$$\rho\left(\frac{C}{4}-\frac{P}{3}\right)=\rho\left(\frac{C}{4}-\frac{P}{5}\right)+\frac{1}{3}\rho(d_P)=\rho^*(C-P)+\frac{1}{3}\rho(d_P),$$

and by hypothesis

$$\rho^*(C-P)=\rho\left(\frac{C}{4}-\frac{Si}{4}\right),$$

whence

$$\rho(d_P)\sim 3\left[\rho\left(\frac{C}{4}-\frac{P}{3}\right)-\rho\left(\frac{C}{4}-\frac{Si}{4}\right)\right]\sim 225\ \mu\text{rad}.$$

Similarly, for a Group VI element,

$$\rho\left(\frac{C}{4}-\frac{S}{2}\right)=\rho\left(\frac{C}{4}-\frac{S}{6}\right)+\frac{1}{2}\rho(2d_S)=\rho^*(C-S)+\rho(d_S);$$

using

$$\rho^*(C-S)=\rho\left(\frac{C}{4}-\frac{Si}{4}\right);$$

we have

$$\rho(d_S)=\left[\rho\left(\frac{C}{4}-\frac{S}{2}\right)-\rho\left(\frac{C}{4}-\frac{Si}{4}\right)\right]\simeq 52\ \mu\text{rad},$$

and, finally, for a Group VII element, for example chlorine, we have

$$\rho\left(\frac{C}{4}-\frac{Cl}{1}\right)=\left[\rho\left(\frac{C}{4}-\frac{Cl}{7}\right)+\rho(3d_{Cl})\right]=\rho^*(C\text{—}Cl)+3\rho(d_{Cl}),$$

$$\rho(d_{Cl})=\frac{1}{3}\left[\rho\left(\frac{C}{4}-\frac{Cl}{1}\right)-\rho\left(\frac{C}{4}-\frac{Si}{4}\right)\right]=19\ \mu\text{rad}.$$

The contributions by the lone electron pairs calculated in this way are listed in Table 5. Evidently the magnetic rotation due to a lone electron pair is often very considerable (compared with the contribution by the bond electron pair) and is a maximum for Group V elements. This result is consistent with the well known fact that phosphorus is a more powerful electron donor than sulphur and SX_2 molecules are stronger Lewis bases than XCl. The previous conclusions are based to a significant extent on the occurrence of a systematic additivity (which has not yet been discussed) of the magnetic rotation due to bonds, provided that the latter are covalent, normal, diamagnetic, and localised. The experimental evidence for such systematic behaviour has quite recently received valuable theoretical support in a paper by Daudel, employing analysis based on the "cell" theory† [41–44]. Systematic additivity is confirmed with the aid of the cell concept provided that three criteria are satisfied[45].

1. There is a clear subdivision of molecular space into cells (the probability of the residence of a single electron within a specified sphere is close to unity).

2. The quantity A is the sum of the A_i which are in turn expressed thus:

$$A_i=\int_{E-L_i} dv_{p+1}\ \ldots\ dv_n \int_{L_i}\psi^* A_{op}\psi dv_1\ \ldots\ dv_p,$$

and $A=\Sigma A_i$ (it is assumed that the cell L_i contains p electrons).

Table 5.

Element	Group V	Group VI	Group VII
Element E	N	O	F
$\rho(D)_E$, μrad	86	(—4.3)	(+0.5)
Element E	P	S	Cl
$\rho(D)_E$, μrad	255	52	19
Element E	As	Se	Br
$\rho(D)_E$, μrad	267	103	55
Element E	—	—	I
$\rho(D)_E$, μrad	—	—	131

3. The values of A_i for a given type of cell vary little in the series of molecules investigated.

Criterion *2* is fundamental to the interpretation of Daudel et al.[45], who were able to show that magnetic rotation satisfies it and therefore the classification of the additive properties in the Faraday effect is justified[46,47].

Since this is so, subsequent solution of problems in structural chemistry on the following basis is permissible: *all structural features of compounds with covalent, diamagnetic, and localised σ and π bonds must be duly reflected to some degree in a deviation from the law of additivity*. However, before concluding the section of definitions, we feel it desirable to consider the deeper significance of the systematic scheme. Such a scheme is very useful to the experimenter, who can ascertain by simple addition the purity of a compound just obtained. However, in terms of ideas, one must be firmly convinced that the bond constant is a constant quantity regardless of the environment of the bond in the remaining part of the molecule. This is undoubtedly shocking to critical minds.

† See Daudel's book[185] (Editor) [the original French term is "loge" (Ed. of Translation)].

How is it possible for magnetic bond rotation to be invariant in a molecule, while all other properties (vibration frequencies, bond lengths, ionic character, etc.) change? This remark in fact led us in 1964 to make a closer examination of the implications of the systematic scheme.

We know that the magnetic polarisability of a σ bond depends primarily on the shape of its electron cloud. We believe that the simplest semiempirical parameter providing a description of this configuration should be the partial ionic character of the bond as defined by Pauling. If we wish to find a relation between the rotation ρ_{AB} of a covalent σ bond (A–B) and the amount of its ionic character I_{AB}, it is necessary to have at ones disposal a method for calculating the effective value of I_{AB} for various possible situations in the molecule. Ultimately we decided on an iterative method[48] based on the use of self-consistent Pauling exponential functions modified and extended to the molecules M(XYZ...). A formal description of this procedure was given by Daudel in 1946 for symmetrical molecules MX_n.[49] In this way we were able to compare the effective values of I_{AB} obtained for all bonds in any covalent compound with the experimental values of ρ_{AB} obtained for these series of compounds without needing to postulate the constancy of the modulus of bond rotation, which is now regarded as a function of I_{AB}.

Table 6.

Compound	I_{BC}	ρ_{BC}	I_{BCl}	ρ_{BCl}
BCl_3	—	—	12.2	143.4
BCl_2R	3.9	57.9	13.1	140.7
$BClR_2$	4.6	50.4	14.4	136.8
BR_3	5.1	45.0	—	—

This enabled us to demonstrate a linear relation between ρ_{AB} and I_{AB}, which is demonstrated in Table 6 for certain most common bonds of boron[50] and phosphorus[51]. We chose these examples from others, since subsequently the corresponding equations will prove useful. Examination of Table 6 shows in the first place that b_{AB} is in all cases negative: it is quite logical that a higher value of I_{AB} is associated with a greater shift of the electron cloud and its concentration at the more electronegative atom. On the other hand, its deformability under the influence of the magnetic field is weaker and consequently the Faraday effect associated with this bond is smaller. The numerical value of b_{AB} is equally interesting. For similar bonds of boron and phosphorus (B–C and P–C, B–O and P–O), the b_{AB} values are virtually identical, which must be attributed to the similarity of the electronegativities (1.9 and 2.1 on Gordy's scale[52]). We may note further that b_{AB} decreases and tends to zero when the difference between the electronegativities δ_X of the atoms A and B increases. The limit is virtually attained for the (B–O) and (P–O) bonds ($\delta_X = 1.5$), which suggests that any (A–B) bond with $\delta_X \geqslant 1.5$ will have $b_{AB} = 0$ and will therefore give rise to a constant magnetic rotation regardless of the molecule in which this bond is located. In particular, the (P–F) bond is of this type, provided of course it is a σ bond. As this is correct, there arises immediately the following valid question concerning all that has been said above: how to reconcile the experimental finding of a systematic additivity of the moduli (constants) and the existence, proved theoretically, of a linear variation of these constants as a function of I. It is simplest to analyse one example, which provides a perfectly clear illustration: Table 6 shows how the ionic character of the (B–C) and (B–Cl) bonds varies in the $BR_{3-x}Cl_x$ series; evidently in the mixed compound $BRCl_2$, I_{BC} and I_{BCl} are respectively smaller and bigger than the corresponding quantities in BR_3 and BCl_3. Since b_{BC} and b_{BCl} are negative, ρ(B–C) and ρ(B–Cl) will be respectively bigger and smaller than the values in BR_3 and BCl_3. Thus it is sufficient to show numerically, which is not difficult, that the two deviations cancel out, since the essential features of the systematic additivity with constant moduli again become evident (Table 7).

Table 7.

Bond	$\rho_{ij} = a_{ij} + b_{ij} I_{ij}$	Bond	$\rho_{ij} = a_{ij} + b_{il} I_{ij}$
B–O	$\rho = 32.6 - 0.7 \cdot I_{BO}$	P–O	$\rho = 110 - 0 \cdot I_{P-O}$
B–Cl	$\rho = 180 - 3 \cdot I_{BCl}$	P–Cl	$\rho = 294 - 3.3 \cdot I_{PCl}$
B–C	$\rho = 99.6 - 10.7 \cdot I_{BC}$	P–C	$\rho = 182.9 - 9.2 \cdot I_{PC}$

The systematic additivity is in fact due to the cancellation of the terms $b_{BA}I_{AB}$ within the molecule. Thus everything falls into place. We believe that this result is doubly valuable. Firstly, it shows that the existence of systematic additivity is not fortuitous and, in addition, it provides a simple interpretation of the existence of certain σ covalent molecules which do not obey systematic additivity no matter which property one attempts to treat as an additive function. We preferred not to discuss this in Section II, in order not to draw readers' attention to details, which might have made it difficult to assimilate the main ideas. However, the time has now come to deal with this question: it concerns essentially molecules of the type $CCl_{4-x}H_x$. As early as 1910, Pascal[53] noted their anomalous diamagnetic behaviour, while Gallais and Voigt somewhat later[23] arrived at a similar conclusion concerning the Faraday effect.

Evidently, there should be no intramolecular compensation in these molecules. This compensation occurs only if the electronegativity of the central atom M is outside the range of electronegativities of the substituents X and Y (and b_{MX} and b_{MY} are negative). Halogenomethanes do not exhibit additivity, since this condition does not hold for them and indeed

χ_H	χ_C	χ_{Cl}
2.10	2.55	2.97

The observations which have worried the specialists in the field of the additive properties of matter for many years can be explained similarly[50]. The additivity of the Faraday effect was discussed and demonstrated in such detail in order to employ the deviations from this law for the solution of specific problems in structural chemistry.

V. MAGNETO-OPTICAL INVESTIGATION OF CONJUGATION PHENOMENA

In 1960 we made a detailed study of additive properties in the presence of electrons delocalisation in the molecule. Our investigation concerned primarily conjugated aliphatic

systems (pure hydrocarbons). The results are presented in Table 8; we established that the presence of a delocalised π-electron system in open-chain molecules always leads to a considerable positive deviation from additivity[54]. This fundamental result implies that the experimental molecular rotation (A) of a conjugated compound is always higher than the theoretical value (B) which may be calculated by additivity on the assumption that the molecule contains only localised bonds. Thus the exaltation of magnetic rotation (E) due to conjugation (briefly, conjugation exaltation) proves in addition to be constant for a given conjugation fragment and, conversely, is appreciably different for different conjugation fragments (Table 8). Analogous results were obtained for a large number of conjugated aliphatic moieties incorporating (C=O) and (C=N) bonds[55-58].

Since the existence of E is associated with the delocalisation of π electrons, it was logical to find if E depends in some simple manner on the parameters employed in theoretical chemistry to describe delocalisation. For this purpose, we calculated in terms of the Hückel approximation the π-electronic structures of all the molecules investigated. We obtained the bond indices p_{rs}, the charges q_r localised at the atoms, and the free valence indices I_r,[59-61] and concluded that the sum of the free valence indices is in fact the required parameter, since the E vary linearly with it, as shown by Table 9 and Fig. 3, the correlation coefficient obtained by least-squares treatment of the results exceeds 0.96.

We shall note immediately that there exist apparently two $E = f(\Sigma I_r)$, straight lines, one (D_1) referring to moieties incorporating only double and triple bonds and the other (D_2) describing mixed moieties.

Table 9.

P { >C=C< $E=0$ $\Sigma I_r=1.464$; —C≡C— $E=0$ $\Sigma I_r=1.464$

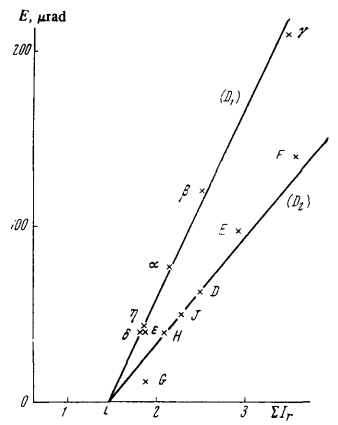

Figure 3.

This difficulty undoubtedly shows that the method of calculation employed (the Hückel approximation) does not allow a description of the second case with the same rigour as the first. In fact the calculation does not take into account a significant interaction between π-electron systems and the π-electron system of the triple bond, when it is conjugated with a double bond, which leads to low values of the bond indices and an appreciably high value of the sum of the free valence indices. Evidently, a more refined method of calculation would yield for compounds with mixed moieties a lower sum of the free valence indices compared with the values in Table 9, which would shift the points on the (D_2) straight line to the (D_1) line. Therefore, we shall subsequently place greater reliance on the coefficients corresponding to (D_1) and we will employ only these in all our discussions. Before proceeding to further exposition, we must make a small detour. The physical chemist, observing empirically a simple relation between

the measured quantity and some theoretical parameters, can adopt two attitudes: he can either take the risky course of remaining blissfully satisfied or he can attempt to show that the relation obtained is in no way due to chance. The first attitude was in fact ours until we decided to adopt the second. More precisely, we adopted this point of view when we were able to show that the magnetic rotation of buta-1,3-diene is a linear function of a sum of the type $\Sigma c_i c_j$ (c_i and c_j are the coefficients of non-adjacent atomic orbitals in molecular orbitals), a sum which represents none other than the ineffective bond indices in the molecule, i.e. the free valence indices. This is valid with sufficient rigour only for aliphatic systems, which we shall call "unsubstituted", where the atoms of the conjugated moiety are linked only to hydrogen or alkyl groups. In fact, it was established that a substituent X other than those mentioned above alters E and ΣI_r to such an extent that the (D_1) straight line cannot be used[62]. However, despite this, one may attempt, by continuing to develop our concepts, to obtain from the data for the Faraday effect extremely interesting results. For example, if we examine a family of compounds of the type R–C=C=C(X) [sic! (Editor of Translation)] (where X = H, CH_3, Cl, OR, or NH_2), it is evident that E varies appreciably as a function of X (Table 10). This is also valid for the series of α-unsaturated carbonyl compounds (Table 11).

Table 10.

Compound	E, μrad	p_{23}
R–C≡C–C(H)=O	18	0.247
R–C≡C–C(R′)=O	12	0.240
R–C≡C–C(OH)=O	25	0.262
R–C≡C–C(Cl)=O	17.5	0.247
R–C≡C–C(NH_2)=O	5	0.232

Castan's classical calculation[63-66] of the π-electronic structure by Julg's method shows that the observed changes in E can be related in both cases to changes in the indices of the "single" (C_2–C_3) bond by expressions of the type

$$E_e = 940\, p_{23} - 253,$$
$$E_a = 810\, p_{23} - 183.$$

The first is valid for ethylene derivatives and the second for acetylene derivatives[67]. The relations are of definite interest from the standpoint of both the Faraday effect and quantum chemistry.

1. They throw light on the apparently random distribution of E values obtained from experimental observations and indicate the extreme sensitivity of the Faraday effect to minute changes in the electronic characteristics of conjugated molecules: thus in ethylene derivatives Δp_{23} of the order of 0.04 of an electron corresponds to a change ΔE of the order of 35 μrad.

2. They make it possible to predict the numerical value of the magnetic rotation for those compounds of the type investigated for which experimental data are not available.

3. They permit a refinement of the Couloumbic integrals and the effect of the substituent X when these are not known with adequate precision. In particular, Castan confirmed the integrals proposed by Peradjordi[68] for the amide group, whereas in the literature there exist discrepancies on this question.

4. Finally, they demonstrate the existence of a definite threshold, in terms of bond indices, beyond which conjugation effects must not be expected in the Faraday effect, namely for ethylene derivatives starting with 0.269 and for acetylene derivatives starting with 0.226.

This unusual result suggests that in an unsaturated system there may be electron delocalisation which is not reflected in the Faraday effect, i.e. the deformation of molecular orbitals under the influence of the magnetic field is too insignificant for observation. The existence of a threshold accounts for the zero exaltation of conjugation in α-diketones; although these compounds are in fact evidently conjugated, their $p_{23} = 0.152$ is significantly below the detection threshold, as shown by Castan and Labarre[69].

Table 11.

Compound	E, μrad	p_{23}
CH_2=CH–C(H)=O	45	0.296
CH_2=CH–C(CH_3)=O	19	0.288
CH_3–CH=CH–C(H)=O	43	0.315
CH_3–CH=CH–C(CH_3)=O R–CH=CH–C(CH_3)=O CH_3–CH=CH–C(R′)=O	35	0.307
CH_3–CH=C(CH_3)–C(H)=O	37	0.308
$(CH_3)_2$C=CH–C(H)=O	54	0.328
CH_2=C(CH_3)–C(H)=O	—	0.288

Having investigated in this way the "linear" conjugated systems, we now consider the behaviour of conjugation exaltation in cyclic systems. The idea underlying the first study in this field by Graffeuil and coworkers[70] is quite analogous to that just discussed. The study was based on a large number of hydrocarbons containing one or several benzene rings. A linear relation was observed between the conjugation exaltation E_{Ar} and ΣI_r with the same initial abscissa as for the (D_1) straight line. However, now the experimental points lie on another straight line (D_2):

$$D_1 \quad E_{Al} = 111\,(\Sigma I_r - 1.464),$$
$$D_2 \quad E_{Ar} = 200\,(\Sigma I_r - 1.464).$$

This implies that, for a conjugated system characterised by the value of ΣI_r, the exaltation E_{Ar} (for cyclic molecules) greatly exceeds E_{Al} (for alicyclic molecules).

$\Delta E = E_{Ar} - E_{Al}$ reflects to some extent the transition from conjugation in open chains to conjugation in rings or to "aromaticity". The existence of ΔE is due to the presence in the aromatic molecule of delocalised π electrons the increased mobility of which under the influence of an applied magnetic field may be observed. Thus we immediately discover that ΔE is due to the Pauling–Pople current characteristic of a cyclic molecule. This hypothesis is the starting point of an exciting study, since under these conditions the Faraday effect constitutes a cardinal method for investigating the entire problem of aromaticity. Moreover, ring currents, as an expression of the magnetic properties of the substance, are as important as the susceptibility and nuclear magnetic resonance, where, incidentally, the existence of the Pauling–Pople current was first demonstrated.

The same conjugation exaltation might also be expected for all aromatic molecules with a specified value of ΣI_r. However, if one examines for this purpose the entire multiplicity of mono- and poly-substituted benzenes, it is immediately seen that such expectation is in vain: Table 12 lists certain values of E obtained in a number of investigations [71-76] and readily shows small deviations upwards and appreciable deviations downwards from 182 μrad, which is characteristic of benzene. It is also evident that for all such molecules ΣI_r remains virtually constant, at least when the calculation is performed in the same way with respect to the benzene ring. The question arises as to the factor, electronic or geometrical, which has such a marked influence on the conjugation exaltation of the molecule and its aromaticity. An answer was obtained after the investigation of the $(\sigma + \pi)$ electronic structures of 60 substituted benzenes, which we calculated ourselves [77-80].

Table 12.

№*	E, μrad	G	№*	E, μrad	G

18	148	0.063	22	12	0.159

*The numbering corresponds to the curves in Fig. 4.

The methods of calculation employed were similar [48,77]. One may conclude that, whereas the bond indices are always close to the value (0.667) observed for benzene, the gradient of the $(\sigma + \pi)$ electronic charge localised at the six carbon atoms in the benzene ring deviates more or less appreciably from the zero value which obtains in benzene (Table 12). The charge gradient gives rise to potential barriers at the vertices of the ring, reducing the ability of delocalised π electrons to generate the ring current. It was found that, although the aromaticity of the molecule does evidently depend on the π-electron density, it is also a function of the distribution of σ-electron density. Thus we arrive at Musher's objection to the concept of the ring current, at least in its classical form. The results of our magneto-optical studies show that the molecule can have a high delocalised electron density and nevertheless have no ring current, provided that the gradient G is sufficiently large.

Fig. 4 confirms the validity of the foregoing, since it reveals a very important linear relation between E and G. [81] It should be noted that the definition of G is quite independent of the nature of the atoms in the molecule. Clearly, this quantity can be calculated with equal success for both hydrocarbons and heterocycles, for example pyridine, and for heteroatomic cyclic compounds, for example borazine. Subsequently we shall find it very important to be able to measure the relative aromaticity of the molecule under specified conditions in terms of the quantity G, i.e. to be able to use the same concept to describe both benzene homologues and heterocycles of the same symmetry; this makes it unnecessary to introduce the concept of pseudoaromaticity, so frequently encountered in the literature, when a heteroatom replaces a carbon atom in the ring.

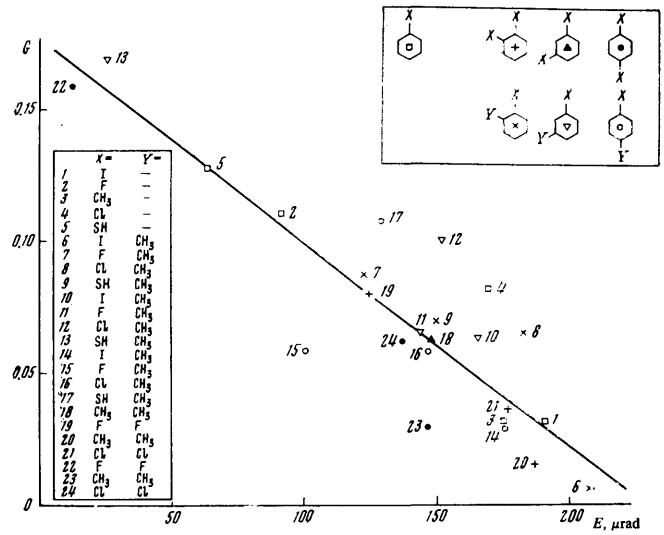

Figure 4.

The sum total of the results led us to the following definition [82]: a cyclic molecule is aromatic when the distribution of the delocalised π electrons is such that they can be put in motion under the influence of an applied magnetic field [in consequence of the absence of an appreciable gradient of the $(\sigma + \pi)$ charge localised at the vertices of the molecule]. The Pauling–Pople current then arises. This aromaticity can be either measured experimentally with the aid of the Faraday effect (the measured E) or predicted theoretically by calculating the $(\sigma + \pi)$ electronic structures (the definition of G and p_{rs}). Thus we have two equivalent means for determining to what extent the molecules belong to a particular type, provided of course that the charge distribution along the ring belongs to the same symmetry group. This conclusion follows from the following observation: when E is expressed as a function of G for compounds belonging (in the sense just described) to the D_{3h} group (borazines and boroxins) [83-85] or to the C_{2v} group (furan, thiophen, etc.) [86], we obtain in each case a linear relation—the corresponding graph is parallel to that shown in Fig. 4. However, for each group the symmetry of the distribution of the localised $(\sigma + \pi)$ charge (at the vertices of the ring), there exists a specific $E = f(G)$ straight line which cannot be made to coincide with the line in Fig. 4 whatever assumptions are made in the calculation. Thus we arrive at Musher's second objection to the ring current. It largely recapitulates the previous postulate.

1. It is impossible to compare the aromaticities of benzene and a molecule which does not belong to the D_{6h} group. Even if we are entitled to measure the aromaticities of substituted benzenes relative to that of benzene itself, this can only be done provided the Coloumbic integrals, correctly estimated from ultraviolet spectra, show

only small deviations from the value of α, as for X = P, Cl, I, and SH; on the other hand, for aminobenzenes we obtain from the ultraviolet spectra $\alpha C(NH_2) = \alpha - 0.6\beta$,[87] which corresponds to a C_{2v} symmetry of the benzene ring rather than D_{6h}.

2. It appears that certain benzene derivatives cannot be classified as aromatic compounds at all. In particular, this applies to fluorobenzene, which has an extremely low value of E_{Ar}, lower than that which benzene should have if it were "aliphatic", i.e. if the ring current were altogether absent. Clearly, we hesitated for a long time before publishing such a surprising conclusion. Our doubts continued until we recognised that fluorobenzenes are nitrated and sulphonated with difficulty‡, which may be regarded as a chemical criterion of the quasi-non-aromaticity of fluorobenzene.

We have discussed thoroughly the problem of the aromaticity of substituted benzenes. However, the rule which we have proposed is evidently general: we have used it also to solve the problem of the aromaticity of substituted borazines and boroxins of D_{3h} symmetry—the problem which has been the subject of controversy, as shown by the literature. We calculated the $(\sigma + \pi)$ electronic structure of molecules of this type, the magnetic properties of which have been investigated systematically by Laurent and coworkers[88-91] and the relative aromaticity scale, which we obtained using the calculated values of G, is very satisfactorily confirmed by experimental data[92].

The concept of aromaticity in terms of our definition was then applied[86] to pentagonal heterocycles of the C_{2v} group. The data obtained yielded the familiar result that pyrrole and furan are virtually non-aromatic, while thiophen is aromatic owing to overlapping of the 3d orbitals of sulphur, which promotes the appearance of a ring current.

We showed that the aromaticity of pyridine is 5–6 times lower than that of its N-oxide[93]. This becomes clear after examining the structure of the (N→O) donor–acceptor bond, which reduces the electron density at the nitrogen atom, while its enhanced value in pyridine is responsible for the potential barrier which prevents the occurrence of a ring current.

Finally, Bonnafous[94] investigated the aromaticity of nitrobenzenes and nitrotoluenes[94]. However, this problem, which is associated with the nature and magneto-optical properties of coordination bonds, will be set aside for discussion in the appropriate section.

Another magneto-optical criterion of aromaticity, for which we had great hopes in 1967 bearing in mind its operational simplicity, was discussed similarly. This criterion was suggested by Zimmerman and Foster's NMR experiments[95]: they showed that the signal due to benzene protons is displaced towards weaker fields on diluting benzene with a chemically inert solvent and Pople suggested that this may be due to a change in the ring current on dilution[96]. A similar experiment by Crasnier on the Faraday effect showed that the molecular magnetic rotation of benzene decreases exactly linearly on dilution by a solvent such as hexane. We believed that we had a simple means for measuring the "intensity" of the ring current in the molecule and became even more firmly convinced of this after a study[82] showing that the corresponding decrease in the above solvents is greater the greater is the initial "intensity". The first measurements for fluorobenzene, p-difluorobenzene, chlorobenzene, and bromobenzene, in n-hexane solution[82] enabled us to establish a relative aromaticity scale identical with that which is deduced from the measurements of E and calculations of G. However, this agreement gradually disappeared as the number of molecules investigated increased and soon it was necessary to conclude that the straight line obtained for a given aromatic compound (see iodobenzene[80]) varies from one solvent to another so much that we are simply unable to take into account the solute–solvent chemical interaction. Precisely because of these considerations, we undertook a new study of the criterion of aromaticity "in solution" by measuring the molecular rotation of benzene in 16 solvents; the results[97] are presented in Fig. 5 and in Table 13.

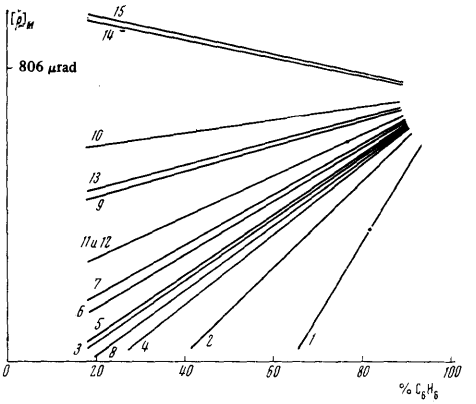

Figure 5.

14	Dimethyl sulphoxide	$y=-0.111\ x+819.9$	0.99	1.4780	0.284

*The numbering corresponds to the curves in Fig. 5.

They require the following comments. (1) The variation of $(\rho)_M$ is exactly linear over a wide range of concentrations, which is confirmed by the correlation coefficients r; (2) however, the decrease observed for hexane, on which earlier we intended to base the criterion of aromaticity in solution, is by no means general—in particular, it is evident that in certain cases there is an increase and not a decrease of $(\rho)_M$; (3) as regards the order in which the solvents investigated can be arranged, it is at first sight difficult to grasp whether, for example, their macroscopic

‡ Electrophilic substitution reactions of fluorobenzene (including nitration) are well known, see, for example, Stock and Brown[186] (Editor).

polarisability is an appreciable factor or not—from this point of view it is surprising that carbon tetrachloride and dimethyl sulphoxide give similar experimental relations.

It is customary to say that the solute–solvent interaction depends directly on the polarity and the polarisability of the components of the system under consideration. Bearing this in mind, it was logical to check whether the changes in $(\rho)_M$ are a function of polarisability. For each solvent, we calculated the molecular polarisability P from the Lorentz formula

$$P = \frac{(n_D^{20})^2 - 1}{(n_D^{20})^2 + 2}$$

and showed (Fig. 6) that there is a significantly linear relation between P and the experimental data for the Faraday effect[97]. However, it is evident that the decrease of $(\rho)_M$ does not depend directly, as might have been expected, on the "intensity" of the ring current in the molecule when the substance is diluted but is more likely to be associated with solute–solvent interactions, which cause a more or less pronounced change in the internal electric field. The overall effect of the internal electric field and the external magnetic field is in fact observed. Hence one must assume that the investigation of "aromatic" molecules in solution by the magneto-optical method cannot yield a criterion of aromaticity. However, this conclusion must be extended also to the results of analogous NMR studies, as suggested simultaneously both by our group[67] and by Falk and coworkers[98].

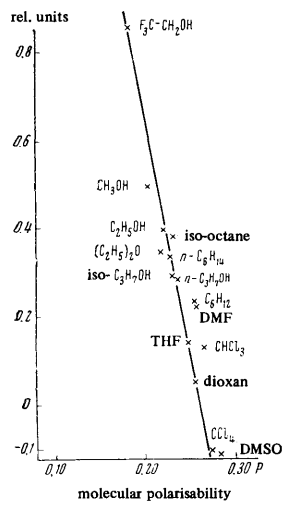

Figure 6.

Some Comments on the Term Aromaticity

We have just seen that measurements of the Faraday effect on the one hand and the knowledge of electronic structures on the other permit the determination of the relative aromaticity of the molecule by a method which is extremely similar to that employed in NMR, i.e. on the basis of the ring current concept.

However, it is quite evident that aromaticity does not always imply the presence of a ring current. Organic chemists will recall the tendency of the molecule to undergo nitration and sulphonation, while to others aromaticity implies the equality of bond lengths, high stabilisation energy, enhanced diamagnetic anisotropy, ultraviolet absorption very close to the visible region, and finally intense spin delocalisation (in ions and radicals). Nevertheless, it appears clear that the word aromaticity has lost any kind of simple significance and that we are unable to give it a true definition. An additional difficulty arises because we cannot measure the aromaticity of the molecule and even relative scales based on the measurements of various chemical and physical properties are not absolutely consistent.

From our standpoint, the time has now come to reject the use of the term aromaticity in order to eradicate from speech and print the ambiguity which consists in the postulate that "aromatic means benzene-like and conversely". In fact we have already seen that certain substituted benzenes characterised by a low value of E and a large gradient G cannot be classified as aromatic. Our suggestion that the term aromatic be rejected should also be welcomed because there exist numerous prefixes (non-, anti-, quasi-, pseudo-, homo-, ...) to this term. Clearly "the time is now right" for this. However, as mentioned by Coulson[99], the problem does not consist in finding a new word to replace the term aromaticity: it appears preferable to introduce a series of new concepts such that each should refer to one of the numerous chemical or physical properties the sum of which makes it possible to comprehend the essential features of aromaticity. On the basis of these considerations, we suggest that the concept of "potential strobilism" be adopted to describe the property measured both in connection with the Faraday effect and in NMR in studies on planar cyclic molecules with delocalised π electrons, i.e. when there is a ring current. Thus the strobilism has a potential existence in the molecule and can be discovered by the investigator by applying an external magnetic field. Since the strobilism is a potential property of the molecule in an unperturbed state, one may postulate a direct relation between it and the electronic and geometrical characteristics of the ground state: the distribution of both σ and π electrons, group symmetry, etc.

In conclusion[81] we should like everyone to be clear about the essential nature of our demarche: physicists and chemists observe different effects of "aromaticity"—a pleasant smell, capacity for nitration and sulphonation, a ring current, magneto-optical exaltation, and diamagnetic resonance energy (incidentally this is more of a mathematical term). However, no one can answer the problem whether or not these are consequences of the same property.

In the first place it is extremely desirable to define and express quantitatively the information which each particular method can yield. The various refined concepts will be combined spontaneously provided this is possible in principle.

VI. THE FARADAY EFFECT AND THREE-DIMENSIONAL CONJUGATION

We have already seen that the Faraday effect makes it possible to observe and analyse very refined phenomena of classical electronic delocalisation. However, it must

be emphasised that other methods also allow this—naturally with varying success. However, there is one field where the magnetic rotation of polarisation occupies a privileged position and we should like to devote a few lines to this. Whilst attending in 1967 a seminar in Paris held by Prof. Heilbronner, we heard for the first time of the phenomenon of "three-dimensional conjugation". The exceptionally unusual ultraviolet spectroscopic behaviour of 5,6-diphenylnaphthacene or rubrene was discussed: it exhibits an anomalously large bathochromic shift compared with naphthacene, although it is known that owing to steric hindrance the phenyl groups in the 5- and 6-positions are virtually perpendicular to the plane of the polyacene. It followed from the discussion that the magnitude of the observed effect can be accounted for only by the axial overlapping of the $2p_z$ orbitals of the benzene rings, which imparts to the molecule a three-dimensional resonant structure. We immediately wished to discover whether or not this phenomenon can be observed by means of the Faraday effect and, apart from rubrene, concentrated attention on simpler molecules where three-dimensional conjugation might be expected on general grounds—for example cyclo-octatetraene. This compound exists in the form of a "tube" with D_{2d} symmetry; the carbon–carbon bonds are alternately 1.50 and 1.35 Å long, which indicates the absence of delocalisation of the ring π electrons. Thus, using the general relations of the Faraday effect, we should obtain an experimental molecular magnetic rotation lower than or at least equal to the theoretical value (821 μrad) obtained from additivity. However, in fact the experimental rotation (1008 μrad) exceeds by 187 μrad the expected value. In the present state of our knowledge, such appreciable exaltation of the magnetic rotation compared with the value observed for benzene (182 μrad) can only be explained by three-dimensional conjugation analogous to that in the case of rubrene. Together with Chalvet[100], we succeeded in showing that this kind of exaltation of the Faraday effect corresponds to an overlap integral $S(2p_\sigma, 2p_\sigma)$ smaller approximately by a factor of 2 than for rubrene. This agrees satisfactorily with the intramolecular distances in the compounds under discussion.

Preliminary results of this kind led us to attempt the use of the Faraday effect for the solution of problems in conformational analysis. There are no literature data on the geometrical structure of cyclo-octa-1,4-diene at 20°C. This molecule can exist either in the chair or in the boat form or can oscillate rapidly between them. However, the experimental molecular magnetic rotation is exactly equal to the theoretical value and apparently suggests that cyclo-octa-1,4-diene is planar at 20°C. This is one of the most exciting fields of study for the Faraday effect. So far we have not investigated classical molecules with a geometry allowing possible three-dimensional conjugation (we may refer to Daudel[101]) in view of the lack of the necessary specimens. We hope that our readers will include chemists who will become interested in the possibility of investigating three-dimensional conjugation using the Faraday effect and will be kind enough to get in touch with us in connection with this problem.

VII. DONOR–ACCEPTOR σ-BONDS

Previously we considered in detail how electron delocalisation in diamagnetic compounds containing only normal covalent bonds influences the Faraday effect. Deviations from additivity are observed also when one is dealing with a molecular structure containing a coordinate bond and we shall now discuss the most important features of this phenomenon. As early as 1957, Laurent was the first to undertake a series of studies[102–105] on the electronic nature of the coordinate bonds in compounds of boron halides (Lewis acids) with bases. Complexes of this type should indeed be investigated first, since they provide a rare example of a coordinate bond of purely σ type. Gallais and Laurent suggested that the formation of a $(D^+ - {}^-A)$ coordinate bond (using Lowry's notation) between a base (LMND) and an acid (XYZA) be characterised in terms of the magneto-optical constant equal to the difference $\Delta\rho$ between the molecular magnetic rotation of the complex and the sum of the molecular quantities referring to the pure initial compounds:

$$\Delta\rho = (\rho)_M(\mathrm{LMND^+ - {}^-AXYZ}) - [(\rho)_M(\mathrm{LMND}) + (\rho)_M(\mathrm{AXYZ})] .$$

Table 14.

Compound	Δρ, μrad	Compound	Δρ, μrad
$F_3B \cdot NR_3$	−506	$R_3Al \cdot PR_3$	− 94
$Cl_3B \cdot NR_3$	−140	$Br_3Al \cdot PR_3$	+ 79
$F_3B \cdot PR_3$	−535	$R_3Al \cdot OR_2$	+ 17
$Cl_3B \cdot PR_3$	−164	$Br_3Al \cdot OR_2$	− 33
$F_3B \cdot OR_2$	−350	$R_3Al \cdot SR_2$	+ 49
$Cl_3B \cdot OR_2$	− 23	$Br_3Al \cdot SR_2$	+ 86
$F_3B \cdot SR_2$	−350	$R_3Ga \cdot NR_3$	−130
$Cl_3B \cdot SR_2$	− 26	$R_3Ga \cdot PR_3$	−200
$Br_3Al \cdot NR_3$	−234	$R_3Ga \cdot OR_2$	− 85
$Br_3Al \cdot NH_3$	+ 35	$R_3Ga \cdot SR_2$	− 52

The important findings arising from such a treatment are the virtually permanently negative sign of $\Delta\rho$ and its large absolute value (Table 14). The analogous studies for aluminium compounds by Gallais and de Loth[31] and for gallium compounds by Laurent et al.[106] made it possible to extend the initial conclusions. Usually the absolute values obtained for $\Delta\rho$ were lower than those measured by Laurent for complexes based on BF_3. The authors concluded that, when a covalent bond leads to a negative value of the magneto-optical constant as defined above, the most likely reason is donor–acceptor interaction. At the same time it is evident that $\Delta\rho$ reflects not only the rotation due to the donor–acceptor bond but also the magneto-optical effect associated with all the changes occurring when the donor atom is attached to the acceptor atom. We endeavoured to separate the various factors contributing to $\Delta\rho$ and attempted to specify in each case the corresponding effects in order to isolate in a pure form from $\Delta\rho$ the magnetic rotation $\rho(D^+ - {}^-A)$ due to the donor–acceptor bond[107]. This is particularly necessary, since the negative sign of $\Delta\rho$ does not correspond to the formation of diamagnetic complexes. It has been shown[108,109] that purely magnetic rotation due to the $(D^+ - {}^-A)$ σ bond should be positive. The considerable decrease of magnetic rotation is due to secondary effects in the formation of such a bond. A complete examination of the secondary factors governing the change $\Delta\rho$ leads not only to an estimation of the purely magnetic rotation due to $(D^+ - {}^-A)$ bonds but also to a fairly complex analysis of the coordination phenomenon as a whole. More precisely, the postulate that $\rho(D^+ - {}^-A) \geqslant 0$ makes it necessary to estimate in each specific case the importance of the secondary factors and poses the problem of the multiplicity of the $(D^+ - {}^-A)$ bonds.

The most permanent of the secondary factors which may be taken into account directly in the Faraday effect is the marked decrease of the magnetic polarisability when a free electron pair of the donor atom is converted into an electron pair involved directly in bond formation. This is particularly important since donor–acceptor bonds are usually characterised by considerable charge transfer[110,111]. This marked decrease of polarisability, which leads to a decrease of the magnetic rotation in certain cases, is sufficient to account for the negative sign of $\Delta\rho$. As an example, we shall consider the compounds $R_3Al.PR_3$ ($\Delta\rho$ = −94 μrad). We know the contribution $\rho(d\mathrm{P})$ by the free electron pair of the donor atom (+255 μrad) assuming sp^3 hybridisation of the phosphorus atom[39]. Assuming that at the instant of formation of the complex, the free electron pair is replaced by the paired bonding electrons, we find that the rotation due to the ($P^+-{}^-Al$) bond is

$$\Delta\rho = 255 + \rho(P^+-{}^-Al) = -94 \ \mu\text{rad},$$
$$\rho(P^+-{}^-Al) = -94 + 255 = +161 \ \mu\text{rad},$$

i.e. is positive.

Table 15.

Compound	$-\rho(d_P)$	$\delta G^{C_{3v}}_{D_{3h}}$	$-\pi_{AXYZ}$	$\rho(D^+-{}^-A)$	$\Delta\rho$
$R_3Ga\cdot OR_2$	0	−85	0	0	− 85
$R_3Ga\cdot NR_3$	− 86	−85	0	+ 41	−130
$R_3Ga\cdot PR_3$	−255	−85	0	+140	−200
$Cl_3B\cdot OP_2$	0	−23	0	0	23
$Cl_3B\cdot SR_2$	− 52	−23	0	+ 49	− 26
$Cl_3B\cdot PR_3$	−255	−23	0	+114	−164

However, the above considerations are not sufficiently general, because many factors which frequently play a major role have not been taken into account. For the case of a purely σ donor–acceptor bond, we shall recall the most important of these: (a) the formation of the complex is frequently accompanied by a change in hybridisation and in the partial ionic character; we shall denote this by δG in order to recall the change in the symmetry group; this applies equally to a Lewis base and acid; (b) the multiplicity of the normal covalent bond (π_{AXYZ} and π_{DLMN}) in isolated donor and acceptor molecules is also altered at the instant of the formation of the complex§. Table 15 shows how important are these two factors. We shall consider initially the compound R_3GaOR_2 for which $\Delta\rho$ = −85 μrad. Then, as incidentally for all complexes containing an ($O^+-{}^-A$) bond, one may postulate that the electron pair of the oxygen atom is involved in the formation of this bond and hardly plays any [other] part; earlier we concluded that even the magnetic rotation due to the lone electron pair of the oxygen atom is close to zero[39]. In this situation [all the (GaR) bonds are undoubtedly single] one must postulate that the decrease of the magnetic rotation in the Faraday effect expressed by $\Delta\rho$ can only be due to factor a [when $\rho(O^+-{}^-Ga) \geqslant 0$ is postulated]. Essentially the sp^2 hybridisation of the gallium atom in GaR_3 monomer becomes close to the sp^3 hybridisation in the complex. This change is accompanied by a decrease in the polarisability of the (Ga–C) σ bonds, which, as we have shown earlier, always reduces the magnetic rotation. Expressing this by

$$(|\delta G|^{C_{3v}}_{D_{3v}}),$$

we find that in this case δG = −85 μrad.

If we consider further other gallium compounds ($R_3Ga.PR_3$, $R_3Ga.NR_3$), the use of the value of δG obtained for the second factor and the magnetic rotations due to the lone electron pairs of the phosphorus (about 255 μrad) and nitrogen (about 86 μrad) atoms yields positive values for the true rotation due to the ($P^+-{}^-Ga$) and ($N^+-{}^-Ga$) bonds¶. Similar considerations apply also to the compound $Cl_3B.OR_2$, for which $(\delta G|^{C_{3v}}_{D_{3h}}) = 2-23$ μrad†. In general this result is consistent with the higher magnetic polarisability of the (Ga–X) bond compared with (B–X). If we now substitute the value −23 μrad in the expression for $\Delta\rho$ for the compounds $Cl_3B.SR_2$ and $Cl_3B.PR_3$, we obtain for the true magnetic rotation due to the ($S^+-{}^-B$) and ($P^+-{}^-B$) bonds positive values of ρ (+49 and +114 μrad), which are lower than the corresponding contribution $\rho(d\mathrm{S})$ and $\rho(d\mathrm{P})$ due to the lone pairs.

The effect of the factor b (the multiplicity of the bonds in isolated molecules of the donor or acceptor) is clearly shown in complexes based on BF_3. It has long been known that $\Delta\rho$ for such complexes is much higher than for the analogous complexes with BCl_3.[102]

Table 16.

Compound	$-\rho(d_D)$	$\delta G^{C_{3v}}_{D_{3h}}$	$-\pi_{AXYZ}$	$\rho(D^+-{}^-A)$	$\Delta\rho$
$F_3B\cdot OR_2$	0	−23	−327	0	−350
$F_3B\cdot SR_2$	− 52	−23	−327	+32	−370
$F_3B\cdot PR_2$	−255	−23	−327	+70	−535

Table 16 shows how $\Delta\rho$ may be used to obtain the constants for the ($D^+-{}^-A$) bonds for certain BF_3 complexes. Assuming that to a first approximation the factor

$$|\delta G|^{C_{3v}}_{D_{3h}},$$

is constant for both BF_3 and BCl_3, the formation of $F_3B.OR_2$ will differ from that of $Cl_3B.OR_2$ only due to the disappearance of the double bond character of the (F–B) bonds on transition from the isolated BF_3 molecule to the complex‡. This process leads to a decrease of the magnetic rotation by 327 μrad, which agrees only in order of magnitude with the real rotation (416 μrad) observed, for

§ The bases NR_3, PR_3, OR_2, and SR_2 have been investigated; evidently π_{DLMN} is zero in all cases. We also suggest that δG is negligibly small for these bases, because there is virtually no change in hybridisation.

¶ For example $\rho(N^+-{}^-Ga) = \Delta\rho + \rho(d_N) - \delta G = -130 + 86 + 85 = +41$ μrad.

† When the multiplicity of the (B–Cl) bond in an isolated BCl_3 molecule is neglected.

‡ The considerable double bond character of the B–X bond has been confirmed by the large changes in the asymmetry parameter (η = 45% for B–Br and η = 45% for B–I in BX_3 with respect to X, which corresponds to amounts of double bond character of 13.3 and 15.6%)[127,188] (Editor).

example, for $R_nBF_{3-n}.NR'_3$.[112] Thus we have to recognise the existence in this case, as incidentally also in certain others discussed below, of a third factor responsible for the high negative value of the observed $\Delta\rho$. We now substitute $\pi_{BF_3} = -327$ μrad in the expression for $\Delta\rho$ for the compounds $F_3B.SR_2$ and $F_3B.PR_3$; this leads to positive values of $\rho(S^+-{}^-B)$ and $\rho(P^+-{}^-B)$ lower than the corresponding $\rho(d_S)$ and $\rho(dp)$. It is interesting to note that the results for the $(P^+-{}^-B)$ bond were obtained[113] from a study of the magneto-optical properties of the compounds $H_3B.PR_3$ by means of an analysis which differs significantly from that described above. In the compounds investigated $\Delta\rho \simeq -480$ μrad and the relative contributions by factors which must be taken into account are $-\rho(d_P) = -255$ μrad, $(\pi_{AXYZ}) = 0$, and $-\delta G = -300$ μrad. The resulting value of the modulus $\rho(P^+-{}^-B)$ is positive (+85 μrad) and is the same as that found from a series of $F_3B.PR_3$ compounds. Nevertheless there is a significant difference between the contributions of the factors constituting $\Delta\rho$ on passing from $F_3B.PR_3$ or $Cl_3B.PR_3$ to $H_3B.PR_3$: in the latter case the δG term is very large, so that the homopolarity of the (B–H) bond entails a high value of the b_{BH} coefficient[50] and a large change in it on passing from the hypothetical BH_3 molecule to the BH_3 group in the real complex. In conclusion of the first part of the discussion, we may note that we appear to be in a position to explain in specific cases the order of magnitude of the factors contributing to $\Delta\rho$ assuming that the contribution by the donor–acceptor bond in the compounds investigated is positive. The problem of the multiplicity of this bond has clearly remained outside the discussion. The observed large negative values of $\Delta\rho$ can be reasonably accounted for by factors characterised by the negative quantities $-\rho(d_D)$, $-\pi_{AXYZ}$, and $-\delta G$, the last sometimes predominating.

Table 17.

Compound	$-\rho(d_D)$	$\delta G^{C_{3v}}_{D_{3h}}$	$-\pi_{AXYZ}$	$\rho(D^+-{}^-A)+\pi$	$\Sigma(D\cdot A)\ \Delta\rho$
$R_3Al\cdot OR_2$	0	−50	0	+ 67	+17
$R_3Al\cdot SR_2$	−52	−50	0	+151	+49
$R_3Ga\cdot SR_2$	−52	−85	0	+ 85	−52

The general analysis would have to be continued further if there existed a theoretical possibility of a multiple donor–acceptor bond. In the series of compounds in which we are interested such a possibility would exist theoretically if the d orbitals of the acceptor atom could effectively overlap the sp^3 hybridised orbitals of the donor atom. For boron–oxygen and gallium–oxygen bonds, this is excluded on energetic grounds, but is possible for aluminium–oxygen, aluminium–sulphur, and gallium–sulphur bonds. We shall consider from this standpoint the $(O^+-{}^-Al)$ bond in $R_3Al.OR_2$ (Table 17). One lone electron pair on the oxygen atom is involved in the formation of the donor–acceptor bond and the other occupies the $(2s, 2p)$ hybrid orbital, which cannot overlap the $3d$ orbitals of the aluminium atom on symmetry grounds. However, the overlap integral $S(2p, 3d)$, although small (of the order of 0.5 eV) is not zero. Bearing in mind the previous postulates $[\rho(d_0) = 0]$, it follows that $[\rho(O^+-{}^-Al) = 0]$, and, assuming that $\delta G\left|{}^{C_{3v}}_{D_{3h}}\right.$ should be about −50 μrad, we find from the interpolation of the values obtained for boron (−23 μrad) and gallium (−85 μrad) compounds that we can write $\Delta\rho = +17 = \delta G + \pi(OAl)$, whence $\pi(OAl) \simeq 67$ μrad. This value of $\pi(OAl)$ appears to be sufficiently high to reflect some multiplicity of the O–Al bond. In any case, if the $(O^+-{}^-Al)$ bond has some multiplicity, this is even more true of the $(S^+-{}^-Al)$ bond, where the overlap integral $S(3p, 3d)$ is numerically much larger than $S(2p, 3d)$. Indeed, for $R_3Al.SR_2$,

$$\rho(S^+-{}^-Al)+\pi(SAl)=151 \quad \mu\text{rad},$$

and, assuming that the rotation due purely to $(S^+-{}^-Al)$ must be less than or at least equal to $\rho(d_S) = +52$ μrad, we arrive at $\pi(SAl)$ of the order of 100 μrad. This may be interpreted as an increase of the multiplicity of the coordinate bond in sulphur compounds which are isologous with oxygen compounds. Among gallium compounds there also exist examples where the $(D^+-{}^-Ga)$ bonds have a definite π character; this is possible for $R_3Ga.SR_2$ [from the standpoint of the overlap integral $S(3p, 4d)$]. According to Table 17, $\rho(S^+-{}^-Ga) + \pi(SGa) = +85$ μrad; assuming that $\rho(d_S) = +52$ μrad, one must postulate that $\pi(SGa)$ is at least 33 μrad.

Table 18.

Compound	$-\rho(d_D)$	$\delta G^{C_{3v}}_{D_{3h}}$	$-\pi_{AXYZ}$	$\pi(D^+-{}^-A)$	$\rho(D^+-{}^-A)$	$\Delta\rho$
$Cl_3B\cdot NR_3$	−86	−23	0	0	−31	−140
$F_3B\cdot NR_3$	−86	−23	−327	0	−70	−506

We have considered how it is possible to obtain the approximate magnitude of various factors contributing to the overall value of $\Delta\rho$, using a detailed analysis of the mechanism of the formation of the complexes. We emphasise yet again that a significant feature is the hypothesis that the actual magnetic rotation due to the δ or $(\delta+\pi)$ donor–acceptor bond must never be negative. There are, however, several examples for which analysis of $\Delta\rho$ within the framework of the assumptions made here precludes the assignment of a positive magnetic rotation to the donor–acceptor bond. Thus Table 18 shows that the data for the $Cl_3B.NR_3$ and $F_3B.NR_3$ molecules can yield negative $\rho(N^+-{}^-B)$ (−31 and −70 μrad). Possibly the calculation of $\rho(N^+-{}^-B)$ for these compounds is not sufficiently accurate because the rotation due to the (N–C) bonds in the complex differs appreciably from the corresponding value for the isolated NR_3 molecule. In reality, from the standpoint of the Faraday effect, the (N–C) bond is very sensitive even to the replacement of one R by hydrogen. For example, on going from tertiary to secondary and primary amines, there is an appreciable change in rotation[114]. Possibly the presence of the $(N^+-{}^-B)$ bond also affects $\rho(N^+-{}^-B)$, but at the present time we are not in a position to take this into account[115].

VIII. DONOR–ACCEPTOR ($\sigma + \pi$) BONDS

It is clear from the foregoing that the Faraday effect constitutes a physicochemical method which is especially sensitive in the study of donor–acceptor σ bonds on the

one hand and in the detection of π electrons (both localised and delocalised) on the other. Therefore the idea of applying this technique in the investigation of dative bonds, where there is a superposition of a donor–acceptor σ bond and one or several coordinate π bonds, in order to obtain evidence for the multiplicity of dative bonds is extremely attractive. When such a study was planned at the beginning of 1960, the literature of the period contained a relatively large number of papers where it was postulated that certain bonds are of the donor–acceptor $(\sigma + \pi)$ type. We undertook an investigation with the aid of the Faraday effect in order to contribute to the solution of the problem.

A. THE (PO) BOND IN COMPOUNDS OP(XYZ)

The nature of the PO bond like that of oxygen–nonmetal bonds, has been the subject of discussion in the literature from the standpoint of the currently most popular hypotheses and its treatment reflects the general ideas which are dominant at the given time. Initially this bond was thought to be double[116] but later it became described as of the donor–acceptor type when the octet concept prevailed[117]. With progress in the study of geometrical structures, it was, however, found that the (PO) bond is too short to be regarded as single and it became represented as having a definite multiple character[118], which led many investigators to the conclusion that it has double bond character. However, numerous observations are in poor agreement with this somewhat schematic concept. In particular the fact that molecular magnetic rotations of $OP(OH)_3$ and $OPCl_3$ are lower than the corresponding values for $P(OH)_3$ and PCl_3 was observed long ago by Voigt[119]. However, all our knowledge about π bonds shows that π electrons exhibit very high magneto-optical activity and therefore it is quite incomprehensible why $OP(OH)_3$ should have a smaller rotation than $P(OH)_3$ if its structure were indeed represented by the formula $O = P(OH)_3$. The same remark is valid also for any comparisons between OP(XYZ) and P(XYZ).[120] This conclusion inevitably leads to the structure O←P(XYZ) on the basis of numerous examples of complexes in which the formation of a donor–acceptor σ bond leads to an appreciable decrease of the magnetic rotation (cf. the previous section). We can now understand the causes underlying the problem formulated in this way, which we thought interesting to solve with the aid of the Faraday effect. Starting in 1961, Labarre and Voigt undertook the synthesis and magneto-optical study of a large number of compounds of the type P(XYZ) and OP(XYZ).[121–123] Initially the results were interpreted on the basis of additivity, which should obtain in tervalent phosphorus compounds (molecules with covalent diamagnetic σ bonds)[36,37]. Indeed they discovered the relation $\rho = a + bI$, which was already discussed in Section III.[51] They succeeded, together with Gallais, in employing the method involving the resolution of the magnetic rotation of the compound OP(XYZ) into bond constants in order to determine the true magnetic rotation due to the (PO) bond[36,37]. It should be noted that all the geometrical and electronic factors which must be invoked to describe the addition of the oxygen atom to the P(XYZ) molecule were rigorously defined and numerically calculated with a high degree of accuracy[124,125].

Table 19 lists the values of ρ(PO) obtained and it is immediately seen that this quantity depends markedly on the nature of the atoms or groups of atoms attached to phosphorus. It was logical to relate certain changes to the parameters which describe the real electronic structure of the $(\sigma + \pi)$ bond using the classical procedure in quantum chemistry or more precisely to the multiplicity of this bond in our case. Initially we employed the results of Wagner's calculation[126], since the formal mathematical treatment was based on a model of the (PO) bond in which the σ and π bonds were treated as of the donor–acceptor type. Wagner calculated the relevant indices of the (PO) bonds, which ranged from zero for (OPR_3) to two for (OPF_3) (see Table 19).

Table 19.

Compound	p_π (Wagner's data)	p_π (authors' data)	ρ(PO), μrad
OPF_3	1.983	1.911	91
$OP(OR)F_2$	1.682	1.661	88
$OP(OR)_2F$	1.381	1.414	86
$OP(PR)_3$	1.079	1.165	82
$OP(OR)_2Cl$	1.115	0.983	77
$OP(OR)_2R$	0.720	0.778	66
$OP(OR)Cl_2$	1.151	0.621	55
$OPR_2(OR)$	0.360	0.391	40
$ORCl_3$	1.188	0.349	39
OPR_3	0	0.003	0
$OP(SR)_3$	—	0.004	0

In 1967 the existence of a simple and unambiguous relation between the true magnetic rotation ρ(PO) and Wagner's π-bond indices was demonstrated for the entire set of molecules investigated[36,37]. Although the corresponding curve had a maximum, M. C. Labarre, Voigt, and Gallais expressed doubts concerning certain experimental points.

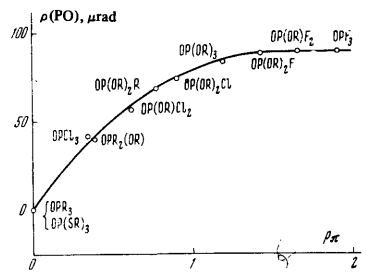

Figure 7.

Therefore Castan and Dagnac-Amans investigated in 1969[124] the electronic structure of OP(XYZ) using a formal treatment very close to Wagner's[126], but, in order to avoid a number of approximations and inaccuracies, they improved significantly the method of calculation. As in the method of Gallais and coworkers[48], the charge transferred via σ bonds was calculated using modified Pauling exponential functions[127]. The new values of the π indices are listed in Table 19 and Fig. 7 shows that the maximum about the existence of which doubts had been expressed has indeed disappeared. It is clear from the foregoing that the monotonic relation between ρ(PO) and p_π in Fig. 7 indicates that the (PO) bond is of the donor–acceptor $(\sigma + \pi)$ type.

B. THE (PS) BOND IN COMPOUNDS SP(XYZ)

The hopeful result from the study of the nature of the PO bond led us to further investigation of other bonds of the $(\sigma + \pi)$ type. For example, M. C. Labarre and Voigt[128,129] made an attempt to determine the nature of the (PS) bond in the compounds SP(XYZ). The data on molecular magnetic rotation made it possible to determine the true rotation due to the (PS) bond in each case and to demonstrate a considerable variation of ρ(PS) as a function of the substituents X, Y, and Z.[36,37] Measurements of the susceptibility[130], refraction[131], and dipole moments[132] confirmed the amplitude and direction of the deviations observed in the Faraday effect but the possible relation $\rho(PS) = f(p_\pi)$, analogous to that found above for ρ(PO) still cannot be obtained in an explicit form because the method of calculation of Castan and Dagnac-Amans is unsuitable for sulphur derivatives [difficulties associated with the calculations of the overlap integrals $S(3p_S, 3dP)$]. On the other hand the multiplicity of the (SO) bond in the compounds OS(XY) and $O_2S(XY)$ can be calculated by the method of Castan and Dagnac-Amans[20,133]. The variation of the calculated bond indices is in this case quite parallel to the variation of the true magnetic rotation due to the (SO) bond, as can be seen from Table 20 and Fig. 8. It should be noted that the method of calculation itself may be better than that proposed by Moffitt in 1950.[134] The calculations showed that there is no abrupt change in the electronic nature of the (SO) bond in the compounds OS(XY) and the same bond in the $O_2S(XY)$ molecule. From the common sense point of view, one may predict that for one sulphur–oxygen bond the variation of multiplicity is a monotonic function of X and Y.[115]

Table 20.

Compound	p_π	p(SO), μrad
OSF_2	1.602	109
SO_3	0.939	134
O_2SF_2	0.908	117
SO_2	0.871	161
$OS(OR)_2$	0.667	102
$O_2S(OH)E$	0.573	99
OSCl(OR)	0.338	73
$O_2S(OR)_2$	0.268	76
$O_2S(OH)_2$	0.237	82
$O_2S(OH)Cl$	0.119	35
$OSCl_2$	0.010	39
O_2SCl_2	0.001	0

Physical chemists and especially infrared spectroscopists have for many years given most contradictory interpretations for one of the donor–acceptor $(\sigma + \pi)$ bonds, namely the (NiP) bond in the tetrahedral complexes $Ni[P(XYZ)]_4$.[135] Even if it were possible to show by various methods that the characteristics of this bond vary appreciably as a function of P(XYZ), it would still be doubtful if such changes are determined by the variation of the contribution by π electrons while, that by σ electrons remains constant, or vice-versa, or finally whether the observed effect is an overall one. In a magneto-optical study of a large number of $Ni[P(XYZ)]_4$ complexes carried out in 1967 by Cassoux and coworkers, it was assumed *a priori* that the investigation may be performed by a method analogous to that employed for the analysis of the (PO) and (SO) bonds using the results of most thoroughly tested quantum-chemical procedures. However, even Ballhausen and Gray, the most outstanding specialists in this problem[136], were unable, as far as we are aware, to obtain a result which satisfied them. Cassoux and coworkers synthesised a large number of nickel complexes and measured the Faraday effect for them[137–140], and, using the principles of additivity and numerical analysis of various geometrical and electronic factors associated with the coordination of four P(XYZ) molecules to the nickel atom, found the true rotation due to the (NiP) bond in each complex. Depending on the nature of the atoms or groups of atoms X, Y, and Z, ρ(NiP) varies. However, it was found that there are in addition deviations of the dispersion of the magnetic rotation from the normal value (the definition was given at the beginning of the review), although the first absorption band in the ultraviolet spectrum is sufficiently distant from the wavelengths observed in the Faraday effect for the complexes to be regarded as necessarily having the normal dispersion (Table 21). This anomaly is well known to specialists in the Faraday effect in the *absorption* region and is characteristic of complexes of transition elements with a high symmetry (T_d and O_h).

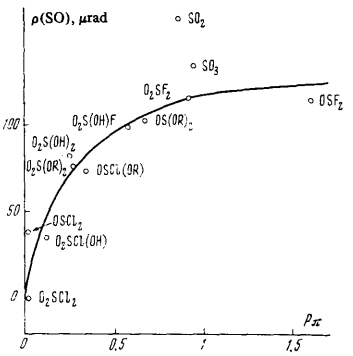

Figure 8.

Table 21.

Compound	ρ (Ni-P)	$\frac{\rho_{545}}{\rho_{578}}$	λ_{max}
$Ni(PCl_3)_4$	1266	1.20	315
$Ni[P(OR)Cl_2]_4$	1157	1.17	284
$Ni[P(OR)_2Cl]_4$	1019	1.16	265
$Ni[P(OR)_3]_4$	871	1.15	237
$Ni[P(OR)_2F]_4$	734	1.15	225
$Ni[P(OR)F_2]_4$	647	1.15	225
$Ni(PF_3)_4$	529	1.15	224

In this case the analysis must be performed not only in terms of the law of additivity but also in terms of the dispersion of the magnetic rotation.[16] Cassoux and coworkers in fact solved the problem in this way. Using Serber's formal treatment[141], they determined the dispersion curve in the region of transparency for A and B (both positive), characteristic of each of the complexes investigated. Then, using the values of A and B, they found the contributions to the magnetic rotation by the σ and π components of the

(NiP) bond[142-144]. It is significant that both contributions vary simultaneously and the multiplicity of the (NiP) bond is in all cases low and variable. These conclusions agree essentially with the results obtained by Bigorgne from infrared spectra[135].

There is yet another special case of a donor–acceptor bond to which a few lines should be devoted, namely the (NO) bond. The electronic structure of the NO_2 group was based for a long time on hypotheses involving mesomerism, i.e. the (NO) bond was regarded as simultaneously a donor–acceptor and a multiple linkage. In fact calculation in terms of such a model does not yield satisfactory results. Its authors asserted, on the basis of certain erroneous assumptions, that with its aid it is possible to obtain the correct dipole moments of such molecules as nitromethane. The reason for this was fortuitous agreement between calculation and experiment without taking into account the contribution by the lone electron pairs of the oxygen atom, which Coulson estimated to be 2D.[145] Therefore in 1967 Bonnafous continued the investigation of the electronic structure of the NO_2 group using this time not mesomeric hypotheses but the more logical Julg model[146]: the group is described in terms of a superposition of two normal (N–O) covalent bonds and a delocalised π system with four electrons: two from the sp^2-hybridised nitrogen atom and one $2p_z$ electron from each sp^2-hybridised oxygen atom. Under these conditions, LCAO calculation of the electronic structure using a calibration based on the ultraviolet spectrum[77] and an iterative procedure[48] yielded a new value of the dipole moment of the NO_2 group, in good agreement with the experimental moment, and also the corresponding absorption bands associated with the $\pi-\pi^*$ transition in the ultraviolet spectrum[147]. It follows from the results of the calculation that the (NO) bond between two atoms with markedly different charges is indeed multiple but the degree of charge transfer in the (NO) bond is 0.25 instead of 0.5 corresponding to the mesomeric concept. The Julg–Bonnafous model agrees most closely with data derived by physicochemical methods (dipole moments, ultraviolet spectroscopy, aromaticity, reactivity) for a large number of compounds, among which we may note nitroethylene[148], nitrobenzene and nitrotoluenes[94], nitropyridines[149], and others.

IX. THE FARADAY EFFECT AND CONFORMATIONAL ANALYSIS

There are certain exceptions from the law of additivity which now give rise to the possibility of investigating conformations with the aid of the Faraday effect. In this field the following important observations have been made: experimental magnetic rotation of cyclopentane, cyclooctane, cyclohexane, and their homologues (Table 22), showing deviations from additivity. In one case this maybe due to steric causes and in another to deviations from a planar structure, which are characteristic of cyclohexane derivatives with fixed carbon atoms in the ring (boat or chair). On general grounds, the decrease of magnetic polarisability in the Faraday effect must be attributed to the characteristics of the configuration, an increase in the barrier to rotation, etc. The law of systematic additivity is known to be fully valid in the absence of steric hindrance for cyclic germanium and silicon compounds with a confused conformation ("pelote).[150] In other cases the strain in the system inevitably leads to experimental magnetic rotations much lower than the theoretical values based on additivity. For example, for the compound

the interaction between the π-electron system of the (C=O) bond and the vacant 3*d* orbitals of the silicon atoms causes a 70% deviation from the theoretical additive value[150]. It is interesting to note that no deviations are observed when the silicon atom is replaced by germanium (this is consistent with self-evident considerations) or by carbon, which indicates that the intensity of the (2*p*, 4*d*) interactions is low. This result agrees fully with the literature: indeed, if the energy levels of the atomic 2*p* orbitals of the carbon atom are much lower than the corresponding levels of the 4*d* orbitals of the silicon atom, the required overlap integral is negligibly small [in particular, the interatomic distances are also large in this case; calculation shows that $S(2p_C, 4d_{Ge}) \simeq 0$]. The foregoing is fully consistent with the semiconductor properties of macromolecules of the type[151]§.

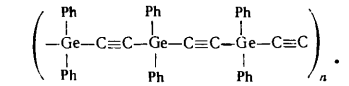

Table 22.

Compound	$[\rho]_M^{exp}$, μrad	$[\rho]_M^{theor}$, μrad	Compound	$[\rho]_M^{exp}$, μrad	$[\rho]_M^{theor}$, μrad
Cyclopentane	349	365		296	303
Cyclopentene	406	427		361	376
Cyclohexane	405	428		421	449
Cyclohexene	451	490		498	522
Cyclo-octane	570	584			
Cyclo-octene	632	646			

One can also postulate that the Faraday effect permits a clear distinction between, for example, the axial and equatorial positions of substituents in cyclohexane, as follows from the depolarisation of diffuse Rayleigh scattering. M. C. Labarre showed that the magnetic rotation of the $C_6H_{11}X$ molecule is a maximum for the equatorial configuration. For the simplest derivatives of cyclohexane, the size of the change in magnetic rotation can reach 15% (X = CH_3, Cl, OH, or NH_2). One can show that the substitution of X = PCl_2 or $P(OR)_2$ takes place preferentially in the axial position in view of the appreciable interaction of the ($P^+-{}^-Cl$) pair with the axial ($C^+-{}^-H$) pair (carbon in the 3-position)[152]. This was quite recently confirmed by electron diffraction for the compound $C_6H_{11}PCl_2$.

§ It is noteworthy that analogous compounds with silicon atoms in the chain also exhibit semiconductor properties. However, the activation energy for conduction in germanium polymers is smaller by a factor of 2 (0.6 and 1.2 eV). The conduction mechanism has still not been explained satisfactorily[189] (Editor).

At the end of the section we must emphasise that there exist two problems in conformational analysis where the Faraday effect can apparently not assist in any way: the classical *cis–trans* isomerism and hydrogen bonding. As regards the first problem, quite hopeful results were obtained by Foehr and Fenske (1949), who made measurements for 2-*cis*- and 2-*trans*-isomers of butadiene (the difference between the magnetic rotations is 7%, [153] which, according to Mulliken's treatment [154], must be attributed to the presence of *cis*- and *trans*-isomers). However, the studies by Castan [155] on a number of acids and esters of α-unsaturated acids showed that the difference between the magnetic rotations of the *cis*- and *trans*-isomers does not exceed 2%, which is quite insufficient to obtain definite results. The same may be said about the studies of hydrogen bonding by the Faraday effect method from the results of the measurements by Gallais and Wolf [156,157] on solutions of various peroxides in chloroform. They observed that the molecular magnetic rotation is insensitive to the presence of the (O...H) hydrogen bond in the series of compounds investigation. On the other hand, analysis of the aromaticity of various phenols and their ethers with the aid of the Faraday effect demonstrated its insensitivity to intramolecular hydrogen bonding.

X. THE FARADAY EFFECT AND THE STUDY OF NON-ISOLATED COMPLEXES IN SOLUTIONS

Earlier we showed that, with certain exceptions, the magnetic rotation in the Faraday effect corresponds exactly to additivity. However, this applies equally to mixtures of substances, at least when there are no solute–solvent interactions. Then, according to the Verdet law,

$$\rho = \sum_0^k \rho_k v_k \left(c \sum_0^k v_k = 1 \text{ ml} \right),$$

where ρ is the Verdet constant for the mixture of substances and ρ_k is the constant for each component. The above relation has been the subject of numerous refinements and tests; we may quote as historical references the work of Schonrock [158], de Mallemann and coworkers [159,160], Hori and Okazaki [161], and Andersen and Asmussen [162]. We may suppose that, when deviations from additivity are observed, we are dealing with chemical interactions between the various substances in the mixture. Numerous deviations from additivity observed in the work of Gallais and coworkers between 1936 and 1952 make it possible to identify and detect non-isolatable complexes, which is sometimes impossible by other methods, particularly polarography. We may point to tetraiodomercurates [163], iodobismuthates [164], thiocyanatomercurates [165–167], bismuth thiosulphates [168], bismuth(III) thiocyanates [169], etc. as examples. In this case the Faraday effect permits a reliable detection of the complex in the mixture [170,171]. The method can be also successfully employed to refine the mechanisms of the neutralisation of acids by bases [172]. Recently R_nGaCl_{3-n} complexes with aliphatic amines were successfully investigated [173].

XI. THE FARADAY EFFECT AND VAN VLECK FERROMAGNETISM

Finally we shall consider a completely specific case of deviations from additivity. It has now been known for 100 years that, despite its diamagnetism, the covalent compound $TiCl_4$ exhibits a negative Faraday effect both in the liquid [174–176] and in the vapour [177]. This is also true of $TiBr_4$. [178] However, as far as we are aware, up to 1968 no other example of molecules with an electron deficit showing an analogous behaviour in its magnetic rotation has been discovered, except for the permanganate ion [179], for which, according to the Faraday effect, a temperature independent van Fleck paramagnetism could be postulated [180]. Stone [181] showed that the positions of the ground and excited electronic energy levels explain the negative paramagnetic contribution to the magnetic rotation. For $TiCl_4$, this paramagnetic contribution may be dominant when certain postulates are made. The studies by Gervais et al. [108] on a series of covalent titanium(IV) compounds led to the conclusion that the (TiO) bond is also characterised by a negative constant for magnetic rotation and resembles in this sense the (TiCl) and (TiBr) bonds. In a study on the magneto-optical and magnetic properties of $TiCl_3OR$, Choukroun and Gervais [182] found that the $OTiCl_3$ group is responsible for paramagnetism of the van Vleck type due to the (TiCl) and (TiO) bonds. Gervais interpreted [183] additional studies on the Faraday effect in the visible region for the compounds $Ti(OR)_4$ from the standpoint of the dispersion associated with the TiO_4 group,

$$\frac{v^2}{(v^2 - v_0^2)^2}$$

in accordance with the term V_A in Serber's formula [141].

In the latest studies by Gervais and coworkers, the complexes of $TiCl_4$ [109] and $ROTiCl_3$ [184] with various alkyl orthotitanates were investigated. The study of the magneto-optical properties in the transparency range of complexes of transition elements with a high degree of symmetry must be accompanied by measurements in the absorption range. A monograph by Schatz and MacCaffery [16] deals with the Faraday effect in the absorption region.

---o0o---

Thus the Faraday effect in the transparent region constitutes a characteristic physicochemical method capable of solving important problems in structural chemistry. The overall molecular magnetic rotation may be resolved on the basis of the additivity of the properties of matter into a series of components—naturally within the framework of certain postulates. An analogous assignment of various characteristic constants to definite chemical bonds is used also in other spectroscopic methods. On the other hand, all experimental deviations from additivity provide an effective means for investigating a wide variety of problems such as the delocalisation of π electrons in conjugation, the structure of donor–acceptor (σ) and ($\sigma + \pi$) bonds, molecular conformation, and finally temperature-independent paramagnetism when a transition element is involved in certain bonds.

This review presents the results of recent work on the nature of the Raman scattering of light and on the relation between the parameters of the Raman lines and other molecular constants; the problems encountered in applying line intensity data to studies of the interaction of atomic groupings in organic molecules are discussed in detail. Various types of conjugation are considered, including the effect of substituent atoms on π-bond systems (with special reference to the position of the atoms in the Periodic Table), and the possibility of characterising molecular fragments in the presence and in the absence of conjugation. 328 references.

I. INTRODUCTION

The study of mutual interactions of atomic groups in polyatomic molecules is one of the most important problems in organic chemistry. This approach offers a relatively compact description of a vast multitude of experimental data, and thus enables available data to be applied more effectively to the production of compounds possessing desired properties. It is no exaggeration to say that if the properties of complex molecules could be described by a simple additive scheme the whole of organic chemistry would be reduced to a set of tables of increments, similar to the table of refractive index increments. In practice, however, the number of compounds showing specific properties is almost inexhaustible —this arises from the mutual interactions of atomic groups, which are difficult to study partly because of the complexity of the overall picture and partly because of the limitations of the various methods of investigation. It is desirable, therefore, to carry out combined physical and chemical studies, including atomic vibration spectroscopy (Raman and infrared spectra).

The Raman spectrum consists of a set of lines with frequencies $\nu - \omega_m$, in the vicinity of the exciting line ν. The normal vibration frequencies ω_m of the atoms in the molecule can be used to determine the elastic coefficients of the chemical bonds and the interaction coefficients.

Recent advances in the techniques of Raman spectroscopy—in particular the advent of spectrometers using laser radiation (see Refs. 1-3)—have considerably extended the scope of the method. Spectra can now be obtained from crystalline powders [4-8], polymers [9,10], coloured compounds, and also from samples available in very small quantities (a few mg, and in some cases as little as 0.001 mg). [6,11-13] Line intensities have been measured with solid [5,7] and gaseous samples, and the resolution of closely spaced lines has been improved (see for example Fig. 1). The use of laser light facilitates measurements at low frequencies (see Fig. 2) and allows fast processes to be studied with measurement times of the order of a millisecond [14].

Contrasting the relative advantages of Raman and infrared spectroscopy, we note that the strongest lines in the Raman spectra of symmetrical molecules are those due to totally symmetric vibrations. In keeping with their polarisation, they show little broadening associated with a latent or apparent rotational structure [15,16], and their half-width usually lies in the range 2-20 cm^{-1}. [16-18,24] Conversely, the strongest bands in infrared spectra are those due to antisymmetric vibrations, and also those of strongly polar bonds, which are broadened not only by the rotational motions of the molecules but also by the greater sensitivity of their frequency to intermolecular interactions.

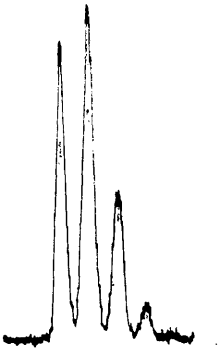

Figure 1. Fine (isotopic) structure of the ~460 cm^{-1} line of CCl_4 at 77°K.

Considering the differentials of the dipole moment $d\mu/dQ_m$ and $d^2\mu/dQ_m^2$ (where Q is the normal nuclear coordinate), we may conclude that the stronger an infrared spectral band is, the more likely it is to be broadened in the case of liquids [19]. Furthermore, overtones are relatively more intense in infrared spectra, and they give rise to more overlapping lines.

Whereas the frequencies observed in infrared and Raman spectra are largely duplicate information, the same is far from being true of the line intensities. It must be admitted, however, that most workers report only qualitative assessments of the intensity ratio of Raman lines for individual spectra: these are useful for assigning the lines, but they cannot be used to compare the lines of different compounds. A universal, objective scale of molar intensities, proposed [17] in 1940, defined the rational conditions for a quantitative comparison of the intensities of lines of different compounds, and made it possible to examine different groups of organic compounds.

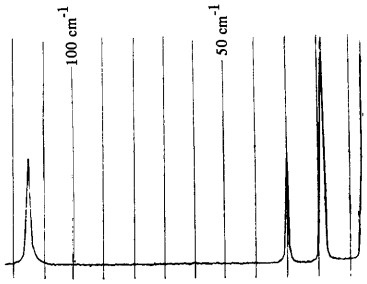

Figure 2. HgI_2 spectrum (He–Ne laser spectrometer). Curves kindly supplied by Dr. E. da Silva (France).

Molar intensity measurements are reproducible, and are an important characteristic of Raman lines. They offer useful additional information on the structure of molecules, on the properties of chemical bonds, on the mutual effects of atomic groups in complex molecules, on electronic excitation levels, on the vibrational modes associated with particular lines [15,16], and on the quantitative composition of mixtures of compounds [17,20,21,24]. Many interesting relationships have been established, and it has been shown that the intensity is one of the parameters most sensitive to conjugation.

This review is particularly concerned with applications of line intensity measurements to studies of the interaction of atomic groups: the relevant literature will be surveyed in the sections devoted to the nature of Raman scattering and to the interrelation between line intensity and other molecular constants.

II. GENERAL VIEWS ON THE NATURE OF RAMAN SCATTERING. SEMICLASSICAL THEORY

The basic Raman parameters can be described by classical theory, by quantum mechanics, or by quantum electrodynamics. Depending on the circumstances, it may be preferable to use one or other of these approaches, or to combine some of their features.

In studies of the line intensities (I_m) of colourless compounds it is usually possible to confine the discussion to the simplest variant of the classical theory, in which one considers the vibrations of the dipole $\mu(t)$ resulting from the polarisation of the electronic shell of the molecule by the field of the light wave. The intensity of the Raman lines depends on the depth of modulation of $\mu(t)$, produced by the vibrations of the nuclei, defined as $\frac{\partial\alpha}{\partial q}$. q_0 for diatomic molecules, and $\frac{\partial\alpha}{\partial Q_m}$. Q_{0m}, for polyatomic molecules, where α is the polarisability of the molecule, q is the change in interatomic distance, q_0 is the amplitude of the vibrational ground state, Q_m is the m-th normal coordinate of the nucleus, Q_{0m} and ω_m are the corresponding amplitude and frequency [22]. One can avoid the explicit use of the differentials of α by considering that I is defined by the difference ($\Delta\alpha$) between the values of α at the two extreme positions of the vibrating atoms; this gives almost the same result (slightly more accurate, in fact) [23]. For a discussion of the convergence of the power series $\alpha(Q)$ and of the contribution from the higher differentials of α the reader is referred to Krushinskii [59].

The relative intensity I_m of the Raman line of frequency $\nu-\omega_m$ (or, more briefly, of the "line ω_m") under normal experimental conditions† is proportional to

$$(\nu-\omega_m)^4(45\,\bar{\alpha}_m'^2+13\,b_m'^2)\,Q_{0m}^2; \qquad (1)$$

where ν is the frequency of the exciting light, $\bar{\alpha}'_m$ and b'_m are the mean value and the anisotropy of the tensor $\frac{\partial\alpha}{\partial Q_m}$. [22] A more detailed treatment can be found in the literature [22,25,26,27].

In the semi-classical theory of Raman scattering [28–30] each Cartesian component (x, y, z) of the differential of α with respect to Q_m is given as the sum of contributions from all the electronic excitation levels e:

$$\alpha'_{xm}=\text{const}\sum_e\left[\frac{f'_{xe}}{\nu_e^2-\nu^2+i\nu\gamma_e}-\frac{2f_{xe}\nu_e\nu'_e}{(\nu_e^2-\nu^2+i\nu\gamma_e)^2}\right], \qquad (2)$$

where the prime denotes a differential with respect to Q_m, f_{xe} is the oscillator strength, measured by the area under the u.v. absorption band for the $O\rightarrow e$ transition (for oriented molecules), ν_e is the frequency of the band maximum, and γ_e is the damping coefficient. Eqn. (2) can be rewritten in terms of the matrix elements of the dipole moment instead of f; in this case a somewhat different relative contribution of the first and the second term in the binomials under the summation sign is obtained, but their sum remains the same [12,16]. We shall consider only the more compact form of the expression, given in Eqn. (2). Without going into details, we note that the intensity (I_m) is given by the square of the modulus of α'_m: in the simplest case, $I_m\simeq\nu^4|\alpha'_{xm}|^2Q_{0m}^2$. In the general case all the Cartesian coordinates have to be considered. Lea's conclusion [31] that the semi-classical theory can deal only with the contribution from a single level and is applicable only to a one-dimensional model is quite unjustified.

Formulae (1) and (2) correspond to steady-state vibration conditions of the electronic oscillator: a definite value of the polarisability of the molecule corresponds to each value of Q_m. These conditions obtain either outside the resonance region or within the resonance region but in the presence of strong damping.

†Standard temperature, irradiation with unpolarised light, disordered orientation of the molecules, and observation at a right angle to the direction of irradiation.

According to Eqn. (2), Raman scattering occurs because both the oscillator strength (f_e) and the frequency of the electronic transition (ν_e) vary during stretching of a chemical bond[28-30]. Placzek's "polarisability theory"[22] takes account only of changes in f_e. The origin of the changes in ν_e is evident from Fig. 3, which shows typical potential energy curves for the ground state, $E_0(q)$, and for an electronically excited state, $E_e(q)$. In formula (2) the values of ν_e and ν'_e correspond to the equilibrium position of the nuclei, $q = q^{(0)}$; in Fig. 3 ν_e is given by the length of the vertical arrow $h\nu_{ev^*}$, and ν'_e by the slope of the curve $E_e(q)$, which depends on the change (Δ) of the equilibrium value of q following electronic excitation. $d\nu_e/dq$ can be as high[30,32] as 10 000–100 000 $cm^{-1}/Å$.

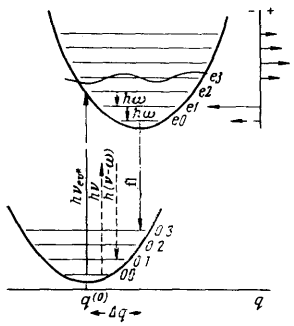

Figure 3. Optical transition model for a diatomic molecule.

From formula (2), and various experimental and theoretical data, we can draw the following conclusions:

1. There is a close relationship between Raman spectra and u.v. absorption spectra. I_m is related to the parameters of the u.v. absorption bands (mainly those in the long-wave region, which are stronger and have a latent or developed vibrational structure corresponding to ω_m, i.e. those with fairly large values of Δ.[16,28-30,33,34] Thus, the intensity is related to the geometry of the molecule in the excited state. The efficiency of particular electronic excitation levels (and the form of the function $I_m(\nu)$) can vary quite significantly for different Raman lines[28,35].

2. When $\nu_e - \nu > 50\,000$ cm^{-1} (aliphatic hydrocarbons under normal Raman excitation conditions), α' and α are practically independent of ν and of ν_e; the intensity of the Raman lines is very low (below the Rayleigh scattering level by a factor of several hundred), and is proportional to $(\nu-\omega)^4$. The Raman lines of cyclohexane[36] are typical of this type of line. The value of α is affected by only a few per cent as a result of nuclear vibrations.

3. When $50\,000 > \nu_e-\nu > 5000$ cm^{-1} (as in the majority of colourless organic compounds) I_m increases rapidly as $\nu_e-\nu$ decreases, both for a series of compounds with decreasing ν_e and for a single compound with increasing ν. On raising the frequency ν of the exciting radiation, the intensity increases faster than by the factor $(\nu-\omega)^4$ of formula (1), since the increase in α' is beginning to have an effect[12,32,33-43]. When several conjugated π-bond systems are present—at least in the case of totally symmetric vibrations—it is not surprising that the second terms in the square brackets of formula (2), containing the factor ν'_e, become dominant[12,32,33,43,44]. Under these conditions the depth of modulation of the molecular polarisability can be as high as 10–20% for small departures from resonance. The polarisability itself is often found to be higher (by 1–10%) than the value expected on the assumption of additivity.

4. When $\nu_e-\nu < 3000$ cm^{-1} (as in coloured compounds) we encounter resonance Raman scattering conditions, first observed in potassium p-nitrophenate[45-47]. This effect is characterised by a very high intensity (though re-absorption can occur under normal experimental conditions). According to Placzek (see Section 25 of Ref. 22), the Raman effect should be replaced by resonance fluorescence when the spectrum is excited within an absorption band. It has been shown[29,30,33], however, that this can only be true at very low damping γ_e (see Section III). Under conditions not very far from resonance it is likely that only one electronic level will be involved, which allows us to ignore the summation over all e in formula (2) and to consider only the contribution from a single electronic level. The imaginary part of α' plays an important role in the resonance region: it determines the depth of modulation of the imaginary part of the polarisability. The achievable depth of modulation of α can be judged by taking p-nitrodiethylaniline as an example: in this compound the difference ($\Delta\alpha$) between the polarisability values for two extreme positions of the vibrating atoms of the nitro group is of the order of 50 $Å^3$ for resonance excitation, whereas the polarisability of the molecule under the same conditions[23] is of the order of 150 $Å^3$.

The resonance denominators in the first and the second term under the summation sign in formula (2) are raised to different powers. Hence, using the function $I(\nu)$, we can identify the cases where either of these terms is predominant: in other words, whether the function $f_e(Q)$ or the function $\nu_e(Q)$ is responsible for the appearance of a Raman spectrum[48], and we can also assess the efficiency of a particular electronic excitation line towards the Raman line under study.

We shall consider the influence on $I(\nu)$ of a single electronic excitation level with large values of Δ_e and ν'_e and a large damping constant ($\gamma_e \gg \omega$) for $f'_e \simeq 0$. Because of the difference in the resonance denominators in the expressions for α'', α', and α,[29,30] the intensity of the overtone increases faster than the intensity of the Raman line of the fundamental as ν increases and the resonance region is approached, and the latter increases faster than the intensity of the Rayleigh line. (Hence, the contribution of Raman scattering to the total scattered intensity increases.) Close to resonance, damping becomes important and the intensity of all the above lines increases more slowly. It reaches a maximum near the maximum of the absorption band, and then begins to fall off (see, for example, Fig. 1 of Ref. 49). We should note that the two maxima in the $I(\nu)$ curve in the region of a single structureless absorption band shown in Fig. 26 of Ref. 25 and Fig. 1 of Ref. 50 are the direct result of the simplifying assumption made[25,50] to describe the electronic level (rectangular well).

A more complete description of the situation is shown in Fig. 4, where the following quantities are plotted: a) the outline of the absorption band $\epsilon(\nu)$; b) the real part of the polarisability Re $\alpha(\nu)$; c) vectors (broken lines) defining the complex polarisability (α) on the complex surfaces for several particular values of the frequency of the incident light (ν). Each of these originates from the position of the corresponding vector on the frequency scale. In this diagram, the projection of the vector on the horizontal axis is the real part of α, and the projection on the vertical axis is the imaginary part of α. Solid-line

arrows denote the complex *derivatives* of α for the same values of ν (the scales of α and α' are in arbitrary units).

The symbol $|\alpha|$ represents the amplitude of vibration of the electronic oscillator, corresponding to a frequency ν for the equilibrium position of the nuclei; $|\alpha + \alpha'|$ relates to one of the extreme positions of the vibrating nuclei; α' (or, more strictly, $\alpha' q_0$) defines the amplitude of the changes in α (occurring with a frequency ω), and the angle between $\vec{\alpha}$ and the horizontal axis is the phase difference between the oscillating field of the light wave and the induced moment $\mu(t)$.

Outside the resonance region, Raman scattering is determined by the amplitude modulation of $\mu(t)$—note that the directions of $\vec{\alpha}$ and $\vec{\alpha}'$ coincide in Fig. 4—and in the resonance region ($\nu \simeq \nu_e$) Raman scattering is determined mainly by phase modulation[23] ($\vec{\alpha}$ and $\vec{\alpha}'$ have different directions). In the latter case, expansion of $\mu(t)$ in a Fourier series gives a whole series of spectral lines $\nu \pm n\omega_m$, where $n = 0, 1, 2\ldots$[51].

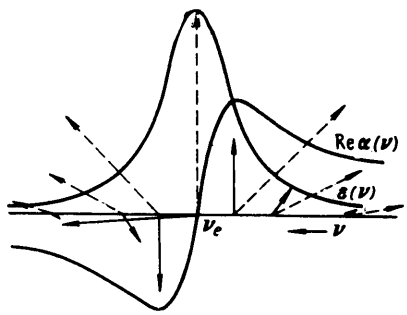

Figure 4. Complex values of α and α' for several values of the frequency ν in the region of the absorption band ($\gamma \gg \omega$, $f_e' \simeq 0$).

When $\nu \simeq \nu_e$, α' is real (see Ref. 25), whereas the contribution of the electronic level to α is imaginary. We must stress the fact that whereas only the real part of α contributes to refraction, both the real and the imaginary part contribute to the intensity of the Raman lines[23]. This is because the nuclear vibrations in different molecules have independent phases.

We have considered the case where ν_e' is the quantity which determines the amplitude of the Raman line. If $\nu_e' = 0$, but $f_e' \neq 0$, the Raman lines for the fundamental and the overtone will have identical $I(\nu)$ functions, coinciding with the corresponding function for the Rayleigh line. Under these conditions, only amplitude modulation of α is possible; as ν is varied, $\vec{\alpha}'$ will vary in the way indicated for $\vec{\alpha}$ in Fig. 4. A proportionality is then found[52] between $\epsilon(\nu)$ and $I(\nu)$, or[41] between $\epsilon(\nu)$ and $I(\nu)/(\nu-\omega)^4$. In general, such a proportionality can be expected for the sum of the intensities of all lines in the scattered spectrum[52]. Experiments on particular compounds with wide absorption bands have shown that $\epsilon(\nu)$ varies in the same sense as $I(\nu)$,[32,33,46] approximate (or exact[53]) proportionality being found in the region of strongest absorption[32].

Most of the existing experimental data on $I(\nu)$, particularly when far from resonance, are difficult to interpret because the u.v. absorption spectra have not been investigated over a sufficiently wide region. This explains also, at least in part, the conflicting conclusions which have been reported on the relative role of the factors f_e' and ν_e' (see Ref. 52–56 and comments in Ref. 57, 58).

A more convincing interpretation of $I(\nu)$ can be obtained in the case of compounds with a strong, isolated, long-wave absorption band. Thus, the intensity of the lines for the nitro group in a series of aromatic nitro compounds has been shown[32] to increase with ν very much faster than expected from f_e'. Even more revealing are the results for the esters of polyene acids (see Section XI), which include a very wide range of $\nu_e - \nu$ values (from 1000 to 30 000 cm^{-1}).[12] In this case it is clear that the factor ν_e' makes a contribution at least an order of magnitude greater than that of f_e' even at $\nu_e - \nu \simeq 10\,000$ cm^{-1}.

It follows from various other results (including fluorescence spectroscopic data) that Δ_e and ν_e' are usually different from zero in totally symmetric vibrations. In diatomic molecules, which have been most thoroughly investigated, it is usually found that $\Delta > 0$ and lies between 0.05 and 0.2 Å; f_e', on the other hand, is relatively small (see discussion in Ref. 59). Lastly, there is a striking agreement between the normal vibrations found in the fine structure of u.v. absorption bands and those found in resonance Raman spectra[11,34].

The form of $I(\nu)$ becomes more complicated if the terms contributed to α' by different electronic levels (or by the two terms for the same level in formula (2)) are of opposite sign[48,57,58]. In such cases, I_m can decrease and even vanish as ν increases over some range of values below resonance, and it can increase quite rapidly beyond that region. However, this behaviour has never been observed in practice; this is in keeping with the view that the contribution from f_e' is small, and can be of either sign, whereas ν_e usually decreases and the polarisability increases when a chemical bond is stretched.

Experimental confirmation has been obtained for the results of the semi-classical theory which predict different $I_m(\nu)$ functions for the different Raman lines of a given compound[35,36], steeper $I_m(\nu)$ functions for small γ,[11] particularly for overtones close to resonance at fairly large values of Δ_e[11,60–62] (but see Ref. 53), and many other effects.

The classical theory of Raman scattering in the simple form discussed above cannot deal with resonance radiation with $\gamma_e < \omega$, i.e. in the presence of vibrational structure in the u. v. absorption band (strictly speaking, when $\gamma_e < 2\nu_e' Q_{0m}$[23]). These conditions are met, for example, in studies of polyacenes, polyenes, and polyynes. Under these conditions the electronic oscillations lag behind the displacement of the vibrating nuclei and cannot reach a steady state. "Forced" and "natural" vibrations of the oscillator become indistinguishable, and beats are produced by the continuous change in the frequency ν_e.[52,63]

In these circumstances the concept of polarisability of a function of nuclear coordinate, used[22] in the "polarisability theory", becomes meaningless. The polarisability can be replaced by a more general function[52], which is time-dependent, similar to the "transfer function" $K(\nu, t)$ used in electronics. This function is determined by solving the equation of motion of the electron, of frequency ν_e, modulated by the motions of the nuclei. Ultimately we obtain a set of Fourier components similar to the polarisability matrix elements used in quantum theory[51]. The most interesting feature of this new variant of the classical theory is its great similarity to the quantum-mechanical theory. In many respects, the general form of the absorption and emission spectra given by both theories is almost the same. It is incorrect to say that the classical theory is concerned with the frequencies of transitions between two continuous potential energy curves for the two electronic levels involved,

whereas the quantum theory deals with transitions between discrete electronic-vibrational sublevels: both theories predict a continuous absorption spectrum for high values of γ and a spectrum with a discrete vibrational structure for $\gamma < \omega$.[51,52]

A further generalisation of the classical theory to include the case of irradiation by a broad-band light source is given in Ref. 63 and 64.

III. QUANTUM THEORY OF RAMAN SCATTERING

The quantum theory of scattering deals with the probability of a change in the vibrational quantum number v, brought about by that part of the energy of the quantum of incident light $h\nu$ which undergoes changes and finally appears as scattered light. The probability of a change in v from 0 to 1 without a change in the electronic state (00 → 01 transition) is defined by the matrix element of the polarisability α_{01}.

It has been shown[23,30,48,52] that the concept of a total wave function ψ for a molecule, expressed as a product of nuclear (u_{ev}) and electronic (φ_e) wave functions, leads to an expression of the type of Eqn. (3):[65]

$$\alpha_{01} = \frac{2}{h}\sum_e \sum_v \frac{\nu_{ev} A_{0v} A_{v1}}{\nu_{ev}^2 - \nu^2 + i\nu\gamma_{ev}} M_{0e}^2 (1 + D_{ev}), \qquad (3)$$

where ν_{ev} is the frequency of the electronic-vibrational transition 00 → ev, in s^{-1}, M_{0e} is the matrix element of the dipole moment of the 0 → e transition, obtained from the electronic wave functions of the ground (0) and the excited (e) state, A_{0v} are the integrals for the combination of the nuclear wave functions of the sublevels 00 and ev, A_{v1} are the integrals for the combination of the sublevels ev and 01, D_{ev} allows for the dependence of M_{0e} on Q. The expressions for α_{00} and the other α_{0n} terms differ from Eqn. (3) only in respect of the subscripts after A. The resonance denominator can be averaged, and the summation with respect to v of the numerators can be replaced by the overlap integrals of u_{00} and $M(Q)u_{01}$, only if $\Delta_e \simeq 0$.

Fig. 3 shows, together with the potential energy curves, the vibrational sublevel systems $0v$ and ev (horizontal lines) which are considered in the quantum theory. $h\nu$ is a quantum of incident light (under resonance excitation conditions) which is transformed into a quantum of scattered light ($h(\nu-\omega)$). The frequency ν_{ev}* corresponds to the maximum of the absorption band of the compound ("Franck–Condon" transition, 00 → ev*). It is clear that the frequencies ν_{ev}, unlike the frequency ν_e which appears in Eqn. (2), cannot be treated as a function of Q (see comments in Ref. 54).

According to Eqn. (3), α_{01} is made up of contributions from several sets of v sublevels in the electronically excited levels. When the individual sublevels merge into a single wide band (for $\gamma_e > \omega$), formula (3) in no way loses its relevance. The contributions from ev sublevels lying above and below ev* have opposite signs (see right-hand side of Fig. 3): when the spectrum is excited far from resonance these contributions effectively cancel out, the summation over v is close to zero,[48] and the Raman line has a very low intensity. As ν approaches the value ν_{e0} the contribution from all the sublevels increases—particularly the lower ones. The compensation of the positive and the negative contributions is progressively lost, and there is a rapid increase in α_{01} and in the line intensity[48].

According to the present theory, Raman scattering results from the presence of a developed (or latent) vibrational structure in the absorption band ($\Delta_e \neq 0$), and also from the dependence of M_{0e} on v (or on Q).

The formulae of the quantum theory are quite different from those of the simple variant of the classical theory. However, when conditions are far from resonance, both sets of formulae predict almost identical intensity values provided that ν_e is taken to be the frequency at the *maximum* of the absorption band[57] (see also Ref. 42 and 66). Under these conditions[22], $\alpha_{01} = \frac{\partial \alpha}{\partial Q} Q_0$. The summation of the ev contributions with different resonance denominators in the quantum mechanical formula (3) corresponds to making allowance for ν_e' in the classical theory; allowing for the small difference in M_{0e} for the different sublevels (or for the parameter D_{ev}) is equivalent[48] to introducing the factor f_e' in formula (2).

Analysis of formula (3) allows us to characterise the secondary resonance radiation of light from various molecules, not involving intermediate transitions in the excited state, for different relative values of γ and ω and for different half-widths (Γ) of the incident light band.

Most of the experimental data on resonance Raman scattering, including those for nitro and nitroso compounds[46,47,49,67,68], relate to the case of $\gamma > \omega > \Gamma$ (excitation by a narrow line, very wide absorption band). Under these conditions resonance scattering differs from non-resonance scattering mainly in the greater line intensity of the former[52]; the relative intensity of the overtones can also be abnormally high.

For somewhat lower values of γ ($\omega > \gamma > \Gamma$ and $\Delta_e \neq 0$), when the absorption band has a developed vibrational structure, one of the characteristics of the normal scattering spectrum tends to be lost (unshifted lines are strongly predominant, and Raman overtones are very weak[69]). This is because a single ev vibrational sublevel makes an overwhelming contribution to the matrix elements of the polarisability α_{0n}. It is possible to find an overtone line with a higher intensity than the fundamental Raman line, and the latter can be stronger than the unshifted scattering line[52]. The secondary radiation acquires some of the features of resonance fluorescence ("transition phenomena of the first kind"). Spectra of this type have been observed in solutions of diphenylpolyenes[11] (Fig. 5) and esters of polyene acids[12] (see discussion in Ref. 27). On going to the conditions $\omega > \Gamma \simeq \gamma$, the similarity between resonance radiation and resonance fluorescence increases: the outline of the bands becomes very similar to the outline of the characteristic lines of the oscillator ("transition spectrum of the second kind"). The situation is illustrated in Fig. 6, and discussed in Ref. 69 and 328.

If γ becomes very small, and comparable with the rotational frequencies ω_{rot} ($\omega_{rot} > \gamma > \Gamma$), different rules apply to the changes in rotational quantum number and the depolarisation of the lines increases. In the first instance, only one rotational sublevel in the ev level can now contribute to α_{0n}, instead of two or three. The increased depolarisation is associated with the onset of "afterglow" under the conditions of molecular rotation. An example of this situation is given[86] by the excitation of the iodine vapour spectrum by the narrow argon laser line, which falls in the region of the fine structure of the I_2 absorption band. On moving still further towards the condition $\omega_{rot} > \Gamma > \gamma$, the predominant spectrum of the secondary radiation should show all the characteristics of resonance fluorescence (including a well developed afterglow).

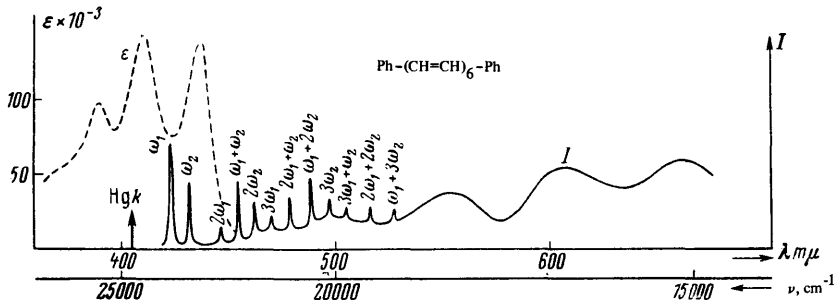

Figure 5. Transition spectrum of the secondary radiation from a solution of diphenyldodecahexaene (full line). The narrow Raman lines are on the left, the fluorescence bands on the right. The exciting Hg*k* line is shown by an arrow. The absorption spectrum is shown by a broken line [11].

On the whole, we may conclude [63] that, depending on the spectral composition of the incident light and on the properties of the oscillator, the secondary radiation can show the typical features of light scattering or of fluorescence, or of an intermediate type of radiation, or alternatively it may combine the properties of one of these types in one part of the spectrum with those of the other type in a different part of the spectrum.

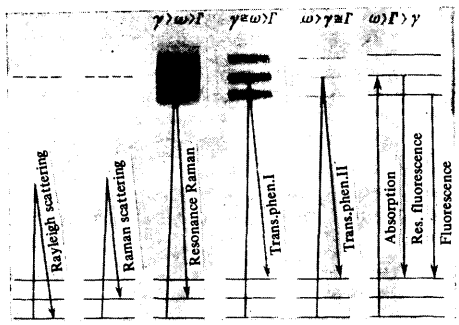

Figure 6. Optical transitions for large and for small damping (γ) of the electronic oscillator (ignoring rotational sublevels). The lower horizontal lines denote the energy of the $\overline{Ov}$ sublevels of the electronic ground state; the upper lines or bands denote the sublevels (ev) of the excited electronic level e.

The theory of Raman scattering summarised above explains [52] the ability of "quenching agents" to eliminate fluorescence with little effect on the intensity of the normally scattered light and of resonance scattering in the same material [37,49]. Normal fluorescence is due to emission from the long-lived, lower vibrational sublevels of ev (arrow labelled fl in Fig. 3), whereas resonance scattering occurs when the sublevels of ev which contribute to α_{on} have a short life-time: these sublevels are, of course, relatively unaffected by quenchers [69].

The simple quantum-mechanical theory and the Kramers–Heisenberg–Weisskopf formula do not extend to resonance scattering by a system with a non-diagonal damping matrix. The off-diagonal elements determine the relationship between the various excitation levels through the field of the radiation: they are considered in models which include quantisation of the light field [70].

IV. EXPERIMENTAL OBSERVATION OF RAMAN RESONANCE SCATTERING SPECTRA

The observation of Raman spectra usually presents no difficulty when the exciting line is not very far removed from the absorption band of the material: data are available for a large number of compounds, including nitroaniline [28,56], Michler's ketone [37,71], nitrostyrene [72], vitamin A, [37] etc. The case of excitation at a relatively large distance from the absorption band ($\nu_e - \nu > > 12\,000$ cm^{-1}) will not be considered here: it includes Harrand's experiments [73] with cinnamaldehyde, chalcone, etc.

Resonance Raman spectra have been obtained for many organic and inorganic compounds of different types and showing both continuous absorption and absorption bands with a fine structure. In addition to the experiments with potassium *p*-nitrophenate mentioned above, spectra have been obtained for solutions of other nitro and nitroso compounds [46,47,42,67,68,74,75], polyenes [11,12,76], derivatives of azobenzene and azonaphthalene [54,75,77,78], pseudoisocyanine [74], Malachite Green [37], $KMnO_4$, [79] iodine [80], and many others (see Ref. 81 for a detailed review). Spectra have also been reported for solids: nitro compounds [5,82], semiconducting crystals [83,84], *F*-centre spectra for alkali halide crystals [85], impurity ions [86], etc. [87] Specially interesting results were obtained with vapours [86]. In all cases the molar intensity of the Raman lines was very high. The largest intensity coefficient was reported for the ester ROOC–(CH=CH)$_7$–COOR: for the 1550 cm^{-1} line it had the value 400×10^6, higher than the strongest acetone line [12] by a factor of 20×10^6. Hence, the line can be observed at concentrations as low as 0.00001% (see Section XI). With lower values of γ the intensity of the secondary emission lines can be even higher (by several orders of magnitude).

Electronic transitions polarised along the chain are characteristic of molecules with an elongated system of conjugated bonds. The corresponding Cartesian component of α_{on} is overwhelmingly dominant under resonance conditions, and hence the degree of depolarisation ρ of most of the Raman lines approaches the value 0.5. [15,67,28,72,88,89] In planar, branched systems ρ can tend towards a different limit of 2/9 (see the results for benzophenone [88]).

Excitation experiments in the absorption region do not always yield positive results [68,37]: this is evidently because the intensity of the line under study includes a contribution from the electronic level, which is to some extent a function of f'_e and ν'_e. When $\nu'_e = 0$, the observation of Raman scattering in the resonance region should be difficult if not impossible, both because the intensity is lower and because of interference from fluorescence bands [27].

Re-absorption of the radiation, even in the region of the strongest absorption bands ($\epsilon > 100\,000$), does not preclude the observation of the stronger Raman lines in sufficiently dilute solutions. An optimum concentration can be defined for each compound [67,75,90]: the formula is given in Ref. 90.

Resonance Raman spectra have provided a broader understanding of the interaction of light with molecules, have led to important results on the relationship between scattering, absorption, and fluorescence spectra, have increased the technological possibilities of Raman spectroscopy, and have given a satisfactory explanation of the effect of conjugation on Raman spectra in systems with different numbers of branches. Perhaps the most interesting results are those on the intensity of resonance Raman spectral lines excited in the region of an absorption band with a developed structure, and in different parts of such a band. These experiments have confirmed the early suggestion [46] that several maxima can appear in $I(\nu)$ under conditions of this type, and also the predictions [33,29] of the life-time of the excited state of a molecule. More details will be found in Section XI.

V. CHARACTERISATION OF MOLECULAR FRAGMENTS IN THE PRESENCE AND IN THE ABSENCE OF CONJUGATION

It is conventional, in studies of intramolecular interactions, to separate the inductive effect from the effects of conjugation (see, for example, Ref. 91 and 92). This procedure, though convenient, is arbitrary to some extent. Different authors use a slightly different interpretation of the inductive effect. In what follows, the term will be used to denote the polarisation of one fragment of a molecule by the electric field produced by another fragment, without redistribution of the electron density in the intervening region.

Conjugation, on the other hand, is the interaction between the electron clouds of two or more chemical bonds. The interaction can be described by a partial *overlapping* and *combination* of their wave functions, set up on the assumption of no interaction (for example, if the conformation of the molecule is unfavourable), with the assistance of the *vacant orbitals* of the fragments. The three aspects which are italicised above differ in their relative importance towards the manifestations of conjugation in different properties of the molecule. Hence, the possibility of establishing simple general correlations is extremely remote.

There is no difference in principle between the various types of conjugation ($\pi-\pi$, $n-\pi$, $\sigma-\pi$, $\sigma-\sigma$). [92,93] They differ only in the form of the overlapping wave functions: the form specifically determines the influence of the mutual orientation of the interacting fragments upon the conjugation. Conjugation increases the number of possible electronic transitions, it has a powerful effect on the optical properties of the molecule, and it leads to a redistribution of the electron density between different groups.

The contribution of the lowest vacant orbitals of the two fragments of the X=C–C=Y system to the filled molecular orbitals is the basis of the so-called "π-electron delocalisation", which amounts to a delocalisation of the valency lines (but in no way characterises the motion of electrons). The redistribution of electron density between non-identical groups of atoms is described in terms of the preferential occupancy of the vacant orbital of one of the fragments. The extent of redistribution is affected by solvation, by the formation of transition complexes, by the application of an external field, by electronic excitation, and during vibration of the atoms. The latter is relevant to the intensity of infrared absorption bands. Depending on the frequency ω and on the extent of overlap of the orbitals of the fragments, the conditions for adiabaticity may or may not be met. The same is true of the frequency of the external field. The aspect which relates to chemical reactions is discussed in Ref. 94.

Conjugation and the redistribution of electron density, under equilibrium configuration and during atomic vibrations, have a significant effect on the frequencies and on the stiffness of chemical bonds. The inductive effect is invoked by many workers, but its role is often exaggerated (see, for example, Sections X and XI and Ref. 95, 96). It is important to note that the relative importance of the various factors which determine the intensity and the frequency of Raman lines is by no means the same: the mutual relationship is far closer in the case of optical properties such as the intensity of Raman lines, polarisability, dispersion, and u.v. absorption spectra (see Sections II and III, and Ref. 97).

The intensity of the Raman lines is one of the molecular parameters most sensitive to conjugation. The reason for this high sensitivity is the presence of higher-power terms in the resonance denominators (see Eqn. (2)). At the same time the intensity (as in the case of the u.v. spectra) is often relatively insensitive to the inductive effect (see Sections IX, X, XI, and also Ref. 95, 96, 98, and particularly Ref. 99 and 100, where reference is made to the Taft constants). When the spectrum is excited close to resonance the intensity is more clearly related to the properties of the particular excited electronic level. Far from resonance and at low field intensities the strength of the Raman lines (like the polarisability) is best described in terms of the characteristics of the electronic ground state.

When the spectra are used to gain information on particular atomic groups in complex molecules it is important to remember that entirely different conditions apply to the localisation of electronic excitation and of normal atomic vibrations. It is not hard to think of a model of the molecule such that electronic excitation is delocalised, but atomic vibration is not, and vice versa. The first case includes molecules in which the fragments involved in conjugation have very different mechanical parameters: for a vibration largely localised in one particular (i-th) bond, $\frac{\partial \alpha}{\partial Q_m} \simeq \frac{\partial \alpha}{\partial q_i}$. But even if the mechanical parameters are similar and the normal vibration can extend to both fragments, we cannot in principle exclude the possibility of

transition to a localised characteristic—from $\frac{\partial \alpha}{\partial Q_m}$ to $\frac{\partial \alpha}{\partial q_i}$ and from $\frac{\partial \nu_e}{\partial Q_m}$ to $\frac{\partial \nu_e}{\partial q_i}$. It should be noted, however, that the partial differentials with respect to q_i (with q_j = const) involve some arbitrariness in the choice of the other internal coordinates $j \neq i$. This is not surprising: the type of deformation of the molecule for a given change of q_i depends on which of the other internal coordinates remain unchanged (see Ref. 101).

As regards the separation of α and also $\frac{\partial \alpha}{\partial q_i}$ into the contributions from particular chemical bonds, which is often attempted, this approach has physical significance only if the bonds are very different, i.e. if local electronic excitation is possible. When the bonds are identical (e.g. in n-alkanes) the electronic excitation levels relate to the whole chain, as in the case of polyenes, but we can formally define the "polarisability" of individual C–C bonds; this procedure gives satisfactory numerical results only when the frequency ν_e is well removed from the frequency ν of the incident light. The increments of α (and also of α') are additive in this case because slight variations in the very high frequencies ν_e and the splitting of the energy levels for different lengths of the –C–C– chain have a negligible effect on the resonance denominators of the expressions for α and α' as compared with (for example) variations in ν_e for the closely spaced levels of polyenes. (Of course, differences in ν_e are also relatively larger in the polyene series [93].) We note that even when identical groups are very weakly conjugated they are included in equal measure in the molecular orbitals.

It should be evident from this example that additivity in the properties of complex molecules (i.e. the ability to describe molecular constants as the sum of increments proper to individual atoms or bonds) is not directly linked, in general, to the location of the actual physical phenomena in which these properties manifest themselves. The concept of delocalisation of the electronic excitation energy and of the atomic vibration energy is quite well defined if specific time constraints are assumed: we have already pointed out that the splitting of levels due to coupling between oscillators is not small, and the "measurement time" and the mean life-time of a state are quite large.

By assuming constant contributions from particular chemical bonds to α and to $\partial\alpha/\partial q$, successful predictions for different molecules can be made, and (if conjugation is absent) good results are obtained for the polarisability and for α'.[102–105] However, the differentials of the polarisability are more sensitive than is α to interactions between groups, and this sets a limit to the usefulness of the additive approach. It is a relatively useless formalism [107] to extend the scheme by taking the differentials $\partial\alpha_j/\partial q_j$ into account, as was done in an attempt to calculate the contribution of an individual bond to the exaltation of refraction [106]. Yet, the most interesting and important cases do involve non-additivity, and one must turn to the values of $\partial\alpha/\partial Q$ and $\partial\alpha/\partial q_i$, and direct measurements of Raman line intensities. Nevertheless, various workers have tried to separate the polarisability parameters of different bonds [54,108].

The possibility of describing the donor–acceptor properties of atomic groups by means of some simple coefficient is very attractive. In practice, however, these properties are strongly dependent on the specific combination of atoms in the group and on their mutual orientation. It is more profitable to consider separately two types of donor–acceptor property: 1) involving an increase and 2) involving a decrease in the multiplicity of the bond between the two interacting groups [109,110]. The OH group must be considered to be a donor group according to its donor–acceptor properties of the first type, and an acceptor group according to its properties of the second type. Depending on its angle of rotation, the amino group can be assigned either to the electron-donating groups of the first type or to the acceptors of the second type. The redistribution of the electron density between the groups depends on the difference between their donor–acceptor properties of the first kind and on the difference between their donor–acceptor properties of the second kind. Thus, every group can be characterised by two coefficients, each of which depends on the angle of rotation of the group.

The possibility of locally characterising the mechanical properties of chemical bonds, even in the absence of conjugation, is very limited. Neither the force constant K_{ii}, nor the interaction coefficient, nor the "independent force constant" (i.e. independent of the choice of the coordinate system for the molecule [101]) can give an accurate characterisation of an individual chemical bond. Strictly speaking, the i-th bond can be characterised only by a set of coefficients (for example, the K_{ij} matrix) which includes off-diagonal coefficients [111,112]. Among these, the most interesting and important are those which describe the interaction of neighbouring chemical bonds: even in paraffin hydrocarbons these coefficients do not vanish [112]. Conjugated double bonds also can interact very significantly [112–115]. All these effects stem from the dependence of the contributions to the inductive effect upon the nuclear coordinate, from the influence of atoms which are not chemically bound, and from conjugation and its associated redistribution of the electron density between the bonds [101]. The off-diagonal coefficients K_{ij} as a rule are much smaller than K_{ii}, but their differences can be as important as the differences in K_{ii} when molecules with different amounts of conjugation are compared. Examples may be quoted ($\omega_{C=O}$ in succinimide, succinic anhydride, etc.) where the difference in frequency between two stretching vibrations is determined mainly by the K_{ij} coefficients. Some data on the relationship between K_{ii}, the order of the chemical bond, and the interatomic distances can be found in the literature [113,116,117].

