma_R^m/\sigma_R^0 = 0.5$ and for iodine $\sigma_R^m/\sigma_R^0 = 0.3$).

Since in a correlation analysis it is assumed that the σ-constants of the substituents are proportional to the charges induced by the substituents in the meta- or para-positions of the benzene ring, correlation between the σ-constants and ^{13}C chemical shifts should be expected. A comparison of the m-^{13}C chemical shifts with the σ_m^0-constants (Fig. 1) shows, however, the absence of a linear relation between these two parameters; for CH_3, NH_2, and $N(CH_3)_2$ there is not a correspondence, even in sign.

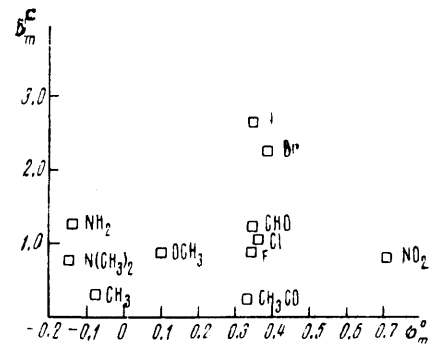


Figure 1. Comparison of the chemical shifts of m-^{13}C and the constant σ_m^0.

Judging from the values of the σ-constants of the substituents the electronic charge on the meta-carbon atoms in fluorobenzene and iodobenzene should be the same, whereas according to the NMR spectra the meta-carbon atom in iodobenzene is much less screened than that in fluorobenzene; m-chlorobenzoic acid is stronger than m-iodobenzoic acid, furthermore according to the results on the ^{13}C chemical shift m-chlorobenzoic acid should be weaker than m-iodobenzoic.

Bystrov [43] (see Chapter 1, section 7) attempted to find a correlation between the m-^{13}C chemical shifts and the inductive (δ_I) and mesomeric constants of the substituents (σ_R^m), and proposed the following equation:

$$\delta_m^C = -1.7\sigma_I + 0.82\sigma_R^m - 0.4. \quad (20)$$

Eqn. (20) is not used for halogen atoms. Actually, the experimental results show a monotonic decrease in the screening of m-^{13}C on going from fluorobenzene to iodobenzene, and according to Eqn. (20) the screening decreases in the reverse direction, from iodobenzene to fluorobenzene (the values calculated for F, Cl, Br, and I were respectively 1.57, 1.36, 1.32, and 1.14).

Table 6. ^{19}F chemical shifts in monosubstituted benzenes (in magnetic units in relation to fluorobenzene).

We will compare the chemical shifts of m-^{13}C in halogenobenzenes with the chemical shifts of ^{19}F in m-halogenofluorobenzenes and consider the correlation between the ^{19}F chemical shifts in the latter compounds with the σ-constants of the halogens. As Table 6 shows, the ^{19}F chemical shifts in *meta*-fluoro-substituted halogenobenzenes are located in a weak field in relation to fluorobenzene and the least screening to the ^{19}F nucleus is in *meta*-difluorobenzene and then in order of screening follow I, Br, and Cl. Since the m-^{13}C chemical shifts in the halogenobenzenes alter monotonically from F to Cl the correlation between the screening of the ^{13}C nucleus and the ^{19}F chemical shifts is not expected.

Gutowsky and coworkers [49] attempted to find the relation between the ^{19}F chemical shifts in *meta*-substituted fluorobenzenes and the Hammett σm-constants. The correlation they proposed is:

$$\delta_m^F = -5.92\sigma_m \quad (21)$$

which, in general, is badly observed—for example, for ethyl m-fluorobenzoate the experimental value of σ_m^F is 2.19 m.u. (magnetic units), and the calculated value is 0.15 m.u.—particularly for the halogeno-substituted compounds. Thus the ^{19}F chemical shifts in m-difluorobenzene and m-fluoroiodobenzene are at lower fields than those in the chloro- and bromo-substituted compounds, yet according to Eqn. (21) they should be found at strong fields.

Taft [47] examined the linear relation between the ^{19}F chemical shifts in meta-substituted fluorobenzenes and the inductive constants (σ_I), expressing it by the equation:

$$\delta_m^F = -7.1\sigma_I + 0.6. \quad (22)$$

However, correlation (22) cannot be regarded as satisfactory. For various substituents there are considerable departures of the calculated values of the ^{19}F chemical shift from the experimental ones, for example, for the $CO_2C_2H_5$ group the calculated δ_m^F is −1.53 m.u. and the experimental is −0.15 m.u., for NH_2 and C_6H_5 the calculated values of δ_m^F (−0.10 and −0.10) differ from the experimental ones (respectively 0.50 m.u. and 0.15 m.u.) even in sign. The absence of a linear relation between δ_m^F and σ_I for halogens is shown in Fig. 2.

However, the problems of the accuracy with which Eqns. (21) and (22) are obeyed does not exist in considering the problem of the effect of the substituent on the electronic density at the meta-carbon atom in the compounds used for measuring the constants of the substituents, since, as Fig. 3 shows, there is no correlation between the ^{13}C and ^{19}F chemical shifts. The absence of a correlation between the m-^{13}C chemical shifts in the monosubstituted benzenes and the ^{19}F chemical shifts in the meta-substituted fluorobenzenes is not unexpected. When such a strongly electronegative atom as fluorine is introduced into the meta-position a considerable non-additive redistribution of the electron densities can take place.

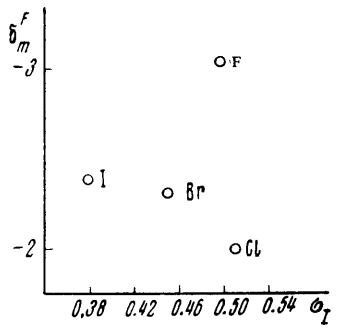

Figure 2. Comparison of the ^{19}F chemical shifts in m-halogeno-substituted fluorobenzenes with the σ_I constants.

In examining the effect of substituents on the screening of a para-carbon atom in monosubstituted benzene we must return to Table 4, from which clearly all the halogens—and also the CH_3, OCH_3, NH_2, and $N(CH_3)_2$ groups—increases the electron density at the para-carbon, and the effect decreases in the order F > Cl > Br > I.

A comparison of the p-^{13}C chemical shifts in the monosubstituted benzenes with ^{19}F chemical shifts in the para-substituted fluorobenzenes enables a correlation to be found between these two parameters, expressed by Eqn. (23):

$$\delta_p^C = 1.52\delta_p^C, \quad \delta_p^C = 0.66\delta_p^F. \tag{23}$$

Although Eqn. (23) is obeyed for certain substituents (Br, I, CH_3) with moderate accuracy, it allows the degree of screening of p-^{13}C to be evaluated for those monosubstituted benzenes for which there are no experimental results on p-^{13}C chemical shifts.

There is also a correlation between the proton chemical shifts [45,51] and the ^{13}C chemical shifts [45] that can be expressed by Eqn. (24), which is satisfied for most groups:

$$\delta_p^C = 17.3\,\delta_p^H + 0.5, \tag{24}$$

where δ_p^H is the chemical shift of para-protons in m.u.

The question naturally arises as to the correspondence between the p-^{13}C chemical shifts in the monosubstituted benzenes or the ^{19}F chemical shifts in para-substituted fluorobenzenes (since there is a correlation between these two parameters) and the σ-constants of the substituents.

Gutowsky and coworkers [49] proposed the correlation equation:

$$\delta_p^F = -17.9\sigma_p + 4.84, \tag{25}$$

which expresses the relation between the ^{19}F chemical shifts and the σ_p Hammett constants, which for most substituents is not obeyed. Taft and coworkers, having proposed various versions [51-53] of equations relating the ^{19}F with the constants of the substituents, finally settled on Eqn. (26):[54]

$$\delta_p^F = -29.5\,\sigma_R^0 - 7.1\,\sigma_I + 0.6 \tag{26}$$

in which σ_I is an inductive constant, σ_R^0 a mesomeric constituent of the σ^0 constant of the substituent.

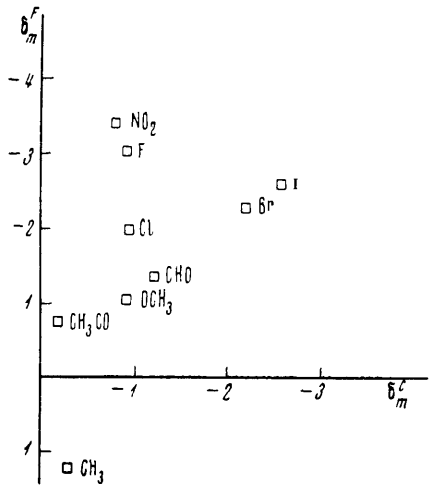

Figure 3. Comparison of the chemical shifts ^{13}C and ^{19}F of *meta*-substituted fluorobenzenes.

Hence, according to Taft, the relation between the contributions of the mesomeric and inductive effects for the reactivity of para-substituted compounds is determined by the ratio σ_R^0/σ_I, since—according to Eqn. (26)—the contributions of the mesomeric and inductive effects in the electron density of the para-carbon atom in monosubstituted benzenes is determined by the ratio $4\sigma_R^0/\sigma_I$. It is quite unknown why the influence of the mesomeric effect of the substituent in para-substituted fluorobenzene is four times its influence in para-substituted phenylacetic acids (from the dissociation constants of which the values of σ^0 are derived). On the contrary, it would appear that the introduction of a fluorine atom instead of the $-CH_2COOH$ group should (since according to the mesomerism–resonance theory the fluorine atom exhibits a large +M effect) suppress the mesomeric effect of halogen atoms in the para-position:

It must be pointed out that Eqn. (26) is satisfied by only certain substituents, and for many others there are considerable discrepancies between the calculated and experimental ^{19}F chemical shifts, for example, for Br, I, CH_3, OCF_3, CF_3, SCH_3, CN, and CH=O.

As the above shows, in the mesomeric–resonance interpretation of results on the NMR-spectroscopy of halogen-containing compounds the mesomeric effect of the halogen atoms plays an even greater part than in the treatment of acid–base equilibria.

The discrepancy between the results from ^{13}C NMR spectroscopy, which shows increased electron density at the *p*-carbon atom of halogenobenzenes, with the σ_p constants of the halogens, which indicate a decreased electron density at the carbon, linked with the reaction centre, can be attributed to various causes.

One of these could be the change in the electron density distribution of the halogenobenzene as a result of the introduction of reactive groups (OH, COOH, CH_2COOH) into its para-position, so that the halogen will show less screening of the *p*-carbon atom.

Another reason for the non-correspondence between the ^{13}C (or ^{19}F) chemical shifts and the σ_p-constants of the substituents, derivable from acid–base equilibria, could be the influence of diverse solvation processes. The role of the solvent in acid–base equilibria appears clearly in the change in the σ-constants of various substituents, especially tendency towards the formation of hydrogen bonds with water or alcohols, such as OH or NH_2. The variations in the values of the σ-constants of, for example, the OH group in *m*- and *p*-hydroxybenzoic acids with the nature of the solvent is very great and there is even a reversal of sign for the σ_m constant [55]. A considerable solvent effect on the value of the σ′-constant of bromine is observed in 4-bromocyclo[2,2,2]octane-1-carboxylic acid and the σ′-constant in this series changes particularly sharply for the $N(CH_3)_3^+$ group [56].

The σ-constants of the halogens in halogenophenols and halogenbenzoic acids change considerably on going from aqueous [57] to alcoholic solutions [58]. Thus in aqueous solution *m*-chlorophenol is less dissociated than *m*-bromo- and *m*-iodo-phenols, whereas in 50% aqueous ethanol *m*-chlorophenol is the strongest acid of these three substituted phenols. *m*-Fluorobenzoic acid is weaker than the other halogenobenzoic acids in aqueous solution but in 50% aqueous ethanol it is equal in strength to *m*-iodobenzoic acid, dissociates somewhat better than *m*-chlorobenzoic acid, and much more than *m*-bromobenzoic acid.

In aqueous solution *p*-fluorobenzoic acid ($\sigma = 0.06$) is considerably weaker than the other *p*-halogenobenzoic acids ($\sigma = 0.23–0.27$), whereas in 50% ethanol it does not differ so markedly from them ($\sigma_F = 0.20$, $\sigma_{Cl,Br,I} = 0.24–0.26$).

There are many similar examples of the pronounced differentiating effect of the solvent on relative changes in the values of the σ-constants of the substituents (for example, see Bykova and Petrova [59]).

PMR spectra are very convenient for the quantitative estimation of the influence of the solvent on the change in the electronic structure of a molecule. Diehl [60], who investigated the chemical shifts of ring protons in meta- and para-disubstituted benzenes in various solvents (hexane, acetone, benzene) found the additive nature of the effect of the substituents to be expressed as follows:

$$L_{\alpha,total} = \sum L'_{\alpha} + L_{H,\alpha}, \qquad (27)$$

where $L_{\alpha,\text{total}}$ is the total effect of the solvent α, L'_{α} the effect of the solvent α on the chemical shifts of the ortho-, meta-, and para-protons, and $L_{H,\alpha}$ the effect of the solvent on the chemical shifts of the protons of unsubstituted benzene.

By using the values found experimentally for L_H for acetone (-13×10^{-2} m.u. for a 5% molar solution in acetone) $L'_{o,x}$, $L'_{m,x}$, and $L'_{p,x}$ (listed in Table 7) the chemical shifts of the protons in monosubstituted benzenes can be found and then the changes in the electronic structure of the molecules in given solvent estimated.

The following diagrams show the chemical shifts of the protons in chlorobenzene, bromobenzene, toluene, and anisole in hexane and acetone solutions [61]:

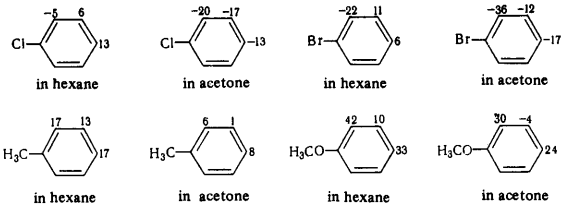

Table 7. Values of the increments L' in acetone solution (in 10^{-2} magnetic units in relation to benzene).

Substituent	L'_o	L'_m	L'_p
NH_2	−5	10	
OH	2	3	
OCH_3	1	−1	4
F	−5	−7	
CH_3	2	1	4
Cl	−2	−10	−13
Br	−1	−10	−10
I	0	−9	
CN	−9	−10	
NO_2	11	−13	

Clearly, with a polar solvent (acetone), the screening of the para-protons, and consequently also *p*-^{13}C, varies considerably. Nevertheless, as in hexane solution, the para-protons in the halogenobenzenes are screened to a greater extent than in the benzene molecule but in acetone solution they are less screened.

In acetone solution the screening of the para-protons of toluene and anisole is also reduced but nevertheless it remains greater than in benzene.

Since the polarity of water is greater than that of acetone, a change in the same order in the electron distribution in substituted benzenes also takes place in aqueous solutions. At the para-carbon atoms of the halogen-substituted compounds the charge decreases to the same extent as the electron-accepting properties of the XC_6H_4 radicals—it surpasses the electronegativity of phenyl and the *p*-halogenobenzoic acids are stronger than benzoic; the electron-accepting property of the para-tolyl and para-anisyl radicals remains less than that of the phenyl in water, as a result of which *p*-tolyl and *p*-methoxybenzoic acid are weaker than benzoic acid. Since the degree of solvation of a molecule depends both on the nature of the substituent and the type of reaction centre, the constants of the substituents do not remain constant even in a single solvent, which also explains the existence of different scales of substituents.

Let us return to a consideration of the quantum-chemical approaches to the solution of the problem of the screening of the nuclei of atoms. Karplus and Das [62] derived, on the basis of Hartree–Fock molecular wave functions, the complex relation between the ^{19}F screening in aromatic molecules and the ionic character, the order of the fluorine–carbon bond, and the hybridisation of the fluorine atom being considered. To simplify further

calculations the change in the hybridisation of the bonding orbitals of fluorine was not considered. As a result of a series of assumptions the following expression was derived for the ^{19}F chemical shifts in difluorobenzene:

$$\Delta\delta^F(\text{m.u.}) = (\delta^F - \delta^F_{\text{fluorobenzene}}) \times 10^6 = 777\,\Delta\rho - 765\,\Delta I \qquad (28)$$

where $\Delta\rho$ is the difference between the orders of the C–F π-bonds in difluorobenzene and fluorobenzene, and ΔI the difference between the polarities of the C–F sigma bond.

It was not possible to calculate the ^{19}F chemical shift in difluorobenzene from Eqn. (28) owing to the uncertainty in the values of ΔI. From the experimental results on the screening of ^{19}F in the difluorobenzenes and the calculated values of $\Delta\rho$, values of ΔI can be calculated by Eqn. (28). It appears that the contribution to the screening of ^{19}F from the mesomeric effect of fluorine is ~ 80% of the total influence of the fluorine atom found in the para-position to another fluorine atom. ΔI for *o*-difluorobenzene is negative ($\Delta I = -0.0246$), which shows that the polarity of the C–F bond is not increased when fluorine is introduced into the ortho-position of fluorobenzene; it decreases, and 75% of the total contribution to the ^{19}F screening comes from the fraction of this incomprehensively reversed inductive effect.

In the work mentioned the order of the fluorine–carbon bonds was calculated in parametric form by the molecular orbital method using the Hückel approximation (LCAO MO). It must be borne in mind that it does not follow from the approximate quantum-chemical calculations that delocalisation of the unshared pairs of electrons of the heteroatom of the substituent actually occurs; this is postulated from general considerations. The exchange interaction of an unshared pair with the π-electronic system of the aromatic ring can occur theoretically to a certain extent but it cannot exist at all if this is energetically unfavourable. In the MO method the calculation of the orders of the carbon–element bonds (the degree of double-bond character) is based on the use of parameters (estimated relative values of the coulombic and resonance integrals), arbitrarily chosen in such a way that the results of the calculations show the maximal agreement with the predictions of the resonance–mesomerism theory. The parameters for the halogen atoms are chosen in such a way that the degree of double-bond character of the carbon–halogen bond increases from iodine to fluorine, that is, so that the mesomeric effect of the halogens decreases in the order F > Cl > Br > I.

It is quite significant that in the same paper Karplus and Das compare the ^{19}F chemical shifts with the constants of the quadrupole interaction in substituted chloro- and bromo-benzenes. On the basis of the available experimental results on the asymmetry parameters for chlorobenzene ("which correspond to ~ 3% double bond nature in the C–Cl bond"), they arrived at "the important conclusion that the contribution of double-bond character to the value of $\Delta\delta$ in fluorobenzenes is significant, whereas the agreement in the values of Δq (the difference in the quadrupole interaction constants) can be reached without allowing for double-bond character in chloro- and bromo-benzenes".

In analysing the Ramsey equation for the ^{19}F screening constants with the aid of Hartree–Fock wave functions, making various assumptions about the bond parameters, Prosser and Goodman [63] derived a relation which took into account quantitatively the effect on the screening constant of the charge density of the π-electrons at the fluorine atom, the C–F bond, and the carbon atom connected with the atom being considered. The effect of the polarisation of the C–F sigma bond, that is, the influence of the inductive effect was not considered in this approximation, and the changes in the screening of the ^{19}F nuclei are explained solely by the polarisation of the π-electron cloud due to the mesomeric effect of the substituent.

According to Wu and Dailey [64] the ^{19}F chemical shift in fluorobenzene derivatives is determined by the equation:

$$\Delta\delta^F(\text{m.u.}) = \delta^F - \delta^F_{\text{fluorobenzene}} \cdot 10^6 \simeq 627\,\Delta\rho - 155.1\,\Delta P_{CF} + 574.9\,\Delta\lambda_F \qquad (29)$$

where $\Delta\rho$, ΔP_{CF}, and $\Delta\lambda_F$ denote respectively the changes in the π-electron density at the fluorine atom, the order of the C–F π-bond, and the polarity of the C–F σ-bond in the substituted fluorobenzene compared with fluorobenzene itself. The values of $\Delta\rho$ and ΔP_{CF} were calculated in that investigation by the molecular orbitals method again. The ^{19}F chemical shifts cannot be calculated by Eqn. (29), since values of $\Delta\lambda_F$ are unknown. The latter parameter was found from Eqn. (29) by use of experimental results on ^{19}F chemical shifts. As the positive values of $\Delta\lambda_F$ show, when an electron-withdrawing substituent is introduced into fluorobenzene a decrease in the polarity of the C–F σ-bond does not occur, as should happen under the inductive influence of the substituent. There is an increase in the polarity, that is, the effect of the substituent on the polarisation of the C–F bond is a mesomeric mechanism. In other words, according to Eqn. (29) the screening of ^{19}F is due solely to the mesomeric effect of the substituent (halogens, NH_2, OCH_3, CH_3).

A theoretical discussion of the ^{13}C chemical shifts in substituted benzenes leads to an examination of the influence of the π-electron density and free valency at the given carbon atom, that is, with allowance solely for the mesomeric effect of the substituent [64,65].

Clearly, in the theoretical studies it is assumed that the only or the main factor which determines the screening of ^{19}F and ^{13}C in substituted benzenes is the mesomeric effect of the substituent. On the basis of what has been stated in the section on nuclear quadrupole interaction it follows that at least as regards the halogen-substituted benzenes the approach to the problem of screening in the π-electron approximation is invalid. There are evidently other factors which affect the distribution of electron density in the substituted unsaturated and aromatic systems.

We think that in examining this problem the transmission of the inductive effect of the substituent in them merits special attention. In discussing this problem the homologues of ethylene and toluene must be considered first. These are convenient models in two respects. Firstly, owing to the low polarisation of the alkyl–C bond the effect of the field in these molecules is insignificant and secondly here the influence of the mesomeric effect is excluded, since alkyl groups do not possess it [66–68].

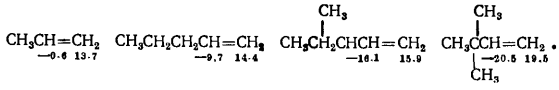
Alkyl groups must be regarded as electron-donating substituents in comparison with hydrogen. This opinion is based on results on the relative strength of aliphatic acids, the dissociation constants of which are affected by the solvation processes. In the ground state of a molecule methyl and other alkyl groups exert an electron-withdrawing action, as should logically follow from the high electronegativity of the carbon atom compared with hydrogen and as appears from the results on magnetic resonance at ^{13}C nuclei. Thus the replacement of the hydrogen atoms in methane by methyl groups leads to a successive decrease in the screening of the central carbon [69], the introduction of alkyl radicals into the ethylene molecule causes a displacement of the signals of the ^{13}C at $C_{(2)}$ to weaker fields [70] than for ethylene, in toluene the chemical shift at $C_{(1)}$ is −8.6 m.u. in comparison with benzene. The ^{13}C

chemical shifts in relation to benzene for various compounds are as follows:

If the alkyl groups exhibited at $+I$ effect, the electronic density at $C_{(1)}$ should also be increased but to a lesser extent than at $C_{(2)}$; if the alkyl groups had a $-I$ effect (as actually happens) then the electron density at $C_{(1)}$ in the ethylene homologues would also be depressed but to a lesser extent than in $C_{(2)}$. Actually the screening of the terminal carbon $C_{(1)}$ in alkenes-1 is higher than in ethylene. Supporters of the hyperconjugation theory explain this by the mesomeric effect of the groups:

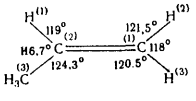
$$RCH_2CH{=}CH_2 \leftrightarrow \overset{H^+}{RCH}{=}CH{-}\overset{-}{C}H_2 .$$

Since the radicals can be arranged according to hyperconjugation effect in the order: $CH_3 > RCH_2 > R_2CH$, but the t-butyl group does not exhibit a mesomeric effect according to hyperconjugation theory, a successive decrease in the electronic charge on the terminal carbon atom of alkenes-1 would be expected on going from propene to t-butylethylene. However, in reality, as is evident from the diagrams below (the numbers denote the ^{13}C chemical shifts in relation to benzene [70]; those for propene were calculated from Savitsky and Namikava's results [71]), the order of change in the screening of the terminal carbon is the reverse of that predicted by hyperconjugation theory:



Hence the $C_{(1)}$ electron density is not determined by either the mesomeric effect of the alkyl groups (since they do not exhibit one), or the inductive effect transmitted along the carbon chain with gradual damping.

How then is the influence of the primary polarisation of the $C_{sp^3}{-}C_{sp^2}$ transmitted to the terminal carbon in alkenes-1? We think that the most important factor which determines the effect of a radical on the electron density in unsaturated and aromatic molecules is the change in its molecular structure on the introduction of a substituent, which will ensure that the potential energy of the system is a minimum. As structural investigations of propene [72] and isobutene [73] show, the replacement of hydrogen atoms in ethylene by methyl radicals involves significant changes in the geometry of the molecules. In propene $\angle H_{(1)}C_{(2)}C_{(3)} = 116.7°$, $\angle H_{(1)}C_{(2)}C_{(1)} = 119°$, and $\angle C_{(3)}C_{(2)}C_{(1)} = 124.3°$, from which it follows that the s-nature of the $C_{(2)}$ orbitals in the direction towards $C_{(1)}$ is 0.400, that is, greater than the s-nature of the orbitals of carbon in ethylene ($s = 0.368$).



From the angles of the bonds at $C_{(1)}$ it follows that the s-character of the $C_{(1)}$ orbitals in the direction towards $C_{(2)}$ ($s = 0.364$) is somewhat less than in ethylene (where $\angle HCH = 117.2°$ [74]) but the total s-character of the $C_{(1)}$ and $C_{(2)}$ orbitals ($s_{C_{(1)}} + s_{C_{(2)}} = 0.764$) exceeds the total s-character of those in ethylene ($2s_C = 0.736$), which naturally leads to an increase in the overlap of the orbitals in propene (in comparison with ethylene) and to the appearance of screening of both carbon atoms. However, the $C_{(2)}$ screening is markedly affected by the negative inductive effect of the methyl group, so that in the end $C_{(2)}$ is less screened than the carbon atoms in ethylene. The decrease in the electron density for $C_{(2)}$ is due to the displacement of the signal from $H_{(1)}$ to weaker field and correspondingly an increase in the electron density of $C_{(1)}$ brings about an increase in the screening of the $H_{(2)}$ and $H_{(3)}$ protons (in comparison with ethylene).

From the geometry of isobutene ($C_{(3)}C_{(2)}C_{(4)} = 115.3°$) there is also an increase in the overlap of the $C_{(1)}$ and $C_{(2)}$ orbitals and a greater screening of $C_{(1)}$.

In chloroethylene [28] $\angle HCCl = 113°53'$ and therefore an increase in the screening of the carbon in the CH_2 groups is to be expected. Values of 115.4° [75], 117°55', [76] and 119° [77] have been given for $\angle HCF$ in fluoroethylene. Judging by the ^1H chemical shifts in the CH_2 group of fluoroethylene, which is at a stronger field than for ethylene [78], the first value is probably the most correct.

The replacement of hydrogen in benzene by any group leads to a distortion of the regular hexagonal form of the benzene ring. This has been shown by a few but completely reliable results. Thus, in nitrobenzene [79] and benzonitrile [80] the benzene ring has the form of an irregular hexagon and in these molecules there is a change (in comparison with benzene) in both the angles and the C–C and C–H interatomic distances. Distortion of the benzene ring can have a very significant effect on the distribution of electron density and so can the change in the s-character of the carbon orbitals in the substituted benzenes which do not possess strongly polarised bonds, for example in toluene. The methyl group, which exhibits a $-I$ effect, withdraws electrons and therefore the increase in the screening of the p-carbon atom in toluene cannot be explained by the transfer of its inductive influence along the chain of atoms. Evidently the introduction of a methyl group distorts the benzene ring so that $\angle C_{(3)}C_{(4)}C_{(5)}$ becomes $> 120°$, the s-nature of the $C_{(4)}$ orbitals in the direction towards the neighbouring carbons is increased and the overlap of the $C_{(4)}$, $C_{(3)}$, and $C_{(5)}$ orbitals and the electron density at $C_{(4)}$ is increased.

If the inductive effect of the halogens (primary polarisation of the C–Hal bond), which exhibit hardly any mesomeric effects, were transferred by an aromatic system, just as in aliphatic compounds, then a decrease in the screening of the p-carbon atoms would be expected. Since the p-^{13}C-chemical shifts in the halogenobenzenes are at higher field than for benzene those changes in the hybridisation of the orbitals of carbon atoms in halogenobenzenes which facilitate the observed effect would be expected. According to one version [81] in fluorobenzene $\angle C_{(2)}C_{(1)}C_{(6)} = 121°$, $\angle C_{(1)}C_{(2)}C_{(3)} = 119°23'$, $\angle C_{(2)}C_{(3)}C_{(4)} = 119°47'$, and $\angle C_{(3)}C_{(4)}C_{(5)} = 120°40'$. In accordance with these parameters the s-character of the $C_{(4)}$ orbitals in the direction towards $C_{(3)}$ and $C_{(5)}$ is 0.338, and that of the $C_{(3)}$ and $C_{(5)}$ orbitals is 0.332. Hence in fluorobenzene the rigidity of the $C_{(4)}{-}C_{(3)}$ and $C_{(4)}{-}C_{(5)}$ bonds is somewhat above that for benzene and there is somewhat greater screening of the $C_{(4)}$ carbon atom. Naturally, during the rehybridisation of the carbon orbitals in C_6H_5X polarisation of the π-electron cloud can also take place but this is scarcely grounds for assuming considerable redistribution of it, since during the rehybridisation the electronegativity of the π-orbitals changes insignificantly (in the $trtrtr\pi$ valence state of carbon the electronegativity of the π-orbitals is 5.58 eV but in the $didi\pi\pi$ state it is 5.64 [5]).

The influence of the internal electric field of the molecules must be taken into account to a greater extent [82].

Hence we conclude that the influence of the primary polarisation of the C–X bond is transmitted in unsaturated or aromatic systems by a mechanism different from that in aliphatic or acyclic systems. Strictly speaking, the generally accepted idea that the "inductive" effect of a substituent appears in an aromatic system just as it does in an aliphatic one does not have any basis. The so-called scale of the σ_I-constants of the substituents in an aromatic system is none other than the scale of the σ_f constants of 4-substituted bicyclo[2,2,2]octane-1-carboxylic acid [83,84].

The comparison of this scale with the scale of σ_I-constants in the benzene ring [85] solely on the basis that between the bicyclo[2,2,2]octane and benzene systems there may be a geometric similarity and therefore the distribution of the $I\sigma$- and F-effects in these systems should be analogous is arbitrary. From these assumptions came attempts to separate the influence of alkyl groups and halogen atoms into inductive and mesomeric constituents, attempts which failed.

On the basis of the experimental value $\sigma'_{Br} = 0.45$ [83] and the derived value of the polar constant of the substituent for CH_2Br (1.00), Taft [85] used the relation

$$\sigma'_R = 0.45\,\sigma^*_{CH_2R} \qquad (30)$$

to calculate the $\sigma'(\sigma_I)$ constant of the substituent, since the constants $\sigma^*_{CH_2R}$ are known for a large number of substituents. However, further experimental determinations of the dissociation constants of 4-substituted bicyclo-[2,2,2]octanes carboxylic acid [84] showed that the ratio $\sigma'/\sigma^*_{CH_2R}$ is not constant for different substituents but varies from 0.08 (for CH_3) to 0.67 (for OH). From relation (30) the $\sigma'(\sigma_I)$ constants for Cl and Br are 0.45 and 0.47 respectively, whereas new experimental results have shown [84] that the σ' constant for Cl and Br are almost equal (0.471 and 0.469). It was found further that the values, calculated from (30), of the σ' constant for CH_3, OCH_3, and OH (0.045, 0.23, and 0.25 respectively) differ considerably from the experimental results—0.008, 0.30, and 0.37 respectively. On starting from the ratio $\sigma'/\sigma^*_{CH_2R} = 0.58$, which corresponds with the experimental results for the OCH_3 group, then considerable differences are found between the experimental and calculated values of σ' for various other substituents. Starting from the experimental values of $\sigma^0_p = -0.15$ and $\sigma'(\sigma_I) = -0.008$ for CH_3, it is found that $\sigma^0_R(CH_3) = -0.14$, that is, it seems that the effect of the methyl group in an aromatic system is due almost completely to its mesomeric effect (which in reality it does not exhibit at all).

---o0o---

Thus the theory of mesomerism as applied to halogen-containing organic molecules does not find experimental confirmation. From an examination of the energetics of the mesomeric state of carbon–halogen bonds the arrangement of the halogens in the following order of decreasing mesomeric effect: F > Cl > Br > I (as assumed in the theory of mesomerism) is not substantiated physically. The dipole moments of halogenomethanes and halogen-substituted benzene, ethylene, and acetylene do not confirm the existence of a mesomeric effect at the halogen atoms. Variations in the lengths of the carbon–carbon bonds are explained not by the mesomeric influence of the halogens but by the hybridisation of the orbitals of the atoms which form the bond. Correlation between the lengths of the carbon–halogen bonds and the hybridisation of the orbitals of the bound atoms shows the absence of a mesomeric effect with the halogens (within the limits of accuracy of the measurements of interatomic distances).

The NQR results show that halogen atoms either do not exhibit any mesomeric effect or show it to such a small extent that it cannot have any significant influence on the physical and chemical properties of halogen-containing organic compounds.

Information about the electronic structure of organic compounds based on their reactivities does not reflect the electronic structure of the molecules in their ground state. Equilibrium constants and constants derivable from them for the substituents characterise the total influence of the substituents in non-specific and specific solvation effects on the distribution of the electronic charges in the molecule. The principal factors which determine the electron distribution on the introduction of a substituent into a molecule is the changes in hybridisation of the atomic orbitals, which ensure that the potential energy of the system is a minimum. The hybridisation of the orbitals of the σ-framework of the molecule, experimentally observable by investigations of the molecular structure of the molecules results in changes in the electronegativity of the carbon orbitals and in the polarisation of the bonds.