The classification of molecules into those which do and those which do not show additive behaviour can lead to entirely different results when different properties are studied, and it can depend on the choice of the internal coordinate system for the molecule [111]. Distinguishing between multielectronic and monoelectronic properties of molecules (Dewar [91]) is a somewhat indefinite approach, lacking a concrete physical basis. We prefer to consider the connection between the parameters and electronic excited levels, and also the "time factors" ("measurement time", etc.).

VI. MEASUREMENT OF RAMAN LINE INTENSITIES. SYMBOLS

The intensities of the Raman lines of different compounds are usually determined by reference to the line intensity of a standard compound. The scale which was first proposed took the 313 cm^{-1} line of liquid CCl_4 as 100 units; the intensity of the unknown line was obtained for equimolar proportions of the compound and CCl_4. [17]‡

‡A different scale, in which intensities are referred to unit volume, has been proposed by Sushchinskii [27].

For analytical purposes, the maximum intensity of the line is measured in a spectrometer with a narrow slit, whereas in structural studies the integral intensity is measured [15,28].

The spectra of the unknown and of CCl_4 can be measured separately, under identical conditions (external standard method), or alternatively one can measure the spectrum of a solution in CCl_4 or in another solvent (internal standard method). [117,118] The advantage of the second method is that the results are relatively unaffected by the refractive index of the liquid, which determines the path of the light rays in the cell, and also by light absorption, temperature, stability of the light source, and the specific properties of the medium containing the molecules under study. These advantages are quite important, because reliable corrections for all these factors have not yet been worked out. In practice, of course, most materials are solids of low vapour pressure, and have to be studied in solution irrespectively of the advantages of the two methods, since direct measurements of line intensities on solid samples are not very accurate.

In order to minimise the angular dependence of the intensity, the usual cylindrical cell for the sample is sometimes fitted with a screen which polarises the light at right angles to the cell axis [119]. Under these conditions, the contribution to the intensity from the anisotropic part of the scattering tensor becomes smaller: the term $45\bar{\alpha}'^2 + 13b'^2$ of formula (1) is replaced by $45\bar{\alpha}'^2 + 7b'^2$, and we have the relation [25,120]

$$45\bar{\alpha}'^2 + 13b'^2 = (1+\rho)(45\bar{\alpha}'^2 + 7b'^2) = \frac{6(1+\rho)}{6-7\rho} \cdot 45\bar{\alpha}'^2.$$

However, equally good results are obtained by using simple diaphragms to limit the range of angles of incidence to 90–15°: with this precaution, no modification of formula (1) is necessary. Corrections for self-absorption in the sample can be applied [37,121,122]; other corrections have been discussed in recent monographs [25,27].

The spectra of vapours are very important means of characterising molecules, but they are very difficult to obtain in most cases, and solution spectra have to be examined instead. Under these conditions, the Raman lines of the solvent can be used as internal intensity standards.

For the most accurate measurements of intensity and frequency over a range of materials it is convenient to use a single, well characterised, and preferably inert solvent. Cyclohexane could be quite useful but for its limited solvent power. Solvent effects on the frequencies of various groups in organic compounds have been reported [19,123,124]; these effects have been used in assigning lines [125,126].

In mixtures of aliphatic hydrocarbons, and in a number of other systems, the molar intensity coefficient is independent of concentration [24,67,75], but a significant concentration dependence is found in many cases (in particular, when the degree of association is a function of concentration).

The intensity of lines from the solute usually increases with the refractive index of the solution, even when a correction for convergence of the beam in the cell is applied. On varying the refractive index of the solvent over the range 1.25–1.60 the intensity coefficient for non-resonance excitation is found [132,133] to vary by ±40%. Various approximate formulae for non-specific intermolecular interactions, based on the Onsager model, are derived by Wahl [132]. Association and complex formation introduce additional complications [134–136].

The influence of solvent type is more marked under near-resonance conditions, when the relationship between the shift in the u.v. absorption band and the intensity change becomes unmistakable [15,33,49] (see formula (2); see also Ref. 66, 67, 136–139).

In gases, the line intensity increases with temperature as predicted by theory. In the liquid phase at room temperature the intensity is higher than in the gas phase by a factor of 1.5–3, but on raising the temperature the difference decreases [140]. Most measurements are made at 20–30°: more accurate temperature control is seldom needed in practice.

An attempt has been made to define line intensity constants which are less dependent on measurement conditions: one of these is the absolute intensity [143], or the "activity coefficient" for scattering [144] to use the more recent terminology:

$$A = q_i(45\bar{\alpha}_i'^2 + 7b_i'^2),$$

where q_i is the degeneracy of the nuclear vibrations; in this formula the normal coordinates have the dimensions cm $g^{1/2}$, and the "activity coefficients" are in $cm^4\ g^{-1}$. The latter can be evaluated from experimental data by eliminating the factors $(\nu-\omega_m)^4$ and $[1 - \exp(-\frac{h\omega_m}{kT})]$ and multiplying by ω_m (see formula (1)). The line of the rotational Raman spectrum of the hydrogen molecule ($J = 1 \rightarrow 3$), which has been reliably characterised, has been proposed [145] as a standard for the experimental determination of A. The following results have been obtained: for gaseous CCl_4 $A_{459} = 13.2 \times 10^{-8}$, [146–149] $A_{313} = 4.3 \times 10^{-8}$, [147] whilst for liquid CCl_4 [140,149] $A_{459} = 34 \times 10^{-8}$, $A_{313} = 10.1 \times 10^{-8}\ cm^4\ g^{-1}$. The ratio of the A values for the measured line and for the 459 cm^{-1} line of CCl_4, $S = A_X/A_{459}$, is called [119] the "standard intensity".

The use of coefficients with dimensions $cm^4\ g^{-1}$ ("absolute intensity") to characterise the line intensity has no particular advantage, and introduces unnecessary complications into the interpretation of experimentally observed quantities. Both from the physical and the chemical points of view, it is quite satisfactory to retain the conventional (relative) intensity coefficients, the differentials of the polarisability, or the polarisability matrix elements α_{0n}. For non-resonance excitation the quantity $2\alpha_{01}$ can be identified with the difference between the polarisabilities at the two extreme positions of the nuclei. For a discussion of the "scattering cross-section" the reader is referred to the literature [22,27,150,151].

In the remainder of this review, molar integral intensity coefficients for room temperature are discussed in the text and listed in the Tables. The intensity of the 313 cm^{-1} line of liquid carbon tetrachloride excited by non-polarised light (λ = 4358 Å), and observed at a scattering angle of about 90°, is taken as 100 units; intensity coefficients referred to this standard are denoted by the symbol I^S. The same standard can be used for excitation by frequencies < 22 938 cm^{-1}. The precision of the intensity measurements varies from ±5 to ±20%, depending on the type of apparatus used.

The following I^S values have been reported for liquids: 109 for the 459 cm^{-1} line of CCl_4, [103,118,140,152–157] 43.5 for the 802 line of cyclohexane, [103,158–161] 24 for the 1176 line of benzene [24,28], 12 for the 1031 line of methanol [37,158]; the results are practically identical whether the measurements are made on the pure liquids or on solutions in CCl_4. Excitation by light of much longer wavelength has very little influence on the relative intensity of these lines.

Measurements with a He–Ne laser have also been reported [141,142].

The following symbols are used throughout the remaining Sections: R, Et, Ph for the methyl, ethyl, and phenyl group respectively, Π for a π-bond or a π-bond system. H atoms attached to carbon are omitted in the structural formulae. Q is the normal nuclear coordinate, q is the elongation of the interatomic distance (natural coordinate) in cm or Å.

VII. INTENSITY OF THE RAMAN LINES OF SIMPLE MOLECULES

The differentials $\partial\alpha/\partial q$ (Table 1) are specially interesting as a link between the intensity of Raman lines and other physical constants of the molecule. The best results, obtained for diatomic molecules, justify a number of generalisations about the relationship between line intensity and the nature of the chemical bond. Values of $\partial\alpha/\partial q$ have been obtained also (for relatively simple molecules) by assuming additivity: these need to be interpreted with greater care. The values listed in Table 2 relate to solutions in CCl_4 or to the pure liquids (except for the values for ions, which relate to aqueous solutions). Numbers in brackets are estimates made by analogy or from u. v. spectral data. Values for some other simple molecules and ions can be found in the literature [179,182, 187,188]. Force constant data are tabulated by Müller and Krebs [181].

It has been known for many years [22] that purely ionic bonds cannot contribute to Raman scattering, because the electron clouds of the cation and the anion are mutually independent. (Ion pairs in close contact can give very weak lines.) Bonds with a weakly covalent character give low-intensity lines because [189] the potential energy curve of the excited electronic level has a small curvature. In the simplest cases, this small curvature can be ascribed to the fact that the energy difference between the bonding and the antibonding molecular orbital is relatively unaffected by bond stretching, since it is due to a difference in the field surrounding the two atoms rather than to overlapping atomic orbitals.

$\partial\alpha/\partial q_i$ is practically unaffected by isotopic substitution. The intensity can vary a little because of the difference in the amplitudes q_i, but this effect is negligible except in the case of the hydrogen isotopes. The intensity and $\partial\alpha/\partial q$ both increase with the multiplicity of the bond; for carbon–carbon bonds $\partial\alpha/\partial q$ is proportional to the order of the bond [166]. For C–H bonds (but not for C–C bonds [187]) $\partial\alpha/\partial q$ is independent of hybridisation of the atomic orbitals of the C atoms [132,166]. The intensity of the lines of MX_n molecules increases very considerably [182] as the valency of the M atom increases. Differences in $\partial\alpha/\partial q$ for chemical bonds of a given type in molecules and ions are generally small; no obvious trend has yet been detected. The intensity and $\partial\alpha/\partial q$ increase with the atomic weight of the atoms involved in bond formation: if σ-bonds are compared, this effect may be explained by the decrease in the energy of the $\sigma \rightarrow \sigma^*$ electronic excitation.

Some of the above aspects are implicit in the approximate empirical formula for MX_4 molecules given by Pauling for $\partial\alpha/\partial q$ in terms of the percentage covalency (p) of the bond, defined by the electronegativity difference between M and X:

$$\partial\alpha/\partial q \sim p(z_M + z_X),$$

where z is the atomic number of the element [178].

Lippincott [190] gives a relationship between the differential $\partial\alpha/\partial q$ and the multiplicity (n) of the bond, the electronegativity of the atoms in the given valency state (χ_1 and χ_2), and the number of filled s, p, d, and f shells. In his model, the potential in the region of each nucleus is described by a δ-function. A local molecular orbital independent of other bonds is obtained by a linear combination of the wave functions of the two atomic orbitals. In Long and Plane's interpretation [179], this model gives the differential of the bond polarisability in the form

$$\frac{\partial\bar{\alpha}}{\partial q} = \frac{\sqrt[4]{\chi_1\chi_2}}{\sqrt{z_1 z_2}} \frac{\sigma n q_0^3}{a_0};$$

where $\sigma = \exp[-\frac{1}{4}(\chi_1 - \chi_2)^2]$ defines the covalent character of the bond, q_0 is the equilibrium distance between the atoms, a_0 is the Bohr radius of the first orbital of the H atom, and z is the effective charge on the nucleus. Lippincott and Nagarajan [190] replace z by empirical functions of the filling of the s, p, d, and f shells; values of x/z are tabulated for all atoms [191]. This formula often leads to serious discrepancies with experiment. It has been used [179] to evaluate bond multiplicity in a large number of molecules and ions.

Non-empirical and semi-empirical quantum-mechanical methods have been used a number of times to calculate $\partial\alpha/\partial q$ for the hydrogen molecule: in general, the results were satisfactory [325]. Further discussion of the application of the additivity hypothesis to polyatomic molecules can be found in Ref. 173, 189, 192–194.

VIII. INTENSITY OF THE CHARACTERISTIC LINES OF THE MOST IMPORTANT ATOMIC GROUPS

Among the most interesting Raman lines of organic compounds are those which characterise the quasi-local stretching vibrations of atomic groups (for example, carbonyl, hydroxyl, cyano, nitro). Their position in the spectrum (Table 3) is relatively independent of the structure of the rest of the molecule. In the few cases where such a relationship was observed, it was ascribed to the effect of conjugation or some other form of intramolecular interaction upon the rigidity of the chemical bond.

The intensity of the Raman lines for quasi-local vibrations usually varies very little among the members of a homologous series. Thus, in the alk-1-ene series from pentene to tetradecene (and also in the cycloolefins [197,276]) the intensity of the so-called "C=C vibration" line lies between 30 and 35 units; similar information exists for other hydrocarbons [24,161,198]. Replacement of the H atoms on the C=C double bond by alkyl groups increases $I_{C=C}$ (to 50 in the case of tetraalkylethylenes); [195,198] calculations by the additive scheme suggest that this effect may arise from the contribution of the new bonds to the differential $\partial\alpha/\partial Q$, without any change in the parameters of the double bond ($\partial\alpha/\partial Q_{C=C}$). [105] It should be noted, however, that the u. v. absorption bands of alk-1-enes and tetramethylethylene appear in different positions, and this effect alone may explain an increase in intensity by 25–30%; thus, the simple "additivity scheme" is not fully adequate in this case. A similar state of affairs is found on going from toluene to hexamethylbenzene (line at ~ 1600 cm^{-1}). [199] A small increase in $I_{C=O}$ and $I_{C\equiv N}$ is observed experimentally when comparing the first with the subsequent members of the ketone [100,200,201] and the cyanide [99,138] homologous series.

Various workers [98,35,202–209] have reported an approximate proportionality between characteristic line intensities and the number of like atomic groups when the latter are separated by one or more carbon atoms with sp^3 hybridisation, or by the group SiR_2 or SnR_2§. Molecules with different bridging groups often show significant deviations from additivity (see Section XIV).

Table 3 lists relative intensity data for the characteristic stretching vibration lines of various atomic groups in molecules of the RX type (mostly, EtX), and also the corresponding $\partial\alpha/\partial q$ differentials; the frequency ω is obtained from data for solutions in CCl_4 (except the starred values, which relate to different solvents); the values of I^S and $\partial\alpha/\partial q$ refer to the pure liquids or to solutions in CCl_4. We note that α' and I^S increase with the multiplicity of the bond, with the atomic weight of the bond-forming atom in X, and also with the intensity of the u. v. absorption band of RX and with its approach towards the visible end of the u.v. spectrum.

The reader is referred to the original literature for an account of the characteristic lines of various types of branched hydrocarbon chain and of cyclic molecules [27,205,208–210].

§The total intensity of the line splitting components should give a more exact proportionality.

IX. EFFECT OF SUBSTITUENTS ON THE SPECTRA OF COMPOUNDS WITH C–C π-BOND SYSTEMS

A large amount of data is available on the effect of various substituents on $I_{C=C}$ and on the differentials $\partial\alpha/\partial q_{C=C}$,[15,16,207,220,226,227,236] on $I_{C\equiv N}$,[99,138,187,235] on $I_{C=O}$,[15,98,100,200,220] and on $I_{C\equiv C}$.[99,203,204,228,230] Among these substituents, the phenyl group has attracted particular interest (see last three columns of Table 3). Table 4, on the other hand, gives some indication of the influence of other groups upon the benzene ring. It was pointed out in 1953 [71] that substituents usually have a stronger influence on the intensity of lines for conjugated bonds than on the intensity of lines for isolated multiple bonds. These relationships are discussed in Section X.

Note. H atoms attached to carbon have been omitted in the formulae. The symbols are defined in Section VI.

Very similar mutual effects are observed in PhX compounds and in compounds with various CC π-bond systems (or one such bond) in place of the Ph group. Hence, many of the conclusions obtained from studies of PhX compounds are capable (in principle) of being generalised. However, compounds in which the π-bond system has degenerate donor–acceptor properties exhibit some additional specific features.

Table 4 lists some intensity coefficients for the characteristic line of the benzene ring, lying in the region 1570–1610 cm^{-1}. Alkylbenzenes have two closely spaced lines (the vibration modes are given in Fig. 1 of Ref. 107). The higher-frequency line is associated with a symmetric vibration of the ring (though some workers have erroneously assigned it to an antisymmetric vibration). Its intensity (but not its frequency) is extremely sensitive to the effect of substituents [125,153]. In the presence of conjugation this line is the predominant one, and the second line of the doublet makes a negligible contribution to the experimentally observed total intensity (designated I_{1600} in the Table). The spectra of PhX contain also a characteristic line at ~ 1000 cm^{-1}, whose intensity is far less sensitive to the nature of X: the ratio I_{1600}/I_{1000} can therefore be used to study conjugation with the benzene ring [153]. Table 4 gives only the I_{1600} values; for molecules containing two benzene rings the quoted value is $0.5 \cdot I_{1600}$.

The third column of Table 4 lists the exaltation of molecular refraction (EMR) for λ = 5893 Å arising from the interaction [107] between Ph and X. The next three columns give the wave lengths of the u. v. absorption band maxima which are genetically related to the benzene bands (λ given in Å for solutions in heptane). The figures in italics are $\epsilon/1000$ values, where ε is the molar decimal absorption coefficient at the band maximum [244]. The penultimate column contains the Hammett σ_{para} constants. Literature references to the quoted I_{1600} values are given in the last column of Table 4.

Table 4 summarises the properties of compounds with different types of substituent X. No direct effect on the spectrum is observed, whether the group is an electron donor, an electron acceptor, or neutral, and also whether or not it contains multiple bonds, unshared electron pairs, or heavy atoms. In each of this types, both "active" and "inactive" groups can be found. There is only one important general rule: large values of I_{1600} and EMR are usually associated with u. v. absorption bands which are both strong and close to the visible region of the spectrum. As a rule, substituents of all types tend to increase λ, I_{1600}, and EMR. [107,244] However, the deviations from additivity of the dipole moments (Δμ, see Ref. 107) are not all of the same sign: hence some justification exists for classifying substituents into electropositive and electronegative types.

When the substituent X in PhX compounds contains CC π-bond systems, both Δμ and σ are almost zero, and yet the deviations from additivity in the optical properties are large. On the other hand, substituents which favour the inductive effect (F, NR_2H^+, SO_2R) have finite (and often large) values of σ and Δμ, but their effect on the optical properties is very slight. Cases have been reported of substituents affecting some optical properties in the positive sense and others in the negative sense. Hence we may conclude that simple (linear) correlations between the optical parameters, the electronegativity of the groups X, and the σ constants are unlikely to exist [107] (see also Sections V and XII).

It is evident, from the general properties of PhX compounds, that the intensity of the Raman lines due to

π-bonds is extremely sensitive to conjugation ($\pi-\pi$, $n-\pi$, $\sigma-\pi$) and relatively insensitive to the inductive effect. Donor–acceptor interactions (leading to a redistribution of the electron density between parts of the molecule), to which anomalies in the dipole moment are ascribed, have only an indirect influence on the optical properties.

A consideration of the system of energy levels or MO energies for models of the type PhX or C=C–X makes it obvious that the absorption bands can be shifted towards longer waves by electronegative, electropositive, or even neutral X substituents in the presence of conjugation [244]. The potential well model of the electron indicates that the electronic levels should move closer together when the well is made wider. Thus, any addition to the molecule which increases the length of the chain (at least, in the absence of steric hindrance) should induce a bathochromic shift of the u. v. absorption bands [93] and increase the intensity of the Raman lines.

Table 5. Spectroscopic evidence for the effect of substituents X (shown above the numerical entries) in compounds of type PhX (I_{1600}, figures on the left) and C=C–C—X ($I_{C=C}$, figures on the right); the differences in $\omega_{C=C}$ between the compounds C=C–C–X and C=C–Alk are shown in heavy type.

Note. Numbers in brackets are tentative estimates of I from u.v. spectral data. "All" denotes the allyl group. This Table was assembled from data in Refs. 232, 245, 246, and also 176.

We shall now consider in detail the influence of substituents not containing multiple bonds. Table 5 gives some indication, in spite of the scarcity of experimental data, of the way in which the position of the substituent atom Z in the Periodic Table affects its influence on a π-bond or a π-bond system (denoted by the letter П) in groupings such as П–Z and П–CH_2–Z.

When Z is directly adjacent to П, the largest effect on the optical properties and on the rigidity of the bonds is produced by the atoms N and S ($n-\pi$ conjugation). The P atom has a significant effect, and its orbitals (including $3d$) contribute to the delocalised MO [226] (see also Ref. 227). The influence of the boron atom is ascribed [242] to the contribution from its vacant $2p$ orbital.

There is a shortage of data on the influence of Z on the force constants (rigidity) of π-bonds in П–Z systems, and indirect arguments are unreliable in this context, because of the appreciable contribution from the C–Z bond to the "π-bond vibration". Increased rigidity in П–Z systems (as compared with П–R systems) has been observed on a number of occasions (fluoro derivatives, chloro-anhydrides); decreased rigidity of C=C, C≡N, C≡C has been found to be induced by the atoms Si, Ge, Sn, [207] O, [247], S, [225,247] and N. [248] The effect of the Si, Ge, and Sn atoms arises mainly from $\pi-d$ conjugation involving the vacant d orbital of the Z atoms, [204,207,249] or from the inductive effect [207,250]; the effect of halogens is mainly inductive [200], that of the N, S, and O atoms is the result of $n-\pi$ conjugation.

Compounds in which Z is from Groups I–III of the Periodic Table have not been investigated in detail, but a significant lowering of the frequency of multiple bonds has been observed (see for example Ref. 251). This effect may be partly due to a decrease in the rigidity of the bond. However, calculated values of $K_{C\equiv N}$ for RHgCN and $Hg(CN)_2$ did not differ appreciably from those for RCN. [252]

Decreased rigidity of a π-bond is often accompanied by an increased intensity of the Raman line. In spite of the contribution of the ordinary C–Z bond to the "π-bond vibration" of the П–Z system in antiphase (provided the mass of Z is not too low), [225] the intensity of the π-bond line is usually increased by substituents [204]. This is closely bound up with the fact that conjugation in its various forms tends to shift the u. v. bands towards the longer-wave end of the spectrum (see above). According to Jones [253], the values of I^S_{CN} for mercuric cyanide and $H_2C(CN)_2$ are practically identical.

X. $n-\pi$ CONJUGATION

The influence of atoms having a labile unshared electron pair on the rigidity of π-bonds and on the optical properties of the compound is usually ascribed to $n-\pi$ conjugation involving a π^* orbital, but some workers have invoked the inductive effect [248]. The rigidity of the π-bond is decreased by a small amount (3–5%), and the rigidity of the C–Z bond is increased by a large amount (up to 30%): [248] this is usually interpreted as some measure of double bond character. It is interesting to note [248] that the off-diagonal force coefficient which determines the interaction between the C–Z and the π-bond has a positive influence in this case: this means that stretching of the π-bond is accompanied by a shortening of the C–Z bond and vice versa [101].

The tendency of the Z atom to $n-\pi$ conjugation depends [254] on the p character of the orbitals of the unshared pair: the most favourable conditions correspond to overlapping of the n and π orbitals in systems.

Compounds with a well developed $n-\pi$ conjugation show a bathochromic shift of the u. v. absorption bands and an increased intensity of the Raman lines for the multiple bond. Some of these systems are listed below in increasing order of effect of $n-\pi$ conjugation on intensity:

AlkO—COR [15,220], AlkO—C=C [15,226,239,255],
AlkS—C=C [225],
R_2N—COR [126,220], R_2N—C≡N [138], Alk_2N—C=C [126],

There is no increase in the intensity of the C=O line for the first member of this series, but in the last two

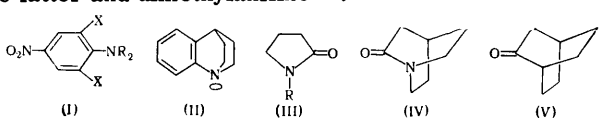
members I_{CO} and I_{NO_2} are increased by over a factor of ten as a result of the presence of the amino group. The fact that the amino group increases I_{CO} by only a factor of 1.5 in R_2NCOR and by a much greater amount in *p*-aminoacetophenone is explained by the relative positions of the strong u. v. absorption bands of these compounds (in the far u. v. for the former, and much nearer the visible region for the latter). The shift of a closely spaced band is reflected more strongly by the resonance denominator in the expression for the intensity than is the shift of a more remote band. (We note, however, that the λ shift produced by an amino group becomes somewhat smaller when the chain of conjugated bonds is extended still further.)

The redistribution of electron density between substituents, which affects the dipole moment of the molecule and $\omega_{C=O}$, is determined by different considerations. The effect is strongest if R_2N and COR are immediately adjacent, somewhat weaker if these two groups are separated by a benzene ring, and weaker still when a more complex system of CC π-bonds is interposed. These observations are easily explained by considering the systems of energy levels of the main fragments of the molecule and the combination of their wave functions with formation of delocalised MO and new electronic transitions (see, for example, Fig. 6 in Ref. 244).

In the light of the above, it is not surprising that the anomalies in optical properties of the molecule $PhCONR_2$ are associated mainly with interactions in the Ph–CO system, whereas the dipole moment anomalies relate to the system $CONR_2$.[220]

On spectral and dipole moment evidence[219,231] conjugation with the SO_2 group is very weak in sulphonamides; the observed shortening of the N–S bond is ascribed[256] to local interaction with the vacant S *d*-orbital.

The $n-\pi$ conjugation conditions are very dependent on the angle of rotation of the conjugated groups. In unsubstituted dimethylaniline, when steric hindrance is negligible, the two methyl groups are symmetrically disposed on one side of the plane of the benzene ring, and the wave function of the unshared pair of electrons effectively overlaps the *p* orbital of the carbon atom. The same is true of 4-nitrodimethylaniline. In the 2,6-disubstituted derivatives of dimethylaniline and 4-nitrodimethylaniline (I), the NR_2 group is rotated through an angle which does not favour conjugation (the direction R...R forms a fairly large angle with the plane of the ring). The influence of NR_2 on the benzene ring and on the nitro group becomes much weaker[257]. In benzoquinuclidine (II) the wave function of the unshared electron pair (shown by an oval symbol in formula (II)) is "cleaved" by the nodal plane of the *p* orbitals of the ring into two equivalent zones: the $n-\pi$ overlap integral therefore vanishes, the unshared pair is practically immobilised, and the nitrogen atom has almost no effect on the optical properties. Nevertheless, benzoquinuclidine is very different in basicity from quinuclidine, and is intermediate in basic strength between the latter and dimethylaniline[258].



(I) (II) (III) (IV) (V)

Some data on the effect of angular rotation on conjugation effects are available for the system  . Thus, *N*-methylpyrrolidone (III) has an almost planar b Od system, and shows distinct conjugation effects: the C=O frequency is lower than in cyclopentanone by 55 cm^{-1}, and $I_{C=O}$ is slightly higher[126]. On the other hand, in quinuclidone (IV), where the overlap integral of the *n* and π* orbitals is zero, $\omega_{C=O}$ is actually much greater than in bicyclo-(2,2,2)-octan-2-one (V).[259] We note that an increase in $\omega_{C=O}$ is usually observed on introducing electronegative substituents (for example, in RCOCl). These results suggest that a given group can behave either electropositively or electronegatively depending on its angle of rotation. It is interesting to note that the basicity of quinuclidone (IV) is much lower than that of quinuclidine[259] in spite of the unfavourable geometry of the N–C=O system from the point of view of conjugation.

Not surprisingly, all evidence of $n-\pi$ conjugation in aromatic amines disappears on forming salts: see the data for $PhNR_2$ and $PhNR_2H^+$ in Table 4.

In Π–OR and Π–SR systems, n,π conjugation is most evident when the fragments are in the same plane. Conjugation is very weak in non-planar mesityl compounds. It has been pointed out[260] that the sulphur atom has both donor properties (resulting from the unshared electron pair) and acceptor properties (resulting from the vacant 3*d* orbital). In some systems the donor properties are almost absent, but the acceptor properties persist because π-*d* overlapping is retained.

Some data suggest a difference in conjugation behaviour between *s-cis* and *s-trans* isomers. Simple vinyl ethers have mainly the *s-trans* form, and they show low $\omega_{C=C}$ and $K_{C=C}$ values and high $I_{C=C}$ values as a result of the influenee of OAlk;[15,226,255] no such behaviour is found with compounds of the type  .[261] In the analogous cyclic compound of sulphur both $\omega_{C=C}$ and $I_{C=C}$ are modified[261], but in every case they are lower than in the open-chain molecule[225].

XI. $\pi-\pi$ CONJUGATION

Molecules with alternating multiple and single bonds usually show a small decrease (0–20%) in the rigidity of the multiple bonds and a more substantial increase (up to 30%) in the rigidity of the intervening single bonds, which has been ascribed partly to atomic orbital hybridisation phenomena and partly to some measure of double bond character (nitrobenzene[262], diacetylene[263,264], glyoxal, acrolein[114], butadiene[113,265], and to a lesser extent diacyanogen[113]). However, different authors have obtained entirely different quantitative results. Some workers conclude that the off-diagonal force coefficient which characterises the interaction of the two π-bonds has a large, negative value[113,114,263]; this implies that the stretching of one π-bond induces an additional force field in the other π-bond, tending to elongate it[101].

The clearest evidence of $\pi-\pi$ conjugation comes from the increased intensity of Raman lines—in particular, the lines associated with stretching vibrations of conjugated multiple bonds. There are some early qualitative reports[266] of unusually strong lines from C=C and C=O double bonds in the presence of conjugation. Quantitative measurements of $I_{C=O}$ in acetophenone and benzophenone[215], I_{NO_2} in nitrobenzene, nitronaphthalene, and nitroaniline, $I_{C\equiv N}$ in benzonitrile and vinyl cyanide, and $I_{C=C}$ in styrene, vinyl cyanide, acrylates, butadiene, and hexatriene[15,28] have shown that a high intensity is characteristic of coplanar systems of alternating multiple and single bonds[28]. An unusually strong C≡C line has been

observed in phenylacetylene [37,229]. When an electronegative group (CN, NO_2, COR) is combined with a system of CC π-bonds, the lines of both fragments show an abnormally high intensity (particularly those of the electronegative group).[28] Oxalates [200,220], and vinyl and phenyl sulphones [219,227,231], show no enhancement of refraction or of Raman line intensity in spite of the non-additivity of the dipole moments in phenyl sulphones (see Tables 3 and 4).

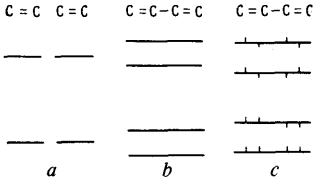


Figure 7. Filled and vacant π orbitals in the C=C-C=C system: *a*) in the absence of conjugation, *b*) and *c*) in the presence of conjugation for two extreme positions of the C atom ("symmetric C=C vibration"). The vertical strokes in diagram *c* denote the sign of the AO contributions.

Experiment has shown that $I_{C=C}$ is approximately 10 times higher in butadiene than in mono-olefins, and 10 times higher still in the triene [15]. Further increase in the number of conjugated double bonds makes the intensity progressively higher [12].

Studies of the absorption spectra and of $I(\nu)$ lead to the conclusion that the difference in ν_e between butadiene and mono-olefins is sufficient to account for a four-fold increase in intensity. If account is taken also of differences in oscillator strength, in the amplitude of the natural coordinates, and in the anisotropy, the ten-fold increase in intensity in butadiene can be explained by applying formula (2).[35] It should be noted that after the transition of an electron to the lowest vacant orbital (π_3^*), the equilibrium value of q_{C-C} should decrease a little and that of $q_{C=C}$ should increase (though by less than in the corresponding $\pi \rightarrow \pi^*$ transition in mono-olefins). The same conclusion follows from the fact that the wave function of π_3^* has nodal points in the region of the double bonds but not in that of the intervening single bond (see Fig. 7). Thus, the equilibrium value of the normal nuclear coordinate for the "stretching symmetric vibration of the C=C bonds" should by changed by electronic excitation, and $\partial\nu_e/\partial Q$ should be non-zero. Systems with different numbers of conjugated double bonds are discussed in detail in Ref. 12.

Facer and Thompson [129] have proposed a formula for the intensity, including terms which allow specifically for the effect of "mesomerism" and for the shift in ν_e, and appear to be unsoundly based.

Calculations for the butadiene molecule by various MMO variants give a π order of between 0.15 and 0.5 for the central C–C bond and between 0.8 and 0.95 for the double bonds. It is stated [267,268] that the alternation of bond orders and force constants [113,269] found in butadiene is retained almost unchanged in the polyene chain. The decrease in the "C=C vibration" frequency with increase of chain length is due to a slightly increased contribution from ordinary bond vibrations, not to a change in $K_{C=C}$.

An increase in the length of the polyene chain has little effect on $\omega_{C=O}$, but it leads to a rapid increase of $I_{C=C}$ and $I_{C=O}$, with extremely high values under resonance conditions, when the frequency of the exciting light (22 938 cm^{-1}) is in the region of the absorption band. With still further increase in chain length the band in the electronic absorption spectra is shifted towards the red and the intensity of the Raman lines (as expected from theory) begins to fall off. The very high intensity obtained by resonance excitation of the spectra of polyenes is due to the relatively small damping constants ($\gamma < \omega$!).

Table 6.

n	$\omega_{C=C}$	$I^s_{C=C}$	$\omega_{C=O}$	$I^s_{C=O}$	ν_e
0	—	——	1760	40	——
1	1664	300	1733	350	48 100
2	1643	5000	1726	800	38 500

6	1562	$17 \cdot 10^6$	——	——	26 300
7	1550	$400 \cdot 10^6$	——	——	24 800
8	1540	$200 \cdot 10^6$	——	——	23 300
10	(1500)	$(50 \cdot 10^6)$	——	——	(20 500)

Data [12,76] for the C=C and C=O lines of the series of compounds EtOOC–$(CH{=}CH)_n$–COOEt (in acetone) are set out in Table 6 together with the position of the main u. v. absorption band (ν_e, cm^{-1}). Values shown in brackets are tentative extrapolations. The u. v. spectra are shown in Fig. 8.

Vol'kenshtein and Yazykova [270] have tried to calculate $I_{C=C}$ for a molecule with conjugated C=C bonds by using the metal model (π-electron approximation); the symmetric vibration of the double bonds was modelled by simply changing the length of the potential well, leading to a change in ν_e. Savin [271,272] applied the π-electron approximation to a single electronic transition, and described the changes in ν_e induced by the vibration of the atoms in the chain by taking account of the coefficients for the type of vibration. In the final variant, the potential was assumed uniform along the chain. Good qualitative agreement with experiment was obtained in both these investigations.

It should be possible to calculate α and α' under non-resonance conditions for any (not too complex) molecule, irrespectively of whether the additive scheme or the free-electron model is applicable, by computing the electronic energy levels and transition probabilities for all the electrons, and their interactions. Of course, calculations based on MMO LCAO are not very precise, but they have some predictive value.

Contradictory views have been expressed on the role of the inductive effect in molecules with conjugated multiple bonds. The question can be answered with greater confidence by comparing molecules in which the mutual orientation of the fragments is different, for example in the "benzene ring–nitro group" system. The deviations from additivity in the optical properties, dipole moments, and many other parameters of the planar, unsubstituted nitrobenzene molecule (the angle of rotation of the nitro group about the C–N bond is $\theta = 0°$) are quite substantial.

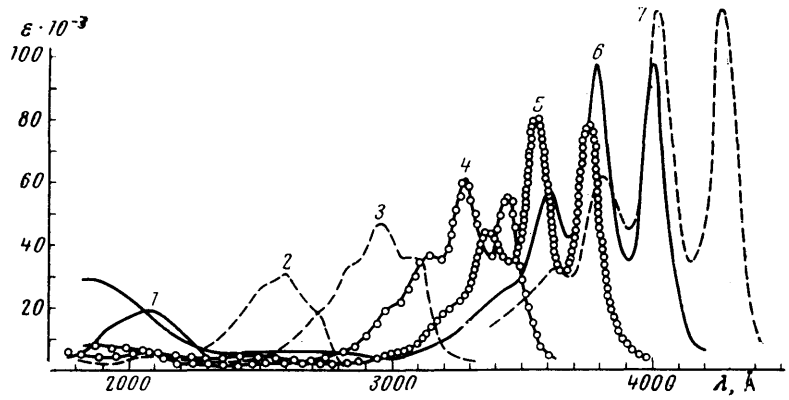

Figure 8. Absorption spectra of heptane solutions of EtOOC-(CH=CH)$_n$-COOEt. The value of n is shown on the curves.

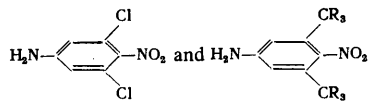
The introduction of substituents in the *ortho*-position increases the value of θ to a greater or lesser extent, which can be calculated from the force field. We express[95] the potential energy of the molecule as

$$U = U_0 + U_u + U_{def} + U_\theta,$$

where U_0 is the energy of the planar molecule in the presence of conjugation and in the absence of steric hindrance, U_u is the energy expended against forces acting between unbound atoms, U_{def} is the energy needed to deform the bond angles, and U_θ is the conjugation energy. U_{def} can be determined by introducing angular force constants, U_u can be determined by means of the Lennard-Jones potential function. A knowledge of the van der Waals radii is not sufficient, because the atoms are not rigid spheres; furthermore, the potential is influenced by any excess of positive or negative charge on the atoms. This explains, at least in part, why Cl, Cl *ortho*-substituents affect the rotation of the nitro group more strongly than CH_3, CH_3, whereas the converse is true of the rotation of the NR_2 group[95].

Table 7 shows a set of data[95,273] for derivatives of nitrobenzene: a) the difference between the nitro-group frequency of the given compound and that of unsubstituted nitrobenzene (1348 cm^{-1}, in benzene solution); b) the intensity I^S of the line of the nitro group (in benzene solution); c) the absorption coefficient at 2500 Å (in heptane solution); d) the deviation from additivity in the dipole moment; e) the estimated angular rotation θ of the nitro group. The figure in brackets is a tentative estimate.

It is evident from Table 7 that the mutual effect of Ph and NO_2 is almost completely suppressed when the angle θ is large. The interaction between the nitro group and substituents in the *para*-position also has been shown to be weakened, for example in the molecules[257,274]



In the latter compound the calculated rotation[274] is $\theta = 80°$, and the intensity of the first strong u. v. band is decreased by a factor of 20. It is interesting to note that the rotated nitro group retains some of its effect on the basicity of the amino group: this is ascribed[274] to the fact that the inductive effect persists even though conjugation has disappeared.

Thus, we may conclude that, in spite of the large polarity of the nitro group, the inductive effect has a negligible influence on the rigidity of chemical bonds in aromatic nitro compounds, on their dipole moments, or on their optical properties, but a large effect persists on the rate constants of chemical reactions with an ionic mechanism.

Table 7. Spectra of X-  -NO$_2$ compounds in nitropropane.

Group X	$\Delta\omega$, cm^{-1}	I^S	ϵ_{2500}	$\Delta\mu$	θ
H	0	700	9600	0.8	0
CH_3	17	250	1900	0.4	55°
Cl	14	50	1300	0.1	70°
Br	10	50	3500	0.1	—
$C(CH_3)_3$	29	(40)	800	—	75°
$PrNO_2$	36	35	—	0	—

On going from trichloronitrobenzene to tribromonitrobenzene, I_{NO_2} decreases (as expected), but ϵ_{2500} increases. It is evident that the "benzene ring–bromine atom" system is beginning to dominate the u. v. spectra, so that any information regarding conjugation with the nitro group is lost. It is equally difficult to detect disturbance of the conjugation from $\Delta\omega$ values, because the frequency is affected by the mass of the halogen atoms. The I^S values are not significantly affected[95] by these factors. Egorov and coworkers[196] have published some interesting results on non-planar fluoro-derivatives of stilbene.

Planar *s-trans* and *s-cis* systems show some interesting differences in the conjugation of their double bonds. The intensity of the C=C lines in diene systems of the *s-trans* type is approximately twice as high as that of the *s-cis* systems[275,276]. This is partly due to the lower contribution of anisotropy in α' to the observed intensity

in the *s-cis* systems. The force field is very different in the two cases, as shown by the relative frequencies of the two forms of stretching vibrations of the double bonds: in *s-cis* dienes (as opposed to *s-trans* dienes) the antisymmetric vibration has the higher frequency, possibly as a result of differences in the off-diagonal force coefficients. The effect of conformation on $I_{C=C}$ is particularly strong in trienes [275].

In  systems, where the C=C and C=O vibrations are fairly well separated [114,277], $I_{C=O}$ is large [15,98,278], and in  systems $I_{C=C}$ is large [277]. In the latter case the vibrations are less localised: the higher frequency, and more substantial contribution from the C=O bond, are assigned [279] to the "anti-phase" vibration of the double bonds, and hence the intensity of the line is small.

Many papers have been published on cyclic diene systems [44,234,275,276,280,281] and on open-chain diene compounds [205,281,282].

XII. CONJUGATION IN X–  –Y MOLECULES

In compounds of the X–C_6H_4–Y type, changes in the frequency ($\Delta\omega_Y$) of the quasi-local vibration of the group Y under the influence of X can be used directly as an approximate criterion of changes in the rigidity of the chemical bond, which can be as high as 10%. Difference of 2–4 cm^{-1} in ω_Y are significant in this respect. The effect on the frequency and on the stiffness of the bonds is most marked for a pair of substituents one of which is an electron donor of the first type in Section V, the other an acceptor (a *k*-acceptor and a *k*-donor in the writer's terminology [109,110]); the effect is smallest when the two substituents are of the same type. The same is true of the deviations in additivity of the dipole moments and of the specific features of Hammett's σ constants. These effects are illustrated in Fig. 9, which shows the correlations between $\Delta\omega_Y$ and the donor–acceptor properties of the group X, characterised by the deviations from additivity in the dipole moments of the molecules PhX. (A positive value of $\Delta\mu$ corresponds to a shift of the electron density from X towards Ph.) The data for NO_2 and NH_2 are arithmetic means of $\Delta\omega^S$ and $\Delta\omega^{as}$. These curves were drawn from measurements of ω in CCl_4. [225,231,283,284] The influence of X on ω_Y is sometimes enhanced by solvation in more "active" solvents, and is less marked when the molecules are isolated as in vapours (see the data for *p*-nitroaniline and other similar compounds [124]).

As regards the influence of substituents on the intensity, the conjugation conditions (in particular, the number of conjugated bonds) are the determining factor for the Raman lines of multiple bonds. Thus, the vinyl group (or a whole system of CC π-bonds) in position X has a negligible effect on the frequency of the lines for the double bonds of the group Y (a few cm^{-1}), but it has a powerful effect on their intensity, which may change by a factor of 1000. This phenomenon is closely bound up with the effect on ν_e.

The large decrease in the frequency ν_e of the first u. v. absorption band when X and Y groups of different types are combined can be explained by considering the energetics of the orbitals of the fragments and of the MO of the X–П–Y system (see Fig. 6 of Ref. 224). A decrease in ν_e has a direct effect on I_Y, but changes in ν_e' and f_e' are also important (see Section II). Some calculations can be found in Ref. 235.

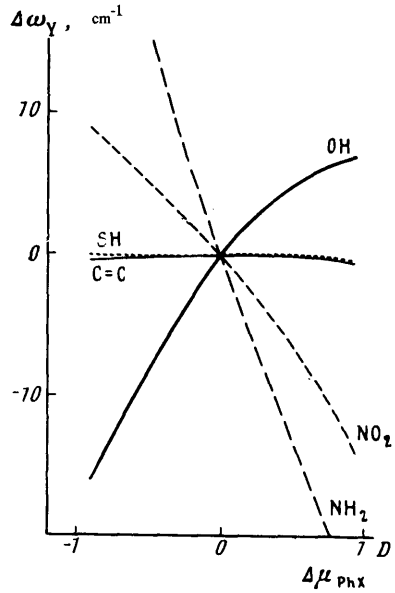


Figure 9. Change in ω_Y under the influence of the group X in X– –Y compounds; the group Y is specified on the curves.

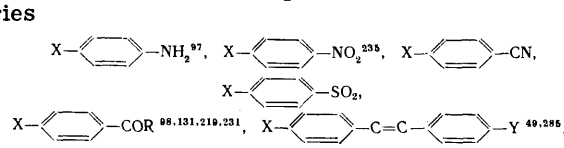
A comparison of various parameters of molecules in the series



has revealed a number of correlations between deviations from additivity in the dipole moments, the $\Delta\omega_Y$ values, and the Hammett constants (σ) for the group X. [97] On the other hand, approximate correlations have been observed between the various manifestations of the mutual effect of the groups X and Y in different optical properties [235]: the greater the deviations from additivity in the effects of X and Y on the u. v. spectra, the more prevalent are large values of I_Y (at least for the lines from double and triple bonds), exaltation of molecular refraction, and dispersion of the refractive index. However, various attempts to establish simple relationships between pairs of the above parameters (e.g. between I_Y and σ_X) have been successful only over a very limited range of compounds (see Ref. 66 and 138).

XIII. CONJUGATION WITH A THREE-MEMBERED RING

Compounds containing a three-membered ring show certain similarities with olefins in chemical properties (for example, in addition reactions involving ring-opening).

Their physical and chemical properties suggest interaction between the three-membered ring and systems of double bonds. A significant increase in the intensity of the Raman lines due to multiple bonds and to the three-membered ring has been observed in cyclopropylketones [201], vinylcyclopropane [286,287], phenylcyclopropane [218,243], and glycidates [127]. It is interesting to note that in *p*-dicyclopropylbenzene the intensity of the line for the benzene ring (I_{1600}) is even higher than in phenylcyclopropane: the behaviour is similar to that of a conjugated chain [243].

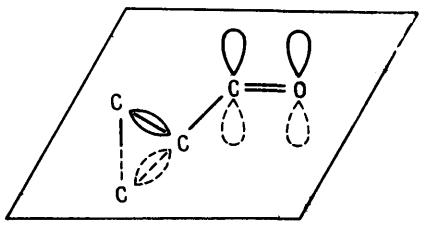


Figure 10. Disposition of the orbitals in the spirocyclopropancyclopentanone ("three-membered ring–double bond") system.

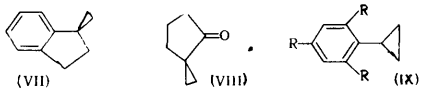
Phenylcyclopropane and *C*-phenylethyleneimine are intermediate between toluene and styrene (see Table 4) in their I_{1600} value and in their u. v. spectra. This evidence of conjugation has been ascribed [288] to hybridisation of the AO of the carbon atom in the three-membered ring, leading to some measure of sp^2 character. The valency electrons which form the ring are assumed to have some π-electron character. The configuration in which the three-membered ring and the π-bond system are in mutually perpendicular planes (see Fig. 10) is most conducive to conjugation [286]: this is found, for example, in spirocyclopropanindane (VII) [288] and spiro-cyclopropancyclopentanone (VIII). [289] In mesitylcyclopropane (IX) the optimum conformation from the point of view of conjugation cannot be achieved, and in this compound I_{1600} is hardly greater than in mesitylene, which suggests that conjugation is almost entirely absent [287].



(VII) (VIII) (IX)

If the C<(C)(C) plane in isopropylbenzene is perpendicular to the plane of the benzene ring, the highest filled σ-orbital of C<(C)(C) can overlap the *p*-orbital of the C_{ar} atom. However, significant perturbation and combination of the wave functions is precluded by the large difference in energy of the orbitals of the two fragments. These effects can occur, however, with the cyclopropyl group, because of the lower energy of its $\sigma \rightarrow \sigma^*$ transition.

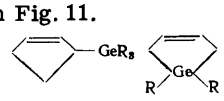
According to Bent [290], the electronegative nitrogen atom in *C*-phenylethyleneimine should enhance the *p*-character of the bonds in the three-membered ring. This is not confirmed by an analysis [218] of Raman line intensity data.

In *N*-phenylethyleneimine, Ph–N<(C)(C), I_{1600} is determined mainly by n,π conjugation, which is controlled by the rotation of the three-membered ring. This compound differs from phenylcyclopropane in having the two C atoms on the same side of the Ph plane. I_{1600} for *N*-phenylethyleneimine is lower than the value for $PhNR_2$ by almost a factor of two: this is ascribed [218] to the more pronounced *s* character of the unshared electron pair of the nitrogen atom.

XIV. SYSTEMS WITH A BRIDGING ATOM (Π–M–Z). σ–π CONJUGATION

Systems of bonds with a bridging atom are extremely interesting. They include some radicals found in the majority of organic compounds. In a number of systems of the type $\Pi-CH_2-Z$ and similar systems with different bridging groups (Π–M–Z), the influence of Z is as strong as in the system Π–Z (see Tables 4 and 5). [232,244] However, the special features of the effect are different in the two cases. Thus, the N atom of the amino group has a strong effect on the spectra in Π–Z systems, but practically none in $\Pi-CH_2-Z$ systems, whereas the opposite is true of the Hg atom. The presence of an unshared electron pair in Z, and the polarity of the substituent, have only a minor significance in systems with a methylene bridge, but heavy atoms have an important effect [220,232,291]: within a given period of the Periodic Table, the effect of Z on the Raman and u. v. spectra of $Ph-C-ZR_n$, $C{=}C-C-ZR_n$, and other similar systems increases somewhat on going from right to left [291]. This tendency is most marked with compounds which include a *k*-acceptor group—for example, $ROC-CH_2-ZR_n$—since conditions are then favourable for donor–acceptor interactions and the rigidity of the double bond is decreased more substantially [245] (see Table 5, which lists $\omega C{=}C$ and I_{1600} for the corresponding allyl and benzyl compounds).

It has been shown [291] that as the atomic weight of the atom Z increases (within a given sub-group of the Periodic Table) the effect of the substituent on the optical properties of $\Pi-CH_2-Z$ systems increases and the frequencies ν_e of the u.v. $\pi-\pi^*$ bands decrease. Under these conditions molecules which are known to be non-planar (as opposed to π,π conjugated systems) show the largest deviations from additivity. Thus, compound (X) has Raman and u.v. spectra [245,291,292] ($I^S_{C=C} = 160$ [292]) very different from those of cyclopentene ($I^S_{C=C} = 28$), whereas molecule (XI) which has an almost planar ring is similar to cyclopentene ($I^S_{C=C} = 25$ for (XI) [292]). The u.v. spectra of these compounds are shown in Fig. 11.



(X) (XI)

These spectra repudiate [292] the view [293,294] that the key role is played by the overlap of two *p*-orbitals of the C atoms adjacent to the double bond with a *d*-orbital of the Si atom (C=C–Si) or with Hg orbitals in systems like C=C–C–Z.

None of the above experimental results, including those concerning angular dependences, in any way conflicts with the view that $\sigma-\pi$ conjugation can be ascribed

to the overlap of the wave functions of the double-bond π-orbitals with the two-centre orbital of the C–Z σ-bond (or the multi-centre orbital of the C–Z group). When the σ-bond is in the plane of the π-bond system (in the nodal plane of the p-orbitals) the overlap vanishes, and when it is at right angles to this plane the overlap is a maximum. On the other hand, when the orbital energies of conjugated π and σ bonds are similar, and the latter bond includes a heavy atom Z, combination of the wave functions is favoured [291]. Several authors have studied the system R_3Si-CH_2-COR, and have variously concluded that the most important effect is the inductive effect [250], the interaction between the unshared electron pair of the oxygen atom and the vacant Si–orbital [295], or the presence of a resonance structure of the type $Si^+C=C-O^-$ (see Ref. 250). In benzyltin and other similar compounds the inductive effect [296] or p_π-d_π conjugation [293,327] are the most important.

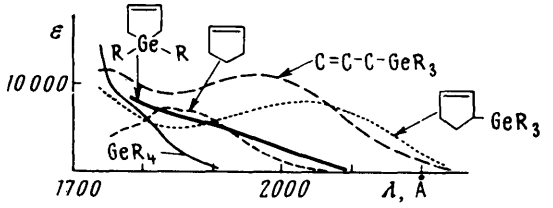


Figure 11. U. v. absorption spectra (in heptane solution).

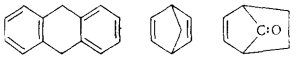
The virtual absence of σ-π conjugation effects in ordinary open-chain organic molecules containing C, H, N, O, and Cl atoms is due to the high energy of the $\sigma \rightarrow \sigma^*$ transition and therefore to the small contribution of the C–Z σ-bond to the highest filled and the lowest vacant MO; the low conjugation energy ($< kT$) does not allow the bonds to take up the orientation most favourable to conjugation.

In systems of the type $\Pi-CH_2-\Pi'$ the deviations from additivity in the Raman (and also the u.v.) spectra are quite insignificant. (The systems which have been investigated include Ph–C–Ph, Ph–C–C–Ph, [220] Ph–C–C=C, [161] C=C–C–C=C, [281] Ph–C–CN, [232] and limonene [15].) However, when the fragments have some well defined orientations (as in tripticene, where the planes of the three benzene rings are at 120° to each other) the first u.v. absorption band has a high intensity [297]. In dihydroanthracene (XII), norbornadiene (XIII), and other similar compounds the anomalies are not very marked; it has been suggested [298] that in these molecules the two electronic oscillators are weakly coupled.



(XII) (XIII) (XIV)

Most workers consider that the most important effect in this type of molecule is the overlap of the p orbitals of the two nearest carbon atoms from different fragments. Depending on the orientation of these AO, large differences in the perturbation of the electronic levels are possible. Thus, in system (XIV) the p orbital of the C atom of the carbonyl group partly overlaps the C=C π orbital (but not the π^*, which has a nodal point in the middle of the double bond). On the other hand, the AO of the unshared electron pair of the oxygen atom overlaps the π^* orbital (though to a very small extent). Hence, the energies of the various electronic transitions are affected in different ways. In the spirene molecules the systems of double bonds lie in mutually perpendicular planes, but some interaction can nevertheless take place; in spiro-nonatetraene we expect interaction between the highest filled and also the highest vacant orbitals of the fragments [299] (see Fig. 12).

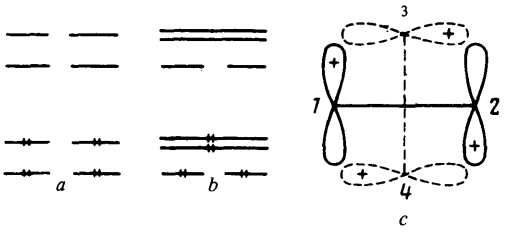


Figure 12. Energy of the π orbitals in the system: *a*) for the two separate fragments; *b*) in the presence of interaction between the fragments; *c*) p orbitals of the carbon atoms *1*, *2*, *3*, *4* (the observer is looking along the symmetry axis *4*). The signs correspond to the upper filled MO.

Cookson [300] considers a system of bonds of the type  . If the central C–C bond is in the *gauche* position with respect to each of the double bonds, its σ orbital is assumed to overlap the π orbitals of the two C=C bonds, with the possibility of splitting of the π electron levels and "σ-coupled π-electron transitions". Under these conditions the C–C σ bond takes practically no part in the electronic transition but it allows delocalisation of the transition.

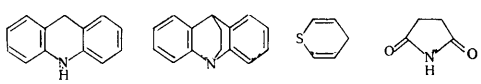
In molecules of the type $X-CH_2-Y$ where X is an electron-donor group of the first type (see Section V) and Y is an electron-acceptor group of the second type, donor-acceptor interaction can occur with increase in the multiplicity of the X–C bond and a corresponding decrease in the multiplicity of the C–Y bond. Under favourable conditions, ions can be formed: $(X^+=CH_2) + Y^-$ (for example, $R_2N^+-CH_2-Cl \rightarrow (R_2N^+=CH_2) + Cl^-$, see Ref. 301). The combination of a donor group of the second type and an acceptor group of the first type gives, in the extreme case, the structure $X^+ + (CH_2=Y^-)$, as in $K^+ + (CH_2=NO_2^-)$.

The cyano group has weaker acceptor properties of the second type than has the Cl group; accordingly, the molecule $R_2N.CH_2.CN$ does not form ions similar to those suggested above for the chloro compound. However, their Raman spectra show a fairly large drop in ω_{CN} and in the rigidity of the C≡N bond; the characteristic absorption band of the amino group at 1900–2000 Å ($n \rightarrow \sigma^*$ transition) is considerably weakened, and the basicity of the amino group is decreased. All these effects are consistent with the participation of the unshared electron pair of the amino group in conjugation of the type described above [232]. Similarly, it has been shown [302] that the N–C bond is shortened and the C–CN bond in lengthened even when the orbitals of the triple bond and of the unshared

pair on the amino nitrogen cannot overlap. The influence of the amino group on ω_{CN} is much smaller in compounds of the type p-$R_2N-C_6H_4-CH_2-CN$ than in R_2N-CH_2-CN, but it can be detected [303]. The effect is entirely absent in the analogous carbonyl compounds, showing that COR has a very low capacity as an electron acceptor [232].

Data on compounds with -O-, -S-, and -NH- bridges and fragmentary and sometimes contradictory. Most of the work has been done on compounds of the Ph-M-Ph type, particularly diphenylamine, which in spite of lack of coplanarity, and some "competition" between the two electron acceptors, shows clear evidence of non-additivity: I_{1600} is higher than in aniline by a factor of 6 (see Ref. 220, where the u.v. spectra are also given). According to the u.v. spectra, the same deviations from additivity are found in acridan (XV). The Raman spectra indicate considerable interaction between the double bonds in N-vinylpyrrolidone. Acetanilide has very strong lines from the C=O group and the benzene ring; in the spectrum of Ph.NR.COR the symptoms of n-π conjugation with the carbonyl group are enhanced, and those of conjugation with the benzene ring are suppressed. This observation has prompted the conclusion that the angular rotation of the NRCOR group relative to the Ph plane is increased, and that conjugation in the N-C=O system is strengthened [126].

The main contribution to interaction in nitrogen-bridge systems comes from the unshared electron pair of the nitrogen atom, which is determined by the relative orientation of the fragments (see above). In the dibenzoquinuclidine molecule (XVI) the unshared pair is immobile, and as a result of this the spectroscopic evidence of interaction between the benzene rings and of n-π conjugation is almost totally absent [304].



(XV) (XVI) (XVII) (XVIII)

Π-S-Π′ systems have smaller deviations from additivity than the corresponding nitrogen-bridge systems. Nevertheless, $I_{C=C}$ for C=C-S-C=C was found to be at least double the value expected on the assumption of full additivity [223,280]. Judging from the u.v. spectra [305], the effect should be even greater in thiopyran (XVII). However, the carbonyl group in the C=C-S-COR system is found [306] to have a negligible effect on $I_{C=C}$. No deviations from additivity can be detected in Π-SO_2-Π′ systems [223,280].

Even smaller anomalies were found in compounds with an oxygen bridge [15,223,226,239,307,308]. $I_{C=C}$, $I_{C=O}$, and I_{1600} are slightly enhanced in compounds with the bond systems C=C-O-COR, Ph-O-C=C, and C=C-O-C=C, and an even more significant effect is found in $C_6H_5.C_6H_4.O.C=C$. In the presence of steric hindrance (for example, in mesityl vinyl ether) interaction effects are almost zero [223,239].

One interesting feature of the spectra of Π-M-Π′ systems with -O-, -S-, and -N- bridges is the fact that the frequencies of the π bonds adjacent to the bridging atom are higher (by 5-10 cm^{-1}) than the corresponding frequencies for Π-M-R and R-M-Π′ compounds; this effect may be due to the increased rigidity of the bonds, and possibly also to the contribution of off-diagonal elements [112,115]. In succinimide (XVIII) and in succinic anhydride the off-diagonal element corresponding to the interaction of the two C=O groups is fairly large; this element is related to the interaction conditions in the two n-π conjugated systems [112].

Very little is known about the influence of heavy atoms in Π-O-Z, Π-S-Z, and Π-NH-Z systems. In systems of this type, n-π conjugation favour a planar conformation, which in turn excludes σ-π conjugation. Mesityl compounds are known to be non-planar, with large θ angles, but no other information is available. Heavy atoms have been shown [291] to have less effect on the u.v. spectrum of the benzene ring in Ph-O-Z systems than in $Ph-CH_2-Z$ systems. The u.v. spectra of $Ph-NH-SiR_3$ do not differ significantly from those of Ph-NH-R. [309] Various workers [187,188,283] have found that the mercury atom in the -Hg-CN system has little influence on $\partial\alpha/\partial q$ for the C≡N bond, but its effect is quite large in -Hg-S-CN systems.

No departures from additivity have been observed in $Si(HC=CH_2)_4$, $Si(C\equiv CH)_4$, and other similar Si compounds, but the influence of heavy atoms through the Si bridge is apparently even greater than through the methylene bridge. Whereas the u.v. spectra of PhR and $PhSiR_3$ are practically identical, the compound $Ph.SiR_2.SiR_3$ (where the Si-Si bond is believed to form a large angle with the plane of the benzene ring) shows a large bathochromic shift of the u.v. band [93], which increases with the length of the chain of silicon atoms [310]. Since such chains give rise to a distinct closing-up of the electronic levels, conditions become favourable for combination of the wave functions of Ph and the substituent [93] (Sakurai and Kumada [311] have termed this a dative p_π-d_π bond). Non-additivity is particularly evident in the spectra of $Ph-(SiR_2)_n-Ph$ when n is large [312]; it is independent of the parity of n and indicative of direct participation of the orbitals of the bridging atoms in the conjugation. The interaction of benzene rings through the Sn-Sn group has been ascribed [313] to participation of the d orbitals of Sn, and in a similar way [242] the interaction through a boron atom has been ascribed to the participation of the $2p$ boron orbital.

The mutual influence of atomic groups in molecules of the type Π-M-Π′ and Π-M-Z is far from being fully understood, and widely different hypotheses and conclusions are currently being discussed. From the whole of the available data it would appear that interaction can take place by a number of different paths, including: 1) direct overlap of the orbitals of relatively close atoms of the groups Π and Π′ or of the orbitals of Π and Z; 2) participation of the orbitals of bridging atoms in the delocalised orbitals of the molecule (for example, in systems with σ-π or π-σ-π conjugation); 3) non-additive interactions (e.g. in n-π conjugation) in Π-M and M-Π′ systems, particularly as regards the population of the AO of the bridge.

Spectroscopic data on conjugation in systems of ordinary bonds are very scarce. U. v. spectral data suggest that the intensity of Raman lines for the chains $(SiR_2)_n$, $(GeR_2)_n$, and $(SnR_2)_n$ should be strongly non-additive [93]. The intensity of the C-I line has been found [314] to be much greater in the $I-CH_2-CH_2-I$ spectrum than in the $I-(CH_2)_3-I$ spectrum.

XV. APPLICATIONS OF RAMAN LINE INTENSITY STUDIES

The previous Sections have been concerned with the application of Raman line intensity data to the study of mutual effects of atomic groups. In addition, a great deal of work has been done on the application of line intensity data to the choice of the correct structural formula for new compounds (see examples in Ref. 315), to determine

conformation, to study tautomerism, association, ionisation, and symmetry in molecules, and also to assign spectral lines to particular types of vibration (see examples in Ref. 15).

Bobovich and coworkers have established the structure of various products which could not be characterised by chemical methods [316-318]. By measuring the intensity of the lines for the benzene ring, the double bonds, and the nitro group in the products of the reaction of bromonitrostyrene with β-dicarbonyl compounds, they were able to choose the correct structure from four possible alternatives, to disprove the originally suggested structure involving conjugation of the nitro group and the phenyl group, and to establish the presence (and the type) of enolisation [318]. The positions of the double bond in phenylaminotriazole and of the acyl group in its acylation products have been established [317]. Six C_6Cl_8 compounds have been assigned to well defined isomeric forms by choosing between fourteen possible structural formula (though not always convincingly) [319].

Shorygin and Alaune [237] have determined the position of equilibrium in salt formation in "aromatic amine + organic acid" systems. Thiocyanato complexes have been examined [188], with the conclusion that mercury is attached to the ligand groups through largely covalent bonds with S atoms, zinc is attached to the same atom through weakly covalent bonds (low value of α'), whereas cadmium is attached to C atoms. The spectra of nitrates in aqueous solution have been studied, and it has been shown that ion pairs ($Zn^{2+} + NO_3^-$) are formed in which the anion has a lower symmetry, and that a covalent bond exists in indium nitrate [320]. From the intensity of cyanate lines it has been suggested [253] that the Au–C bond has some double bond character. Association has been investigated in acetamide [221], benzene [130], and other compounds. The angular rotation of the fragments of the biphenyl molecule has been evaluated from the intensity of the benzene lines [321]. Other applications of Raman line intensity data include the determination of the relative amounts of *s-cis* and *s-trans* isomers in liquid pentenone [322], the determination of the energy difference between the *s-cis* and the *s-trans* isomers of acrolein [323], and the interpretation of u.v. absorption bands [324].

These examples are sufficient to indicate the versatility of the method; its possibilities are far from exhausted, and there is every reason to hope that effort in this direction will be intensified.

Infrared Absorption Spectra of Aliphatic Nitro-compounds and Their Derivatives

V.I.Slovetskii

Data on the infrared spectra of aliphatic nitro-compounds and their salts are discussed and summarised. Relations are established between the position of the nitro-stretching bands in the absorption spectrum and the structure of the radical. A fairly large number of examples are given of the use of infrared spectroscopic data to elucidate the detailed structure of nitro-compounds and their salts, and also to study the behaviour of these compounds in various media. Problems of the assignment of the vibrations in nitro-compounds and in the salts of mononitro- and polynitro-compounds are examined. Possible uses of the infrared relations to identify and analyse nitro-compounds and their derivatives are illustrated. The bibliography contains 237 references.

I. INTRODUCTION

The rapid development of the chemistry of aliphatic nitro-compounds and improvements in the technique of obtaining infrared absorption spectra have led to the accumulation of much factual information on the infrared spectra of nitro-compounds. However, this information is scattered among numerous papers, and no monographs or reviews have hitherto been published on this topic. The present Review discusses and summarises existing data on the infrared spectra of aliphatic nitro-compounds and their salts, and the relations found are used to elucidate the detailed structure of nitro-compounds and to identify them.

II. ASSIGNMENT OF MAIN ABSORPTION BANDS OF NITRO-COMPOUNDS

What are probably the first papers on the infrared spectra of nitro-compounds[1-4] do not discuss the problem of assigning the absorption bands to definite vibrations. From 1940 several papers appeared[5-11] whose authors assigned bands by comparing the infrared and the Raman spectra (intensity and degree of depolarisation) of nitromethane[5-10], its derivatives[6,7,10], and its homologues[5-7,11]. During the same period stretching vibrations of nitro-groups and the carbon–nitrogen bond in certain nitroalkanes and their halogeno-derivatives were assigned by Wittek[12,13] on the basis of the Raman spectra. A later paper by Wittek[14] makes assignments also in polynitroalkanes. Assignment is a fundamental problem in the calculations and in various correlations between structure and spectral characteristics, etc. This makes it clear why papers have hitherto appeared with complete[15-26] or partial[27-33] (stretching vibrations of the nitro-group and the carbon–nitrogen bond—sometimes only stretching vibrations of the nitro-group) assignment of the bands observed in the spectra of nitro-compounds.

Analysis of the papers[19-21,26-38] shows that the antisymmetric stretching vibration ν_{as} of the nitro-group in a series of aliphatic nitro-compounds and their derivatives appears as an intense band in the range 1640–1535 cm^{-1}. Splitting of this band is observed[16,29,42] only with tetranitromethane†. Other absorption bands are usually absent from this range‡, so that the assignment of ν_{as} presents no difficulty. The symmetric stretching vibration ν_s of the nitro-group appears in the range 1385–1280 cm^{-1}, which contains other bands, and there is no generally accepted view concerning the assignment of this vibration. Thus Wittek[13], and following him Iogansen and Litovchenko[29], assign two bands in nitromethane and some of its homologues to ν_s, assuming that the appearance of two bands is due to mechanical interaction between deformation vibrations of the methyl group δCH_3 and the symmetric stretching vibration of the nitro-group. The chief argument of these authors is that the Raman spectrum contains two fairly intense and equally polarised ($\rho \simeq 0.4$) bands in the range 1410–1365 cm^{-1}. In the Reviewer's opinion the assignment of the two bands to ν_s of the nitro-group is unjustified. Such assignment involves the assumption that the intensity of the deformation vibration δCH_3 or δCH_2 is independent of the introduction of electronegative substituents. This is not observed. The introduction into a molecule of strongly electronegative groups such as nitrate[43], sulphonyl chloride[44], etc.[21] produces the same

† The splitting of ν_{as} observed in the spectrum of trinitroethanol[29] is not confirmed by other workers[39-41].

‡ Aliphatic–aromatic trinitromethyl derivatives form an exception[31].

effect as that of the nitro-group: a quite intense polarised ($\rho \simeq 0.4$) band appears in the region of 1400 cm^{-1}, although there can be no question of any mechanical interaction in the case of nitrates, sulphonyl chlorides, etc. It is not surprising, therefore, that other workers[5,6,8-10,15,19-22,27,31,32,34,35,45], including Wittek in a later paper[14], assign only one, lower-frequency band to ν_s in nitromethane and its homologues. The correctness of this assignment is confirmed by experimental data on the infrared spectra of nitromethane labelled with ^{18}O [46]: the introduction of "heavy" oxygen into nitromethane produces a shift in only one, the longer-wavelength band (from 1375 to 1357 cm^{-1}), while the band at 1396 cm^{-1} remains unchanged.

The origin of the splitting of ν_s of the nitro-group in *gem*-dinitro- and 1,1,1-trinitro-compounds is less certain. One absorption band in the infrared spectra of these compounds is usually assigned to ν_s[28,31,32,34,35,37-41,47-59]. Several authors, however, assign two bands to ν_s of the nitro-group[14,25,29,30,60], such assignment again being based on the Raman spectra. The second band in the infrared spectra§ often appears as a shoulder[25]. Furthermore, theoretical calculation has shown[60] that only a small part of the splitting (which totals 50–60 cm^{-1}) can be attributed to mechanical interaction. (Most authors[14,25,29] explain the splitting of ν_s of the nitro-group by mechanical interaction of the vibrations.) It seems to the Reviewer that Raman spectral data cannot be used unequivocally for interpreting ν_s of the nitro-group. Thus the Raman spectrum of chloropicrin contains two intense bands (1306 and 1345 cm^{-1})[12] having similar degrees of depolarisation ($\rho \simeq 0.5$). Nevertheless, in this case all authors assign only one of these bands to ν_s[12,14,17,18,26,27]. Hence the appearance of a second intense polarised band ($\rho \simeq 0.40$) in the Raman spectrum is still not an unambiguous criterion that it is due to a symmetric stretching vibration of the nitro-group.

Assignment of the remaining absorption bands to definite modes of vibration can be found in Refs. 9, 10, 18–26, and 42, but these bands are rarely used in everyday practice, and therefore will not be discussed here.

Useful information on the general form of the infrared spectra of certain nitro-compounds or on the ranges of absorption characteristic of the nitro-group can be found in Refs. 61–68.

III. CALCULATION OF MECHANICAL MODEL OF VIBRATIONS OF NITROALKANES. ELECTRO-OPTICAL PARAMETERS OF NITROMETHANE

The first calculations of the vibration modes of nitroalkanes were made independently in three papers[7-9]. Mathieu and Massignon[7] and Bogdan and Stefănescu[8] calculated for a planar tetra-atomic model of $C-NO_2$ with symmetry C_2. In both cases the frequencies obtained agree well with experiment. Wells and Wilson's[9] calculation regarded nitromethane as two non-bonded groups NO_2 and CH_3, having symmetry C_{2v}. Two years later Wilson[10] refined this calculation, having supplemented the experimental data with the spectrum of trideuteronitromethane; he assumed that neither the geometry nor the potential function of the molecule is changed when hydrogen is replaced by deuterium.

Popov and Shlyapochnikov[60,69] have recently made a fundamental calculation for nitroalkanes (nitromethane, nitroethane, 1,1-dinitroethane, and trinitromethane). They computed the frequencies and modes of the normal vibrations for the mononitroalkanes[69], and determined the sensitivities of the frequencies to variation in the force constants. They conclude[69] that vibrations of the $C-NO_2$ fragment are uncharacteristic in frequency and in mode. The most characteristic is the ν_{as} vibration of the nitro-group. This conclusion does not agree with the views of Müller and Nagarajan[70], who conclude, though from a simpler calculation of a planar tetra-atomic model of $C-NO_2$, that the methyl group has little effect on the skeletal vibrations of the $C-NO_2$ grouping.

The mechanical problem for the 1,1-dinitroethane and trinitromethane molecules has not, in the view of the authors themselves[60], been solved with sufficient accuracy. Nevertheless, their analysis leads them to the conclusion that the force field of the $C-NO_2$ group undergoes no great change on passing from nitromethane to the above molecules. Interaction of the nitro-groups in polynitroalkanes does not directly affect the elastic properties of the nitro-group, but is apparent only on adjacent CN bonds¶.

Solution of the mechanical problem for the nitromethane molecule[69] and experimental data on the absolute integrated intensities of the infrared bands of nitromethane and trideuteronitromethane vapours enabled Popov and Shlyapochnikov[71,72] to determine the electro-optical parameters of the nitro-group—the dipole moments of the bond and their derivatives with respect to the vibrational coordinates. From the results it is concluded[71,72] that the dipole moment of nitromethane is determined in considerable measure by that of the carbon–nitrogen bond (μ_{CN} = 1.8 D). Somewhat later an analogous electro-optical problem for nitromethane was solved by Singh[73]. However, he considers that the differences between dynamic and static dipole moments are due to errors in the calculations, and that the agreement between them can be improved by taking into account the suggestions made by Sverdlov[74,75].

IV. INTENSITY OF ABSORPTION BANDS OF NITRO-COMPOUNDS

As already noted, the nitro-stretching bands are quite intense: the molar extinction coefficient ϵ (M^{-1} cm^{-1}) for the ν_{as} band in nitroalkanes is ~ 500 [28,29,76-79] per nitro-group, whereas ϵ for ν_s of the nitro-group is ~ 100 [28,29,78]. The appearance of conjugation is accompanied by some decrease in $\epsilon\nu_{as}$, whereas $\epsilon\nu_s$ increases[28,29,80]. Data on the integrated intensities† of the nitro-stretching vibrations (ν_{as} and/or ν_s) will be found in Refs. 29, 56, 60, 73, 80, 83–86‡. The integrated intensity A_{as} of the antisymmetric vibration of the nitro-group is found to be additive[29,60,91], varying little with the structure of the radical.

§ Unfortunately the type of spectrum (infrared or Raman) is not indicated in Ref. 30, nor the intensity and degree of depolarisation of the bands.

¶ The invariability of the elastic properties of the nitro-group is not confirmed (see below) by the dependence of ν_{as} for the nitro-group on the inductive effect of the substituent[31].

† For the theory of integrated intensities, their experimental determination, and conversion coefficients between various intensity scales see, for example, the reviews[81,82].

‡ Data on the integral intensities of the nitro-stretching vibrations in nitro-aromatic compounds will also be found in Refs. 87–90.

On the other hand, the intensity A_S of the symmetric vibration depends substantially on the structure of the radical[29,80,83,86,91], and several workers have suggested[83,86,91] that A_S should be used as a measure of conjugation between the nitro-group and the rest of the molecule in conjugated and aromatic nitro-compounds.

Intensities of other bands have been measured only for nitromethane (at ~ 1105[92], 915[73,92], and 656[73] cm^{-1}). The temperature variation in the intensities of two bands (1103 and 917 cm^{-1}) of nitromethane has also been investigated[92].

V. EFFECT OF STATE OF AGGREGATION AND SOLVENT ON INTENSITY AND POSITION OF ABSORPTION BANDS OF NITRO-COMPOUNDS. HYDROGEN BONDS

The effect of the solvent on the position of the nitro-stretching bands has been examined in only four papers[78,84,93,94]. All the authors conclude that solvents produce only slight shifts in the frequencies of both bands§. More detailed examination of the effect of the solvent on the position of the absorption bands indicates a fairly substantial effect on ν_{as} with change in the state of aggregation (transition from the gaseous state to the liquid) and on passing from the gaseous state to solutions, but this effect reduces to zero as nitro-groups accumulate on the same carbon atom. Nevertheless, the values of ν_{as} and ν_S of the nitro-group are almost unaffected in "inactive"¶ solvents[31]. Values of ν_S diminish somewhat on passing from liquid mononitro-compounds to their solutions. Table 1 gives examples illustrating the influence of the solvent on the frequencies of the nitro-group.

The integral intensity of the absorption bands due to the nitro-group also is almost unaffected by the solvent[79,84]. It is interesting that, in contrast to the frequencies, the intensity of the antisymmetric nitro-stretching vibration A_{as} in nitromethane is the same, within the limits of experimental accuracy, in the gas and in solution: $A_{as,soln}/A_{as,gas} = 1.04 \pm 0.06$.[85]

Study of the intramolecular† and the intermolecular hydrogen bonding of nitro-alcohols and nitro-amines, and also of intermolecular hydrogen bonding between various proton-donors and nitro-compounds, is very closely linked with questions of the effect of the solvent on the vibration frequencies of nitro-compounds.

Urbanski[97-100] assumed that nitro-alcohols and nitro-amines form six-membered rings by interaction of the nitro-group with the hydroxyl or the amino-group. He considered that this hypothesis was supported by the displacement of the nitro-stretching vibrations to lower frequencies on the introduction of hydroxymethyl or an amino-group. This effect was intensified by the introduction of two or three hydroxy-groups. Later investigators have assumed that such an effect[31,36,39,40,78,84], if it exists at all, is usually‡ too small to be determined from the positions of ν_{as} and ν_S for the nitro-group. In the application of infrared spectroscopy to the study of hydrogen bonds in a series of nitro-compounds, therefore, the variation in the position, form, intensity, and half-width of the absorption band due to A–H stretching vibrations was determined (AH being a proton-donor compound)[39,40,78,102-108]. The investigations show that the nitro-group is a weak acceptor of hydrogen atoms[40,78,102,103,105,107].

Table 1. Position of nitro-stretching bands for nitromethane and its derivatives in different states of aggregation and solvents.

Compound	Solvent (state)	Frequencies, cm^{-1}			
		ν_{as}	$\nu_{as} - \nu_{as,av}$	ν_S	$\nu_S - \nu_{S,av}$
CH_3NO_2 [a]	gas	1582 [9,60]	19	1384 [9,60]	11
	gas	1586 [15]	23	1377 [15]	4

	liquid	1648 [42] / 1618 [e]	6 / 5	1272 [42]	5
	$CHCl_3$	1642 [29] / 1613 [e]	— / —	1267 [29]	—

(a) The frequencies $\nu_{as,av}$ and $\nu_{S,av}$ have been taken as 1563 and 1373 cm^{-1} respectively, the mean values for a solution of nitromethane in carbon tetrachloride[46,78,84,93].

(b) Region of strong absorption by the solvent.

(c) The authors assume that ν_S is split, and they give values for two bands (see above). Only the longer-wavelength component has been taken here.

(d) The means $\nu_{as,av}$ and $\nu_{S,av}$ have been taken to be the corresponding values of ν_{as} and ν_S for the compounds in carbon-tetrachloride solution.

(e) The means $\nu_{as,av}$ and $\nu_{S,av}$ have been taken to be the corresponding values for a solution of tetranitromethane in chloroform.

On the basis of infrared data Flett assumed[104] that 2-nitroethanol contained only intermolecular hydrogen bonds, whereas Krueger and Mettee consider[103] that an intramolecular hydrogen bond is formed between hydroxy- and nitro-groups in 2-nitro-alcohols, which stabilises the gauche form relative to the *trans*-form.

§ Small shifts in the frequencies of the nitro-group under the influence both of different solvents and of the state of aggregation are maintained also in a series of aromatic nitro-compounds[95].

¶ "Inactive" solvents are those which do not form complexes with the compounds under investigation.

† Tichy[96] has reviewed the use of infrared spectroscopy to detect an intramolecular hydrogen bond in organic compounds. However, he pays little attention to the formation of hydrogen bonds in nitro-compounds.

‡ Exceptions can be found in two papers. Ungnade et al.[93] found a shift of 15 cm^{-1} for ν_{as} of the nitro-group in n-butylamine solutions. This effect became considerably weaker on passing to solutions of nitromethane in n-hexylamine, and was completely absent in its solutions in secondary or tertiary alkylamines. The authors of the second paper[101] observed that the position of ν_{as} for the nitro-group remained unchanged on passing from nitro-amines to their hydrochlorides, while the ν_S frequencies changed. This displacement was attributed to formation of an intramolecular hydrogen bond.

Kuhn and his coworkers found[108] that 2-nitroethanol exists both in a *trans*-form and in a gauche form in the gaseous state and in carbon-tetrachloride solution. In the liquid state it is associated by intermolecular hydrogen bonding. It is true, of course, that many assignments in these papers[103,108] are based not on fact but on hypothesis. Urbanski's observation[97-100] of a variation in nitro-stretching frequency is due, in the Reviewer's opinion, to inductive and steric[31] effects (see Section VI). Quantitative results are listed in Table 2.

Table 2. Effect of β-hydroxy-groups on nitro-stretching bands in aliphatic nitro-compounds.

Compound[a]	Solvent (state)	ν_{as}, cm^{-1}	σ*[b]	Eqn.[c]	ν_{calc}, cm^{-1}	$\nu_{as}-\nu_{calc}$, cm^{-1}	ν_s, cm^{-1}	$\nu_s-\nu_s$ nitro-alkane, cm^{-1}[d]

(a) Nitroalkanes given for comparison.

(b) Necessary values of σ* taken mainly from Ref. 109. Value of σ* for the nitro-group taken from Ref. 110; and $\sigma^*_{RNH_2CH_2^+}$ calculated from values of σ_I.[111]

(c) For equations used in calculation see Table 3.

(d) This column gives the difference between ν_s for the given nitro-alcohol and ν_s for the corresponding nitroalkane.

(e) Values of ν_s not given here, since the papers show a significant lack of consistency in their values[97,98].

This conclusion is supported also by the fact that the absorption band ν_{as} of the nitro-group in nitromethane is almost identical in methanol and in carbon tetrachloride[78], although the latter is an "inactive" solvent, whereas nitromethane forms intermolecular hydrogen bonds with methanol. In other words, the ν_{as} frequency of the nitro-group remains unchanged independent of the presence or the absence of hydrogen bonds, provided that the inductive and steric effects of the nitro-compound remain constant.

β-Nitro-alcohols are capable of partial association in solvents such as carbon tetrachloride[105] or of the formation of stable intermolecular complexes with pyridine[39,106]. In all cases the association constants of the complexes increase with increase in the number of β-nitro-groups[39,105,106].

In concluding this Section we may note several investigations in which nitromethane has been used as solvent, the second component (the proton donor) being water[112-114], phenol[115,116], or a derivative of the latter[116]. Nitromethane has been investigated as solvent also in study of the integral intensity A_{CN} of the C≡N stretching band in benzonitriles and the dependence of A_{CN} on the Hammett σ-constant[117], and also in study of the dependence of the integrated intensity and the half-width of the chloroform band at ~ 760 cm^{-1} on the nature of the solvent[118].

VI. RELATION BETWEEN POSITION OF BANDS DUE TO NITRO-STRETCHING VIBRATIONS AND STRUCTURE OF THE NITRO-COMPOUNDS

A relation between the positions of symmetric and antisymmetric nitro-stretching bands has been sought by several workers. Some have observed[28,95,119,120] a linear relation between ν_{as} and ν_s, although two kinds of straight lines—for electronegative and for electropositive substituents—are present with aromatic nitro-compounds[28,95,120]. Only Flett[90] observes that such a relation does not exist. Iogansen and Litovchenko[91] consider that "the stretching frequencies of the nitro-group correlate poorly with the structure of the molecular residue if they are examined separately and all nitro-compounds are covered". These workers therefore propose to correlate

$$\nu_{av} = \frac{\nu_{as}+\nu_s}{2} \text{ with } \Delta\nu = \nu_{as} - \nu_s.$$

This is regarded[91] as dividing the nitro-compounds into classes, although there is no relation at all between ν_{av} and $\Delta\nu$ (these quantities are discussed below).

Attempts have also been made to find a correlation between ν_{as} of the nitro-group and the effective electronegativity χ of the α-carbon atom[35,121]. A linear relation was demonstrated between these parameters.

Finally, several authors have sought a relation between ν_{as} for the nitro-group and the Hammett and Taft σ-constants[28,31,72,119,120,122-126]. Campbell and Gilow[127] made a theoretical examination of the relation between the σ-values and the shift $\Delta\nu$ in the absorption bands, and discovered the relation

$$\Delta\nu \frac{hC}{2.3\,RT} = -\rho\cdot\sigma - \frac{\Delta(\Delta S)}{2.3\,R} \qquad (1)$$

where h is Planck's constant, C the velocity of light, R the gas constant, T the absolute temperature, ρ a constant, σ the inductive constant of the substituent, and $\Delta(\Delta S)$ a measure of the change in entropy. From this formula a linear relation is to be expected between σ and the shift (in cm^{-1}) in the absorption bands, provided that the term $\Delta(\Delta S)$ is constant. This condition is satisfied if the effect of the solvent is excluded or if it remains constant for a given reaction series. The second, not unimportant condition determines the choice of reaction series. Both conditions were observed in investigations[28,31,72,119,120,122-126] where a linear relation was found between ν_{as} and the Taft and Hammett σ-values. As example Table 3 is taken from a paper[31] in which a large number of nitro-compounds were used to find relations between ν_{as} and the σ*-values.

From the data in Table 3 and the effect of conjugation on the asymmetric nitro-stretching frequency Slovetskii[31] concludes that this frequency is influenced by the inductive and steric effects and also by conjugation. The influence of the steric effect is evident only on passing from nitro-compounds containing one or two α-hydrogen atoms to compounds which do not contain them. The role of the inductive effect has been discussed above. In the simplest cases the effect of conjugation is additive. α-Fluorine atoms exert only an inductive effect. The experimental results[17,18,128-138] do not reveal the presence of a steric or other specific effect.

Analysis of the influence of various factors on the position of the symmetric nitro-stretching frequency in a series of aliphatic nitro-compounds led Slovetskii[31] to the conclusion that the main factor is the steric effect. The shifts in the ν_S frequencies due to the steric effects of different substituents are additive, being dependent on the volume of the substituent but independent of its electron-accepting or donating properties. The inductive effect and the conjugation factor have hardly any influence on the position of ν_S for the nitro-group.

Table 3. Dependence of antisymmetric nitro-stretching frequency ν_{as} on inductive effect σ^* of substituent[31]: $\nu_{as} = \nu_0 + \rho\sigma^*$.

Reaction series[a]	ν_0, cm^{-1}	ρ	Limits		r[b]	s[c]	Quantity of cpd.
			ν_{as}, cm^{-1}	σ^*			
(I) RCH_2NO_2, where R = alkyl, substituted alkyl, or electronegative substituent	1552	16	1578 1546	1.05 −0.15	0.77	4.5	77
(II) $R'R''CHNO_2$, where R', R'' = alkyl, substituted alkyl, electronegative substituent (other than NO_2), or any combination thereof	1550	16	1590 1548	2.15 −0.26	0.85	6.9	74
(III) $R'R''R'''CNO_2$, where R', R'', R''' = alkyl, substituted alkyl, electronegative substituent (other than NO_2), or any combination thereof	1541	20	1610 1534	3.15 −0.37	0.96	6.2	42
(IV) $RCH(NO_2)_2$, where R = alkyl, substituted alkyl, or any electronegative group	1556	13	1608 1570	3.46 1.60	0.85	4.5	24
(V) $R'R''C(NO_2)_2$, where R', R'' = alkyl, substituted alkyl, any electronegative group, or combination thereof	1547	16	1630 1572	5.19 1.53	0.96	3.9	42

(a) All kinds of nitro-compounds, containing any α-substituent other than fluorine, have been used. α-Fluoro-nitro-compounds fall into the reaction series in which a hydrogen atom(s) is present instead of the fluorine atom(s)[31].

(b) r = correlation coefficient.

(c) s = standard deviation.

Thus the positions of the nitro-stretching bands (ν_{as} and ν_S) depend to different extents on steric, inductive, and conjugation effects. Hence the quantities $\Delta\nu = \nu_{as} - \nu_S$[34,91] and $\nu_{av} = \frac{1}{2}(\nu_{as} + \nu_S)$ are fairly random quantities, and it is not surprising, therefore, that no relation was found[91] between them. Contradictory views are held concerning the relation between ν_{as} and ν_S.[28,90,95,119,120]

VII. ABSORPTION BANDS DUE TO ANIONS OF MONO- AND POLY-NITRO-COMPOUNDS§

1. Anions of Mononitro-compounds

The infrared spectrum of the sodium salt of 1-nitropropane was first determined by Mathieu and Massignon[5].

§ We apply the term polynitro-compounds to compounds having at least two nitro-groups attached to the same carbon atom.

Comparison of the infrared and Raman spectra of these compounds enabled the strong band at 1586 cm^{-1} to be assigned to the C=N bond. These workers also noted that the characteristic frequencies of the nitro-group and also of the carbon–nitrogen single bond disappear on passing from 1-nitropropane to its sodium derivative.

A complete assignment of the infrared absorption bands due to salts of nitromethane[139-141] and 2-nitropropane[139] has been made much more recently. Jonathan[139] concludes from the spectral data that the anions have a planar structure with the carbon–nitrogen bond order close to 2: $[CH_2{=}NO_2]^-Na^+$ and $[(CH_3)_2C{=}NO_2]^-Na^+$. Such a structure is supported by all the spectral data and by molecular-orbital calculation. Brookes and Jonathan[140] used the sodium salt of trideuteronitromethane and improved the assignments of ν_S of NO_2^- (the charged nitro-group) in the infrared spectrum of the sodium derivative of nitromethane. Yarwood and Orville-Thomas[141] consider, contrary to the opinion of Jonathan and Brookes[139,140], that the carbon–nitrogen bond in this sodium derivative is close to a single bond and that the anion has a non-planar structure. The authors[141] arrive at this view—erroneous¶ in the Reviewer's opinion—as a consequence of the unsubstantiated statement that the position of carbon–hydrogen stretching vibrations depends solely on the type of hybridisation. All the other investigators[143-148] have found, in the infrared spectra of salts of mononitro-compounds, bands corresponding to a C=N double bond. Moreover, Buczkowski and Urbanski[144] even found two bands (~ 1660 and 1600 cm^{-1}) corresponding to C=N stretching vibrations in the salts of primary nitroalkanes, on which they based the hypothesis that the salts are able to exist in two isomeric *cis*- and *trans*-forms. However, this view is not consistent with the experimental results† (the positions of the absorption bands due to a C=N bond differ by ~ 15 cm^{-1},[149] not by 60 cm^{-1}, in *cis–trans* isomers). Furthermore, account must be taken of the hygroscopic nature of the salts of mononitro-compounds‡ and of the possible appearance of a band at ~ 1660 cm^{-1} due to bound or absorbed water[150].

The conditions of preparation of specimens for determining their infrared spectra were not specified in Ref. 144. Feuer et al.[145] made assignments of stretching vibrations of the charged nitro-group NO_2^- in the salts of nitroalkanes, α-nitro-ketones, and α-nitro-nitriles, and Kerber and Chick[147] in a nitrocyclopentadiene salt. Table 4 gives assignments in salts of mononitro-compounds made by various workers.

2. Anions of Polynitro-compounds

Brown[28] assigned two absorption bands in the infrared spectrum of the potassium salt of dinitroethane to stretching vibrations of the charged dinitromethyl group

¶ The planar structure of the nitromethane anion and the presence of a C=N double bond (the presence of vinyl hydrogen atoms) is supported by the results of another independent method—nuclear magnetic resonance spectroscopy[142].

† The *cis–trans* isomerism of salts of mononitroalkanes in solution is not confirmed by n.m.r. spectroscopy[142].

‡ Jonathan[139] emphasises that the salts which he studied were hygroscopic, and therefore the infrared spectra of the sodium salt of nitromethane varies substantially between specimens prepared with and without the use of a drying chamber.

(ν_{as} = 1242 and ν_s = 1151 cm^{-1}). Later investigators[37,49,53,151-153] note that, on passing from polynitro-compounds to their salts, bands characteristic of nitro-stretching vibrations (see above) disappear from the infrared spectra, while several new bands appear at ~ 1480, ~ 1200, and 1120 cm^{-1}. The appearance of these bands is attributed to vibrations of the dinitromethyl anion[37,49,53,151-153] and of the anion of trinitromethane[151-153], but no assignments are given. Kaplan[154] made empirical assignments for salts of polynitro-compounds by analogy with the covalent nitro-group. He assigned the band at 1269 ± 9 cm^{-1} to antisymmetric N–O stretching vibrations, and that at 1173 ± 10 cm^{-1} to the symmetric vibrations. Kamlet et al.[155] and Lippincott et al.[156] made more justified assignments of bands to vibrations of the dinitromethyl anion using the spectrum of potassium deuterodinitromethane. The latter authors[156] also adduce data on the Raman spectra of the dinitromethane anion and its deuterated analogue. Comparison of the assignments[28,154-159] shows that they do not completely coincide. A somewhat special position in this series is occupied by the work of Singh[157], whose assignments differ from those proposed by other workers[155,156] for the spectrum of potassium dinitromethane.

Slovetskii et al.[158] conclude from infrared band intensity data that the above bands are due to di- and tri-nitromethyl groups, and can be classed as group absorption bands of the corresponding anions. However, the results available at present do not enable a complete assignment to be made in the vibrational spectra of anions of polynitro-compounds. It has been concluded[159] on the basis of calculation that almost all frequencies of polynitro-carbanions are non-characteristic, 2–5 angles and bonds being involved in each vibration. Yet the calculation[159] involved force constants and in some cases bond lengths and angles of the unionised nitroalkanes, which evidently diminishes the reliability of the results. The suggested[158] specific character of the group bands due to the anions of *gem*-dinitro-compounds and trinitromethane is supported by published data[37,154,159,160]: even the presence of conjugation has hardly any effect on the position of these bands§.

Studies have been made of the effect of the solvent on the infrared spectra of the anions of *gem*-dinitroalkanes and trinitromethane[162-164]¶. Integrated and peak intensities have been measured, and determinations also made of the half-width and the exact position of the group absorption bands due to the trinitromethyl, dinitromethyl, and *gem*-dinitroethyl anions both in the crystalline state (compressed with potassium bromide) and in protic and aprotic solvents.

The investigation showed that, for a given anion, the solvent, the possible formation of ion pairs, and the nature of the cation do not influence the integrated intensity or the shape of the bands. Nor does the nature of the cation affect the position of the bands in solutions. However, change in the state of aggregation—transition from the crystalline salt to its solutions—and in the solvent affects the position of the group absorption bands, this effect being different with different bands. The character of the frequency shift as a function of the nature of the solvent led to the conclusion[162,163] that this shift was due to specific solvation of the polynitro-carbanions.

Briefly summarising available data, we can say that, in the salts of mononitro-compounds, the presence of a C=N bond has been shown fairly convincingly, and reliable assignments have been made of the frequencies due to the CNO_2^- grouping. In the salts of polynitro-compounds, however, only the group frequencies have been reliably assigned. The assignments in anions even of the same polynitro-compounds are contradictory, and require further investigation.

Table 4. Assignments of $C{=}NO_2^-$ stretching vibrations (cm^{-1}) in salts of mononitro-compounds.

(a) No assignments are given for these vibrations.

(b) The authors deny the presence of a double bond in the salt.

(c) The paper gives several absorption bands—at 1330, 1270, 1139, 1117, 988, and 955 cm^{-1}—which the authors attribute to antisymmetric and symmetric stretching vibrations of the NO_2^- group.

VIII. USE OF INFRARED-SPECTROSCOPIC METHODS TO ESTABLISH THE STRUCTURE OF ORGANIC NITRO-COMPOUNDS

1. Analytical Application

Consideration of the infrared spectra of nitro-compounds and their salts indicates that the main differences in the spectra which are suitable for analytical purposes occur in the region of nitro-stretching vibrations and group absorption bands due to nitro-carbanions. These differences consist in a certain regularity in the position and intensity of the bands depending on the structure of the compounds.

§ Conjugation in potassium bromodinitromethane is confirmed by X-ray examination[161].

¶ Shokhor et al.[164] do not give experimental data, but merely mention that the infrared spectra of solutions of the alkali-metal salts of trinitromethane exhibit a close similarity independently of the cation and the solvent.

Thus primary and secondary nitroalkanes can be distinguished from tertiary nitroalkanes by the bands due to antisymmetric and symmetric stretching vibrations of the nitro-group, and primary from secondary compounds by the symmetric nitro-stretching band[28,34,45].

A detailed examination of published data[165-189] supports this conclusion, with substances belonging to this group which have functional substituents quite remote from the nitro-group (in any case so long as the inductive effect does not operate[31]). The accumulation of nitro-groups on the same carbon atom leads to shifts in the antisymmetric and symmetric vibrations of the nitro-group to higher and lower frequencies respectively[34], which can also be utilised for analytical purposes[27,28,34,59,182,183,190-194]. Another extremely interesting fact is that the difference in frequency between antisymmetric and symmetric nitro-stretching vibrations ($\Delta\nu = \nu_{as} - \nu_s$) is also characteristic[34,91], having approximate values of 180, 250, and 300 cm^{-1} for mononitroalkanes, *gem*-dinitroalkanes, and 1,1,1-trinitroalkanes respectively. Hence this difference also can be used to distinguish among mono-, di-, and trinitro-compounds. However, the difference ceases to be characteristic when we pass to nitro-compounds having a halogen atom or other functional group in the α-position. In this case considerably greater assistance for analytical purposes may be obtained from the dependence of the position of the stretching bands on the structure of the nitro-compounds (see Section VI), in particular the relation between ν_{as} and the σ^*-values[31]. Table 5 gives as examples a few calculations of ν_{as} (based on the equations in Table 3) and of ν_s. For further details see Slovetskii's paper[31].

Table 5. Calculation of positions of ν_{as} and ν_s bands of nitro-group[a].

Compound	State solvent	ν_{as}, cm^{-1}	σ^*[b]	Eqn. (Table 3)	ν_{as}, calc', cm^{-1}	$\nu_{as} - \nu_{as}$ calc', cm^{-1}	ν_s, cm^{-1}	ν_s, calc', cm^{-1}
$CH_2FCH_2NO_2$	liq.?	1557 [195]	0.40	(I)	1558	−1	1370 [195]	1370
$(C_6H_5)_3CCH(NO_2)COOC_2H_5$	CCl_4	1565 [196]	1.04	(II)	1567	−2	1356 [196]	1359

$CH_3C(NO_2)(CH_2ONO_2)_2$	liq.	1563 [198]	0.86	(III)	1558	5	1350 [198]	1346
$(C_2H_5O_2C)_2C(NO_2)CH_2OH$	liq.	1572 [199]	1.82	(III)	1577	−5	—	—
$H(NO_2)_3CCOOC_2H_5$	liq.?	1588 [200]	2.54	(IV)	1589	−1	—	—
$NC(NO_2)_2CCOOC_2H_5$	liq.?	1610 [200]	3.84	(V)	1608	2	—	—

(a) Experimental data on the positions of the nitro-stretching vibrations can be found in Refs. 201–218 and also in the papers cited earlier.

(b) Values of σ^* taken from Palm's paper[109], and those of σ^* for nitro and nitrate groups from Slovetskii and Fainzil'berg's paper[110]. Several of the σ^*-values can be calculated from those given for σ_I in Charton's paper[111].

A second extremely important fact for the identification of nitro-compounds is the small effect of structure on the integrated intensity of the antisymmetric nitro-stretching vibration[79,91]. This observation can be exploited to determine the number of nitro-groups in compounds of unknown structure[91].

Sometimes there is no need to measure the integrated intensity of a band, a comparison of relative intensities being sufficient, e.g. of ν_{as} and ν_s for the nitro-group[91] or of ν_{as} for two different groups[183]. On the other hand, the intensity of the ν_s band of the nitro-group is considerably dependent on conjugation[29,83,91], another fact which is useful for establishing the structure of nitro-compounds. Furthermore, infrared spectroscopy can be recommended for determining the quantitative composition of mixtures of nitromethane with its simple homologues and analogues—nitroethane, 1-nitropropane, and 2-nitropropane[219].

The transition from nitro-compounds to their anions is accompanied by disappearance of the bands characteristic of the nitro-group and the appearance of a series of bands due to the anions (see Section VII). It must be stressed that the spectrum of polynitro-carbanions is quite characteristic both in its general form and in intensity[162]. The integrated intensities of the strongest bands reach (5–6) × 10^4 cm^{-2} M^{-1} [162] (practical system of units[81,82]). In other words, the presence of an anion can be identified quite reliably from the presence of group absorption bands and measurements of their intensity.

In conclusion we note that, whether in the free form or as the anion, the dinitromethyl group has the same spectral characteristics in the aromatic and heterocyclic series as in the aliphatic series.

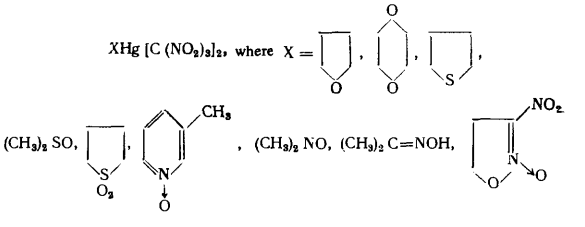
We shall discuss below some examples of the application of infrared spectroscopy to establishing the structure of and elucidating the chemical changes undergone by nitro-compounds and their salts.

2. Structure of Mercury "Salts" of Trinitromethane and Fluorodinitromethane

Infrared spectroscopy has been used to study the structure of the so called mercury salts of trinitromethane and fluorodinitromethane[163,220]. The results confirm that in the crystalline state both "salts" are true organometallic compounds: the spectrum contains bands at 1598, 1312, and 798 cm^{-1} [163,220] corresponding to the trinitromethyl group, and at 1580, 1315, and 835 cm^{-1} [163] corresponding to the fluorodinitromethyl group, while bands characteristic of the corresponding polynitro-carbanion or the covalent aci-form are absent. Bands corresponding to the trinitromethyl anion appear in the infrared spectra of aqueous and dimethylformamide solutions of bistrinitromethylmercury; the proportion of the ionised form diminishes with increase in the concentration of the compound, and may become almost zero on addition of a sufficient amount of the cation involved—Hg^{2+} (as mercuric nitrate)[163]. From these results it is concluded[163,220] that in the crystalline state the so called mercury salts of trinitromethane and fluorodinitromethane are true organometallic compounds, which are capable, under the influence of ionising solvents (protic and aprotic), of dissociating directly into ions without formation of an aci-form.

3. Complexing Power of Bistrinitromethylmercury

Chemical means have been used to isolate the complexes



Study of their infrared spectra showed the presence of frequencies characteristic of the trinitromethyl group—1600 ± 5, 1300 ± 5, and 800 cm^{-1}. [221]

4. Structure of Silver Salts of Polynitroalkanes

Infrared spectroscopy has been used to study the structure of the silver salts of trinitromethane[164,222], dinitroacetonitrile[222,223], dinitromethane[222], and 1,2-dinitroethane[222]. Comparison with the infrared spectra of the mercury and alkali-metal salts of the corresponding polynitro-compounds in the crystalline state have revealed the ionic structure of the silver salts, which are analogues of the alkali-metal salts and differ from the mercury derivatives, which are true organometallic compounds.

In solutions a quite different situation is found. In aqueous solutions of silver salts of polynitro-compounds Slovetskii and his coworkers[222,223] found that equilibrium was established between the true organometallic compound and the ionic form of the salt. The same conclusion was reached[222,223] from the appearance of bands (in the ranges 1610–1580 and 1330–1300 cm^{-1}) due to covalent tri- and di-nitromethyl groups on the addition of the corresponding cation Ag^+ (as silver perchlorate) to the solution or in the spectra of concentrated solutions (e.g. 20 M [sic] aqueous silver trinitromethane). From the infrared spectra it would seem that no other intermediate forms, such as an aci-form, are involved.

Shokhor et al.[164] studied the silver salt of trinitromethane in water and in various non-aqueous solvents. They found that in water the salt has an ionic structure. As the dielectric constant of the solvent decreases, however, the configuration of the trinitromethyl anion changes, and in benzene and dioxan solutions a band due to the covalent silver salt appears (at 1615 cm^{-1}). The appearance of a covalent form is consistent with the experimental data[222], but the change in configuration of the anion contradicts them. Thus the presence of equilibrium between ionic salt and organometallic compound[222] leads to a similar effect observed by Shokhor et al.[164]—diminution in intensity of the band at 1490 cm^{-1} and increased intensity of that at ~ 1600 cm^{-1}—while the dielectric constant of the solution does not decrease in this work[222]. It is not altogether clear why Shokhor et al.[164] find a displacement of the band in the range 1540–1560 cm^{-1}. This may perhaps be due to strong absorption by the solvent in this range. Unfortunately, these workers[164] give no data on cuvette thicknesses, and it is therefore difficult to assess the correctness of their results.

5. Structure of Salts of Polynitro-compounds with Organic Cations. Inner Salts

Infrared spectral data have been used several times[37,224-228] to assess the structure of salts formed by polynitro-compounds with organic cations.

Slovetskii et al.[224] investigated the salts formed by trinitromethane with 4-amino-1,2,4-triazole bases. The infrared spectra showed that in the crystalline state the salts had an ionic structure, the trinitromethane being present as an anion. This is confirmed by the presence of bands characteristic of the trinitromethyl anion (approximately at 1520, 1280, and 1180 cm^{-1}) and by the absence of bands characteristic of nitro-stretching vibrations in the trinitromethyl group (~ 1600 and ~ 1300 cm^{-1}). It was then concluded from the infrared spectra of the salts that the mobile [hydrogen] atom of trinitromethane reacts with two molecules of 4-amino-1,2,4-triazoles to form the so called "ionogenic structures"†. Examination of the region of amino-stretching vibrations showed that the transition from the free 4-amino-1,2,4-triazoles to their trinitromethyl salts was accompanied by displacement of the N–H stretching vibrations to higher frequencies, whereas protonation of the amino-group would have led to lower frequencies. In other words, this fact supports the view that the amino-group is not involved in salt formation. This is further confirmation, in the opinion of the authors[224], that the proton interacts only with the triazole ring in the crystalline salts of 4-amino-1,2,4-triazole.

From an infrared study Glowiak[225] concluded that the benzenediazonium "salt" of trinitromethane had an ionic structure. In the Reviewer's opinion this conclusion does not follow from the data given by this author[225]. In fact, Glowiak observed bands at 1629, 1374, and 1294 cm^{-1}, close to the bands—at 1623, 1372, and 1294 cm^{-1}—in chlorotrinitromethane and differing considerably from those—at 1529, 1418, 1302, and 1263 cm^{-1}—in the potassium salt of trinitromethane. His line of argument is that the chlorine atom in chlorotrinitromethane is appreciably positive in character, whereas the trinitromethyl group is negative. He regards the situation as similar in trinitromethylbenzenediazonium. One can agree with Glowiak's first assertion[225], that the spectra of chlorotrinitromethane and trinitromethylbenzenediazonium are closely similar. However, the opposite conclusion follows from this: since chlorotrinitromethane is a covalent compound‡, the benzenediazonium "salt" of trinitromethane is also a covalent compound—trinitromethylazobenzene. This conclusion is confirmed by comparing the spectrum of trinitromethylbenzenediazonium with that of the potassium salt of trinitromethane, which is known to be ionic.

The structure of inner salts has been established quite reliably from the infrared spectra for 1-guanidino-2,2-dinitroethane[226] and 2-dinitromethylpyridine[37] in the crystalline state. Zeldine and Shechter[226] reached this conclusion from the absence of the 1587 cm^{-1} band characteristic of the dinitromethyl group. Slovetskii et al.[37] deduced the formation of the internal salt 2-dinitromethylpyridine from the presence of absorption bands characteristic of the dinitromethyl anion (strong 1500, very strong and broad 1235, and strong 1130 cm^{-1}) and the absence of bands at 3000 and at 1575 and 1330 cm^{-1} characteristic of stretching vibrations of C–H and N–O respectively in the dinitromethyl group.

6. Structure of Dinitroacetonitrile Tetrahydrate and its Derivatives

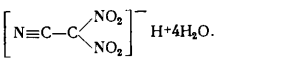
Slovetskii et al.[72,223] used infrared spectroscopy to confirm the structure of dinitroacetonitrile tetrahydrate. This investigation was of fundamental value for the problem of tautomerism in polynitro-compounds.

---

† Until the publication of Ref. 224 the formation of an "ionogenic structure" had been observed by Otting[227] only with 1,2,4-triazoles in which the 4-position was unsubstituted.

‡ That chlorotrinitromethane is a covalent compound is confirmed by various kinds of data, e.g. infrared spectroscopy[35], dipole moments[228], etc. Moreover, measurements indicate[228] that the dipole moment of the C–Cl bond is 0.23 D with the negative end of the dipole on the chlorine atom.

The infrared spectrum of the tetrahydrate proved to be identical with those of the sodium and silver salts but different from that of the *O*-methyl ether. This ether was utilised[72,223] as a fixed model compound having the same structural units—the nitro-group in its true form, the presence of a C=N bond, and the absence of a nitro-group in a charged state—as should have been present in a covalent aci-form. From the results obtained it was concluded that crystalline dinitroacetonitrile tetrahydrate had the ionic structure



Another possible ionic structure for the crystalline tetrahydrate—an internal salt—is inconsistent with the infrared spectral data[223].

7. Study of Structure of Salts of 1,1-Dinitroalkanes and Trinitromethane

Slovetskii and his coworkers[151,152] were the first to use infrared spectroscopy to study the structure of salts of polynitro-compounds. From the spectra of a large number of salts (potassium, sodium, ammonium, and lithium) of *gem*-dinitroalkanes and trinitromethane it was found[151,152] that bands corresponding to the C=N bond and also to the nitro-group in true nitro-compounds were absent from the spectra of the anions. This led to the conclusion[151,152] that the salts of 1,1-dinitroalkanes and trinitromethane contain no C=N bond (unlike the salts of mononitroalkanes[5,139,140,143-148]) and no uncharged nitro-groups, in contrast to the true form of nitro-compounds. Hence the conclusion is drawn[151,152] that all the nitro-groups in salts of polynitroalkanes are equivalent and are equally involved in formation of the anion. It is found furthermore[152] that replacement of the cation (potassium, sodium, ammonium) in the crystalline salts has little effect on the absorption bands of the anion, and from 1,1-dinitropropane onwards there are no changes at all in the spectra with different cations.

Subsequent work has shown that the spectral characteristics of the dinitromethyl anion are the same in salts of aromatic and heterocyclic derivatives[37] as in the aliphatic series. Hence the equivalence of the nitro-groups in anion formation is preserved in the aromatic and heterocyclic dinitromethyl derivatives. The equivalence of the nitro-groups in the anion is maintained in salts of dinitroacetonitrile[72,223] and also on passing to solvated anions[158,163], the configuration of the anions being almost unchanged in the crystalline salt and in solution. This conclusion is confirmed by Mel'nikov et al.,[229] who have compared experimental data on the infrared and Raman spectra of the salts of dinitromethyl derivatives, and consider that the configuration of the anions in solution differs little from the configuration in the crystal. Lippincott et al.[156] regard the infrared and Raman spectra of the potassium salts of dinitromethane and its deuterated analogue as indicating that the dinitromethane anion has a planar structure with equivalent nitro-groups.

Singh[157] assumes that the nitro-groups in the dinitromethane anion are not equivalent. However, he supports this structure with several rather artificial assignments, e.g. vibrations of the nitro-group at 1360 and 1125 cm^{-1} instead of ~ 1550 and 1380 cm^{-1}, the C=N frequency 1445 instead of 1650 cm^{-1} as usual, etc. The artificiality of the assignments and in several cases the errors in interpreting the spectrum§ cast doubt on the correctness of the structure ascribed to the dinitromethane anion.

A very large amount of experimental information on the infrared spectra of the salts of polynitro-compounds is given by Kamlet et al.[155] In their opinion 1,1-dinitrocarbanions need not necessarily have equivalent N–O bonds. In particular, the "cationic effect" may lead to non-equivalence of the nitro-groups and hence to broadening or splitting of the absorption bands. It must be stressed that no bands which could have been assigned to a covalent nitro-group are found in any of the spectra of the 32 salts investigated[155].

Non-equivalence of the nitro-groups owing to their rotation about the C–N bond with increase in the order of the N–O bonds and a corresponding increase in the ν_{as} and ν_{s} frequencies to values approaching those of unionised aliphatic mononitro-compounds are assumed only by Shokhor et al.[164] They base this conclusion on the appearance of a band in the range 1600–1500 cm^{-1} in the spectra of alkali-metal salts (from lithium to caesium) of trinitromethane and methyl dinitroacetate and the appearance of a shoulder in the range 1320–1310 cm^{-1} in the case of the trinitromethane salts. However, later work[158,163] has shown that the appearance of a band in the region of 1550 cm^{-1} in the spectrum of the trinitromethane anion is due to splitting of the band at ~ 1515 cm^{-1}. No other bands characteristic of the $C-NO_2$ grouping are observed in the spectra, even in the region of the symmetric nitro-stretching vibration. Incidentally, the equivalence of the nitro-groups in the anions of polynitro-compounds in solution is confirmed by ^{14}N n.m.r. results[230].

8. Some Other Cases of the Use of Infrared Spectra to establish the Structure of Nitro-compounds

By analogy with the structure of anions of *gem*-dinitro-compounds it might be expected that in polynitroimidazoles, e.g. in 4,5-dinitroimidazole, both nitro-groups would be equally involved in formation of the anion. Epishina et al.[231] established from the infrared spectra that with nitroimidazoles anion formation always occurs at one nitro-group with conversion of the imidazole into an isoimidazole ring.

Infrared spectroscopy has been used also to establish the structure of α-nitro-ketones[144,232]. Acyclic α-nitro-ketones are shown to exist in the keto-form, whereas the alicyclic compounds exhibit a tendency to enolisation (up to 30%). Shlyapochnikov et al.[233,234] concluded from the infrared and Raman spectra that in halogenated trinitromethane derivatives the NO and C–Hal bonds are conjugated.

Ivanov and his coworkers have been able to show by means of infrared spectroscopy that the product of the self-condensation of 1,1-dinitroalkanes is a nitrolic ester[56]. They have also completely confirmed the structure of the *O*-ethyl ethers of dinitromethane and trinitromethane[38].

Slovetskii et al.[34] used infrared spectral data to show the effect of one, two, and three nitro-groups on the antisymmetric stretching vibration of C–H in the methyl group. This effect can be traced as far as the fourth

§ Singh[157] did not observe the intense C–H stretching band in the dinitromethane anion[155,156], explaining this fact, and also the unusual assignment, in terms of the theory of resonance.

carbon atom in the case of mononitroalkanes, the fifth in *gem*-dinitroalkanes, and the sixth in 1,1,1-trinitroalkanes.

Einberg[235] used infrared spectral data to assess the structure of 5-dinitromethyltetrazole and its mono- and di-salts. Although the assignments of bands to vibrations of the nitro-groups in the salts can be disputed, his conclusion that the hydrogen atom in the dinitromethyl group is more mobile than the hydrogen atom of the tetrazole ring is not open to doubt.

Table 6. Frequencies characteristic of different types of nitro-compounds*.

Compound	Frequency, cm^{-1}		$\Delta\nu = \nu_{as} - \nu_s$, cm^{-1}	Ref.
$R'CH_2NO_2$	1554±6;	1382±6		34
$R'R''CHNO_2$	1550.5±2.5	1360.5±3.5	180	34
$R'R''R'''CNO_2$	1538.5±4.5	1348.5±4.5		34
$R'HC(NO_2)_2$	1578.5±3.5	1329±2	~250	34
$RC(NO_2)_3$	1600±3	1302.5±4.5	~300	145
$[R'RC(NO_2)]^-M^+$	1253—1205	1156—1124	—	152
$[RC(NO_2)_2]^-M^+$	~1480, ~1210, ~1120		—	152
$[C(NO_2)_3]^-M^+$	~1520, ~1280, ~1180		—	

* R′, R″, R‴ = Alk; R = H or Alk; M^+ = cation. When electronegative substituents are present, the frequencies vary in conformity with Table 3 and Section VI.

Kamlet and Kaplan[236] ascertained by means of infrared spectroscopy the presence of a dinitromethyl anion in a Michael reaction product of unknown structure. Lindenmeyer and Harris[237] detected a low-temperature isomorphous transition in crystalline tetranitromethane.

---o0o---

In conclusion the Reviewer would like to emphasise yet again the variety of problems and methods of attack in establishing the structure and mutual influence of atoms and groups in nitro-compounds which have been solved by means of infrared spectroscopy. The range of problems begins with establishing the structure of unknown compounds, investigating the effects of conjugation and dissociation processes, and terminates in studying the fine structure of nitro-carbanions and analogues of aci-forms, investigating the specific interaction of anions with the solvent, etc.