The inductive effect of the substituent is transmitted directly solely to the carbon atom connected with it in an unsaturated or aromatic system and subsequently its effect differs qualitatively from that in an aliphatic system.

Results on the screening of para-carbon atoms in benzene derivatives with alkyl groups or halogen atoms as substituents show that the so-called scale of inductive constants in the benzene series σ_I is a speculative concept. This scale, which is a set of constants for the substituents in the 4-substituted bicyclo[2,2,2]octane-1-carboxylic acid series does not correspond with the actual change in the electronic structure of the aromatic molecule under the influence of a non-resonating substituent. Therefore all procedures for the quantitative separation of inductive and mesomeric effects which are based on the use of a scale of inductive constants of substituents in the aromatic series are useless.

Catalytic Dehydrogenation of Hydrocarbons

V.K.Skarchenko

A systematic account is given of data on certain problems in the theory of catalytic dehydrogenation relevant to the reaction mechanism and the elucidation of the nature of the active centres. The intermediate products of the hydrogenation reactions, the role of individual elementary stages, the nature of intermediate surface compounds, the side reactions of dehydrogenation catalysts, and modern hypotheses concerning the structure of the active centres are discussed. The bibliography includes 216 references.

INTRODUCTION

Hydrocarbons of different homologous series are capable of being catalytically dehydrogenated (paraffins, naphthenes, olefins, cyclo-olefins, and alkyl-substituted aromatic hydrocarbons). The reaction results in the elimination of hydrogen and the formation of more highly unsaturated compounds or in cyclisation (dehydrocyclisation). The dehydrogenation catalysts are various metals and oxides. The principal side reactions in catalytic dehydrogenation are cracking, isomerisation, and coke formation. Catalytic dehydrogenation constitutes the basis of one of the most important types of industrial processing of hydrocarbon raw materials. Various aspects of the problem of dehydrogenation of hydrocarbons were examined in previous reviews[1-26].

II. INTERMEDIATE PRODUCTS OF DEHYDROGENATION REACTIONS

1. Olefins as Intermediates in the Aromatisation of Paraffins.

The principal products of the dehydrogenation of $C_{\geqslant 6}$ straight-chain paraffins are aromatic hydrocarbons together with a small amount of olefins. On the basis of the variation of the yield of olefins and aromatic hydrocarbons with contact time (Cr_2O_3, 475°C), Pitkethly and Steiner[27] put forward the hypothesis that heptane is aromatised via the intermediate formation of heptene.

However, a number of objections were raised against this view. Obolentsev and Usov[28] failed to observe maximum yields of olefins as a function of the time of contact under similar conditions. According to Levitskii's thermodynamic calculations[29], in the presence of large amounts of aromatic hydrocarbons the equilibrium yields of olefins are greatly reduced. On this basis, he suggested that olefins and aromatic hydrocarbons are formed simultaneously and the low yields of olefins under the conditions of high yields of aromatic hydrocarbons can be attributed to closeness to equilibrium.

Kazanskii et al.[30], who passed the Synthine fraction over platinised charcoal, failed to detect olefins although aromatisation did occur to a slight extent under these conditions.

Hypotheses concerning the mechanism of the aromatisation of paraffinic hydrocarbons omitting the olefin formation stage were developed for oxide catalysts by Plate[31], Kagan[32], and Kuo Hsie-Shien[33] and for metallic catalysts by Kazanskii, Plate, and Sergienskii[31,34,35]. In connection with this problem, we shall consider certain relations governing the formation of olefins and aromatic hydrocarbons in the catalytic dehydrogenation of paraffins. Shuikin, Timofeeva, and coworkers[36] showed that the olefin/aromatic hydrocarbon ratio greatly increases when the temperature of the dehydrogenation of hexane on an alumina–chromium oxide catalyst and the contact time are reduced. In the present author's studies[37-42], similar relations were established in the dehydrogenation of hexane on chromium oxide–magnesium oxide, chromium oxide–zinc oxide, iron oxide–alumina, and other mixed oxide catalysts and on charcoal.

A decrease in the temperature and in the contact time reduced the total amount of dehydrogenation products. This enabled the author to formulate a more general postulate[43]: a decrease of the conversion of hexane into dehydrogenation products is accompanied by an increase of the olefin/aromatic hydrocarbon ratio in the product. The above relation is valid for catalysts of various chemical compositions and prepared in different ways. Moreover, the olefin/aromatic hydrocarbon ratios and the yields of olefins and aromatic hydrocarbons fit satisfactorily on the curves describing their variation with the overall conversion in the dehydrogenation process. One of such relations is presented in Fig. 1.

Similar curves are obtained from the experimental data data of many investigators for the dehydrocyclisation of paraffins, involving straight-chain C_6-C_{10} paraffins, more than 20 catalysts, different ways of preparation of the catalysts, and different reaction conditions (temperatures in the range 450–600°C and space velocities between 0.15 and 160 h^{-1}). Fig. 2 presents the variation of the ratio of olefin yield to aromatic hydrocarbon yield with the overall yield of the dehydrogenation products.

Thus analysis of extensive experimental data shows that the main factors determining the olefin/aromatic hydrocarbon ratio is the degree of conversion of the starting material into the dehydrogenation products and changes in the chemical composition and methods of preparation of the catalyst, temperature, and the contact time are mainly important only insofar as the conversion depends on them.

The relations governing the relative yields of olefins and aromatic hydrocarbons as a function of conversion led the author to the conclusion that aromatic hydrocarbons are formed consecutively via olefins on both oxide and metallic catalysts[43,56,63-65].

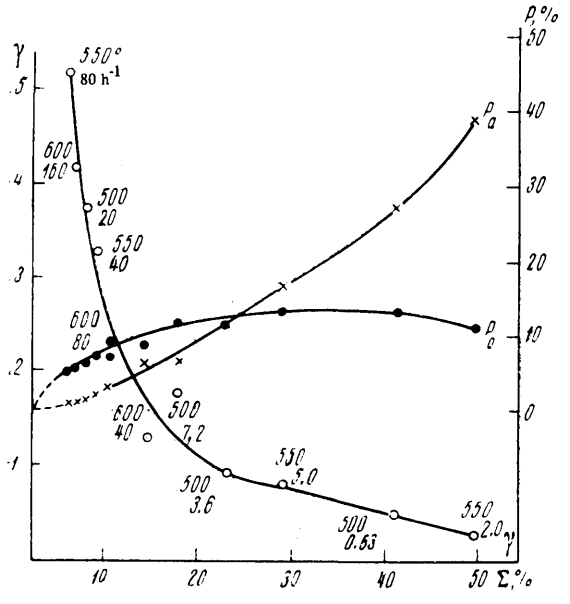

Figure 1. Variation of the yields of the heptane dehydrogenation products—olefins (P_O) and aromatic hydrocarbons (P_a)—and their ratio ($\gamma = P_O/P_a$) with the sum $\Sigma = P_O + P_a$ on the alumina–chromium oxide catalyst at 500–600°C and a space velocity of 0.63–160 h^{-1} according to the experimental data of Mattox[44].

Indeed the curves describing the yields of olefins and aromatic hydrocarbons as a function of their sum may be regarded as related to generalised kinetic curves, used for different experimental data, time having been replaced as the abscissa axis by a quantity which varies proportionately to it. The curves describing the variation of the yields of olefins and aromatic hydrocarbons (Fig. 1) exhibit the distinctive properties of consecutive reactions: the content of the intermediate (olefin) passes through a maximum with conversion and that of the final product (aromatic hydrocarbon) is initially low but increases continuously. The maxima at low yields of olefins can be accounted for by their cracking or closeness to equilibrium[65].

Similar variation of the yields of olefins and aromatic hydrocarbons with the overall degree of dehydrogenation is observed on platinum and oxide catalysts. This shows that, at least on certain metallic catalysts, olefins are also formed as intermediates in the aromatisation of paraffins.

Other data are consistent with this conclusion as well. Thus the rate of aromatisation of mono-olefins is much higher than that of paraffins (Table 1) (which may be regarded as evidence in favour of the intermediate formation of mono-olefins). Addition of hexenes to hexane increases the yields of benzene on the alumina–chromium oxide catalyst[70] and on charcoal[48].

The relative capacity of paraffins to be dehydrogenated to olefins and aromatic products did not change significantly following dilution with hydrogen[66] or on reducing the pressure in the reactor[67]; this should have been the case if the yields of olefins were limited by an equilibrium.

Table 1. Comparative data on the dehydrogenation of straight-chain paraffins and mono-olefins.

Catalyst	Temp., °C	Space velocity, h^{-1}	Yield of aromatic hydrocarbons in dehydrocyclisation, %		Refs
			heptane	heptenes	
Cr_2O_3	450		2.5	16	28
V and Al oxides	480	0.5	6	40	68
Cr, Al, and K oxides	484	0.4	37	52	32
Cr, Al, and K oxides	470	0.8	11	31	69

The conclusion that olefins are formed as intermediates in the aromatisation of paraffins on oxide and non-oxide catalysts is also confirmed by data published in recent years for experiments using tracer atoms (heptane–heptene mixtures at 487°C with contact times in the range 1.1–4 s on the alumina–chromium oxide catalyst[71] and hexane–hexene mixture at 360°C under pulsed conditions in a stream of helium on platinum and nickel[72,73].

Calculations based on Panchenkov's kinetic equation for a heterogeneous-catalytic flow reaction with consecutive stages[74] yields the ratio of the rate constants for the conversion of olefins into aromatic hydrocarbons (k_2) and of paraffins into olefins (k_1): $k_2/k_1 = 7-8$.

2. Dehydrogenation of Lower Paraffins to Mono- and Di-Olefins

In the dehydrogenation of straight-chain butane and pentanes, the products contain a certain amount of diolefins in addition to mono-olefins. The principal factors determining the mono-olefins/di-olefins ratio in the product is the degree of departure from equilibrium. The equilibrium yields of diolefins increase appreciably as the pressure is reduced and the reaction temperature increased[1,7].

Butenes are intermediates in the dehydrogenation of butane to butadiene. The work of Balandin and coworkers on the dehydrogenation of butane–butene mixtures, in which one of the components was labelled with carbon-14, led to this conclusion. The experiments were performed on chromium oxide and on the alumina–chromium oxide catalyst. A 1:1 butane–butene mixture was used in the reaction. The experiments with chromium oxide were performed at 635°C and a 1:9 dilution with water[75].

A quantitative calculation of the ratio of the rates of dehydrogenation of butane to butene (w_1) and butadiene (w_2) and of butene to butadiene (w_3) yielded the following results[76]. Under the above conditions, $w_1 : w_2 : w_3 = 20:1:1000$ for chromium oxide and $w_1 : w_2 : w_3 = 18:1:25$ for the alumina–chromium oxide catalyst (600°C, 250 mmHg), i.e. in both cases butadiene is formed from butane almost entirely via the intermediate formation of butene.

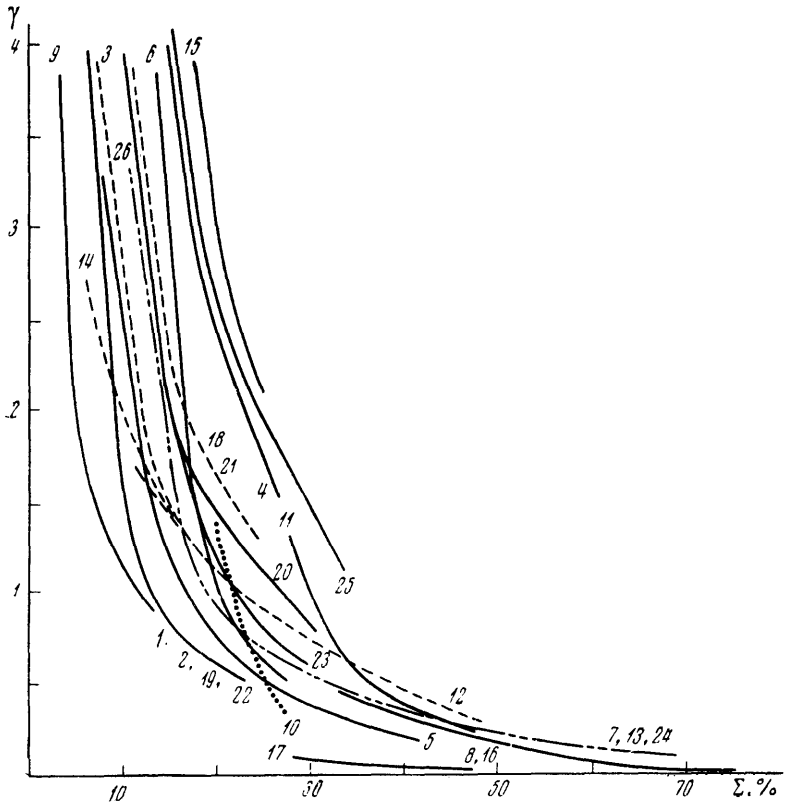

Figure 2. Comparison of the curves relating the ratios γ of olefins to aromatic products with their sum Σ: 1) hexane, Fe, Cr, and Al oxides, 500–525°C, 0.5 h^{-1} [37,39]; 2) hexane, Cr, Mg, and Zn oxides, 425–500°C, 0.5 h^{-1} [40,41]; 3) data from Fig. 1; 4) hexane, $Al_2O_3-Cr_2O_3$, 475–550°C, 0.5–2.1 h^{-1} [36]; 5) heptane, Cr_2O_3, 450–510°C [28]; 6) hexane, Cr, Al, and K oxides, 450–600°C, 9.2 h^{-1} [45]; 7) hexane, $Al_2O_3-Cr_2O_3-K_2O$, 475–527°C, 0.4–0.9 h^{-1} [46]; 8) hexane, $Al_2O_3-Cr_2O_3-K_2O$, 510–550°C, 0.37–2.5 h^{-1} [47]; 9) heptane, V and Al oxides, 450–510°C, 0.5 h^{-1} [48]; 10) heptane, Al, Cr, and Mo oxides, 490°C, 0.15–0.65 h^{-1} [29]; 11) hexane, Al and Cr oxides with Li, Na, K, Rb, Cs, Zn, or Pb additives, 500°C, 0.5 h^{-1} [49]; 12) hexane, Cr, Al, and K oxides prepared in different ways, 500°C, 0.5 h^{-1} [50]; 13) heptane, Al and Cr oxides with Be, Mg, Ca, Sr, Ba, or Zn additives, 530°C, 0.35 h^{-1} [51]; 14) heptane, Cr, K, and P oxides, 450°C, 0.8 h^{-1} [52]; 15) hexane, $Al_2O_3-Cr_2O_3$, some coke deposits, 500°C, 2.1 h^{-1} [53]; 16) heptane, K-162, some coke deposits, 515°C, 0.3 h^{-1} [54]; 17) heptane, Al, Mg, and Mo oxides, 480–530°C, 0.3 h^{-1} [55]; 18) hexane, Al, Mn, and Cr oxides, 400–550°C, 0.5–1.0 h^{-1} [56]; 19) nonane, Fe and Al oxides, 400–550°C, 0.35–1.8 h^{-1} [39]; 20) nonane and decane, Al, Cr, and K oxides, 427–600°C; 0.5–9.2 h^{-1} [45,57,58]; 21) hexane, Pt/charcoal or Al_2O_3, 300–500°C, 0.5 h^{-1} [56]; 22) hexane, MoS_2–silica gel, aluminosilicate, or MgO, 450–550°C, 0.5 h^{-1} [59]; 23) hexane, Cr_2O_3–charcoals, 370–510°C, 0.5–1.5 h^{-1} [42]; 24) hexane, $Pt-Al_2O_3-Na_2O$, 545°C, 0.4 h^{-1} [60]; 25) hexane, $Cr_2O_3-Al_2O_3$ with different porosities, 450–510°C, 0.5–2.5 h^{-1} [61]; 26) hexane, K-5, 450–530°C, 0.3–1.5 h^{-1}, dilution with hydrogen [62].

3. Dehydrogenation of Naphthenes

In the dehydrogenation of six-membered naphthenes, the main products are aromatic compounds. However, sometimes the catalytic reaction mixture contains also a small amount of unsaturated hydrocarbons.

For a long time cyclohexenes were not detected in the products of the dehydrogenation of cyclohexanes on metals. However, in a study of the initial stages of the conversion of cyclohexane on platinum, Block[77] observed by mass spectroscopy not only cyclohexene but also cyclohexadiene in the gas phase. The formation of cyclohexene and cyclohexadiene in the dehydrogenation of cyclohexane on platinum was also established by Paal and Tetenyi[78] by a pulsed technique. Here the curves relating the yields of cyclohexene and benzene to catalyst activity (which corresponds to the degree of conversion) exhibit features characteristic of consecutive reactions.

The intermediate formation of cyclo-olefins is also suggested by data from certain studies on the dehydrogenation of naphthene–cyclo-olefin mixtures by a tracer atom method. Thus cyclohexane on nickel (305–335°C) [79]

and methylcyclohexene on the alumina–chromium oxide catalyst (500°C)[80] are aromatised via an intermediate unsaturated hydrocarbon. However, direct formation of the aromatic hydrocarbon may make a considerable contribution or even predominate. Thus, in the dehydrogenation of cyclohexane on Cr_2O_3 (450°C) and holmium oxide (560°C), only about half the benzene is formed via the intermediate cyclohexene[81], and on the Pd/Al_2O_3 and Re/Al_2O_3 catalysts under reforming conditions benzene is formed almost wholly without the stage involving the intermediate cyclohexene[82].

The dehydrogenation of cyclohexane to benzene without the intermediate formation of cyclohexene can imply that either all the hydrogen atoms are eliminated simultaneously or the ease of conversion of the intermediate surface cyclohexene is much greater than the ease of its desorption. The study of the dehydrogenation of mixtures of hydrocarbons, one of which is labelled with radioactive carbon, as well as kinetic analysis cannot yield information about the stages which occur on the surface without the liberation of the reactants to the gas phase.

In the dehydrogenation of decalin and tetralin, the main product is naphthalene, but in the dehydrogenation of the first compound tetraline is also detected and in that of the second dihydronaphthalene[83]. The yield of tetralin in the dehydrogenation of decalin passes through a maximum as the temperature is increased, while the yield of naphthalene increases in the same temperature range. Dihydronaphthalene can be detected only on catalysts with low activity. Both factors – a decrease of temperature and of the activity of the catalyst—lead to decreased conversion (see Section II, 1). This suggests that the dehydrogenation of decalin proceeds via a stage involving the formation of tetralin and dihydronaphthalene. The main products of the dehydrogenation of ethylcyclohexane are ethylbenzene and styrene. Kinetic data indicate the formation of styrene via ethylbenzene[84].

Table 2. Comparison of the capacities for dehydrogenation of hydrocarbons with different degrees of unsaturation.

Hydrocarbons	Catalysts	References
Heptatriene > heptadiene > heptene > heptane	Chromium and vanadium oxides, Cr_2O_3 — Al_2O_3 — K_2O	28, 32, 68, 69, 85
Cyclohexadiene > cyclohexene > cyclohexane	Cr_2O_3, MoO_3 — Al_2O_3, Pt, Pd, Rh, Ir, Ni, Co, Fe	86–88
Cyclopentene > cyclopentane	Cr_2O_3 — Al_2O_3 — K_2O	9
Tetralin > decalin	Ni, MoO_3 — Al_2O_3	88, 89
Alkyl-substituted aromatic compounds > alkyl-substituted cycloparaffins	Mixed oxide catalyst	90
Cyclohexane > hexane	Cr_2O_3 — Al_2O_3 — K_2O	91
Hex-1-ene > cyclohexane	ditto	92

The rate of dehydrogenation of cyclic hydrocarbons as well as aliphatic hydrocarbons increases with the degree of unsaturation (Table 2), which is consistent with data on the intermediate formation of unsaturated hydrocarbons in the aromatisation of cyclohexanes.

The rate constants for the dehydrogenation of ethylcyclohexane are approximately a power of 10 lower than those for the dehydrogenation of ethylbenzene[90]. Nevertheless considerable amounts of ethylbenzene are formed in the dehydrogenation of ethylcyclohexane and can exceed greatly the yields of styrene. The low yields of styrene under the conditions of the dehydrogenation of ethylcyclohexane are evidently due to closeness to equilibrium in the dehydrogenation of ethylbenzene under the conditions of its formation from ethylcyclohexane[93].

4. Dehydrogenation of Olefins and Alkyl-Substituted Aromatic Hydrocarbons

Small amounts of more unsaturated olefins with the same number of carbon atoms are observed in the catalytic reaction mixtures when $C \geq 6$ straight-chain olefins are aromatised. Data relating the yields of dienes and aromatic hydrocarbons to the contact time and other factors which determine the conversion of mono-olefins (temperature and catalytic activity) on various catalysts (alumina–chromium oxide–potassium oxide, nickel, and platinum) exhibit features characteristic of consecutive reactions[94–96]. Thus one can suppose that the dehydrocyclisation of hexenes and heptenes proceeds via the intermediate formation of dienes.

The relations governing the yields of the products of the aromatisation of hexadienes and heptadienes on the alumina–chromium oxide–potassium oxide and platinum catalysts suggest that direct conversion of the dienes into aromatic hydrocarbons plays a considerable role together with conversion via intermediate trienes[85,97]. In the dehydrocyclisation of C_6 and C_7 trienes, intermediate cyclohexadienes are formed[85,97].

The ratios of the yields of toluene from hept-1-ene, hepta-1,3-diene, and heptatriene on the alumina–chromium oxide–potassium oxide catalyst at 450°C are 1 : 5 : 150,[85] which agrees with the above data concerning the consecutive mechanism of the dehydrocyclisation of olefins.

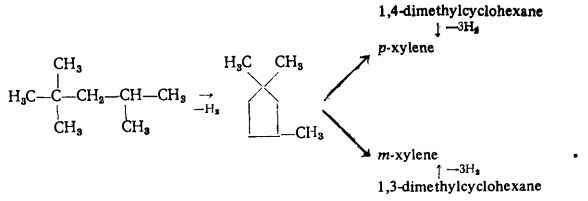
The principal products of the dehydrogenation of diethylbenzene are ethylvinylbenzene and divinylbenzene. The relations governing the yields of these products suggest that ethylvinylbenzene is an intermediate in the formation of divinylbenzene[98]. The dehydrogenation of diethylbenzene is described by the kinetic equation for a heterogeneous-catalytic flow reaction with consecutive stages[74]. On a mixed oxide catalyst at 520–560°C in a 1 : 3 diethylbenzene–water mixture, the rate constant for the dehydrogenation of ethylvinylbenzene to divinylbenzene is approximately twice as high as the rate constant for the stage involving the dehydrogenation of diethylbenzene to ethylvinylbenzene.

5. Naphthenes as Intermediates in the Aromatisation of Paraffins

In the presence of platinum on charcoal or alumina, fairly large amounts of C_5 naphthenes are formed in the paraffin dehydrogenation products. C_5-Dehydrocyclisation of paraffins to naphthenes is promoted by the presence of a five-membered carbon chain and its branching[8].

C_5-Dehydrocyclisation of paraffins is a primary reaction and does not proceed via the formation of olefins, six-membered naphthenes, or isomerisation. This is indicated by many factors[99]. Olefins are more difficult to convert into C_5 naphthenes than are paraffins; C_5-dehydrocyclisation of paraffins with six carbons atoms in the chain proceeds with greater difficulty than for carbon chains with five atoms. In all cases only those cyclopentanes are formed which should arise if the reaction

proceeded without isomerisation at all stages. Thus C_5-dehydrocyclisation of iso-octane yields 1,1,3-trimethylcyclopentane, which is partly aromatised to *m*- and *p*-xylenes under the reaction conditions:

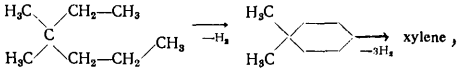


This mechanism of the aromatisation of iso-octane is supported by the following facts. The aromatisation of 1,1,3-trimethylcyclopentane on platinum/charcoal[100] and platinum–alumina[101] catalysts yields the same products (*m*- and *p*-xylenes) as in the aromatisation of iso-octane under the same conditions. On the other hand, in the presence of the alumina–chromium oxide–potassium oxide catalyst the aromatisation of iso-octane has a different mechanism: 1,1,3-trimethylcyclopentane and 2,2,4-trimethylpentane give different aromatic products[101].

In the aromatisation of straight-chain $C_{\geqslant 6}$ paraffins, C_5 naphthenes are formed to a small extent and the fraction of aromatic products formed via C_5 naphthenes becomes insignificant[102].

It has been suggested[22,31,102] that the aromatisation of unbranched $C_{\geqslant 6}$ paraffins proceeds via the intermediate formation of cyclohexanes although so far the latter could only rarely be detected in the reaction product and only in trace amounts. The difficulty of detecting cyclohexane in the dehydrocyclisation of straight-chain hexane cannot be accounted for by its high reactivity. Although cyclohexane is dehydrogenated more readily than hexane, under the usual conditions of the dehydrogenation of cyclohexane it is impossible to achieve a complete conversion [for example, cyclohexane is dehydrogenated with greater difficulty than hex-1-ene (Table 2), which is readily detected in the dehydrogenation reaction products]. In a study of the dehydrogenation of hexane–cyclohexane and hexene–cyclohexane mixtures, where one of the reactants was labelled with carbon-14, Paal and Tetenyi[78] showed recently that cyclohexane is hardly formed as an intermediate in the aromatisation of either hexane or hexene on platinum and nickel.

On the other hand, in the aromatisation of branched hexanes, the intermediate formation of six-membered naphthenes can probably make a fairly considerable contribution. Thus the formation of a conjugated bond in a paraffin containing a quaternary carbon atom is difficult: it can arise only after isomerisation or dimerisation. According to Kazanskii et al.[35], the aromatisation of 3,3-dimethylhexane on a platinum/charcoal catalyst proceeds via the intermediate 1,1-dimethylcyclohexane:



which was detected in the reaction products.

In the aromatisation of paraffins with chain lengths greater than six carbon atoms, account must be taken also of the possible formation of intermediate $C_{>6}$ naphthenes. Thus in the aromatisation of octane on a "non-acid" alumina–chromium oxide catalyst[103], methylcyclopentane, which the authors believed to be an intermediate in the formation of xylenes, was isolated.

The foregoing data show that there is an analogy in the mechanisms of the dehydrogenation of various hydrocarbons. The dehydrogenation reactions accompanied by the removal of two and more hydrogen molecules take place in steps. The intermediate product is as a rule liberated to the bulk phase before further reactions occur. In certain cases (dehydrogenation of cyclohexane to benzene), another type of reaction can predominate—direct conversion into the final product.

$C_{\geqslant 6}$ straight-chain paraffins are formed via olefins, diolefins and (to a lesser extent) triolefins. Cyclisation occurs in later stages of the reaction. This mode of reaction predominates on both oxide and metallic catalysts. The intermediate formation of five and six-membered naphthenes makes a considerable contribution to the formation of an aromatic product apparently only in the dehydrogenation of certain branched hydrocarbons.

III. MECHANISM OF CATALYTIC DEHYDROGENATION

1. Certain Elementary Steps and the Nature of Intermediate Surface Compounds

While the nature of the bulk-phase intermediate dehydrogenation products can be regarded as established in the majority of cases, there are still few data concerning intermediate surface compounds.

The dehydrogenation mechanism can be represented as a sequence of bulk-phase and surface intermediate compounds. For example, in the aromatisation of an olefin or naphthene,

$$\underset{n\geqslant 6}{C_nH_{2n}} \rightarrow \underset{0\leqslant r\leqslant 2}{(C_nH_{2n-r})} \rightarrow C_nH_{2n-2} \rightarrow \underset{0\leqslant r_1\leqslant 2}{(C_nH_{2n-2-r_1})} \rightarrow C_nH_{2n-4} \rightarrow \underset{0\leqslant r_2\leqslant 2}{(C_nH_{2n-4-r_2})} \rightarrow C_nH_{2n-6} \qquad (1)$$

(the surface compounds are indicated in brackets). Each stage of mechanism (1) can in turn consist of two or more substages and conversely not all the stages indicated are obligatory and under certain conditions there is a possibility of the simultaneous elimination of more than two hydrogen atoms from the molecule undergoing dehydrogenation or the conversion in certain stages can take place in steps but without the liberation of intermediates into the gas phase.

With increased reactivity of the hydrocarbons dehydrogenated, homogeneous stages acquire a significant importance together with surface reactions. Thus hexatrienes are known to undergo thermal cyclisation to cyclohexadiene at a temperature as low as 360°C[97,104] and at 300°C cyclohexadiene is converted into benzene[105].

According to the multiplet theory, an intermediate surface compound is formed via a two-point (doublet) or six-point (sextet) adsorption of the molecule being dehydrogenated. There must be structural and energy correspondence between the catalyst and the reacting molecule under these conditions[15].

According to Balandin, reactions such as the dehydrogenation of paraffins to olefins, of olefins to diolefins, and of alkyl-substituted to alkenyl-substituted aromatic hydrocarbons, i.e. reactions involving the dissociation of two C–H bonds, take place via a doublet mechanism. The direct dehydrogenation of cyclohexane to benzene, involving the dissociation of six C–H bonds, has a sextet mechanism. According to Liberman[99], C_5 dehydrocyclisation of paraffins to naphthenes has a sextet–doublet mechanism, in contrast to other dehydrogenation reactions:

the doublet reaction is preceded by adsorption involving a sextet mechanism.

Some data on the nature of the intermediate surface compounds of hydrocarbons were obtained recently by studying the chemisorption of hydrocarbons on catalysts by infrared and ESR spectroscopy, etc. According to modern concepts, the following types of adsorption of olefins on a metal are possible[106]:

Adsorbed at two points via σ-bonds:

$$R_aCH{=}CHR_b + 2M \rightarrow R_a\overset{M}{C}H{-}\overset{M}{C}HR_b \; ; \qquad (A)$$

associatively adsorbed via a π-electron mechanism:

$$R_aCH{=}\underset{M}{C}HR_b \; ; \qquad (B)$$

a dissociatively adsorbed olefin forming compounds of the π-allyl type:

$$R_aCH{=}CH{-}CH_2R_b + M \underset{-H}{\longrightarrow} R_aCH{-}\underset{M}{CH}{-}CHR_b \; . \qquad (C)$$

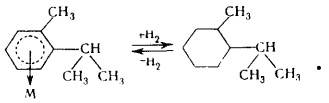
The hypothesis of the formation of an intermediate via one-point absorption does not involve a significant contribution by the geometrical factor of the kind postulated in the multiplet theory.

When an adsorbed olefin in treated with hydrogen, changes occur in the infrared spectrum, indicating the formation of surface alkyl radicals:

$$R_aCH{-}\underset{M}{CHR_b} \; (\text{or } R_aCH{=}\underset{M}{CHR_b}) \underset{-H}{\overset{+H}{\rightleftarrows}} R_aCH{-}\underset{M}{CH_2R_b} \; .$$

The adsorbed alkyl radical is evidently linked to the surface via one σ bond.

The formation of a stable partly hydrogenated form is observed also in the chemisorption of branched cyclic hydrocarbons on nickel, for example[108]:



On the other hand, under the conditions tested (room temperature, residual pressure 10^{-5} mm) the hydrogenation of adsorbed benzene yields cyclohexane, which is readily desorbed from the surface. According to the authors[107], the explanation is that an absorbed unsubstituted six-membered cyclic hydrocarbon is linked to the metal via a π bond which is weaker than a σ bond.

Under conditions approaching more closely those which actually obtain in dehydrogenation (temperatures up to 200°C), the adsorption of cyclohexane involves the formation of a surface cyclohexyl radical. This is indicated by mass-spectrometric data for the ions desorbed from platinum under the influence of a field pulse[77]. Studies of the ESR spectra also established the presence on the surface of nickel of a surface compound with a higher carbon content, which is believed[109] to be an intermediate in coke formation.

When about 10% of the nickel surface has been covered, cyclohexane has an accelerating effect on the ortho–para conversion of hydrogen, the catalytic effect increasing with the temperature of the preliminary adsorption of the hydrocarbon[110]. The acceleration of the ortho–para conversion of hydrogen is evidently related to the radical-like nature of certain surface compounds—products of the partial dissociation of the hydrocarbon molecule.

2. Cyclic Intermediates in the Aromatisation of Paraffins

Some data on the structure of the unstable intermediate compounds can be obtained by studying the dehydrogenation of hydrocarbons containing labelled carbon atoms, i.e. the variation of the product composition and of the reaction rates with the structure of the initial paraffin.

According to the Twigg–Herington hypothesis[111], the cyclisation of a linear molecule requires two-point adsorption via two carbon atoms. For example, the relative probability of the cyclisation of heptane is 4/6, since cyclisation is favoured by 1–2, 2–3, 5–6, and 6–7 adsorption but not 3–4 and 4–5 adsorption.

In a calculation of the relative probability of aromatisation, Kuo[112] began with the hypothesis of one-point adsorption. Then the probability of cyclisation should be equal to the ratio of the number of surface radicals cyclised to their total number. For heptane, the number of semihydrogenated radicals undergoing cyclisation is four, while their total number is seven and therefore the probability of cyclisation is 4/7. Kuo's mechanism, like the Twigg–Herington mechanism, allows the possibility of subsequent isomerisation of the adsorbed hydrocarbon.

According to Raik[113], the probability of cyclisation is determined by the product of the relative number of the possible collisions between the molecule and the catalyst and the relative chemical activity of the atoms. For primary, secondary, and tertiary hydrocarbons, the ratios of the first and second quantities are 3 : 2 : 1 and 1 : 2 : 10. According to this method of calculation, the relative probability of the ring-closure of heptane is 0.54.

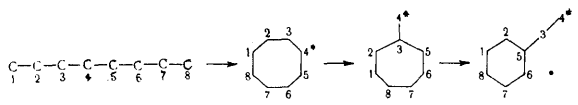
Each of the methods of calculation described explains satisfactorily in many cases the relative rates of dehydrogenation of various hydrocarbons and the composition of the aromatisation products, the differences between them involving a greater or lesser approximation to the experimental data for the individual paraffins. However, nowadays the calculation of the probability of the cyclisation of paraffins requires revision in the light of new data indicating the intermediate formation of open-chain olefins, as a result of which the cyclisation takes place at later stages than the initial adsorption of the original paraffin (see Section II, 1, 4).

The dehydrocyclisation of octane on various catalysts results in the formation of ethylbenzene and all three isomers of xylene[103,111,114–116]. According to the Twigg–Herington mechanism, ethylbenzene may be formed via 1–6 and 3–8 adsorption, and *o*-xylene via 2–7 absorption; *m*- and *p*-xylenes are formed as a result of the isomerisation of the 1–6 or 3–8 cyclic structure with intermediate formation of bicyclic species. One can also postulate isomerisation via the migration of a CH_3 group around the ring in the intermediate 2–7 surface compound[115] or as a result of an octane → iso-octane reaction[116].

However, the cyclisation of an aliphatic hydrocarbon to a six-membered ring is not the only possible pathway leading to the aromatisation of paraffinic hydrocarbons (see Section II, 5 about the formation of an intermediate five-membered ring). The numerous data of Pines and coworkers indicate other possibilities of cyclisation.

Thus one of their studies[103] dealt with the dehydrocyclisation of labelled [4-^{14}C] octane at 522°C on a "non-acid" alumina–chromium oxide catalyst, which is inactive in the isomerisation of hydrocarbons. Experiments showed that ethylbenzene is radioactive in the side chain. The displacement of the radioactive label to

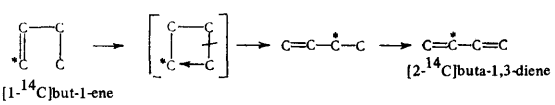
the side chain of ethylbenzene is difficult to account for otherwise than by the formation of an intermediate eight-membered ring:



The side chain contains 5–7.8% of ^{14}C, which corresponds to a 20–31% contribution of the mechanism involving the formation of a surface cyclo-octane. In order to explain the formation of other products, one must also postulate closure to a seven-membered ring and the usual six-membered ring.

Hypotheses concerning the closure of open chains to rings with various numbers of carbon atoms and the isomerisation of intermediate cyclic surface compounds have also been put forward to account for the aromatisation of hydrocarbons containing seven[117–119] and five[120,121] carbon atoms in the chain.

Cyclic intermediates and their isomerisation can play a significant role even in the dehydrogenation of lower hydrocarbons. Thus, according to recent data of Okamoto et al.[122], in the dehydrogenation of [1-^{14}C] but-1-ene over the alumina–chromium oxide catalyst there is a rearrangement involving the migration of ^{14}C from the 1-position in but-1-ene to the 2-position in buta-1,3-diene. The degree of this ^{14}C rearrangement in butadiene at 675°C is 23%. The ^{14}C rearrangement cannot be accounted for by the recombination of C_2 cracking products and indicates the formation of a four-membered ring, for example:



3. The Rate-limiting Stages and Kinetic Equations

There are data showing that the slowest stage in the dehydrogenation of various hydrocarbons is the chemical reaction. The rate of deuterium exchange involving cyclohexene and hence the rates of adsorption and desorption of cyclohexene on Pd/Al_2O_3 and Re/Al_2O_3 are much higher than the rate of dehydrogenation[123]. The same conclusion can also be reached concerning the rates of adsorption and desorption of hydrogen: the para–ortho conversion of hydrogen on Ni–ZnO is much faster than the dehydrogenation of cyclohexane[124]. Calculation of the stoichiometry for the rate-limiting stage in the dehydrogenation of butane on the alumina–chromium oxide catalyst yields a value close to unity[125].

On the assumption that the unimolecular stage of dehydrogenation on a quasihomogeneous surface is rate-limiting and that the adsorption of the reactants is described by the Langmuir isotherm, kinetic equations of the following types were derived[16] for the process under conditions far from equilibrium.

$$w = k\frac{b_i p_i}{1 + \Sigma b_i p_i}, \qquad (2)$$

where b_i are the adsorption coefficients of the reactants. Depending on the relative adsorption coefficients and the ratios of the reactant concentrations, Eqn. (2) yields effective reaction orders ranging from zero to unity with respect to the initial hydrocarbon and from –1 to 0 with respect to the product, in agreement with experiment[16,33,74,124,126–140].

This interpretation of the rate coefficients of the equations has been widely accepted. A fairly large number of determinations have been made of the adsorption coefficients of the reactants on various catalysts, including dehydrogenation catalysts. According to the available data[16,136–138,141–143], the kinetic adsorption coefficients increase in the series paraffins ≃ naphthenes ≤ aromatic hydrocarbons < olefins < diolefins and differ comparatively little on catalysts such as alumina–chromium oxide, alumina–molybdenum oxide, and nickel/Al_2O_3.

The above treatment of rate coefficients involves contradictions in a number of cases and therefore their physical significance is apparently still controversial.

Thus according to the relative adsorption coefficients, the dehydrogenation of paraffins is inhibited by the products (olefins). However, these data are inconsistent with direct measurements of the degree of adsorption. Thus the degree of chemisorption of isopentane proves to be higher than that of isopentene[144]. The hypotheses of intense adsorption of olefins are also apparently inconsistent with, for instance, kinetic dehydrocyclisation data. The consecutive equation for the dehydrocyclisation of straight-chain paraffins is valid only in the form corresponding to the intense adsorption of the product—an aromatic hydrocarbon and not an olefin[74]. At the same time, according to other data (see above), the kinetic adsorption coefficients for aromatic hydrocarbons are lower than those for olefins.

In a study published subsequently[145], it was shown by a chromatographic procedure that the degree of adsorption of hydrocarbons (paraffins and olefins) on the alumina–chromium oxide–potassium oxide catalyst under dehydrogenation conditions is lower than the degree of adsorption of hydrogen. These results make it possible to explain published data on the inhibition of the dehydrogenation of paraffins by olefins within the framework of the mechanism of the inhibition of the reaction by hydrogen[145]. One can add that sometimes in the interpretation of experimental data in terms of equations of type (2) adsorption coefficient $b_i < 0$ are obtained[146]; this is inconsistent with the assumptions made in the derivation of the kinetic equation which must be then regarded as semiempirical or it must be explained in another way. Indeed the hypothesis that the rate of the chemical reaction is limiting can hardly be regarded as universally valid, since the rates of the individual stages can vary markedly depending on the reactant and the state of the catalyst surface.

Kinetic equations analogous to Eqn. (2) or its special forms but with the constants having a different physical significance can also be derived on the hypothesis that the rate-limiting stages are the chemisorption of the initial hydrocarbon (dehydrogenation of cyclohexane on the alumina–chromium oxide catalyst)[147] or the desorption of products (dehydrogenation of methylcyclohexane on $Pt-Al_2O_3$)[148].

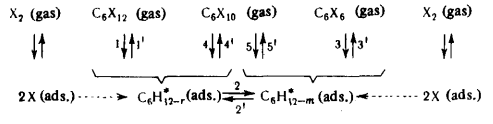
Under the usual conditions of the dehydrogenation of hydrocarbons, transfer processes apparently have a considerable influence and, at a sufficiently high temperature and for small dimensions of the catalyst pores, the rate-limiting stage may be diffusion of reactants.

The present author[61] investigated the effect of the porous structure of the alumina–chromium oxide catalyst on the conversion of hexane. Pore size was varied by

changing the intermicellar liquid. At temperatures above 470°C and for a dominant pore radius in the specimens less than 40 Å (grain size 2–5 mm), the rate of reaction was found to depend on pore size, i.e. transport processes influenced the rate of reaction. At the same time the experimental data are described fairly satisfactorily by the kinetic equation derived on the assumption that there is no diffusion-dependent inhibition.

Diffusion-dependent inhibition has also been noted by other workers: dehydrogenation of butane[7] and dehydrocyclisation of heptane[54] on alumina–chromium oxide catalysts, and dehydrogenation of cyclohexane on platinum deposited on alumina[149].

When dehydrogenation of cyclohexane and deuterium exchange involving it takes place simultaneously on the Ni–ZnO catalyst, the degree of exchange passes through a maximum with increase of temperature from 201° to 298°C, while the degree of hydrogenation increases. According to the scheme proposed by the authors[150],



(where X = H or D), the H–D exchange involving cyclohexane takes place via the intermediate surface compound $C_6H^*_{12}$ - r(ads.) and the dehydrogenation of cyclohexane involves in addition the intermediate surface compound $C_6H^*_{12}$ - m(ads.). Stages 1, 3, 4, and 5 and also the hydrogen adsorption and desorption stages are fast, while stage 2, in which one intermediate surface compound is converted into another, is slow and rate-determining.

The maximum in the rate of isotope exchange can be explained by the effect of the simultaneous occurrence of dehydrogenation on the concentration of $C_6H^*_{12}$ - r(ads.). Exchange reactions do not require the slow stages 2 or 2′ and therefore are fast even at low temperatures. With increase of temperature, the rate of dehydrogenation begins to rise sharply, which leads to a decrease of the degree of exchange. According to this mechanism, when benzene is introduced into the system, the rate of exchange falls but it does not change significantly when cyclohexene is added.

In a cordance with the data presented in Section III, 1, the compounds $C_6H^*_{12}$ - r(ads.) may be dissociatively adsorbed cyclohexene linked via two σ bonds and $C_6H^*_{12}$ - m(ads.) may be a π complex or a series of rapidly interconverted π complexes. The first surface compound may correspond to the edgewise (doublet mechanism) and the second to the planar (sextet mechanism) orientation of cyclohexane on the surface[150].

IV. VARIETIES OF THE DEHYDROGENATING EFFECT OF CATALYSTS

Dehydrogenation catalysts are extremely numerous and have a wide variety of chemical compositions. Thus, the compilation in Plate's book[31], already mentioned 51 elements as active components of catalysts for the aromatisation of paraffins and included the elements of almost all the Groups in the Periodic System, mainly Groups IV–VI. The number of known catalysts and the methods for their preparation are being continuously enlarged.

The same catalyst is capable of dehydrogenating hydrocarbons of various homologous series and structures, provided that it is sufficiently active. Thus fairly high yields of the products of the dehydrogenation of lower C_3–C_5 straight-chain paraffins, the aromatisation of C_6–C_7 straight-chain paraffins and cyclohexane, the dehydrogenation of ethylbenzene, olefins, branched paraffins, five-membered naphthenes, and alkyl-substituted hydroaromatic and other hydrocarbons have been obtained on alumina–chromium oxide–potassium oxide catalysts[9,32,70,91,151,152].

The problem of the effect of the catalyst on the relative yields of various dehydrogenation products is considered below.

1. Side and Secondary Non-dehydrogenation Reactions

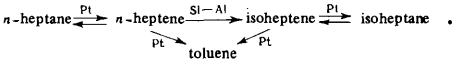
As a rule, there is no parallelism between the hydrogenating activity of catalysts and their activity in cracking and isomerisation reactions[7,31,153–155]. This suggests that the isomerisation and cracking reactions are not caused by the active centres responsible for dehydrogenation.

Numerous facts demonstrating the role of the acidity of the surface of alumina–chromium oxide catalysts in the isomerisation of paraffins have been adduced by Pines and coworkers[156].

The isomerisation of hydrocarbons on a dehydrogenation catalyst may be not only a side reaction but in certain cases may be an important stage in the dehydrogenation processes. Thus the aromatisation of paraffins with a chain length corresponding to not more than five carbon atoms must include the isomerisation stage.

When the alumina–chromium oxide catalyst is poisoned with pyridine or quinoline, there is not only a decrease in isomerising activity but also in the yields of the "abnormal" dehydrocyclisation products of octane (*m*- and *p*-xylenes), which are believed to form via a stage involving the isomerisation of octane to iso-octane or via intermediate cyclic compounds[116] (see also section III, 2).

On the other hand, under reforming conditions (hydrogen pressure, "bifunctional" catalysts), dehydrogenation may be one of the stages in the isomerisation of the hydrocarbon. Thus when heptane is brought into contact with an aluminosilicate or platinum deposited on alumina, isoheptanes are not formed. On the other hand, in the presence of these catalysts, the yield of isoheptanes is 24%. Toluene is also formed[157]. The isomerisation probably proceeds via intermediate dehydrogenation-hydrogenisation stages:



2. Dehydrogenation of Cyclohexane to Cyclohexene and Benzene

According to the multiplet theory, the dehydrogenation of cyclohexane with intermediate formation of bulk-phase cyclohexene proceeds on doublet centres, like the dehydrogenation of paraffins to olefins, and the direct dehydrogenation of cyclohexane to benzene, on sextet centres.

In early studies it was postulated that the doublet centres are characteristic of oxide catalysts and the sextet centres of metallic catalysts. Recently, with improved

experimental techniques for the investigation of catalytic reactions, an increasing number of facts have been observed, showing the intermediate formation of cyclohexene and cyclohexadiene in the presence of metallic catalysts (see Section II, 3)₣ On the other hand, Balandin and coworkers established that cyclohexane is dehydrogenated on oxide catalysts (α-Cr_2O_3), the process showing properties characteristic of sextet reactions. Therefore it is now recognised that doublet and sextet reactions can occur on both oxides and metals[15,16].

Another reason for the presence or absence of an intermediate unsaturated product in the bulk phase can probably be the capacity of the catalyst to form different types of metal–adsorbed hydrocarbon π or σ-bonds (see Section III, 1). For example the rates of desorption of cyclohexene linked to the surface by a single π bond or two σ bonds can differ markedly, as a result of which cyclohexene is evolved into the bulk phase in one case but not in the other.

3. Aromatisation and Formation of Olefins

It has been frequently postulated in the literature that the dehydrogenation of paraffins to olefins and their aromatisation on oxide catalysts take place on different active centres[31,53,158]. The fact that the olefin/aromatic hydrocarbon ratio varied within wide limits when catalysts of different chemical compositions were tested and the poisoning of an active aromatisation catalyst led mainly to decreased yields of the aromatic hydrocarbons and had much less influence on the yields of mono-olefins has been frequently put forward as the main evidence for the above hypothesis.

Thus, when the alumina–chromium oxide catalyst is poisoned with furfural or cyclopentadiene, the content of benzene in the catalytic reaction mixture in the dehydrogenation of hexane diminishes from 8–9 to less than 1% and that of alkenes from 18–19 to 6–7% (at 500°C)[53]. A similar situation was observed also in the coking of an aromatisation catalyst during the experiment[31] and when a dehydrocyclisation catalyst was poisoned with ethylene[158].

Since the dehydrogenation of higher paraffins to olefins was a more difficult problem than their aromatisation, the above concepts led to a large-scale development of studies on the choice of selective catalysts for the dehydrogenation of $C_{\geqslant 6}$ paraffins to olefins, which would be at the same time inactive in the aromatisation reaction. Various workers obtained catalysts which yielded olefins with high olefin/aromatic compound ratios or the product was altogether free of aromatic hydrocarbons[37–42,49,50,159–163]. For example, the dehydrogenation of hexane on a Cr_2O_3–AG-5 charcoal specimen at 430°C and a space velocity of 1.5 h^{-1} gave a yield of hexenes of about 10% for a selectivity of 90–95%, the yield of benzene being less than 1%.[42]

However, as pointed out for the first time by the present author[43], a high selectivity of catalysts for the formation of olefins is associated primarily with their low activity. The increase of the olefins/aromatic hydrocarbons ratio with decrease of the conversion of the starting material into dehydrogenation products is a common property of the process under consideration regardless of the causes responsible for the decrease of conversion, i.e. it is unimportant whether the decrease is a result of the deactivation of the catalysts or a change in temperature or in the contact time. Low conversions constitute a general condition for improved yields of intermediates such as olefins in the dehydrocyclisation of a paraffin.

Therefore in order to account for the experimental data on the poisoning of dehydrocyclisation catalysts as well as other data for the dependence of the relative yields of olefins and aromatic hydrocarbons on the chemical composition of catalysts, there is no need to resort to the hypothesis of the existence of two types of dehydrogenation active centres.

Previously, it was suggested[31,34] that aromatisation on oxide catalysts takes place via a doublet mechanism and on metals via a sextet mechanism. It was then believed that on oxide catalysts the dehydrocyclisation of paraffins takes place via the intermediate formation of olefins and on metals there is a direct conversion into aromatic hydrocarbons. These hypotheses were based mainly on the results of one of the early studies[30], according to which paraffinic hydrocarbons in the Synthine fraction are converted on a platinum/charcoal catalyst into aromatic hydrocarbons without the formation of olefins, the addition of which poisoned the catalyst for the aromatisation reaction.

However, subsequent studies on the aromatisation of individual hydrocarbons yielded numerous data indicating an analogy between the reactions of paraffins on oxide and non-oxide catalysts. Thus the present author's investigations[56,64,65] showed that the relative ability of platinum and also molybdenum sulphide and catalysts containing charcoals to promote dehydrogenation to olefins and aromatic hydrocarbons is almost indistinguishable from that of oxide catalysts (Fig. 2). The dehydrocyclisation of hexane on platinum and nickel as well as on oxide catalysts proceeds via the intermediate formation of olefins (Section II, 1,5). This suggests that one should not draw a distinction between metallic and oxide catalysts as regards the nature of active centres in dehydrocyclisation reactions.

The olefin/aromatic hydrocarbon ratios plotted against the sum of olefins and aromatic hydrocarbon yields on the basis of the results of different investigations give rise to a family of curves (Fig. 2) instead of a single curve as would have been expected in the ideal case if the overall conversion into dehydrogenation products constituted the only factor determining the yields of olefins and aromatic hydrocarbons. The divergence of the curves in Fig. 2 reflects the fact that the ratio of olefins and aromatic hydrocarbons in the products is influenced, apart from the overall conversion, by certain other factors. One of the principal causes of the divergence of the P_O/P_a–$(P_O + P_a)$ curves in Fig. 2 is probably the difference between the experimental methods employed in different studies or series of experiments[65]†.

In order to solve the problem of the effect of chemical composition on the relative capacity of catalysts to promote dehydrogenation to olefins and aromatic hydrocarbons (not associated with a change in activity), additional data are required which allow for other factors which may be important (for example secondary thermal reactions of the products, the presence of impurities in the raw material, etc.).

We shall consider from this point of view the results of one of the latest studies by Timofeeva[164] on the dehydrocyclisation of hexane and nonane on alumina–chromium

† This must be taken into account in the interpretation of experimental data. Otherwise, instead of the curves relating P_O, P_a, and P_p/P_a to $P_O + P_a$, more or less broad bands would have been obtained and the objection[164] against the use of the method in the study of theoretical problems would have been justified.

oxide catalysts promoted in different ways, represented by plots of the olefin/aromatic hydrocarbon ratio against the sum of olefins and aromatic hydrocarbons (Fig. 3).

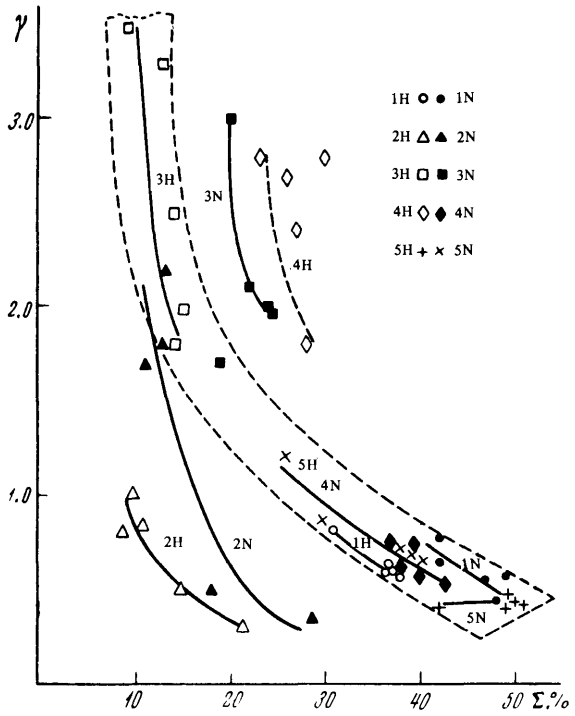


Figure 3. Plots of the ratios γ against the sum Σ of olefins and aromatic hydrocarbons based on Timofeeva's experimental data[164]; H—hexane; N—nonane: 1) $Al_2O_3-Cr_2O_3-Na_2O$; 2) K-16; 3) K-5; 4) $Al_2O_3-Cr_2O_3$; 5) $Al_2O_3-Cr_2O_3-K_2O$.

The majority of experimental points lie within a single narrow band, $P_o/P_a = f(P_o + P_a)$, in which two groups of points are distinguished: one of them refers to specimen *2* (K-16) with respect to hexane and nonane and the other to specimens *4* (alumina–chromium oxide catalyst) with respect to hexane and *3* (K-5) with respect to nonane.

Following Timofeeva[164], one could conclude on this basis that specimen *2* is somewhat less selective and specimens *3* and *4* somewhat more selective than specimens *1* and *5* (K and Na alumina–chromium oxide catalysts). However, the present author believes that such a conclusion would be premature. Indeed the results for hexane and nonane on specimens *3* and *4* do not agree. The data for hexane on specimen *4* are inconsistent with other results of the same author's[45,49,50], obtained on alumina–chromium oxide catalysts both with and without alkali metals, which fit satisfactorily on $P_o/P_a = f(P_o + P_a)$ curves (Fig. 2). The discrepancy between the olefin/-aromatic hydrocarbon ratios in Timofeeva's work[164] is probably associated with the method of analysis of the products, which was not the same in all the experiments.

The conclusion that the active centres for the dehydrogenation and aromatisation of paraffins are of the same type is consistent with the experimental data for the catalytic properties of various substances.

The most active catalysts in the dehydrogenation of lower paraffins to olefins and the aromatisation of $C_{\geq 6}$ paraffins are promoted alumina–chromium oxide catalysts and as a rule the additives introduced into the catalyst or the change in the method of preparation or the treatment of the catalyst have similar effects (activation, increase of activity with time of operation, etc.) on both reactions and also on the dehydrogenation of six-membered naphthenes (Table 3).

Table 3. Effect of certain additives on the properties of dehydrogenation catalysts.

Starting material	Additives	Hydrocarbons	Effect on catalytic properties	Refs.
$Cr_2O_3 - Al_2O_3$	Alkali metal oxides	C_3–C_7 paraffins, cyclohexane, isopentenes	Increase of activity	165–175
ditto	CaO, SrO, BaO	Butane, heptane, cyclohexane	Ditto	51, 167, 176, 177
»	Fe oxides	Butane, hexane	Decrease of activity	37, 178
»	Alkali metal oxides	Isopentane, heptane, cyclohexane	Retardation of attainment of steady activity	168, 173, 179
»	K_2O	Butane, heptane	Decrease of coke formation	167, 180
$MoO_3 - Al_2O_3$	K, Rb, Cs, Ce, Nd, and Hf oxides	Hexane, heptane cyclohexane	Increase of activity	179, 181, 182
$Pt - Al_2O_3$	Na_2O	Hexane, cyclohexane	Activity passes through a maximum	183
$Pd-Al_2O_3$ with added HF	Rare-earth oxides	Hexane, cyclohexane, methylcyclohexane	Increase of activity	185

4. Dehydrogenation of Hydrocarbons with and without a Double Bond

On the basis of the product proportions in the conversion of cyclohexane into benzene and methylcyclopentane and of methylcyclopentane into benzene and cyclohexane, Haensel et al.[186] concluded that, on treatment with sulphur-containing compounds, the activity of a fluorinated alumina–platinum catalyst for the stage involving the conversion of cyclohexene and benzene is lost but its activity in the conversion of cyclohexane into cyclohexene is not lost and therefore the above reactions take place on different active centres. The subdivision of catalyst active centres into those which dehydrogenate paraffins and olefins was adopted by Pines[156] and also certain earlier investigators.

However, when the $Pt-F-Al_2O_3$ catalyst is poisoned with thiophen, a sharper decrease of the yield of benzene is observed in the dehydrogenation of cyclohexane than in the dehydrogenation of cyclohexene[187], which is inconsistent with the data of Haensel et al.[186].

The conclusion that there is no sufficient evidence for a subdivision of active centres into those for the dehydrogenation of paraffins and olefins is arrived at by analysing the experimental data on the effect of chemical composition on the activity of the catalyst. As a rule, all active catalysts for the dehydrogenation of paraffins are also active in the dehydrogenation of olefins. That this is so is shown, for example, by data on the intermediate formation of olefins in the aromatisation of paraffins, which would not otherwise have occurred.

A parallelism is observed between the relative reactivities of saturated and unsaturated hydrocarbons on catalysts of different types on the one hand and on the relative activities of various catalysts in the dehydrogenation of these hydrocarbons on the other. Thus the reactivity of hydrocarbons increases with the degree of unsaturation on alumina–chromium oxide and alumina–molybdenum oxide catalysts, platinum, nickel, etc. (Tables 1 and 2). The differences between the specific activities of individual metals in relation to the dehydrogenation of cyclohexane, cyclohexene, and cyclohexadiene reach several powers of 10.[87] If one neglects the comparatively small changes (by a factor of 2–3), the specific activities of metals in the dehydrogenation of all three hydrocarbons can be arranged in the following sequence:

$$Pd \approx Pt \approx Rh \approx Ir > Ni > Ag \approx Cu \approx Co \approx Fe.$$

The hypothesis that the active centres for the dehydrogenation of saturated and unsaturated hydrocarbons are of the same type does not of course imply that the same catalysts should be optimal for both reactions.

The individual characteristics of the hydrocarbons can be reflected in side reactions and secondary transformations of the products. For example, the capacity of butadiene to cause the coking of the catalyst is much higher than that of butane or butene[183]. To reduce coke formation, the dehydrogenation of butene to butadiene is carried out in the presence of water vapour, which poisons alumina–chromium oxide catalysts. Therefore butenes are not dehydrogenated on the alumina–chromium oxide catalyst, but on other catalysts, which are stable in relation to water, for example the ion oxide–chromium oxide–potassium oxide catalyst.

Other factors can of course also be important, for example the ratio of the rates of the individual stages. Thus if the rate-limiting stage in the dehydrogenation of the less reactive of two hydrocarbons being compared is the chemical reaction, then the rate of dehydrogenation of the more reactive hydrocarbon on the same catalyst may be affected also by factors such as the rate of adsorption or of internal diffusion. Therefore the optimum catalysts for the two hydrocarbons should be different.

5. C_5 Dehydrocyclisation

A parallelism is not observed between the activities of various catalysts in relation to the C_5 dehydrocyclisation of paraffins and other reactions involving the dehydrogenation of hydrocarbons. Thus the activity of platinum on charcoal in the C_5 dehydrocyclisation of isooctane to 1,1,3-trimethylcyclopentane is independent of the temperature at which the catalyst is formed in the range between −10° and 40°C but, when the platinum content in the catalyst diminishes from 20 to 5%, its capacity for C_5 dehydrocyclisation falls sharply[189]. On the other hand the activity of the platinum/charcoal catalyst in the dehydrogenation of cyclohexane passes through a maximum in the first case and in the second case remains virtually unchanged.

These data, indicating that the C_5 dehydrocyclisation of paraffinic hydrocarbons to naphthenes takes place on different active centres than the dehydrogenation of cyclohexane, are consistent with the experimental data on the selection of catalysts. It is known that on many active dehydrogenation catalysts—metals (palladium, osmium, and iridium on charcoal, nickel on charcoal and alumina, etc.) and oxides—it has not so far been possible to achieve the C_5 dehydrocyclisation of paraffins, which occurs only on platinum[8,102,190]. This does not apparently apply to the C_5 dehydrocyclisation of olefins, which, in contrast to paraffins, takes place not only on platinum but also on the alumina–chromium oxide catalyst (for example, the C_5 dehydrocyclisation of dimethylpentadiene to dimethylcyclopentadiene[191].

V. MODERN HYPOTHESES CONCERNING THE NATURE OF THE ACTIVE SURFACE OF DEHYDROGENATION CATALYSTS

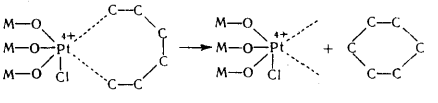
1. Platinum and Certain Metallic Catalysts

The catalytic activity of metals in dehydrogenation reactions is due to their capacity to form chemical bonds with hydrocarbon molecules in the gas phase. According to modern data[106], an olefin (A) adsorbed via two σ bonds on a transition metal is formed by the rehybridisation of the carbon atoms involved in the olefinic bond to sp^3 hybridisation with subsequent formation of two σ bonds between the carbon and metal atoms. In an olefin (B) adsorbed via a π bond, the carbon atoms are in a state of sp^2 hybridisation, the atoms and groups linked to the carbon atoms being located in almost the same plane, parallel to the surface. One surface metal atom is directly involved in the formation of the π bond. The problem of the role of surface chemical compounds formed by the catalyst metal and the carrier of the adsorbed reactant has been widely discussed in recent years. In many cases the role of active reaction centres is attributed to these compounds.

McHenry et al.[192] found in an alumina–platinum catalyst a platinum complex which may be extracted by dilute HF solution or acetylacetone. In the catalyst obtained by impregnating alumina with H_2PtCl_6 solution, the soluble platinum complex may contain also chlorine and a promoting agent—an alkali metal. Platinum may pass into an acid-soluble state not only by forming a complex with aluminium but also as a result of non-stoichiometric absorption of oxygen[193]. Therefore the soluble platinum contained in catalysts is very inhomogeneous in composition.

A partial correlation between dehydrogenating activity and the amount of soluble platinum in the catalyst has been observed in a number of studies.

Bursian et al.[194] attribute to the complex of the alumina–platinum catalyst a structure with a coordination-unsaturated Pt^{4+} ion; its participation in the dehydrocyclisation reaction takes place as shown below (for hexane):



(D)

where M is the cation of the carrier or a structural promoting agent. Thus the catalytic effect of centres containing Pt^{4+} ions is attributed to coordination properties.

A positive aspect of the hypotheses concerning the platinum complex as an active component of the catalyst is that they reflect the common features of metallic and oxide catalysts: the activity of the latter is also attributed to the presence of cations with a definite valence (see below).

However, the soluble complex present in the alumina–platinum catalyst may decompose on reduction of the catalyst to yield metallic platinum, while the activity of the catalyst is fairly high under these conditions[193]. This implies that the presence of the platinum complex is not an essential factor determining the activity of the catalyst. This is also suggested by the catalytic activity of pure metals without a carrier. A specific objection to scheme (D) is that, according to the available data, the initial intermediates in the aromatisation of hexane are hexenes and hexadienes while cyclisation takes place only subsequently and is a rapid step (Section II, 1 and 5). Therefore if the Pt^{4+} ions entering into the complex were effective only in the cyclisation stage of the aromatisation of hexane, they would behave as weak centres and would not play a significant role in catalysis.

The problem of the nature of soluble platinum is closely related to the problem of the degree of its dispersion. Thus, according to Kraft and Spindler[193], platinum dispersed to the maximum extent becomes completely solubilised by treatment with air at 500°C and after the reduction of the catalyst the degree of dispersion of platinum increases still further. The degree of dispersion of platinum and other metals on a carrier can become very high, up to atomic dispersion[195-197].

The structure of the platinum as well as the nature of the carrier were of secondary importance compared with the surface area in tests on the activity of alumina–platinum catalysts compared in different ways and containing different amounts of soluble platinum[193]. Thus the observed correlation between the content of the platinum–aluminium complex and the activity of the catalyst may be accounted for by the fact that the formation and subsequent decomposition of the complex promotes an increase in the degree of dispersion of platinum.

The affect of alkali metal promoting agents in alumina–platinum catalysts consists, apart from supressing the acid centres, in preventing the recrystallisation of platinum because the promoting agent is involved in the formation of a soluble complex.

Hypotheses have been put forward concerning the catalytic role of compounds formed by platinum and the carrier—charcoal ("pseudosandwich" complexes or a combination of platinum crystallites and graphite sextets[198-200]). However, there are still very few data on this problem.

According to Wood[201], adsorbed hydrogen is required for the dehydrogenation of cyclohexane on a metallic catalyst. This conclusion follows from the fact that, under the conditions investigated, the reaction ceased when hydrogen was completely removed from the reactor. The experiments were performed at 125°C and hydrogen was evacuated via a membrane made of the material of the catalyst (a palladium–silver alloy) which is permeable to it. Wood believes[201] that the active centre for the dehydrogenation reaction on the catalyst investigated is an adsorbed hydrogen atom.

2. Chromium Oxide and Certain Oxide Catalysts

According to modern concepts, the hydrocarbon adsorbed on a metal oxide is linked to metal ions and not to oxygen[16,202]. The formation of a bond between the adsorbed hydrocarbon and a transition metal ion takes place via unfilled *d* levels of the metal or via the formation of an *s*–*d* bond.

Some investigators[167,203] established a correlation between the amount of Cr^{6+} contained in the alumina–chromium oxide catalyst and its dehydrogenating activity and in this connection suggested that the hexavalent chromium present in the catalyst acts as a carrier of catalytic activity.

However, this hypothesis is not adequately justified, since under the reaction conditions the reduction of Cr^{6+} and other possible compounds in which the valence of chromium is greater than 3 takes place very rapidly[204], while the activity of the alumina–chromium oxide catalysts persists for a long time. In the regeneration of the alumina–chromium oxide catalyst in a stream of carbon dioxide, higher chromium oxides are not formed and yet such catalysts are not less active than those regenerated with air[205].

The amount of Cr^{6+} in the catalyst depends on the conditions and duration of oxidation and on the nature of the promoting agent. The correlation between the activity and amount of Cr^{6+} in the catalyst observed in some cases might have been due to the fact that the reduction of higher chromium oxides under the reaction conditions is nevertheless not entirely complete and the residual non-reduced chromium, being a constituent of, for example, a spinel with the aluminate of the added metal, has a promoting effect.