The advances made in the technique of obtaining infrared spectra—the use of such acid-stable optical materials as germanium, the improvement of instruments, increase in their accuracy and extension to longer wavelengths of the spectral range recorded—all this considerably broadens the already great possibilities of infrared spectroscopy for solving theoretical and practical problems in organic chemistry.

Table 6 gives the regions of vibration of the nitro-group which are suitable for the identification of nitro-compounds of unknown structure.

Chromatography of Carbohydrates on Ion-exchange Resins

Yu.S.Ovodov

The literature data dealing with an effective method for the analysis of a mixture of carbohydrates using ion-exchange resins are reviewed. The separation of carbohydrates by this method is based on three main principles: (1) ion exchange; (2) adsorption and gel filtration; (3) partition chromatography. The use of ion-exchange resins yields clear cut qualitative and quantitative results and the analytical process may be automated. The method is distinguished by higher reliability and sensitivity and satisfactory reproducibility.
The bibliography includes 81 references.

I. INTRODUCTION

One of the main problems in carbohydrate chemistry is the separation of complex mixtures of mono- and oligosaccharides and the identification and quantitative determination of their components. A wide variety of chromatographic methods are employed for the solution of this problem. Here mention should be made primarily of paper chromatography[1,2], partition column chromatography on cellulose[3], adsorption column chromatography using a mixture of charcoal and zeolites[4], and gas–liquid chromatography[5–8]. Thin-layer chromatography of carbohydrates[9,10] is less widely used, although in many cases it yields good results[10]. It is also interesting to note that considerable advances have been achieved at the present time in the separation and quantitative determination of carbohydrates by chromatography on ion-exchange resins, although this method has not yet attracted the attention that it deserves. The separation of carbohydrates on ion-exchange resins depends on three different processes: (1) ion exchange; (2) adsorption on ion-exchange resins; (3) partition between the aqueous phase of the resin and the organic stationary phase. Nevertheless in many cases only one of these plays a decisive role and one can therefore adopt a conventional classification of such separation into ion-exchange adsorption, and partition chromatography on ion-exchange resins and treat each separately.

II. ION-EXCHANGE CHROMATOGRAPHY

1. Chromatography on Neutral Carbohydrates

The method of ion-exchange column chromatography for the separation of neutral monosaccharides was first proposed at the beginning of the 1950's.[11,12] It is well known that borate ions react with carbohydrates containing vicinal hydroxy-groups with formation of negatively charged carbohydrate-borate complexes. It has been established that a quite satisfactory separation of the mixture of carbohydrates may be achieved on a highly basic anion-exchange resin, such as Dowex-1, when the chromatography is performed in borate buffers[11]. Mannose and fructose, arabinose and xylose, and sucrose and maltose have been separated by this method. However, it should be noted that the method suffers from the disadvantage of unduly large volumes of eluates (up to 1.5 litres), despite the fact that relatively small columns (0.5 × 11 cm) are employed. Subsequently various ion exchangers and modifications of the method were used for the chromatographic separation of the borate complexes of carbohydrates[12–20].

In 1959 Nakamura and Mori[13] described the separation of carbohydrates in 50% ethanol by ion-exchange chromatography using the above principles. In order to overcome the basic disadvantage of the method (large volumes of eluates), Hallén[14] eluted the resin with solutions at a higher ionic strength (0.01–0.03 M borax solution), the fractions being analysed with the aid of anilinium acetate[15]. The method is distinguished by high sensitivity (it is suitable for the separation and determination of microgramme quantities of the carbohydrate) and can be used directly for the quantitative analysis of the hydrolysates. However, unfortunately when this method is employed, satisfactory separation cannot be achieved in many cases. In particular mannose is eluted with lyxose, ribose with fucose, arabinose with galactose, and xylose with glucose. Attempts were made to improve Hallén's system by separating the borate complexes of neutral sugars at an elevated temperature (50°C), pH 6.8,[16] and using Dowex 2 × 8 in the borate-form. The fractions were analysed with the aid of anilinium acetate by a specially developed method[17]. The authors succeeded in achieving a satisfactory separation of a mixture of rhamnose, mannose, fucose, galactose, and glucose. This modification of the method is distinguished by satisfactory reproducibility, permits a quantitative analysis of hydrolysates, and has been successfully employed in the analysis of the monosaccharide composition of many glycoproteins[17]. Automatic analysis of eluates[18–20] and the use of a special anion exchanger[20] made it possible to overcome many disadvantages of the method and to achieve a separation of 12–15 mono- and oligo-saccharides. Ion-exchange resins have also been used to separate polyols, for which paper chromatography gives unsatisfactory results. The method of separation of polyols in the form of borate complexes on highly basic anion exchangers in the borate-form[21,22], which permits the analysis of fairly complex mixtures of such compounds, has been most widely used.

2. Chromatography of Acid Carbohydrates

Chromatography of acids derived from sugars on ion-exchange resins has been described in a number of publications[14,23-34]. Highly basic ion-exchange resins have been mainly used for this purpose. In view of the instability of uronic acids in an alkaline medium (particularly at elevated temperatures), high pH values must be avoided during chromatography. Dziewiatkowski[29] employed Amberlite IRA 401 × 2 (in the acetate-form) with a particle size of 200–400 mesh in a 0.9 × 36 cm column for the separation of uronic acids. The columns were eluted with an acetate buffer (0.1 M sodium acetate, pH 5.9) at a constant flow rate through the column (1 ml/5 min). Satisfactory separation of a number of uronic acids and the corresponding lactones was achieved. Even better results were obtained by Samuelson and coworkers[30,33] who employed Dowex 1 × 8 anion-exchange resin with very small and carefully fractionated particles (down to 13–17 μm) and eluted with acetic acid or sodium acetate solutions.

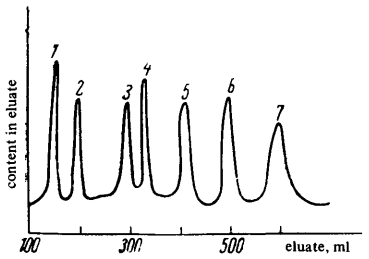

Figure 1. Chromatography of a mixture of uronic acids on Dowex-1 × 8 resin in the acetate-form (particle size 15–17 μm) in a 6 × 880 mm column; elution with 1 M acetic acid at 30°C at a rate of 0.97 ml min^{-1}; mixture components (1.5–2 μg each): 1) D-glucoheponic acid; 2) 6-β-D-glucopyranuronosyl-D-galactose; 3) D-galacturonic acid; 4) D-guluronic acid; 5) L-iduronic acid; 6) D-mannuronic acid; 7) D-glucuronic acid.

Best results were achieved with simultaneous elution by sodium acetate and acetic acid[30,31]. Satisfactory separation of a fairly complex mixture of uronic acids was then observed (Fig. 1). The use of very small particles of resin and their careful fractionation increases the column efficiency and leads to better separation. The time required to separate seven uronic acids is 10–11 h. To reduce this period, larger resin particles were employed. However this greatly impaired the results. Nevertheless, this procedure may be useful in many special cases, for example in the separation of a mixture of galacturonic and glucuronic acids[31]. In these studies the eluates were analysed by carbazole or dichromate methods. The carbazole reaction is known to give different colour intensities with various uronic acids, which permits a rapid identification of the peaks. The nature of the uronic acid may be inferred also from the ratio of the peak areas obtained in the carbazole and dichromate determinations. This quantity is constant and characteristic of different uronic acids.

In ion-exchange chromatography a fully defined elution sequence of the various components of the carbohydrate mixture is observed. Neutral monosaccharides, which are hardly separated under these conditions[34], are eluted initially, are followed by aldobiuronic acids, and finally by simple uronic acids, the elution sequence of which depends on many factors and cannot be predicted beforehand.

In order to separate aldobiuronic acids, we employed dilute sodium acetate solutions[30]. Then it was shown that the use of borax solutions as eluents greatly improves the separation of aldobiuronic acids[33]. The partition coefficients of all the uronic and aldobiuronic acids decrease very rapidly with the concentration of borax solutions.

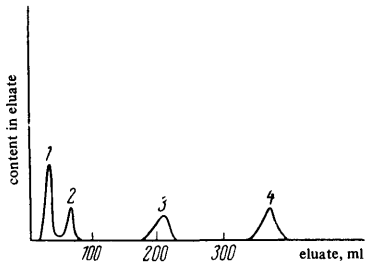

Figure 2. Separation of a mixture of certain aldobiuronic acids on Dowex-1 × 8 resin in the borate-form (particle size 23–25 μm) in a 3 × 870 mm column; elution with 0.12 M borax solution at a rate of 8.45 ml cm^{-2} min^{-1}; mixture components: 1) 4-*O*-methyl-α-D-glucopyranuronosyl-1→2-D-xylose; 2) α-D-galactopyranuronosyl-1→4-D-xylose; 3) β-D-glucopyranuronosyl-1→6-D-galactose; 4) D-glucuronic acid.

This is typical of hydroxyacids forming borate complexes[35], Therefore, in order to achieve rapid elution of the components, one may increase the borax concentration in the eluent solution. Fig. 2 presents as an example the separation of a mixture of certain aldobiuronic acids and D-glucuronic acid. Although carbohydrates are eluted in fairly diffuse bands, their separation is quite satisfactory. Knowledge about the borate complexes of hydroxy acids is very limited, but certain correlations between their positions on chromatograms and structures may be made. One of the rules states that the partition coefficients of hydroxyacids should increase with the number of free hydroxy-groups. Thus one must expect the earlier appearance of 4-*O*-methyl-D-glucuronic acid compared with D-glucuronic acid, which in fact does happen. Similarly, aldobiuronic acids are eluted more slowly than their methylated derivatives.

The study of the effect of the flow rate of the eluent solution on the separation of aldobiuronic acids showed that a sharp decrease of the flow rate leads to only a slight narrowing of the peak and therefore in the ion-exchange chromatography of aldobiuronic acids fairly rapid elution can be successfully employed.

When the temperature is increased, the separation is improved, but the degradation of aldobiuronic acids is at the same time accelerated appreciably. The use of an

automatic fraction analyser greatly accelerates and simplifies the process. In addition, automatic fraction analysis permits a more accurate determination of the peak positions on the chromatogram. It is then found that the deviation of the peak positions of uronic acids on chromatograms does not exceed 2%. The peak position characteristic of each acid can be successfully used for identification.

The separation of aldonic and aldobionic acids on anion exchangers has been described by Samuelson[36-39]. The method has been successfully applied to the analysis of sulphide liquors[41,42] and to the determination of terminal aldonic acid in cellulose[12] and hemicellulose[43].

In the elution by acetate solution a general tendency is observed in the series of hydroxyacids that for the same number of carboxy-groups acids containing more hydroxy-groups are eluted faster than those with fewer hydroxyls[44]. With few exceptions, this rule has been confirmed also in the series of aldonic and aldobionic acids[38,39]. The relation indicates that in this case the molecular size is the main factor determining the partition coefficient. An exception is mannonic acid, which is eluted with pentonic acids and D-glycero-L-mannoheptonic acid, which has a higher partition coefficient than many hexonic acids. These exceptions to the rules may be accounted for by the lower volumes of these hydrated anions, due to intramolecular hydrogen bonding, than for the other diastereoisomers.

From the practical point of view, it is interesting to note that the same elution sequence is reproduced also after prolonged operation of the columns. Anions differing in partition coefficients by 10% and more can be successfully separated. On elution by acetic acid and sodium acetate solution, the following relation between configuration and elution sequence is observed in the series of pentonic and hexonic acids: ribo-, arabo-, xylo-, lyxo-, the acids with the configurations at the beginning of the sequence being eluted earlier. Thus the position on the chromatogram can provide information about the structure of many aldonic acids and is of interest for their identification even when an authentic specimen is not available. As already pointed out, aldbiuronic acids are retained by the resin much less strongly than aldonic acids. On elution by sodium acetate, appreciable differences were observed between the partition coefficients of melibionic, lactobionic, and cellobionic acids, while the differences between cellobionic and maltobionic acids are insignificant[38]. In a borate medium aldonic acids are eluted in the following sequence: xylonic, arabonic, mannonic, gluconic, and galactonic[36,38]. Comparison of the results of chromatography in borate and acetate media shows that borate solutions are preferable for a complex mixture of aldonic acids; aldobionic acids are also satisfactorily separated. However, in a borate medium the latter are eluted almost simultaneously with aldonic acids. Therefore, when it is necessary to separate mixtures of aldonic and aldobionic acids, a preliminary separation of the acids into groups in an acetate medium is required, after which the borate method may be used to analyse the components in the individual groups. A promising method is chromatography on ion-exchange paper, which makes it possible to combine the useful aspects of ion-exchange and paper chromatography. The method has been successfully used by Oertel[25], who employed anion-exchange paper for the separation of uronic acids, lactones, and glucuronides and obtained a completely satisfactory result, despite the fact that the equilibrium between the acid and the corresponding lactone complicates the chromatographic pattern. One may also note the application of cation-exchange papers in the H^+-form for the separation of sugar acids[24]. However, in this case the ion exchanger plays the role of an acid, which is used in the developing systems in paper chromatography in order to avoid "tails". Thus the employment of ion exchange permits the analysis of mixtures of virtually any classes of mono- and oligosaccharides.

III. ADSORPTION CHROMATOGRAPHY

The results obtained by many investigators for the adsorption of polyhydric alcohols by ion-exchange resins[45-48] indicate that the latter may be used to separate carbohydrates by column chromatography. With increase in their size, the affinity of molecular for ion-exchange resins is reduced and thus large molecules are eluted first from the resin. This sequence breaks down, however, for methylated derivatives of carbohydrates, the most methylated derivatives being the last to be eluted by water from the columns[49,50]. The "molecular sieve" effect will also have an undoubted influence and therefore the percentage cross-linking in the resin and the salt form in which it is employed for chromatography are of definite importance. Both cation exchangers[49-55] and anion exchangers[56-58] have been used to separate mixtures of carbohydrates. Water was the eluent in all cases. Best results with cation exchangers were obtained on Dowex-50W (2–8% of divinylbenzene) in various salt forms. The barium-form[50] was used to separate monosaccharides. In one of our papers[51] the successful separation of D-xylose and L-arabinose on Dowex-50W (Ca^{2+}-form) was described. Mixtures of oligosaccharides or methylated monosaccharides have been separated with the aid of this resin in the lithium-form[52]. This form of the resin was also employed in the chromatography of a mixture of raffinose, sucrose, and glucose[49-52]. Satisfactory separation was then observed only for large differences in molecular weight and mixtures of carbohydrates with similar molecular weights could not be separated. More satisfactory results were obtained recently with the same ion-exchange resin in the potassium-form[53-55]. This method permits the fractionation of oligosaccharides in accordance with their molecular weights and the preparative separation of many mixtures with known monosaccharide compositions. Monosaccharides and their derivatives, particularly glucose and its mono- and di-isopropylidene derivatives, have been particularly satisfactorily separated. The use of anion exchangers did not show any advantages compared with cation exchangers. Reducing and non-reducing sugars have been separated on Amberlite IRA-400 (OH^--form) anion-exchange resin[56]. A mixture of raffinose, sucrose, and glucose have been fractionated on the basic forms of De-Acidite FF and preliminary separation of glycosides has been achieved on Dowex-1 resin[58].

The above method of fractionating mono- and oligosaccharides with the aid of ion-exchange resins is in many ways analogous to gel filtration on different types of Sephadex and biogels. The method is distinguished by rapidity and economy and constitutes a useful addition to other procedures for the separation of carbohydrate mixtures[55].

IV. PARTITION CHROMATOGRAPHY

A fundamental study by Samuelson and coworkers dealt with the partition chromatography of carbohydrates on ion-exchange resins. Preliminary studies of the sorption of monosaccharides and polyols from aqueous alcoholic solutions by ion-exchange resins[59-61] showed that the latter may be successfully employed for the partition chromatography of carbohydrates. The early attempts[62,63] gave promising results, after which the method was developed further during recent years.

Since the diffusion of carbohydrates within the resin particles is slow, very finely ground resins are employed for chromatography. The rate of sorption decreases rapidly with increasing concentration of ethanol, and therefore unduly high concentrations of the latter can lead to unsatisfactory separation. A decrease of the flow rate of the eluent solution leads to sharper peaks and the separation is appreciably improved. A higher rate of elution is permissible in the separation of small amounts of carbohydrates[64,65]. In partition chromatography on ion-exchange resins, monosaccharides are eluted before disaccharides and these in turn appear before higher oligosaccharides. Hitherto, in many studies on the partition chromatography of carbohydrates, highly basic anion exchangers with a styrene–divinylbenzene matrix (Dowex-1, Dowex-21, T4, T5B, etc.) have been employed in the sulphate-form with a wide variety of particle sizes. Thus, using a 10 × 840 mm column with Dowex-1 × 8 in the sulphate-form with a particle size of 45–75 μm and eluting with 74% ethanol, Samuelson and Swenson[64,65] successfully separated glucose and sucrose. In the separation of more complex mixtures, they employed stepwise gradient elution. Fig. 3 illustrates the separation of carbohydrates on molecular sieves by this method.

The use of a resin in the chloride-form[66] usually sharply impairs the results. Nevertheless mannose and xylose are satisfactorily separated in this case too. The chromatography of monosaccharides on highly basic resins in the bisulphite-form has been described in a number of papers[66,67]. The method ensures a satisfactory separation of ketoses from aldoses. The use of highly basic anion exchangers with more polar matrices has been described—in particular dextran containing quaternary ammonium ion-exchange groups has been employed[68]. In many cases this led to an improvement of separation but no fundamental differences were observed. Cation exchangers have also been successfully used in the partition chromatography of carbohydrates[69,70].

The fractions were initially analysed[64,65] by the phenol-sulphuric acid method and then an automatic fraction analyser began to be used[65,69,71,72]; part of the eluate and the reactants were then introduced into the analysing system, by a proportionating pump. Automatic analysis yields satisfactorily reproducible results.

In order to elucidate the possibility of separating the various carbohydrates, the positions of the peaks on the chromatograms are determined and the partition coefficients D_V are calculated[66]. Small variations in peak positions may be observed as a function of the rate of elution, the concentration of the eluent, and elution temperature. However, the relative partition coefficients of various carbohydrates depend to a lesser degree on the experimental conditions. Therefore in the identification of different carbohydrates, one may employ the ratios of their partition coefficients and the partition coefficient of any one monosaccharide chosen as a standard. The sorption of sugars by anion exchangers depends on many factors. One of these is partition between the water associated with the resin and the less polar eluent[59]. The effect of this factor should lead to an increase of the partition coefficient with increase in the number of hydroxy-groups and with decrease in the number of non-polar groups in the carbohydrate. One may then expect an increase of the partition coefficient in the series tetroses < pentoses < hexoses, and deoxy- and methylated derivatives should have smaller partition coefficients than the corresponding normal sugars. However, in addition to this factor, the interaction of the carbohydrate with the matrix and the ion-exchange groups of the resin, which may alter the above elution sequence[66], also plays an important role.

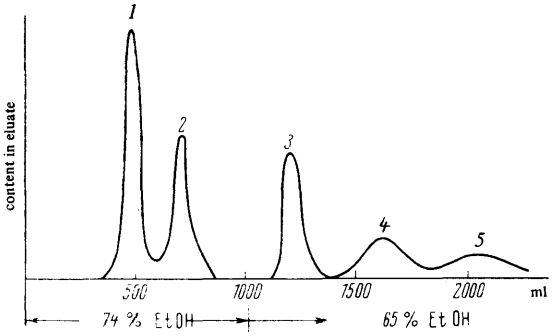

Figure 3. Separation of a mixture of carbohydrates in accordance with their molecular weights on Dowex-1 × 8 resin in the sulphate-form (particle size 45–75 μm) in a 10 × 840 mm column; gradient elution with alcoholic solutions at a rate of 0.8 ml min^{-1} cm^{-2} at 28°C; mixture components: 1) glucose; 2) sucrose; 3) raffinose; 4) stachyose; 5) verbascose.

Thus at the present time the elution sequence within each group of carbohydrates cannot be established *a priori* and is determined only empirically. It is noteworthy that in the majority of cases partition chromatography of carbohydrates and the ion-exchange resins gives a fairly satisfactory separation, which allows quantitative determinations. The sole factor which restricts the application of this method is the extremely low rate of diffusion within the resin particles. Therefore it is necessary to employ very small and as far as possible more porous particles. Thus, when a resin with a particle diameter of 45–75 μm is used, only partial separation of glucose and sucrose is observed, whereas particles with dimensions of 15–40 μm give a complete separation[73]. The employment of small particles permits the analysis also of monosaccharides[73] and it is possible to achieve a quantitative separation of mono- and oligo-saccharides[73,74]. The quality of the analysis depends to a considerable degree on the thoroughness of the fractionation of the resin. An increase of ethanol concentration also improves the results, provided that the consequent decrease of the rate of diffusion is compensated by a decrease of the resin particle size. In order to avoid under these conditions a sharp increase of column resistance to flow and to reduce the duration of analysis, the use of a mixture of an ion-exchange resin and Celite has been suggested[75]. It has been shown in a number of studies[66,69,70,72] that the partition coefficients of

the majority of carbohydrates in aqueous alcoholic mixtures differ appreciably. Fig. 4 presents the separation pattern for a mixture of twelve monosaccharides on an anion-exchange resin in the sulphate-form. The quality of the separation permits a quantitative analysis. The slight overlapping of the rhamnose and fucose peaks and of the arabinose and lyxose peaks does not affect the results of such analysis and, moreover, may be eliminated by increasing the concentration of ethanol or by increasing the column size. It has been established[76] that, in a quantitative determination of the monosaccharides present in wood hydrolysates, partition chromatography on anion-exchangers with automatic determination of the sugar concentrations in the eluates is a more convenient and accurate method than paper chromatography. The use of the orcinol method and careful fractionation of T5B anion exchanger (particle size 10–15 μm) in the sulphate-form permitted the development of an automatic micromethod for the analysis of a mixture of monosaccharides containing 6–30 μg of each component[77]. Partition chromatography on anion-exchange resins has been employed also for the separation of methylglycosides and methylated monosaccharide derivatives[78]. It was found that 94 wt. % ethanol, which ensures the complete separation of a number of the above derivatives, is optimum for elution[78].

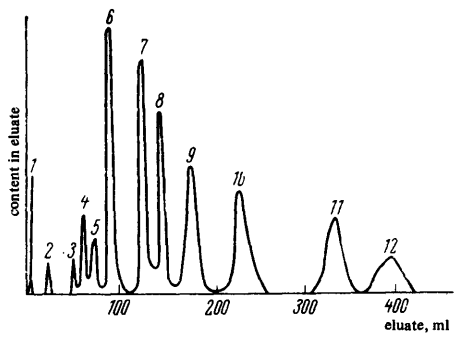

Figure 4. Analysis of a mixture of monosaccharides by partition chromatography on Dowex-21K anion-exchange resins in the sulphate-form (particle size 1–16 μm) in a 6 × 760 mm column; elution with 86% ethanol at a rate of 0.9 ml min^{-1} cm^{-2} at 75°C; mixture components (0.05–0.3 mg): 1) digitoxose; 2) 2-deoxyribose; 3) 2-deoxygalactose; 4) rhamnose; 5) fucose; 6) ribose; 7) lyxose; 8) arabinose; 9) xylose; 10) mannose; 11) galactose; 12) glucose.

Satisfactory separation of monosaccharides has been achieved on Dowex-50W × 8 cation-exchange resin with a very small particle size (14–17 μm) and elution by ethanol–water mixtures[69,70]. The ionic form of the cation exchanger has a marked influence on the partition coefficients. For monosaccharides, the latter increase in the sequence Li < Na < K. For all the sugars and all ionic forms of the cation-exchange resins, the partition coefficients decrease with increasing temperature. This finding accords with the results obtained on anion-exchange resins[71]. With small exceptions, the partition coefficients increase with the number of hydroxyls in the monosaccharide. A typical chromatogram is presented in Fig. 5, which shows that very satisfactory separation of seven different monosaccharides, including rhamnose and 2-deoxyglucose, which are not separated on anion exchangers in the sulphate-form, is achieved on a cation exchanger. Moreover, in contrast to anion exchangers, satisfactory results have been obtained for ketoses on cation exchangers. The lithium-form of the resin gives a better separation of deoxy-sugars than the sodium- and potassium-forms, but in work with the lithium-form a much higher pressure is required to maintain a constant rate of elution.

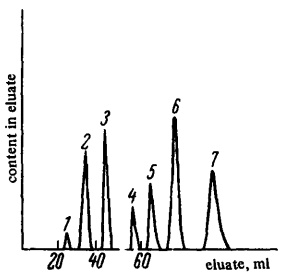

Figure 5. Separation of monosaccharides on Amberlite IR-120 cation-exchange resin in the Li^+-form; elution with 92.4% ethanol at a rate of 1.2 ml min^{-1} cm^{-2} at 75°C; mixture components: 1) 0.2 mg of rhamnose; 2) 0.4 mg of 2-deoxyglucose; 3) 0.6 mg of xylose; 4) 0.4 mg of arabinose; 5) 0.4 mg of tagatose; 6) 0.8 mg of glucose; 7) 1.5 mg of galactose.

One of the significant disadvantages of cation-exchange resins compared with anion exchangers is the poor separation of glucose and mannose. Partition chromatography has been successfully used also for the analysis of mixtures of polyols. Samuelson and Strömberg[79] suggested that in a quantitative determination of the components of such a mixture, they should be subjected to periodate oxidation with subsequent determination of the resulting formaldehyde with pentane-2,4-dione. The method permits an automatic fraction analysis, is distinguished by high accuracy and satisfactory reproducibility, and is suitable for microanalytical work. The subsequent application of the orcinol method, which does not give a colour reaction with polyols, and periodate oxidation permits the analysis of mixtures containing both aldoses and polyols. Various polyols are separated under the conditions already described for carbohydrates. A typical chromatogram obtained for polyols and aldoses on an 8 × 852 mm column with the highly basic T5B anion-exchange resin in the sulphate-form with a particle size of 3-17 μm is presented in Fig. 6. In elution with 86% ethanol at 75.5°C the duration of analysis is 11 h. Very satisfactory separation of the majority of polyols and aldoses is then observed, and only the peaks of dulcitol and mannitol overlap, which precludes an accurate quantitative determination of these polyols. The separation of mannose and dulcitol is also incomplete. To improve the results, elution with higher ethanol concentrations and longer columns are employed.

This leads to a complete separation of dulcitol and mannose, but the duration of analysis increases. To reduce the required period, very careful resin fractionation is necessary. As in the case of aldoses, the partition coefficients of polyols depend on the concentration of the alcohols and increase as it is raised, but the elution sequence is independent of alcohol concentration. A higher resin capacity leads to an increase of the partition coefficients and an improvement of separation. As for aldoses, the partition coefficients decrease with the number of hydroxyls in the polyols. The majority of polyols are eluted before the corresponding aldoses. Only ribitol and mannitol are exceptions.

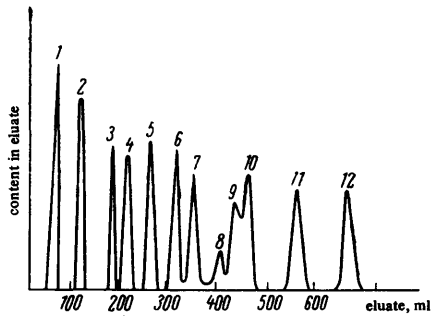

Figure 6. Analysis of a mixture of polyols and aldoses on TB resin in the sulphate-form (particle size 3–17 μm) in a 6 × 852 mm column; elution with 86% ethanol at a rate of 2.51 ml min^{-1} cm^{-2} at 75.5°C; mixture components: 1) glycerol; 2) erythritol; 3) xylitol; 4) arabitol; 5) arabinose; 6) xylose; 7) sorbitol; 8) mannose; 9) dulcitol; 10) mannitol; 11) galactose; 12) glucose.

Cation exchangers have also been used to separate polyols [70]. Resins in the lithium-form give the best results. Satisfactory separation of a complex mixture of polyols is also achieved in this case.

---o0o---

Thus chromatography on ion-exchange resins permits a quantitative separation of very complex mixtures of monosaccharides and oligosaccharides. There is no doubt that the method will be very useful in the quantitative determination of the monosaccharide composition of a wide variety of carbohydrate-containing biopolymers, although the scope of the method as applied to the analysis of natural polysaccharides has so far been inadequately investigated [80, 81].

Vitreous Carbon (Preparation, Properties, and Applications)

V.D.Chekanova and A.S.Fialkov

Vitreous carbon, one of the most important materials based on graphite carbon, is outstanding in its high mechanical strength, resistance towards aggressive media, and imperviousness to gases. Because of these unique properties, there has been a rapid growth in the range of articles made of vitreous carbon and in the number of applications.
The methods of production, formation mechanism, structure, properties, and the range of applications of vitreous carbon are described in this review. 97 references.

I. INTRODUCTION

Modern technology has created a requirement for new constructional materials able to withstand high temperatures and aggressive media. One such material is artificial graphite. This material, however, though inert towards many reactive media, cannot be used at the boundary between two media because of its high permeability (due to the presence of a developed structure of pores and channels).

High-strength materials which are impervious to gases and liquids are urgently needed for a number of industrial applications. So far the need has been met by two materials: pyrolytic graphite[1] and vitreous carbon. These materials differ very substantially in their methods of preparation and in their properties: whereas pyrolytic graphite shows a marked anisotropy of thermal, electrical, and mechanical properties, vitreous carbon shows no anisotropy at all.

This review deals with the methods of preparation, the properties, and the fields of application of vitreous carbon.

Vitreous carbon is a new material, with a number of specific properties not found in the previously known modifications of carbon[2-4].

The study of vitreous carbon offers both practical and scientific interest, because this material is one of the non-graphitising forms of carbon, about which little is known.

II. PRODUCTION OF VITREOUS CARBON AND FABRICATION OF VITREOUS CARBON ARTICLES

Vitreous carbon and vitreous carbon articles can be produced by the thermal decomposition of some carbonaceous materials which give carbonised pyrolysis products without forming an intermediate liquid phase[5].

The first disclosure[6,7] of the production of an impervious form of carbon, using cellulose as the starting material, appeared in 1957. The process involved the following operations: preparation of an aqueous suspension in which the fibrous structure of cellulose is destroyed, precipitation of the product from suspension, and carbonisation with exclusion of air, followed by graphitisation[8-11]. Wheat-chaff cellulose, purified from lignin or xylan[6,12-15], may be used as the raw material for the production of impervious carbon.

Shortly after the first report of the preparation of this material, American, Japanese, French, and other papers discussed its properties and technical-scale production[6-17]. The raw material in this case can be synthetic resin of the resol (A-stage resin) or novolac (soluble phenol–formaldehyde) type[18,19], furfuryl alcohol or furfural[20-22], or polynuclear aromatic hydrocarbons[23,24]. The resins are carbonised with or without a catalyst by slow heating in a reducing or a neutral atmosphere[18,25,26].

Vitreous carbon can be prepared also from previously carbonised cellulose and synthetic resin, taken in the ratio of 3 : 7 by weight[27].

Some work has been done on the effect of filler additives to the cellulose dispersion[12]: the product was shown to remain impervious to gases even after the addition of fillers such as carbon black and colloidal graphite. The effect of the filler is largely dependent on the porosity and particle size of the filler itself. Thus, petroleum coke is too porous to be used as a filler for articles impervious to gases.

The addition of fillers can be a desirable step, since they do not degrade the high-temperature properties of the final product. Fillers lead to shorter production cycles, since they reduce the amount of material to be decomposed and the volume of volatile products evolved during the reaction.

A method[28] of production of vitreous carbon from furfuryl alcohol and furfural employs fillers of the same compounds, after hardening and crushing. This method evolves fewer volatile products, and the shrinkage of the manufactured articles is correspondingly reduced. The process is also cheaper, because hardening residues can be utilised.

Yamada and Takata[29] have proposed a method in which furfuryl alcohol or its initial condensation products are deposited in successive layers on the surface of a former, with or without the addition of carbon powder or chopped fibre. The resulting product is then graphitised or carbonised in the normal way. The advantage of this method is that volatile products are evolved more uniformly from the surface of the formed article during the hardening stage, and the quality of the product is thereby improved.

A preliminary degassing treatment of the components in vacuo is said[30] to improve the mechanical properties of the product, since it reduces the yield of volatiles during carbonisation.

Pyrolysis conditions (and in particular the rate at which the polymers are heated to the maximum temperature, and the time for which they are held at this temperature) can have a profound effect on the direction and the extent of the thermochemical reactions, and on the quality of the resulting non-porous material.

The technological production cycle of vitreous carbon occupies 2–4 months, the duration of the preliminary operations increasing in proportion to the maximum temperature which the vitreous carbon product is required to withstand[2].

Because of the extreme hardness of vitreous carbon, machining operations on the material are not straightforward, but they can be carried out with diamond-tipped tools, ultrasonic cutters, and grinding machines with carborundum wheels[2].

Most of the articles made of vitreous carbon do not require machining. The material is usually pressed to the finished size or cast into a mould[31] with allowance for shrinkage during heat treatment.

Tubular forms are made by the centrifugal forming method[32,33]. In one method of forming large cylindrical objects[34,35] the thermally reactive composition is cast into a former with a cylindrical core. Former and core are counter-rotated during hardening of the resin to avoid adhesion to the walls and to facilitate release of the article from the former.

Articles of many different shapes can be made of vitreous carbon: disks, tubes, cylinders, crucibles, beakers, boats, etc.[3] The maximum size of these articles which can be achieved in practice has been identified: in most cases the wall thickness is less than 3 mm. Tubes up to 1 m long and 40 mm in diameter have been made, as well as beakers of 3-litre capacity, disks up to 250 mm in diameter, and plates 100 × 500 mm. With especially close control over the composition of the resin, and the temperature and pressure during heat treatment, it is possible to make[25] rods 5–10 mm in diameter, articles with a wall thickness up to 6.3 mm, and crucibles up to 10 P in capacity.

In addition to articles of conventional shape, more unusual forms can be made of vitreous carbon: spheres 0.2–1.0 mm in diameter, tape weighing only a few mg per cm length, and vitreous carbon fibre[36-38]. The latter is made from furfuryl alcohol or furfural resin, which is hardened, drawn through a die under a pressure of 5 kg cm^{-2}, and carbonised in an inert atmosphere[39].

Vitreous carbon fibre has recently been prepared by extruding a mixture of resol, novolac, and furan resin (7 : 2 : 1 or 8 : 1 : 1 parts by weight), followed by rapid cooling, hardening, and carbonisation. Depending on the size of the orifice used for extruding the mixture, filaments 6–25 μm in diameter can be obtained[40].

The chemistry of vitreous carbon is the chemistry of the pyrolysis of synthetic resins. On heating a furfural–phenol–formaldehyde resin (FPFR), changes in weight and in composition are observed (Fig. 1 and Table 1)[41,42].

By monitoring the weight loss on heating, the thermal decomposition of the resin to the stage of carbonisation can be characterised. Heat treatment at 1200° gives an abundant evolution of pyrolysis products (low-molecular-weight gaseous species). The loss in weight under these conditions can be greater than 50%. On further carbonisation the weight change becomes insignificant and the weight curve runs parallel to the temperature axis.

The changes in chemical composition indicate a continuous succession of chemical reactions, the solid residue becoming gradually carbonised. On heating the resin at 1200°, the carbon content increases from 68.3 to 97.6% whilst the oxygen content decreases from 21.7 to 0.1%. The nitrogen and hydrogen contents decrease at the same time. However, the product which has been carbonised at 1200° still contains an appreciable amount of nitrogen (1.8%). Graphitisation gives an even purer carbonaceous material.

It has been found experimentally[41] that the insoluble fraction after heating FPFR to 100° amounts to 75%. On further heating the resin to 150°, the proportion of high-temperature compounds increases, and the insoluble frac-

tion becomes 95%. After treatment at a still higher temperature a completely insoluble polymer is obtained. The observed transition from a soluble to an insoluble polymer is evidence of chemical reactions within the material, confirmed by the change in free phenol and furfural contents during hardening of the resin. Thus, whereas a product containing 35% of free furfural and about 4% of free phenol is obtained after heating the material to 80°, no free components can be detected in the solid product after heat treatment at 200°.

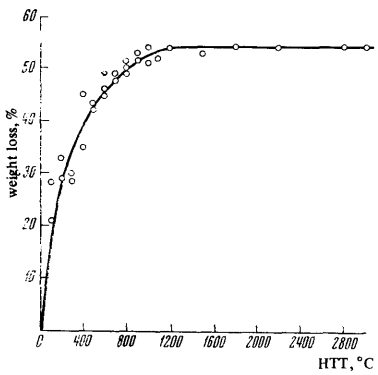

Figure 1. Change in weight of FPFR during heat treatment [42].

The greatest changes occur in the range 80–120°, and effectively cease at 180°. This is because the hardening process occurs mainly over the range 150–180° (as shown by chemical analysis).

Table 1. Composition changes during heat treatment of FPFR.

The hardening process is controlled by a number of factors. In particular, the course of the hardening reaction is determined not only by temperature, but also by the heating rate and the duration of heat treatment. Higher heating rates tend to slow down the hardening process, to lower the proportion of insoluble fraction, and to increase the content of free components in FPFR. Polymers produced by heating the resin to 120° at different rates (1 and 30 deg h^{-1}) showed hardening factors of 89 and 81% respectively, and different contents of free furfural (5 and 10%) and of free phenol (0.9 and 1.3%). The experimental results of Fig. 2 show the variation of the degree of hardening with time of isothermal heating at different temperatures. The hardening time decreases on raising the temperature. Thus, a 10-hour heat treatment at 100° is needed to give 83% of insoluble fraction, as compared with only 5 h at 110°. Thus, the effect of temperature on the degree of hardening can be compensated to some extent by change in reaction time. The 150° curve is the steepest for times below 0.5 h and the flattest above 5 h. This shows not only that the reaction rate increases with hardening temperature, but also that the reaction at this temperature goes effectively to completion in a shorter time than at the other temperatures (120°, and below).

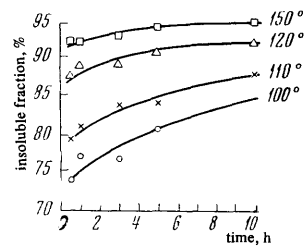

Figure 2. Percentage of insoluble fraction during hardening of FPFR under isothermal conditions [41].

An analysis of the volatile products evolved during hardening detected mainly furfural (95–96%), with a small amount of phenol, in the liquid condensate. The amount of condensate evolved is determined by the heating rate. Thus, on raising the rate from 10 to 40 deg h^{-1} the volume of condensate increases by a factor of 2 (from 20.8 to 42.2%). Hence we may conclude on the one hand that the heating rate determines the yield of polymer, and on the other hand that under these conditions the hardening of the material is due not only to chemical changes but also to the evolution of volatile fractions.

It is well known that many complex processes take place during hardening of phenol–formaldehyde resins [43]. Many workers believe [44–47] that a free-radical mechanism is involved.

The experimental results reproduced in Fig. 3 show the change in the concentration of paramagnetic centres (PMC) during hardening of the resin at temperatures up to 200°. The total number of PMC begins to increase appreciably at 70–80°, and continues to increase up to 120°. An arrest is observed over the range 120–150°, followed by a further increase in the number of PMC. The presence of a significant number of PMC in the original resin, decreasing during the initial heating period (below 70°) suggest that oxidation is occurring. This is confirmed by the fact that when the initial, pure novolac resin is allowed to stand in contact with the air for a long time its viscosity increases, and a fairly large ESR signal can be detected, whereas no such change occurs if the resin is stored out of contact with the air. The paramagnetism in this case may arise from peroxidic or quinonoid radicals formed by the oxidation of terminal groups of the resin molecule, which are also the most readily accessible to oxygen.

It should be noted that the hardened samples were very insensitive to atmospheric oxygen. The reported PMC concentrations relate to measurements in ordinary air.

It is evident from Fig. 3 that the number of PMC begins to increase when the temperature of heat treatment is greater than 70°, and becomes constant at 120–150°. On the other hand, chemical analysis indicates that the interaction between the components (i.e. the hardening process) continues to take place even in this range of temperatures. For example, the proportion of free phenol and furfural decreases gradually throughout the range of heat treatment temperatures. The i.r. spectra of the resin during hardening lead to the same conclusion. Experimental i.r. spectral data for the initial resin and for the material in various stages of hardening are shown in Fig. 4.

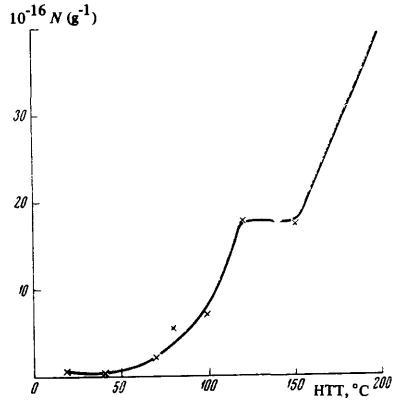

Figure 3. Formation of PMC during hardening of FPFR[42].

Heat treatment at 90° causes a large decrease in the intensity of the absorption band at 1660 cm^{-1} and almost complete disappearance of the 1570 cm^{-1} band. Both these bands arise from the furfural[48]: hence the changes may be explained either by a decrease in the amount of free furfural in the sample, or by volatilisation of this component, or by structural changes. The band at 1570 cm^{-1} is due to vibrations of the diene bonds in the furan ring which are conjugated with a carbonyl group. Hence, its disappearance may be ascribed to a decrease in the number of these bonds or to a decrease in the number of C=O groups (confirmed by the changes in the 1660 cm^{-1} band), or to the opening of one of the C=C bonds.

After heating the sample to 120°, the following changes are noted in the i.r. spectra. The band at 690 cm^{-1} (assigned to monosubstituted benzene rings, i.e. free phenol) disappears completely. The vibrations of the phenolic OH groups also give rise[49] to the bands at 1370 and 1200–1230 cm^{-1}, whose intensity decreases very significantly after heating the sample at 120°. The type of substitution of the benzene rings does not change (bands at 800–700 cm^{-1}), as shown also by the constant intensity of the 1600–1500 cm^{-1} bands which are very sensitive to the type of substitution. The number of aldehyde groups does not change (since the band at 1660 cm^{-1} is unchanged).

The absorption band of novolac at 1370 cm^{-1} is usually ascribed to vibrations of the phenolic hydroxyls. One of the furfural bands occurs at the same frequency. The 1370 cm^{-1} band disappears almost completely at 120°. It follows that the phenolic hydroxyls are involved in the hardening reactions. The nature of the bands in the 900–700 cm^{-1} region suggests that the benzene rings are not highly substituted[50,51]. No tetrasubstituted rings are detected by i.r. absorption. The narrow band at 880 cm^{-1}, which is characteristic of furans, shows that some of the five-membered rings survive the reaction.

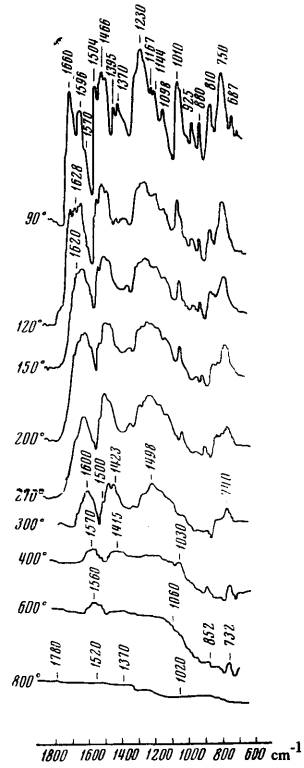

Figure 4. Infrared absorption spectra of FPFR after various stages of heat treatment[41,47].

A particularly interesting band, at 1628 cm^{-1}, can be due either to isolated C=C double bonds or to C=C double bonds conjugated exclusively with the carbonyl group or exclusively with the aromatic nucleus (without conjugation to another C=C bond).

After heat treatment to a higher temperature (150°), the absorption band of the aldehyde carbonyl group (1660 cm^{-1}) is no longer detectable. The strongest band is at 1620–1630 cm^{-1}. The 1370 cm^{-1} band (phenolic hydroxyls) has disappeared completely. The absorption bands associated with the furan ring are weaker, particularly the 930 cm^{-1} band from monosubstituted furan. Changes can be detected in the intensity of the 900–700 cm^{-1} band, and that of the 740–750 cm^{-1} band also shows a marked change. This latter band corresponds to the vibrations of the unsubstituted hydrogen in *ortho*-substituted benzene rings and in monosubstituted benzene and furan rings. The intensity

of absorption in the trough between the bands at 740 and 810 cm^{-1}, due to the formation of di-*ortho*-substituted rings, begins to increase at 150°.

The 1010 cm^{-1} band (from the C–O–C group) is the only furfural band still clearly visible in the spectrum at 200°. The 770 cm^{-1} band (triply substituted rings) is sharply resolved. At 870–880 cm^{-1} we observe a broad absorption band apparently due to the formation of 4-substituted benzene rings. The intensity changes in the region of 1600–1500 cm^{-1} are also interpreted in terms of changes in the type of substitution.

Thus, an analysis of these experimental results suggests that the hardening process occurs mainly in the range 70–150°, and that the process is characterised by a change in the number of PMC. The point at which the concentration of PMC begins to increase, and the point at which it becomes constant, can be identified with the initial and the final hardening temperature. The increase in the concentration of PMC is due to the formation of random molecular networks with a large number of broken cross-linking bonds.

The constancy of the concentration of PMC between 120 and 150° (Fig. 3) is evidently the result of the hardening of the resin to a solid product (of relatively low hardness). Isothermal heating in this temperature range produces only a slight consolidation of the three-dimensional network without forming any new PMC. These conclusions are consistent with the results of chemical analysis, which indicate that most of the free components of the resin have reacted chemically, and they are consistent also with the observed i.r. spectral changes.

In particular, the 1660 and 1370 cm^{-1} bands disappear almost completely at 150°. The most important band is found at 1620–1630 cm^{-1} (double bonds).

The increase in the concentration of PMC at temperatures above 150° is probably caused by pyrolysis of the resin.

The rate of hardening of the resin plays an important part in the formation of PMC. Thus, increasing the heating rate has been found to lower the concentration of PMC (from $\sim 2 \times 10^{17}$ spins g^{-1} at 5 deg h^{-1} to $\sim 0.7 \times 10^{17}$ spins g^{-1} at 20 deg h^{-1}). Evidently, a slow rise in temperature favours both a more complete chemical reaction between the components and the breaking of cross-linking bonds by pyrolytic action.

Isothermal heating at a temperature close to the upper hardening temperature does not alter the concentration of PMC appreciably. Thus, the number of spins was found to be 2×10^{17} and 2.5×10^{17} g^{-1} after heating at 120° for 1 h and 10 h respectively. These results are evidence that hardening occurs in a relatively short time.

The processes which occur during pyrolysis of hardened FPFR are particularly interesting[47]. The structural changes occurring during pyrolysis of the resin are reflected by changes in the i.r. spectra. It can be seen from Fig. 4 that heat treatment at 270° produces a sharp change in the intensity of the 1620–1630 cm^{-1} band. The band at 740 cm^{-1} becomes weaker, showing that the number of disubstituted rings has decreased. At the same time, sharp bands appear at 860 and 770 cm^{-1}, indicating more extensive substitution. The bands associated with the furan ring disappear, except the 1010 cm^{-1} band (C–O–C group). A band at 1260 cm^{-1} is clearly resolved in the region of 1200–1250 cm^{-1}. This band is found in all compounds containing C–O groups: it is often ascribed to aromatic ethers. Since the 1010 cm^{-1} band has not disappeared, any partial bonding of the C–O–C group (or –O–) to unsaturated carbon atoms should give rise to this band. It is difficult to account for the appearance of a broad line at 1600 cm^{-1}, and to decide whether this line is due to the aromatic ring only or whether it is conjugated with lines from C=C bonds.

At 300° all the furan bands have disappeared, including the 1010 cm^{-1} band. The i.r. spectrum now contains only bands associated with vibrations of aromatic rings (1600, 1500, and 740–800 cm^{-1}), and also bands from oxygen-containing groups (1250–1100 cm^{-1}).

After heat treatment at 400°, the oxygen content of FPFR is drastically reduced: all lines in the region 1250–1100 cm^{-1} have disappeared. The i.r. spectrum contains only an absorption band due to double bonds (mainly aromatic) at 1600–1500 cm^{-1}. The extent of substitution increases, as shown by the relatively strong band at 860 cm^{-1}. This effect may be due to condensation of the aromatic rings. The 1415 cm^{-1} band, due to residual $-CH_2$ groups, disappears completely at 600°.

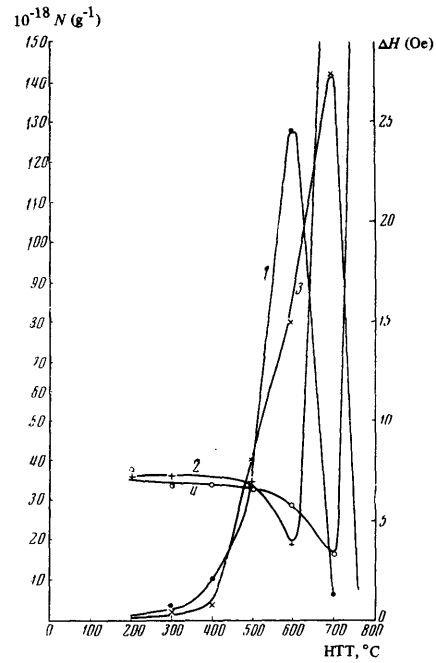

Figure 5. Concentration of PMC (N) and line width (ΔH) as a function of HTT[47]: *1*) and *3*) changes in N for samples heated at 5 and 20 deg h^{-1} respectively; *2*) and *4*) changes in ΔH for samples heated at 5 and 20 deg h^{-1} respectively.

The structural changes in the resin during heat treatment (HT) at temperatures above 200° (Fig. 5) result in changes in the concentration of PMC (curve *1*) and in the line width ΔH (curve *2*). The maximum ESR absorption is found at 600°, a temperature which is characteristic of carbonised substances. According to Trostyanskaya and coworkers[52], the highest concentration of PMC during pyrolysis of phenol–formaldehyde resins occurs in the range 400–500°. Others[53] have found a strong maximum at ~ 700° and smaller maxima in the region 1400–1800° and ~ 2800°. It follows that the position and the strength of the maximum are critically dependent on the type of resin.

The results of Fig. 5, obtained with samples in a vacuum, show that the total number of PMC increases slowly in the range 150–300°. Evidently, the growth in the concentration of PMC in this case denotes onset of pyrolysis, elimination of oxygen-containing groups and low-molecular-weight products, and dissociation of the dimethylimino bonds formed during the curing. The range 300–500° is characterised by a sharp increase in the concentration of PMC, due to the intensification of the above reactions and to the formation of aromatic molecules with unpaired electrons. This is confirmed by the analytical results (Table 1), which show that the most extensive changes in composition occur at temperatures ≥ 300°.

However, the carbonised product still contains a fairly large amount of nitrogen (1.8%) and a trace of hydrogen (0.5%). Thermal dehydrogenation, which sets in when the resin is heat treated above 400°, also contributes to the evolution of hydrogen from the sample (as shown by the results of chemical analysis). This process is partly responsible for the decrease in line width (ΔH) in the temperature range 500–600°, associated with the loss of hyperfine interaction (see curve *2* of Fig. 5). The main line-broadening mechanism in this temperature range, in addition to spin–spin interaction, is probably spin–orbit coupling, as suggested by the strong temperature dependence of the spin–lattice relaxation time. The spin–lattice relaxation time of a resin heat-treated at 600° is approximately an order of magnitude larger than for the same material at room temperature.

However, since the sharp rise in concentration of PMC is accompanied by a relatively small change in ΔH, it may be assumed that different types of paramagnetic centre exist in different regions.

The mechanism of thermal degradation of the resin has been elucidated by measuring the yield of gas as a function of temperature and time (Fig. 6). The composition of the gas is different for different temperature ranges. The strongest gas evolution occurs at 600–800°, the range where the degradation processes are most marked. On further raising the temperature there is a large decrease in the amount of gas evolved.

The degradation process begins to slow down after 25–30 min under isothermal conditions in the temperature range 200–1000° (Fig. 6).

The ESR absorption maximum observed at 600° corresponds with the temperature of maximum gas evolution (Fig. 5). This is evident from the composition of the gases evolved during pyrolysis.

As the pyrolysis temperature is raised, the composition of the gases evolved changes continuously (Table 2). The gas resulting from pyrolysis at 200–500° consists mainly of CO and CO_2. Significant amounts of methane are evolved at 500–800°, with a maximum at 600°, and at the highest temperatures the concentration of methane falls to 3%. The largest change was observed in the hydrogen concentration, which increased to 87% when the temperature was raised to 1000°.

Evidently, pyrolysis of methane can occur at the higher temperatures. The concentration of CO decreases continuously from 46 to 5%, and that of CO_2 from 52 to 3%.

The formation of volatile products by low-temperature pyrolysis is probably associated with the opening of heterocyclic rings, whereas at the higher temperatures (but below 800°) the mechanism is probably dehydrogenation of benzene rings.

The position of the ESR absorption maximum during carbonisation is determined not only by the type of resin but also by the heat-treatment regime. Fig. 5 shows the changes in concentration of PMC and in line width ΔH for a resin subjected to different heating rates (5 deg h^{-1} for curves *1* and *2*, 20 deg h^{-1} for curves *3* and *4*). It is clear that the concentration maximum and the ΔH minimum are shifted towards higher temperatures (> 700°) when the heating rate is changed from 5 deg h^{-1} to 20 deg h^{-1}.

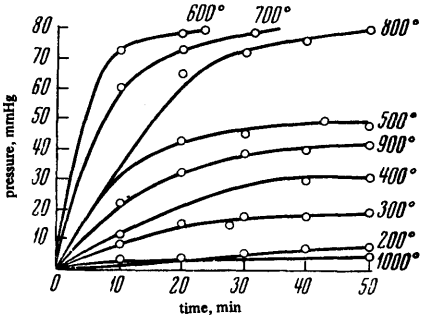

Figure 6. Yield of gas during pyrolysis of FPFR under isothermal conditions at different temperatures [47].

These effects can be understood on the assumption that bond breaking and thermal dehydrogenation (and the resulting structural rearrangements) cannot be fully effective if the heat-treatment temperature (HTT) is allowed to rise above 400° too rapidly.

Table 2. Composition of the gaseous pyrolysis products of FPFR [47].

HTT, °C	Components, expressed as vol.% of total gas evolved					
	CO	CO_2	CH_4	H_2	H_2O	Remarks
200	46	52	—	—	—	2% ($O_2 + N_2$)
300	59	37	—	—	—	4% ($O_2 + N_2$)
400	57	41	2	—	—	—
500	40	38	18	2	—	2% ethylene–ethane
600	19	10	45	26	—	—
700	17	2	38	43	—	—
800	8	2	20	68	2	—
900	6	3	5	84	2	—
1000	5	3	3	87	2	—

The decrease in concentration of PMC when the resin is heat treated above 600° is due to the loss of aromatic hydrogen and to the disappearance of free radicals which accompanies the formation of aromatic structures. The decrease in spin–lattice interaction time, leading to an increase in ΔH, is consistent with this hypothesis. The absence of ESR absorption for HTT > 700° (Fig. 5) is ascribed to incipient ordering of the resulting two-dimensional structure. As a result, the electrical conductivity of the sample begins to increase rapidly. It should be noted that the temperature at which ESR absorption begins to disappear is a characteristic of the particular resin: all the properties of the material begin to change at this HTT. Thus, the hardness and the density show a sharp increase, and the electrical resistivity begins to fall off very rapidly.

Studies of the influence of atmospheric oxygen on the PMC of a carbonised resin have yielded very interesting results. The relative sensitivity to atmospheric oxygen of the PMC in samples which have been exposed to different heating rates is illustrated in Fig. 7. Two regions where the effect of oxygen is large can be clearly seen. Thus, the ratio N_{vac}/N_{air} remains constant in both cases over the range 300–500°. The concentration of PMC also changes very little on heating the resin to 400°. This is because the rate of pyrolysis is very low in this range of temperatures, and the total number of PMC is small. The effect of oxygen becomes significant for HTT above 450°, and the maximum of the N_{vac}/N_{air} ratio coincides with the maximum PMC concentration in both cases. In both regions, the effect of oxygen is stronger when the sample is heat treated by the slower regime (Fig. 7). These experimental results justify the conclusion that the difference in sensitivity to atmospheric oxygen is associated with the extent of the structural changes in the resin, which are less extensive when fast heating rates are used. Hence, the PMC formed during fast heating of the resin are less sensitive to oxygen.

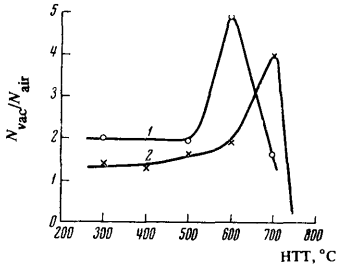

Figure 7. Relative sensitivity of the PMC to oxygen[47]: *1*) heating rate 5 deg h^{-1}; *2*) heating rate 20 deg h^{-1}.

The interaction of atmospheric oxygen with PMC is probably influenced by the oxygen chemically bound in the resin structure. For example, the fact that curve *2* in Fig. 7 has a lower maximum than curve *1* is probably explained by the presence of bound oxygen atoms in the pyrolysis products obtained at 600–700°. Even with the slower heat-treatment regime (5 deg h^{-1}), the products contain 7.86% of oxygen (Table 1). Oxygen atoms chemically combined in the carbonised samples can screen them from the effect of atmospheric oxygen.

Indirect confirmation of this hypothesis is provided by the measured spin–lattice relaxation times for pyrolysis at 600° (1.1×10^{-4} s for a heating rate of 5 deg h^{-1} and 0.12×10^{-4} s for a heating rate of 20 deg h^{-1}). It is well known that the presence of oxygen can lead to shorter relaxation times. The difference in the effect of oxygen on the PMC concentration for fast and for slow heating rates probably stems from differences in the degree of delocalisation of the unpaired electrons.

The presence of regions of different sensitivity may be partly due to the formation of different types of radical, with different reactivities towards oxygen, during the various stages of isothermal heating. This is confirmed by ESR measurements over a range of temperatures. For an HTT of 500°, corresponding to the onset of sensitivity to oxygen, the temperature dependence of the ESR absorption signal shows marked deviations from Curie's law.

III. PROPERTIES OF VITREOUS CARBON

1. Physical and Mechanical Characteristics

The properties of vitreous carbon of different origins (Japanese, French, and Soviet) are listed in Table 3[2–4,18,54]. The preparation of these materials is described in Ref. 55–59. The Table also lists, for comparison, the properties of a number of other materials: cellulose carbon, quartz, glass, high-density impregnated graphite, and ordinary graphite.

It is important to note that the properties of vitreous carbon can show wide variations, depending on the heat-treatment regime. Materials with different physical and mechanical characteristics can be prepared from a single carbonaceous starting material.

Vitreous carbon remains a solid up to 4000°K, and its properties are unchanged up to some temperature close to the sublimation point[60]. Its density is relatively low (up to 1.5 g cm^{-3}) in comparison with most refractory elements and compounds. Vitreous carbon is much harder than the common industrial grades of artificial graphite.

The elastic modulus of vitreous carbon is also higher than the modulus of the common graphitic materials (1500–3100 kg mm^{-2}, as compared with 300–800 kg mm^{-2} for industrial graphite).

The hardness of vitreous carbon is very sensitive to the maximum HTT of the material.

Kotlensky and Martens[61,62] showed, in their study of the mechanical properties of carbonaceous materials, that the strength of vitreous carbon (of any grade) is much higher than the strength of materials prepared from coke and pitch, but lower than the strength of pyrolytic graphite in a direction parallel to the deposition plane.

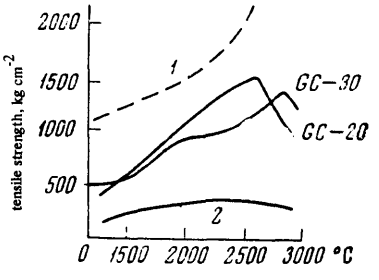

Figure 8. Tensile strength as a function of temperature[62]: *1*) pyrolytic graphite; *2*) graphitised material from pitch and coke. GC-20 and GC-30 are vitreous carbons heat treated at 2000 and 3000° respectively.

The strength of vitreous carbon is influenced by temperature (Fig. 8). The tensile strength of GC-20 vitreous carbon increases with temperature, reaching a maximum of 1400 kg cm^{-2} at 2500°.[62] At still higher temperatures

* The measurements for grades SU-12, SU-20, and SU-30 were made at 1200, 2000, and 3000°C respectively.

the tensile strength begins to fall off, as in the case of most graphitic carbons prepared by traditional methods. In GC-30 vitreous carbon the tensile strength also increases as the temperature is raised from 1900 to 2700°, but it is lower than the strength of GC-20 over most of the range of temperatures. It is not clear from the data whether the tensile strength of GC-30 reaches a maximum at 2700° or whether it continues to increase with temperature.

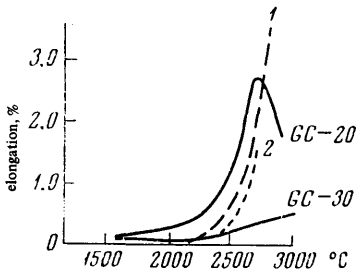

Figure 9. Elongation at break as a function of temperature[62]: *1*) pyrolytic graphite; *2*) graphitised material from pitch and coke. GC-20 and GC-30 are vitreous carbons heat treated at 2000 and 3000° respectively.

At temperatures of the order of 2200° and below the elongation at break of vitreous carbon (Fig. 9) is less than 3%, i.e. of the same order as for materials prepared from pitch and pyrolytic carbons. At 2500° the elongation of GC-20 increases much more drastically than that of the other materials. The increase continues as far as 2700°, and the elongation remains much greater than that of pitch-carbon materials and slightly higher than that of pyrolytic graphite. In GC-30 vitreous carbon the deformation at break is smaller than in GC-20 and other graphitic carbon materials.

Table 4. Properties of different grades of vitreous carbon before and after deformation.

Property	Grade GC-20		Grade GC-30	
	initial	deformed*	initial	deformed**
Density, g cm^{-3}				
In air	1.50	1.29	1.50	1.44
In light petroleum	1.68	1.82	1.68	1.66
Elementary cell parameters, A				
c	7.00	6.85	6.84	6.86
a	2.43	2.43	2.45	2.44

* Sample was deformed by 33% at 2700°.
** Sample was deformed by 65% at 2700°.

The properties of vitreous carbon before and after deformation are listed in Table 4. In contrast to the normal graphitic carbons, vitreous carbon has practically identical properties in different directions[15]. Nakamura and coworkers[63] conclude that vitreous carbon remains isotropic even when it contains small additions of natural or synthetic graphite.

Materials with graphite additives do not differ appreciably in density, hardness, and elastic modulus after heat treatment at 1300 and 2000°. Materials of the same grade, but heat treated at 3000°, have very different properties. A likely explanation is that the presence of graphite assists graphitisation at temperatures above 2000°.

Fischbach[64,65] studied the strength and elongation at break of vitreous carbon samples as a function of temperature, and found that an initially isotropic material becomes anisotropic after deformation. This suggests reorientation of the crystallites in a direction parallel to the strain axis.

Unlike silicate glasses, vitreous carbon has a very high thermal stability. No change could be detected after many fast heating and cooling cycles between 1700° and room temperature[22]. Similar results were obtained after ten cycles of instantaneous heating to 2000° in a stream of nitrogen and quenching to room temperature (after one minute) in carbon powder, and after five cycles of heating to 1000° and quenching in cold water[66]. In this respect, vitreous carbon is superior even to fused alumina.

2. Electrical and Semiconducting Properties

Vitreous carbon is an electrical conductor, but its resistivity is higher than that of the usual grades of graphite and of the same order as that of the carbon-black grades of artificial graphite.

Barykin and coworkers[27], and also a number of foreign workers[67,68], have studied electrical conduction in vitreous carbon and have observed semiconducting properties over a wide range of temperatures.

Yamaguchi[67] measured the Hall coefficient, magnetoresistance, and electrical conductivity of vitreous carbon as a function of heat-treatment temperature (from 1000 to 3200°) and at different temperatures (20, 77, and 330°K). Two types of sample were investigated: impervious (i.e. glassy) and porous (Fig. 10), both prepared from the same starting material. For low heat-treatment temperatures the Hall coefficient of both samples varied with HTT in the same way: it was positive for HTT around 1000°, it became negative (going through a minimum at ~ 1400°) on raising the HTT, and again changed sign becoming positive at ~ 1600° HTT.

In the region of high heat-treatment temperatures the two samples behaved differently: whereas the Hall coefficient of vitreous carbon increased with HTT up to 3200°, without going through a maximum, the Hall coefficient of the other type of sample went through a broad maximum at a heat-treatment temperature of ~ 3000°, and began to fall off beyond that temperature.

The Hall coefficient of both types of sample was much lower than typical values for graphitised materials over the whole range of HTT. At lower measurement temperatures the maximum in the Hall coefficient curve for the second type of sample was shifted towards higher HTT. The Hall coefficient of vitreous carbon was independent of measurement temperature over the whole range of HTT.

The variation of magnetoresistance with HTT was very different for the two types of sample. In vitreous carbon the magnetoresistance was negative, and decreased on raising the HTT. In the second type of sample the magnetoresistance became positive after going through a minimum, and continued to increase rapidly beyond that point.

From these results, the authors conclude[67] that the graphitisation tendency of the two types of sample is differ-

ent: whereas the second sample begins to graphitise at high HTT (~ 3000°), the vitreous sample shows no sign of graphitisation even at a HTT of 3200°.

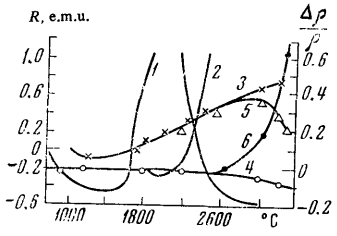

Figure 10. Hall coefficient (R) and magnetoresistance ($\Delta\rho/\rho$) as a function of HTT (measurements at 300°K)[68]. Samples of graphitising material: *1*) R, *2*) $\Delta\rho/\rho$; samples of the first type: *3*) R, *4*) $\Delta\rho/\rho$; samples of the second type: *5*) R, *6*) $\Delta\rho/\rho$.

Yamaguchi ascribes the inability of vitreous carbon to undergo graphitisation to specific structural features of this material. He believes that the second type of sample was structurally inhomogeneous, and that only some isolated regions of the material were able to undergo graphitisation.

Table 5. Pore size distribution in graphitic materials[16].

Material	Pore volume, Å	% or pores in range			Maximum pore size at pressure ≤ 1000 kg cm^{-2}, Å
		$7\cdot10^3$—$7\cdot10^4$, Å	$1\cdot10^3$—$7\cdot10^3$, Å	$1\cdot10^2$—$1\cdot10^3$, Å	
Ordinary graphite	32	27	4	3	$7\cdot10^4$
High-density graphite	11	3.5	1.5	6	$7\cdot10^4$
Impregnated graphite	5	—	2.5	2.5	$7\cdot10^3$
Vitreous carbon	0.35	—	—	0.35	$1\cdot10^3$

The thermoelectric power and Hall coefficient have been measured by Tsuzuku and Saito[69,70] as a function of measurement temperature and HTT. The observed change of the type of current carrier from holes (p-type) to electrons (n-type) and again to holes is interpreted in terms of Mrozovskii's σ-trap model of the electronic structure of the normal soft forms of carbon.

No definite theory of the electronic structure of vitreous carbon can be based on the above results.

3. Pore Structure

The microstructure of vitreous carbon differs drastically from that of graphite (both ordinary and impregnated[16]). The specific, granular pore structure of ordinary graphitised materials is not found in vitreous carbon.

The pore distribution in vitreous carbon, as measured with a mercury porosimeter, also differs from that of ordinary graphite (Table 5).

The most important characteristic of the new material is its low permeability to gases. Davidson[15] measured the permeability of cellulose carbon using tubular samples with 5.08 mm wall thickness. The samples were exposed externally to a helium atmosphere, the inner volume was carefully evacuated, and the tubes were connected to a diffusion pump and helium mass-spectrometer. The permeability of the material was well below 10^{-12} cm^2 s^{-1}. The permeability of vitreous carbon does not change with time: a diaphragm of this material mounted between a vacuum and helium at 1 atm pressure did not change significantly in the course of 700 hours. Other experiments showed that the material remains impervious at elevated temperatures (1000°).

The permeability of vitreous carbon can also be investigated by the density method. An impermeable material should have the same density in different media.

Table 6 lists the measured densities of vitreous carbon for different heat-treatment temperatures and in different media. Density was measured by the ordinary pyknometric method, and also in mercury and in helium[15].

Table 6. Density of vitreous carbons with different HTT in different media[20].

Heat-treatment temp., °C	Density, g cm^{-3}		
	pyknometric	in mercury	in helium
950	1.55	1.53	1.95
1200	1.61	1.59	1.66
1500	1.58	1.58	1.61
2000	1.55	1.56	1.58
2500	1.48	—	—

It is clear from the results of Table 6 that after heat treatment at 950° the pyknometric density of vitreous carbon (1.55 g cm^{-3}) is not the same as the density measured in a helium pyknometer (1.95 g cm^{-3}). The higher value of the density against helium suggests the presence of open pores.

Further heat treatment of the vitreous carbon causes the helium density to decrease to the level observed in the other media, i.e. it produces a closed pore structure. It is assumed that the formation of an isolated pore structure is due to the growth of separate crystallites during heat treatment (the pore diameter being small and comparable with the size of the crystallites). Diaphragms are formed within the pores, and the material becomes impervious to gases.

Intensive studies of helium density as a function of heat treatment temperature and X-ray studies by the low-angle scattering method have shown that the pores in vitreous carbon have extremely small dimensions. By comparing helium density data with low-angle scattering data Davidson concludes[15] that the average pore diameter is ~ 20 Å.

4. Crystal Structure

X-ray analysis has shown that vitreous carbon is a typical non-graphitising material[3].

The crystals in vitreous carbon, ~ 100 Å in diameter, do not have three-dimensional order. The crystallites are separated by voids and by chains of atoms without any particular orientation[5]. The degree of graphitisation of

GC-30 vitreous carbon is about the same as in petroleum carbon heated to 1900°.

Whereas in graphitised materials the interplanar spacing decreases gradually to 3.35 Å as a result of heat treatment, in vitreous carbon this value is constant (3.4 Å) even when the graphitisation temperature is raised above 3000°. Crystallographic studies of the new material have shown that the final product does not contain any large crystals. Well developed crystals are very seldom found, and their diameter is usually no more than a few hundred Ångstroms, whereas the average crystal size in natural graphites is at least 1000 Å.[42]

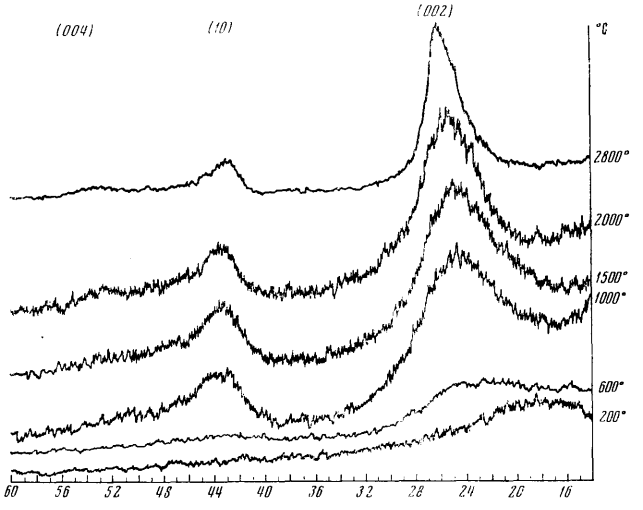

Figure 11. Diffractograms of carbonised FPFR products for different HTT[42].

X-ray diffraction patterns[42] for vitreous carbons heat treated at different temperatures are shown in Fig. 11. The diffraction patterns of the carbonisation products of the resin contain reflections of two types [(001) and (hk0)]. Diffuse (002), (004), (10), and (11) bands are observed in approximately the same angular position as the corresponding three-dimensional reflections from graphite. The (002) and (004) reflections arise from interference between groups of aromatic layers of condensed carbon atoms with sp^2 hybridisation of the valence electrons in the layer. The (10) and (11) bands are due to two-dimensional diffraction by flat layers[71].

A high background level is observed in the diffraction patterns of heat-treated samples. The large background arises from non-coherent scattering of the X-ray beams by carbon in non-aromatic configurations and by various radicals present as an amorphous phase.

On heating the starting material above 100°, complex structural changes take place. These consist mainly in breaking existing bonds and forming new ones, as shown by the diffraction patterns. At 200 and 600° the samples give an (002) diffraction line without a clearly defined maximum. The diffraction peaks from the (10) and (004) planes merge into a smooth curve, and cannot be resolved, suggesting lack of three-dimensional order. After heating at 1000° the (002) diffraction line is clearly visible, with a fairly sharp maximum. The asymmetric outline of the reflections indicates the presence of disordered networks in the heat-treated samples.

On raising the HTT, the following changes are observed: the layer spacing decreases, the layers of condensed aromatic carbon grow in size, the packets of flat hexagonal layers become thicker, and the proportion of amorphous phase decreases (Fig. 12).

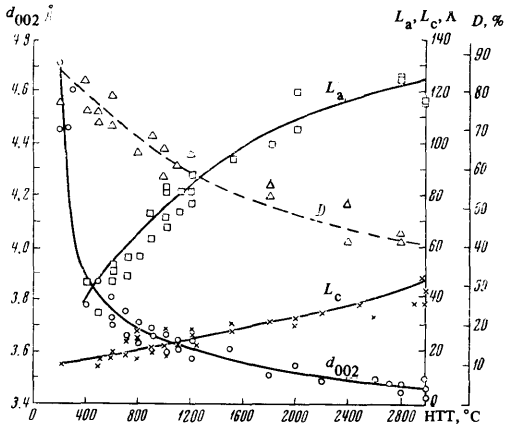

Figure 12. Interplanar spacing (d_{002}), crystallite size (L_a, L_c), and content of disordered phase (D) as a function of HTT in products obtained from FPFR[9].

The change of diamagnetic susceptibility of vitreous carbon with HTT also shows that this material is a typical non-graphitising carbonaceous material. Two regions can be distinguished in Fig. 13. For HTT between 200 and 1200° the diamagnetic susceptibility does not change very appreciably: it goes through an ill-defined minimum at 600–700°, and does not rise above the value -1.0×10^{-6} (CGSM units g^{-1}). At temperatures above 1300° the diamagnetic susceptibility begins to increase more rapidly, and the approximately linear increase continues up to 3000°.

The change in susceptibility with HTT in the low-temperature region is associated with changes in the molecular structure of the starting material, resulting from the polymer degradation processes. These processes involve the breaking of carbon–carbon bonds in macromolecules, and therefore give rise to a large number of unpaired, localised electrons. The appearance of unpaired electrons in a sample is detected as paramagnetism, due to the magnetic moments of these electrons, and this explains the decrease in the net diamagnetic susceptibility[72].

The fast growth of diamagnetic susceptibility at higher HTT is due to the increased size of the hexagonal carbon layers (not exceeding 150 Å, however). This is interpreted[73] as evidence of the end of the pre-crystallisation period. The diamagnetic susceptibility, unlike the susceptibility of well graphitised materials, does not saturate even at a HTT of 3000°. The susceptibility corresponding to this HTT is -5.1×10^{-6}, i.e. significantly different from the mean susceptibility of graphite (-7.2×10^{-6}).

The non-graphitising properties of vitreous carbon are probably due to the presence of a three-dimensional network of cross-linking bonds in the starting materials: this network hinders the rearrangement of structural elements which is the precursor of the formation of graphitic structures during heat treatment [74-77].

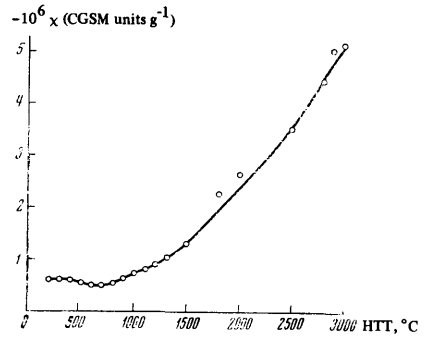

Figure 13. Magnetic susceptibility as a function of HTT [42].

As well as these purely structural effects, the presence of nitrogen atoms may affect graphitisation at temperatures above 1200°, because these atoms tend to hinder densification and the formation of ordered structures on heating.

Particles of different morphology have been detected in samples of SU-30 vitreous carbon by electron microscopy and selected-area electron diffraction [42]. Hence, graphitisation at high temperatures can take place heterogeneously, by evaporation and condensation of carbon atoms. The reason for the formation of morphologically different modifications in the products of high-temperature carbonisation is not clear.

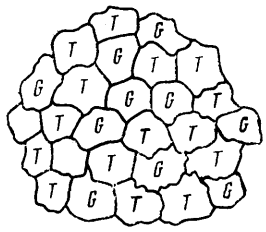

Figure 14. Structural model of vitreous carbon [77-79].

The regions of three-dimensional order, observed in microdiffraction experiments, must have a profound effect on the average structural parameters of the material.

Noda and Furukawa [78-80] studied the structure of vitreous carbon by measuring interplanar spacings, crystallite size, and the content of disordered regions, and also by radial distribution function analysis. Their results led them to a model of the structure of vitreous carbon involving two types of carbon: a tetrahedral modification, in which the arrangement of carbon atoms is similar to the diamond structure, and a trigonal modification, resembling graphite. The vitreous carbon may also contain carbon atoms with other types of bond.

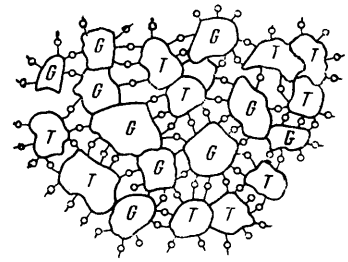

Figure 15. Structural model of vitreous carbon [77-79].

According to this structural model, the tetrahedral atoms (T) in vitreous carbon are responsible for most of the cross-linking bonds which hold together the graphitic layers (G) in a random arrangement (Fig. 14).

The model proposed for low-temperature grades of vitreous carbon, which are known to contain appreciable amounts of oxygen, involves oxygen bridges (Fig. 15) between T and T, T and G, and G and G regions.

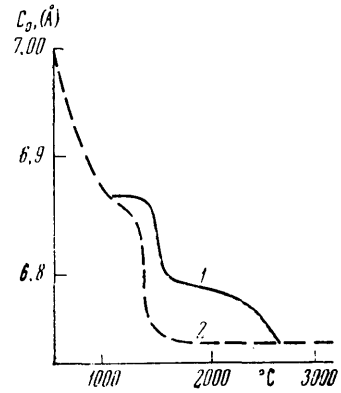

Figure 16. C_0 for GC-7 vitreous carbon (curve *1*) and for carbonised poly(vinyl chloride) (curve *2*) as a function of high-pressure HTT [81-83].

Kakinoki [81] suggests that the oxygen bridges can prevent the formation of ordered structures in vitreous carbon at temperatures up to 1200°, but they are broken down by heat treatment at 2500–3000°.

Noda and Cato [82,83] have shown that the dimensions of the crystal lattice in vitreous carbon can be modified by graphitisation under pressure. Fig. 16 shows the parameter C_0 of vitreous carbon (GC-7 grade) heat-treated under a pressure of 10 kbar and held at that pressure for 3 min.

For comparison, curve *2* gives the C_0 values for poly(vinyl chloride) carbon heat-treated under the same conditions.

The parameter C_0 falls to a very low value (6.72 Å) after heat treatment at 2600° under pressure. This low value of C_0 is not found in vitreous carbon prepared at ordinary pressure (C_0 for the GC-30 grade does not fall below 6.81 Å).

A possible explanation[84] is that the graphitic layers become mobile under pressure, and structural rearrangements towards more ordered structures become allowed.

In spite of the large number of published papers, our knowledge of the structure of vitreous carbon is still very inadequate.

5. Impurities in Vitreous Carbon

The specifications for construction materials used in many sectors of modern industry (nuclear energy, semiconductor technology, etc.) often include stringent purity requirements.

It is claimed[4] that the ash content of vitreous carbon does not exceed 0.02%. In the GC-30 grade, after additional purification, the ash content is decreased to ≤ 0.015%. Spectroscopic analysis results[2] for two grades of vitreous carbon (GC-20 and GC-30S) are summarised in Table 7. The following impurities are present: iron, aluminium, calcium, magnesium, silicon, vanadium, manganese, copper, and boron.

Table 7. Impurities in vitreous carbon[2].

Element	GC-20 before purification	$GC\text{-}30_S$	Element	GC-20 before purification	$GC\text{-}30_S$
Al	24.7	9.4	Mg	5.5	0.1
Ca	72.0	13.0	Mn	10.2	2.0
Co	none detected	none detected	Ni	none detected	2.6
Cr	none detected	none detected	Si	27.3	0.1
Cu	10	4.9	V	53.0	none detected
Fe	>100	>100	B	1	0.1

The impurity content of vitreous carbon is largely determined by the purity of the raw materials and by the temperature of heat treatment.

Lewis and coworkers[85] prepared semiconductor materials in containers made from vitreous carbon and from artificial graphite, and concluded that vitreous carbon is the better crucible material because it does not offer an open pore structure for the migration of impurities. Thus, the impurities present in vitreous carbon are less likely to contaminate the contents of the crucible than the impurities present in graphite.

6. Chemical Stability and Reactivity

Vitreous carbon is very stable towards many aggressive media. It is stable to fused alkalies and salts (sodium hydroxide, potassium bisulphite, calcium fluoride), acids (hydrochloric, hydrofluoric, nitric, sulphuric, chromic), and oxidising agents (bromine, chlorine, and mixtures of hydrogen peroxide and nitric acid and of nitric acid and potassium chlorate)[86,87]. Vitreous carbon is unaffected after two months in a mixture of concentrated HCl and HNO_3, which is known to disintegrate ordinary graphitic materials after 48 h at room temperature. The weight loss in mixed acids is acceptably low (see Table 8).

Outstandingly good anti-corrosion properties were reported also for vitreous carbon in contact with a mixture of nitric and hydrofluoric acid. However, vitreous carbon disintegrates in the presence of alkali metals. The behaviour of various grades of vitreous carbon in the presence of potassium vapour was studied by Halpin and Jenkins[88], who observed the formation of intercalation layers. Sodium vapour also caused disintegration of the vitreous carbon, but only at higher temperatures and with finely divided materials.

Table 8. Weight changes of vitreous carbon in oxidising media[66].

Oxidiser	Weight loss (%) after 50 days at 20 ± 5°		
	GC-10	GC-20	GC-30
98% H_2SO_4 + 60% HNO_3 (1:1 by vol.)	0.12—0.18	0.19—0.27	0.8—1.1
20% H_2SO_4 + 20% HNO_3 (1:1 by vol.)	0.03—0.06	0.19—0.20	0.5—1.2
60% HNO_3 + 35% HCl (1:1 by vol.)	0.04—0.05	0.12—0.15	0.01—0.02
20% HNH_3 + 20% HCl (1:1 by vol.)	0.03—0.10	0.12—0.14	0.05—0.06

Experiments on the interaction of vitreous carbon with fused alkali metal salts have shown that the extent of disintegration depends on the temperature and on the nature of the corrosive agent[89].

The oxidation of vitreous carbon by carbon dioxide has been studied in detail[7,90,91] because of its relevance to the use of vitreous carbon in CO_2-cooled atomic reactors. The conclusion was that vitreous carbon oxidises at about the same rate as reactor graphite if due allowance is made for the active surface areas of the two materials. This quantity depends on the parameters which determine the surface-to-volume ratio.

Table 9. Rate of oxidation of vitreous carbon in carbon dioxide[2].

HTT of vitreous carbon, °C	Experimental temp., °C	Gas pressure, atm	Rate of oxidation $\times 10^6$, $g\,g^{-1}\,h^{-1}$
2000	545±10	0.82	0.31
2300	545±10	0.94	0.27
1455	740±5	1.2	23.8
1620	740±5	1.12	6.6
1780	740±5	1.43	6.3
2000	740±5	1.05	3.0
2400	740±5	1.26	1.1
2010	785±10	0.49	1.79
2400	785±10	2.11	6.9

The rate of oxidation is affected by the gas pressure and by the temperature of heat treatment: it increases on raising the gas pressure and on lowering the HTT (Table 9). Addition of CO to the reaction medium lowers the rate of oxidation.

On raising the HTT from 1455 to 2400°, the reactivity of the vitreous carbon at 740° fell from 23.8×10^{-6} to 1.1×10^{-6} $g\,g^{-1}\,h^{-1}$. The reactivity decreases also at lower experimental temperatures.

Lewis [90] investigated the oxidation of vitreous carbon and pyrolytic graphite in different gases. The flow rate of the oxidising gas was 0.5 litre min^{-1} at temperatures below 800° and 1–1.5 litre min^{-1} above 800°. He concluded that vitreous carbon oxidises more slowly than various forms of pyrolytic graphite (Fig. 17).

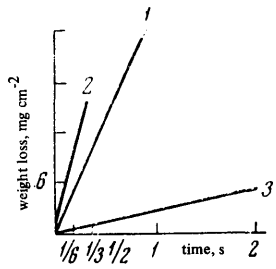

Figure 17. Weight loss of various graphitic materials as a function of time of oxidation in dry air at 750° [90]: *1*) purified graphite; *2*) not purified; *3*) vitreous carbon.

Yamada and Sato [16] studied the oxidation of vitreous carbon samples (15 × 15 × 1 mm) in a flowing mixture of nitrogen and oxygen in the ratio of 81 : 19 (by volume)at a temperature of 800 ± 5° and a flow rate of 0.5 litre min^{-1}. The results (Table 10) show that vitreous carbon is more stable towards oxidation than the other forms of graphitic material.

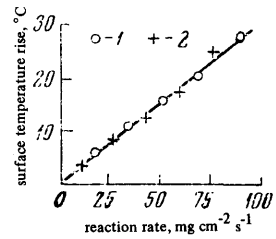

Figure 18. Rise in surface temperature as a function of rate of oxidation: *1*) vitreous carbon; *2*) graphite [90].

Blackman [91] observed the formation of isolated depressions on the surface of pyrographite and vitreous carbon during oxidation. He suggested that these craters are associated with the presence of metallic impurities, which act as oxidation catalysts, but this hypothesis is inconsistent with the finding of similar craters in vitreous carbon prepared from specially purified materials (ash content ~ 5×10^{-6}%). Heat treatment in a stream of pure argon at 800–900° was found to lower the reactivity of the vitreous carbon samples. High-temperature treatment in argon is known [90] to lower the concentration of active centres, possibly by the removal of surface contaminants.

Lewis measured the activation energy for the oxidation of vitreous carbon and other graphitic materials at various temperatures by plotting the logarithm of the reaction rate against reciprocal absolute temperature (Arrhenius curves). The activation energy for the oxidation of vitreous carbon by dry air in the temperature range 600–800° was found to be approximately 43 kcal $mole^{-1}$. On adding 26 vol.% of water vapour to the air the activation energy fell to 31 kcal $mole^{-1}$, and the oxidation rate could either increase or decrease. The activation energy for the oxidation of graphite in moist air fell from 43 to 38 kcal $mole^{-1}$ in the same temperature range. On raising the temperature, the activation energy was found to increase. Among the explanations [90] which have been proposed are the influence of open pores, the accumulation of catalytically active contaminants at the surface of the vitreous carbon, and diffusion in the gas phase.

The oxidation of carbonaceous materials is accompanied by evolution of heat, which may result in an increase in the true reaction temperature. The magnitude of this effect increases with reaction rate. The variation of the rise in surface temperature of vitreous carbon and graphite samples with rate of oxidation [90] is illustrated in Fig. 18.

The rate of oxidation of vitreous carbon in argon containing carbon dioxide and water vapour varies linearly with temperature (900–1400°) and with the concentration of active impurities in the sample.

The mechanism of the oxidation of vitreous carbon has not been fully elucidated.

Grades of vitreous carbon prepared in the Soviet Union (by the present writers) have been found to be stable towards acids (HCl, HF, H_2SO_4), concentrated solutions of alkali (KOH), and bromine. However, our vitreous carbon, like other graphitic materials, is disintegrated (though to a lesser extent) by a mixture of concentrated H_2SO_4 + HNO_3 (1 : 1 by volume) and by chromic acid mixture (a 3% solution of $K_2Cr_2O_7$ in concentrated H_2SO_4).

Table 10. Oxidation resistance of graphitic materials.

Material	Time for specified weight loss (%), in min			
	70	80	90	100
Artificial graphite	68	95	110	140
Thermal graphite	120	138	175	230
High-density graphite	160	185	225	275
Vitreous carbon	205	225	270	365

The vitreous carbon prepared in the Soviet Union is also stable towards the following media: a) fused alkali metal chlorides (NaCl, KCl, etc.) saturated with hydrogen chloride, with pure hydrogen, and also at the interface between the melt and the gas phase at 800–1000°; b) a fused mixture of chlorides and fluorides of the alkali metals (NaCl, HCl, NaF) in the presence of argon and at temperatures in the range 800–1000°; c) a fused mixture of lithium and potassium chlorides in the presence of chlorine at 700°; d) a fused mixture of lithium and potassium chlorides containing uranium oxide chlorides; e) cryolite–alumina melts in an inert atmosphere at 960–1060°.

IV. APPLICATIONS OF VITREOUS CARBON

Vitreous carbon has an important future because of its unique properties (low permeability to liquids and gases, chemical inertness, high stability) and of its low electrical resistivity and high thermal stability in inert media.

Impervious carbon is an important material for the fabrication of cans for fuel elements in nuclear reactors[4,6,92].

The high chemical stability and low electrical resistance of vitreous carbon offer unique advantages in the preparation of electrodes for a variety of electrochemical purposes[93,94].

There are interesting prospects of applying vitreous carbon as a construction material for chemical plant designed to operate in aggressive media: reactive gases and liquids, fused metals and electrolytes, radioactive products[86].

The new material can be used to fabricate laboratory ware for the vacuum evaporation of metals (e.g. aluminium, gold), and for reactions in fused alkalies, in strong acids, or in fused metals (e.g. liquid bismuth)[5].

Apparatus made of vitreous carbon has many definite advantages over alternative materials (nickel, platinum, tantalum, glass, and silicon) for the zone refining of metals and for the preparation of specially pure compounds[76].

Corrosion-resistant coatings for a variety of articles can be made of vitreous carbon.

Because of its high purity, imperviousness to gases, non-wetting properties, and chemical inertness, vitreous carbon is ideally suitable for use as a "crucible" in semiconductor technology and in the optical industry (e.g. for the preparation of large single crystals of CaF_2 and MgF_2).[5]

The electrical resistivity of vitreous carbon is adequate for the fabrication of resistance heaters. Small-scale heater elements made of GC-30 vitreous carbon are becoming commercially available[25].

Vitreous carbon can withstand very high temperatures and is therefore used as a construction material for the production of silicon carbide and to handle liquid bismuth[2,5]. We may expect items currently made of high-purity molybdenum, quartz, pyrolytic graphite, fused alumina, etc. to be gradually replaced by vitreous carbon items[3].

Because of its high resistance to thermal shock, vitreous carbon can be used in high-temperature technology to fabricate sheaths for temperature measuring apparatus operating in aggressive media[2,5], and because of its high mechanical strength it can be used in abrasion-resistant articles such as dies[96] and components for handling piece-parts[3,5].

Addition of 0.5–1.0% of vitreous carbon to carbon powders for the production of electric carbon brushes has been found[97] to increase the service life of the product from 7300 to 11 500 h.

In addition to the above applications, vitreous carbon is beginning to find outlets in a great variety of industrial operations[25,54,76]. Surge arresters for the telephone network were tested under severe conditions and found to be very reliable. Vitreous carbon welding rods for spot-welding aluminium last longer than ordinary graphite rods. The material can be used for casting metallic articles in precision moulds, in the preparation of microphonic powders, and as a heat shield[76].

Thread guides of vitreous carbon, used in the yarn industry, overcome the problem of static electrification which arises when electrical insulators are used for the guides[76].

Vitreous carbon filaments may find applications in space exploration, in aviation, and in other fields of activity by virtue of their low specific gravity, high tensile strength, and high thermal stability.

Vitreous carbon made in the Soviet Union[18] have been very highly rated for use as electrodes in chloride and cryolite–alumina melts, and in mixtures of alkali metal chlorides and fluorides in an atmosphere of argon, hydrogen, chlorine, hydrogen chloride, and H_2 + HCl mixtures at temperatures up to 1000°. Vitreous carbon electrodes are indifferent to melts of lithium and potassium chlorides containing uranium oxide chlorides. Vitreous carbon electrodes are beginning to replace platinum electrodes.

The superiority of vitreous carbon over other graphitic materials is very evident even in containers for molten indium, which overcome the problem of metal "seepage" and give a purer product because they are free from open pores.

Vitreous carbon has been used in research on crystal growth by the electrolysis of molten salts.

Thermocouple pockets made of vitreous carbon have been thoroughly tested, with favourable results.

Because of the unique properties of vitreous carbon, a much longer service life can be confidently expected from articles and fixtures made of this material instead of ordinary graphite. The range of vitreous carbon articles which are becoming available, and the number of applications of the material, are continuously increasing.

I. INTRODUCTION

Reactions involving the carbonylation of unsaturated compounds by carbon monoxide under conditions of homogeneous catalysis in the presence of Group VIII metals and their compounds or acid catalysts are of considerable theoretical and practical interest. They permit the synthesis of valuable products: alcohols, aldehydes, ketones, saturated and unsaturated mono-, di-, and poly-carboxylic acids, their esters, chlorides, amides and lactones, and quinones, [1-9]. Some of these reactions have been achieved industrially[10]. As a result of numerous studies, the optimum reaction conditions have been investigated in detail, active catalysts have been selected, and the compositions of the reaction products have been determined.

New catalysts based on Group VIII noble metals have been found in recent years and certain features of the carbonylation mechanism have been elucidated.

The review deals with the reactions of mono-olefinic and monoacetylenic hydrocarbons with carbon monoxide, with the exception of hydroformylation reactions, which were described previously[11].

II. CARBONYLATION OF MONOACETYLENIC HYDROCARBONS

Acetylenic hydrocarbons are carbonylated in the presence of Group VIII metal carbonyls and hydrocarbonyls according to the overall equation

$$RC{\equiv}CH + CO + HX \rightarrow CH_2{=}CH(R)C\langle^{O}_{X},$$

where HX is a compound with mobile hydrogen.

Acrylic acid was obtained from acetylene, carbon monoxide, and water; acetylenealdehyde and acetylenedialdehyde were not formed. When water is replaced by other compounds with mobile hydrogen (alcohol, mercaptans, ammonia, amines, or carboxylic acids), derivatives of acrylic acid (esters, thioesters, amides, and anhydrides) are obtained[7,12,13]. These reactions are used at present for the industrial manufacture of acrylic acid and its derivatives. $\alpha\beta$-Unsaturated carboxylic acids (the hydrocarboxylation reaction), their esters (hydroalkoxycarbonylation), and other acid derivatives were obtained in the carbonylation of acetylene homologues. The addition of elements of formic acid (H−COOH) to the triple bond took place in accordance with the Markovnikov rule[14]. α-Phenylacrylic acid and not cinnamic acid was obtained from phenylacetylene[12]. The reactions were carried out by stoichiometric or catalytic methods.

The stoichiometric method consists in the reaction of acetylene with nickel, cobalt, or iron carbonyls at a pressure of 1−10 atm and 30−85°C in organic solvents: alcohols, acetone, ethyl methyl ketone, dioxan, tetrahydrofuran (THF), ethyl acetate, pyridine, and anisole, containing an inorganic (HCl, H_3PO_4) or organic (acetic) acid[15-24]. The reactions can be represented by the equation

$$4C_2H_2 + 4C_2H_5OH + Ni(CO)_4 + 2HCl \rightarrow 4CH_2{=}CH{-}COOC_2H_5 + NiCl_2 + H_2.$$

The nickel salt formed is then converted into a hexamine salt, which is treated in dilute aqueous solution with carbon monoxide at 100°C and 100 atm with formation of nickel carbonyl.

Methyl, ethyl, butyl, phenyl, tetrahydrofuryl, α-decalyl and other esters of acrylic acid were synthesised in high yields by this method. The reaction is autocatalytic, the duration of the induction period depending on the structure of the initial acetylenic hydrocarbons, the solvent, the acid, and the reaction temperature[25]. If an additional amount of the reactant is added after the induction period, the nickel complex formed as an intermediate acts as a catalyst. The rate and mode of reaction are influenced by the addition of water, acid, or base, for example pyridine, and also by the solvent. In anhydrous solvents, vigorous hydrogenation takes place: NiCl is formed as an intermediate from $Ni(CO)_4$ and then reacts with HCl to give $NiCl_2$ and H_2. This results in a decrease of the amount of final product. In the absence of acid the reaction does not occur. The acid strength does not influence the yield of acrylic acid, but does affect the yield of its esters[2]. The presence of oxidants in the reaction mixture inhibits the reaction, while reductants do not affect it[25].

The carbonylation of phenylacetylene, hex-1-yne, and methylacetylene by stoichiometric amounts of $Ni(CO)_4$ has been investigated in detail[26-30]. The reactivity of acetylenic hydrocarbons decreases with molecular weight. The addition of acetylene itself sharply increases the rate of reaction of homologues and increases the yield of the final products. Disubstituted acetylenes formed substituted acrylic acids[26,31,32]. Ethyl α-phenylcinnamate was obtained from diphenylacetylene and ethanol in benzene,

while in dioxan the main product was 2,3,4,5-tetraphenylcyclopent-2-en-1-one together with the above ester[32]. In the latter case the reaction probably proceeds via bis-(diphenylvinyl) ketone with its subsequent Nazarov cyclisation[2]. The carbonylation of diphenylacetylene in saturated sodium hydroxide in methanol in the presence of an excess of $Ni(CO)_4$ takes place with formation of *trans*-α-phenylcinnamic acid and 1,2,3,4-tetraphenylbutadiene in 25 and 67% yields respectively. The source of carbon monoxide is the intermediate dark-red $[Ni_3(CO)_8]^{2-}$ anion[33]. When diphenyl- and dimethyl-acetylenes react with $Fe(CO)_5$ under ultraviolet irradiation, tetraphenylcyclopentadienone and tetramethylcyclohexadienone are formed respectively and are isolated as complexes with iron tricarbonyl[34-37].

It is suggested that in the stoichiometric method a carbonium ion, which is formed initially during the acid catalytic process, reacts with $Ni(CO)_4$. In this stage four CO groups are transferred by a series of $Ni(CO)_X-C_2H_2$ complexes[38]. When the reactant ratios are accurately regulated, only "catalytic" amounts of $Ni(CO)_4$ and HCl are required for the carbonylation reaction.

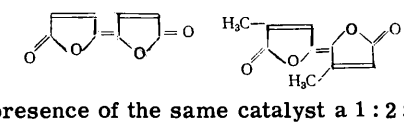
The carbonylation of acetylenic hydrocarbons by the catalytic method takes place at 150–200°C and about 30 atm in a homogeneous system containing 0.5–5% (relative to the solvent) of the catalyst, for which mainly complexes of Group VIII metals, and their halides, sulphides, carbonyls, etc. were employed[7,8,17,20,21,39-43]. Gaseous carbon monoxide is usually taken in an equimolar amount in relation to acetylene. Water, alcohols, tetrahydrofuran, pyran, dioxan, ketones, glycol monoethers, lactones, and *N*-alkyl-lactams are used as solvents[18,20,21,42,44]. Catalysts based on nickel have been investigated in greatest detail. The catalytic activity increases from the chloride via the bromide to the iodide, which, however, promotes also the acrylate polymerisation processes. The best catalyst proved to be $NiBr_2$, since it forms with carbon monoxide an unstable reactive complex NiCOBr, which readily gives up active carbon monoxide on regeneration of $NiBr_2$.[39,45] The active complexes are those of nickel, containing triaryl- or trialkylphosphines, trialkylstibines, and trialkylarsines, for example: $[(C_6H_5)_3P]_2.NiX_2.RX$, $[(C_6H_5)_3P]NiBr_2$, $[(C_6H_5)_3P]_2NiBr_2(C_6H_5Br)$, $[(C_6H_5)_3P]NiI_2C_6H_5Br$,[7,17,46-49] $(R_3P)_XNi(CO)_{4-X}$,[50] $NiBr_2[(C_6H_5)_3N(C_4H_9Br)]_2$, $NiCl_2[(CH_3)(C_2H_5)C_6H_5N]_2$, $[(C_6H_5)_3P.C_4H_9Br]_2C_5H_5N.NiBr_2$, $(C_6H_5)_3P(C_5H_5N.C_4H_9Br).NiBr_2$, $(C_5H_5N.C_4H_9Br).C_6H_5N.NiBr_2$,[51,52] $[(C_6H_5)_3P].[Ni(CN)_2]_3$,[53] $(R_3Sb)_XNi(CO)_{4-X}$,[54] $(R_3Sb)_2NiX_2$,[53,55-58] complexes of NiI_2 or $Ni(CN)_2$ and an alkali metal[59-61], complexes of $NiCl_2$ and acyclic and cyclic acid amides[62], halogen-containing organic complexes of phosphorus, arsenic, and antimony with carbonyl-forming substances[63,64], complexes of NiX_2 with oxygen-containing saturated heterocyclic compounds[64,65], a mixture of metallic nickel and nickel thiocyanate[58], metallic nickel on a carrier containing iodine[66], nickel halides on silica gel[67-75], nickel salts of naphthenic acids, nickel-dimethylglyoxime or a complex of $NiCl_2$ with 1-nitro-2-naphthol, and $NiBr_2$ complexes with ethanolamine, benzoxazole, and 1,3,4-thiadiazole-2,5-dithiol[76,77]. Metallic copper and mercury or their salts and also metallic nickel in an amount of 3–20% of the weight of the catalyst[76,78-81] and $HgCl_2$ (in the stoichiometric process) in an amount of 5–10% of the solvent[82] have been employed as activators of the carbonylation catalysts. The stability of the catalyst was increased by $CuSO_4$, antimony and arsenic chlorides, and hydroquinone[52].

The carbonylation of methylacetylene in the presence of $Ni(CO)_4$ yielded methyl methacrylate[83-85]. In the presence of methacrylic acid at 130°C and 13 atm the overall yield of methacrylic acid and its ester reached 85%. Methyl methacrylate was also obtained at 170–180°C and 10 atm when nickel halides, nickel complexes with $(C_6H_5)_3P$, and cobalt and chromium carbonyls were employed[85]. The side products of the reaction were methyl *trans*-crotonate, methyl isobutyrate, and acetone. Nickel and cobalt carbonyls showed the highest activity. In the carbonylation of butylacetylene in the presence of $[(XC_6H_4)_3P]_2NiBr_2$, where X = H, CH_3, or OCH_3, the activity of the catalyst increased when electron-donating substituents were introduced into the benzene ring of the ligand. The rate of reaction increased in the series X = H, CH_3, and OCH_3 and was proportional to the concentration of butylacetylene and the catalyst. The overall yield of esters was about 80%, the main product being butyl α-butylacrylate together with small amounts of butyl β-butylacrylate[86].

The rate of carbonylation of acetylene in a butanol–methyl acrylate solution at 30–75°C in the presence of $Ni(CO)_4$ depends on the partial pressure of carbon monoxide, being determined by the rate of diffusion of carbon monoxide, and decreases in the presence of an excess of acetylene greater than 40%. Above 75°C the rate of reaction falls by a factor greater than 2. An increase in the amount of the catalyst leads to the acceleration not only of the main reaction but also of the side processes, in particular the polymerisation of acetylene. Dilution of the initial acetylene–carbon monoxide mixture with nitrogen shortens the induction period, and, when the supply of hydrogen chloride is stopped, the reaction ceases rapidly. Cobalt and iron carbonyls are inactive under these conditions[25]. The solvent and the overall pressure have little effect on the rate, but affect significantly the mode of reaction in the range 4–150 atm. In the presence of water the main acetylene carbonylation products were acrylic acid and in *N*-vinylpyrrolidinone the products were saturated dicarboxylic acids[24].

In the presence of cobalt carbonyls and water in a neutral solvent, succinic acid and its homologues are the main products from acetylenes, together with cyclopentanone and monocarboxylic acids[87-89]. Bifurandione is formed in acetone solution[90-93] and in methanol and water solution or in methyl ether the product is dimethyl succinate together with small amounts of methyl acrylate[94-96]. In the presence of cobalt catalysts a mixture of methyl esters of acrylic, succinic, and γ-hydroxypimelic acids and the trimethyl ester of ethanetricarboxylic acid were obtained from acetylene, carbon monoxide and methanol[95-97].

In contrast to the analogous reaction of olefins (see below), the carbonylation of acetylene takes place at a high rate also in the absence of halides and halogens[98]. In the presence of $Co_2(CO)_8$ at 120°C and 250 atm, *cis*- and *trans*-octa-2,4,6-triene-1,4,5,8-diolides were obtained from acetylene, carbon monoxide, and acetic anhydride and, when acetylene was replaced by $CH_3C{\equiv}CH$, the products were *cis*- and *trans*-2,6-dimethylocta-2,4,6-triene-1,4,5,8-diolides[93], which were oxidised to 2,6-dimethylsuberic acid[99]:



In the presence of the same catalyst a 1 : 2 : 1 acetylene–carbon monoxide–hydrogen mixture in an excess of ethanol under a pressure of 50–80 atm and at a temperature of 100–120°C, gives rise to a mixture of products

containing ethyl propionate, propionaldehyde, its acetal, and diethyl succinate and $\gamma\gamma$-diethoxybutyrate. When ethyl alcohol was replaced by isopropyl alcohol, a mixture of isopropyl $\gamma\gamma$-di-isopropoxybutyrate, succinate, and β-formylpropionate was obtained[98,100]. Acetylene, carbon monoxide, and water in the presence of cobalt hydrocarbonyl yielded hydroquinone[101]. The carbonylation of acetylene derivatives in non-aqueous media catalysed by iron carbonyls leads to the formation of cyclic compounds[102].

In the synthesis of acrylate esters from acetylene, carbon monoxide, and alcohols, nickel, cobalt, and iron halides deposited on silica gel are employed as catalysts. The activity decreases in the series Ni > Co > Fe and I > Br > Cl. The reaction conditions were milder and the yield of the ester higher the higher was the molecular weight of the initial alcohol. Nickel naphthenate on silica gel proved to be the best catalyst for the synthesis of acrylic acid itself[97-75].

The carbonylation of acetylene in the presence of ruthenium compounds {the carbonyls $Ru_2(CO)_9$ and $[Ru(CO)_4]_3$, the salt $RuCl_3$, chelate complexes of ruthenium with acetyl acetonate} takes place at 160°C in water, methanol, acetone, or dioxan with formation of hydroquinone and quinhydrone. The amount of catalyst is 1% of the weight of the solvent. The yield of hydroquinone, which reaches 65%, depends on the reaction temperature and the H_2O/C_2H_2 ratio, but is little affected by the partial pressure of carbon monoxide in the range 53–160 atm.[103-105] Hydroquinone and quinhydrone were obtained similarly using rhodium compounds: $RhCl_3$, $Rh(CO)_2Cl$, rhodium carbonyl, and chelate complexes with acetylacetonate[103-106]. However, in a silver-lined autoclave acetylene was converted in the presence of hydrogen chloride and small amounts of $RhCl_3.3H_2O$ into a mixture of acrylic and 3-chloropropionic acid chlorides[107].

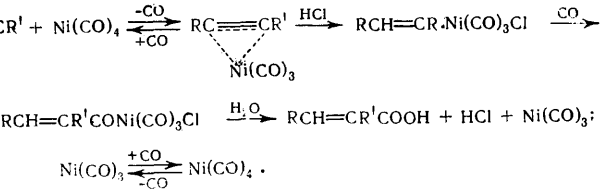
By reaction with $Rh(CO)_2Cl$ in benzene, diethylacetylene was converted into tetraethylcyclopentanephenol [tetraethylcyclopentanophenol ?], isolated as a complex with $RhCl_3$, and partly into 2,3,5,6-tetraethyl-1,4-benzoquinone, and diphenylacetylene was converted into 2,3,4,5-tetraphenylcyclopentadienylrhodium chloride and partly into hexaphenylbenzene[108] [wrong reference (Ed. of Translation)].

In the presence of palladium salts, the carbonylation of acetylene occurred under milder conditions: 60–125°C and 1–45 atm of carbon monoxide with formation of a mixture of saturated and unsaturated mono- and di-carboxylic acids. The butyl esters of acrylic, propionic, maleic, and fumaric acids were obtained in proportions of 24:9:38:10 from a 1:1 acetylene–carbon monoxide mixture in butanol containing 0.1% $CdCl_2$, 1.1% I_2, and 1.8% H_2O. An increase of the concentration of carbon monoxide in the mixture promoted an increase in the yield of the dicarboxylic acid esters. The replacement of I_2 by HI and of $PdCl_2$ by $PdSO_4$ did not influence the reaction. The addition of $SnCl_2.2H_2O$ inhibited the reaction[109].

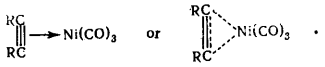
The carbonylation of acetylene in benzene solution in the presence of a $PdCl_2$ complex with dibenzonitrile proceeds with preferential formation of muconic acid chloride containing an admixture of fumaric and maleic acid chlorides[97,110,111].

In the presence of phosphine complexes of palladium, a specific role of the solvent was observed. In a 5:1 chloroform–alcohol mixture at 40°C and 1 atm, acrylate esters were formed. When chloroform was replaced by benzene, toluene, or xylene, catalytic activity was not shown below 80°C, which can be accounted for by the formation in the first case of the complex $Pd[(C_6H_5)_3P]_2.CHCl_3$ which is probably converted during the reaction into the hydride complex $Pd(H)Cl[(C_6H_5)_3P]_2$. A similar complex, obtained by the reaction of chloroform with $Pd[(C_6H_5)_3P]_4$, also catalysed the carbonylation of acetylene under analogous conditions[112].

The carbonylation of acetylenic compounds by the stoichiometric method may be represented by the following scheme[113]:

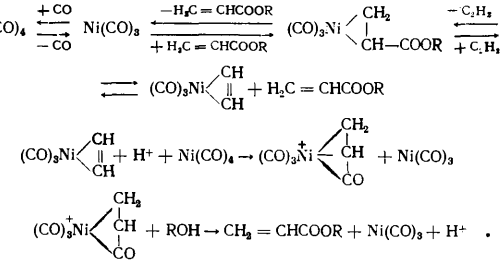


The acetylenic compound reacts with $Ni(CO)_4$ forming a π complex, which is converted under the influence of a proton into a σ-alkenyl and then alkenoyl organometallic compound:



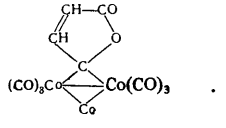
The complexes of nickel, cobalt, and iron carbonyls with acetylenic compounds are widely known. For example, $Co_2(CO)_9.C(C_3H_7)\equiv CH$, $Co_2(CO)_9C(CH_3)\equiv CH$, and $Co_2(CO)_9.CH\equiv CH$ were obtained from $Co_2(CO)_8$, CO, and acetylenic hydrocarbons at 70°C and 190 atm.[114-115]

The carbonylation by the catalytic method has been represented by the following scheme[25,108]:



Thus $Ni(CO)_3$ is regenerated on formation of the reaction products. The dissociation of the metal carbonyl with simultaneous formation of coordination-unsaturated intermediates may proceed with the immediate evolution of two CO molecules, as was observed in the carbonylation of propargyl alcohol[108]:

Analogous intermediate complexes, which are of the type of π complexes of the catalyst and the substrate, were also formed in the case of cobalt, iron and other Group VIII metal carbonyls[115]. Cobalt carbonyl complexes with acetylene are known to be capable of reacting with several CO molecules under the conditions of the carbonylation reaction, forming complexes of the type



Such complexes may be converted further into dicarboxylic acids or into cyclic compounds[114,116].

Recently a major role in the carbonylation reaction has been attributed to hydrocarbonyls. It is assumed that nickel catalysts form in the first stage nickel hydrocarbonyl, which is in fact the true reaction catalyst[85]:

$$Ni(CO)_4 \underset{-nCO}{\overset{+HX}{\rightleftharpoons}} HNi(CO)_{4-n}X \xrightarrow{CH\equiv CR} CH_2=C(R)Ni(CO)_{4-n}X + RCH=CHNi(CO)_{4-n}X \xrightarrow{CO}$$
$$\xrightarrow{CO} CH_2=C(R)CONi(CO)_{4-n}X + RCH=CHCONi(CO)_{4-n}X \xrightarrow{R'OH} CH_2=C(R)COOR' +$$
$$RCH=CHCOOR' + HNi(CO)_{4-n}X,$$

where HX = H_2O, an organic acid, or an inorganic acid and R′ = H or alkyls.

The data presented in this section show that the carbonylation of monoacetylenic hydrocarbons leads to the formation mainly of $\alpha\beta$-unsaturated carboxylic acids, their esters, and other derivatives. The reaction proceeds in the presence of catalysts based on Group VIII metal carbonyls of hydrocarbonyls.

III. CARBONYLATION OF MONO-OLEFINIC HYDROCARBONS.

1. Reactions in the Presence of Catalysts Based on Group VIII Metals

The carbonylation of olefinic hydrocarbons[7,117] takes place under more severe conditions than that of acetylenic hydrocarbons: at 120–280°C and 100–300 atm of carbon monoxide in the presence of cobalt or nickel halides or carbonyls, sometimes activated by magnesium, aluminium, manganese, Cr_2O_3, tin, CuI, and RbI. Complex salts of the type $K_2[Ni(CN)_4]$, nickel and cobalt complexes of amines, and aqueous solutions of iron and cobalt salts of organic acids have also been used as catalysts. The results of earlier studies in this field are compiled in a previous review[1]. The carbonylation of olefins takes place on heating to 160–170°C in a mixture with a stoichiometric amount of nickel or cobalt carbonyl in the presence of water and acetic acid according to the mechanism

$$4RCH=CH_2 + 4H_2O + Ni(CO)_4 + 2CH_3COOH \rightarrow 4[RCH(CH_3)COOH + RCH_2CH_2COOH] + (CH_3COO)_2Ni + H_2 .$$

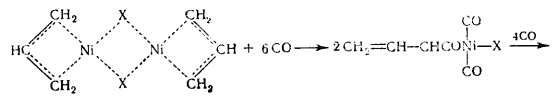
The principal characteristics of the carbonylation reaction are the same for both olefins and acetylenic hydrocarbons[7,98,117–120], certain reactive olefins, such as for example, bicyclo-[2,2,1]heptene, react under the same conditions as acetylenic hydrocarbons[121]. Straight-chain α-olefins enter into the reaction most readily with formation of a mixture of straight-chain and α-methyl-substituted carboxylic acids in proportions of 1 : (1.5–2.5) in the presence of nickel catalysts and 3 : 1 in the presence of cobalt catalysts[120–122]. Activators of nickel catalysts (I_2, HI, CH_3I, KI) accelerate the reaction and increase the yield of the straight-chain acids. In the presence of the $Ni(CO)_4 + NiI_2$ catalyst, C_2–C_4 olefins are converted into acids in yields up to 90%, which increase when solvents such as methanol, acetone, and dioxan, which readily dissolve both the olefin and water, are employed[119].

In the presence of $Ni(CO)_4 + NiI_2$, mainly propionic acid (85%) is obtained from ethylene, a mixture of butyric and isobutyric acids (48 : 52) from propene, a mixture of trimethylacetic and α-methylbutyric acids (60 : 40) from isobutene, and a mixture of caproic and α-methylvaleric acids from pent-1-ene. Qualitatively, the same acids are formed from β-olefins as from α-olefins. In the carbonylation of olefins, higher carboxylic acids, aldehydes, and polymers are formed as side products[120]. In the synthesis of butyric acids (yield 96%) from propene, carbon monoxide, and water, in the presence of $Co_2(CO)_8$, the reaction is of first order with respect to water, of zero order with respect to propene, and of a fractional order (0.6–0.8) with respect to the catalyst[122]. When water is replaced by methanol, butyric acid esters are obtained, whose yield increases with increase of carbon monoxide pressure from 25 to 208 atm, with increase of the catalyst concentration, and with decrease of reaction temperatures from 250° to 145°C.[123] The relative amounts of the isomers in the reaction products are influenced by carbon monoxide pressure, reaction temperature, and the nature of the catalyst metal: $Co_2(CO)_8$, $Ni(CO)_4$, or $Ru_3(CO)_{12}$.[124] In order to increase the catalytic activity, tributylphosphine[125] or small amounts of pyridine are added to $Co_2(CO)_8$. Pyridine accelerates the reaction and increases the yield of unbranched products[126–128]. The presence in the reaction zone of small amounts of H_2 does not prevent the formation of acids and their esters, but the hydroformylation of the olefins with formation of an aldehyde or an acetal takes place at the same time[129,130].