Van Reijen et al.[147] concluded from measurements of the magnetic moments and ESR signals of alumina–chromium oxide catalysts subjected to various types of oxidation–reduction treatment that the higher chromium oxides are reduced in a stream of dry hydrogen, i.e. under conditions favouring the formation of an active alumina–chromium oxide catalyst, not only to tervalent but also to bivalent chromium. The proportions of the bivalent and tervalent chromium oxides are determined by the equilibrium

$$2\,CrO + H_2O \rightleftarrows Cr_2O_3 + H_2\,. \qquad (3)$$

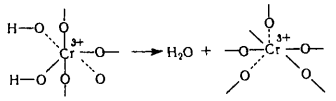
Further experimental evidence for the formation of bivalent chromium in the reduction of alumina–chromium oxide catalysts was obtained by Rubinshtein and coworkers[206]. Thus hydrogen was evolved on treatment of carefully reduced alumina–chromium oxide catalysts with water. When a catalyst reduced with deuterium was treated with water, only protium was detected in the gas. This implies that the hydrogen is formed in the decomposition of water by Cr^{2+} ions, which have reducing properties, and is not evolved as a result of desorption by water.

The amount of Cr^{2+} ions calculated from the volume of hydrogen evolved agreed approximately with the amount of hydrocarbon chemisorbed on the catalyst. On the other hand, the amount of Cr^{3+} ions present in the catalyst was approximately 40 times greater[207].

However, $CrCl_2$ is much less active in the dehydrocyclisation reaction than $CrCl_3$.[208] There are also other data which do not agree with the hypothesis that Cr^{2+} ions behave as dehydrogenation centres. Thus, according to the conditions for equilibrium in reaction (3), Cr^{2+} ions should not be present in the catalyst when the partial pressure of water vapour in the gas is greater than 1.7×10^{-3} mmHg. At the same time, at a water vapour pressure in the reacting gas of 22 mmHg, the alumina–chromium oxide catalyst retains a considerable activity[205]. On the other hand, when the partial pressure of water vapour in the gas was reduced to 3×10^{-4} mmHg, the catalytic activity fell.

The d^3 cationic structure is particularly active in reactions on semiconductors involving hydrogen[209]. The chromium ion in Cr_2O_3 has this electronic configuration. According to Kazanskii and Shvets[210], the active dehydrogenation centres are coordination-unsaturated Cr^{3+} ions.

In specimens containing adsorbed water, all the Cr^{3+} ions are in an octahedral configuration. When one water molecule is eliminated, the coordination is reduced to that of a square pyramid:



and the removal of subsequent molecules can lead to a further decrease of coordination. In order to discover if coordination-unsaturated Cr^{3+} ions present on the surface of catalysts from which water had been desorbed at high temperatures behave as dehydrogenation centres, additional studies are necessary.

Some investigators have suggested that the activity of alumina–chromium oxide catalysts is due to the formation of a specific mixed structure by the components of the catalysts. Krylova et al.[211] observed a maximum styrene content in the catalytic reaction mixture obtained in the dehydrogenation of ethylbenzene and a maximum paramagnetic susceptibility when the chromium content in the catalyst was about 2%. The maximum specific susceptibility at a low chromium content is probably associated with the formation of a Cr_2O_3 δ-phase. As regards the activity of the catalyst, one should bear in mind that chromium oxide is fairly active by itself[7,16] and the mixed alumina–chromium oxide structure would have had to be very active to play a significant role in catalysis.

However, the specimens tested[211] were relatively inactive (the styrene content in the catalytic reaction mixture was only 2–2.5 times higher than in the thermal reaction) and probably their acidity was high. Therefore the decreased yield of styrene observed when the chromium content is increased above 2% may be attributed to the formation of side products. Indeed, in the dehydrogenation of less reactive hydrocarbons (paraffins), a maximum activity was not observed in the presence of amounts of added chromium as low as 2%.[7]

Buyanov et al.[212] attribute the activity of iron oxide–chromium oxide–zinc oxide catalysts in the dehydrogenation of butenes to the presence of a chromium spinel in the catalyst composition. However, iron(III) [38,213] and zinc oxides[214] exhibit a considerable activity in the absence of chromium, let alone chromium oxide itself. Therefore the active centres in iron oxide–chromium oxide–zinc oxide catalysts can probably be the ions of any metal entering into the composition of the catalyst. On the other hand, the formation of solid solutions and mixed structures is more likely to promote the stability of the catalyst, preventing recrystallisation and undesirable chemical transformations of the catalyst, which may be particularly important in the dehydrogenation of butene and other olefins in view of the severe operating conditions of these catalysts.

The available data also do not justify the hypothesis that the dehydrogenating capacity of chromium oxide–magnesium oxide or chromium oxide–silica gel catalysts is due to the formation of mixed active structures[41,215]. The nature of the activating effect of small amounts of water remains obscure. Poorly dehydrated dehydrogenation catalysts are inactive[7]. When the water content in the starting material is increased, the activity of alumina–chromium oxide catalysts passes through a maximum.

One may suppose that water enters into the composition of the active centres of the catalyst and has a promoting effect. The reversible poisoning of the alumina–chromium oxide catalyst by larger amounts of water, can be explained by the blocking of the active centres. Indeed preliminary adsorption of water suppresses the chemisorption of hexane on the alumina–chromium oxide catalyst[216]. In this case there is only physical adsorption of hexane, which is not accompanied by dehydrocyclisation.

---o0o---

The data examined show that the problem of the structure of the active centres remains controversial even for the most thoroughly investigated catalysts. In dehydrogenation reactions, metal atoms (in metallic catalysts) metal atoms or ions (in metallic adsorption catalysts), and metal ions (in oxide catalysts) can behave as carriers of catalytic activity. The composition of the active centres probably includes also chemisorbed atoms or molecules (hydrogen in the case of metallic catalysts and water in the case of the chromium oxide catalyst). The molecule undergoing dehydrogenation can be linked to the surface via one- two-, or multipoint adsorption with different types of chemical bonding (the σ bond or different varieties of coordinate bonds).

Nevertheless only a few types of dehydrogenating effect of catalysts on hydrocarbons have been observed. There is sufficient evidence to suppose that the dehydrogenation and aromatisation of paraffins takes place at the same active centres and probably this can also be said of paraffins, olefins, and naphthenes (except for the direct conversion of six-membered naphthenes into aromatic hydrocarbons).

In all these cases, where there is an analogy in the action of catalysts of different types and in the conversion of hydrocarbons of different homologous series and structures, preference should be given to the model involving an intermediate compound with one- or two-point adsorption rather than multipoint adsorption, and, among the existing hypotheses concerning the structure of the active centres, those which attribute the activity to the material of the catalyst itself and the degree of its dispersion rather than to its various compounds with carriers are to be preferred. Probably an active catalyst, such as, for example, platinum or chromium oxide, retains a considerable dehydrogenating capacity on all carriers of different types capable of ensuring that its degree of dispersion remains stable.

Conversely, the more specific dehydrogenation reactions (C_5 dehydrocyclisation of paraffins, dehydrogenation of naphthenes without an intermediate formation of cycloolefins) can be accounted for by the effect of multipoint active centres or a different type of bonding between the adsorbed molecule and the catalyst surface compared with other dehydrogenation reactions.

Molecular Structures of Acyclic Organophosphorus Compounds

L.S.Khaikin and L.V.Vilkov

The structural data for acyclic organophosphorus compounds published up to 1971 have been systematically reviewed. The geometrical parameters obtained for these compounds have been classified in accordance with the concepts of the valence states of the atoms in the molecules and the types of chemical bonds. Certain general relations governing the geometrical structure of the molecules have been noted on the basis of this classification. The geometrical parameters for a specific phosphorus-element bond may vary within limits greatly exceeding the experimental error as a result of the influence of the immediate environment of the bond. However, the study of the problem of the mutual influence of atoms not linked directly is difficult owing to the lack of the necessary experimental data.
The results of the determination of the conformations of acyclic organophosphorus compounds are presented.
The bibliography includes 231 references.

I. INTRODUCTION

Since phosphorus compounds have been recently acquiring increasing practical value, it is important to investigate the characteristics of their geometrical structures, which are not only of theoretical interest but also constitute the basis for the interpretation of the rapidly increasing volume of experimental data in various branches of chemistry. The geometrical structure of molecules is characterised by certain fundamental parameters—bond length, valence angles, and angles of internal rotation. The most widely used method of calculation of bond lengths is based on systems of covalent radii[1], but it takes into account only the differences in bond multiplicity. The introduction of corrections in accordance with the Shomaker–Stevenson equation[2] makes it possible to take into account the differences between the types of atoms. However, in this case too the calculated bond lengths frequently differs from the experimental values by an amount significantly exceeding the present level of accuracy of the experimental data (about 0.01 Å).

A more logical empirical method is the phenomenological procedure, which has been particularly widely developed by Tatevskii[3-5]. The principle of the method consists in a detailed classification of bonds in molecules based on the classical theory of structure. This classification takes into account, apart from the chemical individuality of atoms and bond multiplicities, the valence state of the linked atoms (the "type" of chemical bond) and also the effect of the immediate environment. The actual role of all these factors, which influence the fundamental geometrical molecular parameters, can be discovered by analysing the experimental data. The most complete review of the stereochemistry of phosphorus compounds is given in a collective volume "Topics in Phosphorus Chemistry"[6]†.

† The Tables published under the editorship of Sutton[7] list the results of all the structural studies up to 1960 (including the studies on phosphorus compounds). There are also a number of reviews in which the stereochemistry of individual classes of organophosphorus compounds are discussed: trihalides[8], fluorides[9], sulphides[10], compounds with a P–P bond[11], compounds of pentacoordinate phosphorus[12-16], etc. Certain problems in the stereochemistry of phosphorus compounds have been examined in the monographs of Wells[17], Van Wazer[18], and Hudson[19], and in a collective volume "Topics in Stereochemistry"[20].

However, the classification of geometrical parameters in this review is not sufficiently logical and clear-cut. In addition, and this is most important, during the five years which have elapsed since the publication of this volume, new studies have expanded and deepened our knowledge about geometrical structure.

In the present review, the geometrical parameters of acyclic organophosphorus compounds have been classified on the basis of the concepts of the classical structural theory‡. Data obtained by spectroscopic (largely microwave) and diffraction (electron diffraction and X-ray diffraction) methods for the determination of molecular geometry published up to 1971 (the data published towards the end of 1970 and the beginning of 1971 are given in the Supplement) have been compiled. More accurate results have been obtained in re-investigations of the same substances. Complexes containing phosphorus–transition element bonds and salts of phosphorus acids have been excluded from consideration.

II. THE VALENCE STATES OF THE PHOSPHORUS ATOM

The phosphorus atom in various compounds coordinates between one and six ligands, but the majority of the known phosphorus compounds have coordination numbers of 3 and 4. Although phosphorus is frequently treated as an analogue of nitrogen, it is characterised by higher coordination numbers. In this respect phosphorus is closer to the heavy Group V elements—arsenic and antimony.

During recent years, compounds with dicoordinate phosphorus stable under normal conditions were obtained and investigated for the first time. In the case of acyclic structures, these are phosphamethinecyanine cations[21-23].

A large group of the phosphorus analogues of nitrogen compounds comprises derivatives of tricoordinate phosphorus. However, tervalent nitrogen can have in this case a planar bond configuration as well as a trigonal pyramidal configuration (with a minimum valence angle of

‡ The classical theory does not always give a sufficiently complete description of the chemical structure of compounds, but it does characterise satisfactorily the coordination numbers of atoms (for example, the tetracoordinate quinquevalent phosphorus in $-\overset{|}{\underset{|}{P}}=O$, $-\overset{|}{\underset{|}{P}}\rightarrow B-$, etc.).

102°). On the other hand, the average valence angles of the phosphorus atom in such compounds vary as a rule between 90° and 100°. On passing to heavier Group V elements, a tendency towards a further decrease of the average valence angle is observed§.

A tetrahedral coordination of ligands is most characteristic of the phosphorus atom. Compounds with a tetracoordinate phosphorus atom are more stable than those with different coordination. According to the classical theory of valence, there is a double bond at the phosphorus atom in such compounds (for non-ionised structures). The actual distribution of ligands can be referred to as tetrahedral in this case only in a conventional sense, since the valence angles of phosphorus within the limits of an individual structure can vary within very wide limits—from 100° to 120°. Here a double bond is involved in the formation of the largest angles.

Table 1. The limits of variation of the length of bonds between the phosphorus atom and the atoms of non-transition elements in acyclic organophosphorus compounds (in Å; on the basis of the data in Tables 2–4 and in the Addendum).

*The distinction between multiple and single bonds is in many cases purely conventional owing to the effect of the environment (if the length of the given bond is adopted as a criterion of its multiplicity).

The stereochemistry of pentacoordinate phosphorus compounds has been the subject of extensive discussion[14,15,32-39]. Of the two most probable geometrical configurations—trigonal bipyramid and tetragonal pyramid—the first is regarded as energetically more favourable, but the energy difference is in many cases small[15].

§ In a spectroscopic study of the compounds $P(SiH_3)_3$,[24] $As(SiH_3)_3$, and $Sb(SiH_3)_3$,[25] it was suggested that their molecular skeleton is planar, in contrast to the analogues in which tin replaces silicon[26] and also $P(GeH_3)_3$.[27] However, this hypothesis was disproved by electron-diffraction[28,29] and a reinterpretation of the infrared and Raman spectra[30,31].

Studies on PX_5 compounds in the gas phase confirmed that the trigonal-bipyramidal structure is energetically more favourable¶.

In the crystalline phase and in solution phosphorus pentahalides are present as PX_6^- anions with octahedral symmetry (tetragonal bipyramid) and tetrahedral cations PX_4^+.

As already stated, the length of a given chemical bond is determined not only by the bond type (and hence the valence state of the atoms involved in it) but also by the effect of the atoms in the immediate environment. Table 1 gives the limits of variation of the experimental phosphorus–element bond lengths in acyclic compounds for various valence states of the phosphorus atom.

III. BOND LENGTHS AND VALENCE ANGLES IN PHOSPHORUS(III) COMPOUNDS

The P—H bond length is relatively insensitive to the effect of the environment (Table 2). The difference between the values obtained by electron diffraction and spectroscopically (the microwave method) for the same molecules is systematic and is associated with the characteristics of these methods[41,42].

On the other hand, the lengths of P—C single bonds vary within wide limits, by up to 0.1 Å, which greatly exceeds the experimental error. The P—C bonds decrease in the series

As for the other element–carbon bonds, the length of each type of P–C bond varies with the type of immediate environment. Thus the length of the bond in $P(CF_3)_3$ and CF_3PH_2 molecules is much greater (by 0.05 to 0.09 Å) than in $P(CH_3)_3$. A similar relation is observed also in derivatives with nitrosyl (CF_3NO [43] and CH_3NO [44]) and carbonyl (CF_3CHO [45] and CH_3CHO [46]) groups. However, in the $N(CF_3)_3$ molecule[47] the length of the N–C bond is smaller by 0.02 Å than in $N(CH_3)_3$ and $(CH_3)_2NH$,[48] while in C_2F_6 [49] the C–C bond is shorter by 0.05 Å than in ethane[50].

The attempt to correlate the change in P–C bond lengths with a change in the C–P–C valence angle involves difficulties. The increase of this angle on passing from methyl to phenyl derivatives is replaced by a decrease in the presence of bonds. A characteristic feature of the P–N bond is that it is always shorter than the sum of the covalent radii (1.83 Å). In the amino-derivatives $X_2PN(CH_3)_2$, the configuration of the valence angles of the nitrogen atom is planar or nearly planar (the average valence angle of the nitrogen atom is $\bar{\alpha}_N = 117.5-120°$). In the ethyleneimine derivative $P[N(CH_2)_2]_3$, where the nitrogen atom forms part of a three-membered ring, $\bar{\alpha}_N$ is reduced to 101° and at the same time the shortening of the P–N bond is much less. A similar behaviour was noted also in a comparison of the structures of organic acid amides and *N*-acetylethyleneimine[51].

¶ It has been asserted in a spectroscopic study[40] that in the solid phase and in solution the $P(C_6H_5)_5$ molecule has the configuration of a square pyramid, which was subsequently disproved by an X-ray diffraction study of the crystalline substance (see Section IV, § 2).

*Compounds with more than one type of bond at the phosphorus atom are quoted in several places according to the number of bond types. To avoid unnecessary repetition, in each case only those angles are quoted in the formation of which the given bond is involved. Here and henceforth the following notation is employed: e.d. = electron diffraction; m.w. = microwave spectroscopy; X-ray = X-ray diffraction.

It is interesting that, in contrast to the >P–N< and >P–N< bonds, the >P–C– and >P–C< bonds are hardly different in length. This is evidence of a difference in the type of interaction of tricoordinate phosphorus with nitrogen and carbon.

When two amino-groups in $P[N(CH_3)_2]_3$ are replaced by halogen atoms (chlorine, fluorine), there is a tendency towards a decrease of the P–N bond length, which is particularly pronounced in the case of the fluoro-derivative.

The effect of the amino-group on the phosphorus–halogen bond is in turn shown by a considerable increase in the length of the latter. Thus the P–Cl bond in $(CH_3)_2NPCl_2$ is longer by 0.04 Å compared with the value found for PCl_3 and the P–F bond in $(CH_3)_2NPF_2$ is longer by the same amount compared with the value found in PF_3.

The effect of the methoxy-group is similar. The P–Cl bond in CH_3OPCl_2 is also longer by 0.04 Å than in PCl_3.

A tendency towards a decrease of the >P– element bond length compared with the sum of the covalent radii on passing along a series of elements in the Periods from left to right and in the Groups from below upwards is noteworthy (Table 1).

IV. BOND LENGTHS AND VALENCE ANGLES IN PHOSPHORUS(V) COMPOUNDS

1. Structures with a Tetracoordinate Phosphorus Atom

The vast majority of data presented in this section were obtained by X-ray diffraction studies on crystals. The structure of the molecules in crystals may be modified under the influence of the crystal lattice forces, intermolecular hydrogen bonds, etc. Moreover, the accuracy of the X-ray method for the determination of the fundamental geometrical parameters is lower than that of the electron diffraction and microwave methods. Therefore here

a detailed determination of the geometrical structure is even more complicated than in the case analysed above.

Quinquevalent tetracoordinate phosphorus forms, in contrast to tervalent phosphorus, a multiplicity of stable compounds with double bonds (as understood in the classical theory structure) (Tables 1 and 3A). The lengths of these bonds vary within wide limits (by as much as 0.15 Å) but in general are shorter than the lengths of single bonds formed by tetracoordinate phosphorus (Tables 1 and 3B).

Recently new more reliable X-ray diffraction data on the P=C bond length in phosphoranylidines have been published. The P=C bond lengths in the $(C_6H_5)_3P{=}C{=}C{=}O$, $(C_6H_5)_3P{=}C{=}C{=}S$, and $(C_6H_5)_3P{=}CH_2$ molecules were found to be appreciably shorter than in other ylidines. In the oxygen derivative the P=C=C angle is 145.0°, which is unusual for carbon, since theoretically the cumulene chain should be linear, as in carbon dioxide[83], keten[84], etc. In the thio-derivative, the length of the P=C bond is greater by 0.04 Å and the P=C=C angle is greater by 22.5°C than in the oxygen derivative. In $(C_6H_5)_3P{=}CH_2$ the P=C bond length is intermediate in the above set of three compounds. Electron diffraction data indicate a pronounced dependence of the P=O bond length on the nature of the environment. It increases by 0.04 Å on passing from $POCl_3$ to $(CH_3)_3PO$, which is accompanied by a decrease of the O–P–X angle. A similar increase of the P=O bond length occurs when one of the chlorine atoms of $POCl_3$ is replaced by C_6H_5 or $(CH_3)_2N$ groups.

It is striking that complex formation involving POX_3 (X = Cl, CH_3, C_6H_5, etc.) molecules proceeds via the phosphoryl bond and is accompanied by an increase in its length.

The single bonds in compounds of tetracoordinate phosphorus are as a rule shorter and the valence angles between them are larger than the corresponding bonds and angles in compounds with tricoordinate phosphorus (Tables 1, 2, and 3B). This relation holds satisfactorily for P–C bonds with carbon atoms in various valence states and in the majority of other cases. At the same time the P–P bond length remains constant (albeit within the limits of a considerable experimental error) for both valence states of the phosphorus atoms and is equal to the sum of the covalent radii. Some of the features of the mutual influence of atoms found in compounds of tricoordinate phosphorus (Section III) are characteristic also of compounds with tetracoordinate phosphorus. In particular, this is confirmed by the shortening of the C–N bond under the influence of fluorine atoms in the $(CH_3)_2NPF_2.B_4H_8$ molecule by 0.06 Å compared with the length of this bond in $(NH_2)_3P.BH_3$. The P–F bond length in the first molecule then proved to be significantly greater than in the absence of the amino-group (an increase by up to 0.07 Å compared with the P–F bond length in $PF_3.B_4F_6$). The effect of the amino-group on the PCl bond length is similar.

The sensitivity of the P–Cl bond to the influence of substituents is characterised by a marked tendency towards an increase in its length on passing along the series $POCl_3 \rightarrow PSCl_3 \rightarrow C_6H_5POCl_2 \rightarrow (CH_3)_2NPOCl_2$ [in the case of tricoordinate phosphorus we have similarly $PCl_3 \rightarrow (CH_3)_2NPCl_2$, CH_3OPCl_2]. The increase of the phosphorus–halogen bond length is accompanied as a rule by a decrease of the halogen–phosphorus–halogen valence angles formed by these bonds.

Complex formation via the P=O or P=S multiple bonds evidently has little effect on the P–C bond length, while the P–Cl bond length becomes appreciably reduced under these conditions.

We also have the following interesting facts.

1. The average $=\overset{|}{\underset{|}{P}}-N\diagup\diagdown$ bond length is greater by only 0.015 Å than the $-\overset{|}{\underset{|}{P}}=N-$ bond length in the $(C_6H_5)_2P(F){=}NCH_3$ molecule (Table 3A). The P–F bond is unusually short in this molecule (1.488 Å).

2. In the compound $PS[N(CH_2)_2]_3$ the $=\overset{|}{\underset{|}{P}}-N\diagup\diagdown$ bond length proved to be the same, within the limits of experimental error, as that of the $=\overset{|}{\underset{|}{P}}-N\diagup\diagdown$ bond. In contrast, as already mentioned, in compounds of tricoordinate phosphorus the $\diagup P-N\diagup\diagdown$ bond length is greater by 0.05 Å than that of the $\diagup P-N\diagup\diagdown$ bond (Table 2). The relative magnitudes of the average valence angles at the nitrogen atoms in $-N\diagup\diagdown$ and $-N\diagup\diagdown$ are the same in both cases (100–101° and 116–120°).

3. In the compound $\begin{matrix}(NH_2)_2P(S)\\ \diagdown\\ N-CH_3\\ \diagup\\ NH_2(NHCH_3)P(S)\end{matrix}$, the lengths of the bonds between the phosphorus atoms and the central nitrogen atom (1.708 Å—the maximum value known for the P–N bond length involving tetracoordinate phosphorus†) is greater by 0.06 Å than the lengths of the remaining P–N bonds in this molecule‡. The central nitrogen atom has in this case a planar bond configuration.

For comparison, we recall that the length of the Si–N bond also increases with the number of Si atoms linked to the N atom in the sequence $ClSi[N(CH_3)_2]_3$ (1.715 Å) [85] → $CH_3N(SiH_3)_2$ (1.726 Å) [86] → $N(SiH_3)_3$ (1.738 Å).[87]

2. Structures with a Pentacoordinate Phosphorus Atom

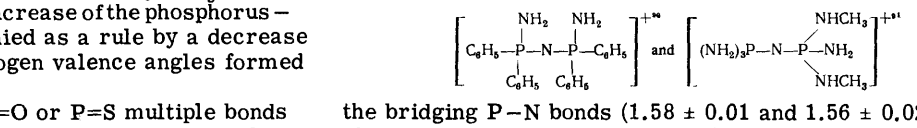
These compounds are relatively unstable. In particular, the stability of pentahalides diminishes significantly with increasing atomic weight of the halogen. The pentaiodide is altogether unknown and the chloride and bromide are ionised in the crystal to $[PCl_4]^+[PCl_6]^-$ and $[PBr_4]^+Br^-$.

---

† The P–N bond length in the $Na^+[PO_3NH_3]^-$ crystal structure, which is 1.77 ± 0.02 Å, was determined by Cruickshank[88] as the length of a single P–N bond. It is close to the sum of the covalent radii of the phosphorus and nitrogen atoms with the Shomaker–Stevenson correction (1.75 Å).

In the $Ca_{1.5}C_3H_3N_2(PO_3)_2.6H_2O$ crystal structure, where the nitrogen atoms form part of an aromatic group, the average length of the P–N bonds outside the ring is 1.786 ± 0.006 Å.[89] The authors of this investigation claim that they found the length of a single P–N bond.

‡ In the cations



and

the bridging P–N bonds (1.58 ± 0.01 and 1.56 ± 0.02 Å) are shorter than the terminal bonds (1.65 ± 0.01 and 1.63 ± 0.02 Å). The P–N–P angles in these structures are 136° ± 1° and 129.2°.

Table 3. Geometrical parameters of acyclic organophosphorus compounds with tetracoordinate phosphorus.

According to Raman spectra [149], in the gas phase the pentachloride also dissociates $PCl_5 \rightarrow PcL_3 + Cl_2$, to an extent which is determined by the temperature and pressure.

In the gas phase the molecules of PF_5, PCl_5, and their derivatives have the configuration of a regular (D_{3h} symmetry) or nearly regular trigonal bipyramid. An empirical rule, according to which the more electronegative or a large series of substituents occupy axial positions in this configuration, was established on the basis of NMR, infrared, and Raman spectroscopic data [12,13]. There are no exceptions to this rule for acyclic structures, at least in the gas phase§.

§ Analysis of the vibrational spectra [150,151], measurements of the dipole moments [151,152], and also NQR and NMR data [153] show that the molecules of all the members of the PCl_nF_{5-n} series exist in the trigonal-bipyramidal configuration with the F atoms in the axial positions. The vibrational spectra of CF_3PCl_4 [154] and $(CF_3)_2PCl_3$ [155] and the ^{19}F NMR spectra of CF_3PCl_3F [156] show that the more electronegative $-CF_3-$ groups (compared with chlorine) are also in the axial positions. The trigonal-bipyramidal structure of the HPF_4 molecule with an equatorial H atom has been established from infrared [157] and microwave spectra [158]. Finally, the validity of the above rule is confirmed by the vibrational spectra of compounds in the series CH_3PF_4, [159] CCl_4PF_4, [160] and CF_3PF_4, [161] according to which the CX_3 groups are localised in the equatorial positions (C_{2V} symmetry). For the methyl derivatives CH_3PF_4 and $(CH_3)_2PF_3$, this was also found by electron diffraction [162].

However, there is a divergence in views concerning CF_3PF_4. Thus in a microwave study [163] it was asserted that the CF_3 group occupies an axial position (C_{3V} symmetry). However, no details of the structure are quoted and the authors do not exclude the possibility of the presence of conformations other than C_{3V}. Earlier an axially substituted model of the CF_3PF_4 molecule was preferred on the basis of NMR spectra [12].

Some evidence for the possibility of the existence of conformational isomers in the case of the CF_3PF_4 molecule (together with the basic structure having the C_{2V} symmetry) was noted in the interpretation of the vibrational spectra [161].

According to electron-diffraction data (Table 4), the non-equivalence of the axial and equatorial bonds increases from 0.043 ± 0.008 Å in PF_5 to 0.104 ± 0.01 Å in PCl_5. It has also been established that, with increase of the number of CH_3 substituents, there is an increase in the length of both axial and equatorial P–F bonds, the length of the axial bond increasing faster. Therefore, on the basis of a calculation of the ratio of the lengths of the P–F axial bonds in PF_5 (adopted as unity by convention) and in substituted fluorophosphoranes, the ionic structure $[R_4P]^+F^-$ was proposed[164] for $(CH_3)_4PF$. However, there is so far no evidence for the existence of ionic structures of pentacoordinate phosphorus fluorides comparable to those found in the chlorides[165-168]. The mixed halide PF_3Cl_2 was investigated by electron diffraction as early as the end of the 1930's. It was established that the F atoms are equivalent and are therefore in the equatorial positions, but the lengths of the P–F (1.59 Å) and P–Cl (2.05 Å). bonds found throw doubt on the correctness of this conclusion. The vibrational spectra indicate that both axial positions in PF_3Cl_2 are occupied by F atoms[13,150]. The general tendency is probably as follows: the lengths of the axial bonds in the trigonal-bipyramidal structures vary approximately between the same limits as the lengths of the corresponding bonds of tricoordinate phosphorus; the lengths of the equatorial bonds are closer to those of single tetracoordinate phosphorus bonds (Table 1).

V. INTERNAL ROTATION AND CONFORMATIONAL ISOMERISM IN ACYCLIC ORGANOPHOSPHORUS COMPOUNDS

The study of intramolecular rotation and conformational isomerism has recently become a central problem in the theory of chemical structure. However, the only possible realistic approach to this problem still consists in the accumulation and analysis of experimental data. There are no general approximate hypotheses which would account for the characteristics of intramolecular rotation. The applicability of each of the numerous empirical methods of calculation of potential barriers is limited to special cases, since these methods do not have a rigorous physical basis. In many cases the geometry of stable conformations of organophosphorus compounds can be satisfactorily accounted for by the mutual repulsion of the non-bonded atoms in the molecule. Owing to the considerable differences between the types of intermolecular interactions, the ratio of the rotational isomers in the mixture may be various depending on the state of aggregation of the substance.

1. Compounds with a P–B bond

An ethane-like staggered conformation, corresponding to minimum steric interactions, is characteristic of compounds of the type $X_3P.BY_3$ [X = H, F, $N(CH_3)_2$; Y = H] in the vapour (according to microwave data[92,93]) and in the crystalline phase (according to vibrational spectra[172] and X-ray diffraction[95]). The barrier to internal rotation (V_3) is 3.24 ± 0.15 kcal mole^{-1} in the $F_3P.BH_3$ molecule[92] and about 3.6–4.5 kcal mole^{-1} in the $HF_2P.BH_3$ molecule[93], i.e. is close to the value in ethane.

2. Compounds with a P–C bond

In the molecules of methylphosphines $P(CH_3)_3$ and $PH(CH_3)_2$ in the vapour phase, the mutual orientation of the methyl groups is also staggered and $V \leqslant 1$ kcal mole^{-1} according to electron diffraction data[56,63] and 2.6 ± 0.5 kcal mole^{-1} according to microwave data[59,62]. Microwave data show that the barriers to rotation in CH_3PH_2 (about 2 kcal mole^{-1}) [55] and CF_3PH_2 (2.36 ± 0.08 kcal mole^{-1}) [57] are approximately the same.

An electron diffraction study of $P(C_3H_5)_3$ vapour[70] showed that the deviation of each of the three cyclopropyl groups from its position in the staggered configuration with C_{3V} symmetry is different (9.5°, −13°, −15°) and "the attempt to interpret the data using the hypothesis that a mixture of molecules with different conformations is present proved fruitless".

Crystalline triphenylphosphine $P(C_6H_5)_3$ was shown by X-ray diffraction[65] to have the C_3 propeller-like conformation with angles between normals to the plane of the base of the phosphorus pyramid and to the plane of the phenyl rings of the order of 60°. In the vapour phase the $(CH_3)_3PO$ molecule[111] has the C_{3V} symmetry with the *trans*-disposition of H atoms relative to the oxygen atom.

Vibration spectra[173] showed that in the liquid phase the more complex structures $CH_2YP(=O)X_2$ (X = F or Cl; Y = Cl, CH_3, or CH_2Cl) exist as mixtures of *trans*- and gauche-conformers with C_S and C_1 symmetry.

In the solid phase of the fluorides, conformers with the C_1 symmetry remain, while in the solid phase of the chlorides the remaining conformers have the higher C_S symmetry.

An electron diffraction study of the vapour of $C_6H_5P(=O)Cl_2$ showed[129] that the most probable conformation of this compound involves a coplanar disposition of the phenyl ring and the P=O bond. This conformation corresponds to minimum steric interaction. Here the barrier to rotation about the P–C bond is approximately 1 kcal mole^{-1}.

The internal rotation of CH_3 groups in the molecules of the pentacoordinate phosphorus compounds CH_3PF_4 and $(CH_3)_2PF_3$ could not be characterised by electron diffraction[162]. The barrier to rotation in CH_3PF_4 is very low (about 10 cal mole^{-1}), which leads to the hypothesis of free rotation. At the same time the barrier to internal rotation in the CF_3PF_4 molecule is 5.0 ± 1.5 kcal mole^{-1} according to microwave data[183].

3. Compounds with a P–N bond

According to low-temperature NMR spectra[174-178], the usual barrier to rotation relative to the P–N bond in the series of aminophosphines $R_1R_2NPR_3R_4$ ($R_1 = CH_3$; R_2 = H, CH_3, or $C_6H_5CH_2$; R_3 = Cl, C_6H_5, or CF_3; R_4 = Cl, C_6H_5, or CF_3) varies in the range from about 9 to 14 kcal mole^{-1}¶. This value is higher than for P–B and P–C bonds (see above). It has also been shown[174] that, particularly in aminophosphines with geminal substitution at the phosphorus atom ($R_3 = R_4$ = Cl or C_6H_5), the barrier depends on the dimensions of the R_1 and R_2 substituents linked to the nitrogen atom. When one of the substituents has a branched chain (for example, $R_1 = C_6H_5CH_2$ and $R_2 = CH_3$), the barrier is higher by 2–3 kcal mole^{-1} (up to about 14 kcal mole^{-1}) than for $R_1 = R_2 = CH_3$ (about 11 kcal mole^{-1}).

Recent studies indicate the possibility of rotational isomerism relative to the P–N bond in compounds with

¶ According to an estimate based on infrared spectra[179], in the compound $CH_3NH-P(CF_3)_2$ the barrier to internal rotation is about 20 kcal mole^{-1}. However, this value is disputed in another study[176].

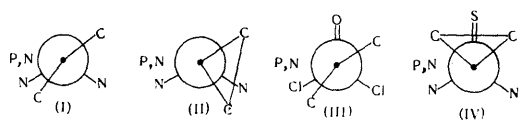
tricoordinate phosphorus[179,180]. This possibility follows in particular from the NMR spectra[180] of the compound $C_6H_{12}NPF_2$. The existence of two *gauche*-isomers has been postulated on the basis of infrared spectra[179] for the compound $CH_3NH-P(CF_3)_2$ in the gas phase, in the liquid, and in benzene solution: the first with a hydrogen atom and the second (in a smaller amount) with a methyl group between CF_3 groups; in this case free rotation obtains at temperatures above 88°C. However, the authors of the investigation[176] believe that in the latter case the characteristics of the infrared spectra cannot be interpreted similarly, i.e. in the sense of the existence of a mixture of isomers. They found that *N*-deuterated specimens $CH_3ND-P(CF_3)_2$ contains two isomers in proportions of 4:1 only below −120°C and on the basis of steric considerations it was postulated that the isomer with the deuterium atom between the CF_3 groups should predominate.

The problem of the energy favouring a particular conformer is controversial. As in the examples examined above, on the basis of NMR spectra[180] preference is given to the *gauche*-conformation of $C_6H_5(CH_3)NPF_2$ as the more favourable. The same conformation was found by X-ray diffraction for the $(CH_3)_2NPF_2$ molecule[73].

At the same time the authors of one of the NMR investigations[174] assert that at least symmetrically substituted aminophosphines $(CH_3)_2NP(C_6H_5)_2$ and $(CH_3)_2NPCl_2$ exist in the sterically less favourable *anti*-conformation. This conclusion was disproved by another NMR study[176] in which preference was given to the *gauche*-conformation of the $(CH_3)_2NPCl_2$ molecule.

On the other hand, electron diffraction showed that in the vapour phase $(CH_3)_2NPCl_2$ has the *anti*-conformation. Moreover, the *anti*-conformation is the most stable in the case of diphosphines (see below) and hydrazine derivatives.

The rotational forms of the $P[N(CH_3)_2]_3$ and $P[N(CH_2)_2]_3$ molecules in the vapour phase found by electron diffraction[71],

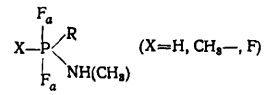


are also not the most favourable from the standpoint of steric interactions (models I and II).

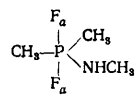
There are comparatively few experimental data for compounds of tetracoordinate phosphorus. Electron diffraction showed[72] that in the vapour phase the $(CH_3)_2NP(=O)Cl_2$ molecules has an asymmetric conformation (model III), the existence of which are confirmed by NQR spectra[181]. On the other hand, X-ray diffraction showed[142] that the $P(=S)[N(CH_2)_2]_3$ molecule has a conformation close to C_{3V} (model IV).

Vibrational spectra demonstrated[182-184] that the monosubstituted amides $RNHP(=S)Cl_2$ exist as mixtures of two rotational isomers in the liquid phase and in solutions. Under these conditions, the disubstituted amides $R_2NP(=S).Cl_2$ exist in a single conformation[182]. It has been noted that the presence of only one isomeric form of $R_2NP(=S)Cl_2$ cannot be explained by steric hindrance to the rotation of the R_2N group about the P–N bond. The geometrical parameters of the fragments about the nitrogen atom in di- and mono-substituted amides are close in magnitude and therefore the steric hindrance should be approximately the same.

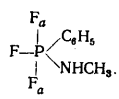
The barriers to the rotation of $NHCH_3$ groups in compounds of pentacoordinate phosphorus of the type



were determined from NMR spectra[185,186]. They vary from 5.0 ± 1.5 kcal mole^{-1} in



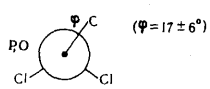
to 12 ± 1.0 kcal mole^{-1} in



These high values are attributed to the existence of intramolecular hydrogen bonds between the $NHCH_3$ groups and one of the axial F_a atoms, as shown by the observed nonequivalence of F_a atoms.

4. Compounds with a P–O bond

Only one conformer of the CH_3OPCl_2 molecule in the vapour and liquid phases with the C_S symmetry was found from vibrational spectra[187]. The barrier to rotation is 1.0 kcal mole^{-1} (1.6 kcal mole^{-1} for the deuterated derivative). It proved impossible to make a choice between the two possible orientations of the methoxy-group. According to electron diffraction data[75], the statistical mean conformation of this molecule in the vapour phase is somewhat distorted relative to C_S:



and is close to the form more favourable from the standpoint of steric interactions.

It follows from the vibrational spectra[188] of $(CH_3O)_3P=S$ that at least two conformers exist in the liquid phase and only one in the crystalline phase. The structure of this molecule in the crystalline phase has not been investigated but X-ray diffraction showed[134] that $(C_2H_5)_3P=S$ has a conformation with C_3 symmetry and the angle $\varphi < 90°$ (see above). The vibrational spectra obtained for the compounds $ROP(=Y)X_2$ (R = CH_3 or C_2H_5; X = F or Cl; Y = O or S) in the vapour, liquid, and solid phases and in solutions[189-194] indicate the presence of at least two conformers in all cases. The specific conformations were not established on the basis of the spectra but it is suggested that one of them has the C_S symmetry.

It has been shown[194] that, on the assumption of the occurrence of attraction (but not repulsion) between the CH_3 group and the Cl and S atoms, it is possible to select two models ($\varphi = 0°$ and $\varphi = 120°$) for the $CH_3OP(S)Cl_2$ molecule, whereupon the calculated frequencies agree with the experimental values for solutions of this substance.

5. Compounds with the P–P bond

From the standpoint of steric interactions, the *anti*-conformation (C_{2h} symmetry) and the *gauche*-conformation (C_2 symmetry) are the most probable for molecules of the type P_2X_4.[11] The halogeno-derivatives probably have the *anti*-conformation, which is the less favourable of the two. This has been demonstrated spectroscopically for P_2Cl_4 in all three phases[195]. Preference is also given to the *anti*-conformation of the P_2F_4 molecule[186]. The problem of the possible change in the conformation of the P_2I_4 molecule on passing from one phase to another was discussed for some time. C_{2h} symmetry was found for crystalline P_2I_4 from Raman spectra[197] and by X-ray diffraction[78]. At the same time measurements of the dipole moments[198] and interpretation of the infrared spectra[197,199] led to the assertion that, in contrast to the crystalline phase, in CS_2 solution this molecule has the C_2 symmetry. However, a subsequent repetition of the spectroscopic study[200] showed that P_2I_4 retains the C_{2h} symmetry also in CS_2 solution and an anomaly in the infrared spectra of the solutions was explained[201] by the equilibrium $3P_2I_4 \rightleftharpoons 4PI_3 + \frac{1}{2}P_4$.

The vibrational spectra of P_2H_4 in the vapour, liquid, and solid phases[202-204] have nevertheless been interpreted on the basis of the *gauche*-conformation. The spectrum of the liquid phase[203] was complicated by the presence of the decomposition products of the compound. At the same time the NMR spectrum[205] demonstrated the equivalence of the hydrogen atoms in P_2H_4. Although the author of the investigation interprets this phenomenon as evidence for rapid interconversion of different conformers, it is also consistent with the possible existence of fixed *anti*- or eclipsed (*cis*-) conformations.

Interpretation of the infrared spectra of $P_2(CH_3)_4$ showed[206] that only the *anti*-conformation exists in the crystalline phase, while in the liquid phase both *anti*- and *gauche*-conformers are present. It proved impossible to arrive at any conclusion concerning the conformation of this molecule in the gas phase. The ^1H NMR spectra[207] of the liquid phase of $P_2(CH_3)_4$ are inconsistent with the existence of the *anti*-conformer.

The *trans*-conformation with C_{2h} symmetry has been found for a number of structures of the type $R_4P_2(=S)_2$ (R = CH_3, C_2H_5, or C_6H_5) in both the crystalline phase (by X-ray diffraction[135-137] and from infrared spectra[208-212]) and in the liquid phase and in dilute solution (from infrared spectra[212]). Certain differences between the spectra of diphosphine disulphides in the crystalline and liquid phases are attributed[11] to the possibility of hindered rotation about the P–C bonds. However, three conformations of $(CH_3)_4P_2 \cdot 2BH_3$ were found in the most stable of the crystalline modifications of this substance[97].

6. "Pseudorotation" in Compounds of Pentacoordinate Phosphorus

The NMR spectra of phosphorus pentafluoride (PF_5) and a number of its derivatives $PX_{5-n}F_n$ are evidence of the equivalence of the F nuclei in these compounds[12-16,213]. In particular, the equivalence in the compounds PXF_4 might correspond to an actual equilibrium configuration of the type of a tetragonal pyramid with C_{4v} symmetry. However, as already mentioned above, only the trigonal-bipyramidal configuration is characteristic of compounds of pentacoordinate phosphorus.

To account for the effect observed in the NMR spectra, the concept of "pseudorotation"—an intramolecular process as a result of which two equatorial atoms are transferred to axial positions and conversely—has been resorted to[15,16,214]. The process is accompanied by a deformation of the valence angles:

As a result, the initial trigonal bipyramid is rotated by 90° relative to the equatorial bond distinguished in the diagram. Such inversion is analogous in a certain sense to the inversion in the ammonia molecule[215] and may be caused by intramolecular vibrations[216]. Calculations yield the following values for the energy barrier to "pseudorotation" (kcal mole^{-1}): 7.6 for PF_5, 10.9 for $PClF_4$, 15.0 for CH_3PF_4, and 13.5 for PCl_5. A systematic analysis of the possible isomeric forms caused by "pseudorotation" in trigonal-bipyramidal molecules has been carried out[217].

At the same time it should be noted that the available data do not as yet allow an unambiguous determination of the true mechanism of the above intramolecular inversion. The Raman spectra obtained[218] for gaseous and liquid PF_5 do not prove the mechanism of this process as described above but they are not inconsistent with it either. In certain specific cases other possible mechanisms of such rearrangements have been postulated[16,219].

---o0o---

The molecular structures of organophosphorus compounds have been examined in this review on the basis of the classical theory of structure. The aim was not to investigate the agreement between approximate electronic concepts, in particular the concept of $p_\pi - d_\pi$ interactions, and the characteristics of geometrical structure. This problem is complex and controversial[220] and requires special analysis.

The characteristics of the geometrical structure of molecules revealed by the analysis of experimental data permit the prediction of the structural parameters for compounds which have not yet been investigated and also make it possible to study the dependence of various properties of materials on their molecular structure.

Structural information is now available for organophosphorus compounds in which the phosphorus atom has different coordination numbers. The length of the phosphorus–element bond depends both on the valence state of the atoms involved in the bond and on the atoms in its immediate environment. The valence angles at the phosphorus atom are fairly characteristic of the given coordination number of phosphorus.

The characteristics of the molecular conformations determined by the rotation about the phosphorus–element bond are less well defined. Steric interactions play a considerable role but do not determine the conformation of the molecules in all cases.

ADDENDUM

After the review had been sent to the printers, a number of new studies on the structure of acyclic organophosphorus compounds were published. In many cases (concerning the reinvestigation of certain structures or more detailed reports with revision of earlier data) the appropriate corrections were introduced into the main text. In addition the following data merit consideration.

The electron diffraction study of the structure of tetramethyldiphosphine[221] $P_2(CH_3)_4$ evidently terminates the controversy concerning the most favourable conformation of this molecule (see above). In the gas phase $P_2(CH_3)_4$ was found to have a conformation close to the *anti*-form. The angle of deviation from the *anti*-form (16°) is less than the error in the determination of the angle in the above study (23°). Among other parameters found for the tetramethyldiphosphine molecule, we have the following:

$r(P\text{—}P) = 2.192\ (0.009)$ A, $\angle CPC = 99.6\ (1.0)°$,

$r(P\text{—}C) = 1.853\ (0.003)$ A, $\angle PPC = 101.1\ (0.7)°$.

The authors of the investigation note that the geometrical parameters of diphosphine are close to those found for their analogues—monophosphines (see, in particular, Table 2).

The vibrational spectra of $N[P(CF_3)_2]_3$ are inconsistent with the planar configuration of the NP_3 fragment and have been interpreted on the basis of its pyramidal structure[222]. The infrared spectrum of the compound in the vapour phase obtained somewhat earlier[223] apparently did not contradict the hypothesis that the NP_3 fragment is planar. However, it has been noted[222] that certain important frequencies were too weak, as a result of which many ambiguities remained. Since, as stated by Hendra et al.[222], conformational analysis did not confirm the planarity of the NP_3 fragment, additional infrared spectra and laser Raman spectra in the liquid phase were measured. The study of all the available spectra[222,223] showed that the nitrogen atom in the compound can indeed be regarded as located outside the P_3 plane. As the same time one cannot exclude the possibility of an equilibrium between the planar and pyramidal structures.

The authors believe that in the pyramidal configuration of the $N[P(CF_3)_2]_3$ molecule the role of the F atoms, despite their electron-accepting properties, is more likely to involve a weakening of the P—N bonds than their strengthening. In this connection it is interesting to recall that in the compound

$$(NH_2)_2P(S)\diagdown N\text{—}CH_3,\quad NH_2(NHCH_3)\,P(S)\diagup$$

investigated by X-ray diffraction in the crystalline phase[141], the length of the bonds between the P atoms and the central N atom is greater by 0.06 Å than that of the remaining $=P\text{—}N\diagup$ bonds. However, the central N atom has a planar bond configuration.

An X-ray diffraction study of the structure of triethynyl phosphine[224] $P(C{\equiv}CH)_3$ showed that in the crystalline phase this molecule has the C_{3v} symmetry. The mean values of the principal geometrical parameters are as follows: $r(P\text{—}C{\equiv}) = 1.75$ Å; $\angle CPC = 101°$. A characteristic feature is the non-linearity of the P—C≡C fragment (the angle of deviation from linearity reaches up to 11°). A similar effect was noted also in the structures $P(C{\equiv}C\text{—}C_6H_5)_3$ [68] and $P(C{\equiv}N)_3$, [69] investigated previously by X-ray diffraction.

Analysis of the infrared spectra obtained in all three phases is evidence of the presence of two rotational isomers with C_S symmetry in compounds of the series $(CF_3)_2PXY$ (where X = O or S and Y = H or D).[225]

An X-ray diffraction study of the structure of triphenylphosphine oxide[226] $(C_6H_5)_3P{=}O$ furnished a criterion allowing a quantitative estimation of the effect of the environment on the length of the bond of the type

$$=P\text{—}C\diagup$$

The length of this bond in the $(C_6H_5)_3P{=}O$ molecule is 1.76 (0.01) Å, i.e. the same as the value found by electron diffraction for the $C_6H_5P(=O)Cl_2$ molecule (see Table 3B). It is striking that the $=P\text{—}C\text{—}$ bond also remains unchanged, within the limits of experimental error, on passing from the $(CH_3)_3P{=}O$ molecule to $CH_3P(O)Cl_2$ (Table 3B). However, in the series

$$(C_6H_5)_3P{=}O \rightarrow (C_6H_5)_3P{=}NR \rightarrow (C_6H_5)_3P{=}C{=}C{=}X \rightarrow (C_6H_5)_3P{=}CH_2$$

the length of the $=P\text{—}C\diagup$ bond increases to 1.82 Å (Table 3B). The remaining parameters of the $(C_6H_5)_3P{=}O$ molecule have the following values:

$r(P{=}O) = 1.46(0.01)$ A, $\angle CPC = 107.1\ (0.7)°$, $\angle CP(=O) = 111.7\ (0.6)°$.

The length of the single P—S bond was determined for only the second time in an X-ray diffraction study of the structure of the $[(iso\text{-}C_3H_7O)_2PS_2]_2$ molecule[227]. In this molecule $r(-P{=}S) = 1.908\ (0.003)$ Å is shorter than $r(=P\text{—}S) = 2.072\ (0.002)$ Å by about 0.16 Å, i.e. by the same amount as in the $[(CH_3O)_2PS_2]_2Te$ molecule (Table 3). The remaining parameters found in this investigation[224] are as follows:

$r(=P\text{—}O) = 1.561\ (0.005)$ A,

$\angle OPO = 96.6\ (0.2)°$, $\angle OP{=}S = 119.3\ (0.2)°$,

$\angle SPO = 108.2\ (0.2)°$, $\angle SP{=}S = 104.8\ (0.1)°$.

The shortening of $r(-P{=}O)$ compared with $r(=P\text{—}O\text{—})$ found by an X-ray diffraction study of the structure of $(CH_3O)_2P(=O)R$ (where R = 3-hydroxy-2,2,5,5-tetramethyltetrahydrofuryl),[228] is only about 0.11 Å. The parameters of this structure are as follows:

$r(-P{=}O) = 1.471\ (0.007)$ A, $\angle OPO = 102.3\ (0.4)°$,

$r(=P\text{—}O\text{—}) = 1.581\ (0.009)$ A, $\angle OPC = 106.5\ (0.4)°$,

$r(=P\text{—}C\text{—}_{ring}) = 1.812\ (0.009)$ A, $\angle OP{=}O = 114.4\ (0.4)°$,

$\angle CP{=}O = 112.0\ (0.4)°$.

According to vibrational spectra[229], the $C_6H_5S\text{—}PF_4$ molecule has an equatorially substituted trigonal-bipyramidal structure.

An X-ray diffraction reinvestigation of the structure of $(CH_3)_4P_2S_2$ (see the data[135] in Table 3) showed[230] that the crystal unit cell of the substance contains two types of molecules with the following parameters:

	Molecule (I)	Molecule (II)
$r(=P\text{—}P=)$	2.245 (0.006) A	2.161 (0.004) A
$r(-P{=}S)$	1.951 (0.003) A	1.970 (0.004) A
$r(=P\text{—}C\text{—})$	1.800 (0.008) A	1.820 (0.008) A
$\angle CP{=}S$	115.0 (0.3)°	115.0 (0.3)°
$\angle PP{=}S$	111.0 (0.2)°	112.0 (0.2)°
$\angle CPC$	103.5 (0.4)°	105.3 (0.4)°.
$\angle PPC$	105.6 (0.3)°	104.3 (0.4)°.

The authors failed to find any cause of the observed differences between the bond lengths in molecules (I) and (II) other than the effect of steric factors.

An electron diffraction study showed[231] that in the gas phase the $(CH_3)_2NPF_2$ and H_2NPF_2 molecules have the *gauche*-conformation [the $(CH_3)_2NPF_2$ molecule has the *gauche*-conformation also in the crystalline phase[73]]. The following fundamental geometrical parameters of these molecules have been quoted:

	$(CH_3)_2NPF_2$	H_2NPF_2
$r(>P-F)$	1.589 (0.003) Å	1.581 (0.003) Å
$r(>P-N<)$	1.684 (0.008) Å	1.661 (0.007) Å
$\angle$ FPN	97 (4)°	101.0 (1.1)°
$\angle$ FPF	99 (3)°	95.3 (1.1)°

It was found that the configuration of the valence angles at the nitrogen atom in the above compound is non-planar in the gas phase (the sum of the valence angles is equal to 348.4° and 346° respectively), while in the crystalline phase the PNC_2 fragment in the $(CH_3)_2NPF_2$ molecule is planar. It was noted that in $(CH_3)_2NPF_2$ the P–N bond length found in the gas phase is higher by 0.056 Å than the value found in the crystalline phase, while the P–F bond length is smaller by 0.021 Å (Table 2).

Thermal Stability of Cation-exchange Resins

N.G.Polyanskii and P.E.Tulupov

Experimental work on the thermal stability of cation-exchange resins in air, water, certain aqueous solutions, and also organic media is summarised for the first time. Conclusions are reached about the effect of various factors on the thrmal stability and about the nature of the processes responsible for the decrease in exchange capacity. Special attention is paid to the existence of an inherent relation between the thermal stability and the catalytic activity of ion-exchange materials. A list of 235 references is included.

1. INTRODUCTION

The action of heat[1,2], radiation[3], and oxidants[4] on carbon-chain polymers often causes irreversible chemical changes in their macromolecules owing to rupture of the carbon–carbon single bond and the occurrence of degradation processes. Ion-exchange materials (resins and membranes) contain also the far less stable bonds between functional groups and the polymer matrix (carbon–nitrogen, carbon–sulphur, carbon–phosphorus, etc.). For this reason the main problem of the thermal, chemical, and radiation stability of ion-exchange materials is the behaviour of the functional groups, which are responsible for the ion-exchange and electrochemical properties under certain conditions.

The importance of this problem arises entirely from the inevitable heat-treatment of exchanger resins and membranes during their preparation and examination of their physicochemical properties. In several actual cases of practical exploitation, exchangers are subject simultaneously to thermal, chemical, and radiation effects.

At the high temperature of the polycondensation of hydroxybenzenesulphonic acid with formaldehyde the exchange capacity of the sulphonated cation-exchange resin may be diminished by desulphonation[5], the formation of sulphones, and the interaction of sulpho-groups with formaldehyde[6], and the three-dimensional structure of the polymer may undergo partial breakdown with oxidation of the degradation products by sulphuric acid[7]. In the preparation of sulphonated cation-exchange resins based on polystyrene and formaldehyde[8] or vinyl polymers[9] an excessive rise in temperature results in a decrease in the exchange capacity.

The drying of exchange resins, which is usually conducted at a high temperature (at or above 100°C) in order to determine their physicochemical properties[10,11], and their preparation for chromatographic separations[12-17] and for the production of heterogeneous membranes[18] may be accompanied by a diminution in the exchange capacity[10,18,19] and by irreversible changes in the structure of the three-dimensional network[20].

Many analytical separations by ion-exchange chromatography are conducted at high temperatures[21-29]. While utilising the kinetic and thermodynamic advantages which this confers, we must reduce to a minimum the chemical changes in the exchange resins that are inevitable with an incorrect choice of temperature conditions for the separation. The regeneration of spent exchangers is often accomplished by means of heated solutions[30-32], the consumption of which decreases with rise in temperature.

Exchangers are often used at high temperatures under industrial conditions, e.g. in the deionisation of industrial waters[33], the purification of radioactive solutions[34], and many catalytic reactions of organic compounds[35]. The correct choice of exchanger, necessarily taking into account its thermal, chemical, and radiation stability, will govern its useful life, and often the successful accomplishment of the desired processes. Thus practical interests demand a comprehensive investigation and survey of data on the thermal, chemical, and radiation stability of ion-exchange materials in all the typical media in which they are used. Results for the radiation stability of ion-exchange materials have been reported in detail in a monograph[36], but data on their thermal and chemical stability are now summarised for the first time.

2. METHODS FOR THE STUDY OF THE STABILITY OF ION-EXCHANGE MATERIALS

Ion-exchange materials are not individual compounds. Their composition and properties depend on the purity of the original monomers and the conditions for synthesis of the polymer, the content of low-molecular-weight compounds in the final product, and its pretreatment. The physicochemical properties are therefore determined on exchanger fractions of definite particle-size distribution, freed from impurities by acid[37-39] or alkali–acid[40-45] treatment, and in individual cases also by washing with organic solvents[46,47]. Ion-exchange membranes are usually prepared by similar methods[48,49], but the possibility of destroying the reinforcing fabric must be borne in mind[49].

Several physicochemical properties—exchange capacity, moisture capacity, relative swelling, density, etc.—must be studied for a complete description of exchangers and their stability, and with membranes the electrical conductivity, selectivity, permeability to water, mechanical strength, and elasticity must also be examined.

The most important physicochemical characteristic of ion-exchange materials is the total exchange capacity. In the case of polyfunctional exchangers and membranes the exchange capacity is also determined with respect to individual functional groups. However, by no means all methods described in the literature for estimating exchange capacity can be used to study the stability of exchangers and membranes. Many authors recommend statistical methods for determining the total exchange capacity of mono- and poly-functional exchangers in the hydrogen or the hydroxide form; these involve treating a weighed portion of the resin with excess of a standard solution of alkali [40,45] or acid [40,50,51] in a closed flask for a definite time. Sometimes a neutral salt is added to the solution to accelerate the exchange of mobile ions [39]. Total exchange capacity is not a happy choice to represent the stability of a polyfunctional exchanger, since different types of functional groups usually split off at different rates, and furthermore carboxylic and phenolic groups may be formed on irradiation or by the action of oxidants.

The most reliable measure of the resistance of an exchanger to a given factor is the capacity which is retained with respect to individual active groups (expressed in mg-equiv. g^{-1} initial resin or as a percentage of its original exchange capacity), determined potentiometrically [40,52-55], conductometrically [56,57], or titrimetrically [40,41]. Potentiometric methods require a large amount of time, and are advisable only for studying reaction mechanisms and the formation of new functional groups. In series of experiments it is more useful to apply rapid methods for the separate determination of the exchange capacity of cation-exchange resins in the hydrogen form [58,59] (direct titration of the resin in the presence of a neutral salt), for whose development much credit is due to Vasil'ev and his coworkers [60-66]. The considerable difficulties involved in the separate determination of the active groups of different strengths in phosphoric-acid cation-exchange resins [67] have not yet been overcome.

Complexometric methods [41,68], which do not require conversion of the exchanger into the hydrogen form, have undoubted advantages in estimating the exchange capacity of the salt forms of cation exchangers.

In laboratory practice, and sometimes also in studies of the stability of ion-exchange materials, use is quite often made of the static exchange capacity [40,49,69,70], which is determined by titrating a solution of a neutral salt, an acid, or an alkali in equilibrium with the test polyelectrolyte. The static exchange capacity depends on many factors—the concentration of the solution, the temperature, the degree of cross-linking of the exchanger, etc.—and therefore cannot serve as a criterion of its stability.

In the determination of the exchange capacity of an exchanger under dynamic conditions an electrolyte solution is filtered through a layer of the resin, and the ions displaced from the active groups are subsequently titrated in the filtrate [38,40,41,67,71]. This method is considerably more complicated than the static method, and requires a large consumption of reagents, but it gives valuable information on the dynamics of ion-exchange processes and on the properties of the exchangers.

Values obtained by the above methods for the exchange capacity may differ from those calculated from the formula of the structural unit, owing to incomplete sulphonation and phosphorylation or the occurrence of secondary processes which convert some of the functional groups into an "inactive" state [72-75]. The content of "inactive" sulphur or phosphorus is determined from the difference between the results of elementary analysis [76] and titration.

Exchange capacity is usually expressed in mg-equiv. g^{-1} dry material. This quantity is to some extent arbitrary, since it is evidently impracticable to obtain "absolutely" anhydrous exchangers without changing their chemical nature. Yet in several cases it is necessary to use dehydrated exchangers.

Conditions of dehydration must be chosen for each type of ion-exchange resin or membrane. It must be remembered that part of the bound water remains in the exchangers, and is capable of exerting a decisive effect on their behaviour towards radiation, heat, and reagents. It is interesting that the cation exchanger KU-2, after being dried at 100°C to constant weight, contains monohydrates of the sulpho-groups or ~ 9% water [77].

Many methods have been described for removing water from cation-exchange resins: these reduce to drying in a thermostat at 90°, [78] 95–100°, [79] 100 ± 50°, [40] 105 ± 2°, [80] 105–110°, [10,11,39,42,81,82] 110–115°, [83] 110–120°, [84] or 120°C [85], distilling off the water azeotropically with an organic solvent [86], or evacuating in the presence of a drying agent [20,45,52,87-94].

Cation exchangers having a polystyrene–divinylbenzene matrix can be dehydrated without danger of destruction by any of the above methods, but the most convenient treatment in practice is to heat in an air thermostat at 110–115°C to constant weight. The less thermostable sulphophenol–formaldehyde and sulphostyrene–butadiene (SBS resin) cation-exchange resins are appreciably desulphonated under these conditions: it is advisable to dry them over phosphorus pentoxide or magnesium perchlorate at a residual pressure of 5–10 mmHg in a vacuum desiccator.

The equilibrium moisture content of an exchanger is measured by the moisture capacity, expressed as the number of grams or millimoles of water retained by 1 g of the resin or 1 mg-equiv. of functional groups in the state of maximum swelling [87,94]. Determined under rigorously standardised conditions, this quantity is of great value for indicating changes in structure of the matrix on heat-treatment, although it must be accepted with the same reservations as the concept of an "absolutely dry" exchanger. The most reliable method for determining the moisture capacity is to remove adherent water from the fully swollen exchanger by centrifuging [45,94-98] (or by squeezing between sheets of filter paper in the case of membranes [99]), and then dehydrating.

The moisture capacity is closely connected with one of the most important characteristics of exchangers—the relative swellability—that govern their mechanical, kinetic, and catalytic properties. The relative swellability is defined as the percentage increase in volume of the resin in the hydrated state with respect to the volume of the dry resin. Most known methods give only apparent values of this quantity. In particular, the simplest method, involving measuring the volume of the anhydrous and the swollen resin in a cylinder [37,40,100] or in a calibrated column [96], gives values which depend on the granularity of the exchanger. Methods based on measurement of the volume [101,102] or the weight [103] of bound solvent yield in effect the moisture capacity, owing to the breakdown of additivity [94]. The true value of the relative swellability can be determined by measuring the specific volumes [94] or from the increase in volume of a pyknometric liquid in a microburette on the introduction of weighed portions of the resin [41]. Quite reliable values of the relative swellability can be obtained by measuring individual resin particles photographically [104], microscopically [96,105,106], or pyknometrically [40,94,107]. A simple pyknometric method [108]

makes it possible to determine simultaneously density, relative swellability, and moisture capacity, which are interrelated functionally. An interesting method has been described[109] for determining the true density of ion-exchange materials in binary solvent mixtures.

The change in the rate constant for the racemisation of (+)-α-isobutyldeoxybenzoin has recently been used[110] as an indication of the thermal stability of the resin Amberlite-15 when heated in inert media. This approach embodies the idea of a close connection between thermal stability and catalytic activity in ion-exchange materials, which has been expressed repeatedly by the Reviewers in a series of publications.

Since direct methods for recording changes in the structure of exchanger macromolecules have not been discussed in the literature, indirect methods (moisture capacity, relative swellability, sorption properties, etc.) are used. The spectrophotometric method gives interesting details of the chemical structure of a resin macromolecule[77,111-116]. Nuclear magnetic resonance[117-120], electron spin resonance[121,122], and the Mössbauer effect[123,124] are undoubtedly of interest for studying the internal structure, in particular the bonding of water in the resin macromolecule. These methods should find wide application for investigating the thermal stability of exchangers. The application of diverse methods for investigating the properties of exchangers in organic media and in the gas phase[112,125] will provide valuable information on the mechanism of the changes which occur.

The complete characterisation of ion-exchange membranes requires also a knowledge of the changes in selectivity[126-130], electrical conductivity[127,131-136], water permeability[128,131,137], mechanical strength, and specific elongation under tension[138]. It must be remarked that publications very seldom give a complete description of the properties of membranes (or of ion-exchange resins), and this lessens the value of the published results. Authors usually determine only the most important electrochemical properties of membranes, such as the conductivity and the selectivity: a more complete description of the physicochemical properties of membranes will be found in only a few papers[127,128,131].

3. THERMAL STABILITY OF CATION-EXCHANGE RESINS IN GASES AND VAPOURS

The systematic study of the thermal stability of exchangers in air was initiated by the work of Saldadze[139,140]. Using a thermographic method, he observed an endothermic change, probably corresponding to dehydration and occurring in the range 100–130°C depending on the nature of the exchanger. Further heating to 400°C was not accompanied by thermal effects which could be recorded, and this was interpreted[139] as evidence of great thermal stability in the exchangers. Somewhat later Evlanov and his coworkers[141] employed chemical and thermographic methods of analysis to show the presence, on the thermogram of the cation-exchange resin KU-1, of a second endothermic effect at 260–270°C, which was ascribed to the detachment of sulpho-groups. Nevertheless, the titrimetric method employed[141], which gave the total exchange capacity (including phenolic hydroxyls), was insufficiently sensitive to detect small losses of sulpho-groups, and led to the erroneous conclusion that the exchanger had high thermal stability at the temperature of the first endothermic effect (105–115°C). For the same reason no change in concentration of sulpho-groups was noticed[139] at 150°C, and the exchange capacity was judged to be constant from the potentiometric titration curve before and after the heat-treatment of sulphonated phenol–formaldehyde cation-exchange resins. By the use of more delicate methods, involving measurement of the exchange capacity with respect to sulpho-groups alone[8,142] or the loss thereof using the acidity of aqueous extracts, Vasil'ev[8], Polyanskii[142-145], and Jacubovic[20] showed that these exchangers underwent desulphonation at 100°C.

The sulphonated copolymer of styrene and divinylbenzene (KU-2 resin) was considerably more heat-resistant, its exchange capacity remaining unchanged even after 2 months' storage in sealed ampoules at 70°C.[139] When the temperature was raised to 150°C, however, losses in capacity of up to 3% were detected analytically after only 1 day[142].

The loss in weight by the sulphonated cation-exchange resins KU-1 and KU-2 at 110°C is due to the removal of water. The only other substance liberated is sulphuric acid, always in equimolecular proportion to the decrease in exchange capacity at sulpho-groups, independently of the duration of heating[88]. Hence under these conditions desulphonation is due to thermal hydrolysis

$$RSO_3H + H_2O \rightleftharpoons RH + H_2SO_4 \qquad (1)$$

involving residual water in the exchanger. The sulphuric acid which accumulates in the resin absorbs some water from the air, and therefore the weight of the cation exchanger passes through a minimum with continued heating[146].