For the synthesis of propionic acid and its methyl and ethyl esters, nickel, cobalt, and iron halides deposited on silica gel (1 : 1), which proved more effective as a carrier than kieselguhr, pumice, and kaolin, are employed as catalysts. The catalysts can be arranged in the following sequences in terms of their activity[69–72,131]: Ni > Co > Fe and I > Br > Cl. It is suggested that the complexes $M(CO)I_2$, where M = Co, Ni, and Fe, are formed initially. They react further with carbon monoxide or methanol:

$$NiI_2 + CO \rightarrow Ni(CO)I_2 \xrightarrow[CH_3OH]{3CO} \begin{matrix} Ni(CO)_4 + I_2 \\ CH_3COOH + NiI_2 \end{matrix} \text{ etc.}$$

The iodides form complexes more readily than the bromides and chlorides. The stability of the complexes $M(CO)I_2$ obtained from the halides and carbon monoxide under pressure[39] decreases in the series Fe > Co > Ni, in opposition to the catalytic activity series[132]. When carbon monoxide was passed through solutions of π-allylnickel halides at 0°C, about ten moles per mole of the dimer were absorbed. The formation of a coordination bond corresponding to butenoylnickel dicarbonyl halides was observed by infrared spectroscopy:



$$\rightarrow 2CH_2=CHCH_2COX + 2Ni(CO)_4 .$$

In the presence of $Ni(CO)_4$, the carbonylation reaction is promoted by traces of acid (HCl), necessary for the formation of halogenonickel dicarbonyl hydride, which is apparently the actual reaction catalyst[133]:

$$HX + Ni(CO)_4 \underset{+2CO}{\overset{-2CO}{\rightleftharpoons}} HNi(CO)_2X \xrightarrow{RCH=CH_2} [RCH_2CH_2Ni(CO)_2X +$$
$$CH_3CH(R)Ni(CO)_2X] \xrightarrow{CO} [RCH_2CH_2CONi(CO)_2X + CH_3CH(R)CONi(CO)_2X] \rightarrow$$
$$\xrightarrow{R'OH} RCH_2CH_2COOR' + CH_3CH(R)COOR' + HNi(CO)_2X.$$

Data have been obtained in support of an analogous mechanism of the carbonylation reactions in the presence of a cobalt catalyst[134–137]. Acylcobalt carbonyl $RCOCo(CO)_4$, formed when the hydrocarbonyl $HCo(CO)_4$ absorbs a mole of carbon monoxide and a mole of olefin, was isolated. When $HCo(CO)_4$ was allowed to react with $RCOCo(CO)_4$, an aldehyde and $Co_2(CO)_8$ were obtained.

A mechanism has been proposed for the hydroformylation of olefins[134]:

$$RCH=CH_2 + HCo(CO)_4 \rightarrow RCH_2CH_2Co(CO)_4 \rightarrow RCH_2CH_2COCo(CO)_3 \rightarrow$$
$$\xrightarrow{CO} RCH_2CH_2COCo(CO)_4 \xrightarrow{HCo(CO)_4} RCH_2CH_2CHO + Co_2(CO)_8.$$

The reduction of $CH_3COCo(CO)_4$ by hydrogen at 25°C [138,139] ceases completely at high carbon monoxide pressures, which suggests that this acyl cobalt carbonyl is relatively inactive[139]. Therefore a different mechanism was adopted in which the catalyst is cobalt tricarbonyl hydride[136]:

$$HCo(CO)_4 \underset{+CO}{\overset{-CO}{\rightleftharpoons}} HCo(CO)_3 \underset{-RCH=CHR}{\overset{RCH=CHR}{\rightleftharpoons}} \underset{HCo(CO)_3}{RCH=CHR} \rightleftharpoons$$
$$\rightleftharpoons RCH_2CH(R)Co(CO)_3 \underset{-CO}{\overset{+CO}{\rightleftharpoons}} RCH_2CH(R)Co(CO)_4 \rightleftharpoons$$
$$\rightleftharpoons RCH_2CH(R)COCo(CO)_3 \begin{cases} \xrightarrow{HCo(CO)_4} RCH_2CH(R)CHO + Co_2(CO)_7 \\ \xrightarrow[H_2]{} RCH_2CH(R)CHO + HCo(CO)_3 \end{cases}.$$

Cobalt hydrocarbonyl catalyses also the migration of the double bond in olefins when it forms an intermediate π complex with the olefin[136,140].

The interconversion of alkylmetal carbonyl and acylmetal carbonyl takes place similarly also for the manganese compounds[141]. This is accompanied by the isomerisation of the carbon skeleton, for example:

$$CH_3CH_2CH_2CH_2COCo(CO)_n \rightleftharpoons \underset{H_3C}{\overset{H_5C_2}{\diagdown\!\diagup}}CHCOCo(CO)_n .$$

The rate of isomerisation greatly depends on the size of the alkyl group[142].

In the carbonylation and hydroformylation reactions, the true catalyst is probably cobalt hydrocarbonyl[137] which in the absence of gaseous hydrogen is formed from $Co_2(CO)_8$ and the hydrogen of the solvent. Acylcobalt carbonyls are hydrolysed or alchoholysed with formation of a carboxylic acid or an ester and the regeneration of the hydrocarbonyl. Acryloyl-, pent-4-enoyl, and allylcobalt tricarbonyls form with sodium methoxide the sodium salt of the corresponding acid, an ester, or an ether. Alkylcobalt and acylcobalt carbonyls form at 0°C stable complexes with $(C_6H_5)_3P$, carbon monoxide being evolved[135]. Trialkyl- and triaryl-phosphine derivatives $RCOCo(CO)_n$ react with sodium methoxide, forming free phosphines, $NaCo(CO)_n$, and carboxylic acid esters[137].

Iron carbonyls proved to be active catalysts in the carbonylation of olefins with formation of alcohols:

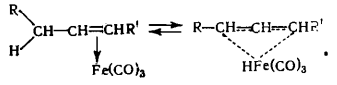
$$C_nH_{2n} + 3CO + 2H_2O \rightarrow C_{n+1}H_{2n+3}OH + 2CO_2 .$$

The reaction proceeds at 60–80°C and 100–200 atm in an aqueous alkaline solution of $Fe(CO)_5$. [143] The replacement of CO in the carbonyl by $(C_6H_5)_3P$ leads to an increase of catalytic activity by a factor of about ten[144]. The complexes formed from iron carbonyls, tertiary amines, and water are also active catalysts of this reaction[145], which occurs at a pressure as low as 10–25 atm. In the presence of ammonia, amines are formed[146].

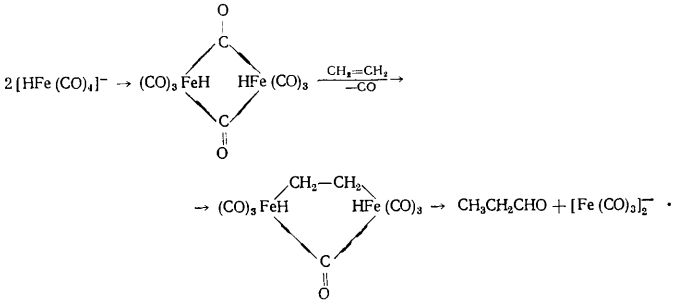
The synthesis of butyl alcohols by this method, has been achieved under industrial conditions[147]. Trimethyl-, and triethyl-amines and *N*-ethylpiperidine are most effective as the amine components of the catalyst. In this case the yield of alcohols reaches 56%. The effectiveness of pyridine and its derivatives is very low[148]. The complex of iron hydrocarbonyl with n-butylpyrrolidine also proved to be an active catalyst for the synthesis of primary butyl alcohols from propene. The conversion of carbon monoxide reached 75%, that of propene 86%, and the content of isobutyl alcohol was 25%.[149] The formation of some alcohols with the iso-structure indicates an isomerising effect of $Fe(CO)_5$.[145] The reaction probably proceeds via a π complex of iron hydrocarbonyl with the olefin in equilibrium with the σ compound[150]:

$$\underset{\downarrow}{RCH=CHR} \rightleftharpoons \underset{\downarrow}{RCH-CH_2R}$$
$$HFe(CO)_3 \qquad Fe(CO)_3$$

The formation of a π complex of the olefin with iron tricarbonyl, which is subsequently converted into a π-allyl complex of iron hydrocarbonyl, is also possible:



The complexes obtained by the reaction of $Fe(CO)_5$ with bases catalyse also the migration of the double bond in olefins. The olefin replaces one CO group and an aldehyde is obtained from the complex formed[151]:



In the carbonylation of olefins in the presence of ammonia or amines using cobalt catalysts at an elevated pressure, carboxylic acid amides are obtained. In the presence of iron catalysts, mainly primary, secondary, and ternary amines are formed, while the yield of the amides is low. The amides can be synthesised also on the catalyst for the Fischer–Tropsch synthesis (Co–ThO_2–MgO–kieselguhr) at 200°C and 150 atm. *N*-(n-propyl)propionamide, 2-ethyl-3,5-dimethylpyridine, and 4-ethyl-3,5-dimethylpyridine were synthesised from ethylene, ammonia, and a 1 : 1 carbon monoxide–hydrogen mixture in hexane. In the absence of hydrogen, *N*-(n-propyl)propionamide was obtained from ethylene, carbon monoxide, and n-propylamine in 60, 55, and 30% yields in the presence of the cobalt catalyst, Co + $Fe(CO)_5$, and $Fe(CO)_5$ respectively.

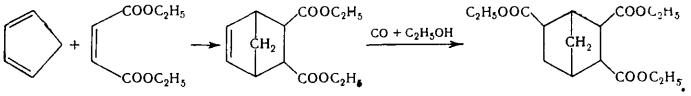
Unsubstituted cyclohexanecarboxamide was synthesised from cyclohexene, carbon monoxide, and ammonia. When ammonia was replaced by a primary amine, the reaction proceeded more smoothly; in the presence of hydrogen, amines are formed as side products[152].

The carbonyls $[C_6H_5Fe(CO)_2]_2$, $[C_6H_5Mo(CO)_3]_2$, and $[Co(CO)_4]_2$ catalyse the reaction of olefins, carbon monoxide, and carbon tetrachloride with formation of compounds having the general formulae RCH(COCl), CH_2CCl_3, and $RCHClCH_2CCl_3$.[153]

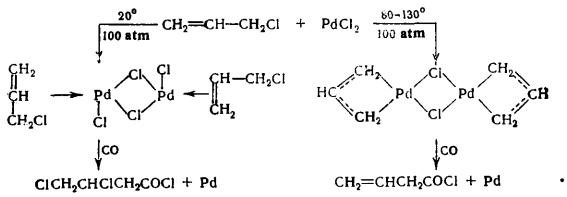
Group VIII noble metals, their salts, and complexes proved to be active catalysts for the carbonylation of olefins. Metallic palladium was active only in the presence of HCl. In the presence of "catalytic" amounts of these metal halides, carboxylic acid chlorides, anhydrides, and esters were formed from olefins, carbon monoxide, and hydrogen chloride in inert solvents at 150–200°C and 600–1000 atm.[154–157]. The reaction of carbon monoxide in benzene solution at 20°C and 50 atm with the Π complex

$C_2H_4.PdCl_2$, prepared by the reaction of ethylene with powdered $PdCl_2$ in benzene, gave β-chloropropionyl chloride in 40% yield relative to the initial *II* complex[155]. An ester of the β-chloroacid is formed in alcoholic solution. The corresponding esters of β-chloroacids were also obtained from C_3-C_5 olefins, carbon monoxide reacting with the terminal carbon atom of the double bond. However, hex-1-ene gave an ester with a branched structure as the main product. An ester of *trans*-2-chlorocyclohexanecarboxylic acid was obtained from cyclohexene. The yields of acid chlorides and esters are low due to the decomposition of a considerable proportion of the π complex with formation of an olefin or a chloro-derivative[158]. At 100 atm and 80°C, ethyl propionate with an admixture of ethyl β-hydroxypropionate and γ-oxocaproate was obtained from ethylene in ethanol saturated with hydrogen chloride in the presence of small amounts of $PdCl_2$, propene gave ethyl n-butyrate and isobutyrate (2:1), and styrene gave ethyl α- and β-phenylpropionates (2:1) with an admixture of α-chloroethylbenzene[155].

In the presence of the complex $[(C_6H_5)_3P]_2PdCl_2$, the carbonylation of olefins leads to the formation of carboxylic acids. In the presence of $[(C_6H_5)_3P]Pd$ and small amounts of hydrogen chloride at 90°C and 700 atm, about 60% of isobutyric acid, 3% of butyric acid, and 36% of methyl butyrate were obtained from propene, carbon monoxide, and methanol.[159] Products of the Diels–Alder synthesis, which are unstable at high temperatures, were carbonylated with the aid of palladium complexes:



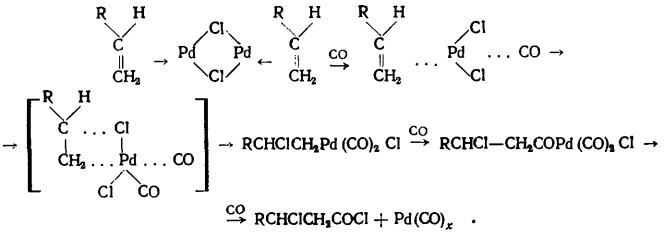
Triethyl cyclohexane-1,2,5-tricarboxylate was synthesised from butadiene by a similar reaction[160]. The differences sometimes observed in the mode of carbonylation depending on the reaction conditions, with formation of β-chlorocarboxylic acid chlorides or esters at 20°C and the analogous derivatives of β-unsaturated acids at 80–130°C, may be explained by the formation of different olefin–$PdCl_2$ π complexes,[158,161]:



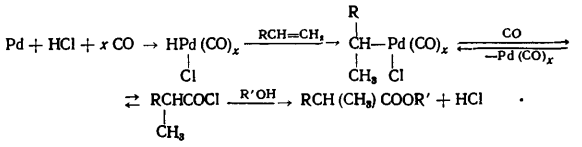
Carbonylation with retention of the double bond takes place with allyl chlorides and allyl alcohols, the same products being obtained from different isomers in consequence of the formation of the same π complex with $PdCl_2$.[159]

In the presence of Group VIII metal halides and chelate complexes in pyridine, olefins react with carbon monoxide and water, also with formation of ketones. Diethyl ketone was obtained from ethylene at 200°C and 1000 atm together with propionic acid, while propene gave acetone, isopropyl ketone, and isobutyrate together with isobutyric acid[162].

In the formation of acid chlorides and esters, the π complex of the olefin with $PdCl_2$ is coordinated to one or two carbon monoxide molecules; in the resulting complex the Cl atom migrates from palladium to the carbon atom of the coordinated olefin and a σ-organometallic compound is formed and reacts further with carbon monoxide. The latter is inserted between the alkyl group and palladium with formation of a β-chloroacylpalladium compound, which is subsequently converted into the chloride of the β-chlorocarboxylic acid:

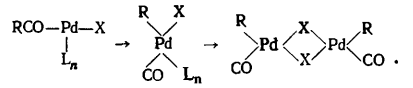


The structure of the initial π complex has been confirmed by NMR data[163]. A mechanism has been proposed for the formation of esters from olefins in the presence of the $PdCl_2$ in ethanol, where the true catalyst is palladium hydrocarbonyl chloride[164–168]:



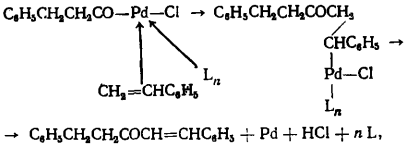
The $C_2H_4-PdCl_2$ complexes are carbonylated with formation of β-chloropropionic acid anhydride, while metallic palladium catalyses the carbonylation of olefins with formation of esters and aldehydes. These reactions are reversible: acid chlorides and aldehydes are decarbonylated to the olefins with intermediate formation of the acyl-palladium bond[165–167]. The first stage in the carbonylation of mono-olefins in the presence of hydrogen halides is believed to be the formation of palladium(II) in the form of metal hydride complexes, whose formation by oxidative addition of the hydrogen halide or hydrogen to transition metals is well known[169,170]. These complexes play an important role as catalysts, not only in carbonylation reactions but also in hydrogenation, double bond migration, and addition reactions.

A number of stages in carbonylation, catalysed by metal carbonyls, including the carbonylation of the phosphine complexes of palladium and platinum, are reversible[171]. The last decarbonylation stage—the conversion of the acylpalladium complex in the absence of carbon monoxide into an alkylpalladium complex proceeds via a "stable tetracoordinate bridge" halogenocarbonyl complex[172] [wrong reference (Ed. of Translation)]:



Subsequently the alkyl–palladium bond is cleaved with formation of an olefin and hydrogen halide or hydrogen. An alkyl palladium–phosphine complex with a β-hydrogen atom in the alkyl group is converted into an olefin and palladium hydride, which decomposes into palladium and hydrogen halide[173].

The decarbonylation of β-phenylpropionic acid anhydride gives 1,5-diphenylpent-1-en-3-one according to the mechanism[165]:



where L = phosphine.

The presence of activators (acids), the solvent, and reaction temperature have a major influence on the redistribution of bonds within the palladium complexes on coordination of carbon monoxide and the dissociation of Pd–Cl bridge bonds[174].

The decarbonylation of carboxylic acid chlorides also takes place under the influence of rhodium complexes:

$$RCH_2CH_2COCl + RhCl[(C_6H_5)_3P]_3 \rightarrow RCH{=}CH_2 + HCl + Cl{-}Rh(CO)[(C_6H_5)_3P]_2 .$$

The chlorocarbonyl complex formed could be isolated[165].

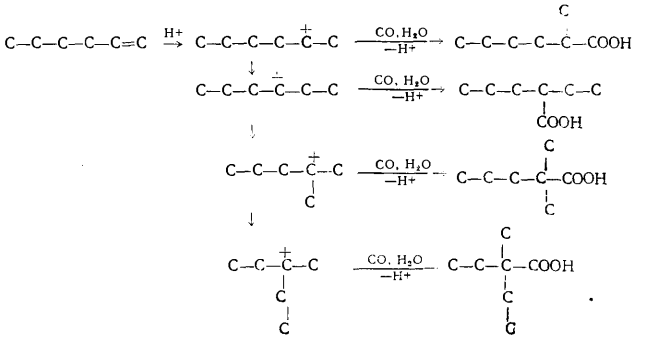
The decarbonylation of aldehydes leads to the formation of an alkane and the complex $ClRh(CO)[(C_6H_5)_3P]_2$.[166] This complex was also obtained by the reaction of the transition metal salts with alcohols, and proved to be an active catalyst for the decarbonylation of aldehydes and acid chlorides[175,176]. Analogous carbonyl halide hydrides are formed by the reaction of hydrogen chloride with carbonylbis(triphenylphosphine)iridium chloride[170] and of methyl chloride with iodo(methyl)bis(triethylphosphine)-platinum[177]. In the presence of soluble variable-valence metal salts, with a positive oxidation potential higher than that of platinum, for example $CuCl_2$, platinum catalyses at 120–150°C and 150–200 atm the carbonylation of olefins in an alcoholic medium with formation of unsaturated and β-alkoxy-substituted carboxylic acid esters. Oxygen was added in portions to the reaction medium[178]. αβ-Unsaturated carboxylic acid esters have been synthesised electrochemically[178,179] from carbon monoxide and olefins in the presence of carbonyl complexes of platinum. It has been suggested that the catalytic activity of Group VIII metal carbonyls in the carbonylation of unsaturated hydrocarbons is associated with the acidic properties of the hydrocarbonyls of these metals, rhodium carbonyl showing the greatest effectiveness in the hydrocarboxylation and hydromethoxycarbonylation reactions of the above hydrocarbons[180].

Ruthenium and rhodium halides and chelate complexes also catalyse the carbonylation of olefins. Propionic acid is formed from ethylene in concentrated hydrochloric acid and in cyclohexane solution mixed with anhydrous hydrogen chloride the products are propionic anhydride and propionyl chloride. The reaction proceeds at 150–210°C and a high carbon monoxide pressure (600–1000 atm).[154]

The data quoted in this section show that the carbonylation of mono-olefins with formation of saturated carboxylic acids in an aqueous medium or of their esters in an alcoholic medium proceeds in the presence of catalysts based on Group VIII metals; cobalt, nickel, iron, platinum, palladium, ruthenium, and rhodium. The true catalysts are the intermediate hydrocarbonyl complexes. One of the primary stages may be the formation of a π complex of the metal hydrocarbonyl with the olefin. An important stage is the conversion of the alkyl into acyl complexes. Catalysts based on Group VIII noble metals, particularly complexes with ligands of the type of triarylphosphines, are already active at 20–50°C and the reaction products can be also acid chlorides, anhydrides, and chlorocarboxylic acids.

2. Reactions in the Presence of Acid Catalysts

The carbonylation of olefins can be achieved in the presence of various acid catalysts[1]. Initially the reaction was carried out at an elevated temperature (100–300°C) and high carbon monoxide pressures (200–1000 atm) in the presence of all the starting materials in the reaction zone. Subsequently the process was achieved in two stages: the reaction of the olefin with carbon monoxide in the presence of 96% sulphuric acid at 0–50°C, and 1–100 atm carbon monoxide pressure and the decomposition of the reaction complex by water with formation of carboxylic acids and regeneration of sulphuric acid[181,182]. The addition of the elements of formic acid (H–COOH) takes place in accordance with the Markovnikov rule. Acids with a quaternary atom, such as αα-dimethyl- and α-ethyl-α-methylalkanoic acids, are always formed from straight-chain α-olefins together with the expected acids having a tertiary carbon atom in the α-position; unbranched carboxylic acids are absent from the reaction products. The number of possible isomers is given by the equation $y = x - 2$, where x is the number of carbon atoms in the initial olefin. All the expected isomeric acids were obtained from straight-chain C_5–C_{10} olefins[183]. The results obtained are described satisfactorily by a mechanism according to which carbonium ions are formed as intermediates:



Olefins branched at the double bond can form only tertiary carbonium ions and the latter are converted exclusively into carboxylic acids with a quaternary α-carbon atom.

Small amounts of the carbonylation products of the dimeric form of the olefin are formed together with the normal reaction products. Trimethylacetic[181,184] and ααγγ-tetramethylvaleric acid were obtained from isobutene. Lower olefins branched at the double bond disproportionate at a carbon atom with subsequent carbonylation. Thus a mixture of C_{11} acids and also equivalent amounts of trimethylacetic and αα-dimethylvaleric acid are formed from 2-methylbut-2-ene together with αα-dimethylbutyric acid. The formation of C_5 and C_7 acids is due to the disproportionation of the isodecene formed initially into C_4 and C_6 olefins. ααγγ-Tetramethylvaleric and methylneopentylacetic acids were obtained from di- and triisobutenes respectively.

For cyclic mono-olefins, the number of possible isomeric acids cannot be determined from the equation derived for unbranched acyclic olefins, since the isomerisation is affected by the ring size and ring strain and also the reaction conditions. 1-Methylcycloheptane- and 1-ethylcycloheptane-carboxylic acids were obtained from cyclo-octene; the products of the direct carbonylation of cyclononene and cyclodecene could not be obtained either[185].

When carbon monoxide is replaced by formic acid, the reaction in the presence of concentrated sulphuric acid proceeds at atmospheric pressure and room temperature[186–188]. Carboxylic acids are obtained in high yields for the molar ratios olefin: $HCOOH : H_2SO_4 = 1 : 4 : 8$. Carboxylic acids with one carbon atom more than in the initial olefin and with a quaternary carbon atom in the α-position were largely formed from unbranched olefins.

A mixture of the carbonylation products of the monomeric and dimeric forms and of the olefins produced by the disproportionation of the dimer was obtained from the olefins branched at the double bond. Cyclo-olefins without a six-membered ring usually undergo ring contraction or expansion with formation of cyclohexanecarboxylic acids. Cyclohexene gives 1-methylcyclopentanecarboxylic acid and alkylcyclohexenes are converted into acids with retention of the six-membered ring. Bi- and poly-cyclic systems are carbonylated in high yields (up to 95%). Thus 5-methyl-bicyclo[2,2,1]hept-2-ene gives 2-*endo*-methylbicyclo[2,2,1]heptano-*exo*-2-carboxylic acid[186].

In the synthesis of carboxylic acid esters using carbon monoxide, a two-stage method is employed, in which the reaction complex formed by the interaction of the olefin with carbon monoxide at 20–40°C and 70–80 atm carbon monoxide pressure in the presence of sulphuric acid is decomposed by methanol or ethanol[189-191]. C_5-C_{10} olefins[192-195] and cyclo-olefins[196,197] have been hydroalkoxycarbonylated by this method. Methyl and ethyl esters, predominantly with a quaternary α-carbon atom, are obtained in high yields[198]. At atmospheric pressure the yield of esters is low, but, on raising the carbon monoxide pressure in the range 5–75 atm, the overall yield of esters increases; however, in the case of isobutene the content of esters with quaternary and tertiary α-carbon atoms shows little change. In the reactions of straight-chain α-olefins, skeletal isomerisation processes are retarded, which leads to a lowering of the yield of esters with a quaternary α-carbon atom[199,200]. An increase of the H_2SO_4 : olefin molar ratio increases the overall yield and the content of the main reaction product for but-1-ene but decreases the content of the main product for isobutene. An increase of reaction temperature has an unfavourable effect[201].

The hydroalkoxycarbonylation of olefins and cyclo-olefins is readily achieved by the reaction with formic acid in the presence of concentrated sulphuric acid at atmospheric pressure close to room temperature with subsequent addition of the alcohol in the second stage of the process. The reaction has been investigated for aliphatic straight-chain C_5-C_9 olefins, C_5-C_6 olefins with the iso-structure[202-205], and also cyclo-olefins: cyclopentene, cyclohexene, 1-alkylcyclopentenes, and 1-alkylcyclohexenes[205-208]. C_1-C_5 saturated alcohols were used in the second stage. In all these reactions the main products were carboxylic acid esters with quaternary or tertiary carbon atoms in the α-position relative to the alkoxycarbonyl group. The corresponding free carboxylic acids were present in the reaction products. The position of the double bond in the initial olefin molecule did not affect the course of the reaction. The relative yield of esters fell and that of free acids increased with increase in the number of carbon atoms in the molecule of the alcohol added in the second stage[209-211].

An increase of the concentration of sulphuric acid, the addition to it of some P_2O_5, an increase of the relative amount of the alcohol added in the second stage, and in increase of temperature lead to an increase of the yield of esters. Thus in the case of pent-1-ene an 80% yield is achieved and the content of the main products in the mixture is 90–98%.

The isomerisation of the carbon skeleton of the initial olefin takes place in the alkylcarbonium ion stage and the acylium ion formed subsequently by the reaction $R^+ + CO \rightarrow R\overset{+}{C}O$, the carboxylic acid, and its ester do not isomerise. A certain amount of carboxylic acids is produced already in the first reaction stage due to the water contained in the sulphuric and formic acids and liberated on decomposition of the latter. Esters are formed both by the reaction of acylium ions with alcohols:

$$R\overset{+}{C}O + R'OH \rightarrow RCOOR' + H^+$$

and by the esterification of the carboxylic acids already formed in the first stage[212-214].

It has been noted[215] that concentrated H_3PO_4 does not catalyse the carbonylation of olefins at all. However, this proved true only of the reaction conditions described: 5–10°C and 100 atm carbon monoxide pressure. Subsequently it was found that at a higher temperature phosphoric acid is active in this reaction[216]. In the presence of 95–100% H_3PO_4, $H_4P_2O_7$, and polyphosphoric acids, C_5-C_{12} olefins of different structures were converted into carboxylic acids at 75–150°C. Under the reaction conditions, H_3PO_4 gives up the water necessary for the formation of a carboxylic acid, and is converted into $H_4P_2O_7$. When a stoichiometric amount of water is added, the catalyst and the reaction product collect in different layers[217]. The catalytic properties of H_3PO_4 were investigated in reactions involving the carbonylation by carbon monoxide of straight-chain C_5-C_{10} olefins, isobutene, di-isobutene, and cyclohexene[218-222]. A mixture of $\alpha\alpha$-dimethyl-, α-ethyl-α-methyl-, α-ethyl-, and α-methyl-alkanoic acids is formed as the main products.

Straight-chain C_7-C_{10} α-olefins yielded only acids derived from their monomeric form, i.e. with the C_8-C_{11} composition. C_5-C_6 α-olefins form in addition small amounts of acids derived from their dimeric form ($C_{11}-C_{13}$ acids), disproportionation products, and also the isomers and dimers of the initial olefin. Isobutene and di-isobutene give rise to the same reaction products: trimethylacetic acid and C_6-C_8 and C_{13} acids. 1-Methylcyclopentanecarboxylic acid, cyclohexanecarboxylic acid, and a mixture of *cis*- and *trans*-decalin-9-carboxylic acid were obtained from cyclohexene. The optimum concentration of H_3PO_4 in the carbonylation of C_7-C_{10} α-olefins increases with the number of carbon atoms in the olefin molecule; in the case of C_5-C_6 olefins, this concentration is below 94%. At higher concentrations the olefin dimerisation and disproportionation processes become intensified. With the increase in the number of carbon atoms in the molecule of the initial olefin from four to seven, the overall yield of acids rises with a relative decrease of the yield of acids having a quaternary carbon atom in the α-position and also derivatives of the dimeric form of the olefin. The optimum reaction temperature is in the range 125–175°C, i.e. higher by about 100°C than in the carbonylation in the presence of sulphuric acid. The optimum carbon monoxide pressure is 70–80 atm, which is higher by 20–30 atm than for sulphuric acid[220].

"Solid" phosphoric acid, prepared by mixing 90% phosphoric acid with kieselguhr and subsequent heat treatment at 200–370°C,[223] catalyses the carbonylation reaction at 50–100°C and 150 atm.

Hydrogen fluoride has also been used as a catalyst for the carbonylation of olefins. Carboxylic acid fluorides are formed from unbranched olefins and carbon monoxide in the presence of anhydrous HF, while in the presence of aqueous hydrofluoric acid the products are carboxylic acids and their esters. When methanol is added, esters are produced. α-Methylbutyric and isononanoic acids and their s-butyl esters were synthesised from but-1-ene at 30°C and a carbon monoxide pressure of 20–30 atm in the presence of HF containing 5% of water. Olefins branched at the double bond are carbonylated more readily than straight-chain olefins, but the reaction products are

carboxylic acid and their fluorides. Esters are not obtained under these conditions because of the instability of the intermediate tertiary alcohols, which are decomposed by hydrogen fluoride. Esters are obtained from C_3-C_{20} olefins and carbon monoxide at higher pressures in the presence of hydrogen fluoride and up to 15% of water. When the initial compounds are measured out accurately, hydrogen fluoride can be reused without additional purification [224-227].

Catalysts based on BF_3, which can be separated from the reaction products without diluting the reaction mixture with water or alcohols, are also employed in the olefin carbonylation reactions. The $BF_3-H_2SO_4$ systems, prepared by passing BF_3 into 45 and 85% sulphuric acid at 0° and 100°C, are used only for branched olefins [215,228,229] and the $BF_3-H_3PO_4$ system, with component ratios ranging from 1.2 : 0.8 to 0.8 : 1.2, is used for the carbonylation of both branched and unbranched olefins. The greater the amount of carboxylic acids with a quaternary α- carbon atom in the reaction products, the more complete and rapid is their separation from the catalyst [230-232].

The BF_3-CH_3OH system, obtained by passing BF_3 into methanol, may be regarded as monomethoxyfluoroboric acid $H(BF_3OCH_3)$; it is active in the hydroalkoxycarbonylation of olefins, particularly cyclic olefins, but it results in a homogeneous reaction mixture [233], which does not separate into the catalyst and the reaction product. In the presence of this system at 15°C and a carbon monoxide pressure of 150 atm, high yields were obtained of the methyl esters of 1-benzylcyclohexanecarboxylic, 1-benzylcycloheptanecarboxylic, and 1-benzylcyclooctanecarboxylic acids from 1-benzylcyclohexene, 1-benzylcycloheptene, and 1-benzylcyclo-octene respectively [234], the methyl esters of C_{12} and C_{23} acids from undec-1-ene, and also the corresponding esters of acids derived from oct-1-ene, isononene, isobutene, tetradec-1-ene, 2-ethylhex-1-ene, and octahydronaphthalene. A mixture of alkoxyfluoroboric acid with boron trifluoride hydrate, containing between one and two moles of a mixture of water and alcohol per mole of BF_3, also catalyses effectively the carbonylation of olefins. When a stoichiometric amount of water is added, the catalyst is readily separated from the reaction products, which consist of a mixture of 70-90% of carboxylic acids and 3-20% of their esters [235].

The BF_3-2H_2O system, obtained when BF_3 is passed into water at 0°C, is active in the carbonylation of olefins. Branched olefins are converted below 10°C and at 50-100 atm into acids in 85% yield. In the presence of $BF_3 . 1.5H_2O$, the trimer of propene reacts at 20°C, giving a high yield of a mixture of not less than eight isomeric C_{10} acids [215,236]. The optimum yield of trimethylacetic acid is obtained from isobutene at a carbon monoxide pressure of 100 atm, 30°C, and the molar ratio $C_4H_8 : BF_3 . 2H_2O = 1 : 1$. [237]

The data presented in this section show that two-stage olefin hydrocarboxylation and hydroalkoxycarbonylation reactions involving carbon monoxide, a compound with a mobile hydrogen atom, and an acid catalyst permit the synthesis of branched carboxylic acids with tertiary and quaternary carbon atoms in the α-position, their esters, and certain derivatives.

The acid catalysts are concentrated sulphuric acid, concentrated phosphoric acid, hydrogen fluoride, and boron trifluoride complexes.

Mixtures of Aminoacids in Human Nutrition

V.M.Belikov and T.L.Babayan

The use of mixtures of individual aminoacids instead of proteins in human nutrition has been the subject of numerous recent investigations. The aim was not only to investigate the process of aminoacid assimilation itself but also to elucidate the question of their possible long term use in food. The large scale and prolonged employment of aminoacid mixtures in therapeutic feeding shows that they constitute an adequate replacement of food proteins and their consumption does not apparently entail any undesirable consequences. Various aspects of the use of aminoacids to improve the nutritional value of second-class proteins by adjusting their [aminoacid] balance are also discussed. However, before reaching final conclusions concerning the ways of utilising aminoacids in nutrition, more prolonged and comprehensive studies are necessary. The review deals with work carried out in the last 10 years.
The bibliography includes 164 references.

I. INTRODUCTION

A considerable proportion of the earth's population, particularly in certain countries in Asia, Africa, and Latin America, suffers nowadays from a chronic deficiency of foodstuffs, mainly protein, which leads to high child mortality both from the malnutrition itself and from the reduced resistance of the organism to infectious diseases and possible genetic damage caused by malnutrition. Owing to the high rate of increase of the populations of these countries, the situation is continually deteriorating[1].

The intensification of agriculture, the use of protein products previously not employed in food, and the tapping of the resources in the ocean are the most obvious ways of solving this problem. These ways are based on an extensive agriculture, i.e. harvesting the crop from larger areas. In addition they inevitably interfere with the earth's ecological system[2].

A new and promising method of obtaining foodstuffs is chemical synthesis. Where protein is concerned, this involves the synthesis of aminoacids and their mixtures and if necessary of polymers from inorganic non-food raw materials[3,4]. Apart from other considerations, this procedure has the advantage that it gives a high yield of production per unit productive area.

However, in an examination of the possible utilisation in food of such products, a number of problems concerning the physiology and biochemistry of nutrition arise. Naturally, before introducing into human nutrition any kind of synthetic diet, one must develop compositions of the latter such that the normal functioning of the human organism, accustomed throughout evolution to food of plant and animal origin, is ensured. This is an exceptionally complex problem.

Body-tissue material and energy are introduced into the organism with food. Although the adaptive capacity of the organism to various sources of food is high, it is nevertheless limited. Therefore excessive abuse of this capacity can eventually lead to the breakdown of the functions of the regulating mechanisms in digestion, which is revealed in a wide variety of diseases associated with different types of food deficiency and when the proper proportions of the nutrient substances in the diet are not maintained. Owing to its internal reserves, the organism itself can correct many errors in the rations, but it does appear to be more satisfactory to extend our knowledge in the field of nutrition in order to provide the organism with its essential requirements to the maximum possible extent. The nature of food to some extent induces the secretion of digestive enzymes—their activity and amount.

The requirement for essential individual food components, including aminoacids, is due to the fact that the organism lacks enzyme systems which can synthesise them at a sufficient rate from non-specific metabolic intermediates. Therefore a thorough investigation of the effect of essential nutrient factors as such on the organism as a whole is necessary before they are introduced into human diet.

The aim of the present review is to examine work concerning the use of synthetic or more precisely monomolecular nutrient substances, primarily aminoacids, in human nutrition.

II. NITROGEN BALANCE AND BIOLOGICAL VALUE OF PROTEINS, AMINOACIDS, AND THEIR MIXTURES

On entering the human organism, protein is fully hydrolysed in the digestive tract to aminoacids, which pass into the blood only in this form and are supplied to all the tissues and body organs where protein is resynthesised. There are data showing that proteins introduced parenterally also break down into aminoacids before being utilised by the organism[5].

Table 1. Soluble diets for the feeding of human patients *per os*.

Substance	Diet according to Winitz*	Diet of Schwartz Bioresearch Inc.
Carbohydrates	(g)	(g litre^{-1})
Glucose	550.0	418.1
Glucono-δ-lactone	17.2	–
Gluconoaldehyde	–	12.8

Sodium benzoate	1.00	–

* All the dry substances were dissolved in distilled water to give a concentration of 50–70%.

Therefore many investigators decided to test directly the effect of introducing into the organism various amino-acid compositions instead of proteins. In experiments on rats, Greenstein et al.[6] showed that diets comprising chemically pure monomers can support growth, reproduction, and life of the experimental animals throughout several generations. Subsequently Winitz et al.[7] demonstrated the possibility of using such diets also to support normal life in healthy man. During a 19-week experimental period 24 male volunteers aged between 24 and 39 were kept on a synthetic diet, whose composition is presented in Table 1.

Physiological observations showed that they all became accustomed to such diets; throughout the experimental period, a positive nitrogen balance was maintained in the majority of the individuals tested.

It is believed that the subject is in nitrogen balance when the amount of nitrogen received with food (I) is equal to the amount eliminated from the organism in urine (U), faeces (F) and via the skin (S):

$$I = U + F + S\,.$$

If I exceeds the sum $U + F + S$, a positive nitrogen balance is obtained, otherwise the balance is negative.

Thus the nitrogen balance is the fundamental criterion in the estimation of the protein state of the organism. If the organism is maintained for a long time in a negative nitrogen balance, its protein reserves are exhausted with an eventual lethal outcome.

In order to maintain a nitrogen equilibrium, different amounts of different proteins are required. If the amount of a protein required to maintain equilibrium is small, the protein is said to have a high biological value. In general the nutrient value of protein is determined by two different factors: (1) digestibility and (2) biological value[8].

Digestibility is determined by the ratio of the absorbed protein elements to the amount introduced. It depends on the exocellular and endocellular proteolythic activity of the intestine and the capacity of all the intestines for absorption. Digestibility is related to the necessity for the simultaneous introduction of all essential aminoacids into the reaction medium during synthesis. The biological value (BV) indicates the ratio of the protein elements absorbed and retained by the organism.

According to the classification adopted by FAO/WHO [9],

$$\mathrm{BV} = \frac{\text{retained nitrogen}}{\text{absorbed nitrogen}}$$

The biological value depends both on the aminoacid composition of the protein and on the digestion and transport of the nutrient substances. In terms of nutrient value, the proteins of mother's milk (90–97%), eggs, cow's milk, cheese, meat, fish (80–90%), and yeast (77%) come first, are followed by grain proteins, and finally by wheat flour (54%).

The studies on the effects of individual aminoacids in proteins on the biological value of the latter begun as early as the beginning of the 20th century by Kellner, Willsk [Wills ?], Hopkins, Abderhalden, Osborn, Mendel, and others, were completed by the systematic work of Rose, who, as it were, summed up the studies concerning the elucidation of the role of protein in nutrition. The nutritive value of protein is closely related to its composition, namely to the content and relative proportions of essential aminoacids. Rose was the first investigator who studied systematically the effect of individual amino-acids on the nitrogen balance. The nitrogen balance technique, which he was the first to employ, still remains the foundation of all metabolic experiments involving human nutrition by aminoacid mixtures[10].

Hegsted[11] quotes different versions of the human requirement for aminoacids (Table 2).

The norms in aminoacid requirement were proposed by the FAO committee in 1957 and were then revised by FAO/WHO experts in 1965.[9] The same organisations put forward as a criterion of protein nutrition the ratio of essential aminoacids (E) to the total amount of nitrogen in a particular protein (T). The E/T ratio is expressed in milligrammes of essential aminoacids per gramme of total nitrogen. Proteins with high, medium, and low nutrient values have E/T = 3, 2, and below 2.

Table 2. Average aminoacid requirements of adult humans.

Aminoacid	For women (according to D.M.Hegsted)		Published data (according to W.C.Rose)		
	mg/day		for women	for men	
			mg/day		
	amount of amino-acids required to maintain a zero nitrogen balance	amount of amino-acids required to maintain an amino-acid balance of +0.5 g/day		minimum	optimum
Tryptophan	168	270	157	250	1200
Phenylalanine in the presence of tyrosine	258	550	220	300	—
Threonine	375	1750	305	500	3600
Isoleucine	550	1700	450	700	3000
Lysine	545	1750	500	800	6000
Methionine (+ 500 mg of cystine)	194	375	180	200	—
Methionine (+ 10 ml of cystine)	700	3450	550	1100	—
Valine	622	1000	650	800	4200
Leucine	727	2600	620	1100	5400

According to Rose, the requirement for protein reduces to 2 sources of nitrogen: (1) essential aminoacids which the organisms cannot synthesise and (2) non-specific additional nitrogen for the synthesis of other aminoacids and nitrogen-containing compounds. The latter can consist either of a single aminoacid or a mixture of non-essential and essential aminoacids. It can be provided also in another form, for example in the form of urea, diammonium citrate, etc. Thus animal and human organisms require both essential and non-essential nitrogen.

Comparing the biological value of natural proteins and the equivalent aminoacid mixtures imitating their compositions both qualitatively and quantitatively, some investigators suggested that the effectiveness of such mixtures is lower than that of protein[12-21]. This conclusion was made largely on the basis of the decrease of the nitrogen balance, loss of appetite, the shortening of the feeding period, and the arrest of growth in young animals. There arises the valid question to what extent one can rely on conclusions based on experiments on laboratory animals with the aim of transferring them to human beings.

In an early paper Hegsted[22] noted that there is a close relation between the aminoacid requirements of man and animals, since the differences in their body structures are not all that great. The rat, being a more rapidly growing animal than man, has a higher overall requirement for nutrient substances. Moreover, the rat's requirement for methionine is higher, due to the growth of its hair covering. It also has a higher requirement for lysine (lysine is known to be required more for growth than for the maintenance of the nitrogen balance). However, the assertion that aminoacid mixtures tested on animals are less effective cannot be regarded as fully reliable, since there are many studies with the opposite findings[23-32].

Guggenheim and Szmelcman[33] actually demonstrated a higher effectiveness of the mixture compared with protein. When rats were maintained on a diet consisting solely of an aminoacid mixture, they gained more in weight and had a higher protein content in their serum and also more nitrogen in RNA and in the liver than the animals receiving the same amount of protein as casein. Sauberlich[32] suggests that correctly balanced aminoacid mixtures can fully replace proteins in diet without an arrest of growth.

III. CAUSES RESPONSIBLE FOR DIFFERENT MODES OF UTILISATION OF PROTEINS AND AMINOACID MIXTURES

These conflicting data led to a number of hypotheses explaining the possible cause of the different ways of utilisation of proteins and aminoacid mixtures. Thus it has been suggested that the rates of absorption of monomeric and polymeric substances are different. Rose and Clark believe that monomers are absorbed faster. However, the studies in recent years showed that the hydrolysis products of food proteins are absorbed at the same rate as the equivalent monomer solutions[34]. Absorption then takes place at an equal and constant rate, is rigorously coordinated, and is of a competitive type[35].

The idea of the possible utilisation of the aminoacids from mixtures by the bacterial flora of the intestine has also been put forward. Abderhalden suggested that the period during which aminoacids derived from proteins remain in the intestine is much shorter than when the free mixtures are introduced. Therefore they are "captured" by bacteria and are at the same time converted into toxic substances. Abderhalden failed to take into account the fact that the diameter of the pores in the filaments of the so called "brush border" of intestinal epithelium, where the concluding stage of the formation of free aminoacids and hexoses takes place, is too small (of the order of 100–200 Å) to allow penetration by bacteria. Therefore aminoacids from proteins cannot be available to bacteria. However, when a complete mixture of monomers is provided, they must be inevitably supplied to bacteria. This view is supported by Ugolev[36]. The reason for undesirable effects in this case may be the multiplication of bacteria, the entry of ammonia and toxic amines into the bloodstream, and the breakdown of dietary balance. Fears were voiced that the gastric intestinal tract may degenerate owing to the reduced functional requirements.

Another consequence of the low molecular weight of the aminoacid may be the so called "osmotic effects" expressed in digestive disorders, vomiting, diarrhoea, etc.[37,38]

Shishova-Kasatochkina et al.[21] suggest that the growth factors, vitamin B_{12}, vitamin A_1, streptogenins, etc. contained in natural proteins, ensure a higher nutrient effectiveness of protein. Moreover, it may be that certain protein-like bonds, providing the synthetic processes in the organisms with additional energy evolved on their dissociation, are absent from the mixtures. This results in a higher calorie requirement in the aminoacid diet compared with the protein diet. In the same study the authors demonstrated on sterile animals that the intestinal microflora does not constitute an obstacle to the utilisation of aminoacid mixtures.

Other workers[39] believe that protein may have an effect on the production of enzymes in the small intestine

and also may act as an agent preventing the inactivation of these enzymes.

A number of investigators relate the effectiveness of the utilisation of mixtures to the intake of the total energy, total nitrogen, and its quality. It was established long ago that, when an aminoacid mixture is ingested by man, it is necessary to introduce more energy into the organism than in the ingestion of casein[40]. In later studies on rats this observation was not confirmed[41]. However, six years later, Akrens et al.[39] undertook a study of the same effect. They carried out a comparative feeding of two groups of rats of different ages with casein and an aminoacid mixture imitating it. For both old and young animals, there was no difference in the gain of weight as a function of the source of nitrogen (from the protein or from the aminoacid mixture) at a low-calorie level of intake. On the other hand, when the rats received a high-calorie diet, the gain in weight was greater with the casein feed.

Kies and Linkswiler[42] showed on man a significant relation between the requirement for a specific amount of essential aminoacids and the level of calorie intake. Thus with increase of the daily intake from 35 to 55 kcal per kilogramme body weight, the fraction of 8 essential aminoacids required to maintain a positive nitrogen balance was reduced.

Swendseid[43] examined the problem of the effect of the total amount of dietary nitrogen on the requirement for essential aminoacids. A number of studies on 60-year-old men showed that their aminoacid requirement increased with the amount of nitrogen in the diet. On the other hand, this type of relation was not observed in experiments on young men and girls. Swendseid notes that this problem is of interest in connection with the establishment of a relation between the total nitrogen, essential aminoacids, and the requirements for them associated with age.

Young and Zamora[44] showed that the level of nitrogen in the diet has little effect on growth when the intake of essential aminoacids is low; for relatively high intakes, in excess of 10% of the total diet, growth is better maintained for higher total nitrogen levels in the diet. The positive results of the introduction into the aminoacid mixtures of an additional amount of arginine, which reduces the toxicity of the ammonia produced on feeding aminoacid mixtures, were noted. Ranhotra and Johnson[30] found that, when newly born rats are fed with a pure aminoacid mixture equivalent to protein, an approximately similar gain in weight is achieved as on feeding with a protein diet. This gain was obtained as a result of an increase in the amount of dietary arginine compared with that employed previously. The optimum requirement for arginine hydrochloride is apparently 0.5% of the total weight of the diet.

Hepburn and Bradley[31] emphasised the protective role of glutamine in aminoacid diets. It also has a detoxicating effect.

The best effect as regards the increase in weight of growing animals was produced by the following mixture of essential aminoacids (expressed in percentages of the dry rations, all in the L-form): histidine 0.25, lysine 0.90, tryptophan 0.11, isoleucine 0.55, valine 0.55, leucine 0.70, threonine 0.50, methionine 0.16, cystine 0.34, phenylalanine 0.42, and tyrosine 0.30.[45]

Despite the proven suitability of aminoacid mixtures in the feeding of experimental animals, the compositions tested directly on human beings are nevertheless of particular interest.

Examination of the literature shows that, in all cases where the suitability of aminoacid mixtures in nutrition was investigated by direct experiments, there was no doubt about the equivalence of aminoacids mixtures and protein.

IV. DETERMINATION OF THE REQUIREMENTS OF THE ORGANISM FOR AMINOACIDS

As already mentioned above, the principal technique adopted to discover the requirement for a particular aminoacid is the nitrogen balance method. In addition, many investigators, in particular Almquist, believe that there is a close relation between the plasma aminoacids and the protein level in the diet. This might in turn serve as a direct method for the determination of the aminoacid requirement.

Exact methods for the quantitative determination of aminoacids (ion-exchange and gas chromatography, sensitive aminoacid analysers, etc.) make it possible to compare the aminoacid composition of the plasma with that of the aminoacid mixtures or protein employed. Morrison et al.[46] established a relation between lysine-deficient diets and the level of lysine in the plasma. Analogous investigations of the plasma and dietary levels of lysine, arginine, and valine were reported by Zimmerman and Scott[47].

McLaughlan and coworkers[48-53] have been concerned with the same problem for many years. They demonstrated an almost linear relation between the amount of free plasma aminoacids and their level in the diet. The same investigators concluded that the method used to detect plasma aminoacids can be applied to determine the human aminoacid requirement.

However, later the same workers[54] established that the method used to determine the blood aminoacids is suitable for the determination of the limiting aminoacids in the diet only when there is a deficiency of one or two limiting aminoacids but is virtually unsuitable for the prediction of a multiple aminoacid deficiency in the diet.

Interesting data in this respect were presented by Swendseid in her report delivered in the summer of 1968 in the Institute of Organic Derivatives of the Elements of the USSR Academy of Sciences. The experiments were performed both on young people—college students (men and women)—and middle-aged people. Measurements were made of the plasma aminoacid level in the post-absorptive period in individuals receiving a series of controlled diets with different amounts of total nitrogen. With 7 g of nitrogen (i.e. 45 g of protein) in their diet, both age groups showed the same average plasma aminoacid level and also equal proportions of essential aminoacids. However, with 3.5 g of nitrogen in the diet, the amount of essential plasma aminoacids gradually fell during the 55 days of the test period. In this case, as the fraction of essential aminoacids (E) decreased, that of non-essential aminoacids (N) rose to such an extent that the total amount of aminoacids in blood plasma remained the same as before or slightly higher. The E/N ratio fell.

On the basis of these experiments, the author concludes that the decrease of the E/N ratio in plasma is associated with prolonged feeding on low-protein diets.

Other workers[55] also showed (on 6 women) that a decrease of the E/N ratio in the plasma to 0.3 and below is evidence of inadequate protein intake. In general, the E/N ratio can serve as an indicator of the protein nutritional status of man[57]. Czech biologists[56] proposed a simplified method for the determination of the E/N ratio in blood plasma (the so called Whitehead test) in healthy and sick people.

The experiments of Nakagawa and Masana[58] on healthy young people showed definite changes in the aminoacid composition of plasma due to an increase in the amount of free aminoacids associated with a deficiency of protein or free aminoacids in the diet. This phenomenon may serve as a test for a subclinical nitrogen deficiency, indicating an enhanced decomposition of tissue proteins.

On the other hand, a specific deficiency of a particular essential aminoacid was not determined. Swendseid investigated this problem too. Measurements were made of the amount of plasma aminoacids after the intake of a diet with a deficiency of any one aminoacid. It was found that, when the amount of lysine in the diet was reduced to about 50% of the requirement, the lysine level in the plasma remained unchanged. Even in its complete absence (less than 100 mg in the total diet), there was no change either in the amount of plasma lysine or in the E/N ratio.

Analogous results were obtained for phenylalanine and tyrosine[59]. Valine deficiency was investigated on two subjects. In one a decrease in plasma valine after the intake of 60% of the level of control valine was observed after 5 days, while in the other the same decrease was noted towards the end of the second day of the experiment. From this, one may conclude that the dietary deficiency of some aminoacids has a more rapid effect on their level in the plasma than for others, which is probably associated with the different metabolic pathways of these aminoacids.

When Rose tested on human beings various aminoacid mixtures, he noted that the deficiency of certain aminoacids did not have an appreciable effect, while the deficiency of others caused vomiting, loss of appetite, irritability, etc.

It is interesting to elucidate whether the deficiency of dietary aminoacids causing these symptoms in man is linked to a change in their plasma level. Then, by controlling the level of aminoacids in plasma, it might be possible to eliminate these undesirable phenomena. A considerable influence of the correct ratio of essential and non-essential aminoacids (E/N) in the diet on the aminoacid composition of the plasma and the growth of animals has been noted.

Young and Zamora[44] found that the optimum E/N ratio in the diet is in the range 1.0–2.66. Harper and Stucki[70] believe that a range between 1 and 4 is possible.

In their extensive review dealing with the role of essential aminoacids in nutrition, Swaminathan and Daniel[61] quote numerous data in favour of the ratio E/N = 1, i.e. the same as that found in chicken egg protein. This E/N ratio is preferable in the diet of children and growing animals, while in adults the nitrogen balance is maintained with E/N = 2:1.

It has been established[62] that, when the total nitrogen content in food is higher, maximum growth is attained with a smaller fraction of essential aminoacids. Thus by increasing the total nitrogen level with the aid of cheap non-specific nitrogen sources, it is possible to achieve the "preservation" of essential nitrogen, i.e. essential aminoacids.

V. THE ROLE OF NON-SPECIFIC NITROGEN AND ITS FORMS

The relatively low requirement by man for essential nitrogen permits the "dilution" of first-class protein by cheap forms of non-essential nitrogen. Kremer[63] emphasises the dual function of non-essential nitrogen in the organism: (1) the provision of material necessary for the synthesis of nitrogen compounds; (2) the prevention of the use of essential nitrogen for these purposes.

The question arises of the form in which non-essential nitrogen is most fully utilised by the organism. It has been found that it can be provided either as a mixture of all the non-essential aminoacids which enter into the composition of a particular natural protein, or as various ammonium and urea salts, or as a single aminoacid, etc.

Watts et al.[64] investigated the relation between the retention of nitrogen, the excretion of ammonia, and the source of non-essential nitrogen. The retention was best on feeding with a mixture of 8 non-essential aminoacids: alanine, arginine, glycine, histidine, proline, serine, and aspartic and glutamic acids, in proportions corresponding to those in beef. Large losses of nitrogen with urine were observed during the intake of proline, histidine, or arginine. The losses with urine were higher during feeding with arginine alone and lower during feeding with histidine, compared with the mixture of non-essential aminoacids. The level of blood ammonia was higher on feeding with glycine alone than on feeding with the aminoacid mixture.

These data are consistent with those presented in the report by Swendseid quoted above. The unsuitability of the replacement of an aminoacid mixture by glycine alone was clearly demonstrated on four adult subjects. However, a 1:1 mixture of glycine and diammonium citrate proved to be a complete replacement for a mixture of 7–8 non-essential aminoacids.

On the other hand, Snyderman et al.[65] demonstrated on unweaned infants that the replacement of 74% of the milk nitrogen by glycine alone does not have a negative effect on the rate of their growth.

Huang et al.[66] investigated on 9 male students the degree to which beef protein can be replaced by an equivalent amount of non-specific nitrogen. The latter (equal amounts of glycine and diammonium citrate) could constitute up to 20% of the basic diet in all 9 subjects without undesirable consequences.

A dependence of the effectiveness of the utilisation of non-specific nitrogen on the total nitrogen level has been noted[67]. This observation was confirmed also by Kies et al.[68]: each of 6 young men received 4 g, 6 g, and 8 g of total nitrogen per day during 3 experimental periods, each lasting 12 days, 1.12 g of nitrogen being in the form of all 8 essential aminoacids, the non-essential aminoacids cystine and glycine, and diammonium citrate. The nitrogen balance was negative with 4 and 6 g of total nitrogen. An increase of nitrogen intake from 4 to 6 g reduced the nitrogen deficiency in 4 out of 6 cases, while an increase of the intake from 6 to 8 g improved the balance in all cases. Kies et al.[69] investigated the optimum amounts of non-specific nitrogen for the retention of nitrogen by the organism of adult human beings under conditions where the essential aminoacids were provided by whole cereal protein. Best retention of nitrogen was achieved when the level of total nitrogen was 12.68 g per day, 6.0 g comprising non-essential nitrogen.

Many investigators have paid more attention to the qualitative composition of non-essential nitrogen than to

its quantitative amount in the diet. It has been shown that not all sources of non-essential nitrogen are equivalent[70]. The key position of glutamic acid in nitrogen metabolism has long been known, while the role of hydroxyproline is insignificant. In many cases the addition of serine and cystine actually has a toxic effect[71].

The inclusion of asparagine in aminoacid mixtures plays a favourable role in their effective application[72,73]. Urea as a possible source of food nitrogen is also of interest. There are data showing that, like animals, man has the enzyme urease, which cleaves urea to ammonia and carbon dioxide[74].

Snyderman et al.[65] investigated the nitrogen balance and the gain in body weight in children receiving 1.1 g of milk protein per kilogramme of body weight with the addition of urea as a source of non-essential nitrogen. The results showed that the urea additive favoured an increase in body weight and in the retention of nitrogen. At the same time urea has been found to have a toxic effect on the human organism[75]. Despite these findings, urea will probably not find wide application in synthetic diets for man.

One may assume that, although the role of non-essential aminoacids in protein nutrition has been investigated in fair detail on animals and man [65,68,76], the determination of a quantitative relation between essential and non-essential aminoacids in the diet requires further work.

VI. AMINOACID MIXTURES TESTED ON MAN

Harker et al[77] suggested that, in a study of the effect of the balance in mixtures, the latter must be constituted on the basis of the composition of the tissues and body plasma. The investigation of various combinations of aminoacid mixtures, made up in proportions according to the natural proteins in human nutrition selected as models, has been the subject of numerous publications. Thus, in experiments on 6 women, Kirk et al.[78] demonstrated a higher effectiveness of a mixture of aminoacids in the proportions in which they are contained in milk proteins and in peanut oil compared with the effectiveness of the set of aminoacids proposed by FAO. In analogous experiments on the same number of female patients, Leverton and Steel[26] did not find any difference in the retention of nitrogen for two aminoacid diets: one based on the FAO standard and the other based on the composition of oat protein with the addition of limiting aminoacids. A similar comparison was also made by Swendseid et al.[79] They investigated on 10 young women (18–25 years) the effect of diets made up of a mixture of pure aminoacids according to the FAO standard and on the basis of the composition of the chicken egg. The results are presented in Table 3.

Best retention of nitrogen was observed for the aminoacid mixture based on the egg composition but the differences in the balances are small for the two mixtures. A clear difference between men and women as regards the requirement for total essential nitrogen has been found. In addition, the authors confirmed in experiments on women their previous observations on men, namely that the requirement for essential nitrogen is in no way related to body weight. The limits of the requirement for essential aminoacids established are between 0.65 and 0.85 g per day for women and between 1.0 and 1.3 g per day for men. However, it is so far unknown whether these differences are associated with different requirements for all these aminoacids or only with any one of them.

Clark et al.[81] showed that the requirement for lysine is the same for both sexes. Thus it is possible that the requirement for essential aminoacids in man is greater than in women owing to certain specific aminoacids.

Other investigators[80] showed that an increase in the content of essential aminoacids in the diet of 6 healthy males from 1.1 to 5.5 g per day (for an overall daily dose of 6 g of nitrogen) was accompanied by a progressive increase in the retention of nitrogen in the organism (on average by 1.9 g of nitrogen per day).

Table 3. The proportions of aminoacids and the daily intake of essential aminoacids based on the FAO composition and the set of aminoacids in egg protein.

L-Aminoacids	Aminoacid : L-tryptophan ratio		Tryptophan intake = 240 mg	
	FAO	egg	FAO, g/day	egg, g/day
Tryptophan	1.0	1.0	0.24	0.24
Isoleucine	3.0	3.7	0.72	0.89
Leucine	3.4	5.4	0.81	1.30
Lysine	3.0	5.4	0.72	1.09
Methionine and cystine	3.0	3.7	0.81	0.99
Phenylalanine and tyrosine	4.0	4.7	0.96	1.13
Threonine	2.0	3.1	0.48	0.74
Valine	3.0	3.9	0.72	0.93
Total essential nitrogen	—	—	0.63	0.86

In experiments on young men, Watts et al.[82] compared the effectiveness of three sets of aminoacid diets: (1) a diet based on the FAO standard: (2) a modified FAO diet; (3) a diet based on the wheat flour protein. The total nitrogen intake was 10 g in all cases. It was shown that the first two diets have the same biological value. When comparable amounts of lysine, a limiting aminoacid in wheat flour, were ensured in the FAO diet and in the diet based on the wheat flour model, the retention of nitrogen in both groups of men was the same. The limiting requirement for total essential nitrogen ensuring a slight positive nitrogen balance in men was established in this series of experiments as between 0.63 and 0.84 g per day, i.e. less than shown by Swendseid but higher than the minimum requirement according to FAO, which is suggested as 0.48 g per day.

According to the data of Swendseid et al.[83], the nitrogen balance in people receiving essential aminoacids in the same proportions as in plasma proved to be negative. It was established that in plasma the concentrations of valine and lysine are relatively higher than in food proteins and the contents of isoleucine and leucine are lower, and that this probably does not constitute optimum conditions for the anabolic processes in the organism.

As an example of an aminoacid diet successfully employed, we may quote that tested by Clark et al.[84] Apart from the essential aminoacids (taken in the proportions specified by Rose), the diet contained 130–140 g of white flour (in the form of biscuits and cake) and also dehydrated milk, cornstarch, sugar, and preserved fruit. The overall calorie content was 2100–3250 kcal.

Non-essential nitrogen (mg per day):

arginine	-620	aspartic acid	-850
histidine	-330	glycine	-580
alanine	-490	serine	-800
proline	-1820	glutamic acid	-5810

The amount of total nitrogen in different series of experiments was 4.5, 6, and 9 g. The amount of the basic mixture of essential aminoacids was increased by factors of 1.0, 1.5, 2.0, and 2.5 and the corresponding mean nitrogen balance was +0.07, +0.22, +0.56, and +0.72. It was found that a daily dose of total nitrogen of both 6 and 9 g is quite sufficient to maintain a positive nitrogen balance, while 4.5 g is clearly inadequate.

Table 4. An aminoacid diet for children (12 year old boys).

Aminoacid	Daily intake, g	N content, g	Aminoacid	Daily intake, g	N content, g
Essential L-aminoacids			Non-essential aminoacids		
Isoleucine	1.00	0.107	Alanine	9.22	1.449
Leucine	1.50	0.160	Arginine	10.81	3.476
Lysine	1.60	0.307	Aspartic acid	10.76	1.132
Methionine	0.80	0.075	Glutamic acid	10.76	1.024
Phenylalanine	0.80	0.068	Na glutamate	12.50	1.035
Threonine	1.00	0.118	Glycine	7.65	1.420
Tryptophan	0.12	0.017	Histidine	1.00	0.271
Valine	0.90	0.108	Proline	4.61	0.561
			Serine	6.92	0.922
			Total nitrogen		12.250 g

In their subsequent investigation Clark et al.[85] studied the effect of an increase of the amount of lysine in the mixture on the retention of nitrogen. The following amounts of lysine were added to the mixture (in place of the previous 1780 mg of lysine per day): 2900, 1800, 2700, and 3600 mg per day. The best retention of nitrogen was noted when the level of lysine was 3600 mg per day. Very valuable data have been presented by Nagakawa et al.[86], who investigated synthetic aminoacid diets on children. In earlier studies by these workers the minimum requirement by school age children for each essential aminoacid, determined separately, was established[87]. Then mixtures of the same aminoacids were made up. Tests were made on 5 boys, 10–12 years old, and were continued for 24 days. The basic diet contained a mixture of aminoacids, corn starch, corn and olive oil, mineral salts, and vitamins. The entire experiment was carried out in two periods: during the first period the total nitrogen intake was 12.25 g and during the second 10.23 g. The energy intake was between 53 and 75 kcal per kilogramme of body weight. The data are presented in Table 4. All the children remained healthy, retaining a constant weight and a good appetite. The average nitrogen retention varied from +0.68 to +1.36 per day. But, as stressed by the authors, a simple positive nitrogen balance is not sufficient for children, who require additional nitrogen for growth and development.

If one bears in mind that the body of 10–12 year old boys contains 3% of nitrogen and that they gain 3 kg in weight per year, the retention of nitrogen should increase by 90 g annually, i.e. by +0.25 g per day. However, an additional 50%, i.e. a total of +0.38 g per day, must be added as a reserve.

Comparison of the data obtained by these workers with the value +0.38 g per day shows that the aminoacid mixtures tested are quite suitable to support the life of children at the normal level.

The necessity for the presence of arginine in the diet is still questionable. The removal of arginine from the diet did not affect the nitrogen balance and also did not give rise to any clinical disturbances. As regards histidine, the authors do not share the view of Albanese, who believes that this is an essential aminoacid for children. The absence of histidine from the diet for 15 days of the experiment did not affect the nitrogen balance.

Cabalska[88] also demonstrated the successful application of aminoacid diets in the feeding of children. Mixtures of aminoacids in the feeding of unweaned infants proved to be particularly effective[89].

Abernathy et al.[90] investigated the nitrogen balance in 58 girls aged 7–9, whose daily doses of total nitrogen amounted to 86–460 mg per kilogramme of body weight. The authors present data concerning the minimum level of essential aminoacids which must be provided with the diet to maintain the nitrogen balance at the normal level (in milligramme per kilogramme of body weight per day):

isoleucine	-24	phenylalanine	-28
leucine	-45	threonine	-20
lysine	-29	tryptophan	-4.9
methionine + cystine	-21	valine	-31

These data were obtained on at least 6 subjects whose daily nitrogen intake was 104–135 mg per kilogramme of body weight.

The American Company Schwarz Bioresearch Inc. is marketing synthetic diets, which consist of aqueous solutions of chemically pure ingredients with a 50% content of dry substances. They are designed for the experimental feeding of both laboratory animals and human beings. The diets are sold in bottles or sealed tubes and if desired may be flavoured. Table 1 gives the composition of one of the diets used for human nutrition. Its calorie content is 1.9 cal ml^{-1}. The specific gravity of the solution is 1.18–1.20 and its pH is 4.85. In the preparation of diets of this kind, the order in which the components are dissolved is very important.

VII. AMINOACID IMBALANCE, ANTAGONISM, AND TOXICITY

When artificial aminoacid diets are made up, particular attention must be paid to the study of the phenomenon of the so called imbalance—the breakdown of the optimum proportions of the aminoacids in the diet, which may arise both in the presence of an excess and a deficiency of a particular aminoacid. The problem of imbalance was investigated in very great detail by Harper and Rogers[91-94]. The imbalance is expressed in a series of symptoms characteristic of a disturbance in nutrition, namely in the arrest of the growth of young organisms and a disturbance of the nitrogen equilibrium in adult organisms, in the fatty degeneration of the liver, in an increase of the number of leucocytes in the blood, in albuminuria, and frequently in convulsions, vomiting, nausea, and other undesirable symptoms.

Some workers believe that an imbalance occurs also when even a slight excess of one or several aminoacids is added to the diet. Such an imbalance is usually less dangerous than in the absence of a particular aminoacid. Harper does not regard such a state as imbalance at all but attributes it to the antagonism and toxicity of aminoacids.

Sauberlich[95] made a comparative study of the toxicity and antagonism of 19 aminoacids fed under different conditions to young weanling rats. All 19 aminoacids were added in an amount of 5% of the weight of the diet, at a low overall nitrogen level. With the exception of alanine, all the aminoacids caused an arrest of growth to different extents.

An excess of methionine caused the most acute toxic effect. It is followed in decreasing sequence by tryptophan, aspartic acid, histidine, tyrosine, phenylalanine, cystine, leucine, valine, isoleucine, glycine, asparagine, arginine, lysine, and threonine. Glutamic acid, proline, and serine caused only a slight arrest of growth.

Antagonism can also occur in the interaction of the following pairs of aminoacids: leucine–isoleucine, isoleucine–valine, isoleucine–phenylalanine, phenylalanine–valine, phenylalanine–threonine, arginine–lysine.

The inclusion of an excess of leucine in a casein diet[94] arrests growth. The addition of isoleucine and valine, neither of which is limiting in this diet, prevents or decreases the arrest of growth, while the addition of threonine, a limiting aminoacid, does not have an effect. The absence of a response to the addition of the limiting aminoacid makes it possible to distinguish antagonism from imbalance. Thus antagonism constitutes the elimination of a harmful effect of an excess of one aminoacid by another with a similar structure, which, however, is not limiting in the given diet.

By virtue of the similarity of their structures, the antagonistic aminoacids probably interfere with one another during transport into the cells and disturb the enzyme equilibrium necessary for protein synthesis.

The toxic responses of the organisms are variable, including the cessation of growth and also irreversible functional and organic disturbances in many organs. Thus a dietary excess of tyrosine (more than 3%) causes an acute affection of the eyes and paws of young growing rats[94]. An excess of methionine completely suppresses growth and causes the atrophy of the cells in certain organs. An excess of phenylalanine interferes with the function of the brain[95].

Doolan et al.[96] observed a severe toxic response in man, expressed in ammonia intoxication following the intravenous injection of a 5% solution of glycine.

There are data[97] showing that sodium monoglutamate, widely used in the Chinese and Japanese cuisine as a taste improving additive to various dishes, causes an illness called the "Chinese restaurant syndrome" expressed in headache, a burning sensation in the stomach, and an increased [blood] pressure. This effect of sodium glutamate is associated with a specific dose. There exist appreciable deviations in the oral threshold doses for different individuals. The syndrome is caused by the following substances: sodium monoglutamate (3 g), potassium mono-L-glutamate (4 g), DL-glutamic acid (5 g), and L-glutamic acid (5 g). The syndrome is not caused by sodium mono-D-glutamate (7 g), sodium mono-L-aspartate (5 g), sodium chloride (10 g), and glycine (5 g). After the intravenous administration of sodium monoglutamate the symptoms occur even with a dose of 50 mg. However, there are doubts whether these may not be the effects of the enhanced sensitivity of the test subjects.

Bearing in mind that L-glutamic acid is a normal metabolic product, the official international medical organisations object to any limitations to the use of sodium glutamate as a taste additive[98].

The above examples of the effect of the toxicity of aminoacids on animal and human organisms make it necessary to refine the dosage in such a way that acute toxicity does not occur. Acute toxicity is understood as entailing the death of all the animals receiving the lethal dose (LD) of aminoacids. The dose which leads to the death of 50% of the animals receiving the test diets is also regarded as lethal, is denoted by LD_{50}, and is defined as follows:

$$LD_{50}=x_s-d\,(\Sigma p-{}^1/_2)^{99},$$

where x_S is the dose for which all the animals die, d the interval between the specified doses, p the ratio of the number of dead animals to the particular dose, and Σp the sum of all the ratios of the numbers of dead animals to all the doses administered to them[99].

As long ago as 1955, Greenstein and coworkers[100] put forward the problem of acute toxicity in the comparison of L- and D-forms of aminoacids. Examples of the comparative toxicities of the DL-, D-, and L-forms of certain aminoacids are presented below:

Aminoacid	LD_{50}, g kg^{-1} for		
	DL-	L-	D-
Methionine	5.95 ± 0.04	4.3	5.2
Threonine	5.85 ± 0.04	3.1	5.3
Valine	6.25 ± 0.05	5.4	6.1

Molle[99] noted that, in respect of acute toxicity, racemic forms are less toxic than the L-forms. On the basis of numerous experiments on laboratory animals, the author concludes that even high doses of the D-isomers have a less toxic effect than the corresponding L-forms. These conclusions are in conflict with the views of Elvehjem[101], who attributes especially high toxicity to racemic aminoacids[101].

Probably D-isomers do not have any unfavourable effects and are simply unused by the organism. Sauberlich also showed that the D-isomers are less toxic than the L-forms. However, DL-aspartic acid has a more harmful effect than the L-isomer. The L- and D-forms of tryptophan have the same toxic effects[95].

Studies on these lines should be continued in the first place, since large-scale application of aminoacids in the food industry will become possible only after an accurate determination of the aminoacid norms in the diet which do not give rise to any acute or toxic effects.

Shtenberg and Ignat'ev[102], who examined the principles of the study of toxicity, recommend that for greater reliability the experiments be performed on three animal species, one of which must be a rodent. It is necessary to test a large number of animals in each group: not less than 100 mice, 50 rats, 100 chickens, 25 guinea-pigs, 3 dogs, and 15 rabbits. The concluding stage of the investigations should involve experiments on volunteers (10–20 people), who should receive the test diet over a period of 10–30 days.

The observation of the initial stage of the changes occurring in the organism under the influence of the experimental diet is of great interest. In a short experiment on rats, Sanahuja and Rio[103] carried out biochemical studies in order to distinguish the initial stage of the changes due to the intake of a non-balanced aminoacid mixture. An increase in the amount of protein, amino-nitrogen, and the content of threonine in the liver was

noted. Probably the initial imbalance is associated with a more rapid protein synthesis in the liver and also with an increase of the glycogen content in the latter. The same phenomenon was also observed by other workers[104,105].

L-Tryptophan causes the accumulation of neutral fat in the liver in the course of 2.5 h after its introduction into the rat organism. The introduction of other aminoacids such as L-methionine, L-lysine, L-tyrosine, and L-threonine did not increase the amount of fat in the liver. The introduction into the organism of ATP, ADP, AMP, adenosine, or folic acid together with L-tryptophan prevents the generation of fat in the liver. Probably the generation of fat caused by L-tryptophan is associated with a decrease of the amount of ATP, whose effect is suppressed when L-tryptophan is administered.

Hunter et al.[105] observed an increase in the amount of liver glycogen after feeding with added glycine and L-tyrosine. This was eliminated by including D-tyrosine in the diet.

Murata et al.[106] noted a favourable effect of L-threonine (but not D-threonine), introduced in an amount of 0.2% of the weight of the diet, in preventing the accumulation of fat in the liver caused by the dietary imbalance.

The metabolic rearrangement shown as a response to the consumption of a non-balanced aminoacid mixture by man was investigated by Soliman[107]. All the investigators studying the aminoacid imbalance note a favourable effect of protein added to the diet.

In experiments on weaned rats with three protein levels in the diet (6, 9, and 12%), Harper et al.[108] showed that 12% of protein prevents the harmful effect of the excess histidine and tyrosine in the diet. Added protein has a similar effect also in the presence of an excess of methionine and threonine.

A high aminoacid content in the diet does not by itself have a toxic effect[109]. In fact rats can digest large amounts of aminoacids in the presence of 80–90% of protein in the diet without an appreciable arrest in growth. This observation is confirmed by the diet of specific groups of men containing up to 200 g of protein per day. Certain Australians, the Gaucho in the South American prairie, and the Masai tribe in Central Africa retain satisfactory wellbeing on a diet of 250–300 g of protein per day.

A characteristic sign of imbalance is a reduced requirement for food. Sometimes it is difficult to conclude whether the decrease of the effectiveness of the nitrogen intake is linked directly to a toxic effect or whether this is a secondary factor, while the primary factor is the reduced requirement for food.

A stimulation of food intake and growth can be achieved by the introduction of insulin[110] and cortisol[111] and also by maintaining the animal at a reduced temperature[112]. One may conclude from this that a principal cause of the arrest of growth in animals receiving non-balanced diets is a decrease of the requirement for food.

The reduction of the requirement for food can reach up to 50%.[113] Leung and Rogers conclude that the central nervous system probably contains receptors sensitive to the concentration of the essential aminoacids in blood plasma.

Arginine plays a positive role in the utilisation of non-balanced diets[114,115]. It reduces the imbalance caused by an excess of the following aminoacids: lysine, tyrosine, histidine, glycine, methionine, cystine, valine, threonine, isoleucine, and phenylalanine. The addition of arginine in an amount of 0.3–2.0% of the weight of the diet eases the imbalance due to the aminoacids enumerated above but does not eliminate the imbalance caused by tryptophan, leucine, and glutamic acid.

Hepburn and Bradley[31] also confirm the idea that the function of arginine and glutamic acid consists in a weakening of the potential toxicity of ammonia arising on feeding large amounts of aminoacids. In this respect glutamine is more effective than glutamic acid. The attempts to determine the role of arginine in the detoxication of an excess of aminoacids have so far been unsuccessful. After a time the imbalance phenomena decrease, which is evidence of a gradual adaptation of the organism.

VIII. ENRICHMENT OF SECOND-CLASS PROTEINS BY THE ADDITION OF AMINOACIDS

It is also necessary to take into account the aminoacid balance in the addition of synthetic aminoacids to second-class plant proteins, such as those derived from wheat, corn, rice, millet, etc. with the aim of increasing their biological value. Similar additives constitute a valuable contribution by aminoacids to human nutrition.

McPherson has noted[116] that, in order to cover the deficit in food products by 1980, it will be necessary to produce an additional 18 million tons of fat, 9.9 million tons of animal protein, and 11.4 million tons of aminoacids. The total amount of aminoacids necessary for addition to human food in underdeveloped countries is 0.5–1.0 million tons per year. The total consumption of protein in Asia, Africa, and Central America reaches only 48–54 g daily per man, while the minimum requirement is 60 g. The greatest world deficiency is experienced in respect of three essential aminoacids—methionine, lysine, and tryptophan.

In 1966 the American Chemical Society[117] examined widely the problem of the sources of additional protein. The following sources of this kind have been suggested: various oil bearing plants (cotton seeds, peanuts, coconuts, sesame, sunflower, etc.), threshed wheat fractions previously employed as cattle-feed, defatted dry milk, various protein concentrates, such as, for example, fish protein or soya protein concentrate.

The problem of the aminoacid additives was specially examined and their advantages compared with the use of protein concentrates for the enrichment of second-class proteins was noted. Chemically pure aminoacids are added in small amounts and therefore cannot affect the organoleptic properties of cereal proteins. The quality of cereal proteins is then enhanced and they are more easily assimilated owing to the improved aminoacid balance. On the other hand, the amount of additive is smaller than in the case where protein concentrates are added.

The amounts of each aminoacid to be added to human food in practice still requires a more accurate determination.

Prolonged experiments on man can help discover the necessary amounts for such enrichment. Howe and coworkers[118,119] showed that aminoacid additives, including lysine, tryptophan, and threonine, improve the quality of proteins, for example those in cereals, making them equivalent to casein.

The amounts of aminoacids employed vary in the range 0.1–0.4% of the total weight of the diet. Tryptophan is an exception—not more than 0.07% should be taken.

In order to evaluate a particular protein and to establish the aminoacid in which it is deficient, Block and

Mitchell introduced the concept of the "chemical score" of the protein. With the aid of this concept, it is possible to compare the aminoacid composition of any protein with that of a protein adopted as a standard. The whole chicken egg is regarded as an ideal protein both as regards composition and its aminoacid balance. Therefore the percentage content of each aminoacid in the test protein is compared with that in the chicken egg. Then the aminoacid which, in relation to its amount in the egg protein, is present in the smallest quantity is regarded as the first limiting aminoacid of the test protein. Its ratio in the two proteins is in fact the "chemical score" of the given protein.

For example, lysine is present to the extent of 2.7% in wheat protein and 7.2% in egg protein. The ratio $\frac{\text{wheat lysine}}{\text{egg lysine}} \times 100 = 37$. Thus the deficiency of wheat lysine is $100-37 = 63\%$ relative to egg protein.

Yuyst, Arnould, and coworkers[120,121], who for many years have been concerned with the problem of the improvement of the biological value of proteins by the addition of synthetic aminoacids, suggest that, before introducing each additive into the cereal protein diet, one should establish accurately the first limiting factor of the given protein, and this should in fact be the first additive. The same authors showed the effectiveness of the addition of lysine to white flour. If the "white flour–lysine" mixture is treated further with threonine and isoleucine together, the latter have an additional improving effect, but this does not occur if the aminoacids are added separately. The addition of valine, methionine, and cystine together or without lysine did not produce any results. Consequently here a clear non-equivalence of particular aminoacids is shown, which gives rise to the problem of further improvement of the necessary norms in the addition of aminoacids to protein.

Lysine and methionine are now manufactured on an industrial scale and their addition to food does not present difficulties; on the other hand, threonine and tryptophan are obtained only in small amounts.

Nevertheless the advances in the chemical synthesis of all the essential aminoacids give rise to hope that the problem of obtaining cheap aminoacids will be solved in the near future[122]. The techniques used to enrich cereal protein by synthetic aminoacids are various[123].

When cereals are employed in the form of ground flour or granules, the enrichment is carried out directly by mixing in the aminoacids. The added aminoacids should be ground to the same particle size as the bulk of the flour. The technique becomes more complicated when the cereals are employed in the form of whole grains. Crystalline pure aminoacids can then be introduced as granules resembling particular grains. When protein concentrates are introduced, the ratio of the true and artificial grains is 20:1 or 30:1 and when aminoacids are added the ratio is 200:1.

Graham[124] investigated the enrichment of wheat used in the form of grains. He suggests various envelopes and also grain imitation. Lysine is added by spray drying and also by a "steeping" technique. Additional work is required to determine whether this lysine can withstand treatment of any kind (mechanical or thermal) during the preparation of fortified flour.

Pokrovskii et al.[125] investigated the effectiveness of the addition of L-lysine hydrochloride to improve the nutrient value of wheat bread. The optimum dose of the preparation (0.25–0.5%) relative to the total weight of the flour used to make the bread was established. The bread should be baked at a temperature reduced by 20–25°C.

Koz'mina's review[126] deals with the improvement of the nutrient value of the grains and the development of "synthetic" grains. Gololobov[127] deals with the problem of the enhancement of the nutrient value of protein by synthetic aminoacids with the aim of increasing the protein resources not only of backward but also of advanced countries. A successful use of aminoacid additives to cereal proteins in children's diet has been reported by Bressani et al.[128]

Parthasarathy et al.[129] added DL-methionine to the diet of children 8–9 years of age, which led to an appreciable improvement of the biological value of the proteins. In this respect, the hydroxy-analogue of DL-methionine is less effective[130].

Other Indian workers[131] suggest that methionine and lysine be added to children's food comprising a soya bean–sesame mixture.

Cantor and Roberts[132] reported an improvement of the quality of the protein in corn food products. They discussed mixtures of corn with various proteins and aminoacids, particularly lysine and tryptophan. Kies et al.[133] established that lysine is the limiting aminoacid in corn.

In a study of a plant mixture containing 47% of autho-clave-treated chick peas, 35% of defatted sesame flour, and 18% of soya bean flour, Guggenheim and Szmelcman[134] showed that it is less effective than casein. The addition of lysine improves its value. However, its value does not alter on addition of either methionine or tryptophan. The addition of threonine together with lysine did not affect the effect of the latter, while methionine reduced it.

Despite the abundance of studies demonstrating the value of aminoacid additives to second-class proteins, there are also others—for example, Hegsted[135] believes that the use of products of this kind is still untimely and uneconomical. The author voices the fear that there are still no quantitative data concerning the optimum content of aminoacids in a particular diet and that they should not be used, particularly in the food of children.

Apart from being used in the food industry to improve the biological value of cereals, mixtures of aminoacids can also be used to enhance and improve the taste of many food products. The literature quotes aminoacids which, when mixed in appropriate proportions, can produce the taste of the following products: onions[136], crab[137], fish[138], soya sauce[139], and chicken and meat broth[140]. Chemically pure aminoacids have the following intrinsic flavours: none (tasteless) (D- and L-alanine, D- and L-arginine, D- and L-aspartic acid, D-glutamic acid, L-histidine, D- and L-isoleucine, D- and L-lysine, D- and L-proline, D- and L-serine, D- and L-threonine, and D- and L-valine), sweet (D-tryptophan, D-histidine, D-phenylalanine, D-tyrosine, D-leucine, L-alanine, and glycine), bitter (L-tryptophan, L-phenylalanine, L-tyrosine, L-leucine), and with a slight sulphurous flavour (D- and L-cysteine and D- and L-methionine).[141]

IX. AMINOACIDS IN MEDICINE—WITH PARTICULAR REFERENCE TO PARENTERAL FEEDING

The use of aminoacids in medicine must be regarded as a special case of their employment in human food. Pokrovskii notes several applications of aminoacids in medicine[142]. Various aminoacids are used in the therapy of many diseases. L-Lysine is very effective in the feeding of premature babies. L-Methionine, which

exhibits lipotropic activity, is indicated in the treatment of the cirrhosis of the liver.

In addition methionine is used in the surgical traumas of the heart, in the myocardial infarct, and also in thyrotoxicosis. There has been a general accumulation of definite data concerning the effect of aminoacids on cardiac function. Thus DL- and L-methionine and L-leucine intensify cardiac contractions, while aspartic and glutamic acids and arginine have an inhibiting effect[143].

The cause of a number of psychoneurotic disorders is an innate disturbance of the aminoacid metabolism (phenylpyruvic oligophrenia, the glycine disease, argininosuccinicaciduria, and Hartnup disease). L-Glutamic acid is used in the treatment of many psychological illnesses, for example, in epilepsy. Efron[144] quotes a list of 14 diseases caused by a disturbance of the aminoacid metabolism; 12 of these are expressed in psychological disorders. Many of these diseases are susceptible to treatment with the aid of aminoacid diets and by vitamin therapy.

A classical example of the successful application of an appropriate aminoacid diet is the treatment of phenylketonuria[145]. The exclusion of phenylalanine from the diet of patients maintains a normal state.

Artificial aminoacid mixtures are also used to feed patients by the intravenous injection of a solution of these aminoacids, i.e. parenterally. Parenteral feeding is indicated in most cases where feeding *per os* is impossible or endangers life. Experimental clinical studies showed that total parenteral feeding using a mixture of aminoacids, glucose, and lipid emulsions can maintain a satisfactory nutritional state in the majority of patients.

In parenteral feeding one usually employs (1) enzymatic hydrolyzates of various proteins, primarily casein, and (2) mixtures of synthetic crystalline aminoacids in the L- and DL-forms containing all the essential aminoacids and some source of non-essential nitrogen (mainly glycine). The D-forms are usually not utilised by the organism and their inclusion in such mixtures is undesirable.

Aminoacid mixtures have the advantage of purity over hydrolysates (inadequately dialysed enzymatic hydrolysates can contain peptides capable of inducing an allergic response) and also there is a possibility of varying their composition depending on the physiological state of the patient.

As early as 1940, Shohl and Blackfan[146] were the first to use an aminoacid mixture for complete parenteral feeding. Since then, this field of medicine has been successfully developing in a number of countries: Sweden, Denmark, Germany, France, Italy, and Poland[147-155]. In the USSR Latvian scientists have been successfully working in this field under the supervision of A. A. Shmidt[156,157].

In 1960 Geyer[158] published an extensive review on the application of parenteral feeding. Trémolières[159] quotes examples of the most thoroughly investigated aminoacid mixtures for parenteral feeding (Table 5).

The limiting aminoacid in the majority of preparations is isoleucine[160]. The problem of the addition of non-essential aminoacids in parenteral feeding has so far been inadequately investigated.

Satisfactory proportions of the aminoacids, similar to those in first-class proteins such as those of milk, eggs, and meat, have been found in the enzymatic hydrolysate of the yeast *Candida tropicalis* and in the product obtained from it after purification and consisting of a mixture of aminoacids and lower peptides[161].

A synthetic aminoacid mixture marketed by the Japanese firm Ajinimoto Co. under the conventional name "aminoacid substances" is used as a highly nutritive food product (in the form of tablets) or as a substitute for blood plasma (in the form of a sterile solution). The mixture contains 16 aminoacids and its composition is as follows (%):

alanine	6.0-7.4	lysine	11.5-14.5
arginine	4.6-6.0	methionine	1.0-1.2
aspartic acid	5.8-7.4	phenylalanine	4.3-5.3
glutamic acid	9.0-11.8	proline	4.2-5.2
glycine	4.0-4.8	serine	3.5-4.5
histidine	3.2-4.0	threonine	3.0-3.6
isoleucine	4.4-5.4	tyrosine	1.0-1.2
leucine	8.4-10.4	valine	4.1-5.1

Table 5. The most thoroughly investigated aminoacid mixtures for parenteral feeding (aminoacids contents expressed as percentages of the dry substance).

Name	Amigène	Merck soln.	Parenamine	Aminosol	Travamine	Trophysan
Total nitrogen	12.9	13.3	13.7	13.4	12.0	15.2
Amino-nitrogen (% of total nitrogen)	75	100	93	69	65	100
Ash	5.5	1.0	—	—	—	1.2
Arginine	3.2	2.5	3.2	4.8	3.8	—
Isoleucine	4.9	8.0	4.5	3.8	3.0	3.2
Histidine	1.0	4.2	2.0	2.0	2.1	—
Leucine	9.1	16.5	6.0	5.6	7.5	5.1
Lysine	5.1	9.4	5.8	7.0	6.8	7.9
Methionine	2.6	4.0	3.7	2.8	1.1	5.2
Phenylalanine	3.9	4.3	2.8	3.0	3.2	4.4
Threonine	2.9	1.9	2.3	5.2	5.3	3.2
DL-Tryptophan	1.3	0.9	1.3	0.9	1.0	1.9
Valine	5.3	7.0	4.7	4.0	5.8	4.4
Glutamic acid	17.1	1.5	—	10.6	10.9	—
Tyrosine	4.6	0.3	1.4	2.6	0.9	—
Glycine	0.4	23.0	—	5.6	—	59.5
Aspartic acid	4.7	0.2	—	5.2	8.1	—
Proline	6.2	—	—	5.8	—	—
Serine	4.9	—	—	5.8	—	—
Alanine	4.2	—	—	3.8	—	—
Hydroxyproline	1.5	—	—	—	—	—
Cystine	0.3	—	—	2.4	2.1	—

Among non-essential aminoacids, best results are given by glycine and glutamic acid. Furst et al.[147] showed that glycine is a necessary source of non-essential nitrogen when essential aminoacids and arginine are administered. This investigator demonstrated the higher effectiveness of a mixture of crystalline aminoacids compared with hydrolysates in the parenteral feeding of surgical patients, while in healthy people a positive nitrogen balance is most pronounced when casein hydrolysates are administered. He also established that the nitrogen balance increases when a mixture of glycine, L-alanine, and L-proline serves as a source of non-essential nitrogen and therefore he believes that alanine and proline are semi-essential aminoacids, the introduction of which into the mixture for parenteral feeding is necessary.

Table 6 gives the compositions of the USSR preparations for parenteral feeding. The data show that in all the preparations an approximately 50:50 ratio of essential and non-essential aminoacids is maintained[162].

Deligné and Wretlind[163] believe it useful to employ a mixture of these non-essential aminoacids rather than other sources of non-essential nitrogen. Breinlich[164] also thinks it necessary to include in the mixture L-histidine,

L-arginine, and vitamin B, sorbitol, and mineral salts in addition to the eight essential aminoacids.

Heller et al.[150] demonstrated that the aminoacids in solutions prepared from casein hydrolysate are better assimilated than the aminoacid mixtures made up in accordance with the composition of plasma. These data are consistent with the ineffectiveness, mentioned above, of the aminoacid mixture based on the plasma model and designed for peroral feeding.

Table 6. Aminoacid composition of protein hydrolysates produced in the USSR for parenteral feeding.

Aminoacid	Aminoacid composition, g per 100 g of conventional protein				
	Aminopeptide	L-103	TSOLIPK hydrolysate	Aminokrovin	Fibrinosol
Phenylalanine	5.8	6.5	4.6	6.8	4.6
Tyrosine	1.2	2.3	3 9	2.2	3.2
Total aromatics	7.0	8.8	8.5	9.0	7.8
Methionine	1.02	1.1	2.1	1.1	2.1
Cystine	1.83	1.3	1.1	1.1	2.1
Total sulphur-containing acids	2.85	2.4	3.2	2.2	4.2
Threonine	4.6	4.9	3.9	4.7	6.8
Tryptophan	2.1	0.5	0.5	0.4	1.2
Valine	9.3	9.1	7.7	10.8	4.8
Lysine	10.1	13.1	9.3	11.3	12.8
Leucine	11.8	12.7	9.1	13.8	8.2
Isoleucine	1.80	1.4	5.9	1.10	4.0
Total essential aminoacids	49.55	52.9	48.1	53.3	49.8
Arginine	4.9	4.8	3.7	3.4	7.0
Histidine	4.7	6.4	4.1	8.3	5.9
Alanine	8.2	9.4	3.1	10.2	4.4
Glycine	4.5	4.7	2.2	4.8	7.5
Serine	4.8	5.6	3.8	3.9	6.7
Proline	3.6	3.0	11.0	4.7	7.4
Glutamic acid	8.4	6.3	15.0	3.7	5.5
Aspartic acid	9.8	6.3	4.3	4.4	1.7
Total non-essential aminoacids	48.9	46.5	47.2	43.4	46.1
Total	98.45	99.4	95.3	96.7	95.9

As in peroral feeding, when an aminoacid solution is introduced intravenously, the correct ratio of total nitrogen to carbohydrates and fats must be rigorously observed and the amounts must be sufficient for the energy needs of the organism.

---o0o---

Summarising the literature data discussed above, certain fundamental conclusions may be made.

1. Aminoacid mixtures based on the composition of first-class food proteins probably constitute an adequate substitute for meat, milk, fish, etc. proteins. Man can subsist for a long time on a diet containing aminoacids with the addition of fats, vitamins, carbohydrates, and mineral salts. The physiological and biochemical parameters are then maintained at the normal level.
2. It is useful to improve the biological value of plant proteins to the level of highly effective animal proteins by the addition of chemically pure aminoacids. It is then necessary to observe the correct aminoacid balance in the overall fortified protein because the breakdown of such balance is in fact primarily responsible for the inadequacy of a particular diet.
3. The aminoacid mixtures introduced into the organism parenterally in the form of solutions constitute an excellent means for the maintenance of a sick organism incapable of food intake in the usual manner for one reason or another. This does not exhaust the applications of aminoacids in medical practice. There are many diseases which are susceptible to treatment by specially compounded aminoacid diets and by vitamin therapy.

In all cases, before the direct application of aminoacid mixtures in human nutrition, it is necessary to test them carefully on experimental animals and volunteers to avoid toxic or allergic effects of the artificial diet. However, science has now at its disposal data showing that there is no reason to over estimate the toxicity, since it can be avoided by the simultaneous introduction into the artificial mixture of appropriate amounts of arginine and glutamate and also by observing the appropriate balance of all the mixture components. When protein hydrolysates are used as food products, particular attention must be paid to the removal of impurities.

It follows from all the foregoing data that individual aminoacids can be used in human nutrition. They will probably play a significant role in increasing the food resources.

Surface Layer Sorbents in Gas Chromatography

V.G.Berezkin and N.S.Nikitina

The methods of preparation, chromatographic properties, and applications of surface layer sorbents have been examined. Chromatographic columns with surface layer sorbents are characterised by a low value of HEPT (0.4-0.5 mm) and a weak dependence of HETP on the flow rate of the carrier gas and the grain diameter of the solid carrier. Compared with the usual (bulk phase) sorbents, the use of sorbents of this new type makes it possible to shorten the duration of analysis by a factor of 3-15, to decrease the experimental temperature by 30-100 deg, and to extend the range of compounds susceptible to analysis.
The bibliography includes 35 references.

I. INTRODUCTION

The improvement of the separation of compounds with similar properties depends in many ways on the efficiency of the columns employed and therefore an increase in column efficiency is one of the important tasks of modern gas chromatography. One of the principal causes of the spreading of chromatographic zones, particularly at high carrier gas flow rates, is the resistance to mass transfer, the magnitude of which is known to depend on the grain diameter of the sorbent employed.

The sorbents used in gas chromatography usually consist either of a solid carrier covered more or less uniformly throughout the entire bulk by a liquid phase (the absorbent) or a porous adsorbent, the adsorption properties of which are also approximately the same throughout the bulk of the grain. During recent years sorbents in which the active substance (the sorbent) are not uniformly distributed throughout the bulk of the grain but only on its "outer" surface have come to be used in gas chromatography; the active substance is not present in the bulk of the grain and consequently the compounds chromatographed are not sorbed there. The sorption processes in such sorbents occur only in a surface layer of small depth equal to the depth of the layer of the active sorbent. The resistance to mass transfer for a sorbent of this type is reduced compared with the usual bulk phase sorbents, since the length of the diffusion path into the depth of the grain is reduced. Consequently, the duration of diffusion τ, which is now determined no longer by the grain diameter of the sorbent d but by the thickness of the active layer d_r, is also shortened. We shall estimate the shortening of the diffusion time assuming that $d = 0.3$ mm and $d_r = 0.05$ mm. In this case

$$\frac{\tau_{bulk}}{\tau_{surf}} \simeq \frac{d^2}{d_r^2} \simeq \frac{0.3^2}{0.05^2} \simeq 30.$$

Thus the use of surface layer sorbents should lead to an improvement of the efficiency of the chromatographic column.

In general sorbents with a surface-active layer may be called surface sorbents, in contrast to the usual bulk phase sorbents.

We believe it is desirable to classify surface sorbents on the basis of the characteristics of the active porous layer in accordance with the scheme in Fig. 1. The surface layer sorbents discussed here are divided into two types based on the type of the solid carrier employed, which can be either uniformly porous or can have a solid impermeable nucleus (for example, porous diatomaceous carriers or glass beads). Depending on the type of carrier, the methods of preparation and certain properties of sorbents of types I and II will differ.

Surface layer sorbents of type I (with an active porous layer on the surface of a solid nucleus) were first proposed by Halasz and Horvath[1] in 1962. Sorbents of type II were first obtained by Cremer in 1959, who introduced carbon black into the pores of Sterchamol to measure its specific surface[2] by the gas-chromatographic method. Granulated surface-porous sodium-borosilicate glasses were obtained by Zhdanov et al.[3] and etched ordinary glass beads were prepared by Ohline and Yoyola[4].

The possibility of using powdered adsorbents introduced into the pores of silica gels for gas-chromatographic analysis was first stated by Vasil'eva et al.[5] Surface layer sorbents of type II were first employed in gas-chromatographic analysis by Bombaugh[6] for the separation of air on molecular sieves deposited on Chromosorb and subsequently the method was employed by Keiser[7] to separate petrol fractions on graphitised carbon black deposited on Chromosorb.

A surface layer sorbent of type II was first obtained for gas-liquid chromatography by the authors of the review[8]. The use of surface layer sorbents gives rise to new possibilities in gas-chromatographic analysis and in the application of gas chromatography to the measurement of various physicochemical characteristics. This review deals with the methods of preparation of surface layer sorbents, the characteristics of the gas-chromatographic separation on them and their principal applications.

II. METHODS OF PREPARATION OF SURFACE LAYER SORBENTS

Surface layer sorbents can be used to achieve one of the familiar types of chromatography (gas–solid, gas–liquid, gas–liquid–solid, etc.)

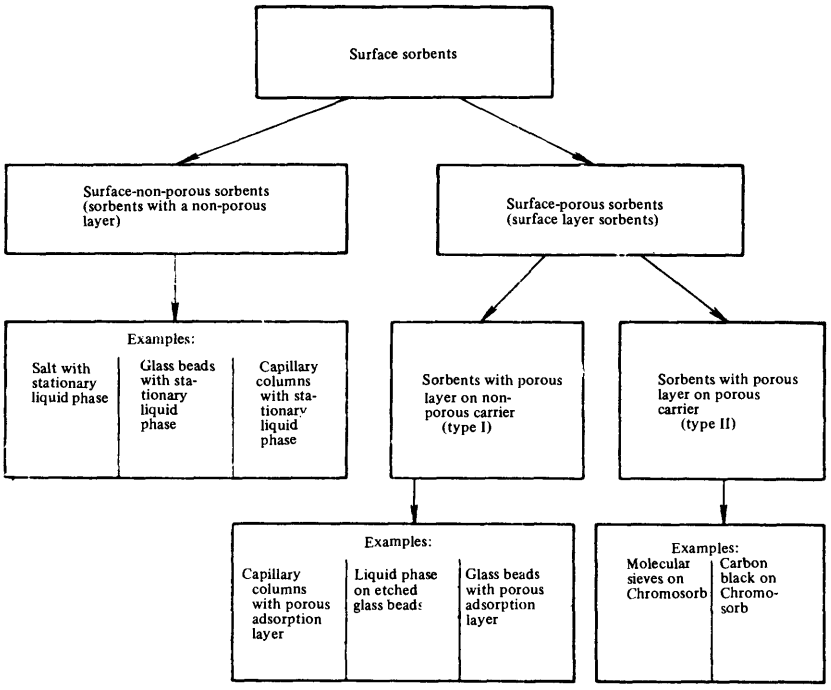

Figure 1. Scheme for the classification of surface sorbents in gas chromatography.

Halasz and Horvath[9] prepared sorbents of type I by precipitating a wide variety of adsorption materials from solutions on to the surface of non-porous glass or metallic beads, metallic spirals, and other carriers. The active sorbents employed were powdered alumina, aerosil, carbon black, or metal oxides with a stationary liquid phase [for example iron(III) oxide with polyesters]. It was found[9] that the particle size in the formation of a porous layer of metal oxides should be less than 0.1 μm. In order to obtain a more stable porous sorption layer, the glass beads were sometimes coated by a thin layer of varnish[9].

In gas–liquid chromatography a porous layer is obtained on beads using either glass microbeads (diameter 1 μm) or diatomaceous earth (diameter up to 10 μm), which are deposited together with the stationary liquid phase in a solvent. In this case the porous layer is retained on the beads by the surface tension forces of the liquid phase[10,11].

Another method for the preparation of sorbents of type I was described by Pope[12], who obtained an active porous layer on the surface of polyethylene beads on heating them to 160–170°C with graphitised carbon black. The polyethylene softens and the carbon black coats its surface.

Surface layer sorbents of type II are prepared using finely dispersed sorbents with a particle size up to 10 μm and solid coarsely porous carriers with a low specific surface: Chromosorb W, Chromosorb G, Celite-545. On mechanical shaking with solid carriers, finely dispersed adsorbents (molecular sieves, carbon black, activated charcoal, aerosil, etc.) enter into the macropores of the carriers and are retained there by adhesion forces, which determine the stability of the surface layer of the sorbent. Surface layer sorbents have been obtained in this way after prolonged mechanical shaking[6,7].

In order to determine the time required to obtain a surface layer sorbent, the variation of the amount of finely dispersed adsorbent deposited on the solid carrier with the duration of mechanical shaking was investigated[13]. This investigation was carried out on graphitised carbon black (particle size less than 1 μm) and Chromosorb W in proportions of 1 : 5. The amount of deposited carbon black was determined by elemental analysis for its carbon content. The deposition of the finely dispersed adsorbent (carbon black) in the pores of Chromosorb W terminates after 10–15 min (Fig. 2). Thus the duration of the preparation of the surface layer sorbent is as a rule short.

In the preparation of a surface layer sorbent of type II for gas-liquid chromatography, a stationary liquid phase is deposited in the usual way from a volatile solvent on a finely dispersed solid carrier with a particle size up to 10 μm, which may be obtained by sedimentation. Then the resulting finely dispersed sorbent is introduced into the macropores of an inert solid carrier by the mechanical shaking of the mixture for 10 mins.[14]

Chromosorb W or G modified by dichlorodimethylsilane or hexamethyldisilazane may be used as the inert solid carrier. Although these carriers are inert in relation to hydrocarbons and other non-polar compounds, it is recommended that for polar compounds the silylated Chromosorbs be additionally modified by a small amount (0.1%) of a polar liquid phase. Microscopic study of the distribution of the finely dispersed sorbent in the grains of a solid carrier showed that the small sorbed particles enter into the macropores of the solid carriers more or less uniformly over the entire "outer" surface, forming a surface layer to a depth of 20–50 μm with about 20% of the sorbent[13]. Another microscopic study[7] also showed that the active sorbent forms a surface layer, but its depth was

found to be 1–3 μm, the content of the active sorbent on the carrier being 5%. On surface layer sorbents of type I, the thickness of the surface layer varies between 1 and 100 μm.[9]

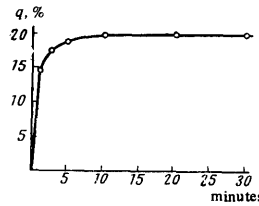

Figure 2. Variation of the amount of graphitised carbon black q deposited on Chromosorb W with time during mechanical shaking.

Thus a number of entirely satisfactory simple methods for the preparation of surface layer sorbents have now been developed.

III. CHARACTERISTICS OF GAS-CHROMATOGRAPHIC SEPARATION ON SURFACE LAYER SORBENTS

1. Retention Characteristics

In gas chromatography the retention values are some of the most important characteristics of the substance chromatographed. The retention on surface layer sorbents is in general due to the retention on the active sorbent and on the solid carrier. Therefore the reduced retention volume V_n for compounds chromatographed on surface layer sorbents can be represented by the following equation for gas-adsorption chromatography:

$$V_N = K_a S_a + K_c S_c \qquad (1)$$

or, for gas-liquid chromatography:

$$V_N = K_l V_l + K_c S_c \ , \qquad (2)$$

where K_a is the gas–active solid adsorbent partition coefficient, S_a the surface area of the absorbent in the column, K_c the gas–solid carrier partition coefficient, S_c the surface area of the solid carrier in the column, K_l the gas–stationary liquid phase partition coefficient, and V_l the amount of liquid phase in the column.

The above equations show that adsorption on a solid carrier can make a definite contribution to the retention volume (if necessary this contribution can be calculated from the equations). Therefore, in the preparation of surface layer sorbent it is desirable to employ inert solid carriers for which $K_c S_c \ll K_a S_a$ ($K_l V_l$).

Comparison of the relative retention times on sorbents of type I and bulk phase sorbents[9,15] revealed a small difference between the retention times.

With only a small contribution by adsorption on the solid carrier, the relative retention volumes of non-polar and weakly polar components on surface layer sorbents of type II correspond to the relative retention volumes on bulk phase sorbents (Table 1). This is the basis of the application of all the relations known for the identification of compounds chromatographed on bulk phase sorbents and the available tabulated relative retention values also to surface layer sorbents.

However, for polar compounds or for sorption-active carriers, such identification must involve an estimation of the contribution to the retention volume of the degree of adsorption of the substances chromatographed on the solid carrier.

Table 1. Relative retention volumes of hydrocarbons on bulk phase and surface layer sorbents of type II.

Substance analysed	Sorbent: squalane on Chromosorb W				Substance analysed	Sorbent: CaA molecular sieve	
	5% squalane		10% squalane				
	bulk phase	surface layer*	bulk phase	surface layer*		bulk phase	surface layer (CaA on Celite)
Benzene	0.18	0.19	0.18	0.18	Oxygen	0.31	0.32
Toluene	0.54	0.60	0.53	0.53	Nitrogen	1.00	1.00
n-Octane	1.00	1.00	1.00	1.00	Methane	1.81	1.75
n-Nonane	3.00	2.94	3.00	3.00	Carbon monoxide	5.30	5.60

*Surface layer sorbent: finely dispersed Chromosorb W with 5% (or 10%) of squalane deposited on Chromosorb W with a grain size of 0.4–0.25 mm.

2. Efficiency of Chromatographic Columns

The efficiency of chromatographic columns is characterised by the height equivalent to the theoretical plate (HETP), which is also determined by the type of sorbent used. Application of surface layer sorbents makes it possible to reduce HEPT, i.e. to increase the efficiency of the column compared with those containing bulk phase sorbents.

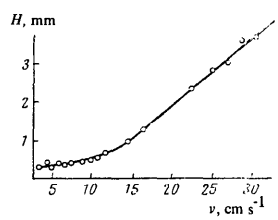

Figure 3. Variation of HETP (H) with carrier gas flow rate (v) for 3-chloropentane on a surface layer sorbent of type I. Experimental conditions: 100 × 0.2 cm column; temperature 90°C; carrier gas–nitrogen; flame ionisation detector.

In all studies dealing with surface layer sorbents of type I, a high efficiency of the columns filled with them was demonstrated. Thus Halasz and coworkers found that the minimum value of HETP on a column with glass beads and a porous adsorption layer is 0.4–0.5 mm.[16] In another study[15] the variation of HETP with the flow rate of the carrier gas for 3-chloropentane on a sorbent of this type is presented (Fig. 3). The data quoted show that HETP increases slightly as the flow rate rises to 15 cm s^{-1}, the minimum HETP being 0.38 mm. The efficiency of a column with polyethylene beads and graphitised carbon black was very high (HETP = 0.5–0.6 mm).[12]

Columns filled with glass beads on the surface of which diatomaceous earth with a stationary liquid phase had been

deposited are characterised by a minimum HETP = 0.8–1 mm.[10,11] It has been shown[4] that a column with etched glass beads (depth of pores 0.4 mm) has an efficiency higher than that of a column with unetched glass beads (Fig. 4).

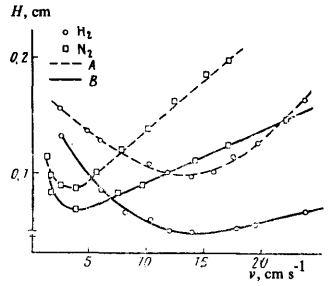

Figure 4. Variation of HETP (H) with carrier gas flow rate for n-nonane[5]: A) column with non-porous (unetched) glass beads; B) column with etched glass beads.

The efficiency of a column with a surface layer sorbent of type I has been compared with one containing a bulk phase sorbent only for porous glasses[3,17,18], and it was shown that the number of theoretical plates for the column with a surface-porous glass is higher by a factor of 2.6–7.5 compared with the column in which the glass is porous throughout the bulk phase, the duration of analysis of hydrocarbon gases being reduced by a factor of 8.

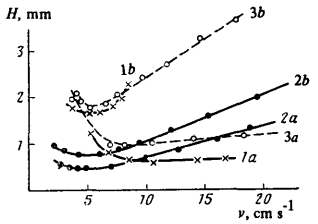

Figure 5. Variation of HETP (H) with carrier gas flow rate (v): 1) n-octane on graphitised carbon black; 2) toluene on Chromosorb W with 10% of squalane; 3) methane on CaA molecular sieves; a) surface layer sorbent; b) bulk phase sorbents.

The dependence of HETP on the mean linear flow rate of the carrier gas was investigated for columns with surface layer sorbents of type II and for the corresponding columns with bulk phase sorbents[14,19–21]. Typical relations between HETP and the carrier gas flow rate for gases on CaA molecular sieves deposited on Celite, for hydrocarbons on carbon black deposited on Chromosorb W, and for hydrocarbons on finely dispersed Chromosorb W on which squalane had been deposited are presented in Fig. 5.

The minimum HETP in these experiments on a column 4 mm in diameter was 0.45–0.50 mm (using a flame-ionisation detector) and 0.8–1.00 (using a katharometer).

A study of the dependence of HETP on flow rate established that, for columns with surface layer sorbents, (1) HETP is lower by a factor of 1.2–1.8 at the optimum carrier gas flow rate and by a factor of 1.7–3 in the range of higher flow rates compared with bulk phase sorbents, (2) the optimum carrier gas flow rate is high, particularly when surface layer sorbents are employed in gas-adsorption chromatography, and (3) the dependence of the efficiency on the rate is less pronounced than when bulk phase sorbents are employed.

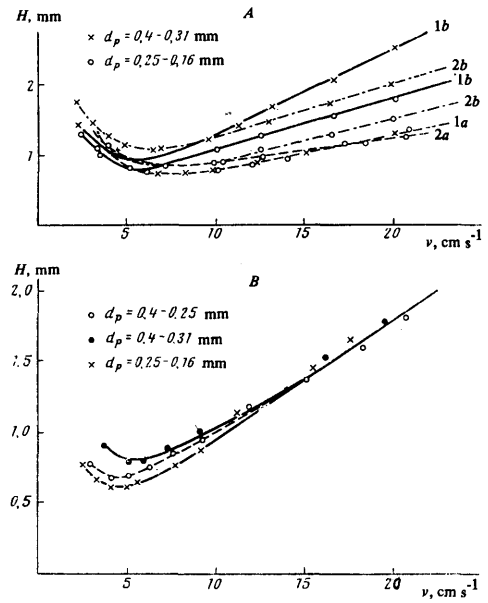

Figure 6. Variation of HETP (H) with carrier gas flow rate for n-octane (curves *1*) and toluene (curves *2*) on sorbents with different grain diameters. A): a) surface layer sorbent; b) bulk phase sorbent; detector–katharometer; carrier gas–helium; B) surface layer sorbent; n-octane; carrier gas–nitrogen; flame ionisation detector ("Khrom-2").

The effects of the grain diameter of the solid carrier on the chromatographic column efficiency has been investigated[14,19]. When surface layer sorbents of type II are used, a slight change in efficiency as a function of the carrier gas flow rate is observed for sorbents with different grain diameters only at low flow rates, while at high flow rates, where the spreading is determined by the mass-exchange kinetics, the difference in efficiency becomes smoothed out. The efficiency of columns with bulk phase sorbents measured under the same conditions decreases with the grain diameter (Fig. 6). The reason for this is that not the entire grain but only the surface layer, whose thickness is determined by the depth of the solid carrier pores and does not therefore change with the grain diameter, is involved in the mass-exchange process.

Consequently, with surface layer sorbents of type II, one can use fairly large solid carrier grains, which has

little effect on column efficiency but reduces the resistance to the carrier gas flow and makes it possible to operate at higher flow rates and with longer columns for low pressure differences.

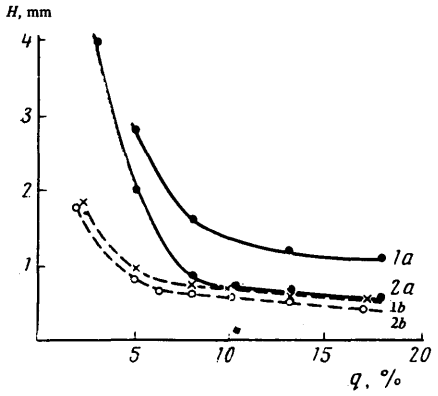

Figure 7. Variation of HETP (H) for toluene (curves *1*) and n-octane (curves *2*) on surface layer sorbents with the content of the active sorbent (g): *a*) column with graphitised carbon black on Chromosorb W; *b*) Chromosorb W with finely dispersed Chromosorb W on which 10% of squalane had been deposited.

The study of the effect on column efficiency of the amount of the active sorbent deposited on the solid carrier showed that, with increase of its content up to 8–10%, the efficiency increases rapidly and then changes only slightly (Fig. 7).

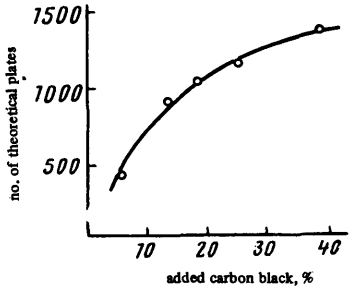

Figure 8. Variation of a number of theoretical plates for n-hexane with the content of carbon black on polyethylene beads[17].

An analogous effect of the amount of active sorbent on the efficiency of the column with a surface layer sorbent of type I was demonstrated in a study[12] where the variation of the number of theoretical plates with the amount of carbon black deposited on polyethylene beads was investigated (Fig. 8). The relation shows that, for low carbon black contents, the number of theoretical plates increases rapidly and then significantly more slowly, starting with about 20% of the black. Thus the dependence of HETP on the amount of active sorbent for surface layer sorbents is of the same type as the dependence of the coefficient of resistance to mass transfer (in the HETP equation for the usual sorbents) on the extraction coefficient[22].