Raising the temperature to 150° and 185°C leads to the accumulation not only of sulphuric but also of sulphurous acid, their total quantity being molecularly equivalent to the losses in capacity at sulpho-groups, and the proportion of sulphurous acid increases with increased duration of the experiment (in a closed ampoule)[147]. The formation of sulphurous acid is explained by redox reactions of the type

$$Red + H_2SO_4 \rightleftharpoons Ox + H_2O + SO_2, \qquad (2)$$

where Red represents a molecule or an atomic grouping having reducing properties and present in the exchanger[61,148-151], and Ox the corresponding oxidised form.

One of the Reviewers has shown[146,147] that the particle-size distribution of different cation-exchange resins has little effect on the relative losses in exchange capacity. Hence thermal desulphonation can be regarded, not as a topochemical process taking place at the surface of the solid phase in contact with air, but as a chemical reaction occurring throughout the exchanger grain.

The structure of the hydrocarbon skeleton of the matrix, the position of the sulpho-group, and the presence of other substituents in the aromatic ring greatly influence the relative loss of exchange capacity. The maximum thermal stability of the cation-exchange resin KU-2 may be due to an especially stable matrix[1,148], which has a saturated hydrocarbon chain structure. The cation-exchange resin SBS, although an addition polymer, exhibits far lower thermal stability, probably owing to the presence of unsaturated bonds in its matrix. At 185°C its stability is comparable with that of sulphophenol–formaldehyde resins[146]. The latter resins, containing phenolic hydroxyls in the aromatic ring, are unstable even at low temperatures (110°C), their rate of desulphonation increasing with the exchange capacity[143]. On comparing the relative losses in capacity[143] of the cation exchangers KU-1 and Wofatit P, we cannot agree with Naumann's statement[152]

that resins containing sulpho-groups in the side-chain should be more stable. The sulphonaphthalene–formaldehyde resin KU-5, which is monofunctional, is more stable when heated in air than is the cation-exchange resin KU-1G, which has a similar exchange capacity, but is considerably inferior to the resin KU-2.

Decreasing the residual water content in cation exchangers (by raising the temperature of the preliminary drying) slows down the thermal hydrolysis (1). Thus specimens of KU-2 which had been dried at 110° and 130°C lost 37.7% and 17.5% respectively of their exchange capacity after being heated in sealed ampoules at 185°C for 24 h.[146] When heated in open weighing bottles at 185°C for 24 h the exchanger KU-2 loses only 14.5% of its exchange capacity. The reason for these differences in rate of desulphonation is that, when experiments are conducted in sealed ampoules, not only the residual water but also the water formed in the redox reaction (2) takes part in the hydrolysis. The rate of the redox reaction is determined by the structure of the macromolecule and decreases in the sequence KU-1 > SBS > KU-2. Thus in experiments with the cation-exchange resin KU-1 in sealed ampoules at 195°C the proportions of the sulphuric acid formed by hydrolysis that take part in reaction (2) after 1, 6, and 24 h are respectively 46%, 90%, and 100%, but in experiments with KU-2 only 5%, 12%, and 31% respectively[147].

Heating a cation exchanger based on phenoxyethanesulphonic acid and formaldehyde in air for 8 h at 100°, 120°, 130°, 140°, and 150°C produces a change in exchange capacity[153] from 4.30 to 4.40, 4.35, 4.10, 3.80, and 3.75 mg-equiv. g^{-1}. Sulphuric acid is detected in aqueous extracts obtained after the resin has been heated at 130° and 140°C. Oligomers pass into the aqueous extract when the experimental temperature is raised to 150°C.

Thus the quantity of sulphur dioxide evolved cannot be the sole criterion of the thermal stability of a resin. It is not fortuitous that the sequence of thermal stability of sulphonated cation exchangers according to Griesbach[154] varies with the temperature: at 150°C Amberlite IR-100 < Wofatit KS < Wofatit P < Dowex 50 < polynaphthalenesulphonic exchanger = Amberlite IR-120 = Wofatit KPS-20; at 200°C Wofatit P < Amberlite IR-100 < polynaphthalenesulphonic exchanger < Wofatit KS < Dowex 50 < Wofatit KPS 200 < Amberlite IR-120. The thermal stability of the benzylsilane exchanger[154], which is desulphonated above 300°C, is especially noteworthy.

A kinetic interpretation of the experimental results is undoubtedly made difficult by the complicated effect of the redox reaction (2) on the thermal hydrolysis (1). In spite of the large quantity of data which have accumulated on the thermal stability of ion-exchange resins, only the first steps have so far been made in examining the kinetics of the decrease in exchange capacity.

During the initial period of heating in open weighing bottles all the cation exchangers investigated show fairly high rates of desulphonation[144,145,155] (see Table 1), after which the process slows down. Application of first-order and second-order kinetic equations did not reveal a law describing desulphonation for all heating times[145]. This may be a consequence not only of variation in the water content of the resin[146], which should ultimately become constant for a given temperature and relative atmospheric humidity, but also of the presence of energetically non-equivalent sulpho-groups in the exchangers.

Observations[156,157] on the effect of heat-treatment in air on the selectivity and the kinetic properties of sulphonated cation exchangers, which is especially marked in the resin KU-1, are of undoubted theoretical and practical interest. In the absence of heat-treatment, KU-1 absorbs potassium, magnesium, and quinine cations quantitatively from solutions of their salts until breakthrough occurs. Both cations are absorbed from binary mixtures of a solution of quinine sulphate with a salt of one of the above elements in variable quantities. After KU-1 has been heated in air at 150°C, however, none of the organic cations nor magnesium is absorbed from mixtures of potassium or magnesium with quinine, salsoline, or ephedrine, whereas potassium is extracted quantitatively from a comparatively large volume of the filtering solution. Since formation of magnesium complexes of the alkaloids is excluded (absorption proceeds normally on the resin KU-1 before heat-treatment), the observed effect is explained by blocking of the surface of the grain by the large organic cations and loss by the sorbent of the capacity for the bulk absorption of strongly hydrated multivalent ions. In the case of the cation-exchange resin KU-2 preliminary heat-treatment in air at 150° and 185°C is apparent only in a slowing down of ion exchange[156–158] and is accompanied by an increase in the exchange volume capacity.

Table 1. Kinetics of the variation in exchange capacity of cation exchangers in open weighing bottles at 185°C.[144,145,155]

Duration, h	Exchange capacity after heat-treatment, mg-equiv. g^{-1} original resin			Relative loss in capacity, %		
	KU-1	KU-2	KU-5	KU-1	KU-2	KU-5
0	2.01	4.75	3.37	0	0	0
1	1.75	4.64	3.00	12.9	2.8	11.0
3	1.66	4.52	2.72	17.4	4.8	19.3
6	1.35	4.42	2.46	32.9	7.0	27.0
12	1.30	4.26	2.26	35.4	10.3	33.0
24	1.18	4.06	1.98	41.2	14.5	41.3
144	0.59	3.00	1.44	70.7	36.8	57.4
312	0.58	2.40	1.27	71.2	49.3	62.4

The change in the kinetic properties of sulphonated cation-exchange resins and their assumption of the properties of ionic sieves, as a result of heat-treatment in air, can reasonably be attributed to contraction of the three-dimensional structure of the macromolecule. This is supported by the decrease in the equivalent moisture capacity[88,143,156,158].

Treatment of KU-2 with superheated steam produces a decrease in exchange capacity and an increase in the selectivity of the Ag^+–H^+ exchange, which is also explained by structural changes in the resin[159]. Heat-treatment of the sulphonated cation-exchanger SBS in a current of superheated steam at 200°C leads to a slowing down of the van der Waals sorption of phenol, nitrobenzoic acid, and other organic compounds[160], doubtless because of the change in the structure of the sorbent.

The mechanism of the contraction of the three-dimensional network has not been finally elucidated, but it is obvious that preliminary heat-treatment in air may become a method for controlling the kinetic properties of ion-exchange materials.

Heat-treatment of sulphonated cation-exchange resins in air is accompanied also by changes in the relative swellability and in the density in dry and swollen states[155,158].

A possible cause of the decrease in the sorption capacity of sulphonated cation exchangers might have been the formation of weakly acidic groups[55]. However, no new groups of this type are formed in KU-1 and KU-2 on heat-treatment at temperatures up to 185°C.[146] This may be evidence of the insignificant part played up to 200°C by oxidative degradation of the macromolecule. Oxidative degradation of the polymer matrix occurs vigorously at around 400°C and is accompanied by the accumulation of carboxy-groups[161].

The application of the modern methods of thermographic, differential thermographic, thermal, and differential thermal analysis to the investigation of ion-exchange resins has undoubtedly given interesting results[161-165]. With sulphonated cation-exchange resins the last of these methods has revealed[161-163] three endothermic changes, at 100–210°, 270–310°, and above 430°C, which were attributed respectively to dehydration, desulphonation, and oxidative degradation of the matrix. An exothermic effect at 370°C is ascribed to depolymerisation of the copolymer[161]. The elementary composition of the exchangers after heat-treatment is assumed[161,162,164] to indicate partial conversion of sulpho-groups into sulphones and the formation of additional cross-links. Among possible modes of formation of sulphones Soldatov et al.[162] assume direct reaction between sulpho-groups and the matrix:

$$RSO_3H + RH = RSO_2R + H_2O. \qquad (3)$$

At 430°C almost all the sulphur in the resin is already in an inactive state (as sulphones)[161]. Further rise in temperature[161,165] produces intense degradation of the macromolecule with breakdown of the sulphones and formation of sulphur dioxide as the chief sulphur-containing product. Ehlers et al.[165] assume the evolution of this gas to be a consequence of the reaction

$$RSO_2R \rightarrow R\dot{S}O_2 + \dot{R} \rightarrow SO_2 + R{-}R \qquad (4)$$

which occurs by a radical mechanism.

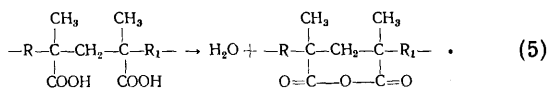
Examination of a single property may lead to erroneous conclusions concerning the behaviour of an exchanger when heated. Thus the existence of two forms of bond between water and functional groups in carboxylated and sulphonated cation-exchange resins (KB-4P and KU-2) was assumed[166] from the number of endothermic effects (at 100–110° and 150–180°C), but this conclusion has not been confirmed by later workers[161-163]. There is also insufficient basis for the conclusion, reached from the results of elementary analysis, that the hydrogen form of the exchanger KU-2, dried at 200°C, contains $1\frac{1}{2}$ molecule of water for every sulpho-group[163]. In view of the partial conversion of sulpho-groups into sulphones[161,162], elementary analysis must be supplemented in this case by alkalimetric titration in order to determine the content of mobile hydrogen ions.

Dependence of the form of thermogravimetric and differential thermal analysis curves on the water content of the original exchanger[162] emphasises the importance of using resins in the same initial state of hydration. The resin dried at 100°C to constant weight, and containing one water molecule for every sulpho-group, may serve as such a state[77].

Desulphonation of the cation exchanger SBR-4 when heated in a current of superheated steam at 200–250°C is accompanied by the formation of volatile products (sulphur dioxide, hydrogen sulphide) and additional cross-links of sulphonyl character with a corresponding contraction of the three-dimensional network and diminution of the moisture capacity[164]. Unfortunately, this interesting investigation[164] was conducted on a non-standard exchanger, which makes it impossible to compare the thermal stability in air with that in superheated steam.

The conversion of sulphonated cation-exchange resins from the hydrogen form into a salt form is accompanied by a significant improvement in their thermal stability in air[140,161,164,167-169]. However, investigation of the behaviour of salt forms of sulphonated cation exchangers is only in its initial stages, and the mechanism of the reactions involved is still obscure.

The behaviour of carboxylated cation exchangers when heated in air has been studied in far less detail than that of sulphonated exchangers, while phosphoric-acid resins have remained almost uninvestigated. From the results of thermographic and chemical examination, together with an analysis of the infrared spectrum, Peryshkina et al.[170] have established that the carboxylated cation-exchange resin KB-4 is stable in the hydrogen form to prolonged heating at up to 120°C. At 200°C the resin loses only water—initially water of hydration, and then water evolved by the condensation of neighbouring carboxyls in the chain:



(5)

Between 200° and 260°C small amounts of carbon dioxide are evolved together with water, as a consequence of decarboxylation[170]. Similar conclusions were reached by Chapiro et al.[171] in a study of the thermal stability of homogeneous membranes based on carboxy-containing monomers. These workers note[171] that reaction (5) slows down when the membranes are heated in a vacuum. Hence atmospheric oxygen plays a definite part in this reaction. The salt forms of carboxylic cation exchangers are more resistant to heating in air than is the hydrogen form[172], as in the case of sulphonic exchangers. The behaviour of the ammonium form of the cation-exchange resin KB-4 is somewhat unusual, for the thermal stability is intermediate between those of the hydrogen and the salt forms[172]. Myagkoi and Suslina's conclusion[172] concerning the energetic non-equivalence of the water of hydration in the exchanger KB-4, which is based on a study of the equilibrium changes in weight of the resin at 100°, 150°, and 200°C, appears to be unsound. The weight of the resin inevitably becomes constant at each temperature, owing to the establishment of sorption–desorption equilibrium between the exchanger and air, provided that decarboxylation and the formation of anhydrides make no significant contribution to the total weight losses.

4. THERMAL STABILITY OF CATION EXCHANGERS IN WATER AND AQUEOUS SOLUTIONS

One of the first papers on the chromatographic separation of rare-earth elements by high-temperature elution[173] mentions the decomposition of the sulphonated phenol–formaldehyde resin IR-1 above 60°C, and Dickel et al.[174] assume that sulpho-groups split off from cation exchangers even during storage of the resins. Calmon and Kressman consider[168] that resins containing cyclic sulpho-groups cannot be used above 40°C, since they undergo hydrolysis with liberation of sulphuric acid. Osborn[175] does not recommend working with ion-exchange resins at temperatures above 70–80°C. Sulphonated cation-exchange resins whose active groups are linked to the aromatic ring through methylene bridges are less liable to hydrolysis[168],

and can be used above 80–90°C. All the authors note that polycondensed sulphonated cation-exchange resins have the greater thermal stability, as when heated in air. According to Lindsay et al.[176] the polymerised cation exchanger Dowex-50 is stable when heated in water up to 105–115°C.

By heating a sulphonated polystyrene cation exchanger in water at 180–210°C Boyd et al.[177] prepared a series of sorbents differing in exchange capacity, in which the quantity of sulphur present in active groups corresponded precisely to that found by elementary analysis. The equivalent moisture capacity of specimens obtained by partial desulphonation passed through a maximum (corresponding to the loss of 50% of the sulpho-groups), its variation showing loosening of the three-dimensional network. The structural changes in sulphonated cation exchangers resulting from their heat-treatment are clearly confirmed by the differences in the coefficients of self-diffusion of ions[177,178] in desulphonated specimens and in the selectivity of ion exchange[91]. The self-diffusion coefficients of Na^+, Ag^+, Zn^{2+}, Y^{3+}, and La^{3+} first increase with decrease in the exchange capacity, pass through a maximum, and then decrease[178]. The equivalent moisture capacity shows a similar variation.

Table 2. Variation in exchange capacity of sulphonated cation-exchange resins when heated in water[146].

Type of exchanger	Temp., °C	Exchange capacity (mg-equiv. g^{-1} initial resin) after heating for			Relative loss in capacity (%) after heating for	
		0	6 h	24 h	6 h	24 h
KU-1	110	2.01	1.84	1.72	8.5	14.4
KU-1	175	2.01	0.17	0.08	91.5	96.1
KU-5	175	1.99	1.77	1.50	11.0	24.6
SBS-3	175	0.91	0.57	0.48	36.7	47.6
KU-2 × 1.5	170	0.87	0.86	0.81	1.3	6.6
KU-2 × 5	170	2.00	1.81	1.61	10.3	19.4
KU-2 × 20	170	1.51	1.21	1.08	19.7	28.3
KU-23 × 3	170	1.17	1.15	1.10	2.0	6.1
KU-23 × 6	170	1.56	1.52	1.47	2.0	5.5
KU-23 × 15	170	1.35	1.25	1.15	7.2	14.9
KU-23 × 20	170	1.40	1.11	0.88	20.6	37.0
KU-2 × 12PS	170	1.87	1.71	1.46	8.8	22.0

The most thorough studies of the thermal stability of sulphonated cation-exchange resins in water have been reported in Refs. 48, 87, 179, and 180. Table 2 gives as illustration the exchange capacity and the relative loss in capacity of specimens when heated in water. The exchange capacity of KU-1 is based on the dehydrated material; in other cases it refers to the state of limiting swelling. The exchange capacity of all the sulphonated resins decreases with rise in temperature and increased duration of heating in water. Owing to the presence of a permanent excess of water, the rate of decrease in the exchange capacity varies more slowly with the duration of heating than in experiments in air. With the same heating time, therefore, the relative loss of exchange capacity is greater in water with some exchangers, and greater in air with others.

Certain conclusions concerning thermal hydrolysis as a cause of the desulphonation of cation-exchange resins in water can be drawn from a comparison of the absolute losses of exchange capacity with the sulphuric-acid content of the aqueous extracts. If thermal hydrolysis is not complicated by redox processes involving the sulphuric acid formed or by the detachment of oligomers containing sulpho-groups, the content of H^+ and SO_4^{2-} ions is double (in number of milliequivalents) the absolute losses of capacity by the exchangers. Table 3 shows that such a correlation has been established, within the limits of experimental error, for the cation exchangers KU-1, KU-2 × 4, and KU-2 × 12PS. In individual cases, e.g. in experiments with KU-5, KU-23 × 15, and especially SBS-3, agreement between losses of capacity calculated from titration of the resin and of aqueous extracts breaks down[146] (Table 3), which may be due not only to redox processes leading to the formation of sulphur dioxide (KU-1 and KU-2) or hydrogen sulphide (SBS) but also to the separation of sulphonic acids of low molecular weight[146,179].

Table 3. Relative loss of exchange capacity after heating for 24 h from titration of resin and of aqueous extracts[146].

Type of exchanger	Temp., °C	Relative loss of capacity (%) from titration of		
		resin	H^+ in extract	SO_4^{2-} in extract
KU-1	175	96.4	95.8	98.5
KU-2 × 4	175	19.5	18.2	19.8
KU-5	175	24.6	23.6	22.2
SBS-3	170	47.6	37.3	—
KU-23 × 15	170	14.8	17.4	17.1
KU-2 × 12PS	170	22.5	23.1	22.3

Table 2 shows that the thermal stability of the sulphonated cation-exchange resins in water diminishes in the sequence—KU-23 × 15 > KU-2 > KU-5 > SBS > KU-1—as in air. In this sequence the condensation polymers KU-32–KU-40 based on aromatic fused-ring systems (anthracene, phenanthrene, pyrene), and the addition polymer KU-3A based on 1-vinylnaphthalene, are probably intermediate in thermal stability[181] between the resins SBS and KU-1. The relative losses of capacity by the exchangers in water depend substantially on the type of exchanger, the chemical structure of its macromolecule, the porosity of the grain (which usually improves stability), and the purity of the initial monomers. Replacement of technical divinylbenzene by the pure *meta*- and *para*-isomers produces some improvement in the stability of the resin, presumably owing to the greater regularity of structure of the macromolecule[182]. Infrared spectroscopy has shown that sulphonation involves partial entry of sulpho-groups into *m*-divinylbenzene[182]. The relative losses of capacity increase with increased quantity of cross-linking agent in gel-like[43] and macroporous[179] samples of the cation exchangers. This rule has been explained hitherto[43,179] by the diminished strength of bonding of sulpho-groups with the matrix due to the increased mutual repulsion between ions as the swelling of the polymer decreases. However, an alternative is to regard the hydrolysis of sulphonated cation-exchange resins as a process catalysed by the hydrogen ions of the sulpho-groups and of the sulphuric acid which is formed. Such a view has been developed in connection with sulphonic acids of low molecular weight[183]. Increase in the degree of cross-linking leads to a decrease in the water content in the exchanger phase, an increased concentration of hydrogen ions relative to water in the vicinity of sulpho-groups, and a consequent increase in the rate of hydrolysis. No direct

connection between degree of cross-linking and the water content of the resin phase exists in macroporous cation exchangers[179]. Their water must be regarded as bound (forming part of hydrate sheaths) and free (filling the pores). Whereas in the desulphonation of gel-like cation-exchange resins[146] the equivalent moisture capacity varies insignificantly, in macroporous specimens it increases continually[179], since the content of free water remains practically unchanged with decrease in the exchange capacity. Moreover, the volume of bound water probably decreases with increase in the content of cross-linking agent even in macroporous exchangers, so that the hydrogen-ion concentration near functional groups and the rate of hydrolysis of the latter also increase.

Many attempts have been made at a kinetic interpretation of experimental results on the hydrolysis of sulphonated cation-exchange resins when heated in water[87,91,146,179,184], but none of them can be regarded as successful, since regularities concerned individual types of exchangers and a limited time interval. Thus a linear relation was found[87] between the logarithms of the loss of capacity and of the duration of heating for the exchangers KU-1 and KU-2, but this rule is by no means always followed by the exchanger KU-5[145] and macroporous specimens[179] based on styrene and divinylbenzene. The relative loss of capacity $\Delta E/E_0$ was found[184] to vary linearly with the duration of heating at 40–90°C with extremely low degrees of desulphonation, and from this the incorrect conclusion was drawn that hydrolysis of the sulpho-groups in the cation exchangers KU-1, KU-11, sulphonated coal, Zeocarb-215, Wofatit P, KU-21, KU-5, and KU-6G conforms to a first-order rate law.

The logarithm of the mean rate of desulphonation of the cation exchanger Dowex-50 × 12 was shown[91] to vary linearly with the reciprocal of the absolute temperature, which indicated that the hydrolysis of sulphonated cation-exchange resins obeys the Arrhenius equation.

In none of the above investigations was the formation of weakly acidic groups detected when sulphonated cation-exchange resins were heated in water. Therefore the conclusions[185] that such groups appear when the sodium form of the cation exchanger Ankalit KT-3 is heated in water at 90–100°C for 100 h, and that some of the sulpho-groups are converted into sulphonyl groups, are somewhat unexpected. In our opinion the basis for these conclusions is insufficient.

Heating sulphonated cation exchangers in water is accompanied not only by a decrease in exchange capacity but also by changes in swelling and moisture capacity. The increase in the swelling of KU-1 and KU-2 as a result of being heated in water at 100°C is accompanied by an increase in their electrical conductivity[186].

Boyd et al.[177] attribute the slight increase in the equivalent moisture capacity of gel-like cation exchangers to a decrease in the number of cross-links in the matrix on heating in water. However, it was shown later[87] that the changes in equivalent moisture capacity are reversible, and level out after drying followed by swelling in water.

The same effects occur when heat-treated KU-2 and KU-1 are regenerated with alkali and acid with complete (KU-2) or partial (KU-1) restoration of the electrical conductivity[186]. In view of the reversible character of the changes in moisture capacity on heat-treatment, one of the Reviewers has attributed them to temporary deformation of the three-dimensional network under the influence of immobilised water[87].

Heating macroporous cation exchangers in water produces a redistribution of pore size, while the total porosity remains unchanged[179]. This observation opens up methods for controlling the properties of ion-exchange materials.

The salt forms of cation exchangers[168] (KU-1[87], MSF[140], polystyrenesulphonate[177], polycyclohexadiene[187]) show considerably better thermal stability than the hydrogen form when heated in water, as in air. At 175°C appreciable desulphonation effects are observed only with KU-1 resin[87]. The thermal stability of sulphonated cation-exchange resins depends on the nature of the gegenion, and diminishes in the sequence of ionic forms $Mg^{2+} > Ca^{2+} > Na^{+} \gg H^{+}$.[180] Thus when KU-1 was heated in these ionic forms at 150°C for 1 day, the corresponding losses in exchange capacity were 21.6%, 25.2%, 29.6%, and 81.2%.[180] The rule found for the series of salt forms can reasonably be explained by desulphonation by the reaction[87,180]

$$RSO_3M + H_2O = RH + MHSO_4 . \quad (6)$$

The hydrogen ions liberated by the hydrolysis (6) undergo ion exchange

$$RSO_3M + MHSO_4 = RSO_3H + M_2SO_4 \quad (7)$$

replacing some of the metal ions in the sulpho-groups and lowering the thermal stability of the exchangers.

The abnormally low thermal stability of the hydrogen form of KU-1 in comparison with other cationic forms was explained by hydration of the hydrogen ion in the resin and by its special polarisation and quantum-mechanical properties[180]. However, if hydrolysis of the sulpho-groups is considered in terms of acid catalysis, the above experimental results find an unequivocal explanation. In fact, heating KU-1 under conditions excluding access of hydrogen ions to the resin phase (in a carbonate buffer)[188] does not result in desulphonation at 150°C. From the above discussion, it is easy to understand why the sodium form is less stable than the magnesium and calcium forms: in conformity with the charge and radius of the hydrated ion, sodium is most easily replaced by the hydrogen ion in the resin phase. However, the magnesium form is more stable than the calcium form, although according to the exchange constants the magnesium ion should be replaced more easily by the hydrogen ion in the resin phase. This apparent discrepancy is eliminated by assuming that the equilibrium

$$(RSO_3)_2Ca + H_2SO_4 \rightleftarrows CaSO_4 + 2\,RSO_3H \quad (8)$$

shifts to the right because the calcium ions in the liquid phase are bound as the relatively sparingly soluble sulphate[180]. A more general view may be to assume that the equilibrium is reversed at high temperatures owing to variation in the molar volumes of the hydrated exchangeable ions[189], as follows from the Gregor–Glückauf equation[190].

Thus the thermal stability of the salt form of a resin in an unbuffered medium can be discussed only arbitrarily, with the realisation that actually it is determined by the proportion of sulpho-groups present in the hydrogen form.

The changes in other physicochemical properties (density, swelling, moisture capacity, etc.) which occur when the salt forms of sulphonated cation-exchange resins are heated in water are essentially the same as those observed with the hydrogen form[87,88].

Published assessments of the stability of sulphonated cation-exchange resins in alkaline and acidic media are contradictory. The suggested[148] low resistance of sulphophenol–formaldehyde exchangers to the action of alkalis is partly confirmed by experiment. Thus the exchange capacity of Wofatit P is diminished by prolonged (> 40

min) boiling with 0.1–1.0 *N* potassium hydroxide solutions, but is unaffected by shorter treatment[140]. Another phenolsulphonic exchanger, Dowex 30, loses its exchange capacity when heated in 1 *N* caustic soda above 100°C, but the observed losses are nevertheless smaller than with the hydrogen form of the exchanger under the same conditions. At high pH-values the polymer structure breaks down with separation of an organic compound even at moderate temperatures. Nevertheless, according to Lindsay et al.[178] the properties of the addition polymer Dowex-50 are unaffected by brief heating in solutions of pH 10.5 and in 1 *N* caustic soda up to 168°C. In weakly alkaline media sulphophenol–formaldehyde cation exchangers[191] and the condensation polymers KU-5 and KU-6 are completely stable both in the cold and on heating[78,192]. The decrease in exchange capacity observed in some cases when phenol–formaldehyde cation exchangers are heated in alkaline media[140,148] is probably due, not to hydrolytic elimination of sulpho-groups, but to degradation of the macromolecule and separation of sulphonates of low molecular weight.

Heating in dilute non-oxidising acids also produces larger losses in capacity of sulphonated phenol–formaldehyde resins than of polystyrene resins. A monograph[193] mentioned the possibility of using sulphonated polystyrene cation exchangers in acid media at temperatures up to 120°C. Other results[139] indicate breakdown of sulphonated phenol–formaldehyde resins on prolonged boiling in dilute hydrochloric and sulphuric acid, but no definite conclusions can be drawn owing to the absence of a comparison between the action of these media and that of water. The loss in capacity of KU-1 at 100°C has been found[194] to diminish with increase in the concentration of sulphuric acid, being 92%, 72%, and 48% after 6 h in the 0.1 *N*, 0.5 *N*, and 1.0 *N* acid respectively. This was explained[194] by suppression of hydrolysis of the sulpho-groups in sulphuric-acid media, but this contradicts other conclusions[147].

Homogeneous sulphonated cation-exchange resin membranes based on polyethylene[195] are not very stable in alkaline media. After being kept in 10 *N* potassium hydroxide solution at room temperature their electrical resistance has fallen from 0.51 to 0.26 ohm cm^2.

Membranes based on fluorinated polymers are probably the most promising with regard to thermal stability and chemical resistance. According to Chapiro and Seidler[171] graft membranes based on tetrafluoroethylene and acrylic acid are stable at room temperature in 6 *N* caustic potash, water, and concentrated solutions of hydrochloric acid, sulphuric acid, and potassium carbonate, but undergo decarboxylation and dehydration with conversion of the carboxyls into anhydrides when heated to 200°C. The polytetrafluoroethylene matrix remains unchanged for 140 h at 200°C.

According to Munari and his coworkers[196,197], sulphonated cation-exchange membranes based on styrene grafted to tetrafluoroethylene can function for a long time in water at 180°C (in the hydrogen form) and at 280°C (in the salt forms), but in concentrated solutions of sodium hydroxide, sulphuric, hydrochloric, and nitric acids, and a mixture of hydrochloric and nitric acids at temperatures above 100°C. Unfortunately, these conclusions were not supported by experimental results.

In oxidising acids the hydrolytic elimination of sulpho-groups is accompanied by degradation and oxidation of the matrix. Thus the addition of potassium chromate to dilute sulphuric acid greatly diminishes the stability of the cation exchanger KU-1 owing to simultaneous desulphonation and redox processes[194]. Kazantsev et al.[198,199] showed by means of infrared spectroscopy that the desulphonation of KU-1 in dilute nitric acid is accompanied by the entry of nitro- and carboxy-groups into the aromatic rings of the matrix. Losses of capacity by KU-1 in 3 *N* nitric acid are enormous even in the cold, reaching 50% after 24 h. Under the same conditions KU-2 loses up to 25% of its capacity. The exchanger SDV-3 is completely desulphonated after being heated in the presence of 1 *N* nitric acid at 90°C for 30 days. Investigation by several independent methods of the behaviour of KU-2 at 20° and 80°C in solutions of potassium bromate and dichromate, hydrogen peroxide, and nitric acid indicated[200] fundamental structural changes in the resin and the occurrence of a variety of reactions.

A study[201] of the stability of the sulphonated cation-exchange resins KU-2, KU-2 × 8chs, KU-2P, and KU-22 in 6 *N* sodium hydroxide solution and in 3 *N* nitric acid at 75°C indicated that KU-2 was the most stable with respect to change in weight. However, variation in weight cannot be regarded as an unambiguous criterion of the stability of exchangers. In nitric acid the exchange capacity of the resins even increases. Atroshchenko et al.[202] observed no changes in capacity or signs of breakdown of the macromolecule when KU-2 was regenerated in the cold with 13–26% nitric acid. However, the exchanger broke down with the evolution of oxides of nitrogen when boiled in 40% nitric acid for 2 h. The working exchange capacity of a filter bed of this resin was 5% less than that of a layer which had been subjected to 16 cycles of treatment with 15% nitric acid in the cold and to 19 cycles with 40% nitric acid. After this the capacity of the resin remained unchanged during normal operation[202].

Cation exchangers containing sulpho-groups in the side-chain (Wofatit P, Stacionit F) are more stable in solutions of various oxidising agents (hydrogen peroxide, potassium permanganate, chromic acid) than are resins having sulpho-groups in the ring (KU-1G)[149]. In our opinion the statement that Wofatit P is more stable than the sulphonated polystyrene cation-exchange resin in permanganic acid and hydrogen peroxide containing iron(III) salts[149] requires verification. Additions of tervalent iron and other ions which accelerate the decomposition of hydrogen peroxide greatly intensify the breakdown of the sulphonated polystyrene cation exchanger Permutit Q in 50% hydrogen peroxide at 60°C, with rupture of cross-links and ultimately complete dissolution of the resin[203]. These processes most probably involve the intermediate formation of hydroperoxides, which are converted into sulphonic acids of low molecular weight. According to Wiley and Reich[204] the stability of sulphonated copolymers of styrene with 8% of divinylbenzene in 3% hydrogen peroxide in the presence of iron(II) sulphate at 75°C is strongly dependent on the purity of the monomers and the nature of the divinylbenzene isomer. The rate of desulphonation is highest with the technical cation exchanger Dowex-50 × 8, and decreases in the series of resins containing *p*-divinylbenzene, technical divinylbenzene, and *m*-divinylbenzene. Complete breakdown of the exchangers is observed after 270–300 min.

Raising the temperature accelerates the changes in capacity, density, and especially swelling of the exchanger KU-2 on treatment with oxidising agents[205]. Correct procedures were used in this work[205] to prove the formation of carboxylic, ketonic, and alcoholic groups when the oxidants attacked C–H bonds in methylene groups and at tertiary carbon atoms. Mixtures of nitric acid with potassium bromate and with potassium dichromate possessed greater oxidising power than these oxidants alone,

hydrogen peroxide, or ammonium peroxodisulphate[205]. The sulphonated cation exchanger and membranes based on $\alpha\beta\beta$-trifluorostyrene[206] show no change in properties when heated with 3% hydrogen peroxide in the presence of Fe^{3+} ions at 70°C for 24 h. Under these conditions the loss in weight of a phenol–formaldehyde exchanger is 97%, and those of sulphonated styrene–divinylbenzene cation exchangers containing 1%, 2%, 4%, 8%, and 12% of divinylbenzene are respectively 62%, 46%, 26%, 11%, and 6%. The great stability of the new exchanger towards oxidants was explained[206] by the greater strength of the C–F bond than of the C–H bonds (103 and 77 kcal $mole^{-1}$).

Many authors assign great importance to elementary oxygen as a sensitiser of the aging of resins[58,84,140,207] by the rupture of cross-links. Industrial establishments, therefore, undertake the deaeration of water or add reducing agents (e.g. sodium sulphite), in this way increasing the useful life of the exchangers to many years[207]. It must be remarked, however, that the important question of the role of oxygen in determining the thermal stability of ion-exchange resins has not yet found due recognition in laboratory investigations, and needs to be studied systematically.

Very little study has been made of the stability of phosphoric-acid cation exchangers towards thermal hydrolysis[208,209]. Published information enables only a few general conclusions to be drawn: with the same structure of hydrocarbon network in the macromolecule the phosphoric-acid exchangers (KF-1, KF-11,[209] and SF [208]) are more stable than the sulphonated exchangers (KU-2), but the stability also falls with increase in the divinylbenzene content. The difference in behaviour between salt forms and the hydrogen form is far smaller than with the sulphonated exchangers[208]. In contrast to the latter, porous specimens of phosphoric-acid resins possess lower thermal stability than the gel-like resins[209]. Changes in exchange capacity after heating in water are larger at the less thermostable strongly acidic groups than at the weakly acidic groups[209]. However, this interpretation cannot be accepted, since the exchangers investigated contained $-PO(OH)_2$ groups, which dissociate in two stages. In our opinion the observed effects are more plausibly explained by variation in the proton-donor power of the active groups resulting from heat-treatment of the exchangers.

5. THERMAL STABILITY OF SULPHONATED CATION-EXCHANGE RESINS IN ORGANIC MEDIA

The use of sulphonated cation-exchange resins as catalysts in various organic syntheses[35] stimulated interest in the study of their behaviour in organic media. Before the appearance of experimental results it seemed to many authors[210,211] that such exchangers should exhibit great thermal stability in organic media. Thus Astle[211] was sure that they could be used in organic media up to 180°C, but expected rapid breakdown under more severe conditions. Saldadze et al.[210] consider that they can be used in hydrocarbon media at 150–170°C.

However, the very first experimental results showed that assumptions of great thermal stability were too optimistic. Thus Andreas[212] used a sulphonated phenol–formaldehyde exchanger as catalyst for the esterification of acetic acid by ethanol and by butanol, and of adipic acid by methanol, and found that the resin was not wholly stable to heating above 120°C. He observed that Wofatit P decomposed with the evolution of sulphur dioxide and formaldehyde at temperatures above 180°C. Losev and Trostyanskaya[213], who used the exchangers MSF and SBS as catalysts for the preparation of butyl butyrate, found that the catalytic activity and the acidity (a measure of exchange capacity) of both resins fell rapidly with increased number of cycles. In view of the poor stability of the exchangers, these workers[213] recommend that they should not be employed above 120°C.

According to Menyailo et al.[214] the exchangers KU-2 and SBS show poor stability when used to catalyse the hydration of propene at 160–170°C. Naumann[152] found the polycondensation exchangers Wofatits P and F to be inferior in stability to the polyaddition resin Wofatit KRS-200. Solubility data indicate that all the resins are more stable in non-polar than in polar solvents.

Systematic investigation of the behaviour of sulphonated cation-exchange resins in various organic media was begun by the present Reviewers[42,47,112,215–217].

The relative losses of exchange capacity found by titrating the resin and the aqueous extracts (R_k and R_a), which are compared in Table 4, indicate that KU-1 is less stable than KU-2 in hydrocarbon media, as when heated in water and in air. The losses in exchange capacity by KU-1 are almost the same in hydrocarbons and in air[215,217]. The thermal stability of KU-2 resin, on the other hand, is lower in hydrocarbon media[42,216,217]. At 100°C, however, the effects of different media even out[42,215].

Table 4. Relative losses in capacity (%) of cation-exchange resins after being heated in various media.

The diminished stability of KU-2 in alkenes[42,216,217] is explained by a weakening of the R–SO_3H bond as a consequence of the formation of a carbonium ion from the alkene and the hydrogen ion of the sulpho-group[215], and also by redox reactions the products of which (H_2O) either take part in or promote thermal hydrolysis. Formation of carbonium ions and redox interaction are less marked with saturated than with unsaturated hydrocarbons, and therefore KU-2 resin is more stable in the former. However, KU-2 is less stable in isopentane[42,216] and benzene[217] than in straight-chain alkanes and in air. Benzene and alkanes containing a tertiary carbon atom probably form π-complexes and carbonium ions with the gegenions of the active groups[218]; they undergo redox interaction with sulphuric acid.

The lack of effect of the medium on the thermal stability of the exchanger KU-1, like the low rate of polymerisation of alkenes in its presence, is explained[215] by steric hindrance to the formation of carbonium ions. It is interesting that the catalytic activity of KU-1 in the polymerisation of alkenes is enhanced by grinding or by pretreatment with methanol in a Soxhlet extractor[219]. However, the activation of the exchanger is only temporary, and disappears after heating at 150°C for a short time[219].

Comparison of the values of R_k and R_a (Table 4) shows that the nature of the medium affects the course of the redox reactions. Identical values of R_a and R_k indicate the transfer of sulpho-groups to degradation products as sulphuric acid owing to hydrolysis (1) involving the residual water in the exchanger. With rise in temperature and increase in duration of heating, sulphuric acid accumulates in the reaction products until it reaches a concentration at which redox reactions involving molecules of the resin and of the medium can occur. The reducing properties are, of course, more pronounced for alkenes than with alkanes[42,216,217]. Reducing activity increases in the series of resins—KU-2, KU-1, SBS.[220]

An empirical linear relation[42] $\lg E = f(\lg \tau)$ describes the kinetics of the variation in the exchange capacity of KU-2 in air, isopentane, and isopentenes, as in water. The slope of the straight line serves as a qualitative indication of the effect of the medium on the rate of desulphonation. The temperature dependence of the loss of capacity in KU-2 obeys the Arrhenius equation[217].

The breaks between the linear portions of the $\lg E - \lg \tau$ graphs probably indicate acceleration of hydrolysis of the sulpho-groups in the exchangers by the redox reaction (2) and its products. The correctness of such an interpretation is supported by the agreement between the abscissa for the break and the start of the redox reactions[42].

The rate of desulphonation is unaffected by the grain-size of the exchanger KU-2, contamination with traces of sulphonic acids of low molecular weight, or the relative proportion of resin and isopentenes[47]. This confirms the fact established previously, that the desulphonation of cation-exchange resins is controlled by an actual chemical reaction (hydrolysis) occurring throughout the resin[146,147].

Increasing the divinylbenzene content from 3% to 7% does not affect the thermal stability of the cation exchanger KU-2, but further increase in the degree of cross-linking (to 17% of divinylbenzene) is accompanied by a decrease in thermal stability. It is interesting that the ratio of the losses in capacity by a strongly and by a weakly cross-linked specimen of the exchanger decreases with rise in temperature and increase in duration of heating. Thus when resins containing 17% and 7% of divinylbenzene are heat-treated for 10, 24, and 48 h the ratio $R_k^{(17)}/R_k^{(7)}$ is respectively 1.94, 1.52, and 0.91.[47] Similar relations have been established in the heat-treatment in water of KU-2 containing 24% and 12% of divinylbenzene[43] for which the ratio of the losses in capacity $R_k^{(24)}/R_k^{(12)}$ after heating at 150°C for 6, 24, and 120 h is respectively 1.94, 1.69, and 1.25. This levelling of the rate of elimination of sulpho-groups from specimens having different contents of divinylbenzene was explained[47] by an equalisation of the electrostatic interaction between functional groups. However, such an explanation is equivocal. An alternative view relates the change in thermal stability to the existence of energetically non-equivalent sulpho-groups, the number of which should increase with increase in the degree of cross-linking in the resin. When the resin is heated in any medium, weakly bound sulpho-groups (e.g. those occupying the *ortho*-position in styrene-2,4-disulphonic acid) should be the first to split off; but when equivalent sulpho-groups remain (occupying the *para*-position), the effect of the degree of cross-linking should level out.

A comparative study of the behaviour of various cation exchangers when heated in air and in isopentenes showed that, as in aqueous media, the thermal stability increased in the sequence KU-1G < KU-1 < SBS < KU-2[146,220]. Addition polymers in the above series are more stable when heated than are polycondensation exchangers. Experiments with KU-1 and KU-2 revealed that polymerisation of the alkenes inevitably led to acceleration of the loss of exchange capacity. Different results were obtained with the resins SBS and KU-1G: the polymerisation of isopentenes is catalysed by SBS, although its thermal stability is the same in air and in isopentenes; yet KU-1G is almost without catalytic effect on this reaction, although its thermal stability in isopentenes is less than in air. This anomaly has not yet been explained satisfactorily, and requires further study.

A detailed chemical, potentiometric, and spectrophotometric (infrared) investigation of the cation exchanger KU-2 established[112] that, under all conditions of heat-treatment in air up to 200°C, all the sulphur is present in sulpho-groups. When KU-2 is heated in isopentane, a small portion of the sulphur passes into an "inactive" state. A considerably larger quantity of "inactive" sulphur is present after the resin has been heated in isopentenes. Successive treatment of the resin with alkali and acid converts part of the "inactive" sulphur into a state which is active with respect to ion exchange, and is included in the determination of sulpho-groups. This "inactive" sulphur is assumed[112] to be present as *S*-esters of thiosulpho-groups $R.SO_2.SR'$, where R and R′ are organic radicals of the resin and of a thiol. The infrared spectra show that severe heat-treatment of KU-2 in air and in isopentane can cause sulpho-groups to migrate from the *para*- to the *meta*-position, and polyphenyl bonds may be formed, with a decrease in the equivalent moisture capacity[112].

Table 5. Effect of content of water in KU-2 resin on its thermal stability at 150°C.[216]

* Exchanger dehydrated at 150°C
** At 110°C.

Bound water is involved in the hydrolysis of sulphonated cation exchangers, and has a great influence on the occurrence of reactions (1) and (2)[216] (Table 5). With increased water content the relative loss in capacity passes through a maximum, whose position and height depend on the nature of the medium. In air the maximum losses of capacity occur in a resin containing 24% of water.

The increase in the rate of hydrolysis of sulpho-groups as the water content of the resin increases to 24% is probably due, not only to the autocatalytic action of the sulphuric acid[216], but also to the easier transport of H_3O^+ ions to the hydrolysable C–S bond. Further increase in the water content of the resin inevitably dilutes the sulphuric acid in the exchanger phase and diminishes its catalytic activity.

In contact with isopentenes the losses in capacity are largest with a specimen of the resin which has been dehydrated at 110°C. Developing the earlier views[216] we must suggest that direct reduction of sulpho-groups by the alkenes with the formation of sulphur-containing compounds is probable, as is redox interaction between sulphuric acid and reducing groups in the resin or the medium. According to Table 5 use of a resin which has been dehydrated at 150°C is most favourable for the occurrence of such processes.

If the choice of catalyst for organic synthesis is guided solely by considerations of thermal stability, well dehydrated exchangers are to be preferred. However, the removal of water may hinder dissociation of the active groups, and thereby have an adverse effect on the catalytic activity of the exchanger. The resin KU-2 in a state of limiting swelling at 150°C catalyses the isomerisation of 3-methylbut-1-ene into 2-methylbut-2-ene and 2-methylbut-1-ene[121], the hydration of isopentenes to t-pentyl alcohol, and the polymerisation of alkenes[216]. In the presence of an exchanger containing up to 24% of water no hydration of isopentenes occurs, only polymerisation. The inability of hydrate water in KU-2 of moisture content 24.2% (or 3.5 mmoles H_2O mg-equiv.$^{-1}$ sulpho-groups) to effect hydration is probably due to its very strong bonding to the sulpho-groups. This is supported by data[222] indicating that absorption of the first three molecules of water on each sulpho-group in the resin is accompanied by a large heat release. The exchanger KU-2 which has been dehydrated at 110°C exhibits the maximum catalytic activity for the polymerisation of isopentenes: further dehydration at 150° and 175°C lowers the activity[216].

The infrared spectra show that catalysis yields sulphur-containing compounds and small amounts of aromatic compounds—degradation products of the polymeric matrix—as well as polymers. Chemical, potentiometric, and polarographic analyses have established the presence of elementary sulphur, thiols, and alkyl sulphides among the products of catalysis[112]. The difference between the total sulphur content found by elementary analysis and the aggregate quantity present as the above compounds was attributed to polysulphides and sulphoxides[112].

Sulphur dioxide and hydrogen sulphide were detected in the gas phase[125]. With experiments in isopentane and in air, the gas phase contained only sulphur dioxide, but the aqueous extracts contained both sulphuric and sulphurous acids[125].

The whole range of reactions which occur when the cation-exchange resin KU-2 is heated in hydrocarbons[112,146], discussed above, can be summarised as indicated below.

Resin Phase

The fall in the exchange capacity is governed by hydrolysis of sulpho-groups involving residual water (reaction 1). This is accompanied by redox interaction of the resulting sulphuric acid with reducing groups of the macromolecule (reaction 2). In media which undergo no chemical reactions, the changes undergone by cation exchangers are confined to these two reactions. In alkenes sulphones may be formed:

$$RSO_3H + C_5H_{10} = RSO_2{-}C_5H_9 + H_2O \qquad (9)$$

and also *S*-esters of thiosulphonic acids:

$$RSO_3H + C_5H_9SH = RSO_2{-}SC_5H_9 + H_2O. \qquad (10)$$

It is quite probable that sulphuric acid may take part in the formation of polyphenyl cross-links:

$$-CH_2-\underset{|}{CH}-C_6H_5 + -CH_2-\underset{|}{CH}-C_6H_5 + H_2SO_4 = 2H_2O + SO_2 + \\ + -CH_2\underset{|}{CH}-C_6H_4-\underset{\diagdown\,CH_2}{\overset{/}{C}}-C_6H_5 \,. \qquad (11)$$

Liquid Phase

The following changes are possible in the liquid phase.

1. Processes involving isopentenes and catalysed by hydrogen ions from the resin: (*a*) isomerisation of alkenes[112,221]

$$CH_3-\underset{|}{CH}-CH=CH_2 \xrightarrow{H^+} \begin{cases} \rightarrow CH_3-\overset{CH_3}{\overset{|}{C}}=CH-CH_3 \\ \rightarrow CH_2=\overset{CH_3}{\overset{|}{C}}-CH_2-CH_3 \end{cases} \qquad (12)$$

(*b*) polymerisation of isopentenes

$$n\,C_5H_{10} \xrightarrow{H^+} (C_5H_{10})_n \qquad (13)$$

(*c*) hydration of isopentenes

$$C_5H_{10} + H_2O \xrightarrow{H^+} C_5H_{11}OH \,. \qquad (14)$$

2. Reactions between alkenes and desulphonation products: (*a*) formation of sulphonates

$$C_5H_{10} + H_2SO_4 \rightarrow C_5H_{11}{-}OSO_3H \qquad (15)$$

$$2\,C_5H_{10} + H_2SO_4 \rightarrow C_5H_{11}{-}OSO_2O{-}C_5H_{11} + 2\,H_2O \qquad (16)$$

(*b*) formation of sulphoxides[223]

$$2\,C_5H_{10} + SO_2 \rightarrow C_5H_9{-}SO{-}C_5H_9 + H_2O \qquad (17)$$

(*c*) formation of thiols

$$C_5H_{10} + H_2S \rightarrow C_5H_{11}SH \qquad (18)$$

(*d*) formation of polysulphides

$$x\,C_5H_{10} + y\,S \rightarrow (C_5H_{10})_xS_y \,. \qquad (19)$$

The sulphur consumed in reaction (19) has been formed by the interaction of sulphur dioxide and hydrogen sulphide: $2H_2S + SO_2 \rightarrow 3S + 2H_2O$.

3. Reactions of derivatives of alkenes: (*a*) disproportionation of sulphoxides into sulphones and sulphides

$$2\,C_5H_9{-}SO{-}C_5H_9 \xrightarrow{H^+} C_5H_9{-}S{-}C_5H_9 + C_5H_9{-}SO_2{-}C_5H_9 \qquad (20)$$

(*b*) formation of aldehydes and thiols from sulphoxides

$$C_5H_9{-}SO{-}C_5H_9 \xrightarrow{H_2O} C_5H_9SH + C_4H_7C\overset{O}{\diagdown\!\!\diagup H} \qquad (21)$$

(*c*) formation of dialkyl disulphides in the presence of atmospheric oxygen

$$4\,C_5H_9SH + O_2 \rightarrow 2\,C_5H_9{-}S{-}S{-}C_5H_9 + 2\,H_2O \qquad (22)$$

(*d*) reaction between dialkyl disulphides and water

$$C_5H_9{-}S{-}S{-}C_5H_9 + H_2O \rightarrow C_5H_9SH + C_4H_7C\overset{O}{\diagdown\!\!\diagup H} + H_2S \qquad (23)$$

(*e*) formation of sulphides

$$C_5H_{11}SH + C_5H_{10} \rightarrow C_5H_{11}{-}S{-}C_5H_{11} \,. \qquad (24)$$

This whole complicated system of changes, including catalytic reactions, has a decisive effect on the thermal stability of the cation exchanger KU-2 in tertiary pentenes and determines the composition of the products.

The existence of a connection between the thermal stability of cation exchangers and catalytic reactions of the medium is confirmed by analogous investigations of resins in alcohols[217,224], phenol[225], and acetone[225]. Table 6 shows that the thermal stability of the cation exchangers KU-1 and KU-2 depends on the nature of the alcohol. Losses in capacity by KU-2 increase, whereas those of KU-1 decrease, as the alcohol molecules become larger. At 150°C the exchanger KU-1 is almost completely desulphonated after 24 h. At 125°C losses in capacity by KU-1 are almost the same in ethanol, n-pentanol, and isopentanol, but considerably greater than in t-pentyl alcohol or decanol. At 100°C the effect of the nature of the alcohol on the thermal stability of KU-1 levels off, and the losses in capacity after 24 and 120 h in ethanol are 16.6% and 36%, compared with 12.2% and 38.8% in decanol[224].

Table 6. Thermal stability of sulphonated cation-exchange resins in alcohols[217,224].

Temp., °C	Duration, h	Loss in capacity of resin, %									
		ethanol		n-pentanol		isopentanol		t-pentyl alcohol		decanol	
		R_k	R_a	R_k	R_a	R_k	R_a	R_k	R_a	R_k	R_a
KU-1 cation exchanger											
125	24	55.2	22.5	62.2	18.7	59.3	15.3	43.1	38.8	26.8	22.5
150	24	92.9	73.5	100	80.4	96.5	69.5	96.1	70.0	39.2	20.0
KU-2 cation exchanger											
150	10	3.0	2.6	7.1	5.5	3.6	5.0	7.4	6.6	10.0	4.8
	24	7.0	5.8	12.0	12.0	9.4	8.6	12.4	11.4	15.6	6.2
	48	8.2	6.8	15.2	11.6	17.2	13.2	14.4	12.2	18.5	1.6

The discrepancy observed between R_k and R_a cannot be explained by redox reactions of type (2), since alcohols are dehydrated to ethers and alkenes

$$2\,C_5H_{11}OH \xrightarrow{H^+} C_5H_{11}OC_5H_{11} + H_2O \quad (25)$$

$$C_5H_{11}O{-}C_5H_{11} \xrightarrow{H^+} 2\,C_5H_{10} + H_2O \quad (26)$$

in the presence of sulphonated cation exchangers[35], and the water that is formed dilutes the sulphuric acid, whose redox potential is lowered. Since no sulphur-containing compounds were present in the gas phase, the discrepancy was explained by the assumed formation of esters of the alcohols with sulphuric acid and with sulpho-groups of the resin[217,224]

$$C_5H_{11}OH + H_2SO_4 \xrightarrow{H^+} C_5H_{11}{-}O{-}SO_3H + H_2O \quad (27)$$

$$C_5H_{11}OH + RSO_3H \rightarrow RSO_2O{-}C_5H_{11} + H_2O\,. \quad (28)$$

As the alcohol molecules become larger, the relative solvation of the KU-2 falls, and the corresponding increase in concentration of active groups accelerates esterification[224]. These factors tend to accelerate the thermal hydrolysis of cation exchangers in alcohols in comparison with the rate of this process in water[224].

Examination of the thermal stability of KU-2 in phenol and in acetone[225] reveals an apparent breakdown in the usual type of relation between catalytic reactions of the medium and the stability of cation-exchange resins. In the presence of KU-2 phenol does not undergo any chemical change other than oxidation by air. Acetone gives various condensation products and water even in the cold. It would appear that KU-2 should be less thermostable in acetone than in phenol. However, experiment indicates that the thermal stability of the resin decreases on passing from acetone to its mixtures with phenol and to phenol itself[225]. This "anomaly" is explained by formation of a large quantity of water on the condensation of acetone; this water is sorbed by the resin and tends to increase its thermal stability[216].

The condensation products of acetone accumulate in the "pores" of the exchanger, shield the sulpho-groups, and may lead to a loss of catalytic activity by the resin even in the absence of thermal hydrolysis. The process of shielding must be distinguished from blocking of the sulpho-groups by their direct interaction with molecules of the medium to form such compounds as esters (with alcohols).

Thus the investigations give an idea of the specific character of the processes occurring in exchanger macromolecules in organic media. First, a correlation between thermal stability and catalytic activity is clearly revealed in cation exchangers. Secondly, the thermal hydrolysis of cation exchangers in organic media is not the only cause of the diminution in exchange capacity, for its competes with blocking and screening of the ion-exchange groups. Thirdly, the relative loss of capacity in organic media is determined by the composition and the properties of the reaction system as a whole (including reaction products), not only by the added liquid reagent. Unfortunately, the question of the effect on thermal stability of the distribution of components between liquid phase and resin has not yet been raised.

---o0o---

Experimental results which have accumulated show that the main reason for the decrease in exchange capacity of ion-exchange materials when heated and subjected to corrosive media is the detachment of functional groups, in most cases by hydrolysis. Among the numerous factors influencing the strength of bonding between active groups and the matrix, and therefore the thermal hydrolysis of the exchangers, the nature of the heat-treatment medium, the chemical structure of the exchanger macromolecule, and the nature of the functional group and its gegenion are especially important.

The medium in which the exchanger is heated affects the decrease in exchange capacity in four cases: (1) the medium or its reaction products interact with the functional groups; (2) the medium undergoes catalytic reactions involving the gegenion of the functional group (polymerisation of hydrocarbons, esterification of alcohols, condensation of ketones, etc.); (3) the molecules of the medium form unstable addition products, including π-complexes, with the functional groups; or (4) the "pores" of the resin grains are filled with reaction products of the medium that shield the functional groups (products of the condensation of acetone, the polymerisation of alkenes, etc.). Hence it follows that the necessity of considering the thermal stability and the catalytic activity of ion-exchange materials together with their reactions is dictated not only by the requirements of a right choice of catalysts but also by considerations of the causal relation between these properties in molecular terms.

Some interesting relations between the chemical structure and the thermal stability of the exchangers have been revealed. As in the lower sulphonic acids, the electron-donor phenolic hydroxyls in sulphonated phenol–formaldehyde cation exchangers facilitate electrophilic substitutions. Therefore all phenolsulphonic acids of high molecular weight undergo hydrolysis more easily than, and are inferior in thermal stability in the media investigated to, sulphonated cation exchangers having a polystyrene–divinylbenzene matrix. The cation exchanger SBS is inferior to KU-2 resin in thermal stability, perhaps because butadiene groups have a stronger polarising action than have divinylbenzene groups on the C–S bond. Increase in the degree of cross-linking of sulphonated polystyrene exchangers is accompanied by an increase in the rate of hydrolysis of the sulpho-groups. Thus variation in the chemical structure of the matrix may be an effective means for the planned synthesis of thermostable cation exchangers.

With matrices of the same structure the liability of cation exchangers to undergo thermal hydrolysis and other processes leading to a change in exchange capacity depends on the nature of the active group. This aspect needs to be studied thoroughly, but it can already be stated that sulphonated exchangers are less stable than resins containing phosphate and carboxylate groups. The hydrogen forms of the exchangers, like the ordinary oxy-acids, are less stable than the corresponding salts. On the other hand, it must be emphasised that very few investigations have been made on the thermal stability of the salt forms, despite their importance; this gap must be filled in the near future.

However, the main task in investigating the thermal and chemical stability of ion-exchange materials is, in our opinion, to study the elementary processes occurring in exchangers and leading to deterioration in their operational properties, and also to establish the kinetics of these processes. Progress in this field will undoubtedly contribute to the development of methods for the planned synthesis of ion-exchange materials having specified properties and satisfying the demands of modern science and technology.

---o0o---

While the manuscript has been awaiting publication, several papers have appeared which have deepened our knowledge of the thermal stability of cation-exchange resins. They include detailed thermographic investigations[226-228], and new generalisations on the thermo-oxidative degradation of carboxylated exchangers[229].

Individual papers[230,231] have raised the question of the useful life of cation-exchange resins as catalysts of organic reactions under industrial conditions at 130–150°C. Experience indicates[230] that, after use as an alkylation catalyst for 40–45 days, KU-2 loses its activity and cannot be regenerated. In our view the development of methods for the regeneration of cation exchangers requires the closest attention, and is urgently required for their practical employment in several catalytic reactions conducted at high temperatures.

The work of Paushkin and his pupils[232-235] on the preparation of thermostable cation exchangers containing a system of aromatic rings in the conjugated chain is worthy of special mention. However, a direct study of thermal stability in various media is required to assess the prospects for new cation exchangers.

Thorough Elimination of Acetylenic Hydrocarbon Impurities from Various Mixtures

G.P.Chernyuk

Acetylenic hydrocarbons are a very undesirable impurity in many instances of polymerisation, oxidation, and other syntheses. The problem of the elimination of acetylene derivatives from various mixtures has been investigated in fair detail: patent data are particularly numerous. This review is based on studies published up to 1970; an attempt has been made to give a systematic account of and to compare the advantages and disadvantages of various methods and procedures for the thorough elimination of the above impurities and certain physical properties of the principal components of the mixtures purified and analytical methods for the determination of the acetylenic hydrocarbon impurities have been examined.
The bibliography includes 383 references.

CONTENTS

I. Introduction 1047
II. Some physical properties of the main components of the mixtures purified 1047
III. Methods for the thorough elimination of acetylenic hydrocarbon impurities from various mixtures 1047
IV. Analytical methods for the determination of acetylenic hydrocarbon impurities in various mixtures 1053

I. INTRODUCTION

One of the particularly undesirable impurities, which are difficult to remove and which have a significant influence on the polymerisation of monomers and the quality of polymers[1-8], cause explosions in oxygen works[9], and inhibit the oxidation of organic compounds, are acetylenic hydrocarbons (AH). Therefore, the increase in the manufacture of large-scale products of the petrochemical industry such as ethylene, propene, isobutene, halogenoethylenes, isoprene, butadiene, and others, produced by the pyrolysis and dehydrogenation of hydrocarbon raw materials or synthesised from raw acetylene, must inevitably involve the development of effective processes whereby acetylenic hydrocarbons can be thoroughly removed. In particular the polymer industry imposes very vigorous requirements on the purity of the monomers. Thus ethylene and propene used in high-pressure polymerisation and vinyl chloride must not contain more than 0.0005 vol. % of acetylenic hydrocarbons[10-13] and their content in isoprene and butadiene should not exceed 0.0004 and 0.005 wt. % respectively[14]. In the future the requirements which will have to be met by methods for the elimination of acetylenic hydrocarbon impurities from industrial mixtures and by methods for the analytical control of technological processes will naturally become more stringent.

Many procedures have been described for the thorough elimination of acetylenic hydrocarbon impurities from hydrocarbon and non-hydrocarbon mixtures involving various methods. However, so far no review has been published on this practically important problem. In the present review the procedures and methods for the thorough elimination of acetylenic hydrocarbon impurities from various mixtures are described and critically assessed from the standpoint of their suitability in practice.

II. SOME PHYSICAL PROPERTIES OF THE MAIN COMPONENTS OF THE MIXTURES PURIFIED[15-25]

The Table lists certain physical properties of the main components of the mixtures purified and also mixtures of the acetylenic hydrocarbon impurities.

III. METHODS FOR THE THOROUGH ELIMINATION OF ACETYLENIC HYDROCARBON IMPURITIES FROM VARIOUS MIXTURES

The following methods are known for the removal of acetylenic hydrocarbon impurities from various gaseous and liquid mixtures: sorption, distillation, catalytic hydrogenation, catalytic oxidation, catalytic polymerisation, and certain others.

1. SORPTION

The sorption purification methods are based on the enhanced absorption capacity of certain sorbents—liquids, salt solutions, and solid porous materials—in relation to acetylenic hydrocarbons. Therefore three technological processes are usually employed for the purification:
(a) absorption by liquids; (b) adsorption by solids;
(c) chemical interaction between the acetylenic hydrocarbon and the sorbent, i.e. chemisorption.

a. Absorption by Liquids

Acetylenic hydrocarbons and in particular acetylene (A) are comparatively readily soluble in many organic solvents[26-28], in contrast to many other hydrocarbon and non-hydrocarbon compounds. This property of acetylenic

Some physical properties of the principal components of mixtures from which the acetylenic hydrocarbon impurity is removed.

hydrocarbons is used to extract them from a wide variety of complex systems in order to free them from this impurity.

A number of procedures have been developed and proposed for the removal of acetylene from coking gas[29-31], cracking gas[32-34], and gases involved in the partial oxidation[35] and high-temperature pyrolysis[36] of hydrocarbons, which contain it in an amount of 7—10 vol. %. Acetylacetone, methanol, kerosene, acetone, dimethylformamide (DMF), *N*-methylpyrrolidinone, ethyl methyl ketone, butyrolactone, and others are employed as selective solvents. The absorption process is usually carried out in several stages, mainly at temperatures between −30° and −70°C and pressures in the range 10—16 atm. The degree of extraction of acetylene is not more than 97—99%.

Many studies have been made on the develoment of a process for the preparation of ethylene free from the acetylene impurities using selective absorption of the latter. The majority of investigators[32-47] suggest that acetylene be selectively extracted from the crude ethylene or the C_2 fraction obtained from the coking and cracking gases or the gases from the pyrolysis of the hydrocarbon raw material. Acetylene is absorbed from the C_2 fraction by selective solvents at a temperature close to the liquefaction temperature of the mixture and at an elevated temperature. However, ethylene containing about $1-10^{-4}$ vol. % of acetylene, compared with its initial concentration in the mixture of 0.05—1.58 vol. %, could be obtained in only a few cases[43,44,46].

The method of selective absorption by organic solvents is used to eliminate acetylene from halogenated hydrocarbon mixtures. Thus treatment of vinyl chloride containing 0.18 vol. % of acetylene with methanol in a countercurrent absorber yields a product containing only 0.006 vol. % of acetylene[48]. Insignificant amounts of acetylene are removed from its chlorination products by passing the hydrocarbons mixed with a solvent (water, acetone, etc.) continuously through an injector or an ejector[49]. Dimethylformamide, dimethyl sulphoxide, *N*-methylpyrrolidinone or their mixtures have been proposed as selective solvents[50-54] for the separation of gaseous mixtures consisting of 67—85 vol. % of vinyl fluoride, 15—31.5 vol. % of acetylene, and admixtures of other hydrocarbons. However, the vinyl fluoride concentrate isolated contained about 0.8 vol. % of acetylene.

When isoprene containing 1.4 mole % of higher acetylene hydrocarbons is treated with an aqueous solution of dimethylformamide at 0°C, the amount of impurity diminishes only to 1.0 mole %.[55] In addition, many absorption procedures for the extraction of acetylene from various gases evolved in the processing of hydrocarbon raw materials with the aim of concentrating it have been described, but these will not be considered here.

b. Adsorption by Solids

The adsorption of acetylene on artificial zeolites of type 4A and 5A, activated charcoal of type KST, and silica gel of type MSM from gases produced in the oxidation of methane by air and oxygen at temperatures between −78° and +80°C has been investigated[56]. According to the results, zeolites show promise in the extraction of acetylene from gases produced by the incomplete oxidation of methane and in the thorough removal of acetylene from industrial gases, for example ethylene.

A process has been developed for the adsorption elimination of traces of acetylene from air in apparatus employing gaseous and liquid oxygen by means of zeolites of types NaA and CaA.[57-59] A high efficiency of purification is achieved at 20–70°C and when the acetylene content in the initial mixture is not more than 2.4 $cm^3\ m^{-3}$. When the average content of acetylene in air is 0.03 $cm^3\ m^{-3}$, one ton of type CaA zeolites purify without regeneration $9 \times 10^6\ m^3$ of air and operate for 300 h. However, CaA zeolites have a high regeneration temperature (350°C) and, when the concentration of acetylene in air is about 1 $cm^3\ m^{-3}$, their dynamic activity falls sharply. The adsorption properties of various ion-exchange forms of type A and X zeolites with various degrees of substitution of sodium by the cations of other metals have been investigated[60]. It has been found that the optimal form is a type X zeolite with a low degree of substitution of sodium by transition-metal cations. Together with a high adsorption capacity in relation to acetylene (15.8 cm^3 of acetylene per 100 cm^3 of zeolite), it has a low regeneration temperature (250° to 300°C). Other investigators[61] recommend KSM silica gel as an adsorbent for the same purpose. At temperatures between −100° and −160°C, it absorbs acetylene from the gas stream almost completely. KSM silica gel has been recognised as the best agent for the purification of the ethylene fraction obtained in the low-temperature separation of coking gas[62]. At a gas space velocity of 840 h^{-1} and a temperature of −100°C and below, it absorbs acetylene to the extent of 30–80% and its homologues to the extent of 80–95%. Treatment of liquid ethylene in an autoclave under a pressure of 19 atm at −30°C in the presence of an adsorbent comprising a mixture of alumina gel and silica gel[63] makes it possible to reduce the acetylene content in ethylene from 4.4×10^{-3} to 7×10^{-4}%.