In a study of the efficiency of columns with surface layer sorbents, it is interesting to estimate the contributions of various processes to the spreading of chromatographic zones. For this purpose, it is useful to employ the Giddings equation[23], which agrees well with the experimental data:

$$H = \frac{1}{1/A + 1/c_m v} + \frac{B}{v} + cv \cdot \qquad (3)$$

Here the first term describes the coupled eddy diffusion, the second the molecular longitudinal diffusion, and the third the mass exchange kinetics.

The coefficients of the Giddings equation, determined from the experimental $H = H(v)$ relations by a graphical method[24] for surface layer sorbents of type II and the corresponding bulk phase sorbents in gas-adsorption and gas liquid chromatography, are presented in Table 2, which shows that, when surface layer and bulk phase sorbents are employed, systematic relations between the coefficients of the HETP equation are observed mainly for the coefficient of resistance to mass transfer C, which is lower for surface layer sorbents by a factor of 3–4 in gas-adsorption chromatography and by a factor of 1.8 in gas-liquid chromatography.

Table 2. The coefficients in the Giddings equation for bulk phase and surface layer sorbents of type II.

Sorbent	Compound chromatographed	Expt. conditions: column length, m	Expt. conditions: temp., °C	A, cm	B_2, cm s^{-1}	C_m, s	C, s
Molecular sieve, bulk phase sorbent	methane	1	20	0.080	0.37	0.0120	0.0160
Molecular sieve on Celite, surface layer sorbent	methane	1	20	0.060	0.60	0.0020	0.0038
Aerosilogel, bulk phase sorbent	n-decane	1	120	0.070	0.78	0.0010	0.0173
Aerosilogel on Chromosorb, surface layer sorbent	n-decane	1	120	0.060	0.55	0.0020	0.0053
Carbon on Chromosorb, surface layer sorbent	n-hexane	1	80	0.014	0.12	0.0006	0.0050
Chromosorb W with 5% of squalane, bulk phase sorbent	n-octane	0,8	60	0.020	0,15	0.0020	0.0110
Chromosorb W with 5% of squalane, surface layer sorbent	n-octane	0,8	30	0.024	0.10	0.0030	0.0061

Table 2 lists the overall coefficients C in the Giddings equation reflecting the resistance to mass transfer, which includes the resistance to mass transfer in the gas (mobile) and stationary phases. In the determination of the separate contributions to mass exchange, the Perrett–Purnell method, based on the measurement of the coefficient C for two carrier gases of different types[25], was employed. The separate determination of these contributions has been made for methane on the CaA molecular sieve and for n-octane on Chromosorb W with 10% of squalane. The results are presented in Table 3, which shows that the resistance to mass transfer in the gas phase is lower by a factor of 10 for methane on the molecular sieves and by a factor of 1.7 for n-octane in gas-liquid chromatography. The explanation is that the mass exchange in the gas phase for surface layer sorbents

of type II does not depend on the grain diameter but on the thickness of the layer of the active sorbent which amounts to 20–50 μm according to microscopic measurements, i.e. is much smaller than the grain diameter. Consequently the diffusion path traversed by molecules into the bulk of the grain is shortened, since the active sorbent is located in the surface layer in the immediate vicinity of the gas stream, which accelerates the mass exchange and permits analysis at higher rates, i.e. the duration of analysis is reduced.

Table 3. Coefficients of resistance to mass transfer in gas at stationary (liquid) phases.

Type of Chromatography	Sorbent	Compound chromatographed	Resistance to mass transfer	
			gas phase	stationary phase
Gas-adsorption	CaA on Celite (surface layer sorbent)	methane	0.0002	0.0036
	CaA, bulk phase sorbent	methane	0.0020	0.0140
Gas-liquid	Chromosorb W with 10% of squalane, surface layer sorbent	n-octane	0.0013	0.0022
	Chromosorb W with 10% of squalane, bulk phase sorbent	n-octane	0.0022	0.0029

The increase of the mass transfer coefficient explains the lower minimum HETP, the less pronounced dependence of HETP on the rate, and hence the considerable decrease of HETP at high carrier gas flow rates for surface layer sorbents; hence, these sorbents are useful for rapid analysis.

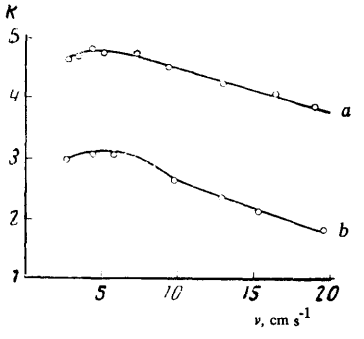

Figure 9. Variation of the separation factor K_1 (toluene–octane) with carrier gas flow rate (v) for surface layer (a) and bulk phase (b) sorbents.

3. The Separation Factor

The real improvement of separation is determined not only by the number of theoretical plates but also by the separation factor, which is one of the principal characteristics determining the usefulness of various sorbents in gas chromatography. The separation factor K_1 is defined by the following equation[26]:

$$K_1 = \frac{\sqrt{2}}{4} K_s \sqrt{N} \quad , \qquad (4)$$

where K_S is the selectivity coefficient and N the number of theoretical plates.

In studies on surface layer sorbents of type I, the separation factor was not as a rule considered as a characteristic of columns with the sorbent. Only in experiments with surface-porous glasses was it shown that the separation factor for hydrocarbon gases is higher by a factor of 1.3 compared with glasses porous throughout their bulk[3].

An experimental comparison of the separation factors for the toluene–octane pair on surface layer sorbents of type II and bulk phase sorbents has been made[14] under the conditions of a constant duration of analysis. Fig. 9 presents the relations between the separation factor and the rate under these conditions. In all cases the separation factor was higher for the surface layer sorbent by a factor of 1.2–1.5 compared with the bulk phase sorbent.

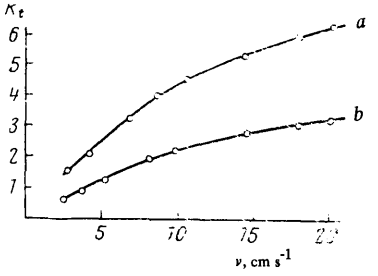

Figure 10. Variation of K_t with the carrier gas flow rate on CaA molecular sieves: a) surface layer sorbent; b) bulk phase sorbent.

Under other comparison conditions (for example, for the same volumes of the sorbent), the time characteristic of the separation factor (K_t) can be usefully employed for the estimation of the separating capacity of surface layer and bulk phase sorbents:

$$K_t = K_1 / t_R \quad , \qquad (5)$$

where K_1 is the separation factor and t_R are the mean elution times of the components for two adjacent peaks.

The separating capacity of columns with molecular sieves in the surface layer and bulk phase versions was estimated by the present authors in terms of the relation between K_t for the nitrogen–methane pair and the flow rate (Fig. 10). Fig. 10 shows that the use of the CaA molecular sieve on Celite as a surface layer sorbent shortens the duration of separation of the gases by a factor of 3 for the same separation factor compared with the bulk phase sorbent. The reduction of the duration of analysis is undoubtedly a valuable advantage of surface layer sorbents.

Thus surface layer sorbents are usually characterised by a higher separation factor and a shorter duration of analysis compared with bulk phase sorbents; they can be used at lower temperatures, which extends the range of compounds susceptible to analysis.

IV. ANALYTICAL APPLICATIONS OF SURFACE LAYER SORBENTS

Surface layer sorbents can be used in the separation of various specific systems in all known versions of gas chromatography. As already mentioned above, the

Table 4. Examples of the applications of surface layer sorbents for the separation of mixtures.

Mixture analysed	Sorbent characteristic	Duration of analysis, min	Conditions of analysis				Refs.
			column length, cm	temp., °C	carrier gas flow rate	detector*	
I. Gas mixtures							
H_2; O_2; N_2; CH_4; CO	CaA molecular sieves on Celite-545 (20 wt.%)	0.2	100×0.4	20	50 cm s^{-1}	K	19, 20
CH_4; C_2H_6; C_2H_4	Surface-porous glass	3	100×0.4	40	7 cm s^{-1}		3
C_3H_8; C_3H_6	Glass porous throughout bulk	24	100×0.4	40	7 cm s^{-1}		3
C_1–C_4 hydrocarbon gases	NaX molecular sieves on Celite-545 (20 wt.%)	18	100×0.3	30—160		FID	19, 20
II. Hydrocarbons							
C_{15}–C_{35} n-alkanes	90% glass beads, 9% iron(III) oxide, 0.9% Carbowax 4000 (monostearate), 0.1% potassium hydroxide	11	200×0.2	190	progr. pressure	FID	27
C_9–C_{16} n-alkanes	Aerosil on Chromosorb G (5 wt.%)	6.5	80×0.4	150	50 ml min^{-1}	FID	21
	Aerosil, bulk phase sorbent	52	80×0.4	150	50 ml min^{-1}	FID	21
C_9–C_{26} n-alkanes	Aerosil on Chromosorb G (5 wt.%)	15	100×0.3	120—300		FID	21
C_6–C_{13} n-alkanes	Graphitised carbon black on Chromosorb R (5 wt.%)	5.5	400×0.2	30—350		FID	7
Aromatic hydrocarbons: trimethylbenzenes, tetrahydronaphthalene, methylnaphthalenes	90% of glass beads, 9% of iron(III) oxide, 0.9% Carbowax 4000, 0.1% of potassium hydroxide		200×0.2	190		FID	15
Terphenyls	Graphitised carbon black on Chromosorb W (20 wt.%)	4	20×0.4	290	10 cm s^{-1}	FID	13
	Granulated graphitised carbon black (bulk phase sorbent)	5.5	20×0.2	360	30 ml min^{-1}	FID	28
cis- and *trans*-Decalins	Graphitised carbon black on Chromosorb W (20 wt.%)	2	100×0.3	120	10 cm s^{-1}	FID	13
	Granulated graphitised carbon black (bulk phase sorbent)	6	200×0.3	210	50 ml min^{-1}	FID	29, 30
α-, and β-isopropylnaphthalenes	Graphitised carbon black on Chromosorb W (20 wt.%)	6	100×0.3	240	12 cm s^{-1}	FID	13
Propyltoluene and xylenes	Finely dispersed Chromosorb impregnated with 15% of a mixture of DS-550 silicone oil and Bentone-245 (60:40) on Chromosorb (16 wt.%)	10	200×0.3	45	60 ml min^{-1}	FID	14

employment of surface layer sorbents has many advantages in the separation of mixtures compared with the usual sorbents. In addition they are characterised by fairly high mechanical strength. This permits the use of programmed temperatures and pressures. Table 4 presents examples of the practical applications of surface layer sorbents for the separation of various classes of compounds. In some cases the compounds were analysed for comparison on bulk phase sorbents.

V. APPLICATIONS OF SURFACE LAYER SORBENTS IN PHYSICOCHEMICAL STUDIES

Surface layer sorbents of type II can be used not only for analytical purposes but also for the measurement of physicochemical characteristics by gas chromatography.

As already stated, a surface layer sorbent of type II was first employed by Cremer[2] to determine the specific surface of carbon black introduced into the pores of Sterchamol, i.e. the first application of the surface layer sorbent in gas chromatography was its employment for physicochemical studies. Indeed, in the investigation of highly dispersed adsorbents by the chromatographic method, when they are used directly to fill the chromatographic column, it is necessary to employ very high pressures in order to achieve the required flow rate of the carrier gas. Therefore, as a rule granules and not the initial powder are employed as packing. The granules are obtained by pressing the powders or by using a binder, but the introduction of the latter into the sorbent composition in general alters its properties. Therefore we believe it simpler, more universal, and more convenient to investigate disperse adsorbents introduced into the pores of solid carriers rather than use specially prepared granules. It is noteworthy that, in the preparation of a column of the same length, a smaller amount of adsorbent is required, which is important in the study of new adsorbents.

Kiselev and coworkers employed a surface layer sorbent of type II to investigate the retention volumes and heats of adsorption of hydrocarbons on graphitised[33] and acetylene carbon blacks[34] and also to determine the specific surfaces of the blacks. A macroporous silica gel with a specific surface of 9 $m^2 g^{-1}$ was used as a solid carrier.

According to Eqn. (1), the interpretation of the chromatographic results is simplest and most accurate when the contribution of the solid carrier to the retention volume is low. Therefore one may recommend as solid carriers macroporous materials with a low specific surface (significantly lower than the specific surface of the disperse adsorbent) on which there is virtually no adsorption of the components investigated. The use of surface layer sorbents has many advantages even in those cases where the preparation of granulated material presents no difficulties. The two methods were compared in the determination of the heats of adsorption of straight-chain alkanes on a surface layer sorbent: NaX molecular sieve[35]. The heats of adsorption obtained with various types of sorbent are virtually identical. In this paper it is also noted that the use of a surface layer sorbent leads to the following possibilities compared with the bulk phase sorbents: (1) the amount of adsorbent may be reduced and very finely dispersed powder may be employed for measurement; (2) the experimental temperature may be lowered (on average by 100 deg); (3) the range of compounds investigated may be extended using higher-boiling substances; (4) measurements may be made under conditions closer to equilibrium owing to the acceleration of mass transfer. It is noteworthy that surface layer sorbents can also be used for the measurement of other characteristics, in particular in the study of kinetics under pulse conditions.

---o0o---

In conclusion we may note that the advantages discovered in many fields of gas chromatography when surface layer sorbents are used and their successful applications permit their recommendation for large-scale employment in chromatographic practice.

Rare-earth Fluorides

L.R.Batsanova

The methods of preparation of simple and double rare-earth fluorides both in the normal, tervalent state and in bivalent and quadrivalent states have been examined. The structures of these compounds, their polymorphic modifications, and the characteristics of the formation of solid solutions are discussed.
The physicochemical properties of fluorine-containing rare-earth compounds have been compared with the type of chemical bonding and the characteristics of the electronic structure of rare-earth atoms. Data are presented on the behaviour of rare-earth fluorides in systems containing the fluorides and oxides of other elements.
The bibliography includes 372 references.

I. INTRODUCTION

In recent years there has been a considerable growth of interest in the study of rare-earth fluorides owing to the development of new applications of rare-earth trifluorides and their compounds with the fluorides of other elements, for example in laser engineering and microelectronics. This requires not only an improvement in the methods of preparation and purification of the fluorides but also the development of ways of growing optical single crystals, refinement of data on their structure, and the elucidation of the structural characteristics of activated fluorides.

An important field of application of rare-earth fluorides is also metallurgy, since in metal thermite reduction the most suitable materials for the preparation of pure metals are in fact the trifluorides [1-5].

The trifluorides are also important in nuclear engineering, analytical chemistry, and the technology of the separation of elements, where use is made of the low solubility of rare-earth trifluorides in water and acids for the separation of the rare earths and isolation of transuranic elements with LaF_3 as a carrier. The comparatively low volatility of the trifluorides at high temperatures constitutes the basis of their application in the separation of uranium as UF_6 from fission products in the course of the regeneration and purification of nuclear fuel [6-8]. Thus knowledge of the chemical and structural characteristics of rare-earth fluorides, of the characteristics of their interaction with the fluorides and other metals, and in general of their behaviour in various systems is important for many branches of modern engineering.

Reviews on rare-earth fluorides deal mainly with an earlier period [9-11] or are concerned only with certain properties of the trifluorides [12], the methods of their synthesis [13,14], or the laser properties of the fluorides [15-17]. Of the publications in recent years, mention may be made

of Toma's review[18] and Brown's monograph[19] on lanthanide and actinide halides.

This review surveys the available information on the chemical and physicochemical properties of rare-earth trifluorides, their compounds with alkali metal and alkaline earth metal fluorides, and rare-earth oxide fluorides and fluorides in which the valence of the rare earth is other than 3. Much attention has been devoted to the structural and crystal-chemical characteristics of these compounds, since they determine many properties important in practice. The problems associated with the laser characteristics of activated fluoride crystals are not discussed, since they are frequently dealt with in the literature, including the chemical literature[15-17].

In this review the rare-earth elements include lanthanides and yttrium.

II. SYNTHESIS AND PROPERTIES OF RARE-EARTH TRIFLUORIDES

1. Preparation of Anhydrous Rare-earth Trifluorides

Anhydrous rare-earth trifluorides are prepared by methods involving the dehydration of products precipitated from solutions of the salts of these elements with hydrofluoric acid or synthesised by fluorinating rare-earth oxides.

1. Hydrofluoric acid precipitates from aqueous rare-earth salt solutions trifluorides containing a certain amount of water[20,21], which depends considerably on the conditions of their precipitation and washing[23-25]. Lanthanum trifluoride almost free from water can be obtained from a solution of the nitrate in 95% ethanol[22].

Hydrated trifluorides lose weight at a temperature as low as 40–60°C,[23,24] but they cannot be dehydrated by heating in air, since water is not completely removed at a low temperature (up to 300°C) and at a higher temperature the trifluorides are partly hydrolysed with formation of oxide fluorides. According to Wendlandt and Lowe[23], most of the water-containing trifluorides lose weight continuously on heating in air from 40° to 900°C and only a few of them (NdF_3, GdF_3) may be obtained by dehydration (350–375°C) without an appreciable contamination by oxide fluorides. The precipitates dried at 100–150°C still contain several per cent of water[26].

In order to prepare the anhydrous trifluorides, the hydrated products subjected to an initial heat treatment at 100–150°C are heated in a vacuum at 300–350°C[2,3,27] or in a stream of hydrogen fluoride and an inert gas[1,2,5,28,29] at 600–1000°C. Sometimes anhydrous trifluorides are prepared by treating their hydrates with an excess of NH_4F or NH_4HF_2, the volatile products being subsequently distilled off[13,30,31].

Heat treatment of hydrated trifluorides enriched in ^{18}O isotope in an inert atmosphere and mass-spectrometric determination of oxygen in the heat-treatment products lead to the conclusion that dehydration terminates at about 500°C without an appreciable formation of oxide fluorides and oxides[32]. However, according to other data[33], the gas phase over lanthanum trifluoride during dehydration in an atmosphere of argon contains a small amount of HF even at 500°C, which must indicate the hydrolysis of LaF_3.

The oxygen content in the trifluorides obtained by dehydration at 300°C and 10^{-2} mmHg usually does not exceed 0.02%.[27,33] However, in many cases the content is higher (up to 0.06%)[5,34]. Probably the powdered trifluorides are contaminated also due to the adsorption of moisture and oxygen from air[1,32]. Therefore it is best to store the trifluorides in a re-melted form or after heat treatment in an inert atmosphere at a temperature close to the melting point of the trifluoride[27,33]. Cryptocrystalline powders which have been stored for a long time must be reheated in a stream of anhydrous hydrogen fluoride or an inert gas.

The trifluorides are precipitated with hydrofluoric acid from salt solutions in plastic (Teflon, polyethylene) or platinum vessels. The precipitation, filtration, and washing operations involving large amounts of precipitates (up to 45 kg) may be performed using special apparatus consisting of reactors with mechanical stirrers and plastic filters[5].

The hydrated trifluoride precipitates are obtained in a finely dispersed form and are therefore difficult to filter. Prolonged filtration may be omitted sometimes by using instead centrifugation and decantation with subsequent drying of the precipitate under an infrared heater or on a water bath[35].

Several methods have been proposed for the preparation of trifluorides in a better crystalline state. One of these consists in treating with hydrofluoric acid a suspension of the rare-earth hydroxide in water[36]. The hydrated precipitates obtained in this way are filtered more readily and contain less impurities. A similar result is obtained when a suspension of the rare-earth carbonate is employed[37]. Readily filtered fluorides can also be prepared by precipitation from chloride solutions at 100°C with liquid anhydrous hydrogen fluoride[5]. Terbium trifluoride is prepared by saturating a solution of the chloride in absolute alcohol with hydrogen fluoride. The oxygen content in the metal obtained from this fluoride was only 0.01%.[38]

2. Methods involving the fluorination of rare-earth oxides are best for the preparation of the anhydrous trifluorides. Gaseous fluorine and hydrogen fluoride or the solid fluorides NH_4HF_2 and NH_4F may be used as fluorinating agents. Gaseous fluorine is rarely employed[39] and the hydrofluorination procedure and the method based on the reaction with ammonium hydrogen fluoride have acquired practical importance. Both methods lead to a good yield and a fairly pure product. Under laboratory conditions, the method involving the fluorination of Ln_2O_3† with ammonium hydrogen fluoride is more widely employed, being simpler and more readily available.

The reaction of rare-earth oxides with anhydrous HF yielded all the rare-earth fluorides[5,29,40,41]. The optimum hydrofluorination temperature is apparently 700°C and its duration ranges from 2 hours upwards, depending on the amount of oxide. In the preparation of the trifluorides in amounts up to 1 kg in 99.8–99.9% yield, Carlson and Schmidt[5] used fluorination with anhydrous HF in a stationary oxide bed. In order to remove the hydrogen fluoride adsorbed by the trifluoride, the reaction products must be cooled in a stream of inert gas.

Direct hydrofluorination in a stationary furnace does not go to completion when the amount of oxide in the charge is increased to tens of kilograms. Fluorination with a rotating oxide bed increases the yield of the trifluoride[42]. The use of a rotating bed prevents the formation of a fluoride crust on the surface of the oxide which interferes with diffusion into its deeper layers. One of the possible

† In this formula and subsequently, Ln denotes a rare-earth element.

types of apparatus with a rotating bed has been described by Carlson and Schmidt[5].

The rate of reaction of Ln_2O_3 with HF and the yield of trifluoride can also be enhanced by fluorination in a fluidised bed. This method has been used to prepare yttrium trifluoride[43]. A reactor for fluorination in a fluidised bed, suitable for the simultaneous treatment of 0.9–1.8 kg of the oxide, is described in the review of Carlson and Schmidt[5]. In this reactor a fluidised bed is produced by a stream of nitrogen, which is replaced by hydrogen fluoride when the temperature in the fluidised bed reaches 150°C. The fluorination of the above amounts of Y_2O_3 at 600–700°C goes to completion in 7–10 h.

The possibility of employing chlorine trifluoride as a fluorinating agent has been investigated[44]. The degree of fluorination of lanthanide oxides by ClF_3 is unequal for different elements of the series and decreases with the atomic number of the element. The fluorination process takes place quantitatively only for the oxides of the lighter elements which have been subjected to a preliminary hydration.

Metallic yttrium, lanthanum, and cerium react with liquid hydrogen fluoride at 150–250°C, forming anhydrous trifluorides[45].

The reaction of rare-earth oxides with NH_4HF_2 and NH_4F. Rare-earth trifluorides can be obtained by treating the oxides with an excess of ammonium hydrogen fluoride or fluoride at 200°C and subsequent removal of the reagent in a stream of an inert gas at 450–600°C.[1,5,46,47] Spedding and Daane[1] obtained in this way the trifluorides of all the rare earths in amounts of up to 1 kg. In order to prepare pure products by fluorination with ammonium hydrogen fluoride or NH_4F, repeated treatment with the reagent is recommended[47]. Although the main bulk of ammonium fluoride sublimes at 300°C, its final removal requires a higher temperature (up to 600°C). The heat treatment must be carried out in a stream of a carefully dried inert gas in order to prevent the hydrolysis of the trifluoride. If the trifluoride obtained is used for reduction to the metal, particular attention must be paid to the complete removal of ammonia in order to avoid the contamination of the metal with nitrogen.

When rare-earth oxides are treated with ammonium hydrogen fluoride or fluoride (200–250°C), double fluorides of the rare earth and ammonium are formed as intermediates, decomposing on heating above 300°C. In addition, double fluorides can be obtained as a result of a double decomposition reaction in the aqueous solution between the rare-earth salts and an excess of ammonium fluoride and can be used to prepare the anhydrous trifluorides[48–51]. For this purpose, they are subjected to thermal decomposition in a stream of a dry inert gas. In this case too the complete removal of NH_4F is achieved on heating to 600°C. A double ammonium rare-earth fluoride obtained by precipitation from aqueous salt solutions with an excess of NH_4F and dried in air can be usefully treated with a large amount of ammonium fluoride, which is then distilled off in a stream of argon or helium[51]. This procedure creates better conditions for the prevention of the pyrohydrolysis of the fluorides.

The trifluorides obtained by the reaction of the oxides with ammonium hydrogen fluoride or by the thermal decomposition of the double compounds of the rare earths and ammonium are quite suitable for use as starting materials in the growing of optical crystals[52,53], but one should remember that on storage they adsorb gases and moisture from air.

The reaction of rare-earth nitrates and alkali metal and ammonium fluorides in a melt of $KNO_3(NaNO_3)$ and NH_4NO_3. Potassium (or sodium) fluoride precipitates anhydrous rare-earth trifluorides from melts of rare-earth nitrates in $KNO_3(NaNO_3)$[54,55]. The precipitation must be carried out with a stoichiometric amount of the reagent, since in the presence of its excess the trifluorides formed initially are converted into double fluorides. The precipitates may be separated from the nitrate by washing with water and decantation.

Ammonium fluoride can also be used as a precipitant for rare-earth ions in an ammonium nitrate melt. In this case it is recommended that the precipitation be carried out with an excess of NH_4F and subsequent distillation of volatile products in a vacuum at 450°C[54].

Precipitation from nitrate melts yields the anhydrous trifluorides of the majority of the rare earths in the form of larger crystals, compared with, for example, the thermal decomposition of the double compounds with ammonium fluoride.

Preparation of optical crystals of the trifluorides. Rare-earth trifluorides have excellent optical properties, are readily alloyed with rare-earth activators, and constitute an excellent base for lasers and photon counters. In this connection the growing of optical trifluoride crystals is a problem of practical importance.

Methods involving crystallisation of the melts are used to prepare optical rare-earth trifluoride single crystals. A necessary condition in the growing of single crystals is the prevention of the pyrohydrolysis of the trifluorides, which leads to the formation of oxygen compounds: even insignificant admixtures of the latter cause a turbidity in the crystal. The single crystals are best synthesised in a fluorinating atmosphere[56,57] but optical single crystals can also be obtained in an inert atmosphere[53,58]. In this method the starting materials must be very carefully freed from oxides and oxide fluorides, while in a fluorinating atmosphere these are converted into the fluorides. The preliminary purification of the starting material consists usually in its hydrofluorination with anhydrous hydrogen fluoride at 700–800°C.[56,58] The necessity for careful drying of the inert gas and hydrogen fluorides must also be emphasised, since the trifluorides are readily hydrolysed at 1400–1500°C even at a negligibly low water vapour pressure[59]. The fluorinating agents which can be employed are fluorine, hydrogen fluoride, and also the fluorides of certain elements, for example PbF_2 and CdF_2,[57,60,61] which are introduced into the charge before fusion, and their oxides as well as the fluorides themselves are evaporated during the fusion process. As in the growing of alkaline earth metal fluoride crystals, a fluorinating atmosphere may be produced from Teflon[62,63], the thermal decomposition products of which react not only with oxides but also with water, forming hydrogen fluoride[63].

The single crystals are grown in graphite or platinum crucibles. Account must be taken of the reducing properties of these materials in relation to certain fluorides, particularly those of europium and samarium[61,64,65], which are apparently promoted by admixtures of certain oxygen compounds[59]. Thus in the growing of lanthanum trifluoride crystals with added SmF_3 and EuF_3 in an inert or a weakly fluorinating atmosphere, partial reduction of the samarium and europium salts takes place, whereas in a strongly fluorinating atmosphere such reduction is not observed[61,64].

Optically homogeneous single crystals of the trifluorides are obtained by Stockbarger's method. All the trifluorides in the hexagonal modification (LaF_3, CeF_3, PrF_3, and NdF_3)[53,56,57,66,67], pure or activated with rare-earth elements, have been obtained by this method or its somewhat modified version. Lanthanum and cerium trifluorides, which are transparent over a wide spectral range, are of great interest as optical materials. Optical crystals with a mixed composition of the type $(La_xNd_{1-x})F_3$ $(0 \leq x \leq 0.5)$ have been obtained from hexagonal fluorides[57]. Good optical crystals of lanthanum trifluoride containing the fluorides of heavier elements, which crystallise in the orthorhombic system, can be obtained only when the content of the latter is low.

Czochralski's method has also been successfully used to prepare single crystals of the hexagonal trifluorides[58,68].

The synthesis of perfect crystals of the orthorhombic trifluorides is complicated by the occurrence of the polymorphic transformation $LnF_3(rhomb.) \rightleftharpoons LnF_3(hex.)$. Only two of these ($DyF_3$, HoF_3), the temperatures of the polymorphic transformations of which are close to the melting points, have been obtained in the form of single crystals with dimensions of several centimetres[57].

2. The Structure of Rare-earth Trifluorides

Rare-earth trifluorides crystallise in the hexagonal or orthorhombic system. Only the hexagonal modification, with a tysonite type structure, is known for lanthanum, cerium, praseodymium, and neodymium trifluorides[69,70]. The orthorhombic modification (YF_3 structural type) is characteristic of the trifluorides of the heavier elements under the usual conditions[29]. A cubic modification of YF_3 has been reported[71], but subsequently it was found[29] that these results did not refer to yttrium trifluoride itself but to its compound with sodium fluoride. Above 555–1100°C, the orthorhombic trifluorides undergo a structural change and are converted into the hexagonal modifications. According to the data of Toma and Brunton[72], the high-temperature forms of the trifluorides of the elements ranging from samarium to holmium have tysonite type structures and can be obtained in a metastable state below the polymorphic transition temperature by means of quenching. The hexagonal modifications of erbium, ytterbium, lutetium, and yttrium trifluorides differ from the tysonite type. Below the phase transition temperature, they are unstable.

Table 1 lists the dimensions of the unit cells of the hexagonal and orthorhombic modifications of LnF_3 and the polymorphic transition temperatures $[LnF_3(rhomb.) \rightleftharpoons LnF_3(hex.)]$.

The first X-ray diffraction studies on tysonite type trifluorides were made by Oftedal[69], who established that the structure of this type has a hexagonal unit cell with the space group $C6_3/mcm(D^3_{6h})$. The subsequent revision of atomic coordinates[74,75] led to the conclusion that the positions of lanthanum atoms in the LaF_3 structure virtually correspond to the model with the space group $C6_3/mcm$, while fluorine atoms are displaced compared with the positions expected for this model; therefore lanthanum trifluoride crystals can be more correctly assigned to the trigonal system (space group $P\bar{3}c1$). The coordination sphere about lanthanum is formed by 9 fluorine atoms at a distance of 2.4–2.6 Å from the metal and two more remote atoms at a distance of 3.0 Å.

A somewhat different structural model was suggested for LaF_3 by Rango and Tsoucaris[76]. This model corresponds to the space group $P6_3cm$. In general the differences between the models are small and the real LaF_3 structure differs little from the ideal case (space group $C6_3/mcm$).

To elucidate the structural characteristics of the hexagonal trifluorides, other methods, particularly NMR, were used together with X-ray diffraction analysis. The ^{19}F NMR spectrum confirms the presence in the trifluoride structures of non-equivalent fluorine atoms and of a unit cell with 6 formula units[77–80]. Analysis of the ^{139}La and ^{19}F NMR spectra of an LaF_3 single crystal together with certain X-ray diffraction data leads to the conclusion that the crystals have hexagonal symmetry (space group $P6_3/cm$), but, according to the authors themselves[78], this result can be explained by the twinning of crystals with trigonal symmetry. At the same time ^{19}F NMR data for CeF_3 were found to agree well with the space group $P\bar{3}c1$.[80] One of the reasons for the discrepancies in the data on the symmetry of crystals belonging to the tysonite structural type may be a disordered distribution of fluorine atoms among all possible sites. The diffusion-dependent narrowing of the lines at room temperature, which is characteristic of ^{19}F NMR spectra, should be noted in this connection[77,81–83]. The observed mobility of fluorine atoms at a relatively low temperature can evidently be accounted for by the presence of defects (vacancies) in the structure[77,83].

Table 1. X-ray diffraction data for rare-earth trifluorides[29,72–75].

* The unit cell parameters are given at a temperature 10–15 deg above the polymorphic transition point[72].

The results of studies on the vibrational spectra of LaF_3, PrF_3, and NdF_3[84–86] agree with the X-ray diffraction data obtained by Zalkin et al.[75] and also by Mansmann[74]. The total number of bands in the Raman spectra of the single crystals of trifluorides belonging to the tysonite structural type, obtained on excitation with an argon laser, agrees with the theoretical analysis for a hexagonal unit cell with 6 formula units (space group $P\bar{3}c1$). Even at room temperature five bands associated with the fully symmetrical A_{1g} vibration and 12 bands corresponding to the degenerate vibrations (E_{1g} and E_{2g}) were observed in the Raman spectrum, in agreement with calculation for $P\bar{3}c1$ symmetry. In the reflection spectrum polarised parallel to the principal axis of the crystal

(region of A_{2u} type vibrations), four bands were found instead of the six postulated on the basis of the calculation, which may be attributed solely to a slight distortion of the LnF_3 structure compared with the more symmetrical model with the space group $P6_3/mcm$.[84]

Although the structural type persists in the LaF_3–CeF_3–PrF_3–NdF_3 series, a decrease of the ionic radii of the elements in this series leads to some distortion of their structure[79]. In consequence of the difference between the ionic radii of lanthanum and other lanthanides, the distortion of the crystal structure is demonstrated also by the ESR spectra of the impurity Ln^{3+} ions in LaF_3 single crystals[87–89]. Paramagnetic ions can substitute 6 non-equivalent lanthanum positions, but the local crystal field around them depends on the nature of the impurity ion, as can be seen from the change in angle formed by the z axis of the g-tensor and the c axis of the crystal[89].

The optical spectra of Ln^{3+} in LaF_3 show a large number of polarised lines, indicating a higher symmetry of the local crystal field operating on these ions in LaF_3[90,91] than would be expected for C_2 symmetry in the distribution of cations in the tysonite structure.

Orthorhombic rare-earth trifluorides crystallise with a structure of the YF_3 type (space group $Pnma$)[29], in which the metal is surrounded by 6 fluorine atoms located at the vertices of a trigonal prism and three fluorine atoms adjacent to the centres of its lateral faces. Eight fluorine atoms are at a distance of 2.3 Å from the metal (yttrium), while the ninth is at a distance of about 2.6 Å. The coordination polyhedron in YF_3 is linked to adjacent polyhedra by the triangular planes of the prism.

The chemical bonds in lanthanide trifluorides are significantly ionic. The amount of ionic character in such compounds, determined experimentally, agrees satisfactorily with the values calculated theoretically with the aid of overlap integrals and by the electronegativity method[92].

The predominantly ionic character of Ln–F bonds can be accounted for by the considerable size of the Ln^{3+} ions and the characteristics of their electronic structures; the formation of covalent bonds involving hybrid orbitals is difficult, because the $4f$ electrons are screened by the outer electron shells and their contribution to the formation of covalent bonds is slight. Nevertheless the presence of partial covalent character is probably due to their involvement (since there is no other possibility), which explains certain regularities in the crystal properties[93–95]. The ^{19}F NMR data on the delocalisation of $4f$ electrons in PrF_3 and NdF_3 also confirm the involvement of $4f$ electrons in the formation of chemical bonds[79]. Calculation of the spin–orbital parameters for Yb^{3+} (and Tm^{2+}) in CaF_2 also indicates the overlapping of the $4f$ and $5p$ levels with the fluorine orbitals[96].

3. Physicochemical Properties of Rare-earth Trifluorides

Table 2 lists certain thermodynamic functions of rare-earth fluorides taken from the literature[24,97–111]. Only the heat of formation of YF_3 ($\Delta H^\circ_{298} = -410 \pm 0.8$ kcal mole^{-1})[97] has been determined by direct combustion of the metal in a bomb calorimeter filled with fluorine[97]. The heats of formation of lanthanide trifluorides were obtained by indirect experimental methods using the heats of formation of the hydrated trifluorides[24,98] and also data obtained in a study of the equilibrium in the reaction between AlF_3 and fused rare-earth chlorides[99,100]. Numerous estimates of the ΔH for the trifluorides have been discussed[102].

The heat capacity of crystalline CeF_3 at 298°K is 22.34 cal mole^{-1} deg^{-1}. Its temperature variation has been described[112]. The entropy of crystalline CeF_3 is $\Delta S^\circ_{298} = 27.6$ e.u.[113] The estimated entropies of yttrium and lanthanum trifluorides are 21.5 and 23.3 e.u. respectively.

Rare-earth trifluorides are fairly refractory compounds (Table 2). With increase of the atomic number of the element, the melting points initially decrease and then, starting with ErF_3 (Toma and Brunton[72]) (with HoF_3, according to other data[57]), increase slightly. The minimum in the melting point curve for the trifluorides corresponds in all probability to the maximum in the polymorphic transition temperature curve [LnF_3(rhomb.) ⇌ LnF_3(hex.)][72].

Table 2. Heats of formation[24,97–101] and thermodynamic characteristics of the sublimation process[103–111].

Compound	M.p., °K (Ref.5)	$-\Delta H^\circ_{298}$ (form.)*, kcal mole^{-1}	ΔH° (subl.) (1470°K), kcal mole^{-1}	ΔS° (subl.) (1470°K), e.u.	ΔH°_{298} (subl.) kcal mole^{-1}	ΔS°_{298} (subl.), e.u.

* The estimated values of ΔH are indicated in brackets (for further details, see Polyachënok[102]).

The heat of fusion of cerium trifluoride was determined as 13.2 kcal mole^{-1};[113] estimated data are available for other compounds[9]. The heats of fusion of DyF_3, HoF_3, and ErF_3 were found from the differences between the heats of evaporation and sublimation[109]. The densities of the fused trifluorides of lanthanum, cerium, praseodymium, samarium, and yttrium, have been published[114].

Close to the melting point, rare-earth fluorides exhibit an appreciable increase in volatility. The temperature variation of the sublimation pressures of the trifluorides has been described[103–111].

The sublimation pressures have been obtained by a torsion-effusion method (Suvorov[12,107] and Searcy and coworkers[103,108,111]) and by a mass-spectrophotometric method (Margrave and coworkers[104–106,109,110]). The absolute vapour pressures over the solid or fused trifluorides can be illustrated by the following examples (mmHg):

LaF_3 $2.2\cdot10^{-5}$—$3.7\cdot10^{-3}$ (1200—1405° K),
CeF_3 $3.7\cdot10^{-4}$—$1.5\cdot10^{-2}$ (1317—1500° K),
DyF_3 $1.1\cdot10^{-3}$—$8\cdot10^{-1}$ (1326—1622° K),
LuF_3 $9.65\cdot10^{-3}$ (1372° K)
YF_3 $1.5\cdot10^{-4}$—$2.1\cdot10^{-3}$ (1256—1434° K).

The heats of sublimation derived from these data are listed in Table 2.

The boiling points of the trifluorides vary from 2600°K (LaF_3) to 2500 °K (LuF_3).[9] The principal component of the gas phase over the solid and fused trifluorides is LnF_3

molecules[103,104,106-111]. Mass-spectrophotometric study of the composition of the gas phase established the presence of the ionic species Ln^+, LnF^+, and LnF_2^+, which are formed as a result of the dissociation of gaseous LnF_3 and not by simple ionisation of the gas-phase species with the corresponding composition. Neutral LnF and LnF_2 molecules have been detected in the LnF_3–Ln (and BaF_2–Nd) systems[104,105,115].

The results of electron-diffraction studies on gaseous lanthanum, neodymium, and yttrium trifluorides have been interpreted[116,117] on the hypothesis of a planar structure of the LnF_3 molecules with a triangular configuration. At the same time calculation of the valence state of these elements suggests a pyramidal structure of the trifluoride molecules with the rare-earth atom at the apex[118].

The estimated heats of formation (ΔH°_{298} kcal mole^{-1}) of gas-phase tri-, di-, and mono-fluorides of certain elements are listed below[104,115]:

	Nd	Sm	Eu	Gd	Dy	Ho	Er
LnF_3 (gas)	303	318	310	310	290	289	283
LnF_2 (gas)	159	160	160	162	157	157	150
LnF (gas)	36	164	58	40	36	40	35

The dissociation energies (D_{298}, kcal mole^{-1}) of the gaseous fluorides are, for example:

	Nd	Sm	Gd	Ho	Er
F_2Ln—F	165	160	150	151	152
FLn—F	143	138	143	136	134
Ln—F	130	127	141	123	136

Optical properties of rare-earth trifluorides. The hexagonal trifluorides exhibit very weak double refraction. The refractive indices increase in the series LaF_3–NdF_3 with the atomic number of the element. The orthorhombic trifluorides (from SmF_3 to LuF_3) have lower refractive indices than the hexagonal trifluorides. The refractive indices of the orthorhombic trifluorides hardly change in the above series[28,47,40]. Nevertheless the molar refractions of the trifluorides decrease linearly with the atomic number of the element, the curve describing the variation of R_M showing only a slight break on transition from the hexagonal to the orthorhombic group.

Lanthanum trifluoride is a valuable optical material, mainly for laser engineering. Single-crystal LaF_3 specimens exhibit high thermal and radiation stability and are transparent over a wide spectral range (from 120–130 nm to 13 nm)[119,120].

Lanthanum trifluoride constitutes a convenient base for the introduction of rare-earth activator ions, since the latter substitute lanthanum ions isomorphously. The isomorphous incorporation of triply charged ions into the LaF_3 structure does not require a charge compensation and therefore the spectroscopic properties of the Ln^{3+} present at a high concentration in such systems are determined largely by a single type of optical centre[68], as a result of which LaF_3 is a suitable material for the investigation of the optical spectra of the lanthanide ions[121-132]. The Ln^{3+} spectra in the visible region and the near ultraviolet, which are due to transitions within the well-screened 4*f* configuration, are comparatively little susceptible to the effect of the crystal field, which causes a splitting of the terms but has only an insignificant effect on the positions of their centres of gravity. A change in the type of chemical bond has a very significant effect on the positions of the centres of gravity of the energy levels of lanthanide ions, as can be seen, for example, from the La^{3+} spectra in the series lanthanum fluoride–lanthanum chloride–lanthanum bromide–lanthanum ethyl sulphate[133]. The same type of behaviour—a shift of the absorption bands towards the long-wavelength part of the spectrum with increasing degree of covalence of the bond—is observed in the transition $LnF_3 \rightarrow LnOF \rightarrow Ln_2O_3$.[134,135]

Keating and Drickamer[136] investigated the effect of a 50 000 atm pressure on the spectra of PrF_3 and NdF_3 crystals in the visible region and the near infrared. The authors explain the increase of the intensities of the individual bands in the spectra by an increase in the extent of interaction of 5*d* and 4*f* orbitals in the excited state as a result of the compression of the substance.

Certain rare-earth fluorides have been investigated to elucidate the possibility of their employment as optical coatings[137,138]. The chemical stability of the trifluorides in films, the pronounced abrasive quality of the coatings, and the possibility of their preparation in a crystalline form are valuable properties. However, the optical constants of the films (refractive indices, extinction coefficients) depend on the condensation conditions, particularly the temperature of the salt. Only films condensed on supports heated to about 300°C exhibit fairly constant properties and have a crystalline structure. The structure of the film varies with the thickness of the layer sputtered on to the support[139,140]. When lanthanum trifluoride is sputtered on to a heated support in a vacuum, an amorphous LaF_3 layer is formed initially and then a cryptocrystalline layer with an arbitrary orientation of the crystals. The succeeding layers have a preferred orientation, but its appearance does not affect the structure of the lower layers[140].

The electronic spectra of rare-earth trifluorides in films have been described[138,141].

The electrical properties of rare-earth trifluorides. The temperature variation of the conductivity of LaF_3 single crystals has been investigated in the range between 300° and 825°K.[83] Ionic conduction makes a large contribution owing to the mobility of fluoride ions. Because of this, LaF_3 single crystals may be used as indicator electrodes for the measurement of the activity of fluoride ions and for its potentiometric determination[142]. Electrodes with an active membrane of LaF_3 single crystals, which are selective in relation to F^- ions, have already found application and permit determinations down to 0.02 μg F ml^{-1} in various materials[143-145]. The introduction of the Eu^{2+} additive into LaF_3 results in a further increase of the electrical conductivity of the crystals[142].

The electrical properties of trifluoride films have been investigated in connection with the use of these materials for the preparation of film condensers[146].

The magnetic properties of rare-earth trifluorides have been described[51].

Chemical properties of rare-earth trifluorides. Under the usual conditions rare-earth trifluorides are stable in air and are non-hygroscopic, but their capacity to absorb moisture and gases from air increases appreciably with their degree of dispersion.

The trifluorides are rare-earth compounds which are least soluble in water and acids. Their solubility in water is approximately in the range 10^{-6}–10^{-5} M, the minimum values corresponding to the middle of the lanthanide series[147]. Yttrium trifluoride is more soluble than the trifluorides of the cerium group. As the pH is reduced (down to 2), the solubility of CeF_3 initially decreases somewhat and then rises sharply (down to pH 0).[148]

In HF solutions the solubility of the trifluorides also initially decreases with increasing acid concentration and then rises slightly[149,150]. The increase of the solubility of LaF_3 was observed starting with 55% HF solution[149]. The solubility of the trifluorides (CeF_3) in liquid hydrogen fluoride is low (≤ 0.04 g in 100 g of HF at 12°C).[151] In NH_4F solutions it is appreciably higher[152].

Rare-earth trifluorides can be dissolved by decomposing them with hot concentrated sulphuric acid, fusion with carbonates and alkalis, and also on heating with concentrated sodium hydroxide solution[153]. Moreover, they dissolve in solutions of Complexone III [disodium salt of EDTA (Ed. of Translation)][44] and certain metal salts, forming more stable complexes with F^- ions, for example, aluminium and beryllium[44,154,155]. An appreciable increase of the solubility of lanthanum and cerium trifluorides, associated with the formation of UO_2F^+ ions, was observed by Deichman and Tananaev[156] in solutions of uranyl nitrate. The solvent power of beryllium salts in relation to rare-earth fluorides is due to the formation of complexes, for example BeF^+,[154,157] which are only slightly dissociated. The formation of these complexes explains the incomplete isolation of rare-earth fluorides in the presence of beryllium in solution[158].

Lanthanum trifluoride reacts on standing with oxalic acid, forming insoluble stable lanthanum fluoride oxalate $La_2F_4C_2O_4$.[153]

Hydrofluoric acid or its salts precipitate trifluorides containing water from rare-earth salt solutions. The precipitates thus obtained are finely dispersed and contain between 0.3 and 1 mole of water per mole of LnF_3. The water content depends both on the nature of the element and the precipitation conditions, washing, and drying of the precipitates[22-24,37,159]. Readily filterable precipitates of more definite composition, $LnF_3.(0.4-0.5)H_2O$ (Ln = La, Pr, Nd, or Sm) are obtained by treating a suspension of rare-earth carbonates in water with an excess of hot hydrofluoric acid[37]. The compositions of the hydrated trifluorides of heavier elements (dysprosium, holmium, praseodymium, and ytterbium) are close to the formula $LnF_3.H_2O$.

It has been frequently noted[22,24,37] that water in trifluorides is energetically non-equivalent. Some of it is probably of the adsorption type and is removed at 40–100°C, while the remainder stays bound even above 300°C.

Refractometric and infrared absorption spectroscopic data for the trifluorides indicate the formation of OH–F hydrogen bonds[24,160]. The hydrated products contain the structures of the anhydrous trifluorides[161]. In the presence of 3–4% H_2O, the volume of the unit cell of the hexagonal trifluorides remains unchanged[37] but the density of water-containing specimens is much lower compared with the anhydrous compounds, indicating in all probability that they have a defect structure which is shown by the appearance of additional vacancies.

The ^1H NMR magnetic resonance spectrum (–130°C) of $LaF_3.nH_2O$ is consistent with the hypothesis of non-equivalent water molecules in trifluorides and indicates a diffusion-dependent mobility of the water in the structure. Its presence influences the mobility of F^- ions[23]. These results also confirm that the hydrated trifluorides have a defect structure.

The study of the solubility in $LnCl_3$–MF–H_2O systems (M = alkali metal and Ln = Er, Yb, or Lu) showed that, for the molar ratio $n = MF/LnF_3 = 1$, a precipitate is not deposited owing to the formation of soluble salts containing the LnF^{2+} complex ions. An increase of n to 3 leads to the formation of an LnF_3 precipitate (evidently hydrated).

When $n > 3$, the trifluorides are converted into double fluorides with the composition $MLn_2F_7.nH_2O$ or $M_2Ln_3F_{11}.nH_2O$.[162] A similar reaction mechanism obtains also in the precipitation of rare-earth ions by ammonium fluoride; the double fluorides $(NH_4)_2Ln_3F_{11}.nH_2O$ and $(NH_4)_4Ln_3F_{13}.nH_2O$ have been isolated from solutions containing an excess of ammonium fluoride[163]. Sodium fluorosilicate precipitates lanthanide ions in the form of their trifluorides[164,165].

Spectrophotometric study of rare-earth salt solutions containing alkali metal fluorides and carbonates showed the formation of the complex ions $Ln(CO_3)_3F^{4-}$, $Ln(CO_3)_2F_2^{3-}$, $LnCO_3F_3^{2-}$, and $LnCO_3F_2^-$.[166] Precipitates of the fluorocarbonates $LnCO_3F.nH_2O$ may be isolated from solutions with a high concentration of the ions and the molar ratios $Ln:CO_3:F = 1:1:1$.[166-168] With the ratios $Y:CO_3:F = 1:1:2$ and $1:1:3$, the compounds $KYCO_3F_2.1.5H_2O$ and $K_2YCO_3F_3.1.5H_2O$ respectively were obtained[168]. Analogous neodymium compounds have also been isolated[167].

In addition fluorocarbonates can be obtained by the reaction of calculated amounts of hydrofluoric acid with a suspension of rare-earth carbonates in water[167,170]. In nature these compounds form the mineral bastnaesite.

The solubility of rare-earth fluorocarbonates in water is about $(2-4) \times 10^{-5}$ M, increasing in potassium carbonate solutions[168]. The fluorocarbonates are dehydrated at 160–180°C; further heating leads to the decomposition of the compounds and terminates above 400°C with formation of oxide fluorides[169,171].

The stability of rare-earth fluoride complexes in solution. The triply charged lanthanide and yttrium ions form complex ions with fluorine which are less stable than the aluminium and scandium complexes (Table 3) but more stable than other halide complexes.

Table 3. Stability constants of the fluoride complexes MF^{2+}.

Element	$\lg\beta_1$			Element	$\lg\beta_1$

				Lu	—	3.47	3.60

The stability constants of the LnF^{2+} complex ions, the main reaction product in the system $Ln^{3+} + HF \rightleftharpoons Ln^{2+} + H^+$, are listed below. They were taken from the literature[162-174]. (See in addition Refs. 175–180.)

The rare-earth fluoride complexes are of the inner-sphere type with a predominantly ionic type of bonding[174]. The relative stability of the LnF^{2+} complexes has been explained[174] by a large positive entropy of formation (Table 4).

As the Ln^{3+} ionic radius is reduced, the stability of the fluoride complexes (LnF^{2+}) increases, but the increase of K_{st} is non-monotonic. (See also the values of ΔF in Table 4.) Apart from the LnF^{2+} ions, the solution may contain the less stable complexes LnF_2^+ and LnF_3(aq.).

The reactions $Y^{3+} + HF \rightleftharpoons YF^{2+} + H^+$, $YF^{2+} + HF \rightleftharpoons YF_2^+ + H^+$, $YF_2^+ + HF \rightleftharpoons YF_3(aq.) + H^+$, and $YF_3 + HF \rightleftharpoons YF_4^- + H^+$ have been investigated for yttrium and their equilibrium constants have been determined (10.0, 2, 2, and 10 respectively) together with the stability constants of YF_2^+, $YF_3(aq.)$, and YF_4^-.[175]

Table 4. Thermodynamic quantities for the reactions $Ln^{3+} + F^- \rightleftharpoons LnF^{2+}$ (25°C, $I = 1$).

Element	$-\Delta F$, kcal mole^{-1}	ΔH, kcal mole^{-1}	ΔS, e.u.	Element	$-\Delta F$, kcal mole^{-1}	ΔH, kcal mole^{-1}	ΔS, e.u.

Gd	4.52	8.90	45.1	Lu	4.93	9.53	48.5
				Y	4.91	8.32	44.5

The hydrolysis constants of the cerium fluoride complexes CeF^{2+} and CeF_2^+ have been estimated[181] as 3×10^{-7} and 4×10^{-10} respectively.

The existence of the complexes LaF^{2+}, LaF_2^+, and LaF_3 in the LiCl–KCl melt has also been established[182].

III. REACTIONS OF RARE-EARTH TRIFLUORIDES WITH THE FLUORIDES OF OTHER ELEMENTS

1. $MF-LnF_3$ Systems

The ratio of the ionic radii of M^+ and Ln^{3+} [183] or the ratio of the cationic field strengths[184] has been suggested as criterion of the formation of compounds in $MF-LnF_3$ systems. When $r_{M^+} : r_{Ln^{3+}} = 0.7$, the formation of compounds by the components is not to be expected at all; if the ratio is in the range 0.7–1.4, a compound $MLnF_4$ is formed and for a ratio of the cationic radii in excess of 1.40 the trifluorides form with alkali metal fluorides compounds having the composition M_3LnF_6.[183] Indeed in the $LiF-LaF_3$ (CeF_3, PrF_3) systems for which the ratio of the cationic radii is 0.64–0.67, no compounds of the components have been observed[185–188], while in systems with heavier elements in the samarium–lutetium series compounds with the composition $LiLnF_4$ are formed[134]. $NaF-LnF_3$ systems ($r_{M^+} : r_{Ln^{3+}} = 0.93–1.21$ give rise to the compounds $NaLnF_4$ [47,48,189] (which decompose in the solid phase possibly only in the case of the very last elements in the rare-earth–Na_3LnF_6 series[184]). In $KF-LnF_3$ systems there is a possibility of the formation not only of $KLnF_4$ but also of K_3LnF_6. There is no information about the formation of K_3LaF_6 in the corresponding system[190] but in all systems with other trifluorides compounds having this composition do exist. It is noteworthy that they are formed when the ratio of the cationic radii is appreciably less than 1.40, although in this case the compounds decompose in the solid phase.

With rubidium and caesium fluorides, all the rare-earth trifluorides apparently form compounds having the composition M_3LnF_6.[48,49,184,191] If the M_3LnF_6 compounds can be heated up to the melting point, they fuse without decomposition, the liquidus curves showing sharp maxima. It is striking that in systems where the M_3LnF_6 compounds are stable in the melt, the $MLnF_4$ compounds are stable only in the solid phase, whereas in the systems where the double fluorides $MLnF_4$ are in peritectic equilibrium with the melt, the M_3LnF_6 compounds decompose (if they are formed at all) without reaching the melting point[184].

The thermal stability of the M_3LnF_6 compounds increases in the series K–Rb–Cs.[48,184,191–194] In all the $CsF-LnF_3$ systems the congruently melting compounds Cs_3LnF_6 are formed, in the $RbF-LnF_3$ systems they are formed starting with PrF_3, and in the $KF-LnF_3$ systems their formation begins with SmF_3 (possibly with NdF_3).

The M_3LnF_6 fluorides may be obtained by fluorinating a mixture of MCl and $LnCl_3$ (or Ln_2O_3) in molar proportions of 3 : 1 at 400°C[195,196] or by sintering a mixture of the alkali metal fluoride and the rare-earth trifluoride in an evacuated tube and in an inert atmosphere (500–600°C)[197]. Compounds with mixed alkali metal cations A_2BLnF_6 and AB_2LnF_6 were synthesised by the same methods[198]. Moreover, K_3NdF_6 and even K_3LaF_6 were synthesised by dissolving the oxide of the corresponding element in the KBF_4–KCl melt[199].

The double fluoride of yttrium and potassium has a structure of the Rb_3TlF_6 type[195]; the tetragonal unit cell parameters are $a = 6.40$ Å and $c = 9.10$ Å ($z = 4$). The compound Cs_3YF_6 has the same structure as K_3YF_6.[195]

The double fluorides M_3CeF_6 and M_3PrF_6 and compounds with mixed alkali metal cations crystallise in the cubic system (of the distorted perovskite type)[195–198].

At 320°C K_3YF_6 undergoes a polymorphic transformation[192]. A polymorphic transformation has also been observed for K_3NdF_6 [200] and Rb_3PrF_6.[171] All the $MLnF_4$ compounds, except $LiTmF_5$, $LiYbF_4$, and $LiLuF_4$, are unstable in the melt or decompose on heating even in the solid phase.

The double fluorides of rare earths and lithium $LiLnF_4$ (Ln = Eu–Lu, Y) can also be obtained by the reaction of LiF and LnF_3 (or Ln_2O_3 in a stream of HF) at 400–450°C. These compounds have a structure of the scheelite type[201,202].

The nature of the interactions between the components in the $NaF-LnF_3$ systems and the products of this interaction have been investigated in greatest detail. The fusion diagrams for these systems have been studied up to 100 mole % LnF_3.[47] One of the compounds in the system is always $NaLnF_4$, which crystallises in the hexagonal system[203–206]. In the $NaF-LnF_3$ [207] and $NaF-CeF_3$ [208] systems the hexagonal modification of $NaLnF_4$ melts incongruently, forming a melt and LnF_3. In the $NaF-LnF_3$ systems (Ln = Pr–Gd) the incongruent fusion of $NaLnF_4$ results in the formation of a cubic phase, while in the systems containing the fluorides of elements ranging from terbium to lutetium the hexagonal modification initially becomes disordered and is then converted into a stoichiometric cubic phase[47].

A structural study of $NaNdF_4$ single crystals showed[209] that this compound is not of the β-Na_2ThF_6 structural type to which the $NaLaF_4$ and $NaCeF_4$ structures had been assigned previously[203,204]. The unit cell of $NaNdF_4$ contains 3/2 formula units and the cations are located in three different positions: the first contains neodymium ions (1 per cell), the second contains neodymium and sodium ions distributed at random (1/2 of each), and in the third sodium ions alternate at random with vacancies. The neodymium ions are surrounded by 9 fluoride ions, while in the β_2-Na_2ThF_6 structural type they should have a coordination number of 8.[209] The double fluorides $NaLnF_4$ of other rare earths have the same structures as $NaNdF_4$ (space group $P6$) or the structures are very similar[47,209,210].

Certain differences in the symmetry of the space group, which are observed on replacement of neodymium ions by those of other rare earths, can probably be accounted for by the partial mixing of the cations in various positions. The mineral gagarinite also has a structure similar to that of $NaNdF_4$.[211]

The cubic (high-temperature) modification of $NaLnF_4$ has a structure of the CaF_2 type; Na^+ and Ln^{3+} ions are distributed at random among the cationic sites in the crystal structure of this type[204]. Like CaF_2, the cubic phases exhibit wide regions of homogeneity, which include LnF_3.

Variable-composition phases are formed in the $NaF-LnF_3$ systems by the substitution of cations in the fluorite type structure (by Ln^{3+}) and the incorporation of additional fluoride ions in the vacancies of this structure[212]. This mechanism is confirmed by the calculation of the fraction of the molar free volume in the unit cell[47].

On formation of cubic solid solutions in the $NaF-LnF_3$ systems (Ln = Pr–Lu or Y), the upper limiting composition corresponds to the compound $Na_5Ln_9F_{32}$, which is the only congruently melting phase in systems containing the trifluorides of elements ranging from europium to lutetium[47,213]. The region of existence of disordered solid solutions expands as the ionic radius of the rare earth decreases. Their lower limiting composition varies from 55.5 mole % LnF_3 in the $NaF-PrF_3$ system to 39 mole % LnF_3 in the $NaF-LuF_3$ system[47]. The unit cell dimensions of the cubic $Na_5Ln_9F_{32}$ phases increase relative to those of the cubic stoichiometric double fluorides $NaLnF_4$.

The cubic solid solutions in the $NaF-LnF_3$ system are unstable below 500–800°C; the lowest temperature bounding the region of their coexistence corresponds to the system containing lutetium trifluoride. The cubic compound $Na_5Ln_9F_{32}$ in the $NaF-LnF_3$ systems (Ln = Pr–Tb) decomposes on cooling into the hexagonal form $NaLnF_4$ and the trifluoride of the corresponding element. In the $NaF-LnF_3$ systems (Ln = Dy–Lu), the $Na_5Ln_9F_{32}$ structure becomes ordered below 737–778°C with formation of an orthorhombic modification, which is also unstable on cooling below 700–450°C. The nature of the distortion of the unit cell is probably evidence of ordering in the distribution of the cations in the $Na_5Ln_9F_{32}$ structure. The cubic phases with the stoichiometric composition $NaLnF_4$ are converted into the hexagonal form below 600–700°C.[47,205,206]

The majority of the $KF-LnF_3$ systems have been only partly investigated[184,189,190]. The most complete data on the fusion and transformations in the solid phase are available for the $KF-YF_3$ system[194]. Apart from the compounds K_3YF_6 and KYF_4, the compounds KY_2F_7, KY_3F_{10}, and KY_7F_{22} were detected in the system[194,214]. The compound KY_2F_7 melts with decomposition at 890°C, forming a melt and KY_7F_{22}. The double fluoride KY_7F_{22} also melts incongruently with formation of a melt and yttrium trifluoride (965°C), while KY_3F_{10} decomposes in the solid phase at 795°C according to the equation $KY_3F_{10} \rightarrow KY_2F_7 + KY_7F_{22}$. Moreover, the formation of metastable solid solutions in the range between 62 and 90 mole % YF_3, the structure of which is derived from that of partly ordered fluorite, is characteristic of this system. When the solid solution is annealed (above 500°C), the structure is ordered further and the KY_2F_7, KY_3F_{10}, and KY_7F_{22} phases are segregated, the structures also being based on the CaF_2 type distorted in various ways.

Zachariasen[203,204] was the first to make an X-ray diffraction study of the compounds $KLnF_4$, using $KLaF_4$ and $KCeF_4$. He established that the double fluorides are dimorphic. The high-temperature modification has a structure similar to that of CaF_2, while the low-temperature modification was found[204] to crystallise in the hexagonal system like β_1-K_2UF_6. However, according to other data[217], the low-temperature modification of $KLaF_4$ has the same structure as $NaNdF_4$ and not β_1-K_2UF_6.

In the study of the $KF-CeF_3$ system, the hexagonal modification of $KCeF_4$ was not detected among the equilibrium phases[216]. Structural analysis of the single crystals of the low-temperature form of $KCeF_4$ obtained from the melt (35 mole % KF and 65 mole % CeF_3) established that they belong to the orthorhombic systems (space group *Pnma*, $a = 6.290$ Å, $b = 3.804$ Å, $c = 15.596$ Å, and $z = 4$).[216]

The double fluorides of the rare earths and alkali metals are incongruently soluble in water. In the $KF-CeF_3-H_2OF_6$ system (up to about 25% KF in the saturated solution) the solid phase contains cerium trifluoride[217]. With increase of the MF concentration, the stability in aqueous solution of the double fluorides of many rare earths increases[162,163,218].

An excess of sodium fluoride does not precipitate homogeneous products from solutions of the salts of the lightest lanthanides (La, Pr, Nd); hexagonal phases having almost the stoichiometric composition $NaLnF_4$ can be obtained in this way from solutions of samarium, europium, gadolinium, dysprosium, and holmium salts[219], while erbium, ytterbium, and lutetium ions are precipitated by an excess of sodium fluoride in the form of cubic fluorite-like phases with the composition $NaLn_2F_7.nH_2O$.[162] Potassium, rubidium, and caesium fluorides precipitate lanthanides (from Nd to Lu) in the form of phases which in the majority of cases are close in composition to the formula $M_2Ln_3F_{11}.nH_2O$.[162,163,219]

According to Ivanov-Emin et al.,[220] M_3LnF_6 and $MLnF_4$ can be obtained by the reaction of rare-earth bromides (or chlorides) with alkali metal fluorides in methanol solution.

The gas phase of the $NaF-YF_3$ and $NaF-LaF_3$ systems was found to contain, apart from NaF and LnF_3 molecules, also those of the compound $NaLnF_4$; there are data for the partial pressures of the components of the saturated vapour and the thermodynamic characteristics of the dissociation of $NaLnF_4$.[221,222]

2. MF_2-LnF_3 Systems

Most attention has been concentrated on systems containing rare-earth trifluorides and alkaline earth metal fluorides. The study of these systems is of practical importance in connection with the possibility of synthesising new phases having valuable optical, electrical, and magnetic properties. The isomorphism of alkaline earth metal fluorides and YF_3 (LaF_3, CeF_3), which has been known for a long time[223], is of especial crystal-chemical interest. An example of this type of isomorphism is provided by the minerals yttrocerite and yttrofluorite, which are widely distributed in nature.

Thermographic[224–231] and X-ray diffraction[232–237] data are now available for many MF_2-LnF_3 systems (M = Ca, Sr, or Ba). The formation by the components of solid solutions with the fluorite structure, the limits of the stability of which vary with the ratio of the cationic radii, is equally characteristic of all these systems. The phase diagrams for the MF_2-LnF_3 systems are usually classified in accordance with the capacity for the formation of other crystalline phases.

The phase diagrams for the MF_2–LnF_3 systems (Ln = La–Nd),[232,236] in which compounds are not formed by the components, are included in the first type. On the LnF_3 side, the systems are characterised by the formation of hexagonal solid solutions with the tysonite structure, which are stable approximately up to 15 mole % MF_2. In systems containing the trifluorides of elements ranging from samarium to dysprosium (holmium) (second type), the region of hexagonal solid solutions is limited on two sides by heterogeneous regions. The composition ~ $Ca_2Ln_5F_{19}$ (or $BaLn_3F_{11}$) corresponds to the limiting solid solution with the LaF_3 structure. As the ionic radius of the rare earth decreases, the region of existence of the hexagonal phase contracts. In the systems with BaF_2, such phases are more stable. On reducing the temperature, they decompose. The third type of diagram combines the systems containing the fluorides of the heaviest lanthanides (Er–Lu) and yttrium. The congruently melting compound $Ca_2Ln_5F_{19}$ (1156°C) is formed in the CaF_2–YF_3 system. Apart from the solid solutions of YF_3 and $Ca_2Ln_5F_{19}$ with the tysonite structure, the system was found to have a region of homogeneity between CaF_2 and $Ca_2Ln_5F_{19}$, the appearance of which is due to the ordering of the structure of the hexagonal phase[236]. A decrease of temperature leads to the contraction of the solid solution regions and their degeneration to a phase with a definite composition $Ca_2Ln_5F_{19}$ which decomposes at about 850°C into YF_3 and a cubic solid solution.

The congruently melting stoichiometric compounds $BaLn_2F_8$ and the incongruently melting phase with the probable composition $BaYF_5$ are formed in the BaF_2–YF_3 and BaF_2–LnF_3 systems, where Ln = Er–Lu. The crystals of the BaY_2F_8 and $BaTm_2F_8$ compounds belong to the monoclinic system (space group $C2/m$) and constitute a new structural type. Their structure consists of a framework of LnF_8 polyhedra connected edge to edge into six-membered rings forming channels in which are located barium atoms (coordination number 12)[238,239].

An exceptional feature of systems incorporating LnF_3 and alkaline earth metal fluorides is the high solubility of LnF_3 in MF_2 in the crystalline state, exceeding in some cases 50 mole % LnF_3. The solubility of LnF_3 in MF_2 increases with the ionic radius of Ln^{3+} also in the series CaF_2–SrF_2–BaF_2. The highest limiting concentration of LnF_3 is observed in the BaF_2–LaF_3 system and the lowest in the CaF_2–LuF_3 system[235]. With decrease of temperature, the stability of the cubic phases is higher the larger is the ionic radius ratio $M^{2+}:Ln^{3+}$.[234]

The unit cell parameters of the solid solutions with the fluorite structure in the CaF_2–LnF_3 systems increase and in the BaF_2–LnF_3 systems decrease with LnF_3 concentration: in the SrF_2–LnF_3 systems an increase in the unit cell dimensions occurs when the Ln^{3+} ionic radius is longer than that of neodymium. In the remaining cases the SrF_2 unit cell dimensions decrease. The substitution by strontium ions in the crystal lattice by neodymium ions does not lead to appreciable changes in the SrF_2 unit cell parameters[235]. In this case the increase of volume, associated with the filling of the free space in the cell by fluoride ions, is evidently compensated by the decrease due to the substitution of the larger cations by the smaller Nd^{3+} ions[234].

In order to explain the mechanism of the formation of solid solutions in the MF_2–LnF_3 systems, the measured crystal densities are frequently compared with the theoretical values for possible isomorphous substitution models. The agreement between the experimental values and those obtained on the hypothesis that additional fluoride ions are incorporated in the vacancies of the MF_2 structure as a result of the substitution of M^{2+} by Ln^{3+} constitutes fairly convincing proof of this type of mechanism[225,231,240]. To some extent it agrees with the ESR spectroscopic data for Ln^{3+} in MF_2 [241–246] and ^{19}F NMR data for CaF_2 containing cerium and ytterbium trifluorides[247]. X-Ray diffraction study of the $Ca_{0.6}Ce_{0.4}F_{2.4}$ single-crystal structure also made it possible to establish the presence in the solid solution of excess fluoride ions. However, their formation does not involve a simple incorporation of F^- ions in the centres of the cubic vacancies of the fluorite structure but the substitution of one ion in the initial structure by two (on substitution of one cation in the structure by Ln^{3+}), the additional ions being displaced along the space diagonal of the cubic vacancy to the extent of 1/6.[248]

The hexagonal solid solutions in the MF_2–LnF_3 systems have defect structures with anionic vacancies[231,234,237].

The study of the spectroscopic characteristics and induced emission parameters showed that activated crystals of solid solutions with the fluorite structure in the MF_2–LnF_3 systems have considerable advantages over simple fluorides and can be used to improve the efficiency of lasers[249–257]. The spectroscopic properties of solid solutions are associated with the characteristics of their structure, which is disordered. The random distribution of rare-earth ions among the cationic sites and the incorporation of fluoride ions in the vacancies of the crystal structure result in an abundance of centres, with various configurations of the surrounding species, where Ln^{3+} ions are located. Probably this is the cause of the broadening of the spectral lines. The removal of the structural degeneracy of the optical centres is also responsible for the weak concentration-dependent quenching of the Ln^{3+} luminescence. As regards their spectroscopic properties, these materials are intermediate between crystals and glasses. This can also be said of the ternary systems MF–MF_2–LnF_3.[203] The polythermal sections (CaF_2–$NaYF_4$ and CaF_2–$Na_2Ln_9F_{32}$) of the ternary systems revealed the formation of continuous solid solutions of the fluorite type. A decrease of temperature leads to an ordering of their structure[203]. Crystals of the CaF_2–$NaYF_4$ system have been used as the medium for lasers[258].

The fluorides of certain divalent elements, which crystallise with a structure of the fluorite type (CdF_2, EuF_2, PbF_2), also form variable-composition phases with rare-earth trifluorides. Fluorite-based solid solutions on the CdF_2 side and tysonite-based solid solutions on the LaF_3 side, separated by the heterogeneous region, have been found in the CdF_2–LaF_3 system, as in the case of CaF_2–LaF_3. With decrease of temperature, the solubility of LaF_3 in CaF_2 decreases appreciably and below 730°C the solid solutions decompose into the components. The hexagonal solid solutions are stable over a wide temperature range; the limiting solubility of CdF_2 in LaF_3 is 10 mole %. In the CdF_2–YbF_3 and CdF_2–YF_3 systems the limits of existence of the cubic solid solutions expand and at the same time there is an increase in the temperature range corresponding to the stability of the cubic phases—the decomposition of the solid solutions begins below 600°C.[259]

The formation of solid solutions in systems with cadmium fluoride involves the same mechanism as in the systems with alkaline earth metals[259,290]. Laser single crystals activated by neodymium have been obtained on the basis of cadmium fluoride containing up to 15 mole % YF_3.[261]

The study of the PbF_2–SmF_3 [262] and PbF_2–YF_3 [263] systems by thermal and X-ray diffraction analysis confirmed the formation of solid solutions.

In the PbF_2–CeF_3 system solid solutions with the CaF_2 structure exist up to about 60 mole % CeF_3. [240] The introduction of CeF_3 into PbF_2 does not affect its unit cell dimensions. Comparison of the experimental densities of the solid solutions in this system with the theoretical values for various types of isomorphous substitution is not inconsistent [240] with a model in which $3Pb^{2+}$ ions are substituted by two cerium ions with formation of cationic vacancies.

In the EuF_2–EuF_3 system [264] solid solutions based on the difluoride are stable up to 50 mole % EuF_3 (about 1300°C).

There is little information about the behaviour of rare-earth trifluorides in systems containing difluorides which do not crystallise with structures of the fluorite type. Data for the BeF_2–LaF_3 [190] and BeF_2–YF_3 [194,214] systems showed that beryllium fluoride in all probability does not form compounds with rare-earth trifluorides. Melts in systems incorporating beryllium fluoride show a tendency to form glasses. The glasses based on beryllium fluoride containing in addition alkali metal (and alkaline earth metal) fluorides are readily mixed with rare-earth trifluorides and the latter can be introduced at a high concentration. An advantage of these glasses is high transparency to ultraviolet light. The glasses formed in certain systems, for example in BeF_2–KF–YF_3–AlF_3, combine a high resistance to moisture with a low tendency towards crystallisation [194,265]. Beryllium fluoride glasses containing alkali metal fluorides, CaF_2, and AlF_3 are regarded as a possible material for lasers [265]. Their spectroscopic characteristics have been described and compared with those of oxygen glasses [266–271]. The principal characteristic of the spectra of Ln^{3+} in beryllium fluoride glasses is a narrowing of the luminescence band compared with oxygen glasses and a better resolution of the Stark components, probably associated with the weaker crystal field in the fluoride media. This results also in a smaller spectral width of the Nd^{3+} stimulated emission region compared with silicate glasses [266].

Certain features of the precipitation of rare-earth trifluorides from aqueous solutions in the presence of alkaline earth metal and other fluorides must be given special consideration. Khlopin and Merkulova [272] investigated the precipitation of RaF_2 with lanthanum trifluoride from aqueous solutions. They noted that, on reducing the concentration of the microcomponent in solution, the crystallisation coefficient tends to zero, i.e. there is a lower limit to miscibility. The presence of this limit was explained by the formation of solid solutions in which substitution in the crystal structure does not involve individual ions but whole blocks and consequently, in contrast to true homogeneous solid solutions, mixed crystals of this type may be regarded as quasi-homogeneous. It is noteworthy that radium fluoride is coprecipitated from the melt (KF–LaF_3 and RbF – LaF_3) [273] with lanthanum trifluoride, forming solid solutions without a lower limit to miscibility, which are evidently analogous to the tysonite phases in systems formed by rare-earth fluorides and alkaline earth metal fluorides. Possibly the mechanism of the coprecipitation of RaF_2 from aqueous solution with LaF_3 is based on the phenomenon of surface adsorption [274]. The appearance of a lower limit to miscibility can be accounted for from these standpoints using the concepts of statistical thermodynamics. According to this explanation, the condensed surface layer is fairly stable when the concentration of the microcomponent is above a certain critical value and can give rise to regions of its intrinsic crystal lattice during the growth of the crystal nuclei. Below this critical concentration of the microcomponent, the surface monolayer is unstable and should not be formed [275].

Data on the cocrystallisation of lanthanide and yttrium fluorides with alkaline earth metal fluorides from melts of the components have been presented [276–278] and the effect of the concentration of the microcomponent, the surrounding gaseous medium, and the ratio of the radii of the micro- and macro-components on the crystallisation coefficient have been discussed (see Klokman's review [279]).

The cocrystallisation of lanthanide and yttrium trifluorides with CaF_2 from solution obeys the homogeneous distribution law [280].

3. MF_3–LnF_3 and MF_4–LnF_3 Systems

Rare-earth trifluorides form solid solutions with one another and with the trifluorides of transuranic elements having the same structures. This property may be used to extract the tervalent rare earths formed in the fission of uranium, from fluoride melts with LnF_3 precipitates [281–283]. Small amounts of plutonium and neptunium are known to be capable of coprecipitating with lanthanum trifluoride, which gives rise to a method for the isolation of transuranic elements from solution on a carrier [284].

Rare-earth trifluorides in the hexagonal modification (of the tysonite type) form with one another a continuous series of solid solutions. The region of existence of the homogeneous tysonite phases with the orthorhombic trifluorides is limited and is narrower the greater is the difference between the ionic radii of the rare earths substituting one another in the unit cell. On formation of solid solutions of rare-earth trifluorides with one another and with the trifluorides of uranium and transuranic elements, the tervalent ions are distributed at random in the crystal structure. The unit cell parameters of the LaF_3(LnF_3) solid solutions decrease with increasing mole fraction of LnF_3. [285]

The interaction of rare-earth trifluorides with those of certain quadrivalent elements is of interest. The monograph of Seaborg and Katz [284] presents data on the almost quantitative coprecipitation of quadrivalent plutonium and neptunium from solutions with lanthanum trifluoride. In a study of the coprecipitation of quadrivalent thorium with LaF_3, Khlopin and Merkulova [286] concluded that they form anomalous solid solutions with a lower limit to miscibility. To confirm the possibility of the existence of solid solutions of rare-earth trifluorides and the tetrafluorides of cerium, thorium, zirconium, and uranium, Schlyter [285] undertook an X-ray diffraction study of the products of precipitation from solutions of their salts by sodium fluoride or hydrofluoric acid. He noted an appreciable decrease of the unit cell dimensions of lanthanum trifluoride precipitated in the presence of cerium and uranium salts; in the presence of thorium, the LaF_3 unit cell parameters remain unchanged, while in the presence of zirconium the decrease was very slight. The X-ray diffraction data for the precipitates thus suggest the formation of LaF_3–CeF_4(UF_4) solid solutions with a tysonite structure [285]. The decrease of the unit cell dimensions under these conditions might suggest that 4 lanthanum ions must be substituted by 3 M^{IV} ions with formation of cationic vacancies. However, thermographic and X-ray diffraction study of the CeF_3–CeF_4 system [287] did not confirm the presence of solid solutions of the components; the fusion diagram for this system is of the simple eutectic type and the interplanar

spacings and refractive indices of the compositions do not exhibit appreciable changes compared with CeF_3 and CeF_4. The coprecipitation of UF_4 (ThF_4) with rare-earth trifluorides from fluoride melts also has not been observed[281]. Possibly the coprecipitation of quadrivalent elements with LaF_3 is a property of aqueous systems only, since under these conditions finely dispersed precipitates with a high adsorption capacity are produced. The question of the behaviour of rare-earth trifluorides in systems containing the fluorides of quadrivalent elements apparently requires elucidation.

IV. RARE-EARTH OXIDE FLUORIDES

When the trifluorides are heated to 450–800°C, they react with atmospheric moisture with elimination of HF as a result of pyrohydrolysis. The intermediates in this reaction are oxide fluorides which on further interaction with water vapour are converted into the oxides (Ln_2O_3).[44,288] The pyrohydrolysis of the trifluorides at the beginning of the lanthanide series takes place at a higher temperature than for the heavier lanthanides and YF_3. Thus, by heating lanthanum and neodymium trifluorides in the presence of water vapour at 800°C, the stoichiometric oxide fluorides LnOF are obtained[289-292], whereas under the same conditions the trifluorides of dysprosium, holmium, erbium, and ytterbium can be fully converted into the oxides; it is sufficient to heat the trifluorides of these elements to 450°C in order to obtain their oxide fluorides.

Rare-earth oxide fluorides can also be obtained by the reaction of the trifluorides and oxides of the elements (at about 1000°C) in a vacuum or in an inert atmosphere[293-297]. The formation of lanthanum oxide fluoride was observed on dissolution of lanthanum hydroxide in lithium or sodium fluoride melts[298] and in the reaction between Ln_2O_3 and NHF_4.[299] They can also be obtained by the decomposition of the rare-earth fluorocarbonates (400–500°C)[169,171].

Zachariasen established[289] by X-ray diffraction of the pyrohydrolysis products of LaF_3 (900°C) and YF_3 (450°C) that in the initial stage a tetragonal phase is formed with a wide region of homogeneity, whose composition can be expressed by the formula $LnO_nF_{3n-2}(1 > n > 0.7)$. When $n = 1$, the tetragonal phase is unstable and is converted into a rhombohedral phase. The rhombohedral oxide fluorides of all rare earths[290-293,297], except CeOF, can be obtained by the pyrohydrolytic method. The pyrohydrolysis of CeF_3 in moist ammonia[290,300] and also the reaction of cerium dioxide with CeF_3 [301,302] (or a mixture of cerium, CeF_3, and CeO_2)[303] always gives rise to a cubic fluorite-like phase. As a result of the departure of its composition from stoichiometry, the unit cell parameter varies from 5.66 to 5.73 Å.[301-303] The structure of the variable-composition cubic phase contains both tervalent and quadrivalent cerium ions. At 1150°C the limiting solubility of CeO_2 in CeF_3 corresponds to the composition $CeO_{1.1}F_{0.9}$ ($a = 5.68$ Å).[303] The rhombohedral modification of CeOF can be obtained by the reaction of Ce_2O_3 and CeF_3 in a vacuum (1150°C)[302].

The rhombohedral LnOF phases (space group $R\bar{3}m$, $z = 2$) have the stoichiometric composition (or a very narrow region of homogeneity). The unit cell dimensions of the oxide fluorides are listed in Table 5.

On heating above 500–600°C the rhombohedral oxide fluorides undergo the reversible transformation of $LnOF_{rhombohedr} \rightleftharpoons LnOF_{cubic}$. In general the polymorphic transformation temperature changes only slightly in the lanthanide series (494°C for LaOF, 524°C for NdOF, 588°C for HoOF, and 592°C for ErOF).[296] At high temperatures the oxide fluorides decompose with evolution of gaseous LnF_3.[296] At room temperature the cubic oxide fluorides are metastable but can be obtained from elements ranging from lanthanum to europium by cooling the products of the reaction of LnF_3 and Ln_2O_3 at 800–1200°C.[293-296]

The cubic oxide fluoride phases have a structure of the CaF_2 type and are characterised by a random distribution of oxygen and fluoride ions among the anionic sites of the crystal lattice of this type. At room temperature it is stabilised by crystal lattice defects[296,304,305], i.e. the F^- ions incorporated in the vacancies. It is striking that the formation of the cubic phase has been detected in a study of the pyrohydrolysis products of NdF_3 (and PrF_3) for compositions very close to stoichiometry but with an excess of the fluoride[306]. The rigorously stoichiometric oxide fluorides are rapidly converted into the low-temperature form on cooling and it is apparently difficult to obtain their cubic phases by quenching[307].

Table 5. X-ray diffraction data for rhombohedral rare-earth oxide fluorides[289-291,295,297].

Compound	a, Å	$\alpha°$	d(X-ray), g cm^{-3}	Compound	a, Å	$\alpha°$	d(X-ray), g cm^{-3}
LaOF	7.132	33.01	6.02	TbOF	6.751	33.09	7.89
PrOF	7.016	33.03	6.39	DyOF	6.685	33.10	8.25
NdOF	6.953	33.04	6.69	HoOF	6.637	33.16	8.52
SmOF	6.865	33.07	7.19	ErOF	6.625	33.21	8.65
EuOF	6.827	33.05	7.37	YbOF	6.545	33.30	9.18
GdOF	6.800	33.05	7.67	YOF	6.697	33.20	5.14

An increase in the number of interstitial defects, i.e. an increase of the concentration of LnF_3 in LnOF, leads to a more ordered distribution of anions, characteristic of the tetragonal phase in the structure of which the oxygen and fluoride ions form alternating layers[289].

In general the region of existence of the tetragonal phase becomes narrower on increasing the atomic number of the cation[296]. The unit cell dimensions of the LnO_nF_{3n-2} tetragonal phase increase as n diminishes[288,296]. However, it should be borne in mind that the data of recent investigations of the phase diagrams of the oxide fluorides[307-309] by high-temperature X-ray diffraction analysis, by annealing the phases obtained at a high temperature, and by synthesising the oxide fluoride single crystals show that the diagrams are still more complex. In particular, the existence, at least in certain systems, of wide tetragonal phase regions is doubtful. In systems containing the oxide fluorides of elements ranging from samarium (and also yttrium) the tetragonal phases have a narrow region of homogeneity or are altogether absent. Moreover, even in systems containing the oxide fluorides of the elements at the beginning of the lanthanide series the region of tetragonal solid solutions is separated from those of the cubic and rhombohedral phases by a two-phase region. At about 700°C it is converted into a phase belonging to a crystal system of lower symmetry. In addition, in some systems the rhombohedral phases LnO_nF_{3n-2} with $n \simeq 0.6$–0.8 have been found in certain systems at a high temperature[307]. Possibly many systems do not contain homo-

geneous regions but discrete ordered (orthorhombic) phases, whose composition may be expressed by the general formula $(Ln_xO_{x-1}F_{x+2})_4$. The single crystals of the oxide fluorides of certain elements having this composition having been synthesised, for example $Y_{28}O_{24}F_{36}$ and $Er_{20}O_{16}F_{18}$. The structures of these phases are characterised by a unit cell comprising several layers of fluorite cells (7 in yttrium oxide fluoride and 5 in erbium oxide fluoride)[308].

In the crystal structures of the oxide fluorides the rare-earth ions can substitute one another. Such mixed phases have been investigated for the CeF_3–La_2O_3 (Pr_2O_3, Y_2O_3) systems. The following regions of homogeneity have been found in these systems: 14–60 mole % La_2O_3, 20–55 mole % Pr_2O_3, and 34–55 mole % Y_2O_3.[310] The cubic unit cell parameters (CaF_2 structural type) for equimolar compositions are 5.765 Å ($CeLa_2O_3F_3$) and 5.675 Å ($CePr_2O_3F_3$). $CeY_2O_3F_3$ has a rhombohedral unit cell ($a = 6.72$ Å; $\alpha = 30°20'$, $z = 2$). In the solid solutions of these systems either the vacancies are filled (when the fluorine content is less than in the equimolecular product) or anionic vacancies are formed (when the fluorine content is greater than in the equimolecular product).

Cerium trifluoride (and probably the trifluorides of other rare earths) forms non-stoichiometric phases also with oxides of bi- and quadri-valent metals. ThO_2 dissolves up to 62.5 mole % CeF_3. The formation of solid solutions with a cubic fluorite-type structure in this system is accompanied by the filling of the vacancies by fluoride ions. With increase of the content of dissolved CeF_3, the ThO_2 unit cell parameter increases from 5.0 to 5.78 Å.

Cerium trifluoride forms with the oxides of bivalent elements (MgO, CaO, SrO, BaO) solid solutions in the ranges 25–65% MgO, 35–80% CaO, 30–67% BaO, and 25–70% SrO. In the CeF_3–MgO (CaO) and CeF_3–SrO systems the crystals of the solid solutions belong to the orthorhombic system ($z = 2$). Depending on the compositions of the solid solutions of CeF_3 and MgO, the crystal structure contains an excess or a deficiency of cations, while in the crystal structure of the CeF_3(SrO) solid solutions there is an excess or a deficiency of anions. This mechanism is also characteristic of the formation of cubic fluorite-type solid solutions of CeF_3 and BaO [the unit cell parameter of the phase with equimolecular composition ($CeBaOF_3$) is 6.12 Å].[310]

The oxide fluorides of the rare earths and lithium $LiLnOF_2$ have been obtained by the pyrohydrolysis of mixtures of LiF and LnF_3 (or by heating compressed LiF and LnOF discs)[297].

Rare-earth chalcogenide fluorides. By sintering rare-earth sesquisulphides and trifluorides at 450–1000°C in evacuated sealed tubes, the sulphide fluorides LnSF may be obtained[311–314]. The sulphide fluorides of elements ranging from lanthanum to erbium crystallise with a structure of the PbClF type. The compounds YSF, HoSF, and ErSF are dimorphic. The crystals of their second modification (and also of YbSF and LuSF) belong to the hexagonal system (the structural type is unknown). Lanthanum selenide fluoride LaSeF crystallises in the orthorhombic system[312].

Variable-composition sulphide fluorides and selenide fluorides have been found in the CeF_3–MS and CeF_3–MSe systems (M = Ca, Sr, or Ba). The structures of the solid solutions produced in these systems are derived from that of fluorite distorted to different extents. The nature of the substitution of ions in their formation is similar to that in the CeF_3–MF_2(MO) systems[315].

V. FLUORIDES OF BIVALENT AND QUADRIVALENT RARE EARTHS

Compounds with the rare earths in the bivalent state are known for samarium, europium, thulium, and ytterbium. Of the difluorides, SmF_2, EuF_2, and YbF_2 have now been obtained in a pure form. They are synthesised by reducing the trifluorides with hydrogen[316–319] or by the corresponding rare-earth metal[320,321] at a high temperature. Reduction with hydrogen (1300–1400°C) yields only europium difluoride with a composition close to the stoichiometric formula. Stoichiometric samarium and ytterbium difluorides could not be obtained by this procedure. The composition of samarium fluoride obtained by the reduction of SmF_3 varies from $SmF_{2.3}$ to $SmF_{2.5}$. Similarly an F : Yb ratio less than 2.24 was not obtained in the product of the reduction of ytterbium trifluoride with hydrogen[319]. The stoichiometric difluorides of these elements can be obtained by the reduction of the trifluorides by the metal thermite method (1500–1900°C) in sealed molybdenum or tantalum crucibles. Thulium can be reduced in the same way, although pure thulium difluoride has not been obtained[321]. The bivalent metal fluorides can also be prepared by the double decomposition of a solution of Ln^{II} sulphate and sodium or ammonium fluoride in an atmosphere of an inert gas[319,322].

Rare-earth difluorides crystallise with a fluorite-type structure[323] and like fluorite form with rare-earth (and also aluminium) trifluorides solid solutions involving the filling of the vacancies[264,320,324]. This in fact accounts for the non-stoichiometric composition of the difluorides and the variability of their unit cell parameters quoted in different studies. For the same reason, the experimental values of the effective magnetic moment of EuF_2 differ from the theoretical value[318]. The antiferromagnetic ordering observed in EuF_2 is also associated with its contamination[325–327].

Cubic solid solutions based on the fluorite structure exist in the range $LnF_{2.0}$–$LnF_{2.25}$.[321] The unit cell parameters vary under these conditions from 5.87 to 5.84 Å (Sm), from 5.84 to 5.81 Å (Eu), and from 5.60 to 5.57 Å (Yb). A phase having a different structure was detected in the LnF_2–LnF_3 systems for the ratios F : Ln = 2.25–2.45.[321] Mössbauer spectra indicate the presence of Eu^{2+} and Eu^{3+} ions in the structure of the cubic phases and density measurements confirm the mechanism of their formation involving the insertion of the anions[321].

Rare-earth difluorides melt at a higher temperature than the trifluorides (above 1400°C)[325]. The compounds $MLnF_3$ are apparently formed with alkali metal fluorides. The double fluoride $CsEuF_3$ has the perovskite structure[328]. Europium difluoride forms with AlF_3 the compound $EuAlF_5$ which has the same structure as $SrAlF_5$.[324]

The bivalent state in the fluoride compounds of other rare earths can be achieved by irradiating with X-rays alkaline earth metal fluoride crystals activated with Ln^{3+}.[329,330] The reduction to doubly charged lanthanide ions is also possible by chemical methods[331], electrolysis in the solid phase[332–334], or by the action of powerful light pulses[335]. Lanthanum, neodymium, dysprosium, holmium, erbium, and thulium have been obtained in the bivalent state in fluoride matrices and investigated by physical methods. Under the action of radiation and on heating $CaF_2(Ln^{3+})$ crystals in an electric field, only some of the Ln^{3+} ions pass to the bivalent state. The percentage reduction of Ln^{3+} to Ln^{2+} depends on the radiation dose and the concentration of activator ions[336]. On average, the conversion reaches 5–10%. An appreciable increase in

the efficiency of the reduction has been achieved by heating $CaF_2(Ln^{3+})$ crystals in alkaline earth metal vapour at 750–950°C (the "additive") method. In this case it is possible to convert into the bivalent state up to 50–70% of neodymium, dysprosium, holmium, erbium, and thulium ions[337], which exhibit high stability to the action of light and heat[331,333,338,339].

The study of the optical spectra of Ln^{2+} in alkaline earth metal fluorides (and in other matrices) is of practical importance in connection with the problem of lasers. This field has been particularly developed in the work of Feofilov and coworkers[330,340]. Stimulated emission both under pulsed and continuous conditions has been achieved with bivalent rare-earth ions. The $CaF_2(Dy^{2+})$ laser, which has the smallest threshhold power, is of a special interest.

The local crystal field around Ln^{2+} in MF_2 has a high symmetry. The replacement of fluorine by other halogens (Cl, Br, I) should result in a lowering of the symmetry of the environment and the removal of the degeneracy of the levels[340]. A narrow luminescence band has been obtained for mixed MFHal crystals of this type activated with Dy^{2+}.[341]

The adsorption and luminescence spectra of Sm^{2+} and Tm^{2+} in beryllium fluoride glasses have been investigated[342,343]. The doubly charged ions in glasses based on beryllium fluoride are stable and are not oxidised on heating up to temperatures corresponding to the softening of the glasses.

The quadrivalent state is characteristic of cerium, praseodymium, and terbium, which can be obtained in the form of tetrafluorides or their double compounds with alkali metal fluorides. Quadrivalent neodymium and dysprosium have also been obtained in the form of complexes.

Anhydrous cerium tetrafluoride can be prepared by fluorinating cerium dioxide or cerium trifluoride[344,345]. The purest fluoride is obtained when elemental fluorine is employed as the fluorinating agent (350–500°C [346]). Hydrofluorination (with HF) of cerium dioxide at 250–325°C leads to a product containing a small amount of oxygen (possibly water) and at 400°C to phases whose composition varies from $CeF_{3.14}$ to $CeF_{3.87}$.[346] Anhydrous cerium trifluoride interacts with bromine trifluoride, but a stoichiometric product is not obtained, its maximum fluorine content corresponding to the formula $CeF_{3.83}$. Cerium tetrafluoride crystallises with a structure of the UF_4 type (monoclinic unit cell with the parameters $a = 12.60$ Å, $b = 10.60$ Å, $c = 8.30$ Å, and $\beta = 126°$).[347] The ^{19}F NMR spectrum of powdered CeF_4 showed line splitting above 287°K, which was tentatively explained by a structural transformation of the tetrafluoride[348].

In a neutral atmosphere cerium tetrafluoride is stable at the normal pressure up to 550°C. Above this temperature the tetrafluoride decomposes appreciably with evolution of fluorine and also sublimes. In a vacuum cerium tetrafluoride decomposes above 230°C.[349] Hydrogen reduces CeF_4 at 200–300°C. Cerium tetrafluoride reacts with the dioxide at 400°C, forming the trifluoride: $3CeF_4 + CeO_2 \rightarrow 4CeF_3 + O_2$. In dry oxygen cerium tetrafluoride is stable up to 700°C. Moist oxygen decomposes it at 500°C with formation of cerium trifluoride and dioxide. At 1000°C water vapour hydrolyses CeF_4 quantitatively to CeO_2. Cerium tetrafluoride is insoluble in water, but the latter gradually decomposes it to CeF_3. By dissolving cerium dioxide in an excess of hydrofluoric acid, it is possible to obtain the hydrate $CeF_4.H_2O$. Its structure differs from that of the anhydrous tetrafluoride[346]. When it is dehydrated at 200°C in a vacuum, the $CeF_4.0.3H_2O$ phase is formed without appreciable structural changes. In an inert atmosphere the hydroxide continuously loses weight between 80° and 440°C and is converted into CeF_3. It cannot be completely dehydrated without loss of fluorine[346].

The solubility of CeF_4 in liquid hydrogen fluoride (0.1 g in 100 g of HF) is higher than that of CeF_3.[151] The results of various workers[350,351] for the composition of the solid phase in equilibrium with the saturated solution at high HF concentrations and data concerning the possible existence of $CeF_4.HF$ are contradictory.

Fluorination of a mixture of alkali metal chlorides and cerium dioxide in molar proportions of 2 : 1 and 3 : 1 at 400–500°C yields compounds with the compositions M_2CeF_6 and M_3CeF_7.[352,353] The analogous compounds with ammonium fluoride can be obtained by allowing a concentrated NH_4F solution to react with hydrated cerium tetrafluoride; for the ratio $z = NH_4F : CeF_4 \geq 5$, the product is $(NH_4)_3CeF_7$, whereas with z between 2 and 5, $(NH_4)_2CeF_6$ is formed. If the ratio $z \leq 2$, the precipitate formed in the reaction has the composition NH_4CeF_5.[354] According to Penneman and Rosenzweig[355], in the CeF_4–NH_4F–H_2O system at 25°C the solid phase with the highest ammonium fluoride content is $(NH_4)_4CeF_8$, which is stable in the concentration range 28.9–45 wt.% NH_4F in the saturated solution. This compound was to be expected on the basis of refractometric measurements and by analogy with the UF_4–NH_4F system.[356] In addition, the fluoride $(NH_4)_7Ce_6F_{31}$ was obtained from solutions at a low NH_4F concentration (1%)[355] and the reaction of CeO_2 and NH_4F at 200°C gave $NH_4Ce_2F_9$.[346]

The reaction of CeF_4 with alkaline earth metal and lead fluorides gives the compounds $MCeF_6$.[357,358] One of the methods for their preparation involves the reaction of hydrofluoric acid with CeO_2 in the presence of the corresponding metal carbonate or the fluorination of a mixture of CeF_4 and the alkaline earth metal chloride (at 100°C). With the exception of Na_3CeF_7 and $(NH_4)_3CeF_7$, the compounds M_3CeF_7 crystallise in the cubic system and the compounds M_2CeF_6 in the hexagonal system of the type characteristic of modifications of uranium fluoride complexes[352,353]. The majority of the fluorides were investigated by X-ray diffraction in powder form. Revision of the crystal structure, for example of that of $(NH_4)_2CeF_6$, after preparing the single crystals established that this compound belongs to a system of lower symmetry[359] (space group $Pbcn$; $a = 7.03$ Å, $b = 12.10$ Å, and $c = 7.44$ Å). The double fluorides of cerium(IV) and alkaline earth metals and lead crystallise with a structure of the tysonite type. In the crystal structures of these compounds the cerium and M^{2+} ions are distributed at random among the cationic sites[358].

Double compounds of cerium are incongruently soluble in water[360,361]. The cerium ammonium double fluoride $(NH_4)_4CeF_8$ is immediately converted on heating into $(NH_4)_2CeF_6$, which decomposes at 240°C with formation of NH_4CeF_5. The final thermal decomposition product is cerium trifluoride.

In contrast to CeF_4, praseodymium tetrafluoride cannot be obtained in a pure form by high-temperature fluorination with elemental fluorine[349], although it is stable in the form of compounds with alkali metal fluorides[316,362,365] or in the form of solid solutions with CeF_4 obtained by fluorinating a mixture of CeF_3 and PrF_3.[316] The only method for the preparation of pure PrF_4 is the decomposition of Na_2PrF_6 with liquid hydrogen fluoride[366]. The method involves the extraction of sodium fluoride and it is recommended that the extraction be performed in the presence of gaseous fluorine[367] to avoid the contamination of PrF_4 with praseo-

dymium trifluoride. The effective magnetic moment of the tetrafluoride thus obtained agrees with the theoretical value[368].

Praseodymium tetrafluoride has the same structure as CeF_4 ($a = 12.47$ Å, $b = 10.54$ Å, $c = 8.18$ Å, and $\beta = 126.4$). [367] Compounds of the tetrafluoride with alkali metal fluorides can be obtained by fluorinating mixtures of MCl and Pr_6O_{11} (400–500°C)[362] or of PrF_3 and MF (450°C)[367]. Depending on the proportions of the components in the initial mixture, the compounds M_3PrF_7, M_2PrF_6, $MPrF_5$, and $M_7Pr_6F_{31}$ are formed. The quadrivalent state of praseodymium in these compounds has been confirmed by chemical[362,363], spectrophotometric[362,363,369,370], and magnetic methods[363].

Fluoropraseodymates have the same structures as the analogous uranium tetrafluoride compounds; Na_2PrF_6 crystallises in the orthorhombic system (space group *Immm*) like γ-Na_2UF_6, while $Na_7Pr_6F_{31}$ has the same structure as the rhombohedral fluoride $Na_7U_6F_{31}$. [367]

Terbium(IV) fluoride has been obtained by the reaction of its trifluoride with elemental fluorine (300–500°C). [349] It crystallises with a UF_4 type structure, like CeF_4 and PrF_4. A compound of TbF_4 with caesium fluoride (Cs_3TbF_7)[352,363,371], crystallising in the cubic system, has been obtained. Fluoroterbates analogous to Cs_2CeF_6 and Cs_2PrF_6 could not be obtained[371].

All the compounds of quadrivalent praseodymium and terbium are stable only in dry air and at room temperature. The majority of fluoropraseodymates are decomposed by water with formation of hydrated praseodymium(III) fluorides or double fluorides[363,364]. Their thermal stability may be increased to 1200°C by the formation of solid solutions with fluorozirconates, fluoroniobates, etc.[365]

The quadrivalent state can probably be achieved for neodymium and dysprosium in the form of compounds with caesium fluoride[316,352,364]. The compositions of these compounds are approximately represented by the formulae Cs_3NdF_7 and Cs_3DyF_7. [364,372] According to magnetic measurements, about half the dysprosium atoms in the compound $Cs_3DyF_{6.7}$ are in the quadrivalent state.

Progress in the Halogenation of Organic Silicon Compounds

G.V.Motsarev, K.A.Andrianov, and V.I.Zetkin

The Review deals mainly with the direct halogenation of organic silicon compounds by halogens and halogenated compounds as among the most important methods for the preparation of organosilicon compounds containing halogen in the organic radicals. With respect to preparative possibilities, experimental simplicity, and in individual cases the yields obtained, the direct chlorination and bromination of organic silicon compounds has no equal. The preparation of halogenated alkyl (and aryl) silanes by various methods has been partly covered in previous monographs and reviews[1-8], but the direct halogenation of organic halogenosilanes has not yet been adequately reported in the review literature. The present paper makes an attempt to fill this gap. It gives a detailed discussion of the conditions and the mechanisms of radical halogenation (mainly with chlorination as example) under the influence of various initiators (ultraviolet radiation, peroxides, azo-compounds, γ-rays), and also electrophilic substitution and cleavage of the silicon-carbon bond in aryl- and alkylaryl-chlorosilanes. Besides substitutive halogenation, involving replacement of hydrogen in organic radicals by halogen atoms, the addition of halogen at double bonds present in these radicals is also surveyed. A list of 335 references is included.

I. INTRODUCTION

Typical polysiloxane materials, despite their valuable technical properties, are no longer able at present to satisfy completely the increasing demands of modern technology, especially with respect to stability to heat and thermal oxidation, resistance to oils and fuels, lubricating and adhesive properties, etc.

A promising method for the controlled modification of the properties of polyorganosiloxanes is to introduce functional groups into the organic radicals framing the siloxane chains. The presence of a polar substituent in a hydrocarbon radical attached to a silicon atom increases the polarity of the polymer molecule and therefore improves the adhesion, mechanical strength, and other properties of practical importance.

The production of modified organosilicon polymers of this type demands appropriate monomers with functional groups, primarily halogeno-derivatives (especially chloro-derivatives) of various alkyl- and aryl-chlorosilanes. These are convenient initial compounds for obtaining other carbon functions of silicon—amines, nitriles, alcohols, acids, thiols, thiocyanates, etc. This is probably the reason for the rapid development of research on the halogenation of various organosilicon compounds.

Before examining the halogenation of organic silicon compounds we must consider certain specific properties of silicon, distinguishing it from carbon and resulting from the intermediate position which it occupies between this typical non-metal and the Group IV metals (germanium, tin, lead). This is important for a correct understanding of the influence of these characteristics on the reactivity of silicon–carbon and silicon–halogen bonds (compared with carbon–carbon and carbon–halogen bonds), which must be taken into account in order to accomplish the halogenation of organosilicon compounds.

II. SOME SPECIFIC FEATURES OF THE SILICON ATOM INFLUENCING THE REACTIVITY OF ITS ORGANIC COMPOUNDS

While occupying a position between carbon and germanium in the Periodic System, silicon is closer to the latter in most of its properties[4,6] (see Table).

Physical properties of the elements—carbon, silicon, and germanium—and their bonds with carbon and chlorine.

Element	Nuclear charge	Electronic structure	Covalent radius	Electronegativity (Ref.9)	Coordination No.	Energy of bond, kcal mole^{-1}, with		Ionic character of bond with Cl, %
						carbon	chlorine	
Carbon	6	$1s^2 2s^2 2p^2$	0.77	2.5	4	84.9	77.9	6
Silicon	14	$1s^2 2s^2 2p^6 3s^2 3p^2$	1.17	1.8	6	75.0	90.3	30
Germanium	32	$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^2$	1.22	1.7	6			

By readily donating its valency electrons, the silicon atom is more liable to be attacked by various reagents than is the carbon atom in compounds of similar structure.

The comparatively high energy of the silicon–chlorine bond in chlorosilanes is explained by the considerably lower electronegativity of the silicon atom compared with carbon, which, combined with the great polarisability of the electron sheath of the silicon atom, ensures that the silicon–chlorine bond shall be highly reactive. The lower energy of the silicon–carbon bond than of the carbon–carbon bond promotes greater lability of the former, especially in electrophilic substitutions[4]. Silicon is able to form additional bonds by filling vacant 3*d*-orbitals. In most of its compounds silicon is electronically unsaturated[10,11], because its capacity for coordination is not completely utilised in these compounds.

The above specific structural features of the silicon atom and the bonds it forms with carbon and halogens have a definite effect on the reactivity of organosilicon compounds towards halogens.

III. STABILITY OF THE SILICON–CARBON BOND UNDER CONDITIONS OF HALOGENATION

The halogenation of alkylhalogenosilanes at various temperatures involves not only the compounds undergoing halogenation, an elementary halogen, and a catalyst (usually a metal chloride) but also the hydrogen halide which is liberated. All these factors (halogen, hydrogen halide, catalyst, and temperature), either individually or in combination, are able under certain conditions to cleave the silicon–carbon bond. Before considering the halogenation of organosilicon compounds, therefore, it is advisable to discuss the stability of this bond to the above reagents.

The greater polarity of the silicon–carbon bond and the shielding effect of the silicon atom make this bond thermally more stable than is the carbon–carbon bond.

When halogens act on aliphatic compounds of silicon, the hydrogen atoms of the alkyl group undergo radical replacement by halogen. The rate of cleavage of the silicon–carbon bond by bromine or iodine depends on the structure of the initial silane[12], and is greatly increased in the presence of a catalyst of the aprotic acid type. Thus boiling tetraethylsilane with iodine in the presence of aluminium iodide splits off two ethyl groups with the formation of diethyldi-iodosilane[13]. The action of aluminium chloride on tetraethylsilane in chloroform splits off all four ethyl radicals even under ordinary conditions. Iron(III) chloride, bismuth chloride, and mercury(II) chloride also detach aliphatic radicals from the silicon atom under considerably more severe conditions[14]. Tetra-alkylsilanes undergo fission in the presence of aluminium chloride[15].

The introduction of halogen atoms into the alkyl group of an organosilicon compound facilitates its detachment from the silicon atom, the stability of the silicon–carbon bond depending on the position of the halogen relative to the silicon atom[6,8]. α-Halogenoalkylsilanes are relatively stable, with the exception of chloromethyltrialkylsilanes. The introduction of a halogen atom into an aliphatic radical in the β-position with respect to silicon produces a sharp decrease in the stability of the silicon–carbon bond. A γ-halogen atom weakens the bond to a lesser extent than does a β-halogen.

Mono- and di-chloromethyl derivatives of silanes are stable towards acids[16], but in the presence of alkalis quantitative elimination of α-chlorinated alkyl groups takes place. As was to be expected, the polarity and hence the sensitivity of the silicon–carbon bond to nucleophilic reagents falls in the sequence $CCl_3 > CHCl_2 > CH_2Cl$.[17–19] The stability of the silicon–carbon bond improves with increase in the length of the aliphatic chain containing halogen in the α-position to the silicon atom[20], but when a β-halogen atom is present these compounds, on treatment with acids and alkalis, also readily undergo the so called β-decomposition with formation of an alkene[21–25]. The tendency of the molecule to β-decomposition increases markedly with increase in the number of alkyl radicals attached to the silicon atom, and completely substituted derivatives, e. g. $(C_2H_5)_3SiCH_2CH_2Cl$, decompose even on distillation (at 80°C). γ-Decomposition, with the formation of cyclopropane (or propene) and its derivatives, takes place similarly to β-decomposition, but less vigorously.

Halogens and hydrogen halides are able to detach aryl radicals from the silicon atom with the formation of a silicon–halogen bond. Thus the phenyl groups in tetraphenylsilane are eliminated by the action of bromine[26–28]. The removal of an aromatic group by bromine and iodine becomes easier with the accumulation of alkyl radicals on the silicon atom[29,30]. Under more severe conditions (270–300°C) dry chlorine is also able to split off phenyl radicals[31,32]. The stability of the $Si-C_{Ar}$ bond is greatly affected by the nature of other atoms and groups attached to the silicon. Electronegative substituents make cleavage of the bond more difficult, as is shown especially clearly by phenyltrichlorosilane, which can be chlorinated normally by an electrophilic mechanism[32]. Depending on the nature of the substituents the stability of aromatic silicon compounds towards the action of bromine in solvent solution[33] diminishes in the sequence

$$o\text{-}NO_2C_6H_4Si(CH_3)_3 > p\text{-}NO_2C_6H_4Si(CH_3)_3 > m\text{-}NO_2C_6H_4Si(CH_3)_3 > C_6H_5Si(CH_3)_3$$

The products of this reaction indicate that the usual electrophilic replacement of the trimethylsilyl group by bromine has taken place[34]:

$$C_6H_5Si(CH_3)_3 + Br_2 \rightarrow C_6H_5Br + (CH_3)_3SiBr$$

Hydrogen halides act similarly to halogens on the $Si-C_{Ar}$ bond. Comparison of the stability of the aromatic silanes to acid reagents[16–18,35–79] has provided quantitative estimates, based on the Hammett constants δ, of the influence of nuclear substituents on the stability of $Si-C_{Ar}$ bond. It was found that the strength of the bond increases with increase in δ. Nuclear substituents having $\delta > +0.4$ (*m*-CN, *p*-CN, *m*-NO_2, *p*-COOH, *p*-CH_3CO) so strengthen the bond that it is not cleaved by electrophilic reagents[37].

Among the strongest electrophilic reagents are aluminium chloride, iron(III) chloride, and other metal chlorides normally employed as catalysts in the halogenation of aromatic silicon compounds. Aluminium chloride vigorously cleaves the $Si-C_{Ar}$ bond in diphenyldichlorosilane[53], tetraphenylsilane[54], phenyltriethylsilane[55], phenyltrichlorosilane[56–58], and also several other phenyl- and halogenophenyl-silanes[54,56,57,59]. The action of aluminium chloride is especially clearly developed in certain solvents: e.g. in chloroform aluminium chloride cleaves not only the $Si-C_{Ar}$ bond but also the Si–Si, Si–O–Si, and $Si-CH_2C_6H_5$ bonds[53]. It was assumed originally[53–58] that reaction between aromatic silanes and aluminium chloride involves the intermediate formation of phenylaluminium dichloride. Later investigations have shown[60,61] that the true cleaving agent is the acid $HAlCl_4$, formed from aluminium chloride and hydrogen chloride, the latter resulting from the hydrolysis of chlorosilane and aluminium chloride by moist air. In the absence of moisture (or hydrogen chloride) aluminium chloride is unable to effect the cleavage

of phenylchlorosilanes. Yet fission of the Si–C_{Ar} bond in the presence of aluminium chloride is appreciably accelerated by passing hydrogen chloride through the reaction mass[62]. Chlorides of other metals, e.g. iron and antimony, have a more moderate effect on the Si–C_{Ar} bond[58,63-65]. Phosphorus pentachloride is a strong electrophilic reagent, rupturing the silicon–carbon bond in aliphatic and aromatic silanes[27,46].

In contrast to alkylchlorosilanes the introduction of a halogen atom into a phenyl radical produces only a slight increase in polarity of the Si–C_{Ar} bond. In this case the bond is stabilised, as is confirmed by the resistance to alkaline hydrolysis of chlorophenyltrichlorosilane and ethylchlorophenyldichlorosilane[80]. Increasing the number of chlorine atoms in the phenyl group has hardly any effect on the Si–C_{Ar} bond.

IV. RADICAL HALOGENATION (CHLORINATION, BROMINATION) OF SILICON-CONTAINING ALIPHATIC COMPOUNDS

1. Preparation of Chloroalkyl Compounds of Silicon

Chlorination of alkylchlorosilanes in liquid and vapour phases takes place by a radical–chain mechanism. Chlorine and sulphuryl chloride are usually employed as chlorinating agents. Chlorination is initiated by ultraviolet radiation, ionising radiations, peroxides, and other chemical initiators.

(*a*) Chlorination by chlorine

Systematic investigation of the chlorination of aliphatic organosilicon compounds began in 1945, when the photochemical liquid-phase chlorination of several methylchlorosilanes was first achieved[16], after which study of this reaction was continued on a wide scale[17,18,67-76]. Several regularities were found in the chlorination of these compounds. The rate of chlorination of methylchlorosilanes decreases in the sequence

$$(CH_3)_4Si > (CH_3)_3SiCl > (CH_3)_2SiCl_2 > CH_3SiCl_3$$

When one chlorine atom in dimethyldichlorosilane is replaced by a methyl group, the rate of chlorination is increased ninefold[67], which is probably explained by the difference between the induction effects of chlorine atoms and of methyl groups.

In the chlorination of methylchlorosilanes the chlorine exhibits a tendency to replace successively hydrogen atoms in the same methyl group, which indicates that the chloromethyl group is more rapidly chlorinated than is an unsubstituted methyl group. As a consequence, only trichloromethyltrichlorosilane can be obtained by the photochemical liquid-phase chlorination of methyltrichlorosilane[17,68,69,77]. Increase in the number of methyl groups attached to silicon increases the possibility that a second chlorine atom will enter an adjacent methyl group. Thus the chlorination of dimethyldichlorosilane involves the successive replacement by chlorine of the hydrogen atoms only in one methyl group; trimethylchlorosilane yields an appreciable quantity of methylbischloromethylchlorosilane; and the main product of the chlorination of chloromethyltrimethylsilane is bischloromethyldimethylsilane[97,78]. Thus chlorosilyl groups possess a well developed orienting effect[67,73].

It is interesting to compare the chlorination behaviour of methylchlorosilanes and their carbon analogues[67]. Neopentane and tetramethylsilane react readily with chlorine on ultraviolet irradiation[11] to form analogous products, as is evident from the ratios

$$\frac{(CH_3)_3SiCHCl_2}{(CH_3)_3Si(CH_2Cl)_2}=0.66 \qquad \frac{(CH_3)_3CCHCl_2}{(CH_3)_2C(CH_2Cl)_2}=0.67$$

No such analogy is found in the chlorination of trimethylchlorosilane and t-butyl chloride. In an equimolar mixture of these compounds the former is chlorinated more slowly and with preferential substitution by chlorine of hydrogen atoms in the same methyl group, as is evident from the proportions of the chlorination products

$$\frac{(CH_3)_2(CHCl_2)SiCl}{CH_3(CH_2Cl)_2SiCl}=4.9 \qquad \frac{(CH_3)_2(CHCl_2)CCl}{CH_3(CH_2Cl)_2CCl}=0.67$$

These results show that differences in the direction of chlorination are determined primarily by the nature of the central atom.

The marked difference in rates of chlorination between methyl and chloromethyl groups attached to a silicon atom makes it difficult to obtain monochloro-derivatives of methylchlorosilanes, especially chloromethyltrichlorosilane. To obtain an appreciable yield of these compounds the chlorination of methylchlorosilanes is usually conducted at very low degrees of conversion of the initial silane[79]. A high yield of monochloro-derivatives can be achieved by continuous removal of the products from the reaction zone[73,81-89]. This principle has been used in the liquid-phase photochlorination of methylchlorosilanes[90,91] and in obtaining poly(monochloromethyl)silanes[92].

Elementary fluorine has been used[93,94] as initiator for the chlorination of methylchlorosilanes. The mechanism assumed for the reaction is

$$(CH_3)_2SiCl_2 + F_2 \rightarrow CH_3(\dot{C}H_2)SiCl_2 + HF + F\cdot$$
$$(CH_3)_2SiCl_2 + F\cdot \rightarrow CH_3(\dot{C}H_2)SiCl_2 + HF$$
$$CH_3(\dot{C}H_2)SiCl_2 + Cl_2 \rightarrow CH_3(CH_2Cl)SiCl_2 + Cl\cdot, \text{ etc.}$$

Azoisobutyronitrile, which readily generates free radicals when heated above 60°C, has recently become widely used as an initiator for the practical chlorination of organic compounds. Chlorination can be effected with 0.05–0.1% of this initiator in the dark at 70–90°C. Under these conditions the initiator dissociates into $\cdot C(CH_3)_2CN$ radicals, which react easily with chlorine. It is important to note that this compound is widely used in industry at the present time for processes taking place by a radical–chain mechanism. Its use has eliminated the defects inherent in photochemical chlorination (difficulty of producing powerful reaction vessels, danger of fire and explosions, etc.).

The initiated chlorination of organosilicon compounds by elementary chlorine in the presence of azoisobutyronitrile was first proposed in 1956,[95] and has now found practical application for the production of monochloro-derivatives of methylchlorosilanes. This is conducted in the liquid phase at 55–70°C, the content of the initiator in the original silane being initially not more than 0.1%. Subsequently the initiator is added periodically to the reaction mixture, or it is introduced continuously into the latter as a solution in the initial silane.

Chlorination of methylchlorosilanes in the presence of azoisobutyronitrile proceeds in conformity with the usual scheme for a chain reaction:

$$NC(CH_3)_2CN{=}NC(CH_3)_2CN \xrightarrow{\Delta} 2(CH_3)_2\dot{C}CN + N_2$$
$$(CH_3)_2\dot{C}CN + Cl_2 \rightarrow Cl\cdot + (CH_3)_2C(Cl)CN$$
$$CH_3(CH_3)_{3-n}SiCl_n + Cl\cdot \rightarrow \dot{C}H_2(CH_3)_{3-n}SiCl_n + HCl \quad (n=1-3)$$
$$\dot{C}H_2(CH_3)_{3-n}SiCl_n + Cl_2 \rightarrow CH_2Cl(CH_3)_{3-n}SiCl_n + Cl\cdot$$

Depending on the molar proportions of the reactants—the silane and chlorine—it is possible in this way to obtain a wide range of derivatives of methyltrichlorosilane, dimethyldichlorosilane, and trimethylchlorosilane containing chlorine atoms in the methyl groups[96-100]. The main rules of the substitution of hydrogen by chlorine atoms in methylchlorosilanes when chlorinated in the presence of azoisobutyronitrile proved to be the same as for photochemical chlorination. Figs. 1–3 illustrate the dependence of the composition of the chlorination products on the molar ratio of the reactants. The results show the detailed effect of the chlorosilyl group on the direction of the chlorination of methylchlorosilanes, and enable optimum conditions to be selected for obtaining their monochloro-derivatives. It is interesting that the content of monochloro-derivatives in the reaction mixture remains almost constant (at 9–10% for chloromethyltrichlorosilane, and 26–30% for methylchloromethyldichlorosilane and chloromethyldimethylchlorosilane) within a certain range (1 : 0.2–1.0) of molar ratios of silane to chlorine.

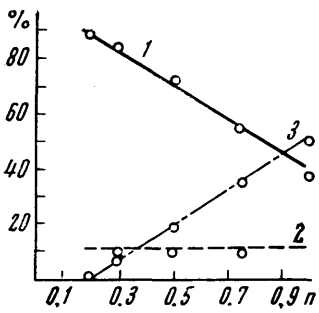

Figure 1. Dependence of composition of chlorination products of methyltrichlorosilane on number n of moles of chlorine per mole of the silane: 1) methyltrichlorosilane; 2) chloromethyltrichlorosilane; 3) dichloromethyltrichlorosilane.

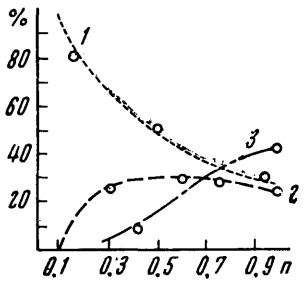

Figure 2. Dependence of composition of chlorination products of dimethyldichlorosilane on number n of moles of chlorine per mole of the silane: 1) dimethyldichlorosilane; 2) methylchloromethyldichlorosilane; 3) dichloro-derivative.

A detailed investigation of the chlorination of methyltrichlorosilane and dimethyldichlorosilane has shown that the composition of the reaction products depends not only

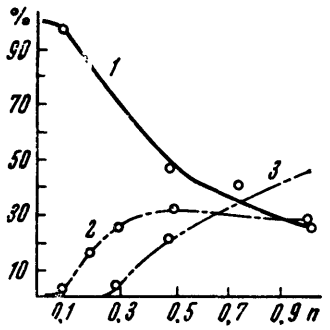

Figure 3. Dependence of composition of products of the chlorination of trimethylchlorosilane on number n of moles of chlorine per mole of the silane: 1) trimethylchlorosilane; 2) chloromethyldimethylchlorosilane; 3) dichloro-derivative.

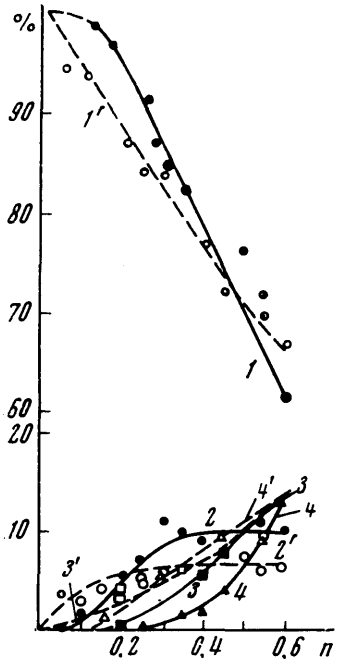

Figure 4. Dependence of composition of products of the chlorination of methyltrichlorosilane on number n of moles of chlorine per mole of the silane for chlorination in the dark in the presence of azoisobutyronitrile (full lines) and during exposure to ultraviolet radiation (broken lines): 1), 1′) methyltrichlorosilane; 2), 2′) chloromethyltrichlorosilane; 3), 3′) dichloromethyltrichlorosilane; 4), 4′) trichloromethyltrichlorosilane.

on the molar proportions of the reactants but also on the nature of the initiator[101] (Figs. 4 and 5). With azoisobutyronitrile as initiator the content of monochloro-derivative in the reaction mixture is 40–70% higher than in photochemical chlorination. It is interesting that, whereas in photochemical chlorination polychloro-derivatives of methyltrichlorosilane are formed at the molar

ratio $CH_3SiCl_3 : Cl_2 = 1 : 0.05$, this occurs with azoisobutyronitrile at a corresponding ratio of 1 : 0.15–0.2. The composition of the polychloro-derivatives is also different in the two cases: whereas in photochemical chlorination trichloromethyltrichlorosilane is formed (1–2%) at the molar ratio $CH_3SiCl_3 : Cl_2 = 1 : 0.15$, when azoisobutyronitrile is used the trichloro-derivative appears in the reaction mixture only at a molar ratio of the reactants of 1 : 0.25, and in only one-sixth of the quantity (0.2%) obtained with photochemical chlorination. Even with the same degree of conversion of the initial silane the quantity of polychloro-derivatives formed per unit weight of the monochloride in the presence of azoisobutyronitrile is 40–70% of the amount obtained in photochemical chlorination (Figs. 6 and 7). Thus the photochemical chlorination of methylchlorosilanes by elementary chlorine is a less selective process than chlorination initiated by azoisobutyronitrile.

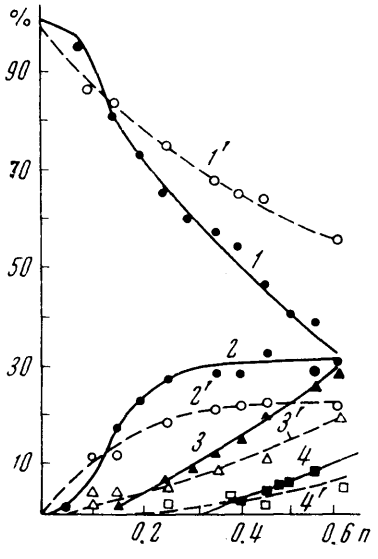

Figure 5. Dependence of composition of products of the chlorination of dimethyldichlorosilane on number *n* of moles of chlorine per mole of the silane for chlorination in the dark in the presence of azoisobutyronitrile (full lines) and during ultraviolet exposure (broken lines): 1), 1′) dimethyldichlorosilane; 2), 2′) methylchloromethyldichlorosilane; 3), 3′) dichloro-derivative; 4), 4′) trichloro-derivative.

The continuous chlorination of methylchlorosilanes in the presence of azoisobutyronitrile has been described[98]. In order to obtain an equivalent yield of the monochloro-derivative the process must be conducted at a lower degree of conversion of the initial silane than in the batch process (e.g. for methyltrichlorosilane 3–4% instead of 10%). The degree of conversion can be increased appreciably by the continuous chlorination of the residue of the initial silane directly in a fractionating column packed with Raschig rings[102]. Methylchlorosilane containing 2–2.5% of the initiator is fed to the upper part of the column, and chlorine gas enters the middle portion. The chlorination products are led from the reaction zone into the lower part of the column, where they are separated from unchanged methylchlorosilane. The latter returns to the reaction zone, where it mixes with the initiator solution supplied to this point. The products collect in the still. This procedure is possible only when a chemical initiator, e.g. azoisobutyronitrile, is used, but cannot be applied to photochemical initiation, since the packing would cut off the action of the light. Under these conditions the conversion of methyltrichlorosilane and dimethyldichlorosilane reaches 70–80% with a yield of monochloro-derivatives of 70–75% (based on the silane used).

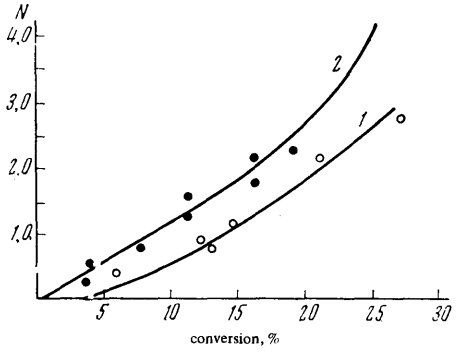

Figure 6. Dependence of quantity *N* of polychlorinated derivatives of methyltrichlorosilane formed per unit weight of the monochloro-derivative on degree of conversion of initial silane for chlorination: 1) in the presence of azoisobutyronitrile in the dark; 2) on ultraviolet exposure.

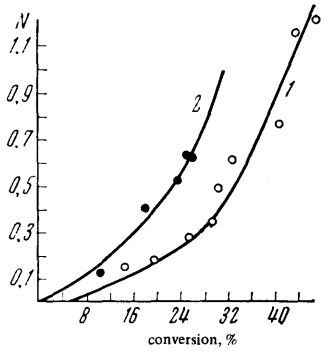

Figure 7. Dependence of quantity *N* of polychlorinated derivatives formed per unit weight of the monochloro-derivative on degree of conversion of dimethyldichlorosilane during chlorination: 1) in the presence of azoisobutyronitrile in the dark; 2) during exposure to ultraviolet radiation.

Another chemical initiator which merits attention is acetyl cyclohexanesulphonyl peroxide[103], which easily decomposes at 30–70°C to form free radicals:

$$C_6H_{11}SO_2OOCOCH_3 \rightarrow C_6H_{11}SO_2O^{\cdot} + CH_3COO^{\cdot}$$

With the chlorination of methyltrichlorosilane and dimethyldichlorosilane as examples this peroxide has been shown to be a more active initiator than is azoisobutyronitrile[104].

Considerably less work has been done on the preparation of polychlorinated methylchlorosilanes and methylpolysiloxanes.

Trichloromethyltrichlorosilane is easily formed by the photochemical chlorination of methyltrichlorosilane in the absence of a solvent at high temperatures[17] or in chloroform under ordinary conditions[68]. The photochemical chlorination of dimethyldichlorosilane extends[68] to the substitution of only five hydrogen atoms, but in the chlorination of trimethylchlorosilane up to eight hydrogen atoms are replaced. Later investigations have confirmed[105,106] that the chlorination of dimethyldichlorosilane in the presence of azoisobutyronitrile proceeds easily to the trichloro-derivative, after which the process is abruptly retarded. Pentachlorodimethyldichlorosilane is formed with great difficulty, requiring the prolonged action of excess of chlorine at 105–110°C. Under these conditions the main process is accompanied by secondary cleavage of the chlorination products at the silicon–carbon bond with the formation of carbon tetrachloride and trichloromethyltrichlorosilane, so that bistrichloromethyldichlorosilane cannot be obtained in this way. Cleavage is greatly diminished by conducting the chlorination of dimethyldichlorosilane under milder conditions—in a solvent (carbon tetrachloride) at 20–25°C (ultraviolet irradiation)—when yields of up to 60% of bistrichloromethyldichlorosilane have been obtained[105,106].

The polychlorination of trimethylchlorosilane is still more difficult[107]. Tristrichloromethylchlorosilane has been obtained in 50% yield only by the prolonged action on trimethylchlorosilane of a large excess of chlorine (molar ratio 19:1) in the presence of azoisobutyronitrile and a small amount of carbon tetrachloride at 53–65°C.

Most polychlorinated methylchlorosilanes are white crystalline substances, sensitive to atmospheric moisture and to heat. Since it is difficult to separate mixtures of these chlorides by distillation, they are converted into alkoxy-derivatives, which can be separated by normal fractional distillation. The following compounds—$CCl_3Si.(OC_2H_5)_3$, $CH_3Si(CCl_3)(OC_2H_5)_2$, $(CCl_3)_2Si(OC_2H_5)_2$, and $(CCl_3)_3SiOC_2H_5$—and also several intermediate chloromethylethoxysilanes—$CH_3Si(CHCl_2)(OC_2H_5)_2$, $CCl_3Si(CH_2Cl).(OC_2H_5)_2$, and $CCl_3Si(CHCl_2)(OC_2H_5)_2$—have been isolated in this way[105,107].

Ethoxytrichloromethylchlorosilanes decompose violently when heated rapidly. Thus trichloromethyltrichlorosilane, in contrast to mono- and di-chloromethyltrichlorosilanes, decomposes readily at 160–175°C:[108]

$$2CCl_3SiCl_3 \rightarrow 2SiCl_4 + C_2Cl_4$$

Tristrichloromethylchlorosilane and ethoxytristrichloromethylsilane are stable when heated, but replacement of a chlorine atom by hydrogen even in only one trichloromethyl group sharply lowers the stability of such a molecule[109]. The exhaustive chlorination of polychloromethylchlorosilanes in a fluidised bed of catalyst (activated carbon) at 300°C results in high yields of carbon tetrachloride and silicon tetrachloride[110].

The polychlorination of linear and cyclic methylsiloxanes exposed to ultraviolet radiation[16,109,111–113] is accompanied by cleavage of Si–O–Si bonds, with the formation of compounds of low molecular weight containing Si–Cl as well as Si–O bonds.

The chlorination of a dimethylsiloxane elastomer as a 5% solution in carbon tetrachloride in the presence of azoisobutyronitrile at 50°C proceeds slowly to the formation of a polymer of mean composition $[(C_2H_2Cl_4)SiO]_n$ and is accompanied by degradation of the molecule[114]. On storage the chlorinated polymer gradually decomposes. Analysis shows that the elastomer chain contains all possible chloromethyl groups—CH_2Cl, $CHCl_2$, and CCl_3—which indicates that it is impossible to obtain a perchlorodimethylsiloxane polymer whose macromolecules are built up solely of $(CCl_3)_2SiO$ units.

In contrast to the dimethylsiloxane elastomer, octamethylcyclotetrasiloxane is chlorinated in the presence of azoisobutyronitrile (at 60°C) without cleavage of Si–O–Si bonds[115], a complicated mixture of chlorides of various degrees of substitution being formed. Chloromethylheptamethylcyclotetrasiloxane has been isolated from the products of the photochemical chlorination of octamethylcyclotetrasiloxane[70,116]. The chlorination of hexamethyldisiloxane is not accompanied by fission of the siloxane bond when the products are able to escape from the reaction zone, so that the yield of monochloro-derivative is quite high[86,117]. Under analogous conditions methoxytrichlorosilane gives $ClCH_2OSiCl_3$, exhaustive chlorination of which yields CCl_3OSiCl_3.[119,120] The products of the photochemical chlorination of methylchlorodisilanes

$$(CH_3)_n Cl_{3-n} SiSiCl_{3-m} (CH_3)_m \; (n\,m = 0, 1, 2;\; n+m>1)$$

at 0–100°C are $(ClCH_2)(CH_3)_{n-1}Si_2Cl_{6-n}$.[121]

Perchlorinated methylchlorosilanes and methylsiloxanes may decompose spontaneously and explosively[109].

The chlorination of the higher alkylchlorosilanes exhibits special features due to the nature of the alkyl radicals.

Ethyl derivatives of silicon react readily with chlorine. Tetraethylsilane is chlorinated under normal conditions in the absence of initiators with the formation of mono- and di-chloro-derivatives[122,123], the reaction being accelerated appreciably by the addition of phosphorus pentachloride[20,22,124]. Study of the photochemical chlorination of ethylchlorosilanes[73,125–129] has established certain rules for the direction of chlorination. In effect only hydrogen attached to an α-carbon atom in tetraethylsilane is replaced by chlorine. The activity of hydrogen atoms attached to a β-carbon atom increases appreciably with the accumulation of chlorine atoms attached to silicon in ethylchlorosilanes; thus the monochloro-derivative formed by the chlorination of ethyltrichlorosilane contains a considerable quantity of the β-chloride ($CH_3CHClSiCl_3 : ClCH_2CH_2SiCl_3 = 1 : 1.6–1.8$). The chlorination of ethylchlorosilanes in the presence of azoisobutyronitrile[130] maintains essentially the same effects of silyl groups on the rate and the direction of chlorination as in the photochemical process. The yields of monochloro-derivatives of ethylchlorosilanes are equivalent in the two cases, but the simplicity of the apparatus required indicates that preference should be given to chlorination initiated by azoisobutyronitrile.

The polychlorination of ethyltrichlorosilane and diethyldichlorosilane in the presence of azoisobutyronitrile (at 80°C), and also on ultraviolet irradiation[130–133], in contrast to the corresponding chlorination of methylchlorosilanes, does not involve fission of the silicon–carbon bond and leads to the formation of the perchloroethyl derivatives [$C_2Cl_5SiCl_3$ and $(C_2Cl_5)_2SiCl_2$]. Under these conditions tetrachloroethyltrichlorosilane has been isolated from the products of the polychlorination of ethyltrichlorosilane. The hydrolysis of polychloroethylchlorosilanes with water and aqueous alkalis is accompanied by β-decomposition with the formation of tetra- and tri-chloroethyl-

enes. The dehydrochlorination of tetrachloroethyltrichlorosilane under the influence of high temperatures and also of quinoline[131] involves β-decomposition; the main product of dehydrochlorination under the influence of aluminium chloride is trichlorovinyltrichlorosilane. This compound is formed also by the dechlorination of perchloroethyltrichlorosilane in the presence of copper powder[131].

A β-orienting effect is still more strongly developed with ethylfluorosilanes ($CH_3CHClSiF_3$: $ClCH_2CH_2SiF_3$ = 1 : 4.4),[134] which is explained by the considerably greater electronegativity of the fluorine than of the chlorine atom. It is interesting that, when ethylmethyldichlorosilane undergoes chlorination, the chlorine enters mainly the ethyl radical[135]. Attempts have been made[126,136] to explain the rules of the chlorination of ethylchlorosilanes by the electronic structure of these compounds.

The orienting effect of the trichlorosilyl group is apparent also in the photochemical chlorination of propyltrichlorosilane[87], as is indicated by the relative proportions of 1-, 2-, and 3-chloropropyltrichlorosilanes formed (0.7 : 1 : 1). As with ethyltrichlorosilane, 70% more of the β-chloro-derivative than of the α-chloro-derivative is formed from isopropyltrichlorosilane[137]. These and other papers[138,139] refer to the need to remove monochloro-derivatives from the reaction zone. This method has been used also for the chlorination of bistrichlorosilylmethane[87], 1,2-bistrichlorosilylethane[23,87,140], and several other chloroalkylchlorosilanes[78,92,139,141]. The photochemical chlorination of $CF_3CH_2CH_2SiCl_3$ and $CF_3CH_2CH_2SiCl_2CH_3$ leads to the formation of monochloro-derivatives containing the chlorine atom in the CF_3CH_2CHCl radical mainly in the α-position relative to the silicon atom[142,143]. With $CF_3CH_2CH_2SiCl(CH_3)_2$ and $CF_3CH_2CH_2SiCl_2C_2H_5$ the direction of chlorination is determined not only by the trifluoromethyl group but also by the nature of the chlorosilyl group[144].

The liquid-phase photochemical chlorination of more complicated organosilicon compounds has been described[19,145-149], and also the preparation of polychloro-derivatives of several other alkylchlorosilanes[150-153].

Cobalt-60 γ-radiation has been used to initiate the chlorination of alkylchlorosilanes, in particular trimethylchlorosilane[153,154]. The chlorination of methylchlorosilanes under the influence of radiation[155-158] conforms mainly to the same rules as their chlorination under the influence of ultraviolet radiation and in the presence of chemical initiators. The composition of the products, determined by the molar proportions of the reactants (silane and chlorine), is independent of the dosage rate. The radiation chlorination of a dimethylsiloxane elastomer has been reported[159,160]. The radiation chlorination of ethyltrichlorosilane[157,158] leads to the formation of α- and β-chloro-derivatives in the proportions 1 : 1.7, in agreement with results for the chlorination of ethylchlorosilane on exposure to ultraviolet radiation[73] and in the presence of azoisobutyronitrile[130].

A new method for obtaining chlorinated polyorganosiloxanes proposed recently is based on the combined hydrolytic polycondensation and chlorination of silicon-containing compounds by the hydrolysis of alkylchlorosilanes containing no chlorine atom in the hydrocarbon radicals, with simultaneous introduction of oxidants such as hydrogen peroxide, manganese dioxide, etc. into the reaction[161]. These convert the hydrogen chloride, formed by hydrolysis, into chlorine, which chlorinates the organic radical attached to the silicon. In this case three reactions—hydrolysis, condensation, and chlorination—take place in a single stage, but the apparent simplification in fact does not yield a polymer of high quality, and the technology is greatly complicated by the additional stage of purifying the final product from oxidants. In contrast to known processes of the oxidative chlorination of hydrocarbons, therefore, the above reaction is of no practical interest.

Little information has been published on the vapour-phase chlorination of alkylchlorosilanes at elevated temperatures (in the absence of ultraviolet radiation). Ethylchlorosilane at 350°C yields α- and β-monochloro-derivatives in the ratio 1 : 1.08.[141] When vinyltrichlorosilane is chlorinated under these conditions the main product is CH_2 : $CClSiCl_3$;[162] at a lower temperature (100–200°C) the reaction shifts towards formation of $ClCH_2CHClSiCl_3$. The chlorination of $F_2CHCF_2SiCl_3$ (at 150–200°C) yields $ClCF_2CF_2SiCl_3$.[163]

Unsaturated organosilicon compounds are chlorinated extremely readily by elementary chlorine to form predominantly addition products[69,77,162-169]. In contrast to vinyltrichlorosilane, however, trichlorovinyltrichlorosilane does not add chlorine at the double bond in the absence of illumination at 0–100°C.[170,171] The presence of lithium chloride under these conditions accelerates the addition of chlorine. Ultraviolet irradiation produces an especially marked acceleration of the reaction, its mechanism changing from heterolytic to a chain (homolytic) mechanism. The presence of an electron-donor trimethylsilyl group in the vicinity of the double bond in the trichlorovinyl radical facilitates the addition of chlorine to the double bond: thus trimethyltrichlorovinylsilane readily adds chlorine at the double bond in the absence of irradiation at 20°C.

(*b*) Chlorination by sulphuryl chloride

Chlorination by sulphuryl chloride is usually accomplished in the presence of the free-radical type of initiators. With methylchlorosilanes this method of chlorination initially gave negative results[21,172,173]. Subsequently the use of chlorobenzene as medium enabled the temperature of the reaction to be raised and this accelerated the decomposition of benzoyl peroxide into the free radicals necessary for the occurrence of chlorination. In this way sulphuryl chloride can be used to chlorinate trimethylchlorosilane[173] and other methylchlorosilanes[69,174]. Under these conditions it is comparatively easy to chlorinate also bistrichlorosilylmethane and 1,2-bistrichlorosilylethane in spite of the presence of two trichlorosilyl groups[87]. In bistrimethylsilylmethane the methyl groups are the first to be chlorinated[175]. There are references to the chlorination with sulphuryl chloride of other silicon compounds containing a methyl group and a methylene group[21,176-179]. The chlorination of alkylchlorosilanes with sulphuryl chloride during exposure to ultraviolet radiation[180,181] enables individual chloro-derivatives of different degrees of substitution to be obtained depending on the molar ratio of the reactants. Such selectivity is not observed when chlorine is used.

The chlorination of methylchlorosilanes with sulphuryl chloride can be initiated by azoisobutyronitrile[182], which decomposes into free radicals at a lower temperature than is observed with benzoyl peroxide.

Ethylchlorosilanes are readily chlorinated by sulphuryl chloride in the absence of solvents, when 1- and 2-chloroethylchlorosilanes are formed[21,82,183]. Chlorine enters ethylmethyldichlorosilane predominantly in the ethyl group[184]. The chlorination of tetraethylsilane yields only

the α-isomer[22,73,84,185]. With decrease in the number of ethyl radicals attached to the silicon atom the β-orienting effect of the trichlorosilyl group is more strongly developed when sulphuryl chloride is used than on chlorination with chlorine[21,77,125,183,186]. For example, the proportions of 1- and 2-chloroethyltrichlorosilanes obtained with sulphuryl chloride are 1:2.5, compared with the 1:1.6–1.8 with chlorine.

The directional effect of a chlorosilyl group is evident also in the chlorination of higher alkylchlorosilanes by means of sulphuryl chloride[24,188,189]. Several cyclic organosilicon compounds react effectively with sulphuryl chloride[190–193]. The above regularities are observed also in the chlorination of alkylchlorosilanes containing chlorine atoms in the alkyl group, although the orienting effect of the trichlorosilyl group is then more complicated. Thus 2-chloroethyltrichlorosilane yields only the 2,2-derivative, whereas 1-chloroethyltrichlorosilane forms equal proportions of 1,1- and 1,2-dichloroethyltrichlorosilanes.

(*c*) Chlorination by *t*-butyl hypochlorite

t-Butyl hypochlorite can be used to chlorinate alkylchlorosilanes and alkylpolysiloxanes, the reaction being initiated with peroxides and ultraviolet radiation. Compounds of the types $(R_3Si)_2O$ (R = CH_3), $(R_2SiO)_4$, $C_6H_5SiR_3$, R_3SiCH_2Cl, R_4Si, and $(R_3Si)_2$ can be chlorinated by means of this agent[194,195]. However, this method is of no practical interest because of the difficulties of manipulations with t-butyl hypochlorite, resulting from the violent decomposition of the latter under the influence of light, heat, or contact with rubber.

2. Preparation of Bromoalkyl Compounds of Silicon

In contrast to chlorine, bromine does not always react with alkylchlorosilanes. It reacts extraordinarily easily with hydrocarbon derivatives of silicon[196–201], especially with the higher tetra-alkylsilanes[196,197]. As with chlorination, bromine first enters an α-position in tetraethylsilane[143,196–199]. A similar situation is found in the bromination of $(iso\text{-}C_3H_7SiO_{1.5})_8$ by means of *N*-bromosuccinimide[202].

Bromination of methyl- and ethyl-chlorosilanes has proved possible only by the combined action of bromine, chlorine, and ultraviolet radiation[179,183,203–206]. Sulphuryl chloride can be used instead of chlorine[207].

The photochemical bromination of linear and cyclic methylsiloxanes with a mixture of bromine and chlorine leads to the formation of mono- and poly-brominated derivatives[200,203,208,209]. Incompletely methylated polysiloxanes have been selectively brominated with bromine in the presence of a stoichiometric quantity of pyridine[210].

Bromine is easily added at the double bonds in unsaturated organosilicon compounds[167,211,212]; under certain conditions substitutive bromination is possible[213]. The bromination of allyltriethylsilane[25] and allyltrimethylsilane[214] is accompanied by β-decomposition of the reaction products. Allyldiethylsilane, naphthyltriallylsilane, and vinyltriethylsilane add bromine without cleavage of the silicon–carbon bond[25]. Trichlorovinyltrichlorosilane, unlike vinyltrichlorosilane, does not add bromine at 20–80°C.[171] Nor does trichlorovinyltrimethylsilane react with bromine at 20°C, although it readily adds chlorine under these conditions, as mentioned above. When the temperature of the reaction is raised to 80–85°C products resulting from cleavage at the silicon–carbon bond—bromotrichloroethylene and trimethylbromosilane—are formed exclusively[171].

V. ELECTROPHILIC HALOGENATION (CHLORINATION, BROMINATION) OF SILICON-CONTAINING AROMATIC AND ALIPHATIC–AROMATIC COMPOUNDS

Systematic study of the direct halogenation of aromatic and aliphatic–aromatic compounds of silicon began in 1948 with the catalytic chlorination of phenylchlorosilanes. Earlier work had been concerned mainly with the preparation of monohalogeno-derivatives of certain aromatic silanes by the organomagnesium method[215,216]. The direct halogenation of aromatic compounds of silicon is an electrophilic substitution catalysed by metal halides. This reaction easily leads to the substitution by halogen of the hydrogen atoms in the aromatic ring.

1. Preparation of Chloroaryl Compounds of Silicon

The first mention of the direct chlorination of phenyltriethylsilane appeared in 1874.[217,218] In 1941 the patent literature reported the possibility of obtaining polychlorophenylchlorosilanes by chlorinating diphenyldichlorosilane and methylphenyldichlorosilane with chlorine in the presence of iron and antimony halides as catalysts at 70 to 120°C.[219] Later investigations of the electrophilic chlorination of aromatic silanes established that, in the presence of iron, iron(III) chloride[220], antimony(III) chloride[25,222], aluminium chloride[221], iodine, or phosphorus pentachloride[222], different numbers of chlorine atoms can be introduced into the phenyltrichlorosilane[223–225] and diphenyldichlorosilane[224] molecules depending on the molar ratio of the reactants and the temperature. In the absence of a catalyst this reaction does not take place even at high temperatures (150–200°C). The electrophilic chlorination of phenyltrichlorosilane and diphenyldichlorosilane has been described also in several other publications[80,226–233].

Depending on the conditions—the presence of a catalyst and its nature, the duration of the action of chlorine, and the temperature—the substitutive chlorination of phenylchlorosilanes is accompanied by the parallel cleavage of the $Si-C_{Ar}$ bond[32,224,234]. This side-reaction occurs only in the presence of catalysts—metal halides—which form the sequence $AlCl_3 > FeCl_3 \gg SbCl_5$ according to their dearylating activity, in conformity with which this reaction occurs more or less intensely[57,58]. Cleavage of the $Si-C_{Ar}$ bond can be diminished by conducting chlorination at a lower temperature and in a solvent[235]. As already stated above, hydrogen chloride must be present in the reaction mixture for phenylchlorosilanes to be cleaved by metal halides (e.g. aluminium chloride)[60,61]. The chlorination of phenylchlorosilanes in the presence of iodine is not accompanied by rupture of the $Si-C_{Ar}$ bond.

The reactivity of arylchlorosilanes in electrophilic halogenation is determined by the nature of the atoms and groups attached to the silicon atom. In recent years various aromatic compounds containing a silyl group in the benzene ring or in a side-chain have been subjected to electrophilic halogenation. The results have provided a more exact idea of the orienting influence of the silyl group and have revealed the reactivity of several arylsilanes and alkylarylsilanes towards electrophilic substitution as a function of the nature of the atoms and groups attached to silicon.

The *meta*-orienting nature of the trichlorosilyl group, which is a consequence of its electron-acceptor properties, is clearly evident in the fact that the benzene ring in phenyltrichlorosilane is so deactivated that it does not react with either chlorine[224] or bromine[236] at 150–200°C, in contrast to benzene itself, which with bromine is able to give phenyl bromide in the absence of catalysts even at 60°C.[237] This *meta*-orienting power is distinctly shown also in the electrophilic chlorination of phenyltrichlorosilane, which gives a mixture of the *meta*-, *ortho*-, and *para*-isomers in the proportions 75 : 21 : 4 [238] and 74 : 24 : 2.[226] The trifluorosilyl group had a still stronger *meta*-orienting effect under these conditions (82 : 18 : 0).[239] Further investigations have shown[240] that on electrophilic chlorination phenyltrifluorosilane is more subject than phenyltrichlorosilane to cleavage at the silicon–carbon bond, so that only mono- and di-chloro-derivatives of phenyltrifluorosilane can be isolated from the reaction products.

It must be emphasised that, despite the deactivation of the aromatic ring in phenyltrichlorosilane, it can be chlorinated with chlorine in the presence of ionic catalysts even below 0°C with the formation solely of substitution products, in which the *meta*-isomer predominates[241]. A similar effect of the trichlorosilyl group is evident in the chlorination of phenyltrichlorosilane by means of iodine trichloride[242]. As a consequence of the presence of strongly polarised chlorine in this latter agent, the reaction takes place readily even at −40°C with the formation of a mixture of mono- and di-chloro-derivatives. Rise in temperature to −20°C appreciably accelerates the reaction, and under these conditions chlorination is accompanied by partial iodination of the aromatic ring. At 20°C the reaction occurs violently with the evolution of elementary iodine and the formation of substituted mono-, di-, and tri-chloro-derivatives. Unlike iodine trichloride the monochloride does not react with phenyltrichlorosilane at 20°C.[242]

With rise in temperature to 200°C the *meta*-orienting effect of the trichlorosilyl group on the chlorination of phenyltrichlorosilane becomes weaker (*meta* : *para* : *ortho* = 60 : 15 : 25).[243] At 350–400°C the trichlorosilyl group loses its *meta*-orienting power (39 : 39 : 22).[244]

The chlorination of phenyltrichlorosilane by means of sulphuryl chloride exposed to ultraviolet radiation[181] is extremely sluggish and is accompanied by cleavage of the $Si-C_{Ar}$ bond.

The introduction of an *ortho*–*para*-orienting substituent (methyl) into the phenyltrichlorosilane molecule results in some activation of the aromatic ring, so that *p*-tolyltrichlorosilane, in contrast to phenyltrichlorosilane, reacts with chlorine in the absence of a catalyst at only 95–100°C.[245] In the presence of metal halides [iron(III) chloride, antimony trichloride] *p*-tolyltrichlorosilane is easily chlorinated as far as the replacement of three hydrogen atoms in the aromatic ring. When an attempt is made to obtain the tetrachloro-derivative, cleavage of the $Si-C_{Ar}$ bond takes place. The results obtained for the interaction of a halogen with *p*-tolyltrichlorosilane indicate that the latter behaves normally in electrophilic substitutions: the entering halogen atom is directed by both existing substituents (1-methyl and 4-trichlorosilyl), in conformity with their nature, to position 2.

The introduction, into the aromatic ring of phenyltrichlorosilane, of a second kind of orienting group (trichloromethyl), which is a *meta*-orienting substituent, results in strong deactivation of the benzene ring. In fact, *p*-trichloromethylphenyltrichlorosilane is difficult to chlorinate at 100–110°C even in the presence of catalysts[245], mono- and dichloro-derivatives being formed; further chlorination of this compound results in cleavage of the $Si-C_{Ar}$ bond. A chlorine atom entering the aromatic ring of *p*-trichloromethylphenyltrichlorosilane is directed by both substituents (1-trichloromethyl and 4-trichlorosilyl) to positions 2 and 3.

The trifluoromethyl group has a still stronger deactivating effect on an aromatic ring, so that *p*-trifluoromethylphenyltrichlorosilane and *p*-trifluoromethylphenyltrifluorosilane, in contrast to *p*-trichloromethylphenyltrichlorosilane, do not react with chlorine at 120°C even in the presence of iron(III) chloride[246].

A similar effect is observed when two trichlorosilyl groups are present in the aromatic ring. Electrophilic chlorination of bistrichlorosilylbenzene takes place with great difficulty, and leads to the substitution of only one hydrogen atom in the aromatic ring. Further chlorination results in cleavage of the $Si-C_{Ar}$ bond[247].

The methylene bridge separating the trichlorosilyl group from the aromatic ring in benzyltrichlorosilane produces marked changes in the orienting influence and the deactivating effect of the trichlorosilyl group[248]. Unlike phenyltrichlorosilane, benzyltrichlorosilane reacts with chlorine even at ordinary temperatures to form *p*-chlorobenzyltrichlorosilane. In the presence of catalysts the whole possible range of chloro-derivatives containing 1–5 nuclear chlorine atoms is formed: the first chlorine atom enters the ring only in the *para*-position, and the next two chlorine atoms *ortho* to the trichlorosilylmethyl group[248,249]. In contrast to phenyltrichlorosilane, these reactions are not accompanied by cleavage of the silicon–carbon bond. Similar results have been obtained for the electrophilic chlorination of benzylmethyldichlorosilane: methylpentachlorobenzyldichlorosilane $C_6Cl_5CH_2SiCl_2CH_3$ has been isolated from the products of the reaction[250].

It is interesting that the trichlorosilyldichloromethyl group, in contrast to the trichlorosilylmethyl group, is *meta*-orienting towards a chlorine atom entering the aromatic ring. Thus the electrophilic chlorination [in the presence of iron, iron(III) chloride, antimony(V) chloride] of $\alpha\alpha$-dichlorobenzyltrichlorosilane yields *m*-chlorophenyldichloromethyltrichlorosilane[242]. Further chlorination gives the trichloro-derivative. The compound containing five chlorine atoms in the ring cannot be obtained because of cleavage of the silicon–carbon bond.

The replacement of halogen atoms attached to silicon by the less electronegative alkyl groups leads to a change in the orienting effect of the silyl group. A detailed study of this phenomenon has been made on the electrophilic halogenation of methylphenyldichlorosilane[251–253] and phenyltrimethylsilane[239,254].

The chlorination of phenylmethyldichlorosilane in the absence of catalysts at 50–115°C results in nuclear substitution (to give mono-, di-, and tri-chloro-derivatives) and is accompanied by appreciable cleavage of the $Si-C_{Ar}$ bond. At 145–150°C compounds of the type $C_6H_{5-n}Cl_n \cdot SiCl_2CCl_3$ appear, which under these conditions readily decompose at the $Si-C_{Alk}$ bond to form carbon tetrachloride and $C_6H_{5-n}Cl_nSiCl_3$.[254] The chlorination of phenylmethyldichlorosilane in the presence of antimony trichloride[252,253] leads to the formation merely of the dichloro-derivative and is accompanied by considerable cleavage of the $Si-C_{Ar}$ bond. On chlorination in the presence of iodine[253,256], especially under mild conditions (in carbon tetrachloride at 10–12°C),[253] degradation is greatly diminished, so that trichlorophenylmethyldichlorosilane can be obtained. The yield of polychloro-derivatives is increased by chlorinating in the presence of iodine

the monochloro-derivative, chlorophenylmethyldichlorosilane[257]. The rate of chlorination of the aromatic ring and the rate of cleavage of the $Si-C_{Ar}$ bond increase in the sequence $C_6H_5SiCl_2CH_3 < C_6H_5SiCl(CH_3)_2 < (C_6H_5)_2SiClCH_3$.[256] Phenylmethyldichlorosilane does not react with sulphuryl chloride in the presence of ionic catalysts.

During electrophilic chlorination phenyltrimethylsilane undergoes considerable cleavage at the $Si-C_{Ar}$ bond, so that the yield of the monochloro-derivative does not exceed 50%.[254]

Phenylmethyldichlorosilane yields ~60% of the *m*-chloro-isomer, but chlorination of phenyltrimethylsilane gives mainly the other two isomers (*para* + *ortho* : *meta* = 78 : 22).[239,254] Thus the replacement of chlorine atoms attached to silicon by electropositive methyl radicals changes the *meta*-orienting power of the silyl group into an *ortho*–*para*-orientation effect.

It is interesting that the presence of the trichloromethyl group attached to silicon in phenyltrichloromethyldichlorosilane results in considerable deactivation of the aromatic ring and strengthening of its bond with silicon. In its behaviour towards electrophilic chlorination this compound resembles phenyltrichlorosilane, the trichloromethyldichlorosilyl group, like the trichlorosilyl group, having a *meta*-orienting effect[258]. Phenyltrichloromethyldichlorosilane behaves similarly on electrophilic bromination[259].

The chlorination of 1-naphthyltrichlorosilane[260] in the presence of the usual catalysts for the halogenation of aromatic compounds [iron(III) chloride, antimony trichloride] at 55–100°C yields various chloro-derivatives (from mono- to tetra-chloronaphthyltrichlorosilanes) in yields of 60–90%. Cleavage of the silicon–carbon bond does not occur and, in spite of the prolonged action of excess of chlorine (molar proportions of $1\text{-}C_{10}H_7SiCl_3 : Cl_2 = 1 : 25$), the reaction terminates at the formation merely of the tetrachloro-substituted derivative. Attempts to obtain more highly chlorinated products by raising the temperature (to 150°C and above) have been unsuccessful, since cleavage of the silicon–carbon bond occurs under these conditions.

Several publications have appeared on the ionic chlorination of certain other aromatic silanes—biphenyl-4-yltrichlorosilane[261], *p*-xylyltrichlorosilane[262], and tetraphenylsilane[263]. Polychloro-derivatives of aromatic silanes have been obtained by chlorinating the latter in the presence of a mixed catalyst ($FeCl_3 + SbCl_5$),[229] and also in the presence of aluminium chloride and iron(III) chloride in an organic solvent[238,263]. Chlorination of polytitanophenylsiloxanes[264] and polyaluminophenylsiloxanes[265] in the presence of a catalyst (phosphorus pentachloride) in carbon-tetrachloride solution gives the corresponding polymers having chlorine atoms in the phenyl groups, which possess improved thermal stability in comparison with the original compounds.

2. Preparation of Bromoaryl Compounds of Silicon

With rare exceptions the direct bromination of arylsilanes is accompanied by cleavage of the $Si-C_{Ar}$ bond[27-29,33,215,239]. The tendency for the aromatic ring to become detached from the silicon atom diminishes as chlorine atoms accumulate on the silicon. Thus the bromination of phenyltrichlorosilane in the presence of iron(III) chloride gives a quite high yield of mono- and di-bromo-derivatives[203,224,226,236]. It is interesting that most (69%) of the bromophenyltrichlorosilane formed comprises a mixture of the *p*- and *o*-bromo-isomers (38% and 31%). These results indicate that the trichlorosilyl group exhibits an anomalous *ortho*–*para*-orienting effect during bromination.

Extraordinary ease of detachment is exhibited by the trifluorylsilyl group when phenyltrifluorosilane is brominated in the presence of iron[239]. Under mild conditions of bromination it is possible to obtain monobromophenyltrifluorosilane (in 52% yield)[240], which is a mixture of isomers (*meta* : *para* + *ortho* ≃ 60 : 40).

Phenylmethyldichlorosilane reacts readily with bromine in the absence of catalysts at 0–25°C to form mono- and di-bromophenylmethyldichlorosilanes[266]. Further increase in the extent of bromination under these conditions, as well as bromination in the presence of ionic catalysts, leads to considerable cleavage of the reaction products at the $Si-C_{Ar}$ bond. The first bromine atom to enter the aromatic ring of phenylmethyldichlorosilane occupies predominantly the *ortho* and *para* positions (*meta* : *ortho* : *para* = 25 : 35 : 40).

Phenyltrimethylsilane is cleaved quantitatively by bromine at the $Si-C_{Ar}$ bond, even under mild conditions.

Publication of a series of papers on the direct bromination of phenyltrichlorosilane[236], benzyltrichlorosilane[248], *p*-tolyltrichlorosilane[254], and phenylmethyldichlorosilane[266] has been followed by other investigations in this field. Study of the electrophilic bromination of compounds of the type $C_6H_5[CH_2]_nSiCl_mR_{3-m}$ ($n = 1, 2$; $m = 0-3$; and $R = CH_3$, C_2H_5) showed that in all cases the $[CH_2]_nSiCl_m$·R_{3-m} groups are strongly *ortho*–*para*-orienting[249,267]. The high reactivity of benzyltrimethylsilane compared with benzyltrichlorosilane is explained by conjugation of the silicon–carbon bond with the aromatic ring[267]. The bromination of benzyltrifluorosilane, in contrast to that of phenyltrifluorosilane, is not accompanied by cleavage of the silicon–carbon bond, the sole product being the *p*-bromo-isomer[239].

3. Mechanism of Electrophilic Substitution and Cleavage of the $Si-C_{Ar}$ Bond in Aryl- and Alkylaryl-chlorosilanes

The characteristic features of the substitutive chlorination of aryl- and alkylaryl-chlorosilanes agree well with the generally accepted mechanism of electrophilic substitution in the aromatic series:

$$Cl_2 + MCl_3 \rightleftarrows \overset{\delta+}{Cl} \ldots Cl \ldots \overset{\delta-}{MCl_3} \rightleftarrows \overset{+}{Cl}\,[MCl_4]^-$$

(M = Fe, Al, Sb)

$$C_6H_5SiCl_3 + \overset{+}{Cl}\,[MCl_4]^- \rightarrow \left[\text{C}_6\text{H}_5(\text{SiCl}_3)(\text{Cl})\right]^+ [MCl_4]^- \rightarrow C_6H_4ClSiCl_3 + HCl + MCl_3$$

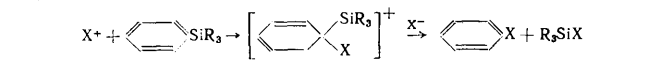
Phenylchlorosilanes react by a similar mechanism with iodine trichloride, which acts here as a reactive electrophilic form of the halogen[242]:

$$ICl_3 \rightleftarrows \overset{+}{Cl}\,[ICl_2]^-$$

$$C_6H_5SiCl_3 + \overset{+}{Cl}\,[ICl_2]^- \rightarrow \left[\text{C}_6\text{H}_5(\text{SiCl}_3)(\text{Cl})\right]^+ [ICl_2]^- \rightarrow C_6H_4ClSiCl_3 + HCl + ICl$$

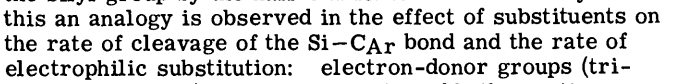
As already noted above, a characteristic feature of the electrophilic halogenation of arylsilanes and alkylarylsilanes is the accompanying secondary degradative halogenation involving cleavage of starting materials and products at the $Si-C_{Ar}$ bond with the formation of halogenated aromatic derivatives not containing silicon. A definite relation exists between such cleavage and electrophilic substitution in aryl- and alkylaryl-chlorosilanes[37-52,69,268-273].

Thus trialkylsilyl groups are detached from an aromatic ring by a mechanism of electrophilic substitution[33,44-51]:



In this case electrophilic attack on the aromatic ring by the halogen cations, leading to formation of an intermediate addition product, is accompanied by nucleophilic attack on the silyl group by the halide anions. In conformity with this an analogy is observed in the effect of substituents on the rate of cleavage of the $Si-C_{Ar}$ bond and the rate of electrophilic substitution: electron-donor groups (trimethylsilyl, etc.) increase the rates of both reactions; electron-acceptor groups (trichlorosilyl) decrease the rates. The tendency of the $Si-C_{Ar}$ bond to undergo cleavage by the halogen falls rapidly in the sequence $C_6H_5Si(CH_3)_3 > C_6H_5SiCl(CH_3)_2 > C_6H_5SiCl_2CH_3 > C_6H_5SiCl_3$. The rate of cleavage is determined not only by the nature of the silyl group but also significantly by induction and steric effects, the nature of the halogen, the catalyst, and other factors.

Cleavage of the $Si-C_{Ar}$ bond by the hydrogen halide formed during halogenation in the presence of ionic catalysts takes place by an analogous mechanism of electrophilic substitution[60-62,239,274]:



where R = Alk, Cl, F; X = Cl, Br; and M = Fe, Al, Sb.

The sequence of increasing stability of aromatic silanes to cleavage by the $HX.MX_3$ complex under conditions of halogenation is

$$R_3'SiR < RR'SiCl_2 < R_2SiCl_2 < RSiF_3 < p\text{-}R'C_6H_4SiCl_3 < p\text{-}CCl_3C_6H_4SiCl_3 < RSiCl_3,\ RSiCl_2(CCl_3),$$

where R = C_6H_5 and R′ = CH_3.

Fluorine atoms, in spite of their greater electronegativity, are for steric reasons incapable of resisting nucleophilic attack on the silicon atom, so that cleavage of the $Si-C_{Ar}$ bond takes place more easily in phenyltrifluorosilane than in phenyltrichlorosilane.

VI. RADICAL HALOGENATION (CHLORINATION, BROMINATION) OF SILICON-CONTAINING ALIPHATIC–AROMATIC AND AROMATIC COMPOUNDS

1. Substitutive Halogenation with Replacement of Alkyl Hydrogen Atoms by Chlorine and Bromine

The photochemical chlorination of alkylarylchlorosilanes yields substitution products containing chlorine in the alkyl radical or in the aliphatic portion of an aralkyl group[179,275-280]. It is interesting that *o*-tolyltrichlorosilane, in contrast to *p*-tolyltrichlorosilane, is not chlorinated, probably because of the steric effect of the trichlorosilyl group[155,277], for the less bulky trifluorosilyl group does not exert such hindrance. Benzyltrichlorosilane can be chlorinated with sulphuryl chloride in the presence of benzoyl peroxide[173].

Tolyl and benzyl groups in hydrocarbon derivatives of silicon are easily brominated by *N*-bromosuccinimide, usually without cleavage of the $Si-C_{Ar}$ bond[179,281,282]. Tetra-*p*-tolylsilane and certain other hydrocarbon derivatives of silicon are exceptions[179,283]. When benzylsilane is brominated in weak daylight (at 8°C), α-bromobenzyltribromosilane is formed. Heating a mixture of benzylsilane and bromine in sunlight yields αα-dibromobenzyltribromosilane[284].

The radical chlorination of aliphatic–aromatic chlorosilanes has been studied in the greatest detail on *p*-tolyl- and benzyl-trichlorosilanes, and also on phenyl- and *p*-tolyl-methyldichlorosilanes, in the presence of azoisobutyronitrile as initiator.

Chlorination of *p*-tolyl- and benzyl-trichlorosilanes in the presence of this initiator[95,97,285] takes place without cleavage of the reaction products at the silicon–carbon bond. The process can easily be controlled with the formation of compounds of a desired degree of substitution. A distinguishing feature of these reactions is the formation of the monochloro-derivatives in high yields with complete conversion of the initial silane (in contrast to aliphatic chlorosilanes). Among polychloro-derivatives *p*-trichloromethylphenyltrichlorosilane is of practical interest as the starting material for the preparation of *p*-trifluoromethylphenyltrifluorosilane. α*H*-Hexachlorobenzyltrichlorosilane $C_6Cl_5CHClSiCl_3$ has been isolated from the products of the photochemical chlorination of pentachlorobenzyltrichlorosilane[286]; the product of the exhaustive chlorination of benzyltrichlorosilane cannot be obtained.

The chlorination of phenylmethyldichlorosilane can occur selectively—either in the methyl group or in the aromatic ring—depending on the nature of the catalyst. Initiation with azoisobutyronitrile leads to the formation of all possible products in which the methyl group is substituted[287,288]. The ability of the chloromethyl group to be chlorinated more easily than the unsubstituted methyl group is clearly evident in phenylmethyldichlorosilane, just as in the methylchlorosilanes, which is indicated by the ~10% content of the dichloro-derivative in the reaction mixture on conversion of the initial silane. Under otherwise similar conditions the content of polychloro-derivatives in the reaction mixture is appreciably higher in the continuous chlorination of phenylmethyldichlorosilane[289] than with a batch method of chlorination: i.e. the situation is the same as in the chlorination of methylchlorosilanes. The exhaustive chlorination of phenylmethyldichlorosilane in the presence of azoisobutyronitrile at 110–115°C is not accompanied by side-reactions and gives a 90% yield of phenyltrichloromethyldichlorosilane. When the temperature is lowered to 45–50°C, the reaction mixture contains partly chlorinated products; and raising the temperature to 145–150°C lowers appreciably the yield of phenyltrichloromethyldichlorosilane owing to degradation of the chlorination products at the silicon–carbon bond. Because of the high selectivity of the reaction it is desirable to obtain this product by a continuous counterflow scheme[290]. The chlorination of benzylmethyldichlorosilane in the presence of azoisobutyronitrile (at 110°C) results in the formation of αα-dichlorobenzyltrichloromethyldichlorosilane[250]. This compound is obtained also by photochemical chlorination, but then a nuclear addition product, hexachlorocyclohexylmethylmethyldichlorosilane, is also formed[250].

The rate of chlorination of the methyl group in compounds of the type $C_6H_{5-n}Cl_nSiCl_2CH_3$ decreases with increase in *n*.[291] When *n* = 1 the *p*-chloro-isomer is chlorinated considerably more easily than is the *meta*-isomer, although chlorination of *p*-chlorophenylmethyldichlorosilane is slower than that of unsubstituted phenylmethyldichlorosilane.

Sulphuryl chloride proved to be a milder chlorinating agent for phenylmethyldichlorosilane, and was more selective, so that a high yield of phenyldichloromethyldichlorosilane could be obtained[292].

The chlorination of *p*-tolylmethyldichlorosilane in the presence of azoisobutyronitrile at 110–115°C (molar ratio

silane : chlorine = 1 : 3) leads initially to replacement of the nuclear methyl hydrogen atoms. With a large excess of chlorine (1 : 10) *p*-trichloromethylphenyltrichloromethyldichlorosilane is formed in 80% yield[293]. The fact that the aromatic ring of *p*-tolylmethyldichlorosilane contains a substituent of the first kind [*sic*—presumably means +*I* group (Ed. of Translation)] (a methyl group) *para* to the silicon atom weakens the $Si-C_{Ar}$ bond, as is indicated by the greater ease of cleavage of this compound than of phenylmethyldichlorosilane.

2. Addition of Chlorine at Double Bonds and Replacement of Nuclear Hydrogen Atoms by Chlorine

Phenyltrichlorosilane readily undergoes photochemical chlorination at ordinary temperatures (20°C) to form a product—hexachlorocyclohexyltrichlorosilane $C_6H_5Cl_6.SiCl_3$—in which chlorine atoms have added to the aromatic ring[294-296]. The yield decreases with rise in temperature, and at 120°C the photochemical chlorination of phenyltrichlorosilane proceeds solely as a substitution reaction (Fig. 8).

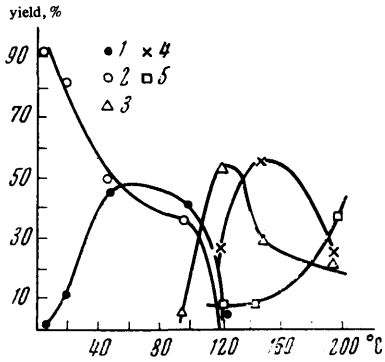


Figure 8. Temperature dependence of yield of products of the photochemical chlorination of phenyltrichlorosilane (for molar ratio $Cl_2 : C_6H_5SiCl_3 = 10 : 1$):
1) $C_6H_5SiCl_3$; 2) $C_6H_5Cl_6SiCl_3$; 3) $C_6H_4ClSiCl_3$; 4) $C_6H_3Cl_2SiCl_3$; 5) $C_6H_2Cl_3SiCl_3$.

The additive chlorination of phenyltrichlorosilane is a chain reaction initiated by free chlorine atoms according to the usual scheme:

$$Cl_2 \xrightarrow{h\nu} Cl^{\cdot} + Cl^{\cdot} \quad (1)$$

$$C_6H_5SiCl_3 + Cl^{\cdot} \rightarrow C_6H_5ClSiCl_3^{\cdot} \quad (2)$$

$$C_6H_5ClSiCl_3^{\cdot} + Cl_2 \rightarrow C_6H_5Cl_2SiCl_3 + Cl^{\cdot}, \text{etc.} \quad (3)$$

A free-radical mechanism is indicated by the fact that additive chlorination can be conducted in the presence of azoisobutyronitrile in the dark[297]. The overall rate of addition is limited by stage (2). Subsequent stages take place at very high rates, so that intermediate addition products—dichlorocyclohexadienyltrichlorosilane and tetrachlorocyclohexenyltrichlorosilane—cannot be detected in the products of the photochlorination of phenyltrichlorosilane: two components—phenyltrichlorosilane and hexachlorocyclohexyltrichlorosilane—are present in the reaction mixture, independently of the molar ratio of the reactants (silane and chlorine) (Fig. 9). The linear dependence of the logarithm of the phenyltrichlorosilane concentration on the duration of chlorination (Fig. 10) indicates that the reaction is of the first order with respect to the silane. The stepwise addition of chlorine to the aromatic ring is proved by the fact that the chain can be terminated by means of iodine, and tetrachlorocyclohexenyltrichlorosilane $C_6H_5Cl_4SiCl_3$ isolated[297].

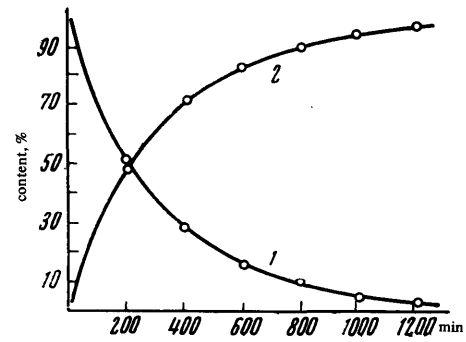

Figure 9. Dependence of composition of reaction mixture on extent of chlorination (at +5°C):
1) $C_6H_5SiCl_3$; 2) $C_6H_5Cl_6SiCl_3$.

The course of the radiation chlorination of phenyltrichlorosilane, initiated by cobalt-60 γ-radiation[18,148], is analogous to the photochemical process.

Hexachlorocyclohexyltrichlorosilane is a mixture of stereoisomers[101]. Its structure is confirmed by the infrared spectrum, which contains no absorption bands characteristic of an aromatic ring. Aqueous alkali hydrolyses this compound with detachment of the hexachlorocyclohexyl radical from the silicon atom. The hexachlorocyclohexane formed as an intermediate is dehydrochlorinated under these conditions and converted into trichlorobenzene. With absolute alcohols hexachlorocyclohexyltrichlorosilane forms the corresponding hexachlorocyclohexylalkoxysilanes. It is inert towards chlorine at 150°C and on exposure to ultraviolet radiation, and also at 75–100°C in the presence of iron(III) chloride. When heated to 550–580°C it splits off hydrogen chloride and is converted into trichlorophenyltrichlorosilane. The product of partial additive chlorination, tetrachlorocyclohexenyltrichlorosilane, is able to eliminate hydrogen chloride at 250°C with the formation of dichlorophenyltrichlorosilane.

Phenyltrifluorosilane forms an addition product, hexachlorocyclohexyltrifluorosilane, more easily than does phenyltrichlorosilane[295].

If the silane contains alkyl radicals as well as the phenyl group, the rate of addition of chlorine to the aromatic ring drops sharply. Thus the photochemical chlorination of phenyltrimethylsilane and *p*-tolyltrichlorosilane involves mainly substitution of the methyl hydrogen atoms, the yield of addition products not exceeding 10–12%.[295] The introduction of halogen atoms and trichloromethyl, trifluoromethyl, and trichlorosilyl groups into the aromatic ring of

phenyltrichlorosilane results in almost complete inhibition of additive chlorination.

Benzyltrichlorosilane gives a high yield of the nuclear addition product hexachlorocyclohexylmethyltrichlorosilane, which is formed on photochemical chlorination together with products in which the methylene hydrogen atoms have been replaced by chlorine[101,285,294].

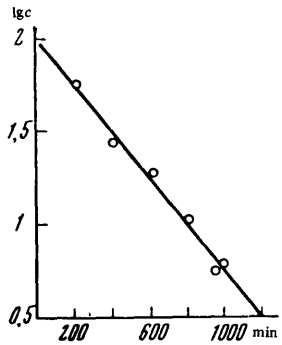

Figure 10. Dependence of logarithm of concentration of phenyltrichlorosilane on duration of chlorination.

Under the same conditions the additive chlorination of diphenyldichlorosilane proceeds relatively easily, but chlorine adds to only one aromatic ring to form hexachlorocyclohexylphenyldichlorosilane $C_6H_5Cl_6SiCl_2C_6H_5$.[295]

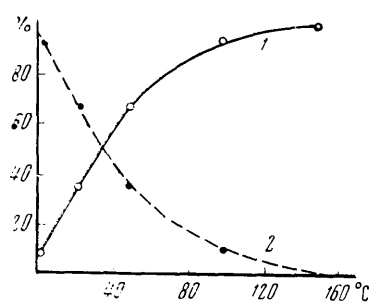

Figure 11. Temperature dependence of composition of products of the photochemical chlorination of phenylmethyldichlorosilane ($Cl_2 : C_6H_5SiCl_2CH_3 = 3.5 : 1$): 1) nuclear addition products; 2) products of substitution in the methyl group.

Addition of chlorine to 1-naphthyltrichlorosilane occurs especially easily with ultraviolet irradiation and a low temperature (0–5°C), but in spite of the prolonged action of excess of chlorine (molar ratio 1-$C_{10}H_7SiCl_3 : Cl_2$ = 1 : 12) the product is 1-$C_{10}H_7Cl_4SiCl_3$.[259,294] This indicates that the addition of chlorine to double bonds probably occurs only in one six-membered ring of 1-naphthyltrichlorosilane. At high temperatures, and also under the influence of iron(III) chloride, the compound 1-$C_{10}H_7Cl_4SiCl_3$ eliminates hydrogen chloride and is converted into dichloro-1-naphthyltrichlorosilane[260].

The action of chlorine on phenylmethyldichlorosilane in daylight at temperatures not above 5°C yields only the nuclear addition product hexachlorocyclohexylmethyldichlorosilane[294,298,299]. Raising the temperature to 20–25°C accelerates substitutive chlorination; at 50°C and above the main product is chlorophenylmethyldichlorosilane. The photochemical chlorination of phenylmethyldichlorosilane at 0°C gives an addition product[299,300]. With rise in temperature substitution in the methyl radical becomes predominant, and is the only process at 95–100°C (Fig. 11). The radical mechanism of formation of hexachlorocyclohexylmethyldichlorosilane is confirmed by the occurrence of additive chlorination in the presence of azoisobutyronitrile at 45–50°C.

The radiation chlorination of phenylmethyldichlorosilane by means of cobalt-60 γ-rays differs from its photochemical chlorination only in that rise in temperature leads to substitution of hydrogen atoms not in the methyl group but chiefly in the aromatic ring[157,169] (Fig. 12). With radiation chlorination the highest yield of chloromethyl products is observed at 20–30°C. Similar results have been obtained for the radiation chlorination of a phenylmethylpolysiloxane polymer[159].

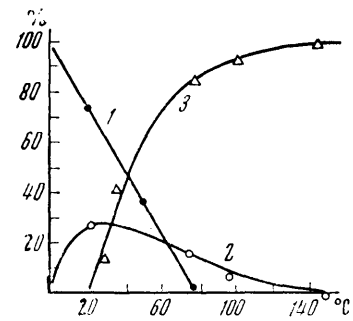

Figure 12. Temperature dependence of composition of products of the radiation chlorination of phenylmethyldichlorosilane: 1) nuclear addition products; 2) products of substitution in the methyl group; 3) nuclear substitution products.

It is interesting that no compounds containing both a hexachlorocyclohexyl radical and di- and tri-chloromethyl groups attached to silicon have been found among the products of the photochemical and radiation chlorination of phenylmethyldichlorosilane. This indicates considerable deactivation of the aromatic ring in phenyltrichloromethyldichlorosilane owing to the presence of the trichloromethyl group. This is confirmed by the exceptional inertness of this compound not only towards thermal and ionic chlorination but also towards additive chlorination[258].

Analysis of the data indicates a definite correlation among the electrophilic character of the substituent, the rate of additive chlorination of substituted aromatic com-

pounds of silicon, and steric hindrance. The sequence of increasing capacity for additive nuclear chlorination in aryl- and alkylaryl-silanes is

$$p\text{-}CF_3C_6H_4SiF_3,\ p\text{-}CCl_3C_6H_4SiCl_3,\ C_6H_4(SiCl_3)_2 < C_6H_4Cl_2SiCl_3 < < C_6H_4ClSiCl_3 < C_6H_5(CCl_3)SiCl_2 < (C_6H_5)_2SiCl_2,$$
$$\alpha\text{-}C_{10}H_7SiCl_3 < C_6H_5SiCl_3 < C_6H_5SiF_3 < C_6H_5(CH_3)SiCl_2,\ C_6H_5CH_2SiCl_3.$$

VII. CHLORINATION OF PHENYLTRICHLOROSILANE IN THE PRESENCE OF IODINE AND ON γ-IRRADIATION

The chlorination of phenyltrichlorosilane is distinguished by interesting features. Depending on the conditions chlorine either adds to the aromatic ring or replaces hydrogen atoms [101]. Photochemical chlorination at 0–50°C involves solely addition of chlorine. With rise in temperature the rate of substitutive chlorination increases with formation mainly of the *o*-chloro-isomer (43%). A similar reaction is observed in the chlorination of phenyltrichlorosilane in the presence of azoisobutyronitrile at 120–125°C. A still stronger shift towards predominant formation of the *o*-chloro-isomer (67%) occurs in the presence of iodine as catalyst [101,241,301]. Thus under the above conditions the trichlorosilyl group loses its inherent *meta*-orienting power.

An interesting property of iodine as catalyst is that it is able to activate equally the nuclear addition of chlorine and its nuclear substitution [101]. Both in the chlorination of benzene in the presence of iodine [302–304] and in that of phenyltrichlorosilane under similar conditions [101] there is simultaneous formation of substitution products (chlorophenyltrichlorosilane) and products of partial additive chlorination (tetrachlorocyclohexenyltrichlorosilane).

The addition of chlorine to an aromatic ring usually takes place by a radical mechanism. Since the formation of atoms and radicals is excluded in chlorination in the presence of iodine, the most probable mode of addition under these conditions must be assumed to be heterolytic, in which the iodine polarises the chlorine and promotes its addition:

$$Cl{-}Cl + I_2 \rightleftarrows \overset{\delta+}{Cl} \ldots \overset{\delta-}{ClI_2}$$

$$C_6H_5SiCl_3 + Cl^+ \rightarrow \left[\text{C}_6\text{H}_5(\text{SiCl}_3)\text{Cl}^+\right] \xrightarrow{+Cl^-} \text{C}_6\text{H}_5(\text{SiCl}_3)\text{Cl}_2 \qquad \text{(I)}$$

$$\text{C}_6\text{H}_5(\text{SiCl}_3)\text{Cl}_2 + Cl^+ \rightarrow \left[\text{C}_6\text{H}_5(\text{SiCl}_3)\text{Cl}_3^+\right] \xrightarrow{+Cl^-} \text{C}_6\text{H}_5(\text{SiCl}_3)\text{Cl}_4 \qquad \text{(II)}$$

The cyclohexadiene system in (I) is highly reactive, and therefore the intermediate dichlorocyclohexadienyltrichlorosilane (I) cannot be isolated from the reaction products. Formation of the dichloro-derivative (I) is confirmed by the appearance among the chlorination products, together with tetrachlorocyclohexenyltrichlorosilane (II), of a considerable quantity of *o*-chlorophenyltrichlorosilane, obviously resulting from dehydrochlorination of (I):

$$\left[\text{C}_6\text{H}_5(\text{SiCl}_3)\text{Cl}_2\right] \xrightarrow{-HCl} \text{C}_6\text{H}_4(\text{SiCl}_3)\text{Cl}$$

This change in the usual electrophilic mechanism of substitutive chlorination probably explains the loss of the *meta*-orienting power of the trichlorosilyl group in the chlorination of phenyltrichlorosilane in the presence of iodine.

The radiation chlorination of phenyltrichlorosilane, initiated by cobalt-60 γ-rays [157] at 0–20°C, involves predominantly nuclear addition of chlorine to form hexachlorocyclohexyltrichlorosilane, and in this respect resembles photochemical chlorination. With rise in temperature nuclear substitution begins, and at 100°C the chlorination of phenyltrichlorosilane already consists solely in substitution. The isomeric composition of the monochlorophenyltrichlorosilane obtained under these conditions shows that in radiation chlorination the chlorosilyl group exerts its normal *meta*-orienting effect (*meta* : *ortho* : *para* = 75 : 20 : 5).

Substitutive chlorination of the phenyl group under the influence of γ-radiation is not inhibited by either oxygen or air. This suggests that the replacement of hydrogen atoms in the aromatic ring of phenyltrichlorosilane during radiation chlorination occurs by an ionic mechanism involving chlorine cations [157,305] formed by the radiolysis of chlorine:

$$Cl_2 \rightsquigarrow \begin{cases} Cl_2^+ + e^- \\ Cl^+ + Cl^- + e^- \end{cases}$$

The radiolysis of silanes is accompanied by the appearance in the reaction mass of excited molecular and splinter ions, which are able to react with a chlorine molecule:

$$[Ion]^+ + Cl_2 \rightarrow [ion]\,Cl + Cl^+$$

The primary Cl^+ ions can then react with a molecule of the initial silane:

$$C_6H_5SiCl_3 + Cl^+ \rightarrow C_6H_4ClSiCl_3 + H^+$$

The proton, on reacting with molecular chlorine, may liberate fresh chlorine ions:

$$H^+ + Cl_2 \rightarrow HCl + Cl^+ + 2.5\ eV$$

Regeneration of Cl^+ ions by these reactions will probably continue until either H^+ or Cl^+ combines with a negative ion, which will correspond to the stage of chain termination.

The only argument against an ionic mechanism for the radiation chlorination of phenyltrichlorosilane is the relatively high temperature of the reaction, since the lifetime of positive ions is too short under these conditions. It increases as the temperature becomes lower, and also in the presence of substances having a high electron affinity and a considerable capture cross-section for thermal electrons. In the present case chlorine and also phenyltrichlorosilane itself may fill this role. Hence there may be factors which promote reaction by an ionic mechanism at high temperatures.

VIII. PREPARATION OF ORGANOSILICON COMPOUNDS CONTAINING FLUORINE (IODINE) IN THE ORGANIC RADICALS

It is not possible to fluorinate organic radicals attached to a silicon atom directly by means of fluorine, because of the accompanying degradation of the molecule to be fluorinated. However, the valuable properties of fluorinated organosilicon polymers have stimulated research aimed at finding other methods for preparation of the corresponding monomers. The principal methods known at present will be described briefly below.

1. Organoelementary Method

The first organosilicon compound containing a fluorine atom in the organic radical was obtained[306] from *p*-fluorophenylmagnesium bromide and trimethylchlorosilane. A large number of diverse compounds of this type have since been obtained by Soviet[307-310] and foreign[311-313] workers. By means of Grignard reagents it is relatively easy to obtain various derivatives from silicon tetrachloride, silicochloroform, tetraethyl orthosilicate, and other compounds. Aromatic and aliphatic fluorine-containing compounds can be used to prepare the Grignard reagent. Compounds based on unsaturated polyfluorides, e.g. tetrakistrifluorovinylsilane[314], can be obtained by the organomagnesium method.

The reactions can be conducted under milder conditions if organolithium compounds are used[315-317], and the yield of the fluorinated organosilicon compounds is higher. In comparison with the use of magnesium that of lithium has not found sufficiently wide application.

Sufficient experimental data have now been published to derive the main principles of the organoelementary synthesis of fluorinated organosilicon compounds.

2. The Swarts Reaction

The Swarts reaction can be used to exchange halogens in an organic radical for fluorine atoms[318]. Halogen atoms attached to silicon are replaced at the same time. To diminish the consumption of antimony trifluoride and antimony pentachloride use is made e.g. of the following scheme[246,319]

$$CH_3C_6H_4SiCl_3 \xrightarrow{HF} CH_3C_6H_4SiF_3 \xrightarrow{+Cl_2} CCl_3C_6H_4SiF_3 \xrightarrow{SbF_3+SbCl_5} CF_3C_6H_4SiF_3$$

Various aryl- and alkyl-fluorosilanes can be obtained by means of the Swarts reaction. Exchange for fluorine depends on the position of the halogen in the organic radical: in 1-bromo-3,3,3-trichlorpropylmethyldichlorosilane and 1,3,3,4,4,4-hexabromobutylphenyldichlorosilane, for example, the 1-bromine atom cannot be replaced by fluorine[320,321].

Several difficulties in conducting the reaction and the limited choice of compounds diminish the possibilities of the Swarts method for introducing fluorine atoms into the organic radicals of alkylsilanes and arylsilanes.

3. Addition at a Silicon–Hydrogen Bond

Many investigations have been undertaken with the aim of obtaining fluorinated organosilanes by the addition of unsaturated fluorine-containing compounds at a silicon–hydrogen bond. This reaction was first accomplished[322,323] in 1954 with the addition of silicochloroform to 1,1-difluoroethylene and tetrafluoroethylene. During many subsequent researches various catalysts and initiators have been found and a large number of diverse compounds have been prepared. Addition is initiated by ultraviolet radiation[324], cobalt-60 γ-rays[325,326], and various compounds such as peroxides[327]. It takes place by a radical–chain mechanism:

$$HSiCl_3 \xleftarrow{h\nu} Cl_3Si^{\cdot} + H^{\cdot} \quad Cl_3Si^{\cdot} + CF_2{=}CF_2 \rightarrow Cl_3SiCF_2CF_2^{\cdot}$$
$$Cl_3SiCF_2CF_2^{\cdot} + HSiCl_3 \rightarrow Cl_3SiCF_2CF_2H + {}^{\cdot}SiCl_3$$

Good results have been obtained by using platinised carbon and especially chloroplatinic acid as catalyst[328,329]. The action of platinum is explained in the literature as involving both heterogeneous and homogeneous catalysis.

Individual examples have been reported of the addition of fluoroalkenes at a silicon–hydrogen bond in the presence of boric acid in an autoclave at high temperatures[330], etc., but they have not interested investigators.

Among all the known methods, addition at a silicon–hydrogen bond is in several cases of the greatest practical interest for the industrial production of fluorinated organosilicon compounds.

4. Other Reactions

In contrast to the well known industrial processes for the direct synthesis of alkyl- and aryl-chlorosilanes, only the simplest halogenated fluorocarbons react directly with a silicon–copper alloy[331], and the yield is low.

Several compounds have been obtained by the Diels–Alder method[332], and by the addition of compounds of the type RCF_2Br or RCF_2I (where R = F or a radical) at the double bonds of alkenylsilanes in the presence of radical initiators[333]. Fluorinated esters[334] and ethers[335] have also been obtained. However, these methods for preparing fluorinated organosilanes have no practical interest.

The literature contains no serious investigations on the preparation of organosilicon compounds containing iodine in the organic radical. Individual publications in which preparations of iodinated organosilanes are encountered are of no theoretical interest and still less of practical interest.

The Chemical Properties of Thioamides

K.A.Petrov and L.N.Andreev (deceased)

The principal chemical properties of thioamides are surveyed—hydrolysis, reduction and oxidation, and reactions with inorganic and organic amines, acid chlorides, aldehydes and ketones, alkyl halides, and halogenated amines, ketones, and acids. A list of 274 references is included.

CONTENTS

I. INTRODUCTION

Thioamides are reactive compounds, and have been well studied. The changes they undergo on oxidation, reduction, reaction with inorganic and organic amines, and addition to halogenated amines, ketones, acids, and esters are widely used in obtaining derivatives of pyrimidine, purine, and uracil, thiazoles, vitamin B_1, etc. [1-16].

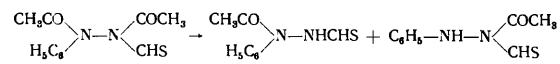
There is a vast literature on the chemical properties of thioamides, which has not yet been systematised. Existing reviews [17-23] are concerned mainly with the preparation of thioamides; the chemical properties are not dealt with adequately [17,18,21-23]. The Soviet literature contains no reviews on the chemical properties of thioamides. This is the reason for publishing the present Review.

II. HYDROLYSIS OF THIOAMIDES

Like amides of carboxylic acids, thioamides can be hydrolysed by water, better in the presence of acids or alkalis. The products are usually carboxylic acids, but sometimes amides and nitriles. Unsubstituted thioamides are relatively easily hydrolysed with the formation in acid medium mainly of carboxylic acids, but in the presence of alkalis aromatic thioamides yield carboxylic acids, nitriles, and amides. Thus thioacetamide is hydrolysed by bases and acids to acetic acid, hydrogen sulphide, and ammonia [24]. With boiling water or hot 1 *N* hydrochloric acid thiobenzamide yields benzoic acid, hydrogen sulphide, and ammonia; but with caustic potash it forms benzonitrile and hydrogen sulphide (ammonia also is formed on heating with 1 *N* caustic potash). [25] Phenylthioacetamide behaves similarly: with dilute hydrochloric acid it gives phenylacetic acid, hydrogen sulphide, and ammonia; but on heating with caustic potash phenylacetonitrile and hydrogen sulphide are obtained [26].

Thioamides are more difficult to hydrolyse than are the corresponding amides [27]. *N*-Thiobenzoylmorpholine is hydrolysed in 10 *N* caustic potash at only one-tenth the rate of *N*-benzoylmorpholine [28].

N-Substituted thioamides are considerably more difficult to hydrolyse than are the unsubstituted compounds. Thus *N*-benzylthiobenzamide hydrolyses very slowly even when boiled in 50% sulphuric acid, whereas thiobenzamide is hydrolysed with the formation of benzoic acid even by boiling water. Phenyl *N*-phenyl-*N*-thiobenzoylthiocarbamate $C_6H_5.CS.N(C_6H_5).CSOC_6H_5$ is hydrolysed slowly by sulphuric acid, one of the products being thiobenzanilide [29]. The hydrolysis of *N*-phenyl-*N'*-thioformyldiacetohydrazide in 10% caustic soda does not affect the thioformyl group, the product being *N'*-phenyl-*N*-thioformylacetohydrazide contaminated with other substances [30]:



The great stability of the thioanilide group in comparison with thiocarbamoyl [31] is evident also in the hydrolysis of *N*-phenyldithio-oxamide: it has proved possible to choose conditions under which only the thiocarbamoyl group is hydrolysed. In the hydrolysis of thioamides of oxalic and oxamic acids the carbon–carbon bond is not broken if a thioanilide group is present, but it is broken in the presence of unsubstituted thiocarbamoyl groups [31].

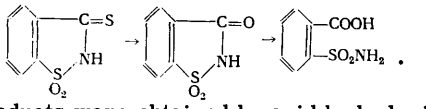
An ester group present in an *N*-substituent can be hydrolysed without decomposition of the thioamide molecule. Thiobenzoylglycine $C_6H_5CS.NH.CH_2.COOH$, which resists the action of alkali in the cold, can be obtained by hydrolysing its ethyl ester with alcoholic caustic potash in the cold [32], but when thiobenzoylglycine is boiled in acid or alkali, sulphur is split off [33], with the formation of hippuric acid, thiobenzoic acid, glycine, and hydrogen sulphide [34].

The hydrolysis of thioamides is substantially influenced also by the nature of the radical attached to the carbon of the thiocarbamoyl group. Thus *N*-β-benzylidynethiopropionylmorpholine $C_6H_5.C\vdots C.CH_2.CS.NC_4H_8O$ is not hydrolysed by boiling for 10 h with 20% alcoholic caustic potash or in concentrated hydrochloric acid; *N*-β-benzylidenethiopropionylmorpholine $C_6H_5.CH:CH.CH_2.CS.NC_4H_8O$, however, is not hydrolysed by alkali under similar conditions, but is hydrolysed by acids [35,36].

Cyclic thioamides are relatively stable to hydrolysis [37].

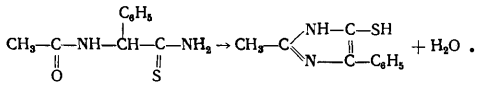
Hydrolysis does not occur when thiosaccharin is treated with sodium carbonate solution in the cold, but the soluble sodium salt of thiosaccharin is formed. The same effect was observed by the action of aqueous ammonia in the cold and on heating, and also with caustic soda solution in the

cold. Boiling with caustic soda hydrolyses thiosaccharin to saccharin, after which cleavage of the ring occurs [38]:



The same products were obtained by acid hydrolysis. Hydrolysis of *o*-sulphamoylthiobenzanilide with hot dilute alkali also gives *o*-sulphamoylbenzoic acid.

Several thioamides undergo cyclisation during alkaline or acid hydrolysis. For example, α-acetamido-α-phenylthioacetamide is rapidly cyclised when heated with a 10% solution of caustic potash [33]:



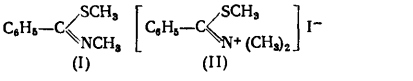
When α-phenyl-α-acetamidothiopropionamide is heated with 20% hydrochloric acid or with dilute caustic potash (with subsequent acidification), it also undergoes cyclisation, to 2,4-dimethyl-4-phenylimidazoline-5-thione [33].

Isothioamides are relatively stable to alkaline hydrolysis, but are easily hydrolysed in the presence of acids†.

Bis-*N*-phenylbenzimidoyl sulphide $C_6H_5.C(:N.C_6H_5).S.C(:N.C_6H_5).C_6H_5$ is stable to hot concentrated alkali, but is easily hydrolysed by acids to form a mixture of benzanilide and thiobenzanilide [39].

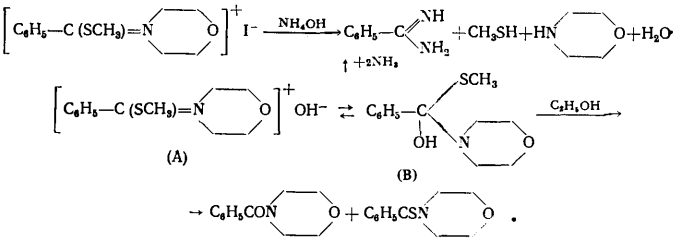
Immonium salts of isothioamides are considerably more easily hydrolysed, usually with the formation of good yields of thiolic esters:

This reaction is used for the hydrolysis of stable thioamides [40]. Thus *N*-phenylthioacetylmorpholine is hydrolysed with difficulty. If, however, it is treated with methyl iodide in acetone, the product‡ is easily hydrolysed by hot water to methyl phenylthioacetate, which is then converted into phenylacetic acid. When ammonia is used instead of hot water, the final product of hydrolysis is phenylthioacetamide.



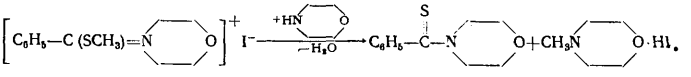
The difference in stability to hydrolysis between isothioamides and their alkylated products—salts of quaternary ammonium bases—can be illustrated by other examples. *S*-Methyl *N*-methylthiobenzimidate (I) is stable in concentrated potassium hydroxide solution, but its quaternary salt (II) is not stable [43]. When (II) is treated with strong alkalis, the methylthio-group is split off and *NN*-dimethylbenzamide is formed. The cation $C_6H_5.C(OH):N(CH_3)_2^+$ is assumed to be formed as an intermediate. A methylthio-group combined with a carbon atom attached to a quaternary nitrogen atom is found to be extremely reactive [42]. Homologues of (I) and (II) behave similarly towards alkaline hydrolysis [42].

The quaternary salt, formed by addition of methyl iodide to *N*-thiobenzoylmorpholine $[C_6H_5.C(S.CH_3):NC_4H_8O]I^-$, dissolves in aqueous ammonia (21°Bé) [44] with the formation of benzamidine. A probable intermediate is the pseudo-base (B) corresponding to the hypothetical hydroxide of the quaternary base (A):

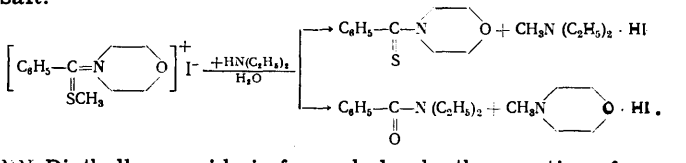


The pseudo-base (B) was isolated [44], but could be not be analysed, although there is other, indirect evidence of its structure. When boiled in alcohol, it is converted into a mixture of *N*-benzoylmorpholine and *N*-thiobenzoylmorpholine with the liberation of methanethiol or methanol. A quaternary salt was obtained with hydrogen iodide. On treatment with aqueous ammonia the pseudo-base (B) gives benzamidine [44].

The quaternary salt reacts similarly with primary amines [44]. *NN'*-Dimethylbenzamidine has been obtained by the action of methylamine. However, hydrolysis with an aqueous solution of a secondary amine follows a different path, the quaternary salt now acting as a methylating agent. Reaction with morpholine gave *N*-thiobenzoylmorpholine and *N*-methylmorpholine:



With diethylamine the main product *N*-thiobenzoylmorpholine was accompanied by a small quantity of *NN*-diethylbenzamide, the normal hydrolysis product of the quaternary salt:



NN-Diethylbenzamide is formed also by the reaction of ethyl thiobenzoate with diethylamine. In the presence of tertiary amines hydrolysis of the salt yields only thiolic esters [44]. Other examples are known of the hydrolysis of unsubstituted and substituted thioamides and isothioamides [45-47].

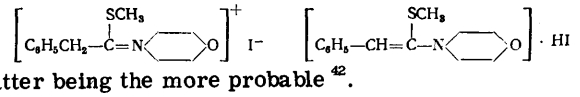
III. REACTIONS OF THIOAMIDES WITH INORGANIC AND ORGANIC AMINES AND SODIUM AZIDE

The reaction of thioamides with inorganic amines (hydroxylamine and hydrazine) is accompanied by replacement of sulphur by the amine residue and sometimes by the amino-group by transamidation:

where X = OH, NH_2, NHR^1, NR^1R^2.

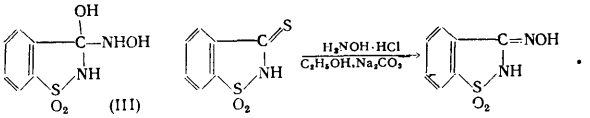
†Isothioamides, being strong bases, give salts with strong mineral acids, but excess of acid hydrolyses them to thiolic esters and ammonium chloride. In this respect the dibenzoyl derivative of thiobenzoxamic acid $C_6H_5.C(S.CO.C_6H_5):N.CO.CO.C_6H_5$ is exceptional: it is stable to hydrolysis in boiling dilute hydrochloric acid, but is hydrolysed by alcoholic caustic potash. The hydrolysis products are benzoxamic and thiobenzoic acids contaminated by thiobenzoxamic and benzoic acids [41].

‡Two structures are possible for the addition product of methyl iodide and *N*-phenylthioacetylmorpholine



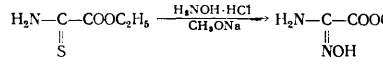
the latter being the more probable [42].

Thiobenzamide when boiled with an alcoholic solution of hydroxylamine gives hydroxyiminobenzamide [48,49]. When *NN'*-diphenyldithio-oxamide $C_6H_5.NH.CS.CS.NH.C_6H_5$ is treated with hydroxylamine, dihydroxyimino-*NN'*-dithio-oxamide $C_6H_5.NH.C(:N.OH).C(:N.OH).NH.C_6H_5$ is formed [49]. Rubeanic acid reacts with hydroxylamine hydrochloride in alcoholic sodium carbonate solution for form dihydroxy-imino-oxamide [50]. Under the same conditions saccharin yields the stable addition product (III), and thiosaccharin yields a hydroxyiminoamide [51]:

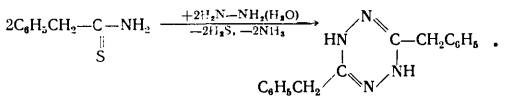


It is assumed that an addition product is formed initially with thiosaccharin also, from which hydrogen sulphide splits off [51].

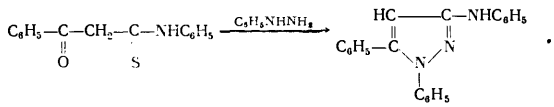
Ethyl thio-oxamate reacts with hydroxylamine hydrochloride in alcoholic sodium methoxide solution to give ethyl hydroxyimino-oxamate [52]:



The reaction between thioamides and aqueous solutions of hydrazine involves replacement of sulphur and trans-amidation with the formation of 3,6-disubstituted 1,4-di-hydro-1,2,4,5-tetrazines [53]:

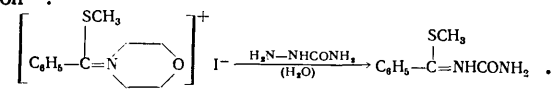


β-Carbonylthioamides (or addition products of enamines and isothiocyanates) react with hydrazine or phenyl-hydrazine to form aminopyrazoles [54]:

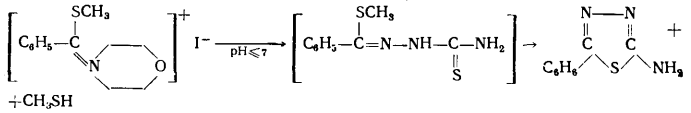


3-Anilino-1,5-diphenylpyrazole

3-Anilino-4-ethylpyrazole and 3-anilino-5-phenylpyrazole have been obtained in this way (by boiling the corresponding thioamides with ethanolic hydrazine for $1\frac{1}{2}$–2 h). Hydrazine reacts similarly with other thioamides [55]. With mono- and di-thio-oxamides sulphur is replaced by the hydrazine residue [56–58]. The isothioamide, *N*-*α*-methylthiobenzyli-denemorpholinium iodide $[C_6H_5.C(S.CH_3):NC_4H_8O]^+I^-$, reacts with excess of hydrazine to give a good yield of 1,4-dihydro-3,6-diphenyl-1,2,4,5-tetrazine [44]. The same compound is formed by the action of hydrazine on thio-benzamide [53]. The above morpholinium iodide does not give a cyclic product with semicarbazide in aqueous solution [59]:



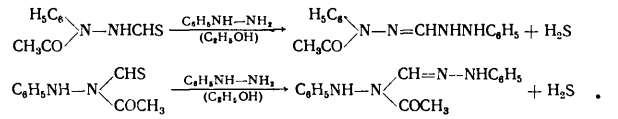
But cyclisation occurs with thiosemicarbazide in acid or neutral medium to form 2-amino 5-phenyl-1,3,4-thiadia-zole. It is supposed that even here the primary product is analogous to that obtained with semicarbazide, but methanethiol is then eliminated to give the thiadiazole [60]:



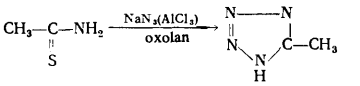
+CH_3SH

If these reagents interact in the presence of weak or strong bases in aqueous solution or in non-aqueous solvents, cyclisation does not occur, but 1-*α*-morpholino-benzylidenethiosemicarbazide is formed. In dilute acids this compound is cyclised to 1,3,4-thiadiazole [60].

The reaction of acylated phenylthioformylhydrazides with phenylhydrazine involves replacement of sulphur by the phenylhydrazine residue:



With sodium azide thioamides form tetrazoles. Thio-acetamide reacts with excess of sodium azide in the presence of aluminium chloride in oxolan to give 5-methyl-tetrazole (yield 55%):[61]



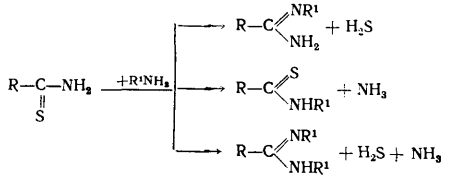
Similarly pentamethylenetetrazole (Cardiazole) has been obtained from *ε*-caprolactam. Since nitriles also give tetrazoles with sodium azide, it is assumed that nitriles are formed as intermediates in these reactions.

Thioamides and isothioamides react differently with primary, secondary, and tertiary amines.

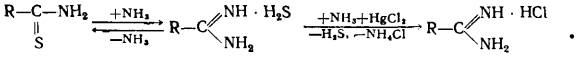
Tertiary amines, being acceptors of hydrogen sulphide, decompose thioamides to the nitrile and hydrogen sulphide. Boiling thioacetamide or thiobenzamide in pyridine yields the corresponding nitrile and hydrogen sulphide [62]. Pyri-dine initiates this reaction by forming the pyridinium salt of the thioamide.

Secondary amines usually transamidate thioamides: in ethereal solution thioacetamide and piperidine yield *N*-thioacetylpiperidine [63]; and diethylamine and thioform-amide give *NN*-diethylthioformamide [94].

Primary amines, like inorganic amines, replace the sulphur by the amine residue and effect transamidation with the formation of *N*-substituted amidines, *N*-substituted thioamides, or mixtures of these products:

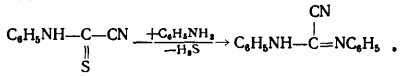


The formation of salts of amidines by the reaction of aliphatic and aromatic thioamides with concentrated solu-tions of ammonium hydroxide was established as long ago as the nineteenth century [65,66]. The yield of amidines was increased by adding mercury(II) chloride, which shifted the equilibrium by forming mercury sulphide:



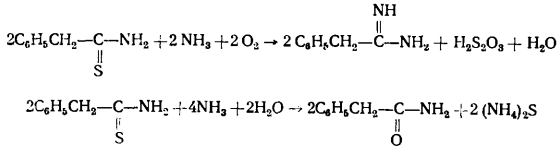
The action of primary amines under similar conditions yields *N*-substituted amidines. Aniline hydrochloride reacts with phenylthioacetamide in absolute ethanol to form *N*-phenylacetamidine [67], and with thiobenzamide to give *N*-phenyl- and *NN'*-diphenyl-benzamidines [68]. *NN'*-Diphen-ylbenzamidine has been obtained by the reaction of thio-benzanilide with molten aniline hydrochloride [69].

The reaction of thio-oxanilonitrile with aniline in boiling benzene gives the amidine in 40% yield, the nitrile group being unaffected [70]:



With change in the conditions the amidine undergoes hydrolysis with formation of the corresponding amide.

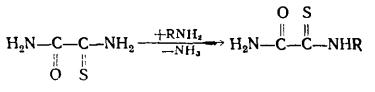
Phenylthioacetamide reacts with ammonium hydroxide solution at room temperature to form phenylacetamidine and a thiosulphate:



and on boiling to give phenylacetamide and ammonium sulphide [95].

With *NN'*-disubstituted thioamides (e.g. dimethylthioformamide) primary amines form *NNN'*-trisubstituted amidines. Thus *NN'*-dimethyl-*N*-naphth-1-ylformamidine has been isolated as its complex with trinitrobenzene by boiling a mixture of dimethylthioformamide, 1-naphthylamine, and sodium methoxide [71].

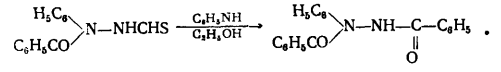
Thioamides undergo transamidation on being heated with amines. Ammonia is evolved when thioacetamide is boiled in butylamine, with the formation of *N*-butylthioacetamide, the yield being almost theoretical [70]. This reaction has been used to obtain several *N*-alkyl- and *N*-aryl-thioamides and *NN'*-dialkyl- and *NN'*-diaralkyldithio-oxamides [70,72-74]. It should be noted that only the thiocarbamoyl group is involved in this reaction, the carbamoyl group being unaffected. The interaction of monothio-oxamide with various amines yields *N*-alkylmonothio-oxamides [75]:



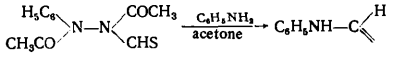
where R = CH_3, C_4H_9, $C_{12}H_{25}$.

A mixture of a thioamide and an amine can be replaced by a mixture of the amide, phosphorus pentasulphide, and the amine: the thioamide obtained initially reacts with the amine to form *N*-substituted derivatives. Aliphatic, aromatic, aliphatic–aromatic, and heterocyclic amines and diamines have been used in this reaction [64,76].

N-Benzoyl-*N*-phenyl-*N'*-thioformylhydrazide reacts differently with aniline when boiled in aqueous–alcoholic solution [77]:

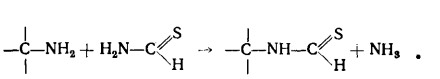


Diacetylphenylthioformylhydrazide reacts with aniline in acetone as follows [30]:

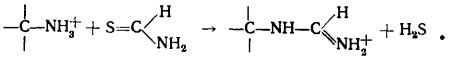


The reaction between thioamides and amines has been studied also in the case of thioformamide and amino-acids [63]. The carbonates of arginine and L-lysine, and also the ethyl ester of glycine, react with thioformamide in methanol at room temperature to give crystalline products. Glycine, L-leucine, DL-alanine, and histidine with excess of thioformamide yield similar products only on being heated to 60°C.

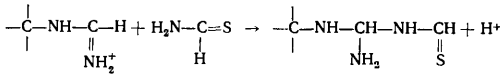
Only amino-acids containing free amino-groups react easily with thioformamide, the products being thioformyl derivatives:



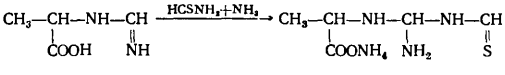
The amino-groups of monoamino-acids (glycine, DL-alanine, L-leucine), the terminal amino-group of L-lysine, and the NH group in the imidazole ring of histidine, which are present as amphoteric ammonium ions, react with thioformamide at 60°C with the elimination of hydrogen sulphide and the formation of formamidine derivatives:



In the cases of L-leucine, DL-alanine, and L-lysine the latter react with a second thioformamide molecule:



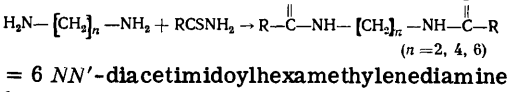
N-Formimidoyl-alanine and -leucine react with molten thioformamide and with ammonia to give products identical with those obtained from the amino-acids and thioformamide at 60°C:[78]



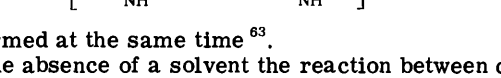
Thioformamide reacts in the cold also with proteins. The products, "thioproteins", are probably analogous to those obtained with amino-acids [63,79,80].

Sometimes thioamides do not react with ammonia and primary amines. For example, the ester group in ethyl monothio-oxamate $N_2N.CS.COOC_2H_5$ is probably converted into a carbamoyl group, while the thiocarbamoyl group plays no part in the reaction [81]. Alcoholic solutions of ammonia or the primary amine have been used. Treatment of ethyl thio-oxamate or ethyl thio-oxanilate $C_6H_5.NH.CS.COOC_2H_5$ with aniline at 140°C gives monothio-oxanilide $C_6H_5.NH.CS.CO.NH.C_6H_5$. [82,83]

Diamines (ethylene-, tetramethylene, hexamethylene-) react with monothioamides in ethereal solution to form *NN'*-dithioacyl derivatives [63]:

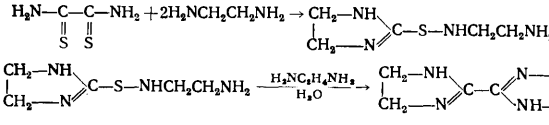


When *n* = 6 *NN'*-diacetimidoylhexamethylenediamine thiosulphate



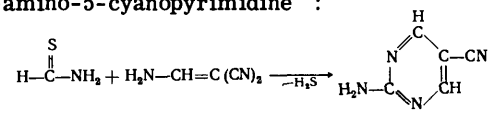
was formed at the same time [63].

In the absence of a solvent the reaction between dithio-oxamide and ethylenediamine hydrate involves transamidation and replacement of sulphur by an imido-group to give 2,2'-bi-imidazolinyl [84]. In hot alcoholic solution (molar ratio of dithio-oxamide to diamine = 1 : 2) 2-2'-aminoethylaminothio-Δ^2-imidazoline was isolated as an intermediate product. [85] On being heated with ethylenediamine hydrate this compound is converted into 2,2'-bi-imidazolinyl:

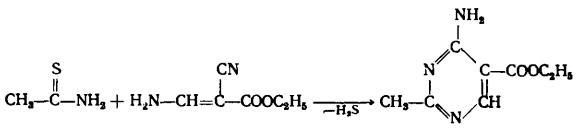


Ethylenediamine hydrate reacts with dithioadipamide, both in the absence of solvent and in alcohol, also with the formation of a cyclic product—tetramethylene-2,2′-bis-imidazoline

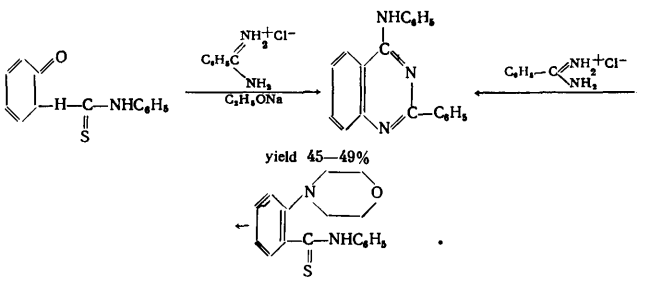
The reactions between thioamides and amines are widely used for synthesising pyrimidine and purine derivatives. Thioformamide reacts with aminomethylene-malononitrile on boiling with alcoholic sodium ethoxide to form 2-amino-5-cyanopyrimidine [86]:



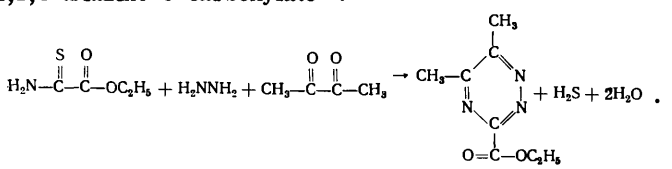
Under similar conditions thioacetamide reacts with ethyl β-amino-α-cyanoacrylate $H_2N.CH:C(CN).COOC_2H_5$ to give ethyl 4-amino-2-methylpyrimidine-5-carboxylate [87]:



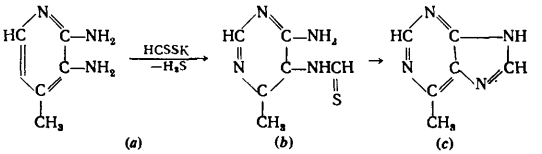
Pyrimidine derivatives are obtained also by the reaction of β-carbonylthioamides with benzamidine in the presence of sodium ethoxide [54]:



The action of ethyl monothio-oxamate on hydrazine and butane-2,3-dione gives a good yield of ethyl 5,6-dimethyl-1,2,4-triazine-3-carboxylate [88]:

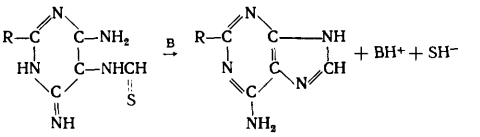


The reaction of 4,5-diamino-6-methylpyrimidine (*a*) with a salt of dithioformic acid gives 4-amino-6-methyl-5-thioformamidopyrimidine (*b*), which cyclises into a purine derivative (*c*) by interaction of the amino- and thioamido-groups:



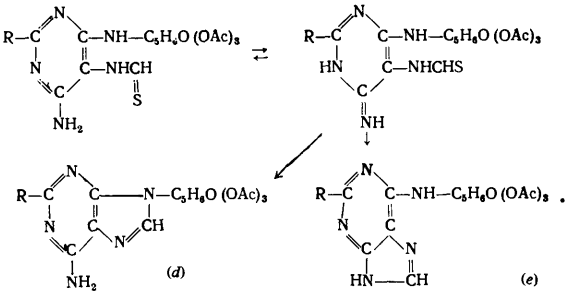
The reaction is conducted in hot pyridine or quinoline solution or in a solution of sodium ethoxide in anhydrous alcohol. In aqueous solution the yield is often diminished by hydrolysis of the thioformamide. The best media for this reaction are alcoholic solutions of sodium ethoxide, although the reaction is then slower than in excess of pyridine or quinoline, but the yields are considerably higher. The molar ratio of the pyrimidine derivative to the alkoxide is 1 : 1. [89]

Pyrimidine derivatives containing a 2-methylthio-group (e.g. 4,6-diamino-2-methylthio-5-thioformamido-pyrimidine) are the easiest to cyclise [89]. It is assumed that ring closure is effected by the action of the base on a tautomeric form of the pyrimidine [83,89]:

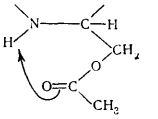


where R = H, CH_3, CH_3S.

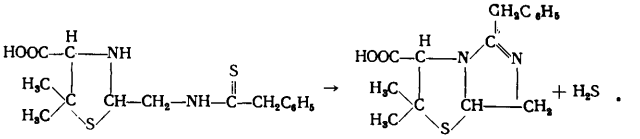
The cyclisation of 4-amino-6-glucosidoamino-5-thio-formamidopyrimidine, its triacetyl derivative, and many other compounds has also been accomplished [89]:



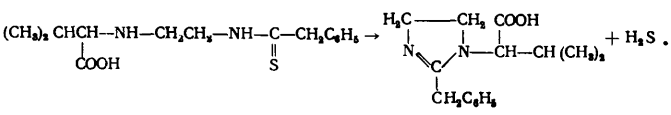
Cyclisation in alcoholic sodium ethoxide yielded in all cases only the 9-glucosidoaminopurines (*d*): the isomeric 6-glucosidoaminopurines (*e*) were not formed. Since the 6-triacetylglucosidoaminopyrimidine is easily deacetylated, it is cyclised in pyridine or in a solution of potassium acetate and acetic acid in anhydrous acetonitrile. In these cases not only the 9-triacetylglucosidoaminopurine but also a considerable yield of the 6-triacetylglucosido-aminopurine (*e*) are formed [90]. Cyclisation is assumed to involve formation of an intermediate product by hydrogen bonding between the 2′-acetyl group of the sugar residue and the hydrogen of the glucosidic NH group. Such ring closure induces a negative charge on the glucosidic nitrogen and thereby enhances the reactivity of the 6-amino-group:



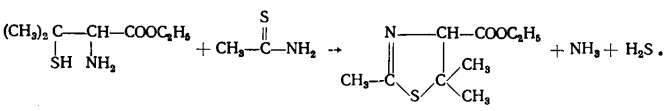
Heterocyclic systems other than purine derivatives have been obtained in a similar manner. Thus boiling 5,5-dimethyl-2-phenylthioacetamidomethylthiazolidine-4-carboxylic acid in quinoline yields benzylpenillamine [91,92]:



The ethyl ester of this acid could not be made to react [93]. The next example of the preparation of heterocycles is the synthesis of imidazoline derivatives [94]:



The ethyl ester of penicillamine with thioacetamide forms ethyl 2,5,5-trimethyl-Δ^2-thiazoline-4-carboxylate [95]:

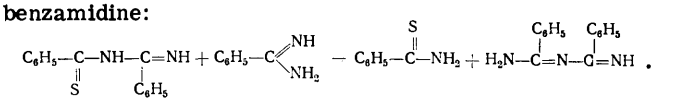


Investigation of the reactions of *N*-benzimidoylthiobenzamide $C_6H_5.CS.N:C(NH_2).C_6H_5$ with ammonia, amines, and amidines [81] indicated that this thioamide is stable in an alcoholic solution of aniline for several days. On addition of mercuric oxide, however, *N'*-*N''*-phenylbenzimidoylbenzamidine $C_6H_5.N:C(C_6H_5).N:C(C_6H_5).NH_2$ was formed rapidly [96]. In alcoholic ammonia and in the absence of a desulphurising agent, *N*-benzimidoylthiobenzamide is rapidly split into benzamidine, thiobenzamide, triphenyltriazine, 3,5-diphenyl-1,2,4-thiadiazole, and nitrogen- and sulphur-containing compounds of basic character, whose structure has not been established [96]. The disubstituted 1,2,4-thiadiazole is probably formed by oxidation of thiobenzamide [97] and *N*-benzimidoylthiobenzamide [98].

The reaction between *N*-benzimidoylthiobenzamide and benzylamine at room temperature gave thiobenzamide (58.5%), *N*-benzylbenzamidine (78%, as the picrate), *N*-benzylthiobenzamide (3.5%), and benzamidine (1.2%, as the picrate). *N*-Benzylbenzamidine and *N*-benzylthiobenzamide were probably formed by secondary reactions of benzylamine with benzamidine and thiobenzamide respectively.

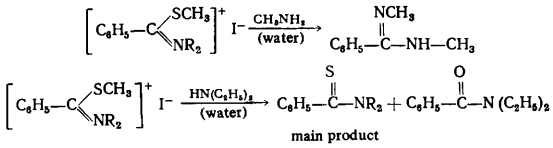
It is assumed that *N*-benzimidoylthiobenzamide

is cleaved both by ammonia and by benzylamine mainly at bond *2*. This occurs also with benzamidine, when the main products are thiobenzamide and *N'*-benzimidoylbenzamidine:

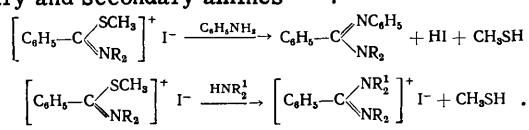


In contrast to benzamidine, substituted amidines—*N*-phenylbenzamidine and *N*-benzylbenzamidine—do not react with *N*-benzimidoylthiobenzamide at room temperature. In boiling benzene, however, *N*-phenylbenzamidine forms small amounts of triphenyltriazine and *N*-phenyl-*N'*-*N''*-phenylbenzimidoylbenzamidine $C_6H_5.N:C(C_6H_5).N:C(C_6H_5).NH.C_6H_5$. The latter product results either from disproportionation of the triphenyldiamine or from a secondary reaction with benzamidine.

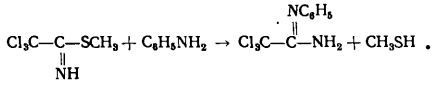
S- and *N*-Substituted thioamides and their salts react with primary, secondary, and tertiary amines in aqueous solution as follows [60]:



In non-aqueous media these salts react differently with primary and secondary amines [40,48]:



The action of alkylthioamides on aniline is a general method for obtaining *N*-phenylamidines [46,99,100]:



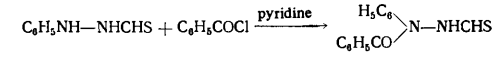
The thermal stability of alkyl thioimidate hydrochlorides increases as the alkyl group becomes larger.

IV. REACTIONS OF THIOAMIDES WITH ACID CHLORIDES

The reactions of thioamides with chlorides of carboxylic acids, imidoyl chlorides, sulphur monochloride and dichloride, thionyl chloride, sulphuryl chloride, and benzenesulphonyl chloride have been studied. With chlorides of carboxylic acids the main reaction is acylation of the thioamides, *N*-substituted thioamides are formed with imidoyl chlorides, and with the other reagents *N*-imidoylthioamides and their oxidation products are formed.

Thioacetamide reacts with acetyl chloride to give an extremely unstable crystalline product [101].

A few cases of benzoylation have been reported. The action of benzoyl chloride on a warm solution of thiocamphorimide, ethyl iodide, and magnesium produces benzoylation of the imido-group of thiocamphorimide [102]. The acylation of 2-phenyl-1-thioformylhydrazide by benzoyl chloride in pyridine leads to the formation of 2-benzoyl-2-phenyl-1-thioformylhydrazide:



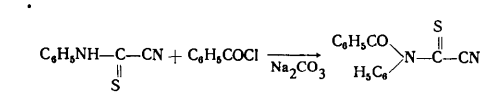
the product being soluble in alkalis. If two equivalents of benzoyl chloride are used, the product is insoluble in alkalis. A similar reaction occurs with acetyl chloride.

Benzoyl chloride reacts also with *S*-benzyl thiobenzohydroximate in pyridine [41]:

Salts of *N*-benzylthioacetamide and *N*-benzylthiobenzamide are easily acylated by acetyl and benzoyl chlorides [103]:

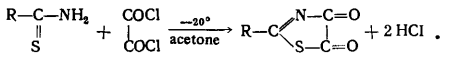
where $R^1 = CH_3$, C_6H_5.

The benzoylation of thio-oxanilonitrile in aqueous sodium carbonate solution yields benzoylthio-oxanilonitrile [104]:



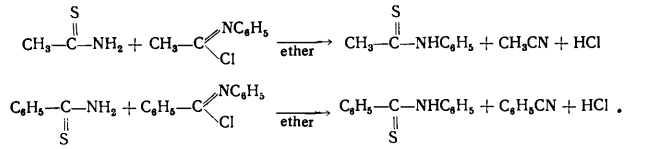
but in caustic soda solution the amide $C_6H_5.CO.N(C_6H_5).CS.CO.NH_2$ is obtained.

The action of thioamides on oxalyl chloride (either in the absence of a base or in the presence of e.g. pyridine) produces derivatives of thiazoline-4,5-dione [105]:

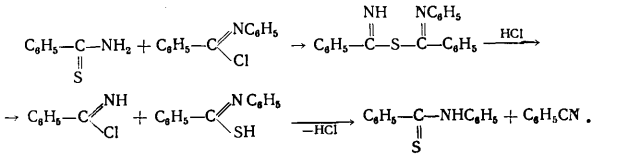


With cyclohexylthioamide in the absence of a base the acid-catalysed elimination of cyclohexene takes place [105].

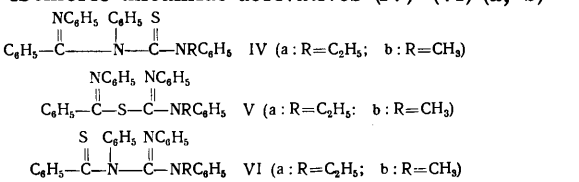
Unsubstituted thiobenzamide and thioacetamide react with *N*-phenylimidoyl chlorides in ethereal solution to form thioanilides [106]:



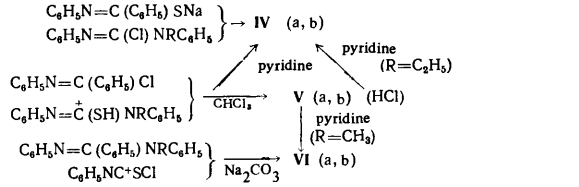
This reaction, like that of nitriles with thioamides, involves the intermediate formation of a product which is cleaved by hydrogen chloride into thiobenzanilide and benzonitrile:



Three isomeric thioamide derivatives (IV)–(VI) (a, b)

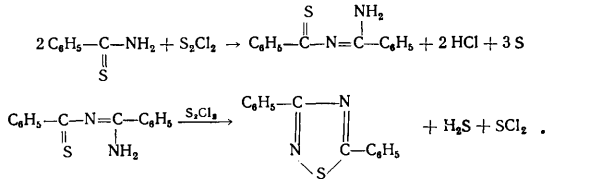


have been obtained by the reaction of thioamides with an imidoyl chloride [107] (scheme cited in Ref. 18):



Reaction of the sodium salt of thiobenzanilide with the imidoyl chloride $C_6H_5.N:CCl.NR.C_6H_5$ ($R = C_2H_5$, CH_3) did not yield the expected product (V), but (IV) was formed. Treatment of the hydrochlorides of (Va) and (Vb) with pyridine results in (IVa) and (VIb) respectively, the main product being the free base (V) in both cases. When (VIa) is heated it is converted into (IVa), and (IVb) into (VIb). In these cases also (V) is an intermediate product.

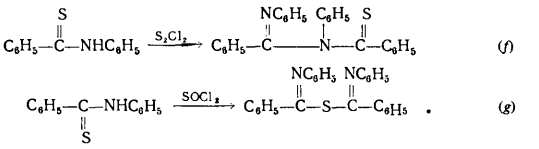
On the slow addition of sulphur monochloride to a solution of thiobenzamide in ether in the cold [104,108] *N*-benzimidoylthiobenzamide and 3,5-diphenyl-1,2,4-thiadiazole are formed, the latter being an oxidation product of the former [109]:



N-Benzimidoylthiobenzamide separates also when the reaction is conducted in alcoholic potassium carbonate solution. The same products are obtained by the interaction of thiobenzamide and thionyl chloride in ether in the cold, when sulphur, sulphur dioxide, and hydrogen chloride are also liberated [39]. Thiobenzamide and other thioamides react similarly with sulphuryl and benzenesulphonyl chlorides: in the latter case the main products are 3,5-diphenyl-1,2,4-thiadiazole and sulphur [39], and in the former case *N*-benzimidoylthiobenzamide.

On reaction of thioacetamide with thionyl chloride, thioacetamide, sulphur, sulphur dioxide, and hydrogen chloride separate. The same result is obtained by the action of thionyl chloride on thioacetanilide.