The possibility of the employment of continuous adsorption for the removal of acetylene from vinyl chloride[64-66] and for the selective extraction of acetylene from gases produced by the incomplete oxidation of methane[67-71] has been investigated. When Hungarian activated charcoal with a specific surface of 996 $m^2\ g^{-1}$ was employed and the process was carried out at 20°C, a pressure of 1.5 atm, and a space velocity of about 200 h^{-1}, fractions virtually free from acetylene were obtained.

c. Chemisorption

In order to improve the efficiency and selectivity of the processes for the sorption extraction of acetylenic hydrocarbons from various mixtures, the chemisorption principle, i.e. chemical binding of acetylenic hydrocarbons by sorbents, which usually contain copper, silver, or mercury compounds, has been used in a number of cases.

Numerous studies have been made[72-86] on the selective elimination of acetylenic hydrocarbons from the C_4 fractions with a high content of diolefins, for example butadiene, before the extraction of the latter.

Acetylenic hydrocarbons are chemisorbed from such gaseous or liquid fractions by treatment with an aqueous ammonia solution of copper(I) acetate at temperatures between −10° and +10°C. The acetylenic hydrocarbons then form soluble complexes with copper and remain in solution. They are desorbed by heating the solution to 80–105°C, sometimes using a desorbing gas, for example ammonia[83]. On desorption, part of the artylenic hydrocarbons are polymerised; the high-molecular-weight compounds are separated by passing the solution through a layer of activated charcoal. The acetylenic hydrocarbon impurity (0.15–0.3 wt. %) can be extracted by this procedure only to the extent of 70–95%. It has been stated[80] that, under the purification conditions, butadiene is sorbed by the solution 150 times less effectively than acetylenic hydrocarbons. In order to remove small amounts of acetylenic hydrocarbons from gaseous mixtures, the hydrocarbons are chemisorbed by an ammoniacal solution of copper(I) chloride with formation of copper acetylide precipitates. In particular, the use of this solution for the thorough elimination of the acetylene impurity from vinyl fluoride[8,87] results in an acetylene content in the purified gas not greater than 4×10^{-5} vol. %. With this method of purification, the content of higher acetylenic hydrocarbons in alkenes diminishes from 0.3 to 0.001 wt. %.[88] Acetylenic hydrocarbons are removed from streams of ethylene and butadiene by passing them through a solution of copper(I) chloride in dimethyl sulphoxide[89]. It has been noted that the copper acetylides formed under these conditions are less explosive and more stable than those known hitherto. Thorough removal of acetylenic hydrocarbons from hydrocarbon fractions containing butadiene or isoprene is achieved by rapidly passing the gaseous mixtures at 50° to 100°C through a suspension of metallic sodium in xylene[90-92]. The acetylenic hydrocarbons are then completely extracted: acetylene is bound as the acetylide and the higher acetylenic hydrocarbons are polymerised.

Procedures have been described[93-95] for the removal of acetylene from gaseous mixtures containing it in amounts of 14–29 vol. % by passing them through a suspension of VB or VIB metal halides or complexes in aliphatic or naphthene hydrocarbons. The degree of extraction of acetylene is 76–96%. A method for the elimination of acetylene from crude ethylene by treating a stream of ethylene with an aqueous solution of a mercury(II) salt in the presence of oxygen and iron(III) ions has been patented[96]. Such treatment for 1 h results in a decrease of the concentration of acetylene in ethylene from 0.67 to 0.003 vol. %.

Chemisorption by solids is used to eliminate acetylenic hydrocarbons from gas streams, for example from ethylene. Zeolites based on silver[97] and also silver halides and copper(I) and mercury(I) halides or oxides dispersed on porous carriers (alumina gel, silica gel, etc.) have been proposed as sorbents[98,99]. A high efficiency of purification is achieved only when the amount of the acetylenic hydrocarbon impurity in the streams undergoing purification is very low. For example, when the process is carried out using a type X zeolite containing about 35 wt. % of silver at 65°C and a space velocity of 18 000 h^{-1}, ethylene containing 2×10^{-5} vol. % of acetylene is obtained when the initial acetylene concentration is 6×10^{-4} vol. %.

The sorption methods for the removal of acetylenic hydrocarbon impurities are frequently employed on a semi-industrial or industrial scale[32,34,36-39,41,42,57-61,67-71,73,86]. However, in most cases[32,34,44,53,62,63,77,83,84] they do not reduce the acetylenic hydrocarbon content in the mixtures purified to the required limit. For many hydrocarbon systems the selectivity of the sorption method is low, as a result of which a considerable amount of the main products (up to 10%) is lost together with the acetylenic hydrocarbons removed. The industrial employment of the chemisorption procedures involves serious difficulties. The process becomes explosive, since explosive copper acetylides are always formed[100]. The spent solutions are not satisfactorily regenerated[101], which leads to a non-productive consumption of copper salts. Therefore the chemisorption method is largely used in analytical chemistry for the detection and quantitative determination of very low

concentrations of acetylenic hydrocarbons, in particular acetylene, in gaseous mixtures[102-120]. Moreover, the sorption procedures for the removal of acetylenic hydrocarbons involve a considerable consumption of reagents, are complicated, and laborious. Nevertheless, in large-scale manufactures, the absorption of acetylenic hydrocarbons by selective solvents at a low temperature under high pressure is an effective method for the preliminary separation of comparatively large amounts of acetylenic hydrocarbons present in various hydrocarbon systems. The subsequent additional thorough elimination of small amounts of acetylenic hydrocarbons can be achieved by other methods.

2. DISTILLATION

The distillation methods are most suitable for the separation of complex hydrocarbon mixtures into individual fractions in terms of the number of carbon atoms. The isolation of individual components from these fractions and even more so the removal of acetylenic hydrocarbons with the same number of carbon atoms involve considerable difficulties and require clear-cut fractionation. Nevertheless the method of low-temperature fractionation is used in some cases to remove acetylenic hydrocarbon impurities from hydrocarbon mixtures.

Procedures have been proposed for the preparation of pure vinyl chloride by fractionating the acetylene hydrochlorination products[121-123] or the products of the interaction of acetylene with 1,2-dichloroethane[124]. The yield of vinyl chloride containing 0.005 mole % and less of acetylene amounted to about 90% on a column equivalent to 30 theoretical plates (t.p.) with a reflux number of 10.

The possibility of the preparation of specially pure vinyl chloride by a fractionation method has been investigated and it has been shown[125] that, in a column with the same efficiency as above but with a reflux number of 23, it is possible to isolate about 90% of vinyl chloride containing less than 0.001 mole % of acetylene and other impurities, except methylacetylene. The removal of the latter requires a column equivalent to more than 60 theoretical plates. Other investigators[126] obtained by this method vinyl chloride containing 5.5×10^{-7} mole % of acetylene.

When the boiling point of the acetylenic hydrocarbons and the main substances are very close, for example in the case of diolefins and higher acetylenic hydrocarbons or vinyl fluoride and acetylene, the usual fractionation method is relatively ineffective and leads to the loss of considerable amounts of the products purified. In such cases extractive[127,128] or azeotropic fractionation[129-133] is employed. A gaseous mixture comprising vinyl fluoride and 1,1-difluoroethane is freed from the acetylene impurity by azeotropic fractionation with ethane, which forms with acetylene an azeotrope boiling at −94.5°C. The product specimens obtained contained 1–5 vol. % of ethane and 0–2 vol. % of acetylene[129,130]. Azeotropic fractionation of mixtures containing butadiene with an admixture of isobutane[131,132] resulted in a decrease of the concentration of vinylacetylene from 0.49 to 0.08 wt. %.[122] It has been suggested that rectified isoprene be freed from the acetylenic hydrocarbon impurity by azeotropic fractionation in the presence of isopentane and maleic anhydride[133]. Columns equivalent to 60–90 theoretical plates are normally employed. With a reflux number of 50, the acetylenic hydrocarbon content in the mixture becomes only several times smaller.

The distillation methods for the removal of acetylenic hydrocarbons are widely used in the industrial manufacture of vinyl chloride and butadiene. The purification processes are carried out on high-efficiency columns with high reflux numbers. Nevertheless they do not ensure a high degree of purification[134] and result in a loss of up to 10% of the desired product even when the difference between the boiling points of the components is considerable[123,125]. A clear-cut low-temperature fractionation is restricted by the risk of explosion of acetylenic hydrocarbons in the liquid and solid states and in the gaseous state under pressure. The extractive and azeotropic fractionation procedures somewhat alleviate the above difficulties but here too the desired products are frequently contaminated by additional impurities[129,130]. Therefore the distillation method can be employed successfully for the preliminary elimination of acetylenic hydrocarbons in the purification of various products with subsequent additional fine purification by more effective methods, for example by hydrogenation[135].

3. CATALYTIC HYDROGENATION

The first studies on the selective hydrogenation of acetylenic hydrocarbons in the presence of olefins were carried out in the USSR.[136,137] It proved possible to reduce even very small amounts of acetylenic hydrocarbons to ethylenic derivatives in the presence of a large excess of the latter. It was shown that the process selectivity depends on the catalysts employed and the hydrogenation conditions.

Palladium dispersed on various carriers (alumina gel, silica gel, activated charcoal, glass, etc.) is widely used as a catalyst for the removal by selective hydrogenation of the admixture of acetylenic hydrocarbons from concentrated olefinic fractions (C_2 and C_3),[11,138-157] butadiene[158-161], coking gas[162-166], and vinyl fluoride[167]. The hydrogenation is usually carried out in the gas phase at 100–320°C, 5–50 atm, and a space velocity up to 20 000 h^{-1} using catalysts containing 0.001–0.1 wt. % Pd. In many cases[143,148,160,166] the amount of acetylenic hydrocarbons in the streams undergoing purification diminishes from 0.8 to $(1-5) \times 10^{-4}$ vol. %. In order to enhance the initial selectivity, the catalyst is first treated with hydrogen at a working pressure and a temperature higher by 30 deg than the working temperature[168,169]. Frequently, in order to ensure a high selectivity of the catalyst in the hydrogenation of acetylenic hydrocarbons, it is promoted with copper, silver, iron[170-175], chromium[176,177], lithium[161,178], ruthenium, and rhodium[179,180], the process is carried out in the presence of water vapour[181], and the mixture undergoing purification is inhibited with alkyl sulphides[182], halogeno-derivatives of aromatic hydrocarbons[183], or cyclohexane derivatives[184].

Catalysts containing platinum are used to eliminate acetylene from ethylene mixtures[185] and coking[186,187] and other industrial gases[188] at an elevated temperature and pressure. The concentration of acetylene in the purified streams is 2×10^{-4} vol. % and less. Methods have been patented in which concentrated C_2 and C_3 fractions are freed from acetylenic hydrocarbons by liquid-phase hydrogenation between −40° and +50°C and at pressures between 12 and 36 atm on palladium, platinum, or mixed nickel–thorium catalysts[189-191]. The content of acetylenic hydrocarbons then falls from 0.7 to 0.002%.

Apart from platinum subgroup metals, other metals and their compounds are also employed as catalysts for the

selective hydrogenation of acetylenic hydrocarbons. In particular, nickel on kieselguhr is used for the liquid-phase hydrogenation of acetylenic hydrocarbons in the butene–butadiene fraction of the gases obtained in the pyrolysis of petroleum products[192,193], in the dehydrogenation products of isopentane and isopentenes, or in concentrated isoprene[194,195]. As a result, acetylenic hydrocarbons are removed to the extent of approximately 75–95%. The elimination of small amounts of acetylenic hydrocarbons from olefins and diolefins is achieved by hydrogenation over catalysts consisting of reduced nickel[196-201], a mixture of nickel[202,203] or cobalt[204] oxides and sulphides, and nickel or cobalt[205] phosphides on a porous carrier. The process is carried out at 20–315° and pressures up to 70 atm; it yields a product containing less than 1×10^{-4} vol. % of acetylenic hydrocarbons. When ethylene containing 7.6 vol. % of acetylene is passed through a catalytic solution of a nickel cyanide complex at 0–60°C, the effluent gas contains only 0.2 vol. % of acetylene[206]. Mixed nickel–chromium catalysts on carriers are used in the purification of cracking gases[207] and in the gases produced in the pyrolysis[208,209] of a hydrocarbon raw material and in the ethylene fraction of coking gas[210] and the crude ethylene–propene fraction[211]. Selective hydrogenation is carried out at 100–400°C, pressures up to 30 atm, and a space velocity in the range 300–6000 h^{-1}. As a result, virtually complete elimination of acetylenic hydrocarbons from the mixtures is achieved. Catalysts consisting of mixtures of the oxides of cobalt and molybdenum[212,213], nickel and molybdenum[214], and cobalt, nickel, and molybdenum or chromium[215-218] or the sulphides of cobalt, nickel, and molybdenum[219,220] on alumina proved to be effective and selective catalysts. In order to improve the selectivity of the hydrogenation process and to increase the useful life of the catalyst, acetylenic hydrocarbons are removed in the presence of water vapour or sulphur compounds[216]. The above catalysts ensure the elimination of acetylenic hydrocarbons from olefins and diolefins to the extent of 92–100%. Iron–chromium and copper–chromium catalysts promoted with alkali and alkaline earth metal compounds are used to eliminate acetylenic hydrocarbons from olefinic and diolefinic hydrocarbons[221-231] and the gases produced in the processing of mazut[232] at 30–370°C, a pressure up to 70 atm, and a space velocity in the range 200–1000 h^{-1}. The purified products contain about 3×10^{-4} vol. % of acetylenic hydrocarbons, while their initial concentration was 0.16 vol. %. It has been noted that iron–chromium catalysts[221-224,232] give rise to a prolonged induction period in the course of which the products underoing purification are consumed. The purification of converter gas on a zinc–chromium–copper catalyst[233], of pyrolysis gases on an aluminium–chromium–nickel catalyst[234], and of ethylene on a copper–chromium–manganese catalyst[235] has been investigated. In many cases these catalysts ensure virtually complete removal of acetylenic hydrocarbons and have considerable advantages over other catalysts tested, for example those containing palladium, platinum, iron, etc. The effective elimination of acetylene from coking gas[236,237] and concentrated olefins[238] is achieved by its selective hydrogenation on silver catalysts at 150–400°C, 11–15 am, and a space velocity of 3000–4000 h^{-1}. The concentration of acetylene in the gases after purification is 0.0003–0.008 vol. % for an initial concentration of 0.15–0.8 vol. %. The acetylenic hydrocarbon impurity is removed from olefins and diolefins by hydrogenation at 38–315°C, pressures up to 70 atm, and a space velocity in the range 100–2500 h^{-1} using copper catalysts[239,240], sometimes promoted with zinc[241] or Group VIII metals[242]. For example, acetylene is hydrogenated to the extent of 97% on a copper–zeolite catalysts[240], the yield of ethylene being 60% and of ethane 40%. Processes for the removal of acetylenic hydrocarbons from butadiene on an iron powder catalyst at somewhat elevated temperatures and pressures[243], from coking gas on a boron oxide catalyst at 300°C, 50 atm, and a space velocity of 2000–10 000 h^{-1},[244] and from olefin-containing mixtures by bringing them into contact with a palladium–molybdenum catalyst at 200–430°C[245] have been described. Three catalysts (their composition has not been published) for the selective hydrogenation of acetylene in gases from the thermal cracking of ethane, propane, and heavy hydrocarbons have been investigated[246]. The catalysts were tested at 177–316°C, 3–10 atm, and a space velocity of 500 h^{-1}. The concentration of residual acetylene in the purified gases did not exceed 1×10^{-4} vol. %.

The method of selective catalytic hydrogenation has been recognised as the most economical among the existing procedures for the removal of acetylenic hydrocarbons from hydrocarbon mixtures[247,248]. It is widely used in industry[11,144,164,166,181,193,208,218,233,246-252] and in most cases ensures the required degree of purification. However, the hydrogenation method frequently requires the use of expensive palladium and platinum catalysts, which are the most selective[253] but are also very sensitive to other impurities[254] and are difficult to regenerate[255,256]. Moreover, in the purification process the desired products are hydrogenated together with the acetylenic hydrocarbons[193-195,200,208,250,257]. The activity of the catalyst employed is particularly high in relation to the hydrogenation of conjugated bonds in diolefins[192,193,195,256,258] and therefore the losses of the latter in purification are considerable, reaching 8–20%.[145,161,193] As a result it proved possible to achieve the simultaneous elimination of acetylenic hydrocarbons and diolefins from mixtures with a high olefin content[149,176,189-191,209,234,259]. In the case of acetylenic hydrocarbons which also contain a double bond, the hydrogenation of the triple bond is not selective[258,260,261]. Many hydrogenation catalysts have a very prolonged (up to several days) induction period during which the desired products are consumed[222-224] and some of them lose their initial selectivity during operation[262] and lead to the occurrence of side reactions with formation of a wide variety of substances[263-265]. Therefore studies are being made in order to find and develop new catalysts and hydrogenation methods. In particular, in the elimination of acetylenic hydrocarbons hydrogenation is combined with a preliminary application of other methods, for example fractionation, in order to reduce the losses of the main products[135,266].

4. CATALYTIC OXIDATION

Thermal oxidation of acetylene requires the use of relatively high temperatures and leads to a complex composition of the reaction products[297]. When the process is carried out in the presence of catalysts[268,269], it is possible to reduce the reaction temperature appreciably and to obtain only carbon dioxide and water as the final oxidation products.

The catalytic oxidation method is most widely used in the removal of acetylene from air in the manufacture of oxygen[9,270-276]. It has proved possible to oxidise acetylene on catalysts at the temperature to which air is heated in compressors for the collection and compression of air (at about 150°C). Catalysts based on silver[9,271,273-276],

manganese[9,270-273], copper[9,270,271,273], palladium, and rhodium[277-279] are the most effective in the oxidation of small amounts of acetylene in air. Manganese ore promoted with silver[280], MnO_2, or Hopcalite[281] are used under industrial conditions. The purification processes are usually carried out at space velocities up to 60 000 h^{-1} and pressures up to 7 atm. After purification the acetylene content in air is 1×10^{-6} vol. % and less.

The method of selective catalytic oxidation is also used for the removal of small amounts of acetylene from certain hydrocarbon mixtures. It has been suggested that gas mixtures with a high ethylene and butadiene content and also hydrocarbon and petroleum cracking gases be freed from an admixture of acetylene using as catalysts metallic copper or CuO on carriers[282-286]. The process is carried out at a temperature of 120–375°C, a space velocity of 100–300 h^{-1}, and in the presence of a 25% excess of oxygen. The purified mixtures virtually do not contain acetylene. However, since the excess oxygen is always consumed in the oxidation of other hydrocarbons, considerable losses of the desired products are observed. In order to improve the selectivity of the purification process, it is recommended that platinum subgroup metals be employed as oxidation catalysts[287-290] and that acetylene be removed with the aid of catalytic solutions or the gas stream be saturated with water vapour. The purification is carried out at 20–300°C and 1–3 atm in the presence of variable-valence metal salts ($CuCl_2$, $FeCl_3$, etc.).

Thus the method of elimination of the acetylene impurity from hydrocarbon systems by its oxidation to carbon dioxide and water requires the employment of expensive catalysts, in particular those based on silver and platinum and also an excess of oxygen, which makes the process liable to risk of explosion and gives rise to considerable losses of the main substance as a result of oxidation.

5. CATALYTIC POLYMERISATION

Several extensive reviews have been published on the condensation and polymerisation reactions of acetylene and its derivatives[26,291,292]. For the purpose under discussion, catalytic methods of polymerising acetylenic hydrocarbons are of interest, since they make it possible to achieve a high degree of process selectivity and high conversions of the acetylenic hydrocarbons. Copper and its compounds have the most intense polymerising effect of acetylenic hydrocarbons.

Recently attempts have been made to employ the capacity of acetylenic hydrocarbons for rapid and easy polymerisation in the elimination of such impurities from various gaseous mixtures. Several procedures for the removal of the acetylenic hydrocarbon impurity from the liquid C_3 fraction[293], the ethane–ethylene fraction[294], olefins[295,296], and products of the oxidative pyrolysis of methane[297] with the aid of aqueous solutions of univalent and bivalent copper have been described. At 60–100°C and in some cases under a high pressure, acetylenic hydrocarbons are converted into liquid and solid polymers, which are separated from the catalytic solution by distillation and filtration. The degree of extraction of the acetylenic hydrocarbons depends markedly on the rate at which the mixture to be purified is passed through the catalytic solution and amounts to not more than 99.6–99.7%. This entails the formation of explosive copper acetylides. In order to improve the process selectivity, it is recommended that acetylenic hydrocarbon be eliminated[294,295] in the presence of oxidants (O_2, air, copper oxides, etc.) capable of maintaining the pH of the solution in the range 1–4.5.

More far-reaching polymerisation of acetylenic hydrocarbons with formation of solid polymers is also employed for the selective removal of the acetylenic hydrocarbon admixture from various hydrocarbon mixtures. In this case the polymerisation products are deposited on the surface of the catalysts and are periodically removed by burning off with an oxygen-containing gas when the catalysts are regenerated. Methods have been patented for the removal of acetylenic hydrocarbons from butadiene[298,299], halogenated olefins[300,302], olefins[299,302-305], and a mixture of olefins and diolefins[306]. The purification processes are usually performed in the gas phase in the temperature range 0–500°C at atmospheric or elevated temperature (up to 35 atm) and a space velocity in the range 500–2500 h^{-1}. Copper and its oxides[298-301,304,305], $CuAl_2O_4$,[302] a catalyst for the cracking of hydrocarbons, for example the aluminosilicate catalyst, deactivated with an alkali metal oxide[303], crystalline zeolites with pore diameters of 6–15 Å and containing between 0.5–12 wt. % of the metal promoting the acetylenic hydrocarbon polymerisation reaction (copper, nickel, cobalt, silver, etc.),[306] and a copper–aluminium alloy with an activated surface[307] are employed as catalysts. As a result of purification, the acetylenic hydrocarbon content decreases in most cases to $(1-5) \times 10^{-4}$ vol. %. It has been stated[298,308] that there are considerable losses (up to 7–12%) of the substances purified in consequence of polymerisation and other reactions on catalysts.

The advantages of the above methods of purification are as follows: elimination of the risk of explosion in the process[300-302,307]; the attainment of exceptionally high selectivity of the catalysts in relation to the polymerisation of acetylenic hydrocarbons to solid polymers[301,302,307]; high efficiency of the elimination of acetylenic hydrocarbons over a wide range of the process parameters and acetylenic hydrocarbon contents in the mixtures purified; ease of regeneration of the catalysts[298-302,304,305,307,308], etc. Therefore, it appears that the method of elimination of acetylenic hydrocarbons from hydrocarbon systems by selective polymerisation to solid polymers is the most convenient, compared with other procedures available, is technologically simplest, and comparatively cheap. It is very promising for the removal of small amounts of acetylenic hydrocarbons from various mixtures, i.e. for a high degree of purification. This is why this method of purification is of considerable practical interest for the large-scale manufacture of monomeric olefins, their halogeno-derivatives, diolefins, and other products, from which very small amounts of acetylenic hydrocarbons must be carefully removed. It is significant that this method is used for the additional purification of the stream of product after the removal of acetylene by selective catalytic hydrogenation.

The present author[309] made for the first time a systematic study of the fair elimination of acetylenic hydrocarbon impurities from hydrocarbon mixtures by the polymerisation method. The catalyst based on the copper spinel of aluminium was recognised as the most effective and promising[302,310]. Therefore all the principal characteristics of the purification and regeneration process were investigated on this catalyst[310,311]. In particular, it was shown that the spinel catalyst has a high mechanical strength and is most promising for continuous purification processes with a stationary bed[311]. A design calculation was made as an example for an industrial purification reactor and the optimum process conditions were selected[312].

6. OTHER METHODS

Apart from the methods discussed, other methods have been proposed for the removal of acetylenic hydrocarbons from various gas mixtures, among which the following may be mentioned.

In order to eliminate 0.1–1.0 vol. % of acetylenic hydrocarbons from a gas, it is mixed with SO_2 to give the proportions SO_2 : acetylenic hydrocarbon = (0.6–2.3) : 1. The resulting mixture is brought into contact at a temperature between −18° and 93°C, a pressure of 0.1–0.4 atm, and a space velocity of 200–1500 h^{-1} with a catalyst consisting of $AgNO_3$ on an inert porous carrier[313].

It is recommended that acetylenic hydrocarbons be removed from vinyl fluoride[314,315], the C_2 fraction[316], and propene[317] by selective hydrochlorination at 100–150°C in the presence of catalysts, for example $HgCl_2$ on activated charcoal. The resulting chloro-derivatives of acetylenic hydrocarbons are readily removed from the mixtures purified by the distillation method. As a result of purification, the acetylenic hydrocarbon content decreases, for example from 1.48 to 0.051 vol. %.

Methods have been described for the removal of acetylenic hydrocarbon impurities from hydrocarbon gases, in particular pyrolytic gas, by amination[318–320]. This method of purification is based on the fact that at an elevated temperature and in the presence of catalysts acetylenic hydrocarbons react with ammonia to form heterocyclic compounds (picolines)[321]. The purification is carried out at 170–400°C using zinc and molybdenum oxides[318,319] or copper(I) chloride[320], all deposited on activated Al_2O_3, as catalysts. For example at 350°C, atmospheric pressure, and a space velocity of 50 h^{-1} in the presence of 10 wt. % NH_3, the content of acetylene in pyrolytic gas decreases from 0.25 to 0.001 vol. %. The ethylenic hydrocarbons present in pyrolytic gas remain unchanged.

The concentration of acetylenic hydrocarbons in the C_4 pyrolytic fraction decreases from 0.03 to 0.007 vol. % when it is passed over an oxide catalyst (Al_2O_3, SiO_2, MgO, or their mixture) with an effective acidity of 1.5–8 at 27 to 120°C.[322] The catalyst must be subjected to a preliminary heat treatment at 480–650°C for 1–24 h.

In order to remove the acetylene impurity from vinyl fluoride[323], the gas mixture is treated with a solution of mercury salts in 10–50% H_2SO_4. Acetylenic hydrocarbons are removed similarly from diolefins[324]. It has also been recommended that mixtures of vinyl fluoride, acetylene, and 1,1-difluoroethane be brominated at 0°C with subsequent distillation of the bromination products[325]. Pure vinyl fluoride is obtained in a yield of about 80% by the debromination of 1,2-dibromo-1-fluoroethane with zinc dust in an alcoholic medium.

IV. ANALYTICAL METHODS FOR THE DETERMINATION OF ACETYLENIC HYDROCARBON IMPURITIES IN VARIOUS MIXTURES

A necessary condition for the further improvement of the methods for the thorough elimination of acetylenic hydrocarbons from various systems is the development of highly sensitive analytical control procedures at the right time. They should make it possible to determine with adequate accuracy the composition of a wide variety of complex mixtures, to estimate quantitatively small amounts of acetylenic hydrocarbon impurities in the mixture, to carry out rapidly large-scale analyses, to achieve a continuous analytical control of the operation of industrial apparatus, and to regulate automatically the course and conditions of technological purification processes. Nowadays various methods are used for this purpose: chemical, physicochemical, and physical.

The characteristic red colour of copper acetylide, obtained in ammonia solutions of copper(I) salts, is used for a qualitative detection of traces of acetylene in various mixtures[102,103,310]. Test papers[104] and also a microchemical method for the determination of acetylene[105] have been developed on this principle. In order to maintain a stable colour of the precipitate for a long time and to increase the sensitivity of the reaction, it is recommended that reducing agents and gelatine be added to the solution. The sensitivity of the freshly prepared reagent with respect to acetylene is 2×10^{-4} vol. %. A method developed for the semiquantitative determination of acetylene in gas mixtures[326] depends on the fact that in the presence of acetylene the yellow colour of the reagent [silica gel impregnated with a mixture of $PdSO_4$ and $(NH_4)_2MoO_4$] becomes yellow-green. The sensitivity of the reagent is 10^{-3} vol. %. Sometimes acetylene is detected in mixtures using the formation of a protective layer on Ag_2CrO_4.[327] When acetylene reacts with Ag_2CrO_4 solution in nitric acid or ammonia, a flakey orange or yellow precipitate is formed. The minimum amount detectable is 1 μg of acetylene.

Among the chemical and physicochemical analytical methods for the quantitative determination of small amounts of acetylenic hydrocarbons, the commonest are absorption, titrimetric, colorimetric, and other methods. The best reagent for the determination of acetylene in hydrocarbon gas mixtures by the volumetric absorption method is an alkaline solution of potassium iodomercurate[328–332]. It has been shown that small amounts of acetylene in oxygen and in air[333] and also in other gases[334] may be determined volumetrically using solutions of copper and silver salts. The acetylene content in concentrated vinyl fluoride has been determined by absorption in bromine water[130]. It is noteworthy that the volumetric method is usually applicable when the content of the acetylenic hydrocarbon is high, i.e. is not less than 0.5%. In this case the error of the determination is ±0.2 abs. %. The use of special apparatus makes it possible to determine from the change in volume even lower concentrations of acetylenic hydrocarbons in the mixture. However the error of the determination then increases appreciably, since the absorption solutions containing copper, silver, and mercury also absorb a certain amount of other components of the mixture analysed (olefins, diolefins, carbon monoxide, molecular oxygen, etc.).

The alkalimetric titration method[335], which depends on the interaction of acetylene and its monosubstituted derivatives with $AgNO_3$ solution followed by titration of the liberated nitric acid with alkali in the presence of a mixed indicator (an alcoholic solution of Methyl Red and Methyl Blue) has been widely adopted in analytical practice for the determination of the overall content of acetylenic hydrocarbons. It is used to determine the admixtures of acetylenic hydrocarbons in ethylene[335], butadiene[14,102], isoprene[336,337], nitrogen and air[338], and also in other mixtures[339–341]. A combined method for the separate determination of acetylene and higher acetylenic hydrocarbons has been described[342,343]. The amount of acetylene is calculated from the weight of the readily crystallisable complex $C_2Ag_2.AgNO_3$ formed when acetylene reacts with a concentrated solution of $AgNO_3$. Higher acetylenes do not form a precipitate. Therefore the overall content

of acetylenic hydrocarbons is found by alkalimetric titration and the content of higher acetylenes is obtained by difference. A method for the determination of small amounts of acetylenic hydrocarbons in gases[103], based on their interaction with an ammoniacal solution of $AgNO_3$ and subsequent titration of the excess $AgNO_3$ with NH_4SCN, has been recommended. Titrimetric methods make it possible to determine the contents of acetylenic hydrocarbons in mixtures to within 5 rel. % with a sensitivity of 10^{-4}%.

Small amounts of acetylene in various gas mixtures are determined successfully with a high accuracy by a colorimetric method[107-111] based on the interaction of acetylene with copper(I) salts in ammoniacal solution. The finely dispersed copper acetylide colours the solution red-violet. Acetylene is determined by colorimetric measurements on the solution against a standard scale[107,108,112-116]. Special apparatus has been designed and methods for the colorimetric determination of acetylene has been improved[117-119]. In some cases[120], in the determination of small amounts of acetylene in air it is sorbed on silica gel at −78°C and the sorbent is then treated with a mixture of an ammoniacal solution of $CuCl_2$ and a solution of $NH_2OH.HCl$. The colour of the silica gel is compared with a standard scale. For this purpose, a linear colour method of determining acetylene in air has been developed[344,345]: air is passed through an indicator tube filled with coarsely porous ShKS silica gel impregnated with potassium iodide; a pale-brown layer is formed in the indicator powder, whose length is proportional to the concentration of acetylene in air. The sensitivity of colorimetric analytical methods is 1×10^{-4}% and the accuracy of the determination is not more than to within 0.05 abs. %.

A polarographic method is used to determine dissolved acetylene[346,347] or its admixtures in gaseous products, for example in chloro-derivatives of ethylene[348,349].

Among physical methods for the analytical determination of acetylenic hydrocarbons in various mixtures and specially pure compounds, gas–liquid partition chromatography has been widely and successfully used. Chromatographic analytical methods have significant advantages over other procedures, namely they are universal, i.e. they yield information about a number of impurities, are very sensitive, rapid, and accurate, it is possible to work with very small samples of materials, the analysis can be automated, etc. Therefore they are the most promising. Numerous studies on the chromatographic analysis of specific systems containing acetylenic hydrocarbon micro-impurities are being systematically published in the periodical literature on science and engineering. Ethylene[350-358], propene[359,360], isobutene and butadiene[14], vinyl fluoride[361,362], vinyl chloride[363-366], pyrolysis gases and the ethylene fraction[367-369], coking gas[370], and other products[371-373] have been analysed by gas–liquid partition chromatography. In most cases apparatus with flame-ionisation or argon detectors is employed. A wide variety of adsorbent, depending on the nature of the products analysed, are used as packing for chromatographic columns. The sensitivity of chromatographic analytical methods with respect to acetylenic hydrocarbons is $10^{-3}-10^{-7}$%, the accuracy of the determination being to within (5–20) rel. %.

Among other physical methods for the analytical determination of acetylenic hydrocarbon impurities, which do not require the separation of the initial mixtures into components, certain spectroscopic procedures are employed. Infrared spectroscopic data are used to determine the purity of ethylene and the content of acetylenic hydrocarbons in ethylene[374,375], vinyl fluoride[376], and other mixtures[377-379]. Certain improved analytical techniques have been proposed[380]. The sensitivity of the method is 4×10^{-3} vol. % and the accuracy of the determination is to within 10 rel. %. Attempts have been made to employ the mass-spectrometric method for the analysis of certain mixtures, for example coking gas[381] and the gases in the synthesis of vinyl fluoride[382] in order to determine the acetylenic hydrocarbon impurity. However, isomeric hydrocarbons and compounds with the same number of carbon atoms in the molecule are difficult to determine by the mass-spectrometric procedure. In the analysis of complex mixtures, the sensitivity and accuracy of this method are greatly impaired. A combination of the gas–liquid chromatographic and mass-spectrometric methods appears promising[383].