Sulphur monochloride and thionyl chloride give different products with the same thioamide. With thiobenzanilide the former yields *N*-*N'*-phenylbenzimidoylthiobenzanilide (*f*) and the latter the isomeric product di-*N*-phenylbenzimidoyl sulphide (*g*):[39]



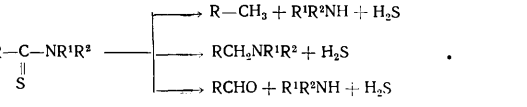
However, the structures of products (*f*) and (*g*) have not been proved. In both cases sulphur, aniline hydrochloride, and benzanilide were isolated§.

Thiobenzanilide forms with benzenesulphonyl chloride a small quantity of *N*-*N'*-phenylbenzimidoylthiobenzanilide, the yield of which is increased by using the sodium salt of thiobenzanilide. Another product of the reaction is benzenethiosulphonic acid $C_6H_5.SO_2SH$. [39]

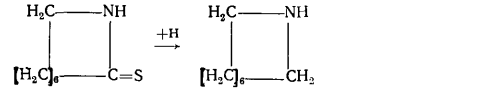
Substituted thioformamides $HCS.NR_2$ react with sulphur monochloride, sulphur dichloride, and thionyl chloride in the presence of pyridine in dichloromethane to form the chlorothioformamides $ClCS.NR_2$ (i.e. they are chlorinated. [111]

V. REDUCTION OF THIOAMIDES

Thioamides are reduced in the presence of Raney nickel in neutral solvents, by the action of metals in acid medium and of metal amalgams, and electrolytically [112,113]. Depending on the method of reduction the products are hydrocarbons, amines, aldehydes, and other substances:



The methods of reduction differ substantially in their effectiveness. For example, the lactam of the thioamide of ω-amino-octanoic acid (perhydroazonine-2-thione) is not reduced by magnesium amalgam in moist ether, by aluminium amalgam in aqueous alcohol, or by zinc dust in acetic acid [38], whereas sodium in glacial acetic acid yields a small quantity of perhydroazonine, and electrolytic reduction in 55% sulphuric acid with a lead cathode at 30°C gives an 85% yield of perhydroazonine [38]:



We shall examine below all the above methods for reducing thioamides.

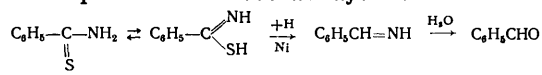
---

§Benzanilide is probably formed by decomposition of the sulphide $C_6H_5.N:C(C_6H_5).S.C(C_6H_5):N.C_6H_5$ (or its isomer). If this sulphide is treated initially with hydrogen chloride in absolute ether, and then with dilute sodium hydroxide solution, it is split into benzanilide and thiobenzanilide [110].

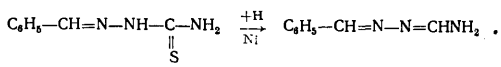
1. Reduction of Thioamides in the Presence of Raney Nickel [114]

The course of the reduction of thioamides may vary with the nature of the Raney nickel. In the presence of Raney nickel which has been partly deactivated in boiling acetone the thioamide is reduced to the aldehyde in good yield [115]:

Thus the corresponding aldehydes were obtained when thiobenzamide and thio-*p*-toluamide were reduced in ethanol at room temperature for several days [116]:

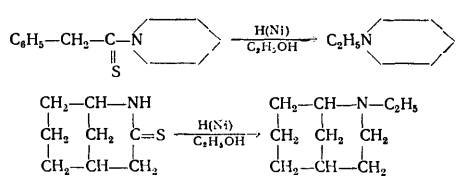


Desulphurisation of the thioamide and formation of a carbon–nitrogen bond are observed also in other cases. Thiourea and its derivatives are reduced to formamidines [117,118]. Thiosemicarbazones are reduced similarly [119]:

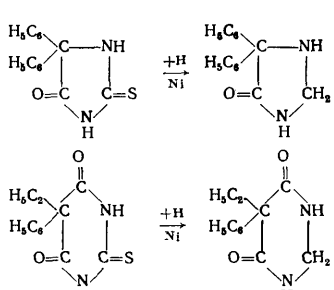


Reduction on Raney nickel prepared in the usual way converts thiocarbonyl into methylene groups [120].

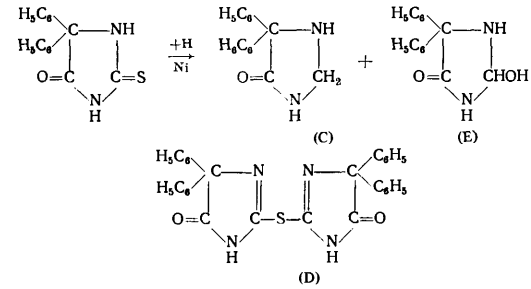
The solvent has a substantial influence on the reduction. With *N*-phenylthioacetylmorpholine in 8% alcohol ethylmorpholine and ethylbenzene are formed in quantitative yield as a result of *N*-ethylation, but in dioxan phenethylmorpholine is obtained [120]. *N*-Ethylation occurs on reduction in ethanol in other cases. For example, the thiopiperidide of phenylacetic acid gives a 44% yield of *N*-ethylpiperidine [120,121], and the thiolactam of 3′-aminocyclohexylacetic acid a 76% yield of 2-ethyl-2-azabicyclo-[3,3,1]nonane [122]:



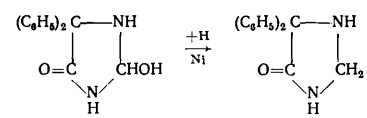
The reduction of heterocyclic thioamides has been studied in detail on thiohydantoins and thiobarbituric acids. The reduction of these compounds in ethanolic solution (boiling for 2–5 h) leads to replacement of sulphur by hydrogen and formation of the normal reduction products. Examples are the reduction of 5,5-diphenyl-2-thiohydantoin [123,124], and of 5-ethyl-5-phenyl-2-thiobarbituric acid [125–128]:



When the thiohydantoin is reduced under milder conditions (ratio of thiohydantoin to Raney nickel 1 : 5 by weight, boiled for 30 min), approximately equal quantities of 4-oxo-5,5-diphenylimidazolidine (C) and bis-5-oxo-4,4-diphenyl-Δ^2-imidazolin-2-yl sulphide (D) are formed together with a small quantity of 2-hydroxy-4-oxo-5,5-diphenylimidazolidine (E):[129]

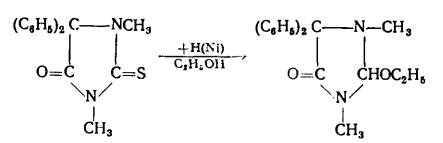


Further reduction in the presence of Raney nickel in boiling ethanol for 2 h converts (E) into a good yield of the imidazolidone [129]:



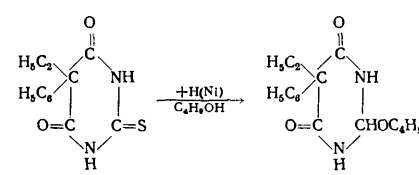
2-Hydroxy-derivatives analogous to (E) are formed also by the reduction of other thiohydantoin derivatives [123].

Tetra-substituted thiohydantoins on reduction in ethanolic solution are ethoxylated (cf. *N*-alkylation) with the formation of 2-ethoxy-derivatives [129]:



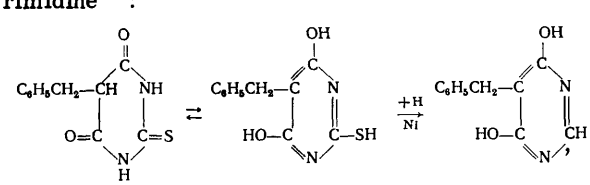
Replacement of ethanol by methanol, propan-1-ol, and cyclohexanol yields the corresponding 4-oxoimidazolidines [129].

The reduction of derivatives of thiobarbituric acid yields initially the 2-alkoxy-derivatives [129]:



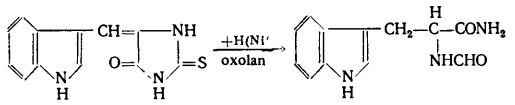
On further treatment with hydrogen both alkoxy- and hydroxy-derivatives are converted with quantitative yields into the normal reduction products [129].

5-Mono-substituted 2-thiobarbituric acids react on reduction in the tautomeric pyrimidine-2-thiol form, since the product of the reaction is always a 4,6-dihydroxypyrimidine [129]:

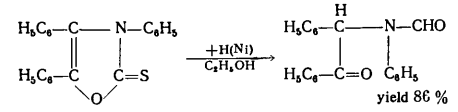


When 5-alkylidene- and 5-benzylidene-2-thiohydantoins are reduced in moist oxolan solution, the thiohydantoin

ring undergoes fission with the formation of amides of α-formylamino-acids:



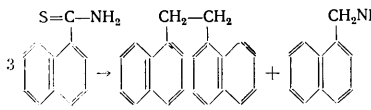
This reaction is used for the preparation of α-amino-acids [124]. 3,4,5-Triphenyl-Δ^3-oxazoline-2-thione in ethanol undergoes analogous reduction [130]:



Other examples of reduction with Raney nickel will be found in Refs. 131–142.

2. Reduction of Thioamides by Metals in Acid Medium and by Metal Hydrides

The reduction of thioamides by this method often yields hydrocarbons, amines [143], and aldehydes. 1,2-Di-1'-naphthylethane and 1-naphthylmethylamine have been obtained on reduction of the thioamide of 1-naphthoic acid:



Thiobenzamide on reduction gives stilbene, benzylamine, and 1,2-diphenylethane. The action of zinc and hydrochloric acid on *N*-benzimidoylthiobenzamide $C_6H_5.CS.NH.C(:NH).C_6H_5$ gives only *N*-benzylbenzamidine $C_6H_5.CH_2.NH.C(C_6H_5):NH$, [144] and *m*-ethoxythiobenzamide gives *m*-ethoxybenzylamine [145]. When iron powder is heated with thiobenzamide in 50% acid for 4 days a 60% yield of benzaldehyde is obtained [146]¶. Tin in hydrochloric acid converts *N*-benzyl-*p*-nitrothiobenzamide into *N*-benzyl-*p*-aminothiobenzamide (yield 95%): the thiocarbamoyl group is not reduced [148].

Reduction of thiobenzamide with lithium hydride in ether at −60°C for 15 min gave benzonitrile (30%) and benzylamine (8%); [114] and from 2-thiohomophthalimide and 5-methyl-2-thiohomophthalimide have been obtained 1,2,3,4-tetrahydroisoquinoline (40%, as the picrate) and 1,2,3,4-tetrahydro-6-methylisoquinoline (40%, as the picrate) respectively [37].

3. Electrolytic Reduction of Thioamides

Solutions in hydrochloric and sulphuric acids are used for the electrolytic reduction of thioamides. With relatively dilute acids amines are usually formed, but in concentrated acids (80% sulphuric acid) predominant formation of aldehydes occurs.

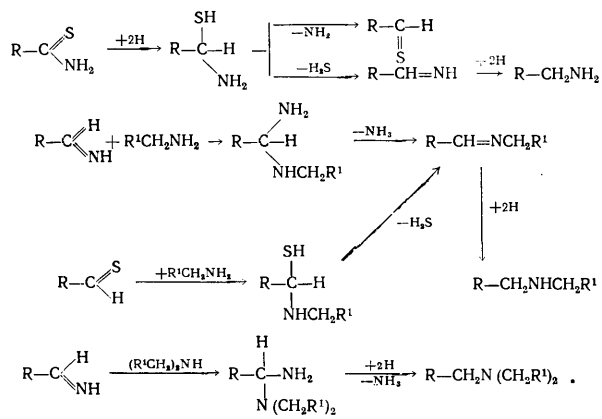
Phenylthioacetamide is reduced in solution in alcohol and hydrochloric acid to phenethylamine; *NN*-dimethylthiobenzamide in 60% sulphuric acid gives the corresponding tertiary amine in 75–100% yield; and *N*-alkylthioamides are reduced to secondary amines [146]. When, however, *NN*-dimethylthiobenzamide was reduced in 80% sulphuric acid, benzaldehyde (40%) was obtained together with small quantities of dimethylamine and benzyldimethylamine [112,113,149].

¶Thiobenzamide is converted into benzaldehyde also by the action of zinc and caustic potash (yield 42%). [147]

4. Reduction of Thioamides with Metal Amalgams

Aluminium and sodium amalgams are used for the reduction of thioamides, with ether and ethanol as solvents. The amalgams are added to the reaction mixture slowly and in slight excess. The reduction products are primary and secondary amines [146], their relative proportions depending on the thioamide. The reduction of thiobenzamide with an amalgam in moist ether yields benzylamine (85%) and dibenzylamine (8%); but when phenylthioacetamide was reduced under these conditions the products were phenethylamine and diphenethylamine in yields of 26% and 66% respectively [149].

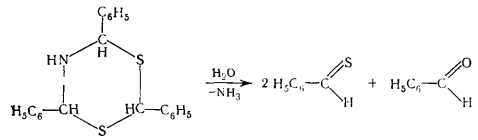
Different products are formed if reduction takes place in the presence of an amine [146]. In the presence of ethylamine, for example, phenylthioacetamide yields a mixture of phenethylamine, diphenethylamine, and *N*-ethylphenethylamine. The thioamide is probably reduced initially to an α-amino-thiol, from which hydrogen sulphide splits off to form an aldimine. The latter is either reduced further to a primary amine or added to a primary or a secondary amine to form a secondary or a tertiary amine respectively. Formation of the various products can be represented by the schemes



The formation of secondary amines can be explained by transamidation of the thioamide and reduction of the *N*-substituted thioamide:

Sodium amalgam has been used to reduce phenylthioacetamide and thiobenzamide in alcoholic solution [26,150]. Phenylthioacetamide gave a small quantity of 2-phenethylamine, but the main product was a solid, probably 2,4,6-tribenzyl-5,6-dihydro-1,3,5-dithiazine. The principal reduction product of thiobenzamide was thiobenzaldehyde; small quantities of benzylamine, benzonitrile, and benzaldehyde were also isolated. In this case it is assumed that 5,6-dihydro-2,4,6-triphenyl-1,3,5-dithiazine is an intermediate reduction product, hydrolysis of which

yields benzaldehyde and thiobenzaldehyde [150]:



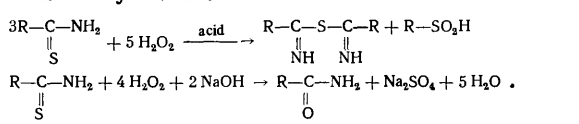
N-Substituted thioamides are reduced by sodium amalgam initially to the corresponding amines, after which other products are formed as a result of secondary reactions, as has been shown above [146].

VI. OXIDATION OF THIOAMIDES

The great variety of oxidising agents—hydrogen peroxide, acid hydroperoxides, nitrous, nitric, and sulphuric acids, halogens, hexacyanoferrates(III), potassium permanganate, ozone, metal oxides, alkene oxides, and other oxidants—have been used for oxidising thioamides.

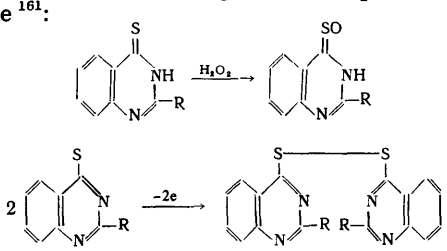
1. Oxidation of Thioamides by Hydrogen Peroxide and Hydroperoxides of Acids

The reaction between thioamides and hydrogen peroxide is conducted under acid, neutral, or alkaline conditions. In acid and neutral media disulphides, sulphinic acids, and other products depending on structure of the thioamides, but in alkaline medium the corresponding oxo-compound is always formed [37,151-155]:



For example, thiobenzamide is oxidised by hydrogen peroxide in aqueous alkali to benzamide [151]; disulphides are not formed by this method of oxidation [153]. The oxidation of thioamides in alkaline medium takes place at low temperatures, its rate depending on the concentration of hydroxide ions. The reaction is used for the quantitative determination of sulphur in thioamides [151,156,157]. The oxidation of thioamides has been studied in detail [12,97,151-160].

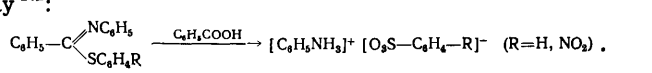
Dihydroquinazoline-4-thione on oxidation with hydrogen peroxide in neutral medium gives the sulphoxide and the disulphide [161]:



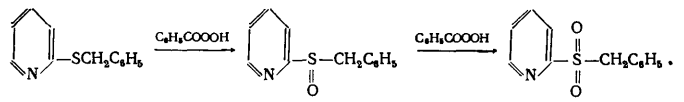
The oxidation of unsubstituted and mono- and di-*N*-substituted thioamides by hydrogen peroxide in neutral and weakly alkaline media (water, methanol to which pyridine has been added, or pyridine itself) often gives rise to *S*-oxides of thioamides [155,162-171] which are more stable than the thioamides themselves [162].

When isothioamides are oxidised with perbenzoic acid in chloroform, anilides are obtained [172]:

Sometimes anilinium sulphonates are obtained in this way [172]:

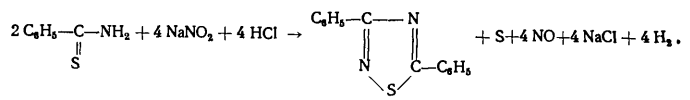


Sulphoxides [and sulphones] are other possible products [172]:



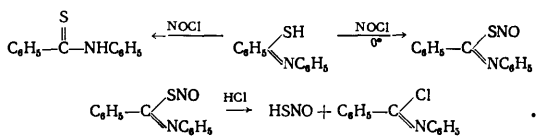
2. Oxidation of Thioamides by Nitrogen Compounds

Various compounds of nitrogen (nitric and nitrous acids, nitrosyl chloride, nitrogen dioxide, pentyl nitrite, etc.) are used, the nature of the products depending on the oxidant and the thioamide. If a solution of sodium nitrite is added to a solution of thiobenzamide in a mixture of ethanol and hydrochloric acid, the thiobenzamide is oxidised to 3,5-diphenyl-1,2,4-thiadiazole [45]:

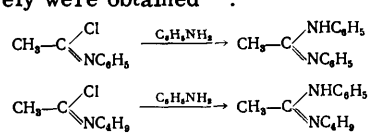


The same product is formed (in 75% yield) by the oxidation of thiobenzamide with nitric acid in acidic aqueous and non-aqueous media [173].

The oxidation of thiobenzanilide by nitrosyl chloride in ethereal solution in an atmosphere of nitrogen in the cold gives *N*-phenylbenzimidoyl chloride (yield 44%) and benzanilide [174]. It is assumed that an *S*-nitroso-derivative is formed as an intermediate:



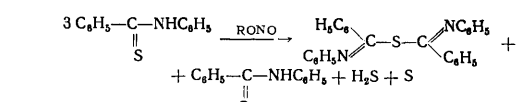
When thioacetanilide and *N*-butylthioacetamide were subjected to the same treatment with nitrosyl chloride, the imidoyl chlorides could not be isolated owing to their instability. However, their formation was proved by the action of excess of aniline on the reaction mixture, when *NN'*-diphenylacetamidine and *N'*-butyl-*N*-phenylacetamidine respectively were obtained [174]:



In pyridine oxidation of thiobenzanilide by nitrosyl chloride takes a different course: the oxidation products are di-*N*-phenylbenzimidoyl sulphide $C_6H_5.C(:N.C_6H_5).S.C(:N.C_6H_5).C_6H_5$ and an oily product; the latter decomposes slowly into sulphur and a sulphide [174].

With nitric oxide in ether in the cold *N*-butylthioacetamide gives *N*-butyl-*N*-nitrosoacetamide [174].

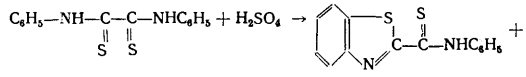
The reaction of thiobenzanilide with pentyl nitrite and ethyl nitrite at 0°C yielded after 2 days benzanilide and di-*N*-phenylbenzimidoyl sulphide [174]:



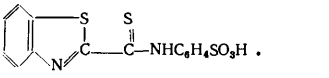
where $R = C_5H_{11}$, C_2H_5.

3. Oxidation of Thioamides by Sulphuric Acid

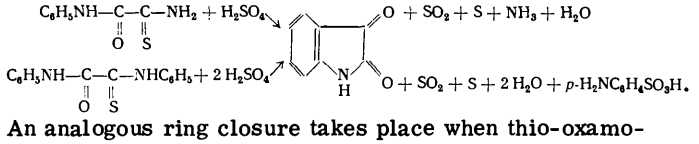
The oxidation of thioamides by sulphuric acid is used to obtain benzothiazole, isatin, and indole derivatives. The action of oleum or concentrated sulphuric acid on dithiooxanilide at room temperature gives a quantitative yield of benzothiazole-2-carbothioanilide [31]:



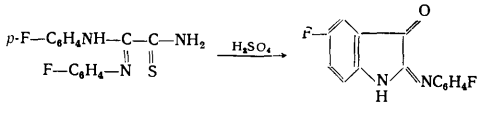
On being warmed with sulphuric acid this product is sulphonated to give



When oxanilothioamide or monothio-oxanilide is heated with 95% sulphuric acid until sulphur dioxide ceases to be evolved, isatin is obtained in 25% yield [31]:

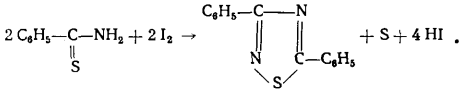


An analogous ring closure takes place when thio-oxamo-*NN'*-di-*p*-fluorophenylamidine is oxidised with sulphuric acid to give an indole derivative [175]:



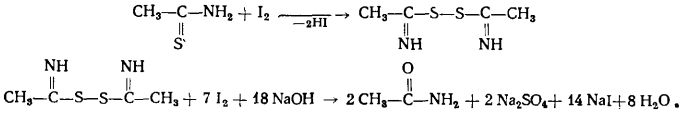
4. Oxidation of Thioamides by Halogens

On treatment with excess of iodine in alcoholic solution thiobenzamide undergoes condensation with elimination of a sulphur atom and formation of 3,5-diphenyl-1,2,4-thiadiazole [176]:



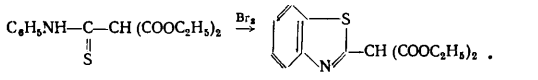
This product has previously been regarded as the isomeric 2,5-diphenyl-1,3,4-thiadiazole [26]. The reaction is probably common to thioamides in which the nitrogen atom is unsubstituted. According to the early results thiobenzamide is not oxidised by iodine [69,174].

In alkaline solution thioamides are oxidised by iodine to amides [157]. This reaction is used for the quantitative determination of thioamides. With thioacetamide the reaction can be expressed by the equations [157]

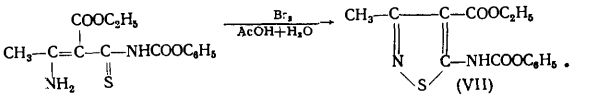


The intermediate disulphide has been isolated only when the thioamide is oxidised by iodine in a mineral acid. Bromine or a mixture of potassium bromide and bromite can be used instead of iodine in acid medium. Dithiooxamides are oxidised by iodine in acid medium better than is thioacetamide.

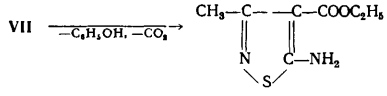
The oxidation of thioanilides by bromine in formic or acetic acid yields benzothiazoles [8,177,178]:



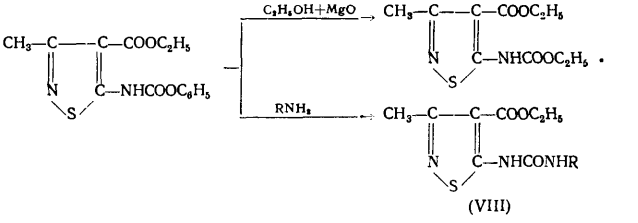
Phenyl 4-ethoxycarbonyl-3-methylisothiazol-5-ylcarbamate (VII) has been obtained in this way [179]:



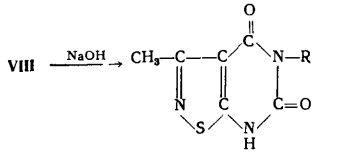
When (VII) is treated with a weak base, or when it is boiled in aqueous dimethylformamide for a long time, phenol and carbon dioxide are split off with formation of the amine:



Other nucleophilic reagents will remove only the phenoxy-group from (VII):



The latter compound can be cyclised on heating to form isothiazolo[5,4-*d*]pyrimidines:



where R = H, CH_3, C_6H_5, OH, NH_2.

Isothiazoles are products of the oxidation of thioamides by bromine in acetic acid and in other cases [8,180–183].

5. Oxidation of Thioamides by Hexacyanoferrates(III)

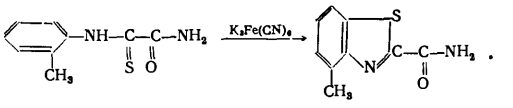
The oxidation of thioacetanilide and thiobenzanilide derivatives by means of potassium hexacyanoferrate(III) in alkaline aqueous solution involves cyclisation with the formation of benzothiazole derivatives (Jacobson's method) [184]. Thioacetanilide derivatives yield 2-methylbenzothiazole derivatives, ease of cyclisation being affected by the nature of the substituent (methoxyl, methyl, chloro, nitro), its position in the anilide ring, and the solubility of the thioacetanilide derivative in the alkaline solution [185–187]†. Thus the yield of 2-methylbenzothiazole

†*p*-Nitrothioacetanilides are unable to form 2-methyl-6-nitrobenzothiazole. This is explained by the existence of the isomeric structure

in which thiol–enolisation [sic], and hence also ring closure, are difficult. In this case oxidation results in the formation of a 50% yield of *p*-nitroacetanilide [186].

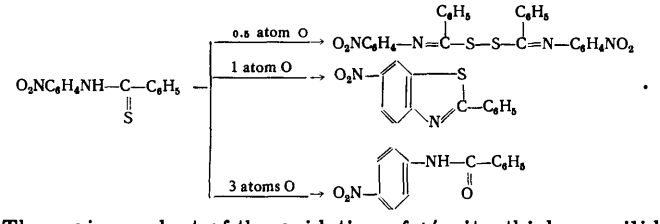
increases as the solubility of thioacetanilide increases with rise in the sodium hydroxide concentration to 2 *N*, after which it falls appreciably [186].

Various derivatives of thio-oxanilic acid are easily cyclised to benzothiazoles under the influence of potassium hexacyanoferrate(III):



If a large excess of the ferricyanide is taken, the reaction is complete in 10 min [82].

Sometimes cyclisation does not occur on the oxidation of thioanilides by potassium hexacyanoferrate(III) in alkaline solution, other products being formed [188]:

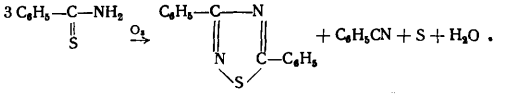


The main product of the oxidation of *p'*-nitrothiobenzanilide in cold alkaline solution was a derivative of dibenzimidoyl disulphide [189], and in hot alkali the main product was *p'*-nitrobenzanilide. In both cases the yield of 6-nitro-2-phenylbenzothiazole was small [186,189,190].

The action of potassium hexacyanoferrate(III) in alkaline solution sometimes converts a thioamide into a nitrile and an oxamide [82]. Thio-oxanilonitrile $C_6H_5.NH.CS.CN$ and thio-oxanilamide $C_6H_5.NH.CS.CO.NH_2$ have been obtained by treating *N*-phenyldithio-oxamide with a quantity of the oxidant corresponding to 1 atom of oxygen, when 75% of the thioamide is converted into the nitrile, and 25% into the oxamide. Although thio-oxanilamide can be obtained by heating thio-oxanilonitrile in alkaline solution, it is more probably directly from the phenyldithio-oxamide [82].

6. Other Methods for the Oxidation of Thioamides

Thioamides are oxidised by ozone in inert anhydrous solvents, e.g. benzene and carbon tetrachloride. Thiobenzamide is converted into *N*-benzimidoylthiobenzamide $C_6H_5.C(:NH).NH.CS.C_6H_5$, which is then cyclised to 3,5-diphenyl-1,2,4-thiadiazole [191]:

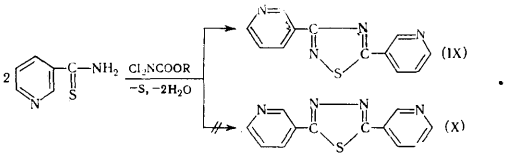


Other products of the reaction are benzonitrile and sulphur [192]. Thio-*p*-toluamide behaves similarly, but thioacetanilide is converted into acetanilide and resinous products. The corresponding amides and nitriles have been obtained also by the action of ozone on unsubstituted thiobenzamide in aqueous medium. The reaction between thioacetamide and ozone in benzene or water, on the other hand, yields acetic and sulphuric acids, ammonia, and sulphur.

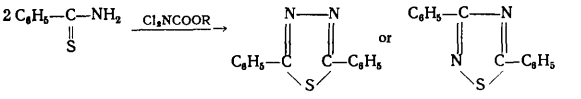
Dithiocamphorimide is oxidised by potassium permanganate to camphorimide [102].

The oxidation of thioamides by selenium dioxide (in alcoholic solution) yields the corresponding amides and selenium trisulphide [159,193-195]. The oxidation of *N*-benzylthiobenzamide gives the amide only when more than 2 moles of the thioamide are taken per mole of selenium dioxide. With equimolecular proportions of the reactants oxidation is accompanied by cleavage of the carbon–nitrogen bond [194]:

NN-Dichlorocarbamates Cl_2NCOOR resemble iodine in their oxidising action on thioamides [17,196,197]. Oxidation is usually conducted in an aqueous suspension of the reactants containing a slight excess of the dichlorocarbamate. Nicotinothioamide is oxidised to 3,5-dipyrid-3'-yl-1,2,4-thiadiazole (IX), not the isomeric 1,3,4-thiadiazole (X):[195]



In the case of thiobenzamide it has not been established whether the oxidation product is a 2,5-disubstituted 1,3,4-thiadiazole or a 3,5-disubstituted 1,2,4-thiadiazole [195]:



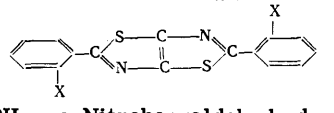
Thioamides can be oxidised also by alkene oxides and certain esters. Thus boiling a solution of thioacetamide in methanol with cyclohexene oxide for 5 h gave acetamide (85%) and a sulphur-containing residue [198]. When thiobenzamide was oxidised by the ethyl ester of phenylglycine $C_6H_5.NH.CH_2.COOC_2H_5$, the products were benzamide, ethyl cinnamate, and sulphur.

The oxidation of thioamides by sodium *o*-hydroxymercuribenzoate $HOHgC_6H_4COONa$ is used for the analytical determination of thioamides [199,200]. Certain *N*-monoarylthioamides are not determined by this method [200].

VII. REACTIONS OF THIOAMIDES WITH ALDEHYDES AND KETONES

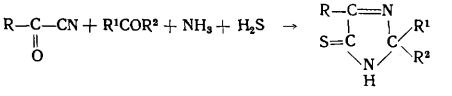
Phenylthioacetamide reacts with benzaldehyde to form an oily product:

which gives a solid salt with platinum(II) chloride [150]. The reaction of dithio-oxamide with benzaldehyde and salicylaldehyde [201] is accompanied by dehydrogenation and the formation of thiazolothiazole derivatives [202]:

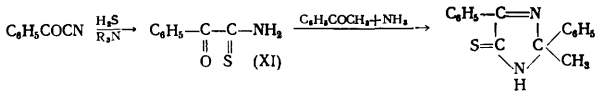


where X = H, OH. *o*-Nitrobenzaldehyde does not react [202].

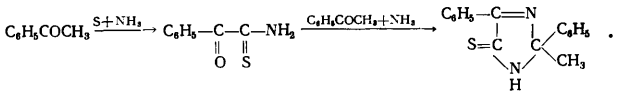
Nor could individual products be isolated from the reaction of thioamides with aliphatic aldehydes and aryl methyl ketones. Acyl cyanides (aromatic and aliphatic) react with ketones in the presence of hydrogen sulphide and ammonia to form substituted Δ^3-imidazoline-5-thiones [203,204]:



α-oxo-thioamides being formed from the acyl cyanide as intermediate products. The action of hydrogen sulphide on benzoyl cyanide in the presence of a tertiary amine in an aprotic solvent gives an excellent yield of the thioamide of phenylglyoxylic acid (XI), which on reaction with acetophenone and ammonia for a few minutes is converted quantitatively into 2-methyl-2,4-diphenyl-Δ^3-imidazoline-5-thione:



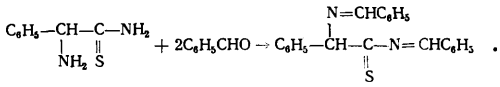
Imidazoline-5-thione derivatives are formed also by the action of elementary sulphur and ammonia on ketones [205]. Reaction between a thioamide and a ketone is assumed to underlie the synthesis of a Δ^3-imidazoline-5-thione by the action of excess of ammonia and sulphur on acetophenone [204,206]:



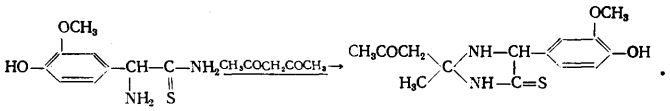
Other Δ^3-imidazoline-5-thiones have been obtained similarly.

When α-amino-thioamides are boiled in absolute alcohol with equimolecular quantities of aliphatic [207] or aromatic [208] aldehydes, ketones [209], and αγ-dioxo-compounds [210], 2,2-disubstituted imidazolidine-4-thiones are formed in good yield:

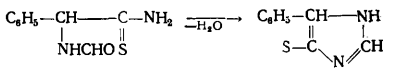
If two equivalents of the oxo-compound are used, heterocycles are not formed [207]:



It is probable that only one oxo-group is involved in the interaction of equimolecular quantities of a thioamide and pentane-2,4-dione, since imidazolidine-4-thiones—not methylenebis-2-imidazolidine-4-thiones—are formed [211]:

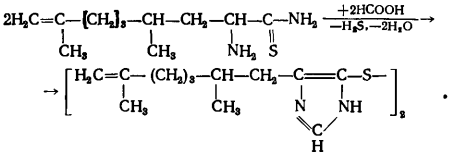


Imidazoline-4-thiones are obtained also by the cyclisation of α-amido-thioamides‡ when boiled in alcoholic solution in the presence of an acid or a base [212-214]:



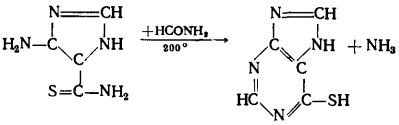
‡The intermediate α-amido-thioamides were obtained by treating α-amino-thioamides with formic acid in the absence of a solvent [207], or by the action of acetic anhydride (1–2 equivalent) or benzoyl chloride on the α-amino-thioamide [33,208]. In this way α-formamide, α-acetamide, or α-benzamide derivatives were obtained; the yields of the latter compounds were low.

When 2-amino-4,8-dimethylnon-8-enothioamide is heated with formic acid the resulting imidazolinethione is oxidised to the disulphide [213]:



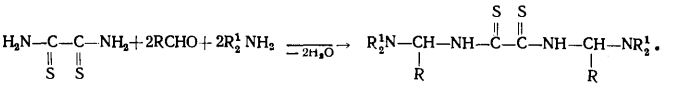
Disulphides are formed also by the oxidation of imidazolinethiones by hydrogen peroxide or iodine.

Cyclic amino-thioamides also react with aldehydes. Thus 4-amino-Δ^2-imidazoline-5-carbothiamide and formamide yield purine-6-thiol [215]:



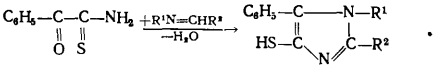
Phenanthraquinone also undergoes this reaction.

The reaction of dithio-oxamide (or an *NN'*-dialkyldithio-oxamide) with a solution of an aldehyde and a secondary amine in chloroform involves condensation of the three reactants [216]:



Benzaldehyde and several aliphatic aldehydes have been used together with dialkylamines, piperidine, and alkylarylamines in this reaction.

Phenylglyoxylthioamide reacts with aldimines (in benzene at 45°C for 2 h) to form 4-mercapto-5-phenylimidazoles [6]:



Primary amines do not undergo this reaction, since the addition product of a primary amine and an aldehyde immediately eliminates water, and the resulting Schiff base does not react with dithio-oxamide. Nor do dithio-oxanilides undergo this reaction; tetra-substituted dithio-oxamides form unstable compounds, which decompose into their components [216]. These products are oils in the case of the reaction of tetra-substituted dithio-oxamides with formamide and the lower dialkylamines, and crystalline solids in other cases.

VIII. REACTIONS OF THIOAMIDES WITH ALKYL HALIDES AND HALOGENATED AMINES, KETONES, and ACIDS

Alkyl and aralkyl halides act on the sodium salts of thioamides to form isothioamides, which are usually prepared in this way. Thus methylated *N*-phenylthioacetamide was first obtained by the action of methyl iodide on the sodium salt of thioacetanilide [217]:

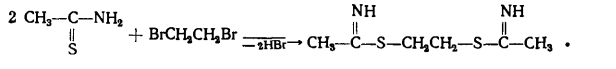
the solvent being ethanol. Heating *N*-benzylthioacetamide in methyl iodide gives a quantitative yield of the hydriodide of S-methyl *N*-benzylthioacetimidate [218]; on treatment with

caustic potash the free base $CH_3.C(:N.CH_2.C_6H_5).S.CH_3$ was isolated in 64% yield§.

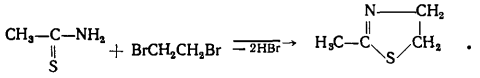
Unsubstituted thioamides also react with the lower alkyl halides to form salts of isothioamides [219]. Equimolecular quantities of the alkyl halide and the thioamide are usually taken, and the reaction is conducted in dry acetone. Propyl and butyl iodides hardly react even when boiled for 2 h.

The sodium and potassium salts of *N*-benzylthioamides react with alkyl halides in xylene solution to form products $C_6H_5.C(SR):N.CH_2.C_6H_5$ in 45–65% yields [159]. The action of alkyl halides on *NN'*-disubstituted thioamides gives salts to which the structure $[R.S.CR^2:NR_2^1]^+X^-$ is assigned [60].

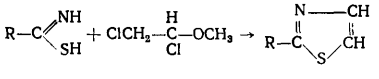
Reaction between dibromoethane and thioamides involves cyclisation with the formation of 2-thiazoles [184], and *N*-arylthioamides yield *N*-aryl-2-thiazole salts. Cyclisation is accompanied by bis-*S*-alkylation. Temperature has a substantial effect on the course of the reaction. Thus thioacetamide reacts with dibromoethane at 100°C to form ethylene diacetimidothioate [47]:



But at the boiling point of dibromoethane (131°C) 2-methyl-Δ^2-thiazoline is formed in low yield [220]:

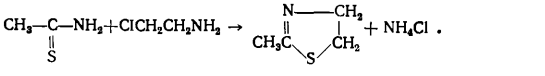


Thiazole and 2-methylthiazole have been obtained in good yield by treating thioformamide and thioacetamide respectively with an aqueous solution of 1,2-dichloroethyl methyl ether at 60°C:



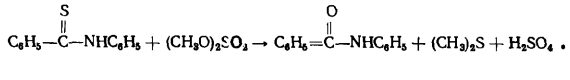
where R = H, CH_3.

Another general method for obtaining Δ^2-thiazolines is the reaction between thioamides and β-halogenated amines. When, for example, thioacetamide is boiled with 2-chloroethylamine for 2 h, at 32.3% yield of 2-methyl-Δ^2-thiazoline is obtained [222]:

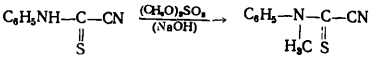


---

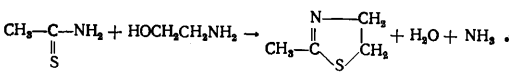
§ Dialkyl sulphates react differently with thioamides. In dry inert solvents dimethyl sulphate does not react with thioamides. In the presence of small quantities of water the process goes as follows [103]:



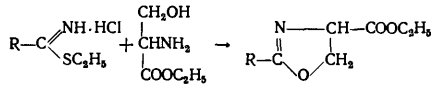
However, alkylation in aqueous alkali yields *N*-alkylated thioamides. For example, thio-oxanilonitrile reacts with dimethyl sulphate in 20% aqueous alkali to form the *N*-methylated product [104]:



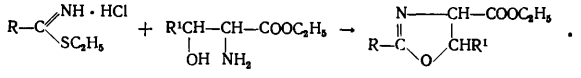
2-Aminoethanol reacts similarly:



Esters of β-hydroxy-α-amino-acids react with salts of isothioamides to form oxazolines. Thus ethyl 2-alkyl- and 2-aryl-oxazoline-4-carboxylates are easily obtained from the ethyl ester of serine:

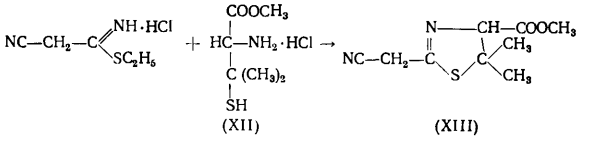


Application of this reaction to derivatives of serine gives 5-substituted oxazoline derivatives [223,224]:

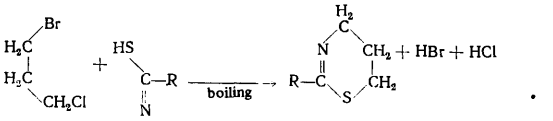


The yield of oxazolines improves substantially as the molecular weight of the ester group in the serine increases from methyl to propyl [223].

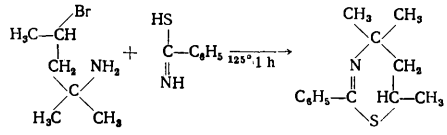
Esters of β-mercapto-α-amino-acids, in contrast to β-hydroxy-α-amino-carboxylic esters, react with thioamides [225,226] to form thiazoles. Thus the ester of penicillamine (XII) and the hydrochloride of ethyl cyanothioacetimidate react in dry chloroform to produce the 2-cyanomethyl-5,5-dimethylthiazoline-4-carboxylic ester (XIII):[227,228]



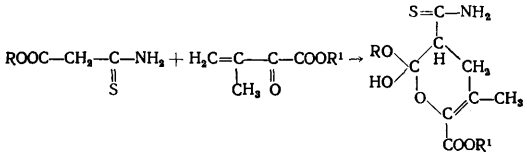
1-Bromo-3-chloropropane reacts with thioamides to form the 2-substituted 5,6-dihydro-1,3-thiazines:



The yields are often theoretical, but only 10% in the case of thioacetamide. 5,6-Dihydro-1,3-thiazines are obtained also by the reaction of thioamides with γ-halogeno-amines:



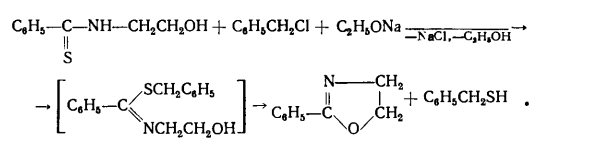
Another method of obtaining Δ^2-dihydrothiazines is the reaction between α-thiocarbamoylacetic esters and vinylglyoxylic esters:



where R = CH_3, $C_6H_5CH_2$, $(CH_3)_3C$. The reaction goes smoothly in neutral medium at room temperature [229].

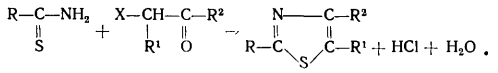
Reviews have been published [184,230,231] on the synthesis of thiazoles, Δ^2-thiazolines, and 5,6-dihydro-1,3(or 4)thiazines, which include this method. A modification of the method is the preparation of Δ^2-thiazolines by treating *N*-2-hydroxyalkyl-amides with phosphorus pentasulphide [184,232]. Thus *N*-2-hydroxyethylbenzamide gives a 68% yield of 2-phenyl-Δ^2-thiazoline [233-237]. Thioamides are assumed to be formed as intermediates [238].

When *N*-2-hydroxyethylbenzothioamide is boiled with sodium ethoxide and benzyl chloride in ethanol (these conditions are usual for the *S*-alkylation of thioamides), 2-phenyloxazoline [111] and phenylmethanethiol [59] are obtained:

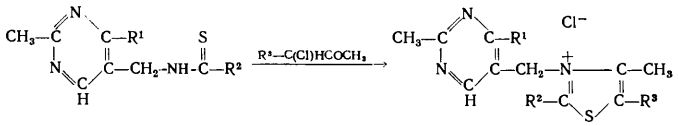


It is assumed that *S*-benzyl *N*-2-hydroxyethylthiobenzimidate is formed initially, and then undergoes cyclisation. Aminoethanol is able also to react differently with thioamides from the way mentioned above [70]. When an equimolecular mixture of this amine and thioacetamide is heated at 75°C, two molecules of each reactant undergo condensation with the evolution of two molecules of ammonia and one molecule of hydrogen sulphide, a sulphide being formed:

Thiazoles can be obtained also by the reaction of thioamides with α-halogeno-ketones and -aldehydes [9,184,239,240]:

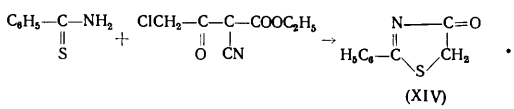


N-Substituted thioamides, e.g. 4-amino-5-thioformamidomethylpyrimidine [241], are converted into the corresponding *N*-substituted thiazoles [76,242-251]:



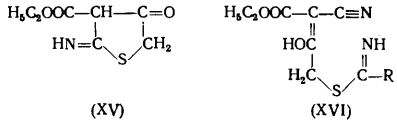
where $R^1 = NH_2$ and $R^2 = R^3 = H$.

When thiobenzamide is heated with γ-chloro-α-cyanoacetoacetic ester in aqueous ethanol for several days, 4-oxo-2-phenyl-Δ^2-thiazoline (XIV) is formed in 75% yield [252]:



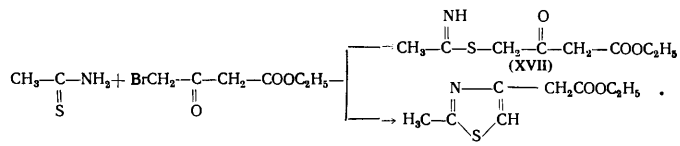
(XIV)

Under these conditions thioacetamide yielded two products



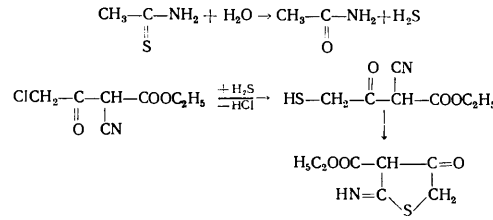
(XV) (XVI)

ethyl 2-imino-4-oxothiolan-3-carboxylate (XV) and a small quantity of a compound $C_7H_7NO_2S$, whose structure was not established. It is assumed that (XV) is formed by cyclisation of the intermediate product (XVI: R = C_6H_5). This hypothesis is based on the formation of ethyl 2-methylthiazol-4-ylacetate when thioacetamide is boiled with ethyl γ-bromoacetoacetate for 30 min and allowed to stand for a long time [253]:

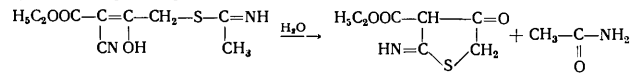


(XVII)

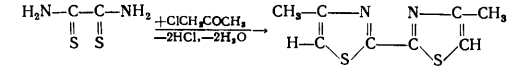
If the reaction is halted and rapid crystallisation is effected, ethyl γ-acetimidoylthioacetoacetate (XVII) is formed [253]. After isolation the latter does not give thiazole derivatives under various reaction conditions. If R = C_6H_5 in (XVI), the mobility of the imino-proton is increased, and favourable conditions are created for ring closure and the formation of (XIV). [252] If, however, R = CH_3, the nitrogen-hydrogen bond becomes more stable, and cyclisation does not occur. Since this hypothesis does not explain the formation of (XV), the reaction scheme



has been suggested. Another explanation of the formation of (XV) is hydrolysis of (XVI: R = CH_3).

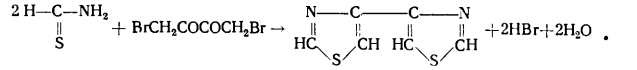


Dithio-oxamides react with α-halogeno-ketones to form bithiazolyls. Thus 4,4′-dimethyl-2,2′-bithiazolyl is readily formed from dithio-oxamide and chloroacetone in alcoholic solution [254]:

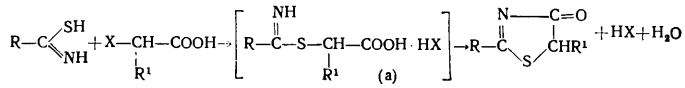


The action of dithio-oxamide on 1,4-dibromobutane-2,3-dione results in the rapid formation of brown polymeric products of high melting point (probably polythiazolines [254]), which are practically insoluble in almost all solvents. Polymeric products are obtained also by the reaction of 1,4-dibromobutane-2,3-dione with dithioterephthalamide and dithiomalonamide [255,256].

Thioformamide gives 4,4′-bithiazolyl when warmed with 1,4-dibromobutane-2,3-dione in alcohol [257]:

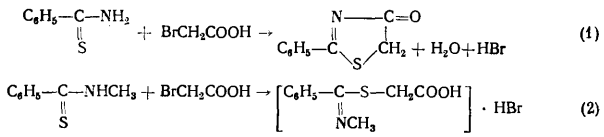


α-Halogeno-carboxylic acids react with thioamides to form 4-oxothiazolines [184,258]. 2-Alkylated and 2-arylated derivatives are obtained from aliphatic and aromatic thioamides [196]:

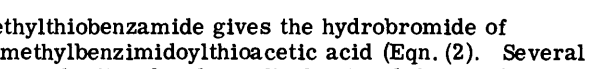


where R = Alk or Ar. Equimolecular quantities of the reactants are usually boiled in water or in toluene. Reaction is slow. An isothioamide salt (a) is formed as the first stage [196]. In some cases (e.g. with α-bromoisobutyric acid) the intermediate isothioamides do not undergo cyclisation.

Thioamides in which the nitrogen atom is not substituted react with bromoacetic acid to form 4-oxothiazolines, whereas *N*-substituted thioamides yield acyclic "isothioamides":[77]

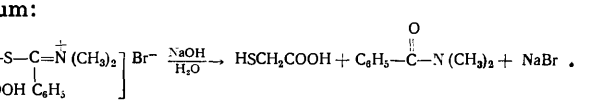


(1)

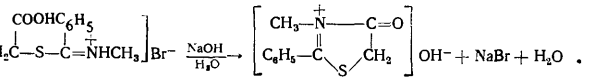


(2)

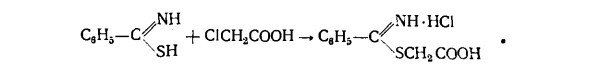
N-Methylthiobenzamide gives the hydrobromide of α-*N*-methylbenzimidoylthioacetic acid (Eqn. (2). Several other *N*-substituted and *NN*-disubstituted thioamides react similarly. *N*-α-Carboxymethylthiobenzylidene-*NN*-dimethylammonium bromide is hydrolysed in alkaline medium:



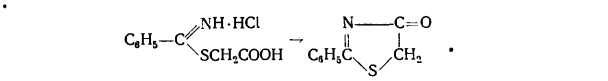
But if the imino-group is incompletely substituted, cyclisation occurs:



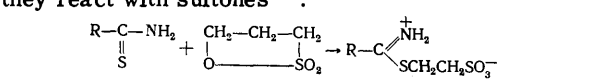
In acid media *N*-monosubstituted thiobenzimidates also give 4-oxothiazolines, whereas *NN*-disubstituted thiobenzimidates yield isothioamides. With chloroacetic acid thiobenzamide forms initially an alkylation product[197,259]:



When heated to 100°C or in the presence of a condensing agent, e.g. acetic anhydride, this gives a 4-oxothiazoline[258]:

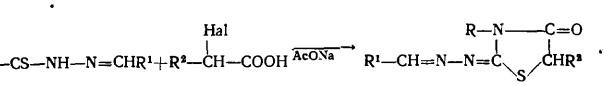


This reaction usually occurs more rapidly and under more moderate conditions with derivatives of aliphatic thioamides. *S*-Alkylation of thioamides is observed also when they react with sultones[259]:

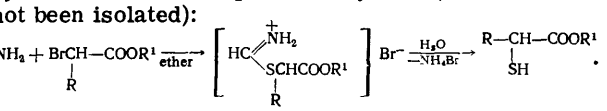


where R = CH_3, C_6H_5, *o*- and *p*-$CH_3C_6H_4$. The reaction is accomplished by boiling in benzene for 1 h. With aromatic thioamides the yield reached ~ 80%.

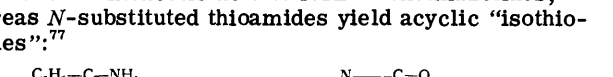
α-Halogenated carboxylic acids react also with thiosemicarbazones in the presence of fused sodium acetate. Cyclisation takes place with the formation of 5-alkyl(or aryl)-2-alkylidenehydrazono-3-aryl-4-oxothiazolidines[260-262]:



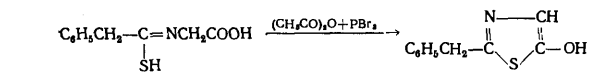
Thioformamide differs from other thioamides in its reaction with α-halogenated carboxylic acids[263]. Thus with α-halogeno-carboxylic esters 50–80% yields of α-mercapto-carboxylic esters are obtained. When the reaction is conducted in ether, salts of α-formimidoylthioalkanoic esters are formed initially, and are easily hydrolysed to the α-mercapto-carboxylates (thiazolones have not been isolated):



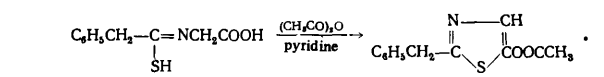
Diethyl dibromomalonate oxidises thioformamide under these conditions:



N-Carboxymethylthioamides R.CS.NH.CH_2.COOH, either as such or as intermediate products at the instant of isolation, are used to obtain thiazole and oxazole derivatives. For example, the action of acetic anhydride and phosphorus tribromide on *N*-α-mercaptophenethylideneaminoacetic acid yields 2-benzyl-5-hydroxythiazole[264]:

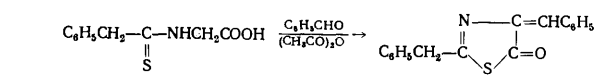


When acetic anhydride and pyridine are used, 2-benzylthiazol-5-yl acetate is formed:

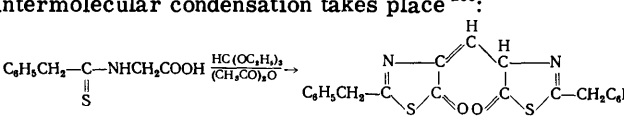


Similarly, 5-ethoxy-2-methylthiazole is obtained by heating the ethyl ester of *N*-acetylglycine with phosphorus pentasulphide[265].

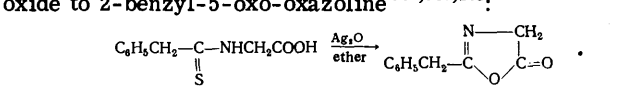
2-Benzyl-4-benzylidene-5-oxothiazoline is formed when thiophenaceturic acid [phenylthioacetylglycine] is treated with acetic anhydride in the presence of benzaldehyde[266]:



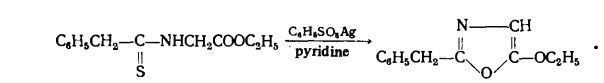
When benzaldehyde is replaced by ethyl orthoformate, intermolecular condensation takes place[266]:



5-Oxazolones are formed by the treatment of an *N*-carboxymethylthioamide with a silver salt or oxide[267]. In dry ether thiophenaceturic acid is cyclised by silver oxide to 2-benzyl-5-oxo-oxazoline[264,267,268]:

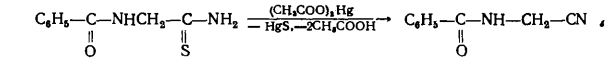


2-Benzyl-5-ethoxyoxazole is formed by treating ethyl thiophenaceturate with silver benzenesulphonate in cold pyridine[269]:

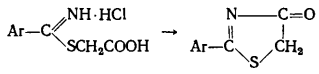


The free acid reacts similarly[61,270].

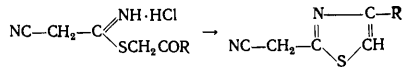
Thioamides in which the nitrogen atom is unsubstituted react with silver salts or the oxide, usually with formation of the corresponding nitrile and precipitation of silver sulphide. When equimolecular quantities of the thioamide of hippuric acid and mercury(II) acetate are mixed, mercury(II) sulphide is precipitated, and hippuronitrile remains in solution[270]:



Aromatic imidate derivatives of thioglycollic acid [271] and its esters [272] form 2-substituted 4-oxothiazolines when boiled in toluene:

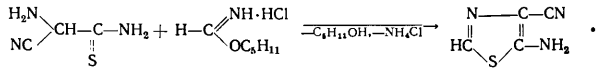


4-Methyl- and 4-phenyl-thiazoles are formed similarly [272]:



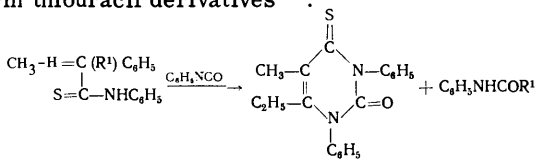
where R = CH_3, C_6H_5.

The thioamide of α-cyanoglycine reacts with isopentyl formimidate to give aminothiazole:



Other formimidates and salts of thioformimidates, however, do not yield definite products [273].

Aminoalkenothioanilides react with phenyl isocyanates to form thiouracil derivatives [274]:



Oxidation of these products by hydrogen peroxide replaces the sulphur by oxygen.

Stereochemistry of the Cathodic Reduction of Halogenated Organic Derivatives

K.P.Butin

Investigations on the stereochemistry of the electrochemical reduction of organic halogeno-derivatives are reviewed, and a comparison is made of the behaviour of these compounds on mercury and on platinum. Specific interaction between the halogen and the mercury electrode is shown to occur during reduction: i.e. direct contact between the halogeno-derivative and mercury is a condition for production of the transition state. In the reduction of optically active halogenocyclopropanes electron transfer occurs from the halogen atom with formation of a carbanion having the same configuration as the original halogeno-compound, but subsequent reactions (protonation, inversion, sp^3–sp^2 transition, etc.) may have a substantial effect on the configuration of the final product. The simultaneous detachment of two halide anions in the reduction of vicinal dihalogeno-derivatives results in the formation of compounds containing multiple bonds. A list of 40 references is included.

I. INTRODUCTION

The electrochemical reduction of the carbon–halogen bond is a heterogeneous process occurring on the electrode surface. Therefore the behaviour of organic halogeno-derivatives during such reduction depends not only on their structure but also on the factors which distinguish heterogeneous from homogeneous processes. Among such factors are primarily (1) the orientation of the transition state in the field of the electrode—i.e. the positions of the atoms and the direction relative to the electrode surface of the dipoles of the bonds undergoing rupture—and (2) the distance from the electrode surface to the point at which the transition state is located, i.e. the length of the path traversed by the electrons from the surface to the molecule of the halogeno-derivative.

From investigations on the effect of solution composition (nature and concentration of electrolyte, nature of solvent, etc.) on the form of the polarisation curves it has been concluded that, in the cathodic reduction of organic compounds, the transition state is adsorbed on the electrode [1].

The present Review will examine the relation between the three-dimensional structure and the electrochemical properties of halogenated organic compounds.

Most monohalogeno-derivatives are reduced at a mercury cathode irreversibly in two stages, which correspond to the successive transfer of two electrons:

$$\begin{aligned} R{-}X + e^- &\xrightarrow{\text{slow}} I \quad \text{(intermediate cpd.)} \\ I + e^- &\xrightarrow{\text{rapid}} R^- + X^- \end{aligned} \qquad (1)$$

Transfer of the second electron is usually rapid, and therefore only one two-electron wave is observed on the polarogram. It is difficult to establish the nature of intermediate compound (I) formed by transfer of the first electron, but it may be assumed to be either a radical-anion $(R{-}X)^\bullet$ or a combination of a radical $R^\bullet$ and a halide anion. The carbanion R^- formed as a result of the two-electron transfer is in most cases a very strong base, and therefore rapidly detaches a proton from a molecule of the solvent (HS), being thus converted into a hydrocarbon:

$$R^- + HS \xrightarrow{\text{rapid}} RH + S^- \qquad (2)$$

The stereochemical result of the formation of a hydrocarbon from a halogeno-derivative may be determined either by the electron transfer (1) or by the protonation (2). If the carbanion formed by reaction (1) has insufficient time to lose its original configuration before capture of a proton, the stereochemistry of the reduction will be determined by the electrochemical stage (1). Apart from structural factors, the configurational stability of the primary carbanion R^- may be promoted also by its interaction with the electrode surface.

A change in the original configuration may occur also at the stage of formation of the intermediate compound I (Eqn. 1), provided that this compound includes the radical $R^\bullet$ (in the case of a radical-anion the configuration would probably be maintained). This possibility creates additional difficulties in interpreting the stereochemical results of the reduction of halogeno-derivatives. In order to reduce to a minimum the effect of isomerisation at the stage of transfer of the first electron, compounds which are reduced at fairly negative potentials must be chosen for investigation of the stereochemistry. In other words, the rate of transfer of the second electron, which depends on the potential, should exceed considerably the potential-independent rate of isomerisation of the radical $R^\bullet$ into the thermodynamically more advantageous configuration. This aspect will be discussed in greater detail in Section III.

The mechanism of the cathodic reduction of organic halogeno-derivatives has already been discussed in several reviews [2–4]. The stereochemistry of the electrochemical reactions of organic compounds forms the subject of a recently published Review [5]. Few papers have been published on the stereochemistry of the cathodic reduction of halogeno-derivatives, almost all during recent years.

II. ORIENTATION OF CARBON–HALOGEN DIPOLE IN THE FIELD OF THE ELECTRODE

Most organic halogeno-derivatives are reduced with a mercury electrode at potentials at which the electrode surface is negatively charged. However, this does not mean that the $R^{\delta+}-X^{\delta-}$ dipole is necessarily arranged with its positive pole towards the electrode surface and the negative pole in the solution. On the contrary, many data show that, when halogeno-derivatives are adsorbed on a negatively charged mercury surface, this dipole is directed with its negative pole towards the electrode[2]: i.e. an electrostatically disadvantageous orientation is established. The reason is that halogens have a specific affinity for mercury. If the Hg←XR interaction energy on formation of the transition state exceeds the change in electrostatic energy accompanying reorientation, an electrostatically unfavourable orientation is established.

In this connection it is interesting to compare the behaviour of halogeno-derivatives on mercury and platinum electrodes. According to Vlček[6] cobalt(III) complexes containing as ligands anions which form with mercury stable complexes or insoluble salts (Cl^-, Br^-, I^-, CNS^-, etc.) are reduced on mercury at abnormally positive potentials. The variation in the reduction potentials of these compounds does not correspond to their position in the corresponding "structural" series which includes complexes with other anions. On a platinum electrode, however, no abnormalities are observed, which indicates "catalysis by the surface of the mercury electrode"[6]. Interaction of the halogenated derivatives with the surface of metallic mercury may lead to the formation of organomercury compounds. In the reduction of allyl iodide, benzyl iodide[8], ethyl α-bromophenylacetate, and several other compounds, which may give relatively stable radicals R$^\cdot$, organomercury compounds are already formed on contact with the electrode surface. In these cases the polarograms of the halogeno-derivatives exhibit two one-electron waves which are identical with the waves of the corresponding organomercury compounds, e.g.

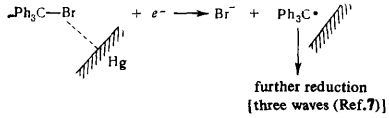
$$C_6H_5CH_2I + Hg \xrightarrow{\text{rapid}} C_6H_5CH_2HgI$$

$$C_6H_5CH_2HgI + e^- \rightarrow C_6H_5CH_2Hg^\cdot \quad (\text{or } C_6H_5CH_2^\cdot + Hg) \text{ (1st wave)}$$

$$C_6H_5CH_2Hg^\cdot + e^- + H^+ \rightarrow C_6H_5CH_3 + Hg \text{ (2nd wave)}$$

In most cases, however, the formation and reduction of organomercury compounds is merely a side-reaction accompanying the cathodic reduction of the halogeno-derivative and is due to interaction of RX with the electrode surface. Nevertheless, chloro-, bromo-, and iodo-derivatives of *o*-, *m*-, and *p*-barenes [1,2-, 1,7-, and 1,12-dicarbaclovododecaborane-12] are fairly easily reduced on mercury, the iodo-derivatives reacting the most readily, with reduction potentials close to the dissolution potentials of mercury. On platinum, however, these compounds are not reduced in the accessible potential range (to −1.8 V relative to the saturated calomel electrode, s.c.e. in anhydrous dimethylformamide. Diphenyliodonium salts behave similarly, being very easily reduced on mercury but not reduced on platinum[8–10].

Fig. 1 shows polarograms of triphenylbromomethane obtained on mercury and platinum electrodes in dimethylformamide. A "normal" two-electron wave is observed on platinum, whereas four waves are observed on mercury, the first of which is located at far less negative potentials †. This is probably due to interaction between the halogeno-derivative and mercury with formation of a triphenylmethyl radical[7]:



Similar phenomena are observed also with diphenylbromomethane and 9-bromofluorene.

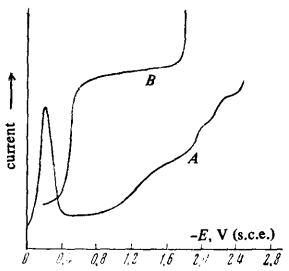


Figure 1. Polarograms for trimethylphenyl bromide in dimethylformamide containing 0.1 M tetraethylammonium bromide at 25°C on:
A) mercury; B) platinum.

These results confirm the earlier conclusion[11,12] that a transition complex involving the metal of the electrode surface is formed in the reduction of halogeno-derivatives. This means that the reducible molecule is tightly "clamped" to the electrode surface, the $R^{\delta+}-X^{\delta-}$ dipole being so arranged that the halogen atom is able to interact with the mercury. Such interaction is possible also with a "perpendicular" orientation of the dipole with its negative pole towards the electrode surface and with orientation parallel to the surface. The true orientation of the halogeno-derivative may be intermediate between these two extreme cases.

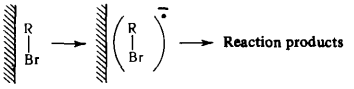
It has been found[13] with a large number of bromoalkanes RCH_2Br that the half-wave potentials do not correlate satisfactorily with the Taft σ^*-constants for the groups R. Correlation with the σ^*-constants of the groups RCH_2 is still less satisfactory. Substantial improvement is obtained by taking into account the steric hindrance due to the substituent R, i.e. by introducing the steric constants E_S into the correlation equation[14]:

$$E_{1/2} = 0.32\sigma^* + 0.12\,E_s - 2.16$$

It follows from this equation that the steric hindrance to electron transfer is considerably smaller than that resulting from an S_N2 reaction of RCH_2Br with such nucleophiles as OH^- or SCN^- (the coefficient of E_S in the above equation is unity). The steric hindrance in the

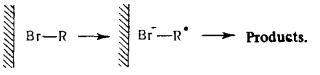
† The first wave exhibits a maximum whose nature is obscure. A similar maximum is always found in the reduction of mercury halides in anhydrous dimethylformamide.

cathodic reduction of these bromides is about the same as in the hydrolysis of esters, when the attacking nucleophile approaches the carbonyl carbon in a direction perpendicular to the C=O bond. It has been concluded[13] from these considerations that, in the cathodic reduction of alkyl bromides, the C–Br bond is oriented parallel to the electrode surface, and "perpendicular attack" takes place on the antibonding σ^*-orbital of the molecule:



Such a mechanism involves the intermediate formation of an unstable radical-anion $RBr^{\bullet}$, which breaks down rapidly into the radical $R^{\bullet}$ and the anion Br^-. Transfer of the second electron to $R^{\bullet}$ occurs rapidly, and does not affect the half-wave potential.

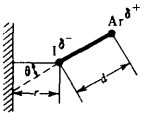
Sease et al.[15] consider that, in the reduction of bromides, the bromine atom is located at the surface of the mercury electrode, and the electron passes from the cathode to the carbon across the bridge formed by the bromine atom:



This hypothesis is based on the observation of reduction waves for compounds containing the bromine atom "in the bridgehead", e.g. 1-bromonorbornane, 1-bromobicyclo[2, 2, 2]octane, and bromotriptycene. If electrons had passed directly to the carbon atom, these compounds would not, in the opinion of the authors, have been reduced, owing to the considerable steric hindrance.

At the present time "perpendicular attack" and attack at the halogen atom are the most widely accepted views.

As the carbon–iodine bond in nuclear-substituted iodobenzenes becomes more ionic, the half-wave potential becomes more negative (the ionicity is determined from the nuclear quadrupole resonance spectra)[16,17]. It is impossible to explain this fact if the electron is assumed to pass to the carbon atom. Caldwell and Hacobian therefore supposed[17] that electron transfer occurs via the iodine atom. A somewhat modified spatial model of the reaction, as compared with that proposed by the authors, is given below:



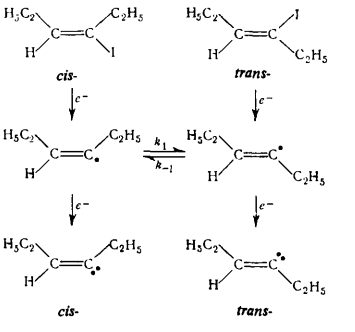
The ArI molecule is inclined at an angle $\frac{1}{2}\pi - \theta$ to the electrode surface, with the iodine atom closer than the carbon atom thereto. In passing to the iodine atom the electron traverses a distance r at an angle θ to the vector of the Ar–I bond. Accepting this orientation of the aryl iodide and putting $\cos\theta = 1$, these authors calculated the distance r between the iodine atom and the electrode surface from the slope of the linear plot of the ionic character of the bond against the half-wave potential. If the positive pole of the dipole is located on the carbon atom combined with the iodine, we have $\alpha = 2$ Å and the calculated value of $r = 1.2$ Å; if, however, the positive pole is located at the centre of the benzene ring ($d = 3.39$ Å), then $r = 1.4$ Å. The mean value of $r = 1.3$ Å agrees well with the van der Waals radius of iodine (1.33 Å). This was regarded as evidence, firstly that the iodobenzene molecule is perpendicular to the electrode surface during reduction, and secondly that the iodine atom is in close contact with the mercury surface[17]. However, the analogous calculation based on Lambert's model, in which the molecule of the halogeno-derivative is parallel to the electrode surface ($\cos\theta = 0$), gives $r = 1.05$ and 1.25 Å when $d = 2$ and 3.39 Å: i.e. the results are close to the values calculated by Caldwell and Hacobian and comparable with the half-thickness of the aryl iodide molecule.

Whatever the orientation of iodobenzene relative to the electrode surface, it follows from these calculations that reduction takes place with the molecule in close contact with the electrode, and electron transfer is effected at a distance less than 1.5 Å. It must be noted that the disposition of the transition state at the surface may depend on the potential of the electrode[1], but this question will not be examined here.

III. MONOHALOGENO- AND *gem*-DIHALOGENO-DERIVATIVES

As has already been remarked, a change in configuration of the group R during the cathodic reduction of halogeno-derivatives may occur either at the stage of formation of the radical $R^{\bullet}$ or at the stage of formation of the carbanion. The possibility of isomerisation of the radical formed as a result of transfer of the first electron has been well illustrated by the work of Fry and Mitnich[18]. The electrolysis of *cis*- and *trans*-3-iodohex-3-enes in dimethylformamide with tetra-n-butylammonium bromide as supporting electrolyte yields a mixture of *cis*- and *trans*-hex-3-enes, in which the *trans*-isomer always predominates (70–94%) independently of the configuration of the initial iodide. The course of the reaction can be represented by Scheme 1.

Scheme 1



In this case *cis*–*trans*-isomerisation can take place only at the stage of formation of the radical, since the vinyl carbanions formed by transfer of the second electron, unlike the corresponding radicals, are configurationally stable owing to the disadvantageous character of the allene structure. The *trans*-radical is thermodynamically more stable (i.e. $k_1 \gg k_{-1}$), and therefore the *trans*-hydrocarbon predominates in the reaction products.

The possibility of a change in configuration at the stage of radical formation is one factor leading to the usually low optical purity of hydrocarbons obtained by the electrolysis of optically active halides (see below).

If the rate of inversion of the radical exceeds the rate of transfer of the second electron, and the radical is able freely to change its orientation relative to the electrode surface, the hydrocarbon formed by reduction of an

optically active halide will be a racemate. If, however, even a proportion of the radicals form a surface compound with the mercury, electron transfer between the electrode and the radical will lead to formation of an optically active product, whose configuration will be determined by the disposition of the transition state on the electrode surface.

It is easy to understand that, in the reduction of saturated halogeno-derivatives, the stereochemistry of transfer of first and second electrons should be the same: otherwise it would be necessary to suppose that, for some unknown reason, the molecule rotates through 180° about an axis parallel to the electrode surface in the interval of time between these two processes ‡, or that the electron moves along a trajectory skirting the molecule. In the subsequent discussion of the stereochemistry, therefore, we shall not divide the transfer of the two electrons into two one-electron stages.

If interaction is assumed to occur between the halogen atom and the surface of the mercury electrode, the initial configuration of the carbanion formed by two-electron reduction of the molecule RX should coincide with the configuration of the initial halogeno-derivative. If, however, the transfer of electrons occurs on the side opposite to the liberated halogen atom, inversion of configuration should be observed. Henceforward we shall term these two cases "attack on halogen" and "attack on carbon" (the former corresponds to the "parallel" or "perpendicular" arrangement of the $R^{\delta+}-X^{\delta-}$ dipole considered above).

A general scheme of the reaction for cases of attack on halogen and on carbon (Fig. 2) shows the following stages—(1) actual transfer of electrons, (2) diffusion of initially formed carbanion from electrode surface into solution, (3) inversion of carbanion in solution, (4) and (5) protonation in solution of uninverted and inverted carbanions respectively, (6) transition of carbanion from sp^3 to sp^2 configuration as a consequence of conjugation with the substituent *d* (e.g. NO_2, COR, CN, etc.), (7) diffusion into solution of carbanion after having assumed a planar configuration, and its subsequent protonation, and (8) protonation of planar carbanion which has been unable to lose its bond with the electrode. It can be assumed from Fig. 2 that the stereochemistry of the cationic reduction of the carbon–halogen bond will depend on the stereochemical direction of five different stages in the process.

Table 1 shows the changes in configuration of the hydrocarbon formed by protonation at different stages in the conversion of the carbanions, compared with the configuration of the initial halogeno-derivative. The overall stereochemical result of the electrode reaction is seen to depend on the relative rates of the different stages: i.e. it is closely connected with the chemical structure of the initial halogeno-derivative and the resulting carbanion. In general it is fairly difficult to predict which stage will determine the stereochemistry to a greater extent, and which to a smaller extent, so that it is difficult to distinguish "attack on halogen" from "attack on carbon". To settle this question it is necessary to choose an organic halogeno-derivative which will give a configurationally stable carbanion on reduction, i.e. a carbanion which will not contain substituents *d* capable of stabilising it by conjugation and localisation of a negative charge on a heteroatom, and which would possess a low rate of inversion.

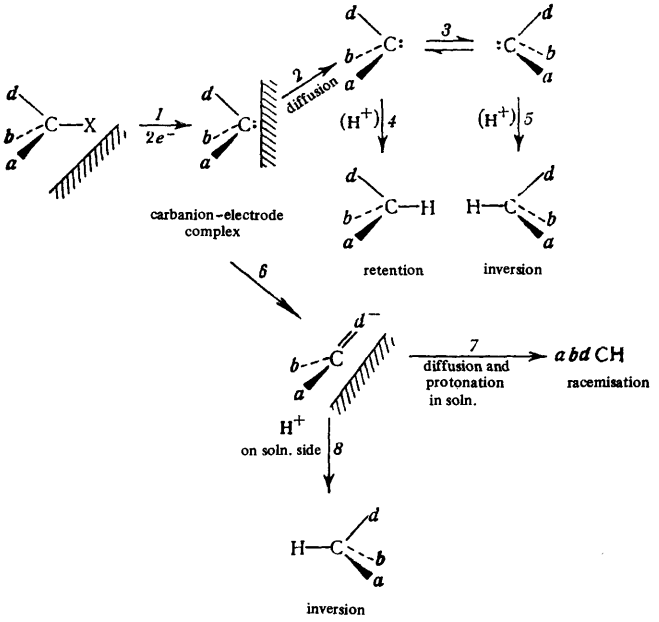


Figure 2. Events occurring during lifetime of carbanion formed by cathodic reduction of an optically active halogeno-derivative. The scheme shows the case in which electron transfer occurs with retention of configuration.

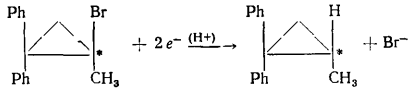
Table 1.

Stage of reaction	*1*	*4*	*3.5*	*6.7*	*6.8*
Attack "on halogen"	retention	retention	inversion	racemisation	inversion
Attack "on carbon"	inversion	inversion	retention	racemisation	retention

These requirements are satisfied by halogenated vinyl and cyclopropyl derivatives. Cyclopropyl anions are inverted at a very low rate [19]—less than twice a second—so that the stereochemical contribution of reactions (3) and (5)—and, in the absence of substituents capable of conjugation, also reactions (6–8) and (6–7)—is not so large. Thus it may be expected that the stereochemistry of the cathodic reduction of cyclopropyl halides will be determined in considerable measure by the stages of actual transfer of electrons (1) and of diffusion of the carbanion into the solution (2). Hence it is not surprising that almost all work on the stereochemistry of the cathodic reduction of halogeno-derivatives has been done on derivatives of cyclopropane. Study of the stereochemistry of these reactions shows that electron transfer occurs with retention of configuration, i.e. on the side of the halogen atom.

‡ This does not apply to the *cis*- and *trans*-iodohexenes discussed above, which by analogy with other π-systems probably have a horizontal orientation relative to the electrode surface. If a stage of isomerisation of the radical is involved, therefore, the stereochemistry of transfer of first and second electrons may be different.

Walborsky and his coworkers[20] electrolysed (+)-(*S*)-1-bromo-1-methyl-2,2-diphenylcyclopropane in acetonitrile at a mercury cathode at a potential of −2.7 V (s.c.e.). This gave a 93% yield of the corresponding hydrocarbon, which had the configuration of the original bromide (25% optical purity):



The current–time curve obtained at a stationary macroelectrode had an unusual form. A mercury-containing product appeared in the solution at the start of electrolysis, and the mean consumption of electrons per R–Br molecule was < 2. Results obtained by cyclic volt–amperometry suggested the mechanism of reduction

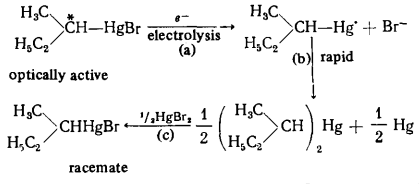
$$R{-}Br + e^- \rightarrow (R{-}Br)^{\cdot-} \qquad RHg_n^{\cdot} + e^- \rightarrow R^- + Hg_n$$

$$(R{-}Br)^{\cdot-} \rightarrow R^{\cdot} + Br^- \qquad RHg_n^{\cdot} + RHg_n^{\cdot} \rightarrow RHg_nR + RHgR + Hg_{n-1}$$

$$R^{\cdot} + e^- \rightarrow R^- \qquad R_2Hg + e^- \rightarrow R^- + RHg^{\cdot} \xrightarrow{Hg} RHg_n^{\cdot}$$

$$R^{\cdot} + Hg_{\perp} \rightarrow RHg_n^{\cdot} \quad R^- + H^+ \rightarrow RH$$

The retention of configuration in this case might have been explained by a double inversion of configuration at the stages of electrolysis of RBr and formation of R_2Hg[5]. According to Dessy et al.[21], however, optically active s-butylmercuric bromide is completely racemised during electrolysis. This is proved by the cycle of reactions



Electrolysis of optically active s-butylmercury bromide produces an organomercury radical, which then dimerises rapidly to di-s-butylmercury. The action of mercury(II) bromide on this last compound yields optically inactive s-butylmercury bromide. It has been duly proved that stage (*c*) occurs with retention of configuration[22], and therefore racemisation should take place at either stage (*a*) or stage (*b*). Disproportionation of RHg· radicals (reaction *b*) involves rupture of only one C–Hg bond: i.e. if stage (*a*) leads to the retention of configuration, the optical activity of RHgBr obtained from R_2Hg should be partly retained. Hence it may be concluded that the RHg· radicals are optically inactive: i.e. racemisation occurs at the stage of formation of RHg· from RHgBr.

This conclusion is consistent also with the fact that the reduction at a mercury electrode of phenylmercuric bromide containing the radioactive isotope ^{203}Hg is accompanied by rapid isotopic exchange between the organomercury compound and the metallic mercury of the electrode, whereas on open circuit such exchange is almost zero[21]. This implies that organomercury radicals are involved in the isotopic exchange:

$$Ph{-}{}^{203}Hg^{\cdot} + Hg \underset{}{\overset{rapid}{\rightleftharpoons}} PhHg^{\cdot} + {}^{203}Hg$$

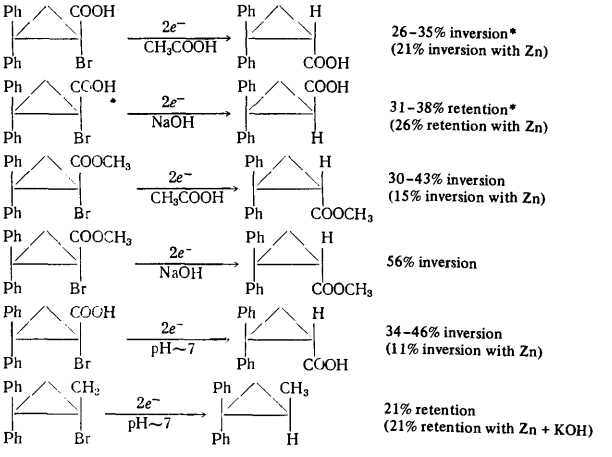
It is natural to expect that such exchange will be accompanied by racemisation, since the reaction involves fission of the carbon–mercury bond§.

§ Thus data on the stereochemistry of the reduction of organomercury compounds cannot be used in discussing the question of the distance between the depolariser and the electrode.

It is clear that the corresponding organomercury compound is not an intermediate product in the reduction of 1-bromo-1-methyl-2,2-diphenylcyclopropane. Besides the reason mentioned at the beginning of this Section, the incomplete retention of the configuration can be explained also by the partial occurrence of the reaction via the organomercury compound and partial inversion of the carbanion in solution (stages (2) and (3) in Fig. 2).

Annino et al.[23] have also investigated the cathodic reduction of optically active 1-bromo-1-methyl-2,2-diphenylcyclopropane in alcoholic medium at potentials of ~2.3 V (s.c.e.). The product was a hydrocarbon of 21% optical purity (retention of configuration), which agrees with Walborsky's results[20]. An investigation was made also of the stereochemistry of the reduction at a mercury electrode of optically active 1-bromo-2,2-diphenylcyclopropanecarboxylic acid and its methyl ester at various solution pH values produced by the addition of acetic acid or of sodium hydroxide to the alcoholic solutions. The results are shown in Scheme 2. The stereochemistry of the cathodic reduction of these bromo-derivatives corresponds qualitatively to that of their reduction with metallic zinc (these results are given in parentheses in Scheme 2).

Scheme 2

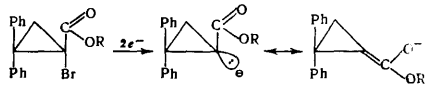


* The expression "30% inversion" means that the result of reduction is a hydrocarbon whose absolute configuration is opposite to that of the initial bromide, while the yield of this hydrocarbon is 30% of the initial bromide of 100% optical purity (the remaining 70% of the total quantity of cathodic reduction product comprises a racemate). The "percentage retention of configuration" is to be interpreted analogously.

The results are explained on the basis of two fundamental assumptions: (1) electron transfer to the cyclopropyl bromide molecule occurs on the side containing the bromine atom, with formation of a carbanion having the configuration of the original bromide; and (2) the general stereochemistry of the process is determined by the stereoselective reaction of the carbanion, either free or shielded by the electrode, with a proton donor.

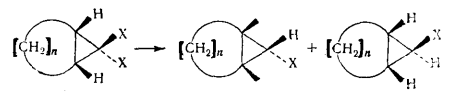
In the case of the brominated cyclopropanecarboxylic acids the carbanion formed by reduction is able to assume

a planar configuration as a consequence of conjugation with the carbonyl group:



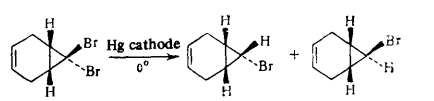
In contrast to 1-methyl-2,2-diphenylcyclopropyl bromide, therefore, such compounds are reduced with retention of configuration. In this case the stereochemistry of the reaction is probably determined by stages (6)–(8) (Fig. 2). The fact that in alkaline medium 1-bromo-2,2-diphenylcyclopropanecarboxylic acid is reduced with retention of configuration (Scheme 2) is probably due to the considerably diminished stabilisation of the planar anion owing to ionisation of the carboxy-group.

The cathodic reduction of *gem*-dihalogenocyclopropanes is highly stereoselective. Fry and Moore[24] have examined the composition of the products of the electrolysis of 1,1-dihalogeno-2,3-tetra(and hexa)methylenecyclopropanes in various solvents. The reaction results in detachment of one halogen atom with formation of a monohalogenocyclopropane, the main product in all solvents being the *cis*-isomer:



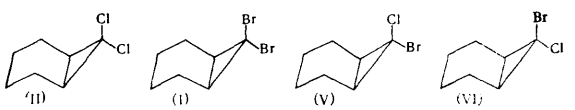
I: $n = 4$, X = Br
II: $n = 4$, X = Cl
III: $n = 6$, X = Br

cis- (*endo*-) *trans*-(*exo*-)



(IV) *cis*- *trans*-

Similar results have been obtained by Annino and his coworkers[25], who investigated the compounds



(II) (I) (V) (VI)

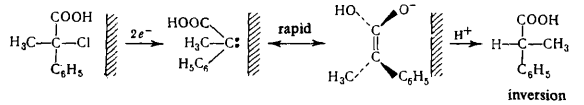
In compounds (V) and (VI), which contain both chlorine and bromine, the bromine is reduced. Table 2 gives the proportions of *cis*- and *trans*-monohalogeno-derivatives (the *endo/exo* ratios) determined by gas–liquid chromatographic analysis of the products of the electrolysis. The ratio of the isomers in the reaction product depends not only on the nature of the solvent but also on the inert electrolyte.

Three conclusions can be drawn from the above results: (1) *cis*-monohalogeno-compounds are the main products of the electrolysis of dibromo- and dichloro-derivatives; (2) the content of the *cis*-isomer increases with increase in the concentration of water in the solution; and (3) the stereospecificity of the reaction is greater with chloro- than with bromo-derivatives. The results can be explained by two alternative schemes: firstly, of two identical halogen atoms, that one is reduced which is located in the *cis*-position to the hydrogen atoms adjacent to the bond between the rings, in which case electron transfer occurs with retention of the configuration; or secondly the *trans*-halogen is reduced with inversion of the configuration.

If "attack on halogen" is supposed to occur (see above), steric hindrance on formation of the transition state is far greater for a halogen in the *trans*-position to the hydrogen atoms of the bridging bond. This is supported by the fact that the reduction of bromine in the two isomeric 7-bromo-7-chlorobicyclo[4,1,0]heptane occurs with greater difficulty in (VI) than in the isomer (V), in which the spatial position of the bromine is more favourable for approaching the electrode surface.

The stereospecificity of the cathodic reduction of different halogens (Cl > Br) is analogous to that observed in the preparation of Grignard reagents from cyclopropyl halides. This occurs with retention of configuration, the loss of optical activity falling in the sequence I > Br > Cl[26]. The mechanism of the reaction RX + Mg → RMgX is probably similar to that of the cathodic reduction of the halides[27]. Preferential formation of *endo*-isomers is observed also in the reduction of compounds (I), (II), and (V) with zinc or lithium amalgam in alcohol[25].

Optically active α-chlorohydratropic acid is reduced with inversion of configuration[28]. This result is explained by "attack on carbon" and accompanying inversion. However, as with the halogenated cyclopropanecarboxylic acids (Table 2), a better explanation is "attack on halogen" and rapid transition of the carbanion into a planar configuration. Owing to the shielding effect of the electrode, subsequent protonation occurs predominantly on the solution side:



inversion

Table 2. Stereochemistry of the electrolysis of *gem*-dihalogenocyclopropanes at a controlled potential.

Compound	Solvent-electrolyte*	Ratio of isomeric products (*endo/exo*)
I	DMF-LiCl	1.6
	96% DMF—4% H_2O—LiCl	3.0
	CH_3OH—LiCl	1.9
	95% CH_3OH—5% H_2O—LiCl	2.7
	95% CH_3OH—5% HCl—LiCl	3.5
	90% CH_3OH—10% H_2O—LiCl	5.3
	CH_3COOH—TEAB	4.0
II	DMF—LiCl	4.3
	96% DMF—4% H_2O—LiCl	5.3
	CH_3OH—LiCl	19.0
	95% CH_3OH—5% HCl—LiCl	only *endo*
	33% HMPTA—67% C_2H_5OH	only *endo*
III	CH_3OH—LiCl	only *endo*
	95% CH_3OH—5% HCl—LiCl	only *endo*
IV	CH_3OH—LiCl-	2.7
	90% CH_3OH—10% H_2O—LiCl	10.0
V	C_2H_5OH—TEAB	3.6
	C_2H_5OH—LiCl	2.6
VI	C_2H_5OH—LiCl	0.38
Mixture of V + VI (1:1)	C_2H_5OH—LiCl	1

* DMF = dimethylformamide; HMPTA = hexamethylphosphorotriamide; TEAB = tetraethylammonium bromide.

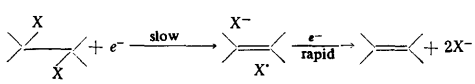
Reduction by zinc in acetic acid proceeds similarly. Ott and Kramer[29] reported that α-chlorohydratropic acid is reduced by this system with inversion of configuration, but by hydrogen–palladium with its retention. According to Brewster[30] inversion of configuration is a result of direct interaction between zinc and the chlorine atom: a carbanion is formed which is then rapidly protonated, before it is able to diffuse into the solution, i.e. to free itself from the metal surface.

Thus it may be concluded that, in the preparative electrolysis of optically active halogeno-derivatives, electron transfer to the molecule RX occurs on the side of the halogen atom in close contact with the electrode surface; this leads to the formation of a carbanion having the same configuration as the initial bromide. However, subsequent events occurring in the lifetime of the carbanion (inversion, resonance stabilisation, diffusion into the solution) may influence considerably the overall stereochemical result of the reaction. Depending on the properties of the organic halogeno-derivative, therefore, either retention, inversion, or complete racemisation of the configuration may be observed.

IV. VICINAL DIHALOGENO-DERIVATIVES

Most cases of the cathodic reduction of vicinal dihalogeno-derivatives involve the simultaneous detachment of two halide anions with the formation of a multiple bond. Thus the electrolysis of 1,2-dibromoethane yields ethylene and ethane[31]. This reaction recalls the formation of alkenes, which occurs when vicinal dibromides are treated with zinc or magnesium. The mechanism of the reduction of such compounds has already been considered in a review[5]. Here we shall discuss briefly only the stereochemical aspects of this reaction.

cis-1,2-Dibromocyclohexane is reduced at a potential of −1.85 V (s.c.e.) and the *trans*-isomer far more easily (−1.0 V)[32]. *meso*-2,3-Dibromosuccinic acid is more easily reduced than is the (±)-isomer[33], and this applies also to *meso*-2,3-dibromobutane-1,4-diol[34]. The greater ease of reduction of *meso*-dihalides implies that *trans*-elimination occurs preferentially. In the case of rigid bicyclic systems the *cis*-dibromides are more easily reduced, since a *trans*-coplanar configuration cannot exist[35,36]. Detachment of the two halogen atoms probably occurs simultaneously:



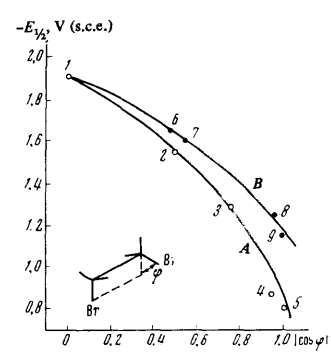


Figure 3. Dependence of half-wave potential of vicinal dibromides on dihedral angle between C−Br bonds:
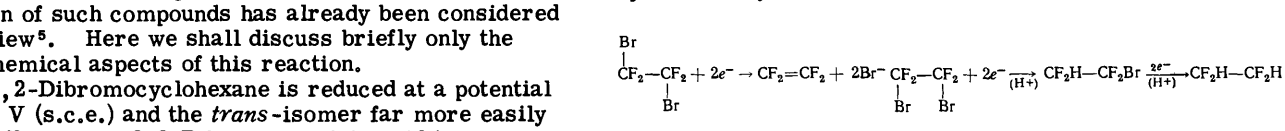
A) compounds having an *anti*-planar configuration ($120° \leqslant \varphi \leqslant 180°$); B) compounds having a *syn*-planar configuration ($0° \leqslant \varphi \leqslant 60°$). It is clear that an *anti*-planar configuration is more favourable.

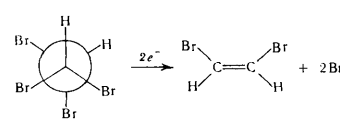
It can be shown that both halogen atoms are involved in formation of the transition state. Zavada et al.[36] determined half-wave potentials for a large number of vicinal dibromides and monobromides. In the series of dibromides $E_{\frac{1}{2}}$ varies from −0.82 to −1.67 V, but in the series of monobromides from −1.90 to −2.16 V (s.c.e.). The compounds were selected so that the steric hindrance was about the same in the two series, i.e. so that it made a relatively small contribution to variation in the reduction potentials. The main reason for the marked variation in the half-wave potentials in the vicinal dibromides is the variation in the dihedral angle φ between the planes formed by each bromine atom with the carbon–carbon bond. The graph in Fig. 3 shows that molecules having an *anti*- or *syn*-planar arrangement of the bromine atoms (φ = 180° or 0°) are reduced at more positive potentials than are molecules in which the angle φ lies between 60° and 120°.

Other evidence of the simultaneous detachment of two bromine atoms has been obtained by Feoktistov and Gol'din[37] in a study of the cathodic reduction of 1,2-dibromotetrafluoroethane. The product of reduction of the *anti*-isomer is tetrafluoroethylene, whereas the *syn*-isomer yields tetrafluoroethane¶:



Not only halogens but also other electronegative groups, e.g. hydroxyl and acetoxyl, may be split off together with a bromine atom[33]. In these cases reduction is also facilitated when the two groups are located in the same plane.

The electrolysis of tetrabromoethane yields a mixture of *cis*- and *trans*-dibromoethylene in the proportions 6:1[39,40]. These results show that *trans*-elimination predominates, since in polar solvents (50% aqueous ethanol was used in this example) tetrabromoethane exists predominantly as the staggered conformation:



cis- and *trans*-Dibromoethylenes are formed in the ratio 6:1, differing considerably from the proportions in the reduction of tetrabromoethane by zinc or by tin(II) chloride (1.2–2:1). The probable reason is that, during electrolysis within the potentials of the limiting diffusion current, i.e. with diffusion control of the reaction, the staggered conformation is unable to pass into the more reactive transoid conformation[40], whereas with kinetic control (dehalogenation by zinc) such conversion is possible.

¶ However, successive replacement of chlorine by hydrogen has been observed[38] in the electrolysis both of diethyl dichloromaleate and of diethyl dichlorofumarate. Reduction of the corresponding dibromo- and di-iodo-esters proceeds "normally": i.e. acetylenedicarboxylic ester is formed[38].

Gas Chromatography at High Eluent Pressures

M.S.Vigdergauz and V.I.Semkin

The influence of pressure on the efficiency of a chromatographic column and on the selectivity of the stationary phase has been investigated. The role of pressure gradients along the column has been demonstrated. It is shown that the efficiency can be drastically increased by turbulence in the carrier gas stream. A special study is made of the use of eluents under supercritical conditions, which permits involatile compounds with a molecular weight up to 4000000 to migrate along the column.
The use of chromatography in studies of non-ideality in the gas phase is discussed. In particular, we have considered the determination of the second mixed virial coefficients in the equation of state for the gas, and the non-ideality corrections needed to determine the activity coefficients of solutes. 115 references.

I. INTRODUCTION

The most significant advances in analytical gas chromatography since 1958 are the use of capillary columns[1] and the development of highly sensitive detectors of the ionisation type[2,3]. These developments have transformed gas chromatography into a universal method of analysis of complex mixtures of organic and inorganic compounds, ranging from permanent gases to substances having vapour pressures of the order of thousandths of a mmHg at the temperature of the experiment[4]. The introduction of detectors sensitive to $10^{-7}-10^{-8}$ mg has allowed the size of the analytical sample to be made as small as $10^{-2}-10^{-4}$ mg.[5] The efficiency of capillary columns, measured in hundreds of thousands of theoretical plates, has now become commonplace[6,7]: conformational isomers[8] can often be separated, and isotope effects[9] can be studied. The time needed for a complete analysis has been shortened to the point that light hydrocarbon mixtures can now be separated in times of the order of a second[10,11].

Because these applications of gas chromatography fulfilled actual practical needs, their realisation was very rapid. It soon became apparent that analytical gas chromatography needed to be developed further before it could be applied to substances of high molecular weight and to relatively unstable compounds (without resorting to reaction chromatography).

Evidently, the scope of chromatographic separation can be extended towards high-molecular-weight compounds by decreasing the distribution coefficients of the sorbates. The major development in gas chromatography in recent years have been in this direction. The main stages in this development have been the introduction of gas–liquid chromatography, the use of carriers very lightly impregnated with the stationary phase, the adoption of capillary chromatography, the development of temperature programming, and the use of weak adsorbents. Actually, the partial Henry coefficient (the ratio of the capacities of the stationary and the mobile phase),

$$\Gamma^{\mathrm{I}} = \frac{t_R}{t_0} - 1 = \frac{c_s \varkappa_{\mathrm{I}}}{c_g \varkappa} \qquad (1)$$

is related to the retention time t_R of the sorbate. (t_0 is the retention time of the non-adsorbed material.) The Henry coefficient is determined by the concentration of the sorbate in the gas (c_g) and the sorption (c_S) phase, and by the ratio of the volumes κ and κ^{I} occupied by these phases in the column.

Thus, the use of gas–liquid chromatography, of weak adsorbents, and also of temperature programming leads to smaller values of c_S, whereas the use of columns with a small percentage of impregnant (capillary columns) decreases κ^{I} and increases κ.

The distribution coefficients can be further decreased (to the point where they are practically independent of the vapour pressure of the sorbate) by increasing the solubility of the sorbates in the mobile phase. To this end, the eluents are applied in the form of gases at high pressure, or liquids.

The earliest report of the successful application of gas chromatography at pressures above 100 atm was due to Klesper and coworkers[12], who were able to separate mixtures of porphyrins. Subsequent work by Giddings and coworkers[13–15], and also by Sie and coworkers[16–18], showed that polynuclear aromatics, polymers with molecular weights in excess of 400 000, and many other high-molecular-weight compounds can be separated by gas chromatography.

Giddings has pointed out[15] that gas chromatography at high pressures has three main advantages over liquid chromatography: 1) the distribution coefficient of the sorbates between the stationary and the mobile phase can be controlled over wide limits by changing the pressure; 2) the analysis is faster because the mobile phase is less viscous and the diffusion coefficients of the sorbates are higher; 3) detectors with much higher sensitivity can be used.

Increase in pressure within the column affects the analysis time, the selectivity of the column, and the efficiency of the process, and therefore pressure is one of the most important parameters of a fast column.

The "speed coefficient" is defined[19,20] as

$$\lambda = \frac{n_p \cdot K^2}{t} \sim k \left(\frac{\Gamma'}{\Gamma'+1}\right)^2 \cdot \frac{n}{t} \qquad (2)$$

where n_p is the number of peaks in the chromatogram, K is the degree of resolution of the least resolved pair, t is

the time of analysis, k_S is the selectivity coefficient for the sorbate, n is the number of theoretical plates, $\Gamma' = \Gamma\frac{K'}{K}$ is the partial Henry coefficient (mean value for the components of the least resolved pair), Γ is the true Henry coefficient (ratio of concentrations of the sorbate, in g ml^{-1}, in the stationary and the mobile phase). Thus, since k_S is determined by the Henry coefficient for the components of the least resolved pair, and t is determined by the Henry coefficient of the most strongly held component of the mixture, all the quantities in the right-hand side of Eqn. (2) are a function of the nature of the eluent and of its pressure.

These relationships are discussed in the present review together with the possible practical applications of gas chromatography at high pressures.

In addition to its advantages in the field of analytical chromatography, the use of high pressures offers new scope in non-analytical applications of gas chromatography. These include methods of studying non-ideality in gases, the determination of the constants for phase equilibria in multicomponent systems, etc., which are also discussed in the following Sections.

II. INFLUENCE OF PRESSURE ON THE EFFICIENCY OF A CHROMATOGRAPHIC COLUMN

The effect of pressure on the efficiency of a chromatographic column has been discussed by many workers[21-34] in the absence of non-ideality effects, i.e. for pressures below 5 atm. Assuming pressure-independence of the dynamic viscosity of the carrier gas and of the permeability of the column, and also assuming laminar flow conditions, the square of the width of the band for a particular component,

$$\sigma_{st}^2 = \int_0^L H\left(\frac{P}{P_0}\right)^2 dx \qquad (3)$$

(where H is the height equivalent to a theoretical plate at the cross-section of the column where the pressure is P, and P_0 is the pressure at the column outlet) is given by

$$\sigma_{st}^2 = L\left(A + \frac{B}{\bar{P}\bar{\alpha}} + E\bar{P}\bar{\alpha} + C_2\bar{P}^{0.5}\bar{\alpha}^{0.5}\right)\frac{1}{\chi^2} + LC_1\bar{\alpha}\cdot\frac{1}{j^2} \qquad (4)$$

Here σ_{st} is the mean standard deviation (the half-width of the peak at a height $1/\sqrt{e}$ of the maximum height) on the layer of sorbent when elution occurs, L is the length of the column, A is the turbulent diffusion term in the equation for the height equivalent to a theoretical plate, B is the molecular diffusion term, E accounts for contributions from the wall effect, from outer diffusion of weakly sorbed materials, and from dynamic diffusion, C_2 is the mass transfer term for outer diffusion (as defined by Zhukhovitskii and Turkel'taub[35]), C_1 is the mass transfer term for inner diffusion, $\bar{P}$ is the mean pressure in the column, $\bar{\alpha}$ is the mean linear velocity of the carrier gas, the parameter χ is given by

$$\chi = \sqrt{\frac{2}{(P_1/P_0)^2 + 1}},\quad j = \frac{3}{2}\frac{(P_1/P_0)^2 - 1}{(P_1/P_0)^3 - 1},$$

P_1 is the pressure at the column inlet, and P_0 is the pressure at the column outlet.

At pressures of hundreds of atmospheres, when the deviations from ideality of the gas are large and neither the viscosity, nor the product $P\alpha$, nor the distribution coefficient of the sorbate are constant along the column, integration of Eqn. (3) leads to very complicated expressions[36].

The factors χ and j have very similar values, so that the ratio j^2/χ^2 does not exceed 9/8. Hence we may conclude[33] that the efficiency of the column is practically independent of the pressure drop and is determined only by the mean pressure in the column. Thus, if we assume that the spreading of the peak is limited by inner diffusion, the number of theoretical plates deduced from the experimental values of retention volume (V_R) and peak width (ω), both in ml, is

$$n = \frac{V_R^2}{\omega^2} = \frac{V_R^{02}}{j^2}\cdot\frac{j^2}{\omega^{02}} = n^0 \qquad (5)$$

Here $V_R^0 = V_R \cdot j$ is the corrected retention volume, $\omega^0 = \omega \cdot j$ is the corrected peak width, n^0 is the corrected number of theoretical plates corresponding to a mean pressure $\bar{P}$ in the absence of significant pressure gradients along the column.

If the term C_1 can be neglected, we may write[37]

$$n = \frac{V_R^{02}}{j^2}\cdot\frac{\chi^2}{\omega^{02}} = n^0\cdot\frac{\chi^2}{j^2} \qquad (6)$$

Thus, the decrease in the number of theoretical plates at high pressure gradients is not very large (and cannot exceed 11.1%†).

It follows that the height equivalent to a theoretical plate is

$$H = \frac{L}{n} = \frac{j^2}{\chi^2}\left(A + \frac{B}{\bar{P}\bar{\alpha}} + E\bar{P}\bar{\alpha} + C_2\bar{P}^{0.5}\bar{\alpha}^{0.5}\right) + C_1\bar{\alpha} \approx H^0 \qquad (7)$$

where H^0 corresponds to a mean pressure $\bar{P}$ and small pressure gradients.

Introducing the symbol $r = \bar{P}\bar{\alpha}$, the minimum value of H^0 is

$$H^0 = A + \frac{B}{r} + Er + C_2 r^{0.5} + C_1\frac{r}{\bar{P}} \qquad (8)$$

If, for simplicity, we ignore the term in C_2,

$$H^0_{min} = A + 2\sqrt{B\left(\frac{C_1}{\bar{P}} + E\right)}, \qquad (9)$$

and the corresponding value of r is

$$r_{opt} = \sqrt{\frac{B}{\frac{C_1}{\bar{P}} + E}} \qquad (10)$$

The effect of pressure on the analysis time can be characterised by the "speed coefficient". If, under the particular experimental conditions, the main contribution to the diffuseness of the bands comes from the terms E and C, it follows that[33]

$$\lambda \sim \frac{n}{t} \sim \frac{1}{E\bar{P} + C_1} \qquad (11)$$

The following conclusions may be made from the above considerations.

1. The efficiency of the column is degraded by operating at higher pressures if the optimum value of the carrier-gas velocity is used for the separation.

† It should be noted that these conclusions are independent of the chosen model for the spreading process. Identical results have been obtained using Giddings' "conjugated" theory[38].

2. The optimum carrier velocity decreases as the pressure in the column increases. Thus, as Fig. 1 shows, the left-hand branch of the hyperbola is shifted towards very low velocities when the pressure is increased.

3. The speed coefficient increases, tending asymptotically to a limit proportional to $1/C_1$, as the pressure decreases. Thus, it is desirable to use a moderate vacuum[33] when a short analysis time is required.

4. For a constant average velocity in the column, the relationship between H and the mean value of $\bar{P}$ is a hyperbola with a slanting, curved branch[28] [see Eqn. (7)].

5. The plot of H against α_0 (where α_0 is the linear velocity of the gas at the outlet of the column) is not a hyperbola. The right-hand side of the curve becomes steeper as the velocity increases[17,33] because of the decrease in the term C_1r/P [see Eqn. (8), with the assumption that $\bar{P}\bar{\alpha} = P_0\alpha_0$].

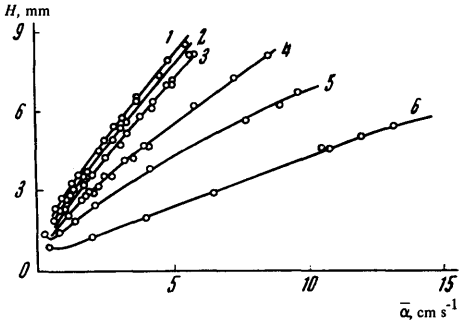

Figure 1. Effect of pressure on the dependence of the HETP on the mean velocity of the carrier gas. Sorbate: pentane; eluent: carbon dioxide. Temperature 40°.[17] Pressure: *1*) 50, *2*) 40, *3*) 30, *4*) 20, *5*) 10, *6*) 5 atm.

The effect of pressures of the order of tens or hundreds of atmospheres on the efficiency of the column is discussed by Giddings and coworkers[39-42]. Assuming that under these conditions the gas velocity is almost proportional to the inlet pressure P_1, Eqn. (7) takes the form

$$H \approx A + \frac{B}{P_1^2} + EP_1^2 + (C_1 + C_2)P_1 \qquad (12)$$

(where the symbols have the meaning already stated).

On the other hand, according to the "conjugated" theory of Giddings[39],

$$H \approx \frac{1}{\frac{1}{A} + \frac{1}{EP_1^2}} + \frac{B}{P_1^2} + C_1P_1 \qquad (13)$$

and, in our terminology, since $t = \frac{L}{\alpha}\Gamma_0$ where $\Gamma_0 = \Gamma\kappa_1 + \kappa$ and $n = L/H$,

$$\lambda \sim \frac{n}{t} \sim \frac{\alpha}{H\Gamma_0} \sim \frac{1}{\frac{H}{P_1}\Gamma_0} \qquad (14)$$

It follows from Eqns. (13) and (14) that the speed coefficient tends towards the limit $1/C_1\Gamma_0$ as the pressure increases (if we ignore the effect of pressure on the selectivity of the column).

Giddings has shown[43] that the minimum time to achieve an efficiency of n theoretical plates for an inlet pressure P_1 is

$$t = nC_1\Gamma_0 \cdot \frac{P_1^2}{P_1^2 - P_c^2}, \qquad (15)$$

where P_c is the "critical" pressure for the prescribed efficiency[44], whose numerical value is of the order of $4 \times 10^{-2}\sqrt{n}$ for conventional packed columns. If a separation criterion $K = 1$ is required, then

$$P_c \approx \frac{0.2}{K_c} \qquad (16)$$

For $P_1 \gg P_c$ and $t = nC_1\Gamma_0$, a very fast action becomes possible. Thus, Fig. 2 shows a chromatogram of petroleum gases obtained in under 1 min at $P_1 = 172.6$ atm.

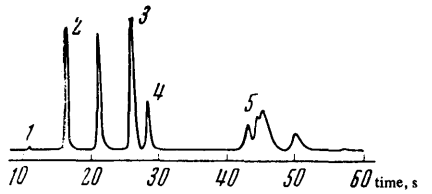

Figure 2. Separation of petroleum gas. Column length 1 m, internal diameter 0.47 mm. Sorbent: aluminium oxide. Pressure at column inlet 172.6 atm. Temperature 25°. *1*) air peak, *2*) propane, *3*) isobutane, *4*) n-butane, *5*) isobutene.

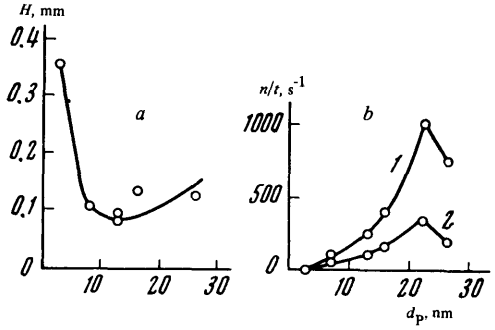

Figure 3. (*a*) Variation of HETP with average particle size of the filling (adsorbent: aluminium oxide)[40]. (*b*) Number of theoretical plates generated per second, *1*) for methane and *2*) for butane, against average particle size of the aluminium oxide[40].

In cases where the effect of non-equilibrium conditions can be almost completely eliminated, it becomes apparent that the efficiency is affected by the turbulent diffusion factor $A = 2\lambda_1 d_P$, where λ_1 is the tortuosity coefficient and d_P is the diameter of the sorbent particles. Fig. 3 shows plots of the height equivalent to a theoretical plate, and of the ratio n/t, against particle diameter for a column of 0.47 mm diameter.

Giddings finds that[43]

$$\frac{n^2}{t} = (10^6 \div 10^7)\Delta P, \qquad (17)$$

where ΔP is the pressure drop in the column.

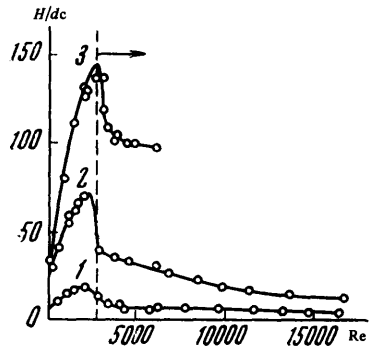

Figure 4. Reduced HETP against Reynolds number for: *1*) methane in nitrogen, *2*) pentane in nitrogen, and *3*) pentane in helium. Capillary column 21.3 m long. Temperature 0°.[45]

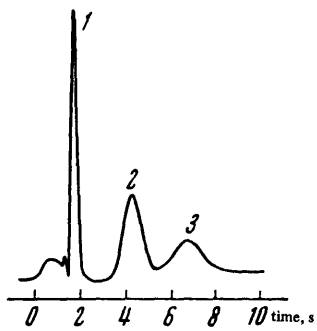

Figure 5. Chromatogram for the separation of light hydrocarbons in a stream of helium (turbulent regime, Re ≃ 7000). Temperature 74°. Pressure at column inlet 144 atm. *1*) propane, *2*) n-butane, *3*) n-pentane.[45]

All the considerations discussed above are based on the assumption of laminar gas flow, which is reasonable for normal gas velocities in a chromatographic column. Turbulent flow, which tends to equalise the velocities in a cross-section of the tube and to improve the mass transfer between the phases[45-52], produces a drop in the right-hand branch of the $H-\alpha$ curve at sufficiently high values of the Reynolds number ($\mathrm{Re} = \frac{d\alpha\rho}{\eta}$, where ρ and η are the density and the dynamic viscosity of the gas respectively, and d is the hydraulic diameter of the tube). Both the velocity and the density of the eluent increase with pressure: for example, for carbon dioxide the ratio ρ/η is 1000 s cm^{-2} at 80 atm (40°), as compared with 1 s cm^{-2} at 1 atm.[17]

Whereas the transition to the turbulent regime occurs at Re = 2130 in capillaries, in packed columns the turbulent regime is reached at Re values of the order of 1–100.[43]

Giddings and coworkers[45] achieved Reynolds number of the order of 16 000 at mean velocities in excess of 2000 cm s^{-1} and pressures up to 2000 atm, corresponding to almost sonic velocities at the column outlet. Fig. 4 shows plots of the efficiency (ratio of H to diameter) of a capillary column, coated with an adsorbent[53], against the Re number. It is evident that the efficiency increases sharply at the transition to the turbulent regime (the quantity H is smaller by a factor of 40 than the value expected from the conventional theory, which assumes laminar flow).

Giddings and coworkers have shown that at Re = 16 000 the speed coefficient is so high that the column generates 2500 theoretical plates per second for pentane (nitrogen carrier gas), and over 8000 theoretical plates for methane. Fig. 5 shows a chromatogram of light hydrocarbons, obtained at −74° and a column inlet pressure of 144 atm, corresponding to Re ≃ 7000.

Similar effects have been noted with packed columns[45].

III. INFLUENCE OF NON-IDEALITY IN THE GAS PHASE ON THE RETENTION OF SORBATES IN A CHROMATOGRAPHIC COLUMN

The influence of non-ideality of the carrier gas on the retention properties of sorbates was first recognised by Goldup and coworkers[54], who showed that the replacement of hydrogen by nitrogen as the carrier gas in long capillary columns operated with an inlet pressure of ~10 atm has a significant effect on the selectivity of the column towards hydrocarbon separation. The effect was ascribed[54,55] to the dependence of the coefficient Γ' upon the second virial coefficient in the equation of state of the gaseous mixture of sorbate and carrier gas. This dependence stems from the familiar expression[56]

$$\Gamma = \Gamma^0 e^{\beta P} \qquad (18)$$

where the coefficient Γ^0 corresponds to $P \to 0$, and β is a coefficient whose value depends on the non-ideality of the gas phase (see Section IV).

The present writers[57,58] have studied the chromatographic behaviour of hydrocarbons from wide petroleum fractions in capillary columns coated with octadec-1-ene and poly(ethylene glycol)-400 using inlet pressures up to 30 atm and helium, nitrogen, argon, and carbon dioxide as carrier gases.

Over that pressure range, an almost linear relationship was observed between the retention index of the sorbate and the mean column pressure, the slope $(\partial I/\partial P)_T$ being sensitive to the structure of the sorbate molecule and having different values for isoalkanes, alkenes, and aromatic hydrocarbons. This effect occasionally leads to an inversion of the elution order. In a poly(ethylene glycol) column, the retention index of alkylbenzenes changes by 30–40 units on raising the pressure to 30 atm, and this effect produces a large increase in selectivity for the separation of aromatic from aliphatic hydrocarbons.

Giddings' treatment[59] of the effect of non-ideality in the gas phase upon the retention characteristics is based on the expression

$$RT\left(\frac{\partial \ln \Gamma}{\partial P}\right)_T = -\delta V_1^0 \qquad (19)$$

where δV_1^0 is the change in partial molar volume of the sorbate on transfer from the liquid to the gas phase. Thus, whereas two sorbates may have practically identical retention characteristics ($\Gamma_1 = \Gamma_2$) at low pressures, it is possible to obtain a selectivity coefficient ($k_S = \frac{\Gamma_2 - \Gamma_1}{\Gamma_1}$) large enough for sharp separation by raising the pressure, provided that the δV_1^0 values for the two sorbates are sufficiently different. Integration of Eqn. (19) gives

$$k_s = -P\Delta(\delta V_1^0)/RT \qquad (20)$$

where $\Delta(\delta V_1^0)$ is the difference between the δV_1^0 values for the sorbates.

Thus, for example, if $k_S = 0.1$ is taken to give an acceptable separation of the sorbates, a pressure of the order of 500 atm is needed to achieve that value at $T = 300°K$ and for $\Delta(\delta V_1^0) = 5$ cm^3 mole^{-1}.

Of course, the latter expression must be used in conjunction with Eqn. (17), which describes the increase in separation with pressure for a constant selectivity coefficient.

Since increase of pressure is accompanied by an increase in the concentration of the sorbate in the gas phase, and therefore by a decrease in the distribution coefficient, the possibility arises of chromatographic analysis of substances whose volatility is insufficient for elution under normal conditions and also of compounds which are unstable at elevated temperatures.

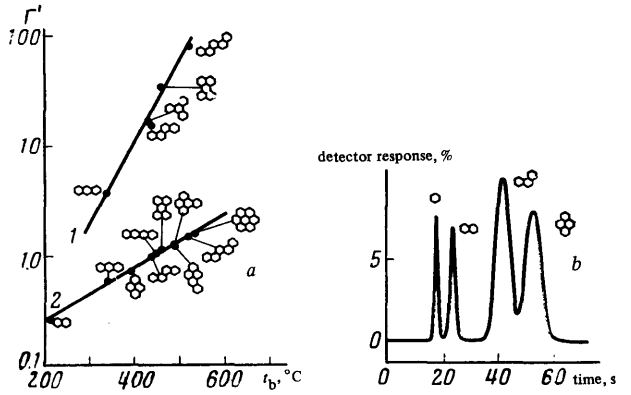

Figure 6. Separation of condensed polynuclear aromatic compounds by fluid chromatography. (*a*) Distribution coefficient against boiling point of the sorbates: *1*) High-temperature (460°) gas chromatography; adsorbent—aluminium oxide treated with NaOH; carrier gas—helium at 1.5 atm. *2*) Fluid-adsorption chromatography at 245°; adsorbent—unmodified aluminium oxide; fluid—isopropanol. (*b*) Fluid-adsorption chromatography; adsorbent—aluminium oxide; temperature 213°; pressure 50 atm.[18,60,61]

Thus, Klesper and coworkers[12] were able to elute from a chromatographic column a mixture of porphyrins, which were thermally unstable at temperatures above 150–170°, by using a mobile phase of Freons under supercritical conditions (150–170°, pressure up to 136 atm). Subsequently, Sie and Rijnders[18,60-62] made a detailed study of eluents (pentane, isopropanol, and diethyl ether) under supercritical conditions, and developed the method of "fluid" chromatography, by which they were able to analyse polynuclear aromatic hydrocarbons and other compounds with boiling points up to 600°. The volatility of the solvates increased by a factor of 10^3–10^4 under their conditions.

Fig. 6*a* shows plots of the coefficient Γ against the boiling point of the sorbate. It is evident that the increase in volatility on going to supercritical conditions is most marked for the heaviest sorbates. The elution of a mixture of benzene, naphthalene, phenanthrene, and pyrene on an aluminium oxide column at 213° and 50 atm (eluent: n-pentane) was completed in ~1 min (Fig. 6*b*).

Giddings and coworkers[13-15] used carbon dioxide and ammonia at supercritical temperatures and pressures up to 2000 atm as eluents. They observed the migration, along a column, of compounds with a molecular weight up to 400 000. The increase in the volatility of the sorbates in this case was of the order of 10^6.

The density of the mobile phase is one of the most important factors determining the solubility of sorbates in the mobile phase‡. Giddings and coworkers[15] considered the relationship between the density of the eluent and its solvent power. They used the Hildebrand solubility parameter[63] δ, whose magnitude can be defined as

$$\delta = 1.25 \cdot P_{cr}^{0.5} \cdot \rho/\rho_{liq}, \qquad (21)$$

where P_{cr} is the critical pressure, ρ is the density of the eluent, and ρ_{liq} is the density of the eluent in the liquid-like state. On reaching the density of the liquid (at pressures of the order of 1000 atm) the solubility parameter reaches its maximum value $\delta_{liq} = 1.25\, P_{cr}^{0.5}$. Assuming δ to be the same for a liquid and for a gas having the density of the liquid,

$$\delta = \delta_{liq} \cdot \rho/\rho_{liq} \qquad (22)$$

Thus, the nature of the eluent and its specific and non-specific interactions with the sorbate play a very important role in high-pressure chromatography, when the solubility of the sorbate in the mobile phase is comparable with its solubility in the stationary phase. For example, when helium is used as the eluent no appreciable change in the volatility of the sorbates is noted up to 2000 atm.[14,15] Migration of Ni-etioporphyrin II and etioporphyrin II has been observed[12] only in dichlorodifluoromethane at 68 atm and monochlorodifluoromethane at 95 atm. These compounds could not be made to migrate in other Freons. Dichlorodifluoromethane has been used also in the analysis of other metal complexes[64]. The use of ethylene as an eluent has been patented[67].

Since the density of the eluent in the supercritical state increases with pressure but decreases with temperature, it is desirable to work at temperatures only just above the critical temperature and at the highest possible pressures. Fig. 7 shows plots of the effect of temperature on the retention of sorbates[18]. Initially, because of the fast decrease in the density of the eluent with temperature, the solubility of the sorbate in the eluent decreases faster than its solubility in the stationary phase (or its adsorbability), and the distribution coefficient increases. At higher temperatures, however, when the density of the eluent has become low enough, the temperature dependence of the solubility of the sorbate in the stationary phase becomes

‡ For this reason, Giddings suggested the name "density chromatography" for this method[15].

predominant, leading to the decrease in retention with increase of temperature commonly observed in chromatography.

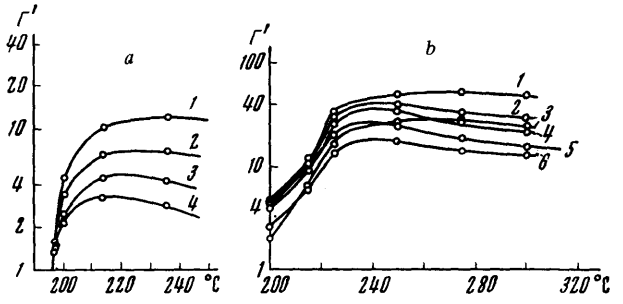

Figure 7. Effect of temperature on the retention of sorbates under fluid chromatography conditions. (*a*) Stationary phase poly(ethylene glycol)-6000 (~23 wt.% on Sil-O-Cel), fluid—n-pentane, pressure 35 atm: *1*) dioctyl phthalate, *2*) dihexyl phthalate, *3*) dibutyl phthalate, *4*) diethyl phthalate[18]. (*b*) Adsorbent—aluminium oxide, fluid—n-pentane, pressure 40 atm: *1*) 10-phenylanthracene, *2*) pyrene, *3*) 1,1-binaphthyl, *4*) 2-phenylnaphthalene, *5*) anthracene, *6*) phenanthrene[60].

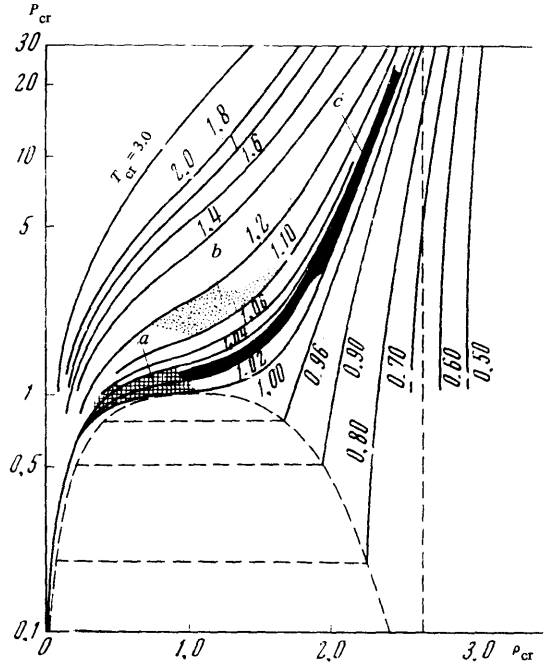

Figure 8. Phase diagram (P_{cr}–ρ_{cr}): *a*) working region of Sie and coworkers[18,60,61], *b*) working region of Klesper and coworkers[12,64], *c*) working region of Giddings and coworkers[13–15].

The diagram shown in Fig. 8 allows the chromatographic conditions used by different workers to be compared. Thus, Sie and coworkers[18,60,61] worked under conditions corresponding to a solubility parameter (δ) for the mobile phase in the range 0.9–2.8. Klesper and his coworkers[12,64] used values of δ between 2.4 and 4.5. On the other hand, Giddings and coworkers[13–15], who worked at pressures up to 2000 atm, obtained gas densities of carbon dioxide (at 40°) and ammonia (at 140°) close to the densities of the corresponding liquids and thus achieved δ values as high as 10. By using these dense eluents they induced migration along the column of compounds such as carotenoids, corticosteroids, nucleotides, carbohydrates, and various polymers. They showed that whereas ammonia (which tends to form hydrogen bonds) has the higher affinity for compounds with hydroxyl and amino groups, carbon dioxide is a better solvent for sorbates showing dispersion and donor–acceptor types of interaction, and can therefore be used to analyse terpenes, polyglycols, esters, alkanes, etc.[13–15] Figs. 9*a* and 9*b* are chromatograms of glycine derivatives and carotenes in dense ammonia and carbon dioxide respectively. The critical parameters of the substances used as eluents are listed in Table 1.

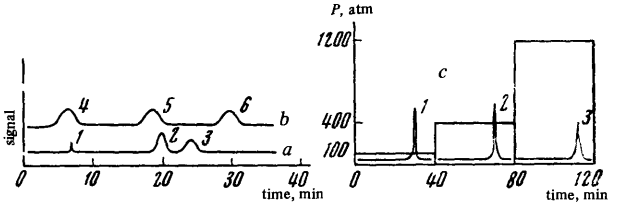

Figure 9. Migration of high-molecular-weight compounds in dense ammonia and carbon dioxide gas. (*a*) Separation in dense carbon dioxide at 500 atm. Column 1.5 m long, filled with 15% of poly(propylene glycol): *1*) air peak, *2*) β-carotene, *3*) α-carotene. (*b*) Separation in dense ammonia at 200 atm. Column 1.5 m long, filled with Porasil B: *4*) glycine, *5*) glycyl glycine, *6*) glycyl-lysyl-tyrosine. (*c*) Separation by a stepped pressure programme, using carbon dioxide at 40°: *1*) squalane, *2*) dinonyl phthalate, *3*) SE-30 silicone rubber (M = 400 000).[13–15]

Table 1. Critical parameters of fluids and working conditions of the columns.

Fluid	T_{cr}, °C	P_{cr}, atm	ρ_{cr}, g cm^{-3}	Working conditions		
				T, °C	P, atm	Refs.
Ammonia	132.3	111.5	0.235	140	< 200	13–15
Carbon dioxide	31.1	75.3	0.468	40	< 2000	13–15
Ethylene	9.90	50.3	0.211	20	100	67
Monochlorodifluoromethane	96	48.71	0.525	150–170	< 136	12
Dichlorodifluoromethane	111.5	40.61	0.558	130–160	< 210	12,64–66
Isopropanol	235.25	47.02	0.2727	245	45–50	18,60–62
Diethyl ether	193.61	36.27	0.2663	200	38–50	62
n-Pentane	196.62	33.31	0.238	213	35–50	18,60–62

By comparing the solvent powers of liquids and dense gases in the liquid-like state (Fig. 10)[14] we may conclude that dense carbon dioxide and ammonia are among the most powerful solvents. Thus, Giddings and coworkers[15] found that in the pentane–carbon dioxide system the solubility parameter δ of the dense eluent could be made greater than the corresponding parameter for the sorbate in the condensed state ($\Delta = \delta/\delta_0 = 1.37$). The same group

showed[15] that a threshold pressure exists at which the concentration of involatile compounds in the mobile phase becomes high enough for detection. Further increase in pressure accelerates the rate of migration of the sorbate.

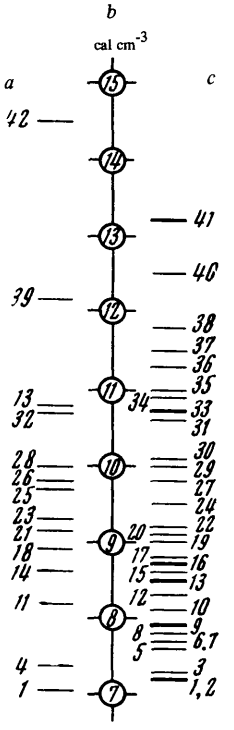

Figure 10. Schematic of (*c*) of the solvent power of gases compressed to a liquid-like state in comparison with (*a*) conventional solvents. (*a*) *1*) n-pentane, *4*) diethyl ether, *11*) cyclohexane, *14*) carbon tetrachloride, *18*) toluene, *21*) benzene, *23*) chloroform, *25*) ethyl acetate, *26*) acetone, *28*) dioxan, *32*) pyridine, *13*) isopropanol, *39*) ethanol, *42*) methanol. (*c*) Gases in the liquid-like state: *1*) n-pentane, *2*) nitrogen, *3*) carbon monoxide, *4*) sulphur hexafluoride.

Thus, in a stream of carbon dioxide the threshold pressure for $C_{18}-C_{36}$ n-alkanes is 87–105 atm, whereas for $C_{11}-C_{18}$ alcohols in a stream of ammonia it is 60–100 atm. Even the substances which are commonly used as stationary phases in gas chromatography can be eluted in a stream of dense carbon dioxide: squalane at 100 atm, dinonyl phthalate at 400 atm, poly(propylene glycol) at 700 atm, SE-30 silicone rubber with a molecular weight of 400 000 at 1200 atm, and Apiezon L at 1500 atm.

Data of this type, describing the migration of various compounds in dense ammonia at 140° and in dense carbon dioxide at 40°, are given in Table 2. At the threshold pressure, the following relationship was observed between the parameter Δ and the distribution coefficient Γ:

$$\Delta = 1 - \left(\frac{RT}{V_1^0\delta_0^2}\ln\Gamma\right)^{0.5} \qquad (23)$$

where V_1^0 is the molar volume of the liquid sorbate.

By analogy with temperature programming for the analysis of substances of widely differing volatilities, a stepwise pressure programme can be devised. Thus, Fig. 9*c* shows a chromatogram for the separation of squalane, dinonyl phthalate, and SE-30 silicone in carbon dioxide, carried out in pressure steps of 40 min duration[15].

++Strong migration; + weak migration; —undetectable migration; *threshold pressure.

The choice of mobile and stationary phases for the separation of multicomponent mixtures has been discussed by Sie and Rijnders[18,60,61]. Thus, if the sorption capacity of the stationary phase is high, the elution of homologues is determined by the molecular weight (see *a*, *b*, and *c* in Fig. 11). But if the sorbate and the fluid are polar and the sorbent is non-polar, or vice-versa, the retention characteristics of the homologues become very similar (*d* and *e* in Fig. 11).

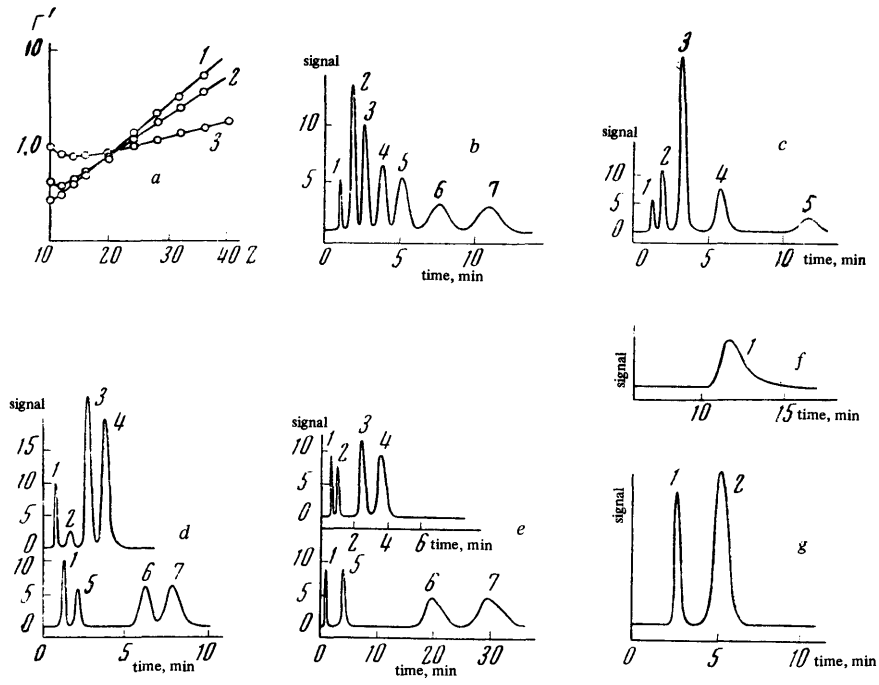

Figure 11. Separation of high-molecular-weight aromatic hydrocarbons in sorbate–fluid–stationary phase systems.

(*a*) Retention of dialkyl phthalates in: *1*) fluid—isopropanol, stationary phase—low-molecular-weight polyethylene; *2*) fluid—n-pentane, stationary phase—low-molecular-weight polyethylene; *3*) fluid—n-pentane, stationary phase—poly(ethylene glycol)-6000. n-Pentane at 213° and 42 atm, isopropanol at 245° and 49.5 atm. Polyethylene (~10 wt. %) and poly(ethylene glycol)-6000 (~23 wt. %) on Sil-O-Cel. *Z* is the number of carbon atoms in the phthalate molecule.

(*b*) Separation of phthalates according to molecular weight. Column length 2 m, inner diameter 6 mm, filled with polyethylene (~10 wt. %) on Sil-O-Cel. Fluid—isopropanol, temperature 245°, pressure 49.5 atm. *1*) Benzene, *2*) dihexyl phthalate, *3*) dioctyl phthalate, *4*) didecyl phthalate, *7*) dihexadecyl phthalate.

(*c*) Separation of some condensed aromatic hydrocarbons on an alumina-packed column. *1*) Benzene, *2*) naphthalene, *3*) phenanthrene, *4*) 1,2-benzanthracene, *5*) picene. Fluid—isopropanol at 245° and 45.2 atm; adsorbent—aluminium oxide.

(*d*) Separation of bi- and triaryl isomers. *1*) Benzene, *2*) biphenyl, *3*) *o*-terphenyl, *4*) *p*-terphenyl, *5*) naphthalene, *6*) 1,1′-binaphthyl, *7*) 2,2′-binaphthyl. Fluid—isopropanol at 245° and 45 atm; adsorbent—aluminium oxide.

(*e*) Separation of close-boiling polynuclear aromatic hydrocarbons. *1*) Benzene, *2*) naphthalene, *3*) phenanthrene (T_b = 336.8°), *4*) anthracene (T_b = 339.9°), *5*) pyrene, *6*) 3,4-benzpyrene (T_b = 495°), *7*) 1,2-benzpyrene (T_b = 493°). Fluid—n-pentane at 200° and 39.8 atm.

(*f*) Shape of the *m*-terphenyl peak (T_b = 364°) under conditions of high-temperature gas-adsorption chromatography. Carrier gas—helium; adsorbent—aluminium oxide treated with NaOH; temperature 350°; pressure 1.5 atm.

(*g*) Separation of *m*- and *p*-terphenyl (T_b = 576°) under conditions of fluid-adsorption chromatography. Fluid—isopropanol at 245° and 50 atm; adsorbent—aluminium oxide[18,60-61].

When considering the retention of sorbates at high pressures it is important to allow for eluent–sorbent interactions. Thus, solubility of the eluent in the stationary phase leads to the formation of a binary phase in gas–liquid chromatography[58]. In the gas-adsorption variant, if both the adsorbent and the eluent are polar the active centres on the surface of the adsorbent are deactivated by eluent molecules, which improves the symmetry of the chromatographic peaks and shortens the elution time. If a non-polar eluent is used, it is possible to add small amounts of a polar substance to the eluent.

In principle, one can define conditions such that the adsorbed eluent acts as a stationary phase and the retention is determined by the difference between the solubility parameters of the sorbate in one and the same compound in the liquid and the gaseous state respectively.

Chromatograms of polyphenyls are shown on Figs. 11*f* and 11*g*. They were obtained at high temperature (350°) on a column packed with alkali-modified alumina, and also by fluid-adsorption chromatography in a stream of isopropanol at 245° and 50 atm in a column packed with unmodified alumina. In the latter experiment, peaks from the heavier hydrocarbon were detected[61]. The influence of modification was observed also with adsorbents consisting of porous polymers[62].

Of course, the range of stationary phases which can be used at high pressures is limited, because of the increase in volatility at high pressure, and the choice of liquid stationary phase must taken account of the threshold pressure (see Table 2). A study of the stability of stationary phases in a stream of dichlorodifluoromethane[64] showed that poly(propylene glycol) and Apiezon M are lost from the column in a few minutes, and SE-52 silicone slowly volatilises. Nitrile silicone rubber was found to be stable up to 210 atm; Kel-F (polytrifluorochloroethylene) and some other phases were not eluted at all.

With pentane and isopropanol as eluents, polyglycols and low-molecular-weight polyethylene were used as stationary phases[18]; silicone rubbers, polysulphone, polystyrene, Apiezon, and some other stationary phases did not migrate in a stream of ammonia[13–15].

Detection can present some serious difficulties when chromatographic analysis is attempted in a stream of dense gas. Kobayashi and coworkers[68–70] used a katharometer and a radioactivity counter (because their sample was radioactive), both working at atmospheric pressure. However, at elevated pressure the use of a katharometer becomes unattractive because of the decreased sensitivity and the noise from density fluctuations and mechanical vibrations. The thermal conductivity of "fluids" is usually not very different from that of the sorbates. Klesper and coworkers[64] used a flow-through spectrophotometer cell working at pressures up to 100 atm.

Sie and coworkers[18,60–62] used a different method of detection. Their apparatus included a condensing system for the eluent, which was then led as a liquid to a quartz u.v. cell sensitive to aromatic compounds.

Lastly, the eluate from the column has been split into two streams[39,71–73], the main stream being discharged to the atmosphere and the remainder led to a flame-ionisation detector. In this method, of course, one must beware of condensation of high-boiling sorbates upstream from the detector. For this reason, Giddings[15] suggests pyrolysis of the eluate, followed by chromatographic or mass-spectrometric analysis of the resulting low-molecular products.

Data on the methods of detection, and also on the methods of introducing the eluent, used by various authors, are listed in Table 3.

IV. DETERMINATION OF PHYSICOCHEMICAL CONSTANTS OF COMPOUNDS BY GAS CHROMATOGRAPHY AT HIGH PRESSURES

Phase equilibria at high pressures and non-ideality of the gas phase can be studied by chromatographic methods only if strict correlations between the unknown parameters and the retention characteristics of the sorbate are available, with due allowance for the effect of pressure on the velocity distribution, on the viscosity of the eluent, and on the distribution coefficient of the sorbate, and also on the solubility of the carrier gas in the stationary phase[34,36,41,55,56,69,71,74–87].

Table 3. High-pressure chromatography conditions.

Expt. No.	Eluent, and maximum column pressure	Method of adding eluent	Method of sample injection	Detector, pressure	Refs.
1	Light gases, 25 atm	Gas cylinder, regulator, valve	Gas pipette, evacuated and filled with sample vapour. Sample injected in a stream of carrier gas	Flame-ionisation detector. Atmospheric pressure	71
2	Light hydrocarbon mixture 68 atm	Gas cylinder, regulator, valve	Piston injector	Katharometer, radio activity detector. Atmospheric pressure	68
3	Isopropanol, diethyl ether, n-pentane, 50 atm	Liquid, entrained by nitrogen, heated to T_{cr}	Pneumatic apparatus with a sample recess. Sample size: 15 μl of 0.1–1 wt.% soln.	Quartz u.v. cell. Eluate in liquid phase. Atmospheric pressure	18 60–62
4	Freons, 210 atm	Compressor	Solution of sample placed on glass piston. Solvent evaporated, piston inserted in sample injector, temperature and pressure raised, valve between injector and column opened	Flow-through spectrophotometer cell operating at column pressure	12 64–66
5	Gases in supercritical state, 2000 atm	High-pressure compressor	Bypass system with high-pressure valves	Flame-ionisation detector. Atmospheric pressure	13–15

For an ideal gas we have the law

$$\alpha = -\frac{K}{\eta} \cdot \frac{dP}{dl}, \tag{24}$$

where α is the linear velocity, η is the dynamic viscosity of the carrier gas, K is the permeability coefficient, dl is an element of length. It follows that the average pressure along the length of the column is

$$p = \frac{\int_0^L P\,dl}{\int_0^L dl} = \frac{\int_{P_0}^{P_1} -\frac{KP^2\,dP}{\eta P_0 \alpha_0}}{\int_{P_0}^{P_1} -\frac{KP\,dP}{\eta P_0 \alpha_0}} = \frac{\int_{P_0}^{P_1} P^2\,dP}{\int_{P_0}^{P_1} P\,dP} = \frac{2}{3} P_0 \frac{(P_1/P_0)^3 - 1}{(P_1/P_0)^2 - 1} = \frac{P_0}{j}, \tag{25}$$

where α_0 is the velocity of the gas at the outlet of the column of length L, j is the pressure gradient factor§ [see Eqn. (4)]. The effective retention volume (corrected for the dead volume of the column and reduced to the mean pressure), which is related to the distribution coefficient of the sorbate between the stationary and the mobile phase, is given by

$$\bar{\bar{V}}_N = (t_R - t_0) V_\alpha J_3^2, \tag{26}$$

where t_R is the retention time of the sorbate, t_0 is the retention time of the non-adsorbed gas, and V_α is the volumetric velocity of the gas at the column outlet. The distribution of pressure along the length of the column is

$$\frac{l}{L} = \frac{P_1^2 - P^2}{P_1^2 - P_0^2}, \tag{27}$$

where the pressure P corresponds to a cross-section at a distance l from the inlet of the column (see Fig. 12).

However, if the pressure is averaged over the dwell time of the sorbate in the column rather than along the length, and noting that $dt = \frac{\Gamma_0}{\alpha} dl$, where Γ_0 is the Henry coefficient[88], the following expression is obtained:

$$\bar{P} = \frac{\int_0^{t_R} P\,dt}{\int_0^{t_R} dt} = \frac{\int_{P_0}^{P_1} -\frac{KP\Gamma_0}{\eta\alpha^2}\,dP}{\int_{P_0}^{P_1} -\frac{K\Gamma_0}{\eta\alpha^2}\,dP} = \frac{\int_{P_0}^{P_1} \frac{P^3\,dP}{\alpha_0^2 P_0^2}}{\int_{P_0}^{P_1} \frac{P^2\,dP}{\alpha_0^2 P_0^2}} = \frac{3}{4} P_0 \frac{(P_1/P_0)^4 - 1}{(P_1/P_0)^3 - 1} = \frac{P_0}{j}, \tag{28}$$

where $j = J_4^3$, and the time-averaged effective retention volume is

$$\bar{V}_N = (t_R - t_0) V_\alpha \cdot J_4^3. \tag{29}$$

It can be shown that $J_3^2 J_4^3 = \chi^2$ [see Eqns. (4) and (25)], and $\bar{P}/\bar{\bar{P}} = J_3^2 J_3^4 = j^2/\chi^2$ [see Eqns. (4), (25), and (28)].

Eqns. (25) and (28) were deduced on the assumption that η and Γ_0 are constant and $P\alpha = P_0\alpha_0$ along the column.

Martire and Locke[75] determined the mean pressure of a non-ideal gas from the expression

$$P\alpha = (P\alpha)_{id}(1 + a_1 P) \tag{30}$$

Here the product $(P\alpha)_{id}$ corresponds to an ideal gas, $a_1 = \frac{B_{22}}{RT}$, and B_{22} is the second virial coefficient in the equation of state for the carrier gas.

In this case integration gives

$$\bar{\bar{P}} = \bar{\bar{P}}_{id} \frac{1 - a_1 P_0 J_3^4}{1 - a_1 P_0 J_2^3} \approx \bar{\bar{P}}_{id}[1 - a_1 P_0 (J_3^4 - J_2^3)] \tag{31}$$

§ In Everett's terminology[56], we assume

$$J_n^m = \frac{n}{m} \frac{(P_1/P_0)^m - 1}{(P_1/P_0)^n - 1}.$$

and

$$j \approx j_{id}[1 + a_1 P_0 (J_3^4 - J_2^3)]. \tag{32}$$

Giddings and coworkers[36] applied Eqn. (30) together with a relationship between viscosity and pressure:

$$\eta = \eta_{id}(1 + b_1 P) \tag{33}$$

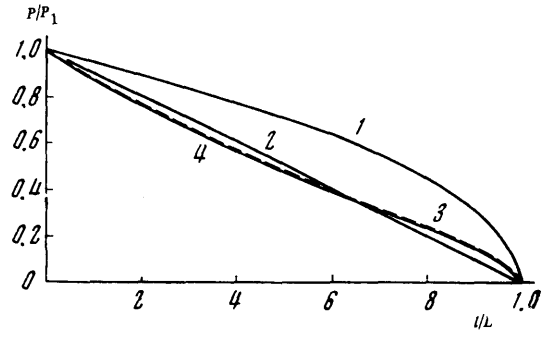

Figure 12. Pressure profile along column. Inlet pressure 1960 atm, outlet pressure 1 atm. *1*) Ideal gas, *2*) liquid, *3*) argon, *4*) nitrogen. Temperature 25°.[41]

The resulting expressions have the form

$$\bar{\bar{P}} \approx \bar{\bar{P}}_{id}[1 - (a_1 + b_1) P_0 (J_3^4 - J_2^3)] \tag{34}$$

and

$$j \approx j_{id}[1 + a_1 P_0 (2J_3^4 - J_2^3 - 1) + b_1 P_0 (J_3^4 - J_2^3)]. \tag{35}$$

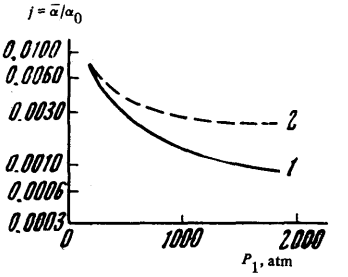

Figure 13. Correction $j = \bar{\alpha}/\alpha_0$ for: *1*) an ideal gas and *2*) nitrogen at pressures up to 2000 atm. Pressure at column outlet 1 atm, temperature 25°. (Constant Γ assumed.)[36]

The pressure profile in real gases is shown[41] in Fig. 12. The quantities j_{id} and j for nitrogen at 25° are compared[36] in Fig. 13. Lastly, Fig. 14 shows[36] the effect of pressure on the ratio $\bar{P}/\bar{\bar{P}}$, which is a correction to the term H in the equation, giving the contribution of diffusion in the gas phase to the height equivalent to a theoretical plate.

The change with pressure of the distribution coefficient Γ of the sorbate can be taken into account by using a linear [55,74]

$$\Gamma = \Gamma^0(1 + \beta P) \tag{36}$$

or a logarithmic [77]

$$\ln \Gamma = \ln \Gamma^0 + \beta P \tag{37}$$

correlation [see Eqn. (18)]. Here Γ^0 is the distribution coefficient extrapolated to zero pressure:

$$\ln \Gamma^0 = \ln \frac{RT}{\gamma_1^\infty V_3 P_1^0} - \frac{B_{11} - V_1^\infty}{RT} P^0, \tag{38}$$

$$\beta = \frac{2B_{12} - V_1^\infty}{RT}, \tag{39}$$

where γ_1^∞ is the activity coefficient of the sorbate at infinite dilution in the pure stationary phase, V_1^0 and V_1^∞ are the molar volume of the liquid sorbate and the partial molar volume of the sorbate at infinite dilution in the stationary phase respectively, V_3 is the molar volume of the pure stationary phase, P_1^0 is the saturated vapour pressure of the sorbate, B_{11} is the second virial coefficient of the sorbate vapour, B_{12} is the second mixed virial coefficient for the interaction between sorbate vapour and carrier gas.

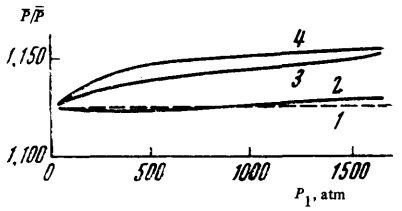

Figure 14. Plots of $\overline{P}/\overline{\overline{P}}$ against pressure at column inlet P_1 for: *1*) ideal gas, *2*) hydrogen, *3*) nitrogen, *4*) argon. Outlet pressure 1 atm, temperature 25°. [36]

Here, and elsewhere in this Review, the subscripts 1, 2, and 3 denote the sorbate, the carrier gas, and the stationary phase respectively.

Windsor and Young [79] obtained an expression for the effective retention volume in terms of the factor β:

$$V_N = \frac{\dfrac{\Gamma^0 V_3 J_3^2}{P_0}\left[\dfrac{e^{\beta P}}{\beta^3}(\beta^2 P^2 - 2\beta P + 2)\right]_{P_1}^{P_0}}{0.5\,[P^2]_{P_1}^{P_0}}, \tag{40}$$

and showed that this expression can be replaced, without significant loss of precision, by a much simpler expression of the type

$$\ln \overline{V}_N = \ln V_N^0 + \beta P_0 J_3^4 \tag{41}$$

(Desty and coworkers [55] used the factor J_3^2, and hence determined the quantity $\overline{\overline{V}}_N$.)

Cruickshank and coworkers [71,80], and also Giddings and coworkers [36], allowed for all three non-ideality factors (a_1, b_1, and β) simultaneously, but their final expressions were unwieldy.

Trestianu [89,91] systematised the published relationships between retention characteristics and column pressure. His results are summarised in Table 4.

Solubility of the carrier gas in the stationary phase is another possible source of variation in retention characteristics. Allowing for this factor, the expression for the effective retention volume at pressures where the third virial coefficient plays a significant role takes the form [80,81,92]

$$\ln V_N = \ln V_N^0 + \beta' P_0 J_3^4 + \zeta' (P_0 J_3^4)^2,$$

where

$$\beta' = \beta + \lambda\left[1 - \frac{\partial \ln \gamma_1^\infty}{\partial x_2}\right]_0,$$

$$\zeta' = \frac{3C_{122} - 4B_{12}B_{22}}{2RT} + \varphi\left[1 - \frac{\partial \ln \gamma_1^\infty}{\partial x_2}\right]_0 + \frac{\lambda^2}{2}\left[1 - \frac{\partial^2 \ln \gamma_1^\infty}{\partial x_2^2}\right]_0 + \frac{kV_1^\infty}{R\Gamma} \tag{42}$$

$\partial\gamma_1^\infty/\partial x_2$ is the change in the activity coefficient of the sorbate in the stationary phase with mole fraction x_2 of dissolved carrier gas, C_{122} is the third virial coefficient for the interaction between the sorbate and the carrier gas, k is a coefficient, λ and φ are constants in the series expansion of the mole fraction x_2 of the carrier gas dissolved in the stationary phase [81]: $x_2 = \lambda P + \varphi P^2 + \ldots$

Table 4. Expressions for j and V_N with allowance for non-ideality of the system [89].

Non-ideality $P\cdot\alpha$	Non-ideality η	Non-ideality Γ	j	V_N	Refs.
—	—	+	J_3^2	$\ln \overline{V}_N = \ln V_N^0 + \beta P_0 J_2^3$	55
—	—	+	J_3^2	$\overline{V}_N = V_N^0(1 + \beta P_0 J_3^4)$	56
+	—	—	$J_3^2[1 + a_1 P_0 (J_3^4 - J_2^3)]$	—	75
+	—	+	$J_3^2[1 + a_1 P_0 (2J_3^4 - J_2^3 - 1)]$	$\ln \overline{V}_N = \ln V_N^0 + \beta P_0 J_3^4$	77
+	+	+	$J_3^2[1 + a_1 P_0 (2J_3^4 - J_2^3 - 1) + b_1 P_0 (J_3^4 - J_2^3)]$	$\ln \overline{\overline{V}}_N = \ln V_N^0 + \beta P_0 J_2^3[1 - P_0 (a_1 + b_1)(J_3^4 - J_2^3)]$ $\ln \overline{V}_N = \ln V_N^0 + \beta P_0 J_3^4[1 - P_0 (2a_1 + b_1)(J_4^5 - J_3^4)]$	36

The general form of the gas solubility correction is

$$\exp\left[\left(\frac{\partial \ln \gamma_1^\infty}{\partial x_2}\right)_0 (\lambda P + \varphi P^2 + \ldots) + \frac{1}{2}\left(\frac{\partial^2 \ln \gamma_1^\infty}{\partial x_2^2}\right)_0 \cdot (\lambda^2 P^2 + \ldots) + \ldots\right].$$

Eqns. (37)–(42) suggest the possibility of determining by a chromatographic method the activity coefficients of sorbates dissolved in the stationary liquid, corrected for the non-ideality of the gas phase (γ_1^∞). Since $V_N = \omega\Gamma$, where ω is the volume of the stationary liquid in the column, the quantity γ_1^∞ can be evaluated by extrapolation of the effective retention volume to zero mean pressure, followed by a correction for the non-ideality of the pure sorbate [second term on the right-hand side of Eqn. (38)]. The mean pressure is expressed as $P_0 J_3^4$.

Chromatographic determinations of activity coefficients from retention characteristics measured at pressures of 12–15 atm (where the influence of the third virial coefficient is not appreciable) have been reported [80,93–101]. Some workers have used several carrier gases in order to achieve greater precision.

The ordinate of the intersection of the linear plots for a single sorbate but different carrier gases (Fig. 15) defines the quantity V_N^0, which is independent of the nature of the chosen eluent. The precision of the chromatographic method of determining γ_1^∞ is evident from Table 5,

where the results are compared with data obtained by the static method.

Locke and Brandt[101] have calculated virial coefficients from the results of experiments at low pressures.

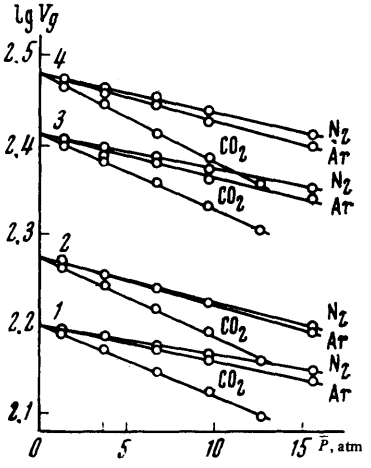

Figure 15. Logarithm of absolute specific retention volume against mean column pressure at 80° in nitrogen, argon, and carbon dioxide for: *1*) dioxan, *2*) n-octane, *3*) toluene, *4*) butyl acetate[73].

Pomazanov and Semkin[102] have determined the activity coefficients of sorbates of different types with a correction for non-ideality of the gas phase, calculated from experiments in columns with a different stationary phase. They were able to show the existence, in an experiment with a homologous series of n-alkanes and a stationary phase of squalane, of a real or hypothetical (i.e. with a non-integral number of carbon atoms) component such that the corrections for B_{11} and B_{12} are mutually compensating and $\gamma^{\infty} = \gamma$.

Table 5. Activity coefficients of hydrocarbons in dinonyl phthalate at 30°. Nitrogen carrier gas[74].

Sorbate	lg γ	lg γ∞	lg γ∞ (static results)
Benzene	—0.250	—0.253	—0.253
n-Pentane	0.022	0.034	0.035
n-Hexane	0.080	0.077	0.076
2,2-Dimethylbutane	0.098	0.103	0.095
Cyclohexane	—0.031	—0.032	—0.032
n-Heptane	0.123	0.117	0.114
n-Octane	0.161	0.153	0.153

Plots like those shown in Fig. 15 enable the second virial coefficients B_{12} for the interaction between sorbates and carrier gases to be determined, since the slope of the linear plot gives the parameter β in Eqns. (37) and (41). Data of this type are not freely available in the literature.

Expanding the compressibility coefficient of the gas mixture in a power series of $1/V$ (where V is the molar volume of the gas mixture)

$$Z = 1 + \frac{B}{V} + \frac{C}{V^2} + \ldots, \tag{43}$$

B and C being the second and third virial coefficient, related to the interaction energy of two and three molecules respectively, we obtain the expression

$$B = x_1^2 B_{11} + 2x_1 x_2 B_{12} + x_2^2 B_{22}, \tag{44}$$

where x_1 and x_2 are the mole fractions of components 1 and 2 in the mixture.

Desty and coworkers[55] used the expression

$$\ln V_N = \ln V_N^0 + \beta P_0 J_2^3, \tag{45}$$

to determine B_{12} for several hydrocarbons mixed with helium, hydrogen, nitrogen, or carbon dioxide in capillary columns with large pressure drops. However, Cruickshank and coworkers have shown[77] that these calculations are subject to large errors and can only be justified if the pressure drop is small. Hence, many other workers have used Eqn. (41) to determine second virial coefficients[72,73,93-96].

Their results (see Table 6) are in good agreement with values obtained by static measurements[103-105]. A number of conclusions regarding the validity of various methods of computing B_{12} have been made from these results. Thus, it has been shown[93,98] that in calculations using the principle of corresponding states the pseudo-critical temperature should be determined by Hudson and McCoubrey's method[107] rather than as the geometric mean of the critical temperatures of the components. It has been shown, also, that Lewis and Randall's rule[108]

$$B_{12} = 0.5(B_{11} + B_{22}) \tag{46}$$

is incorrect.

Semkin and Vigdergauz[73] have noted an approximately linear relationship between B_{12} and the number of carbon atoms in n-alkane molecules, which applies over a range of temperatures and for a number of carrier gases (Fig. 16).

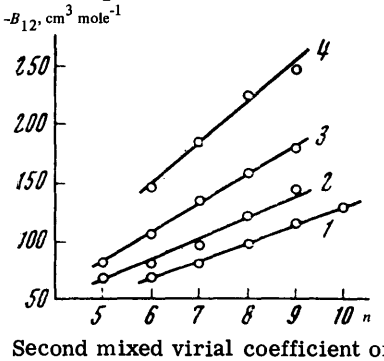

Figure 16. Second mixed virial coefficient of n-paraffins against number of carbon atoms in the molecule. Carrier gas: *1*) nitrogen, 80°, *2*) argon, 80°, *3*) argon, 50°, *4*) carbon dioxide, 80°.[73]

The largest error in the chromatographic determination of virial coefficients arises from the solubility of the carrier gas in the stationary phase. As shown by Everett

Table 6. Second mixed virial coefficients determined by chromatographic and by static methods

*Obtained by interpolation from retention indices.

and coworkers[93], the solubility of carbon dioxide in octadecane produces an increase of β corresponding to an increase of B_{12} of 75 cm^3 mole^{-1}. When the solubility of the eluent is appreciable, the stationary phase should be treated as a binary system, and the retention characteristics should be determined with the help of expressions derived for multicomponent stationary phases[109,110].

By taking one of the experimental sorbates as standard, it is possible to calculate[88] relative values of $\partial \ln \gamma_1^\infty / \partial x^2$ [see Eqn. (42)]. Thus, ignoring the solubility of the carrier gas, the effective value of the second mixed virial coefficient can be obtained:

$$B_{\text{eff}} = B_{12} + 0.5\lambda \left(1 - \frac{\partial \ln \gamma_1^\infty}{\partial x_2}\right) RT. \qquad (47)$$

Putting $\Delta B = B_{\text{eff}} - B_{12}$, we have

$$\Delta B_{\text{rel}} = \left(1 - \frac{\partial \ln \gamma_1^\infty}{\partial x_2}\right)_{\text{rel}}. \qquad (48)$$

The present writers have shown[87,88] that the retention indices of hydrocarbons[111] are almost linearly related to the mean pressure in the column over a range of pressures extending to at least 30 atm.

We have also proposed[72] an interpolation method of determining B_{12} from values of the retention index I:

$$\frac{\Delta I}{\Delta P} = \frac{(I_1 - 100Z)(\beta_{z+1} - \beta_z) - 100(\beta_x - \beta_z)}{b_2}, \qquad (49)$$

where $\Delta P = P_2 - P_1$, $\Delta I = I_2 - I_1$, I_1 and I_2 are the retention indices of the sorbate at column pressures P_1 and P_2 respectively,

$$\beta_i = \frac{2B_{12i} - V_{1i}^{\infty}}{2.303RT}, \quad i = x, z, z+1, \quad b_2 = \lg \frac{V_{gzP_s}}{V_{g(z+1)P_s}}$$

The latter quantity is the logarithm of the relative retention volume of n-alkanes differing by one carbon atom at pressure P_2, and i is the number of the sorbate.

Eqn. (49) allows the B_{12} coefficients to be determined with high precision if the B_{12} values for two normal alkanes are known. This method has been used to determine the second mixed virial coefficients for the interaction between the carrier gas and the components of a directly distilled light petroleum fraction (see Table 6).

In general, the best results are obtained by the interpolation method when the chosen standards are similar in structure to the experimental sorbates, because under these conditions the adverse influence of the solubility of the carrier gas in the stationary phase is minimised. Thus, benzene and styrene were chosen in a study[58] of aromatic hydrocarbons with carbon dioxide as carrier gas and poly(ethylene glycol)-400 as the stationary phase.

The calculation was made by means of the formula

$$\frac{\Delta G}{\Delta \bar{P}} = \frac{\beta^{(x)} - \beta^{(1)} - G_1(\beta^{(2)} - \beta^{(1)})}{(\lg V_N^{(2)} - \lg V_N^{(1)})_2}, \qquad (50)$$

where

$$\Delta G = G_2 - G_1, \quad \Delta \bar{P} = \bar{P}_2 - \bar{P}_1,$$

$$G = \frac{\lg V_N^{(x)} - \lg V_N^{(1)}}{\lg V_N^{(2)} - \lg V_N^{(1)}},$$

and the superscripts (x), (1), (2) correspond to the experimental sorbate and the two standard compounds. G_1 corresponds to pressure P_1, G_2 and $(\lg V_N^{(2)} - \lg V_N^{(1)})_2$ correspond to pressure P_2, and $\beta = \frac{2B_{12} - V_1^0}{2.303R}$.

The values of B_{12} obtained for alkylbenzenes are given in Table 7.

We have also proposed an interpolation method of calculating B_{12} from the linear retention index[115]

$$J = \frac{t_{Rx} - t_{Rz}}{t_{R(z+1)} - t_{RT}} + Z. \qquad (51)$$

An expression relating B_{12} to the change of linear retention index with pressure ($\Delta J/\Delta \bar{P}$) was obtained.

By analogy with the calculation based on logarithmic interpolation [Eqn. (50)], a relationship between $\Delta Q/\Delta \bar{P}$ and B_{12} was derived for compounds of similar structure on the basis of the function

$$Q = \frac{t_{Rx} - t_{R1}}{t_{R2} - t_{R1}} \qquad (52)$$

Here t_{R1} and t_{R2} are the retention times of the standards 1 and 2.

Very similar results were obtained by the two interpolation methods of calculating B_{12} (the linear and the logarithmic retention index method). This points to the desirability of using the simpler, linear functions J and Q.

Kobayashi and coworkers[68-70,82-84,112-114] studied gas–liquid equilibria in multicomponent systems including gaseous and liquid hydrocarbons. Their method consisted in introducing into a flowing mixture of sorbates a sample of an individual sorbate, either radioactive (using a radioactivity detector) or non-radioactive (using a katharometer detector). The distribution coefficient of the k-th component, equal to the ratio of its mole fractions in the gas and the liquid phase, was defined as

$$K_k = \frac{y_k}{x_k} = \frac{ZRTV_{liq}}{PV_N\left(1 - \sum \frac{y_i}{K_i}\right)}, \qquad (53)$$

where Z is the compressibility coefficient of the gas mixture, V_{liq} is the total number of moles of the liquid phase, and $\Sigma \frac{y_i}{K_i}$ is the sum of the ratios for all the components except the k-th.

Table 7. Second mixed virial coefficients (for 80°) obtained by interpolation using Eqn. (50).[58*]

Carrier gas	Ar	CO_2
Sorbate	$-B_{12}$, cm^3 mole^{-1}	$-B_{12}$, cm^3 mole^{-1}
Toluene	123	248
Ethylbenzene	138	271
p-Xylene	143	284
m-Xylene	141	282
Isopropylbenzene	148	286
o-Xylene	146	289
n-Propylbenzene	152	292
1-Methyl-3-ethylbenzene	154	309
Isobutylbenzene	159	–
1,3,5-Trimethylbenzene	160	325
s-Butylbenzene	160	312
1-Methyl-2-ethylbenzene	158	310
1,2,4-Trimethylbenzene	156	340
1-Methyl-3-propylbenzene	167	328
1-Methyl-2-isopropylbenzene	168	329
1-Methyl-4-propylbenzene	169	318
1,4-Diethylbenzene	168	342
n-Butylbenzene	168	345
1,3-Dimethyl-5-ethylbenzene	173	348
1-Methyl-2-propylbenzene	171	327

1,4-Dimethyl-2-ethylbenzene	174	348
1,3-Dimethyl-4-ethylbenzene	174	350
1,2-Dimethyl-4-ethylbenzene	177	354
1,3-Dimethyl-2-ethylbenzene	167	352
1,2-Dimethyl-3-ethylbenzene	168	349
1,2,4,5-Tetramethylbenzene	183	376
1,2,3,5-Tetramethylbenzene	183	380
1,2,3,4-Tetramethylbenzene	178	386

*Standard values of $-B_{12}$. With carbon dioxide carrier: benzene 216 cm^3 mole^{-1}, styrene 300 cm^3 mole^{-1}; with argon carrier: benzene 105 cm^3 mole^{-1}, styrene 148 cm^3 mole^{-1}.

The distribution coefficients of the light hydrocarbons have been determined in this way at pressures up to 136 atm.

Thus, gas chromatography at high pressures is potentially a very important technique both for analytical work and for the characterisation of physicochemical quantities such as the non-ideality parameters of the gas phase and the constants of phase equilibria.

Factors Determining the Optical Activity of Coordination Compounds

V.V.Dunina, E.G.Rukhadze, and A.P.Terent'ev (deceased)

Investigations of the structure of complex compounds based on analysis of the circular dichroism spectra and the dispersion of optical rotation are surveyed. A list of 124 references is included.

I. INTRODUCTION

The past five years have seen a tendency to a new, more differentiated use of circular dichroism spectra and the dispersion of optical rotation in the structural study of complex compounds. This approach is based on recognition that the rotational strength of d–d transitions of the complexing metal depends usually not on one but on a number of factors associated with different structural characteristics of the complex molecule. Accordingly, several contributions to the optical activity of a complex can in general be distinguished. Thus the configurational contribution is due to the helical, dissymmetric arrangement of multidentate ligands about the central metal ion. The conformational contribution is due to the asymmetry of an individual non-planar chelate ring. And the presence of asymmetric carbon atoms in the ligand molecule results in the appearance of a vicinal contribution. The establishment of asymmetry in the donor atoms of the ligand (N*, S*) on coordination with the metal can be regarded as a particular case of this last effect.

The additivity of the individual contributions to the optical activity of complex compounds has been proved quite regularly. It is fully justifiable to divide the total effect observed into component parts, and to distinguish each contribution as a differential curve (of the dispersion of optical rotation or, more frequently, of circular dichroism).

In order to study an actual property of a given compound (e.g. the configuration of an asymmetric carbon atom in a ligand) the corresponding differential curve (the curve of the vicinal effect) is, of course, immeasurably more useful than the overall spectrum observed. Moreover, analysis of the overall curve will definitely give misleading information in all cases in which the contributions of the dominant effect and of the effect under investigation are opposite in sign.

The present Review attempts to analyse some possible modes of inducing rotational strength in d–d transitions of metal complexes and to assess their relative effectiveness. Work published during 1964–1969 is covered. Earlier reviews on optically active coordination compounds summarise the literature of the preceding period[1-3]

or discuss only certain particular aspects of this new and promising field of investigation, e.g. present-day theory [4], problems of stereoselectivity [5], the nature of the Pfeiffer effect [6], etc.

Abbreviations often used in the text for various ligands are listed here for the convenience of the reader.

aa	anion of amino-acid
aaH	amino-acid
gly	glycine
ala	alanine
val	valine
leu	leucine
prol	proline
ox	oxalate
mal	malonate
tartr	tartrate
am	diamine
en	ethylenediamine
N-Meen	*N*-methylethylenediamine
pn	propylenediamine
phala	phenylalanine
o-phen	phenanthroline
IDA	iminodiacetate
EDDA	ethylenediaminediacetate
EDTA	ethylenediaminetetra-acetate
TMDTA	trimethylenediaminetetra-acetate
EDTP	ethylenediaminetetrapropionate
hmc	hydroxymethylenecamphor
$(sal)_2pn$	disalicylidenepropylenediamine
N-Meala	*N*-methylalanine
alada	alanine-*NN*-diacetate
tn	trimethylenediamine
chxn	*trans*-cyclohexane-1,2-diamine
tetraen	tetraethylenepentamine
penten	*NNN'N'*-tetrakis-2-aminoethylethylenediamine
sar	sarcosine

II. EFFECT OF CHELATION

Fundamental work on the chemistry of optically active organic compounds indicates that an asymmetric centre induces a quite measurable rotational strength, even if the chromophore is separated from it by two or three carbon atoms [7]. With complexes of unidentate ligands, such as *dextro*-s-butylamine and *dextro*-α-methylbutyric ester, however, the Cotton effect could not be observed in *d–d* transitions of a metal chromophore separated from the asymmetric centre by only one or two atoms [8].

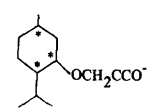
Mercury complexes containing an asymmetric carbon atom directly attached to the metal were investigated on the assumption that the asymmetrising effect falls away with distance more rapidly in coordination compounds than in organic compounds. However, measurements of circular dichroism did not reveal bands above 220 nm with *dextro*-s-butylmercuric bromide, chloride, and quinolin-8-oxide [9]. On the other hand, this was a somewhat unfortunate choice, since the Hg^{2+} ion, in which the d^{10} electron shell is complete, cannot act as a chromophore in the *d–d* range.

A series of papers on transition-metal complexes containing an asymmetric donor nitrogen atom together with other types of asymmetry (configurational, conformational) is not very useful for solving this problem owing to the difficulty of isolating the vicinal effect of the asymmetric donor nitrogen atom from the observed overall curve [10,11].

Nevertheless, it is well known that, in comparison with the above cases of unidentate ligands, bidentate optically active ligands usually induce Cotton effects of considerable amplitude in *d–d* transitions, although the asymmetric centre is sometimes very remote from the chromophore. Still earlier, in 1950, similar observations led Lifschitz [12] to suggest that the induced Cotton effect of *d–d* transitions in complexes of transition metals is of measurable magnitude only if the asymmetry ligand possesses chelating power. This rule might be extremely useful for determining the mode of coordination of potential multidentate ligands in solution. Subsequent investigations indicated that the above statement was too categorical.

From a comparison of the dispersion of optical rotation of the ions $[Co(+)\text{-tartr}(NH_3)_4]^+$ and $[Co(+)\text{-tartr}(NH_3)_5]^{2+}$, which contain bidentate and unidentate tartaric acid respectively, Bhatnagar and Kirshner showed [13] that the two curves are similar in shape, the only difference being that the complex containing the unidentate ligand exhibits half the Cotton effect in the *d–d* region.

Kirshner analysed the contradictory results of this work and that mentioned above [8], and suggested that the increase in optical activity might be due to an increase in the number of asymmetric centres in the optically active ligand. A cobalt(III) complex $[Co(-)\text{-menac}(NH_3)_5](NO_3)_2$, which contains as unidentate ligand the *laevo*-menthoxyacetate ion (I) having three asymmetric centres



(I)

was therefore prepared and examined spectropolarimetrically [14]. The sharp positive Cotton effect in the region of the absorption band due to the cobalt(III) ion in the circular dichroism spectrum is of smaller amplitude than that of the corresponding complex of unidentate *dextro*-tatrate. This result is fully understandable if it is borne in mind that the increase in the number of asymmetric centres was accompanied in this case by considerable remoteness from the chromophore, and that the latter was evidently the dominant factor.

This work was not followed by more correctly designed investigations, and the effect of the number of asymmetric centres on the magnitude of the Cotton effect which they induce remained an open question. Nevertheless, it may be supposed that increasing their number is more likely to produce mutual extinction of their individual contributions with a diminution in intensity of the overall effect.

There is probably a general tendency for the rotational strength of *d–d* transitions to decrease on passing from complexes of bidentate ligands to those of analogous unidentate ligands. This is most clearly demonstrated in an extremely detailed paper by Japanese workers, who investigated complexes of two types—$[Co(NH_3)_4L\text{-aa}]^{2+}$ and $[Co(NH_3)_5L\text{-aaH}]^{3+}$—with bidentate and unidentate amino-acids respectively [15]. The anomaly in the region of the first absorption band of the cobalt(III) ion in the dispersion of optical rotation of complexes of the second type is so weak in comparison with that of their chelate analogues that only qualitative measurements are possible with them. Several reasons may be suggested for such a sharp decrease in amplitude of the Cotton effect on rupture of a chelate ring: the most important are probably [15] the increase in distance between the asymmetric centre and the chromophore—from Co–N–C* for the chelated ligand to Co–O–C–C* for the unidentate amino-acid—and secondly the increase in the conformational mobility of the

ligand—from the rigidly fixed conformation of the chelated amino-acid to a mixture of several conformers of the unidentate ligand—which is due to free rotation of the acyclic molecule.

Since in all the above cases a Cotton effect was observed in complexes of the unidentate ligands, which were in principle capable of chelation, the question of the relation between an anomaly in the visible region and the formation of a metal-containing ring can be finally settled only by examining complexes with truly unidentate ligands. This has been done by Bosnich [16], who isolated a square planar palladium(II) complex *trans*-$[PdCl_2L_2]$ and oxidised it with chlorine to the octahedral palladium(IV) complex *trans*-$[PdCl_4L_2]$, where L represents the optically active unidentate ligand (−)-α-methylbenzylamine. It was obvious from the measured circular dichroism spectra that *d*–*d* transitions of the palladium ions possessed appreciable optical activity in both cases, although here, too, the amplitudes of the Cotton effect were considerably smaller than those usually observed with dissymmetric chelate compounds [17,18].

This result indicates that the rotational strength of *d*–*d* transitions in metal complexes is determined in considerable measure by the remote asymmetric centre of a unidentate ligand, although its interaction with the chromophore is considerably weaker than the effects observed in chelate systems. Attempts to explain the optical activity of complexes of unidentate ligands by any other types of chelation, e.g. outer-sphere chelation [19], appear to the Reviewers quite artificial.

Thus differences in the rotational strengths of *d*–*d* transitions between chelates and the non-chelate type of complexes are only quantitative, not qualitative. This is confirmed by the presence of quite measurable vicinal† effects in almost all complexes of optically active ligands which have now been studied differentially. The main reason for the decrease in rotational strength in the *d*–*d* region on the opening of a metal-containing ring is probably the sharp increase in conformational mobility of the monocoordinated ligand accompanied by considerable mutual extinction of the contributions of the various conformers. Similar effects are well known in organic chemistry [21–23].

An especially significant illustration of this hypothesis is a Japanese study [24] of the dependence of the vicinal effect due to a unidentate ligand—an *ortho*-coordinated α-amino-acid—on its conformational mobility. A substantial increase in the amplitude of the Cotton effect was observed in a series of complexes of the type *cis*-$[Co(L\text{-alaH})X(NH_3)_4]^{n+}$, where the size of the ligand X increases gradually in the sequence

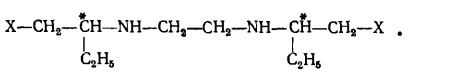
$$H_2O < \text{gly H} < \beta\text{-ala H} < \text{Sar H} < \text{L-ala H} < \text{C-prol H}.$$

This series correlates fairly closely with the restriction of the conformational mobility of optically active unidentate alanine due to its steric interaction with the adjacent ligand X. [24]

This it is evidently no longer possible to suppose that chelation is a necessary condition for the appearance of the Cotton effect in the *d*–*d* region, since it merely increases the rotational strength of these transitions by diminishing the conformational mobility of a unidentate ligand.

†The concept of a vicinal effect was first introduced by Shimura [20].

This conclusion is of both practical and theoretical importance. In practice the rigorous dependence of the induced Cotton effect on the unidentate or multidentate character of the ligand containing the asymmetric centre enables measurements of the dispersion of optical rotation and circular dichroism to be used to study the coordination of potentially multidentate ligands in complexes of undetermined structure



(II)

An example is the determination of the type of chelation of the quadridentate ligand 2,7-diethyl-3,6-diazaoctane-1,8-diol (IIa: X = OH) [25] with copper(II) and nickel(II). Bidentate behaviour of this ligand was simulated by replacing the hydroxyls by chlorine atoms (IIb: X = Cl). This took the asymmetric centres out of the chelate rings, and the centres could contribute to the optical activity mainly by their stereospecific influence on the conformation of the central ethylenediamine chelate ring. The decrease in the amplitude of the Cotton effect by more than 90% on replacement of hydroxyl by chlorine is convincing evidence of the quadridentate behaviour of the ligand (IIa).

A similar principle can be used to determine the mode of coordination of the potentially terdentate ligand cysteine as a function of the acidity of the medium [26].

The copper(II) and nickel(II) complexes of di- and tripeptides provide excellent examples for demonstrating the dependence of optical rotatory power on the number of chelate rings in a complex. Study of the dispersion of optical rotation and the circular dichroism of a series of complex ions with ligands containing a gradually increasing number of potential coordinating atoms showed that the rotational strength of *d*–*d* transitions increases in proportion to the number of chelate rings, with the most highly chelated form possessing the maximum rotational strength [27–29].

This rule is evidently quite general in character, and can be traced in the chelate compounds of metals with diamines and polyamines. The accumulation of metal-containing rings in a complex leads to an increase in optical rotation whether the chelate rings are present in one or more ligands. Thus bisbidentate complexes of the type $[MX_2am_2]^+$ give rotational strengths in the *d*–*d* region double those of the corresponding monobidentate complexes $[MCl_4am]^-$. [30] In the series of complex ions—*cis*-$[Co(NH_3)_2en_2]^{3+}$, $[Coen_3]^{3+}$, $[Copenten]^{3+}$—the amplitude of the Cotton effect, measured from the peak to the trough, increases in the sequence—2200, 7500, 16 000°—in conformity with the presence of two, three, five chelate rings [31].

All these observations demonstrate fairly clearly the same rule: the rotational strength of *d*–*d* transitions of chelate complexes of metals is a function of the number of chelate rings present [32]. This conclusion is of undoubted practical value as a means of studying the coordinating properties of optically active ligands of multidentate type.

Certain theoretical aspects of the relation between the formation of metal-containing rings and the rotational strength of *d*–*d* transitions of the metals can conveniently be noted here. The whole edifice of the modern theory of the optical activity of coordination compounds is based on the necessity of chelation, which produces the dissymmetric departures of the donor atoms in the ligands [33,34], their orbitals [35], or their charges [36] from the regular geometry that are needed for the appearance of the rotational strength of *d*–*d* transitions. Since the chelate

rings are regarded in all cases as the mechanical basis for such deviations, it is undoubtedly of interest to study the effect of the size of the chelate ring on the magnitude of the induced Cotton effect. If the theory is correct, increase in the size of the metal ring should be accompanied by an increase in its flexibility, minimum departures of the donor atoms from their normal positions, and a decrease in the amplitude of the Cotton effect.

A decrease in amplitude of the Cotton effect was actually observed with increase in the length of the carbon chain of the diamine from ethylenediamine to trimethylenediamine in complexes of the type $[Mam_3]^{3+}$, where M = Co^{III}, Cr^{III},[31,37] but this work was followed by several contradictory results[38]. Douglas compared a series of complexes containing a quadridentate ligand (ethylenediaminediacetate) together with carbonate, oxalate, and malonate anions, to give chelate rings containing 4–6 atoms respectively. Contrary to theoretical predictions, all three compounds showed almost identical circular dichroism curves[39]. Moreover, the rotational strength of the complex ion $[Co\,mal_2en]^-$ was double that of $[Co\,ox_2en]^-$, despite the diminution of distortions on the replacement of the oxalate by the malonate ion. Yet the opposite situation is found with the complexes $[Co\,mal_2gly]^{2-}$ and $[Co\,ox_2gly]^{2-}$,[40] and also in a series of complexes of the type $[CoX\,en_2]^+$, where $X = CO_3^{2-}$, ox, mal.[39]

Nor were theoretical predictions confirmed by complexes of multidentate ligands of the type $[CoEDTA]^-$. Diminishing the strain in this system by increasing the size of the chelate rings or by opening them—both diamine rings (in $[CoTMDTA]^-$ and in *cis*-$[CoIDA_2]^-$) and amino-acid rings (in $[CoEDTP]^-$)—did not lead to the expected decrease but to an increase in the intensity of all the bands in the circular dichroism spectrum[41].

These and other similar results[38,42] led to the evident conclusion that it is no longer possible to suppose that the main reason for the optical activity of coordination compounds is the deflection of metal–ligand bonds from their regular geometry as a consequence of the steric requirements of the metal-containing rings. This conclusion receives its most serious support from recent X-ray investigations of optically active complexes[43].

The unnecessary exaggeration of the role of chelation to be found in theoretical and practical papers may be ascribed to the poor sensitivity of the earlier instruments. The impossibility of measuring the Cotton effect induced by unidentate ligands made quantitative differences between chelate and non-chelate systems appear to be qualitative, so that the influence of chelation was erected into an absolute effect. The real reason for the increase of amplitude of the Cotton effect on passing to chelate compounds is the appearance of other contributions to rotation, in addition to the vicinal effect, which result from the specific character of these metallocyclic systems. Such contributions will be discussed in the following Section.

III. CONFIGURATIONAL, CONFORMATIONAL, AND VICINAL CONTRIBUTIONS

The optical activity of octahedral complexes of the type $[M(AA)_3]^{n+}$ or *cis*-$[MX_2(AA)_2]^{m+}$, if the bidentate ligand A is not itself optically active, is a consequence of the exclusively helical arrangement of the chelate rings. This has been termed the *configurational effect*. The examples most often used are cobalt(III)–ethylenediamine complexes —(+)-$[Co\,en_3]^{3+}$ and *cis*-$[CoX_2en_2]^{2+}$—although in general such compounds with non-planar chelate rings contain a contribution from the dominant conformation of these rings besides the purely configurational contribution. It would be far more correct to examine the configurational effect in complexes of planar bidentate ligands such as 1,10-phenanthroline and 2,2′-bipyridyl. Since complexes of the latter type have been known for a long time and have been well studied[44], we shall not discuss the configurational effect in greater detail. We note merely that, since in these cases the metal is both the centre of asymmetry and the chromophore, the Cotton effect in the *d–d* region usually has large amplitudes.

Asymmetric ligand atoms may also cause a Cotton effect whose amplitude is greatly dependent on the distance between the asymmetric centre and the chromophore (the metal ion). This has been termed the *vicinal effect*. It is present in purest form in complexes with optically active unidentate ligands, which have been discussed in the preceding Section. The concept of the vicinal effect includes contributions both by asymmetric carbon atoms in the ligand and by donor atoms (N* in secondary amino-groups, S* in alkylthio-groups) if they become asymmetric on coordination with the metal.

If a ligand forms a non-planar chelate ring on complex formation, an additional, *conformational effect* appears as a consequence of the asymmetry of the individual non-planar metal-containing ring. However, these last two factors are fairly difficult to separate, since formation of the preferred conformer is closely connected with the absolute configuration of the ligand. The two phenomena are often considered together under the concept of vicinal effect[45], although the conformational effect evidently predominates.

Moreover, Larsen and Olsen[8] consider the presence of a Cotton effect in the *d–d* region as proof that the complex contains a non-planar chelate ring with a single dominant conformation: i.e. they attribute the whole of the optical activity to the conformational effect. Such neglect of the vicinal effect cannot be accepted as legitimate if only because there are now sufficient experimental results indicating the presence of strong Cotton effects in the *d–d* region with four-coordinated complexes having completely planar chelate rings. Examples are provided by the dispersion of optical rotation in complexes of (+)-hydroxy methylenecamphor[46] and (–)-α-methylbenzyldithiocarbamic acid[47] containing planar six- and four-membered metal rings respectively.

We shall examine in greater detail these last two effects.

1. Vicinal Contribution

Of all the effects enumerated above the vicinal effect is usually the smallest, as would be expected from the strong dependence of optical activity on the distance between the chromophore and the asymmetric centre.

It would be reasonable to suppose that the largest vicinal effect would be produced by asymmetry of the donor atom of the ligand. Organic compounds containing an asymmetric nitrogen atom are fairly exotic and difficultly accessible owing to the rapid inversion of this centre. On coordination of a secondary amino-group, however, the nitrogen is far more basic than in organic quaternary ammonium salts. This has made possible the resolution into N* enantiomers of several coordination compounds of cobalt(III),[48–51] platinum(II), and platinum(IV)[52] with *N*-substituted diamines and amino-acids.

The optical activity of complexes of the type *trans*-$[MX_2(LL)_2]^+$ with *N*-substituted diamines and amino-acids is assumed to be due solely to the vicinal effect of the asymmetric donor nitrogen atom [48]. This is not altogether true, since it disregards the conformational contribution of the ligand, which is quite large with diamines. Separation of conformational and vicinal contributions and their separate examination is the more important as cases are known in which the absence of information on their relative roles has led to assignment of an incorrect configuration to the complex ion, as has occurred e.g. with the (−)-*trans*-*trans*-$[CoX_2N\text{-Meen}_2]^+$ ion [53].

A similar type of mistake is usually made in discussing the optical activity of *trans*-complexes of optically active diamines in which the nitrogen is unsubstituted [54]. However, this does not lead to large errors, since the C*-vicinal contribution is substantially smaller than the conformational effect, which does not apply to the N*-vicinal contribution.

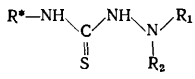
If it is supposed that the circular dichroism of *trans*-$[CoCl_2(S)\text{-pn}_2]^+$ can simulate satisfactorily the contribution of the δ-conformation of coordinated *N*-methylethylenediamine, subtraction of its circular dichroism spectrum from the circular dichroism curve of the (−)-*trans*-*trans*-$[CoCl_2N\text{-Meen}_2]^+$ ion leaves the almost pure vicinal effect of the R–N* asymmetric centre as the resulting curve. The curves obtained in this way show that the N*-vicinal and conformational effects are comparable in magnitude and opposite in sign [55].

The abrupt change in the circular dichroism spectra on passing from ordinary amino-acids to L-proline in complexes of the type $[Cu(L\text{-aa})_2]$ has been attributed to the asymmetry of the donor nitrogen atom [56]. Molecular models make it obvious that only one of the two possible enantiomeric N* configurations can be realised, owing to the steric requirements of this cyclic ligand. This assumption has since been confirmed by X-ray examination [57]. The vicinal effect of the asymmetric nitrogen atom in the coordinated L-prolinate ion results in more intense dichroic bands of certain other complexes, e.g. the $[Co(NH_3)_4L\text{-prol}]^{2+}$ ion. [58] Similar effects are observed in copper(II) complexes containing pseudoephredine and sarcosine [59].

Additional asymmetry, associated with the coordination of secondary amino-groups [60] or alkylthio-fragments of the molecule [61–63], may appear on complex formation by metals with linear multidentate acyclic ligands such as tetraethylenepentamine and also with macrocyclic multidentate ligands [64].

The vicinal effects of asymmetric centres of the carbon skeleton of the ligand which are more remote from the chromophore are substantially smaller than the contributions by asymmetric donor atoms (N*, S*), and this is fully consistent with Chugaev's vicinal rule [65]. An asymmetric α-carbon atom in such ligands as amino-acids develops a far larger vicinal effect than does a β-atom in a side-chain outside the chelate ring. A good illustration of this conclusion is the close similarity in the circular dichroism spectra of the two complexes of the type $[Cu(L\text{-aa})_2]$ in which the amino-acid is respectively L-threonine and L-allothreonine: these amino-acids are respectively *threo*- and *erythro*-isomers, having the same configurations of the α-carbon centres and opposite configurations of the β-atoms [56].

In view of the strong dependence of the vicinal effect on the position of the asymmetric centre in the ligand Lifschitz [12] postulated in 1950 that a necessary condition for the appearance of anomalous dispersion of optical rotation of inner-complex compounds is the presence of an asymmetric carbon atom in the chelate ring. This statement is shown to be too categorical by the work of Jensen [66], who investigated nickel(II) complexes of a series of optically active thiosemicarbazides of general formula



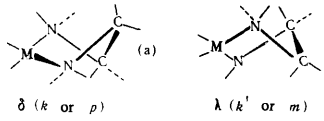
(III)

in which the optically active radical R* is isolated from the chelate ring by a nitrogen atom. Nevertheless, if the α-carbon atom in the radical R* is asymmetric, the circular dichroism spectra indicate quite large rotational strengths of *d*–*d* transitions. Although the reasons for the unusually effective asymmetrising influence of the ligand are not altogether understood [67], the optical activity may be supposed to be due mainly to the vicinal contribution, which merits the closest attention and study.

In view of the important part played by the vicinal effect it is undoubtedly useful in all cases to break down the observed curve of dispersion of optical rotation or circular dichroism into individual contributions, since it will give a clearer idea of several of the finer structural features of the molecules of complex compounds. Furthermore, in individual cases it is possible by means of the curves representing the vicinal effect to obtain a clearer resolution of the components of the *d*–*d* bands than when curves representing the configurational or the total effect are used [68].

2. Conformational Contribution

A consequence of the non-planarity of diamine and certain other chelate rings is the possible formation of at least two conformers of ions of the type *D*-$[Coam_3]^{3+}$. [69,70] In the most stable of them, denoted since Bailar's time as *Dkkk* or lel, all the C–C bonds of the carbon skeleton of the diamines are parallel to the axis of the C_3 complex, and a methyl group (e.g. in *laevo*-propylenediamine) is in the equatorial position. In the less stable isomer *Dk'k'k'* or ob the C–C bonds are oblique. Recently the symbols δ and λ, and also *p* and *m*, have been used most frequently in conformity with the *k* and *k'* notation for enantiomers (IVa, b). [71]



(IV)

However, the situation is evidently not so simple, as is shown by a recent theoretical calculation of conformational energies for ethylenediamine, propylenediamine, and *N*-methylethylenediamine. With ethylenediamine several energetically equivalent symmetrical and unsymmetrical conformations of minimum energy proved to be possible besides the two conformations (δ and λ) recognised by modern theory. Introduction of a methyl group attached to a carbon atom (in propylenediamine) or to a nitrogen atom (in *N*-methylethylenediamine) greatly restricts the number of possible conformations, owing to their strong steric inteacction.

The existence of two principal conformers has been brilliantly confirmed by the X-ray examination of a series

of optically active coordination compounds [43]. It is interesting that, not only the solid state but also in solution, even at room temperature, the predominant conformation of the (−)-propylenediamine chelate ring is the λ-gauche form. This has been shown by a study of the nuclear magnetic resonance spectra of certain platinum(II), palladium(II), and cobalt(III) bis-complexes [73].

Inspection of the literature indicates that the conformational effect of a ligand in a chelate ring depends mainly on the degree of distortion of the latter, on its departure from planarity. In a series of trisdiaminecobalt(III) complexes, for example, the increase in intensity of the circular dichroism bands in the series of ligands—en < pn < chxn—corresponds to the sequence of increasing distortion of the chelate ring by the substituents [74]. The spatial requirements of the ligands increase in the same sequence, and limit the number of possible conformers owing to the sharp increase in the energy differences between them. The diminution in conformational mobility leads to a smaller mutual extinction of the contributions from individual conformations, and hence an increase in intensity of the bands in the circular dichroism spectrum.

The conformational effect, together with the vicinal effect, which is difficult to separate from it, constitutes the basis of the optical activity of *trans*-biscomplexes, such as e.g. *trans*-$[RhCl_2(R\text{-pn})_2]Cl$ and $Na[RhCl_4R\text{-pn}].H_2O$. [75] The Cotton effect in the former complex is double that in the latter, in proportion to the number of chelate rings in the molecule.

An interesting system for studying conformational effects is provided by Schiff bases obtained from optically active diamines and aromatic *o*-hydroxy-aldehydes or -ketones. Examination of the optical rotatory dispersion and the circular dichroism of complexes of copper(II) and nickel(II) with quadridentate Schiff bases of general type $[MSal_2(-)\text{-pn}]$ revealed that the addition of a methyl group to the azomethine carbon atom results in inversion of the signs of the dichroic bands in the region of d–d transitions and a substantial increase in their intensity [76]. Inspection of molecular models showed that, whereas in complex ligands based on aldehydes the δ-conformation of the central diamine chelate ring, with a pseudo-equatorial position of the methyl group of the (−)-propylenediamine, is the preferred conformation, *o*-hydroxyacetophenone gives preference to the (axial-methyl) λ-conformation owing to steric interaction of the two methyl groups. The reversal of sign of the Cotton effect indicates a displacement of the conformational equilibrium $\delta \rightleftharpoons \lambda$ in favour of the latter. It is important to note that the absolute configuration of the diamine plays no part: i.e. the conformational effect predominates greatly over the vicinal effect [76].

Metal complexes of Schiff bases obtained from (−)-*trans*-cyclohexane-1,2-diamine and (−)-propylenediamine provide another example of the predominance of the conformational over the vicinal effect. The circular dichroism spectra of the two series of complexes are enantiomeric, although the configurations of the diamines are the same, RR and R respectively, so that their vicinal contributions have the same sign. The reason for the reversal of sign of the Cotton effect is that the δ-conformation is fixed in the case of the cyclic diamine, whereas the equilibrium in the second case is displaced in favour of the λ-conformation owing to steric interaction between the methyl group of (−)-propylenediamine and the radical R attached to the azomethine carbon atom. The shift in the equilibrium is greater the more bulky the substituent in the R–C(H)=N group. The decrease in such steric interactions in systems containing five-membered chelate rings formed by Schiff bases with pyrrol-2-aldehyde leads to complete similarity of the circular dichroism spectra of complexes based on the two diamines—(−)-propylenediamine and (−)-*trans*-cyclohexane-1,2-diamine [77].

Chelate rings formed by amino-acids were regarded for a long time as almost flat. However, X-ray examination revealed a slight departure from planarity, e.g. in $[Cu(D\text{-ala})_2]$. [78,98] A consequence of the almost planar character of such chelate rings is a marked decrease in their conformational contribution [79,90].

The construction of Dreiding models reveals that even these slight departures of the chelate ring atoms from planarity makes the *k*-conformation of the chelate rings more stable in $[Co(L\text{-ala})_3]$, in which the N–C–C–O chain forms a segment of a left-hand helix, while the methyl groups become quasi-equatorial, which diminishes their mutual steric repulsion [81]. In the *k*′-conformation a bulky substituent occupies an axial position, and the stability of such a conformer is lowered.

Even with greatly flattened amino-acid chelate rings the conformational contribution greatly predominates over the vicinal effect. This has been shown especially successfully by Wellman [82,83], who investigated mixed amino-acid complexes of bivalent copper of general composition Cu : gly : L-aa = 1 : 1 : 1. By displacing the equilibrium $\delta \rightleftharpoons \lambda$ towards the more stable δ-conformer (quasi-equatorial), e.g. by introducing bulky substituents R into the amino-acid or by fixing the second possible conformation λ (quasi-axial) by means of apical interactions of a third donor group with the metal in terdentate amino-acids such as L-histidine and L-$\alpha\gamma$-diaminobutyric acid, this worker demonstrated a reversal of sign and a change in magnitude of the Cotton effect depending on the conformation of the chelate ring, irrespective of the absolute configuration of the ligand, which remained constant.

Thus published results indicate that, of the two effects discussed here—the C*-vicinal and the conformational effects—the latter usually predominates strongly both in diamine and in amino-acid complexes. The vicinal effect of donor atoms (N*, S*) is probably comparable with it in magnitude.

3. Additivity of Contributions and Their Separation

All three effects discussed above—configurational, conformational, and vicinal—are essentially additive, and this applies to the most varied optically active coordination compounds, including various types of chelate rings and different metal ions [80].

The additivity of the contributions makes it entirely legitimate and justified to separate the overall curve observed—of optical rotatory dispersion or circular dichroism—into components corresponding to the individual contributions. The differential curves thus obtained are far more useful for discussing specific details of molecular structure than is the overall spectrum, which represents several such properties. For example, the C*-vicinal effect is uniquely useful for determining the absolute configuration of a coordinated ligand. No error is involved in using the observed spectrum—comprising configurational, conformational, C*-vicinal, and sometimes N*-vicinal contributions—only provided that all the contributions have the same sign, so that sometimes this method cannot guarantee freedom from errors.

Study of the conformational features of a ligand can reasonably start from the curves of the conformational contributions. However, the overall chirality of a com-

plex can be deduced absolutely rigorously only from the purely configurational effect.

Graphical methods are used to isolate individual contributions from the overall curve which is observed. This is effected most simply and conveniently by comparing the circular dichroism spectra with the optical rotatory dispersion curves.

When the circular dichroism spectra of the (+)- and (−)-$[Co\,en(laevo\text{-}pn)_2]^{3+}$ ions are added, for example, the configurational effects for right-hand and left-hand helices, equal in magnitude and opposite in sign, cancel each other out. The resultant curve represents the vicinal effect of four optically active coordinated ligands, and its reduction to one-quarter gives an idea of the vicinal effect of one *laevo*-propylenediamine chelate ring [70]. Subsequent subtraction of the vicinal effects of one, two, or three *laevo*-propylenediamine groups from the experimental circular dichroism spectra of the complex ions—(+)-$[Co\,en_2 laevo\text{-}pn]^{3+}$, (+)-$[Co\,en(laevo\text{-}pn)_2]^{3+}$, or (+)-$[Co(laevo\text{-}pn)_3]^{3+}$—will yield curves of the configurational contribution which, as was to be expected, are closely similar in form and amplitudes of the Cotton effect and resemble the circular dichroism spectrum of the (+)-$[Co\,en^3]^{3+}$ ion, whose optical activity is a consequence of the helical arrangement of the chelate rings [70].

Here, as in papers by many other authors, the vicinal effect includes the conformational effect as well as the actual vicinal effect of the asymmetric carbon atom in the diamine. The two contributions are difficult to separate, since the absolute configuration of the diamine determines the preferred conformation of the chelate ring which it forms.

The additivity of the configurational and the vicinal contributions has been shown in a similar manner, and they have been separated for complexes of the type $[Co\,aa\,en_2]X_2$, where D- and L-alanine, D- and L-leucine, and L-phenylalanine have been used as the amino-acid [84]. The good agreement between the circular dichroism spectra of complex compounds simulating individual contributions and the differential curves of these effects obtained by graphical methods can be regarded as proof of additivity. The configurational effect is represented separately in resolved complexes with optically inactive ligands, e.g. in $(+)_{546}$-$[Co\,gly\,en_2]I_2$, and the vicinal effect in racemic complexes with optically active ligands, e.g. in $[CoL\text{-}phala(NH_3)_4]I_2$. The latter contribution may be expressed also by the sum of the circular dichroism spectra of $(+)_{546}$- and $(-)_{546}$-$[CoL\text{-}leu\,en_2]^{2+}$.

Subtraction of the circular dichroism spectrum of the unresolved complex ion (±)-$[CoL\text{-}phala\,en_2]^{2+}$ from the corresponding curves of each enantiomer yields curves which are mirror images of one another and represent the pure configurational contributions of the two helices of opposite chirality. As was to be expected, these calculated curves are closely similar to the circular dichroism spectra of (+)- and (−)-$[Co\,gly\,en_2]^{2+}$ ions, which do not contain a vicinal contribution [84].

As a consequence of the additivity of the contributions the circular dichroism spectrum of $(-)_{546}$-$Ba[Co\,ox_2L\text{-}ala]$ is well reproduced by adding the circular dichroism curves of $(-)_{546}$-$Ba[Co\,ox_2gly]$ (the configurational contribution alone) and unresolved $Ba[Co\,ox_2L\text{-}ala]$ (the vicinal contribution alone). [85]

Nor are the circular dichroism spectra of dextrorotatory and laevorotatory isomers mirror images of one another with tris-amino-acid complexes of cobalt(III), owing to the additional asymmetry of the α-carbon atom of the α-amino-acid, i.e. the presence of a vicinal effect. The two contributions were shown to be additive, and they were separated for complexes with D- and L-alanine [86], L-leucine, and L-proline [67].

Configurational and vicinal contributions are additive also in the case of mixed complexes of the type $[CoL\text{-}aaL\text{-}aa']^{3+}$ [87], although the considerable increase in steric hindrance in the presence of bulky side-chains, e.g. in L-valine, produces some divergence between observed and calculated curves [88].

The vicinal contributions of different optically active ligands in the same molecule of a complex are also additive and independent, as was shown in a study of a series of complex ions of general type *trans*-(*N*)-$[Co\,alada\,aa]$. [87]

In systems which are not complicated by strong steric interactions the vicinal contributions of several asymmetric centres in the same molecule of a multidentate ligand, e.g. an oligopeptide, are also independent. Evidence of their additivity is the excellent agreement between the observed value of $\Delta\epsilon$ for one of the *d*–*d* transitions of the nickel(II) complex of the tripeptide L-ala-L-ala-L-ala (−2.10) and the sum of the $\Delta\epsilon$ values for the complexes with gly-gly-L-ala, gly-L-ala-gly, and L-ala-gly-gly ($\Sigma\Delta\epsilon = -2.08$). [89]

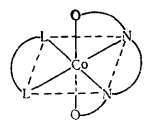
The general rule extends also to the ratio of two—N* and C*—vicinal contributions. In fact the circular dichroism spectrum of $[CoN\text{-}CH_3\text{-}L\text{-}ala(NH_3)_4]^{2+}$ can be reproduced fairly satisfactorily by adding those of the ions $[CoL\text{-}ala(NH_3)_4]^{2+}$ and $(-)_{546}$-$[Co\,sar(NH_3)_4]^{2+}$, representing the vicinal contributions due to the C* and N* centres respectively. The slight discrepancies between the observed and the calculated curve can be explained by the proximity of these two centres and the possibility of some interaction between them [90].

Although the configurational effect and the vicinal effect are far more difficult to separate on the optical rotatory dispersion curves, owing to the more complicated character of the overlapping of individual sigmoid components (inversion curves) corresponding to each optically active absorption band, such work has been undertaken by Japanese [sic] workers [68,91]. From a consideration of the series of complexes—*dextro*-$[CoL\text{-}leu\,en_2]Cl_2$, $[CoL\text{-}leu(NH_3)_4]ClO_4$, *dextro*-$[CoClNH_3en_2]Br$, and *dextro*-$[Co\,en_3]Br_3.2H_2O$—Shimura concluded that the highest molecular rotations in the first of these complexes are due to the fact that the asymmetry about the central metal atom (i.e. the configurational effect) makes a more substantial contribution to the optical rotatory dispersion in the region of *d*–*d* bands than does the asymmetric carbon atom of the coordinated ligand (the vicinal effect). [91]

In this as in most of the investigations mentioned previously the conformational effect was not considered in isolation but together with the vicinal effect. The difficulties of their separation makes even more valuable the use [92] of three complex ions—resolved *cis**-$[CoCl_2^*(NH_3)_2^*en]^+$, unresolved *cis**-$[CoCl_2^*(NH_3)_2^*(-)\text{-}pn]^+$, and optically pure *cis*-$[CoCl_2en_2]^+$—as model compounds in measurement of circular dichroism spectra. In each case the optical activity of the complex is due to mainly one cause—the conformational, vicinal, or configurational effect respectively. The rotational strengths of all three compounds in the same region of *d*–*d* transitions are of the same order of magnitude, although the vicinal effect makes the smallest contribution, and the configurational effect the largest [92].

Isolation of the vicinal contribution from the observed circular dichroism or optical rotatory dispersion spectra has permitted the investigation of the effect of interaction between ligands on the vicinal effect exhibited by the same

ligand in different types of complexes. In effect this work gives indirect information on the conformational component of the total vicinal contribution.



(V)

For example, determination of the vicinal effect of *laevo*-propylenediamine in complexes of the type *trans*-[CoEDDA(LL)]$^+$ (V: LL = en, *laevo*-pn) showed it to be insignificant, contrasting with the fairly large vicinal effect of this ligand in the $[Co(laevo\text{-}pn)_3]^{3+}$ ion [70]. Yet the curves of the vicinal effects of L-alanine in complexes of the type (V: LL = L-ala) and [CoL-ala$_3$] have the same form and differ little in the magnitude of the Cotton effects. Such differences in the behaviour of the two ligands—*laevo*-propylenediamine and L-alanine—when they pass from one type of complex to another are explained by the substantial change in the environment from almost planar amino-acid to distorted diamine chelate rings in the case of *laevo*-propylenediamine, whereas with L-alanine the environment remains almost unchanged [45].

Interligand interactions of this kind probably depend significantly on stereochemical aspects of the environment of the β-carbon atoms in the amino-acids [58].

Thus for the optical activity of d–d transitions in coordination compounds the additivity of the three principal contributions—configurational, conformational, and vicinal—can be regarded as a general rule. The individual contributions can be arranged qualitatively in the sequence —configurational > conformational $\simeq$ N*-vicinal > > C*-vicinal—according to their effect on the intensity of the Cotton effect in this region, which in general yet again emphasises the validity and universality of Chugaev's vicinal rule.

The situation is somewhat more complicated when we consider the optical activity of charge-transfer transitions. Although the individual contributions to the rotational strength of these transitions are additive even in this case, information on the relative roles of each of them is contradictory.

The circular dichroism of trisdiaminecobalt(III) complexes in the visible region (d–d transitions) is an indication mainly of the stereochemistry of the chelate rings arranged about the metal ion (configurational effect). [93] Several investigations suggest that the sign and the amplitude of the Cotton effect due to charge-transfer transitions in the ultraviolet region are given by the sum of the conformational and the configurational contribution, where the former is strongly predominant [39,71,94]. Such predominance was deduced from the fact that the sign of dichroic bands in the region of charge-transfer transitions is determined in many cases solely by the chirality of the diamine chain, irrespective of the absolute configuration of the chelate rings about the metal ion [95]. The presence of both contributions—conformational and configurational—was assumed from a consideration of the optical activity of trisdiamineplatinum(IV) complexes in the region of charge-transfer transitions [96].

The exactly opposite conclusion was reached by Japanese workers [97]. From the opposite signs of the circular dichrosim in charge-transfer transitions (~ 215 nm) for (+)- and (−)-$[Copn_3]^{3+}$ ions having opposite configurations they assumed that the configurational effect is strongly predominant at shorter wavelengths, whereas the vicinal effect predominates at longer wavelengths.

Although the factual information is clearly insufficient to settle this question finally, the conclusions of the first group of investigators seem more reasonable. Actually, Chugaev's vicinal rule indicates that the asymmetry of the metal should determine the optical activity of the internal transitions in the metal (d–d) to a greater extent than transitions of the metal–ligand type (charge-transfer transitions). And conversely, the chirality of an individual chelate ring in the ligand should play the more important part for these latter transitions.

The resolution of the experimental curves representing optical rotatory dispersion and circular dichroism into differential curves corresponding to the individual contributions to the rotation is of undoubted practical value, since it will permit a more correct exploitation of the opportunities offered by spectropolarimetry.

For example, a well known method for determining the absolute configuration of chelate complexes of metals involves comparing their rotatory dispersion or circular dichroism curves with the spectra of complexes whose absolute configuration has been established by means of X-rays. It is quite obvious that, since the configuration of the central metal atom affects only the configurational contribution, the vicinal effects of optically active ligands must be subtracted from the total curve to avoid errors.

On the other hand, vicinal curves obtained by subtracting the configurational contribution from the experimental curve are closely connected with the absolute configuration of an optically active ligand and may provide a means for its determination. Thus the curves of the vicinal effect for *laevo*-propylenediamine and L-alanine have the same general shape, but are mirror images of one another. From this it was concluded that these molecules had opposite absolute configurations [45].

IV. GEOMETRICAL ISOMERISM

Geometrical isomerism is another factor influencing the optical activity of coordination compounds. The elucidation of some generalisations in this field is not only of intrinsic value but also useful as a means for detecting and characterising such phenomena in new systems.

Geometrical isomerism arises in complex compounds of bidentate ligands when the latter are of the unsymmetrical type AB. The possibility of two *cis*- and *trans*-isomers is already apparent in bisamino-acid complexes, although it is rarely taken into account owing to the substantially greater stability of the *trans*-isomer. It is especially interesting that *cis*-[Cu(D-ala)$_2$] has recently been isolated in the solid state, and its structure has been analysed by means of X-rays [98]. However, comparison of the circular dichroism spectra of crystals and solutions of complexes of similar types with other amino-acids showed that the predominant isomer in solution is nevertheless the *trans*-isomer [99].

With amides of amino-acids such geometrical stereospecificity was not so rigorous, and both isomers—*cis* and *trans*—could be isolated in the case of the nickel(II) and palladium(II) complexes of these ligands. The structure of each isomer was assigned on the basis of a study of the effect of solvents on the magnitude, sign, and position

of certain components in the circular dichroism spectrum [100].

The possibility of two geometrical isomers—meridional (mer or 1,2,6) and facial (fac or 1,2,3)—is well known for the trisamino-acid complexes of cobalt(III), rhodium(III), and other metals. Every possible geometrical and optical isomer has been isolated e.g. in the case of the alanine complex $[Co(L\text{-}ala)_3]$. [101]

The differences in the spectropolarimetric behaviour of geometrical isomers are due to their belonging to different symmetry types, resulting in different ways of splitting the bands characteristic of O_h symmetry. For example, the $^1A_{1g} \rightarrow {}^1T_{1g}$ transition is split into two components—of A_2 and E symmetry—in the β-isomers, but into three components—of A_2, B_1, and B_2 symmetry—in the less symmetrical α-isomers. In conformity with this the violet α-isomer of the complex $[Co(L\text{-}ala)_3]$ gives three extrema in the region of the T_1 band in the circular dichroism spectrum, whereas the red β-isomer gives two dichroic components of opposite sign in the same region [81]. The assignment of structures to the α- and β-isomers is supported by nuclear magnetic resonance spectra [67].

Each geometrical isomer exists as two optical isomers, in which the chelate rings are arranged in opposite helices about the metal ion [102]. Thus the total number of isomers of trisamino-acid complexes is increased to four, although this may be greatly diminished by steric hindrance. Thus coordination of the L-prolinate ion yields only one isomer, the fac-Λ-isomer, whose structure has been established by the combined application of electronic spectra, optical rotatory dispersion, and circular dichroism. Similar geometrical and optical selectivity has been observed also with L-hydroxyproline [103].

With terdentate amino-acids the number of geometrical isomers which are theoretically possible is increased to three, each of which occurs as two enantiomers in which the chelate rings are arranged in opposite spirals about the metal atom. Here too, however, steric hindrance reduces the total number of geometrical and optical isomers—to three in the case of D- and L-aspartic acid [104].

Such a terdentate ligand as $\alpha\beta$-diaminopropionic acid, on coordination with cobalt(III) to form a bis-complex, is able theoretically to give five geometrical isomers, three of which are possible only when the two ligands in the complex molecule have the same absolute configuration. In fact it has proved possible to isolate all five isomers with the DL-acid and three isomers with each optically active ligand (D and L). [105]

Geometrical isomerism has hitherto been ignored in connection with bis- and tris-hydroxymethylenecamphor complexes, although the molecule of the chelated ligand has no second-order axis of symmetry and belongs to the AB type of ligands. The most stable was the 1,2,3-isomer, whose structure was confirmed by measuring the nuclear magnetic resonance spectra [106].

Complexes of multidentate ligands of polyamine type [107,108], whose chemistry has been actively developed during recent years, are especially interesting for the investigation of geometrical isomerism. The topology of the coordinated ligand can be in considerable measure controlled by introducing substituents into different parts of the molecule, and the substantial differences in the circular dichroism and optical rotatory dispersion spectra of the various geometrical isomers make these methods, together with nuclear magnetic resonance spectroscopy, especially valuable for structure assignments to individual isomers. However, the number of publications on this topic has recently increased so greatly that the stereochemistry of complexes of multidentate ligands may constitute a subject for a special review.

V. OUTER-SPHERE COORDINATION

The first observations that the molecular rotation of ions of dissymmetric metal complexes depends on the properties of the gegenion were made by Werner as early as 1912. [109] In general this effect is not very large in comparison with those already discussed, but in some cases it plays an important part. An example is the almost tenfold increase in intensity of the dichroic bands due to the (+)-$[Co\,en_3]^{3+}$ ion produced by its outer-sphere interaction with nitrosonaphthoxide ions. The probable reason is strong interaction of the formally forbidden d–d transitions with the charge-transfer transitions which appear on outer-sphere coordination, from which the d–d bands obtain most of their intensity [110].

Most work in this field has been done on the effect of optically inactive ions on the rotatory dispersion or the circular dichroism of optically active complex ions. It is interesting that different transitions are subject to this effect in different degrees depending on their symmetry. Thus the intensity of the positive dichroic maximum corresponding to the $^1A \rightarrow {}^1E_a$ transition in the complex $(+)_{546}$-$[Co\,en_3]Cl_3$ is increased by the addition of all electrolytes other than trisodium orthophosphate, which diminishes the intensity. The negative peak in the circular dichroism spectrum of the same complex ion ($^1A \rightarrow {}^1A_2$ transition) increases in intensity in the presence of all electrolytes, and the orthophosphate anion produces the maximum effect [111].

The effects of trigonal and tetrahedral anions on the optical activity of octahedral complexes of diamines are quite regular. Increase in the concentration of such anions in solution leads in general to a decrease in the rotational strength R of the E_u transition, a compensating increase in that of the A_2 transition, an increase in the rotational strength of the E_g band, and the appearance of a new dichroic component caused by charge transfer from anion to cation.

Quantitative analysis of this latter band has demonstrated the formation in solution of a 1 : 1 ion-pair with complex ions such as (+)-$[Co\,en_3]^{3+}$ and (+)-$[Co(+)\text{-}pn_3]^{3+}$. The main factor in the structure of such an outer-sphere complex is assumed to be a system of hydrogen bonds involving the NH groups of the coordinated diamine molecules [112]. The fact that a similar 1 : 1 outer-sphere complex is not formed with the (−)-$[Co(+)\text{-}pn_3]^{3+}$ ion can be regarded as indirect confirmation of this suggestion. The reason for the marked differences in behaviour of complexes of (+)-propylenediamine having opposite absolute configurations may be the enantiomeric character of the conformations of the chelate rings, only one of which [in the (+)-complex] enables three NH groups to lie in the same direction, parallel to the C_3 axis and convenient for the formation of three NH...X hydrogen bonds with an anion located on the C_3 axis [112].

As a result of this advantage of one of the two conformations the association constants of the lel-$[Co(\textit{dextro}\text{-}pn)_3]^{3+}$ ion were significantly higher than those for the ob-isomer. For example, the values on interaction with the SO_4^{2-} ion were respectively 70 and 43, with *dextro*-$tartr^{2-}$ 30 and 7, and with *laevo*-$tartr^{2-}$ 28 and 16. [113] The differences in the behaviour of *dextro*- and *laevo*-tartrate ions are explained by different relative configurations of the

$^{-}OCO-C-C-COO^{-}$ chain, on its outer-sphere coordination through the two carboxy-groups [114].

The dimeric complex $[Co_2(L\text{-}amO)_3(L\text{-}amOH)_3]^{3+}$ represents a type of association which is rather more complicated than that described above. It is formed by three O–H...O hydrogen bonds between coordinated amino-alcohol molecules L-amOH and their anions $L\text{-}amO^{-}$. [115]

However, the number of possible outer-sphere complexes is not restricted to 1 : 1 products. The above change in the rotational strengths of the components of an octahedral T_{1g} transition is entirely regular for complex ions of many metals—cobalt(III), chromium(III), rhodium(III)—and several anions, such as arsenate, phosphate, selenite, thiosulphate, etc. [116] However, the sign of this effect may be reversed when the concentration of the anion rises above a certain limit. Larsson and his coworkers used similar changes in the circular dichroism spectra to determine formation constants for a series of outer-sphere complexes of general type ML_n, where n = 1–4 when L represented the thiosulphate ion, and n = 1, 2 for the hexacyanoferrate(II) ion. The presence of a maximum effect in the 1 : 1 and 1 : 3 complexes was explained by the fact that formation of a centrosymmetric outer coordination sphere leads to the smallest change in optical activity of the complex cation with even values of n. [117]

In some cases an abrupt change in the circular dichroism spectra is observed only in the third-stage of the formation of outer-sphere complexes, e.g. with *dextro*-$\{[Co\,en_3](SeO_3)n\}^{3-2n}$, [118] or at the third and fourth stages [119].

Analysing possible mechanisms of the effect of outer-sphere coordination on the optical activity of complex ions, Larsson considers that the direct effect of anions on the *d*-orbitals of the metal would be quite small in comparison with the effects observed with inner-sphere coordination. It is most probable that the effect of outer-sphere coordination is indirect—through the mixing of *d*–*d* transitions with the very intense charge-transfer transitions which then arise [117,119].

A second aspect of the same problem is the effect of cations on the optical activity of complex anions. In a study of the molybdate complexes of tartaric and mandelic acids Brown observed that increase in the concentration of simple singly charged alkali-metal cations in the solution was accompanied by an increase in the optical activity, which reached saturation at a certain stage [120]. According to their relative effectiveness the metal ions can be arranged in the sequence

$$Cs^+ > Rb^+ > K^+ > Na^+ > Li^+$$

which is also the sequence of diminishing cationic radius [120].

In order to ascertain which characteristic of an optically inactive ion governs its effect on the optical rotatory dispersion of a complex ion, Albinak [121] made a detailed comparative investigation of the effectiveness of anions (F^-, Cl^-, Br^-, I^-, PF_4^{3-}, SO_4^{2-}, PO_4^{3-}) and cations (Li^+, Na^+, K^+, Rb^+, Cs^+, Mg^{2+}, Ca^{2+}, Ba^{2+}) for a series of salts of two optically active cations (*laevo*-*cis*-$[Co\,ox\,en_2]^+$ and *laevo*-$[Cr\,en_3]^{3+}$) and two anions (*dextro*- and *laevo*-$[Rh\,ox_3]^{3-}$). Comparison of the rotatory dispersion curves within a series showed a clear tendency for the intense long-wavelength rotation maximum to vary with the ratio of ionic charge to ionic size (i.e. the ionic potential) and the polarisability of the optically inactive ion. The plot of molecular rotation against ionic potential is a straight line [121].

A second possibility—coordination of an optically inactive complex ion with an optically active gegenion—has been far less investigated. Mason studied the outer-sphere coordination of hexa-amminecobalt(III) in aqueous solution containing excess of the (+)-tartrate ion, (+)-tartaric acid, or (+)-diethyl tartrate. A completely unexpected result of this work was the discovery of a appreciable Cotton effect in the region of the $^1A_{1g} \rightarrow {}^1T_{1g}$ band, exceeding in magnitude the effect induced in this band by inner-sphere unidentate and even bidentate coordination of the same ligands in the complex ions $[CoL(NH_3)_5]^+$ and $[CoL(NH_3)_4]^+$ respectively. The Cotton effects accompanying inner-sphere and outer-sphere coordination are of opposite sign. The reason for this effect is supposed to be orientation of the species on the surface of the complex ion without elements of symmetry [122].

A similar phenomenon has been noted in the systems formed by the hexa-amminecobalt(III) ion with (–)-α-methylbenzyl acetate [123] and by the tetrachloroplatinate(II) ion with *dextro*-butane-2,3-diol [124].

Outer-sphere coordination is obviously also the cause of the Pfeiffer effect (change in the rotatory dispersion of certain optically active organic compounds, e.g. *dextro*-α-bromocamphor-π-sulphonate and *dextro*-tartaric acid, in the presence of racemic mixtures of certain optically active coordination compounds, e.g. DL-$[Zn(o\text{-}phen)_3]$). This effect was the subject of a recent review by Kirshner [6], and therefore will not be discussed here.

Thus the progress made in recent years in research on optically active coordination compounds gives grounds for hoping that the application of circular dichroism and rotatory dispersion to inorganic chemistry will become increasingly effective, and provide inestimable help in the investigation of those finer aspects of the spectroscopy and the structure of complex molecules to which other present-day methods are insensitive.

Mechanisms of the Hydroxylation of Aromatic Compounds

D.I.Metelitsa

A systematic account is given of various mechanisms for the hydroxylation of aromatic compounds in the liquid phase, and they are discussed critically. Similarities and differences are emphasised in the mechanisms of the action of Fenton's reagent, enzymes, and models of the latter in the hydroxylation of aromatic systems. Mechanisms of radiolytic hydroxylation are examined in detail, and questions concerning the nature of the attacking species and the distribution of the resulting isomeric phenols are discussed. Kinetic data and the mechanism of the hydroxylation of aromatic systems during oxidation together with aliphatic alcohols are examined in detail. A list of 211 references is included.

I. INTRODUCTION

The concept of "aromaticity" in organic chemistry implies the ability of a substance to undergo substitution readily while being stable to the action of oxidants. This concept arose from a study of the properties of benzene, which, although formally unsaturated, readily undergoes substitution and is very resistant to oxidising agents [1]. The great stability of the aromatic ring in homolytic oxidations is explained also by the fact that benzene and its derivatives do not form the corresponding hydroperoxide, which, by decomposing into free radicals, might have initiated further oxidation. Finally, the oxidation of aromatic compounds yields phenols and their reaction products, which act as inhibitors in the chain oxidation of hydrocarbons.

The direct preparation of hydroxy-derivatives of aromatic compounds in a single stage is of great practical importance, since no effective single-stage process has yet been developed e.g. for obtaining phenol from benzene, there are no methods for producing naphthols by the direct oxidation of naphthalene, and only the direct preparation of anthraquinone from anthracene is of importance in industrial organic synthesis [2]. Yet it is known to be possible in principle to oxidise benzene and its derivatives to phenols under mild conditions: for example, there are enzymes which oxidise phenylalanine to tyrosine; micro-organisms assimilate aromatic compounds, converting them into *o*- and *p*-diols and then cleaving the rings to form aliphatic acids [3]; under certain conditions benzene can be oxidised to give a quite high yield of phenol [4].

We shall not discuss here the oxidation of benzene to phenol in the gas and liquid phases by various methods, since a detailed survey of this question has appeared [4]; nor shall we be concerned with oxidation processes involving destruction of the benzene ring [5]: we shall concentrate our attention on the mechanism of the first stage in the oxidation of aromatic compounds—the hydroxylation of aromatic rings with the formation of phenolic derivatives. In several cases the nature of the hydroxylating agents and the mechanism of their interaction with the aromatic systems are not entirely clear. The aim of the Review is to show the similarities and the differences in the mechanisms of hydroxylation by Fenton's reagent and various catalytic systems which simulate the action of enzymes and the mechanisms of hydroxylation in radiation-chemical processes and also in initiated and combined oxidations involving aromatic compounds. Examination of the mechanisms of the hydroxylation of aromatic compounds will enable a deeper insight to be obtained into processes involving their oxidation and also supplement our knowledge of substitution in the aromatic series.

II. MECHANISM OF HYDROXYLATION BY FENTON'S REAGENT AND ITS ANALOGUES

At a certain ratio of its components Fenton's reagent ($Fe^{2+} + H_2O_2$) is a source of reactive HO· radicals, this being confirmed by its initiation of the polymerisation of vinyl compounds and oxidation of aliphatic and aromatic substances. The following mechanism has now been proved and accepted [6-10] for the interaction of iron(II) ions with hydrogen peroxide:

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + HO^- + HO^{\cdot} \quad (0)$$

$$Fe^{2+} + HO^{\cdot} \rightarrow Fe^{3+} + HO^- \quad (1)$$

$$H_2O_2 + HO^{\cdot} \rightarrow HO_2^{\cdot} + H_2O \quad (2)$$

$$Fe^{2+} + HO_2^{\cdot} \rightarrow Fe^{3+} + HO_2^- \overset{H^+}{\rightleftarrows} H_2O_2 \quad (3)$$

$$Fe^{3+} + HO_2^{\cdot} \rightleftarrows Fe^{2+} + H^+ + O_2 \quad (4)$$

$$Fe^{3+} + H_2O_2 \rightarrow Fe^{2+} + HO_2^{\cdot} + H^+ \quad (5)$$

In the presence of excess of Fe^{2+} ions reactions (0) and (1) take place; with excess of hydrogen peroxide in acid solutions, when reactions (4) and (5) can be neglected, reactions (0), (2), and (3) occur. Comparable concentrations of Fe^{2+} and H_2O_2 in acid media result in reactions (0)–(3). The stoichiometry of the reaction is $2Fe^{2+}$ and H_2O_2. The rate constant of reaction (0) has been given as $k_0 = 4.45 \times 10^8 \exp(-9400/RT)\ M^{-1}\ s^{-1}$. Thus with excess of the Fe^{2+} ion in acid media Fenton's reagent and its analogues are efficient sources of HO· radicals.

A large amount of work has been done on the hydroxylation of aromatic systems by Fenton's reagent and its analogues ($Cu^{2+} + H_2O_2$, $Ti^{3+} + H_2O_2$, etc.). [11-26] Studies have been made of the hydroxylation of benzene [11-15,18,20], naphthalene [21], toluene [18,22,24], anisole [24], fluorobenzene [23], phenol and its substituted derivatives [23,25], nitrobenzene [12], and acetanilide [23].

Early papers [11,15] suggested the following mechanisms of interaction between the HO· radical and an aromatic compound:

$$XC_6H_4H + HO^{\cdot} \rightarrow XC_6H_4^{\cdot} + H_2O$$
$$XC_6H_4^{\cdot} + Fe^{3+} + HO^- \rightarrow XC_6H_4OH + Fe^{2+}$$
$$XC_6H_4^{\cdot} + XC_6H_4^{\cdot} \rightarrow XC_6H_4{-}C_6H_4X.$$

The reaction results in the formation of phenol and biphenyl (derivatives of the latter are not formed in nearly neutral media in the presence of oxygen). If oxidation does involve detachment of a hydrogen atom in conformity with the above scheme, an isotope effect should be observed in the reaction between HO· and completely deuterated benzene C_6D_6, provided that the detachment of a hydrogen or deuterium atom limits the rate of formation of reaction products. However, no isotope effect was observed experimentally in the oxidation of hexadeuterobenzene by Fenton's reagent [18], which indicates either that detachment of a hydrogen atom does not occur or that this step does not limit the overall rate of the process. It is noteworthy that removal of a hydrogen atom may occur to a slight extent with rise in temperature, as is indicated by the increase in k_H/k_D from 1.25 (at 20°) to 1.37 (70°C) in the oxidation of a mixture of ordinary and deuterated benzene [27].

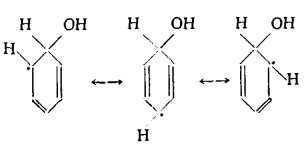
Proskurin and his coworkers [28] were the first to suggest that the HO· radical adds to the benzene ring to form the complex radical $C_6H_6O{\cdot}H$. The existence of this radical was demonstrated by pulse radiolysis combined with flash spectroscopy [29], its absorption spectrum (λ_{max} = 313 nm) has been determined, and the addition rate constant calculated as $(4.3 \pm 0.9) \times 10^9$ M^{-1} s^{-1} at 25°C.

The use of ^{18}O to investigate oxygen transfer in the reaction of benzene with Fenton's reagent and its analogue $Cu^{2+} + H_2O_2$ showed that 15–23% of oxygen is incorporated from water into the phenol if no oxygen is present in the gas phase, and 5% of oxygen from the gas phase if the latter contains oxygen [20]. The results are consistent with the mechanism

$$H_2O_2 + Fe^{2+} \rightarrow HO^{\cdot} + Fe(OH)^{2+}$$
$$C_6H_6 + HO^{\cdot} \rightarrow (C_6H_6OH)^{\cdot} \rightarrow PhOH + H$$

The limiting step is the formation of HO· radicals, not their interaction with benzene.

Dixon and Norman [19] used electron spin resonance to study the free radicals formed in the systems—$H_2O_2 + Ti^3$ and $H_2O_2 + Ti^3 + C_6H_6$—and found that the hydroxy-radicals disappear in the presence of benzene. New radicals appear, to which these workers attributed the structure

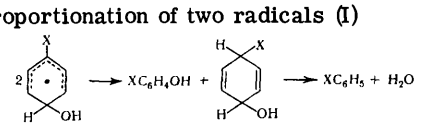


All the above results confirm that the first stage in the reaction between HO· and C_6H_5X (where X is a substituent) is the addition of hydroxyl to the benzene ring with formation of a cyclohexadienyl type of radical. The radical $XC_6H_5O{\cdot}H$ (I) is then able to react in three ways [18]—

(*A*) formation of phenolic compounds

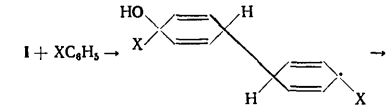
$$I + Fe^{3+} \rightarrow XC_6H_4OH + Fe^{3+} + H^+ \quad (6)$$
$$I + O_2 \rightarrow XC_6H_4OH + HO_2^{\cdot} \quad (7)$$

(*B*) disproportionation of two radicals (I)



(8)

(*C*) formation of biphenyl compounds



(9)

Three mechanisms can be suggested [30,31] for the formation of biphenyl compounds—removal of a hydrogen atom from the C_6H_5X molecule followed by recombination of the phenyl radicals, addition of the radical (I) to C_6H_5X with simultaneous detachment of hydrogen (as shown in scheme *C*), and slow formation of an intermediate complex by addition of the radical (I) to C_6H_5X with a subsequent rapid reaction due to attack by another radical or by the action of an oxidant (HO·, Fe^{3+}, or O_2 with the formation of H_2O, $Fe^{2+} + H^+$, and $HO_2^{\cdot}$ respectively)—among which the third mechanism appears to be the most probable [32,33].

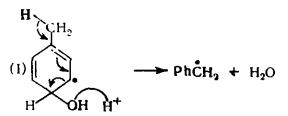
In the presence of oxygen the most probable route for the formation of phenol is reaction of the radical (I) with an oxygen molecule, the rate constant of which is quite large—$(5.0 \pm 0.6) \times 10^8$ M^{-1} s^{-1} at 23°C [34]—so that disproportionation of two radicals (I) (scheme *B*) is improbable. The formation of phenol in preference to biphenyl compounds in the presence of molecular oxygen is explained by the more rapid reaction of (I), with this oxidant than with C_6H_5X (scheme *C*). In the absence of oxygen biphenyl compounds are formed, and also phenol by reaction (1) with Fe^{3+} and by disproportionation (scheme *B*).

Table 1.

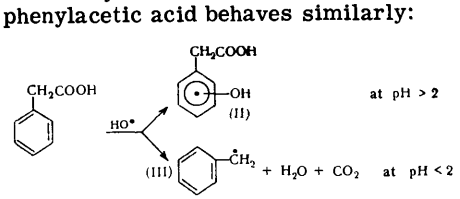
pH	Yield of products × 10^5 (moles)	
	1,2-diphenylethane	cresols
1.3	60	2.7
2.1	16	4.4
3.6	1.5	34

The pH of the medium has a great effect on the rate of oxidation by Fenton's reagent and on the composition of the products. The distribution of isomeric phenolic derivatives is maintained with variation in pH, but the proportions of phenolic and biphenyl products change substantially [24]. Table 1 gives the variation in the composition of the products for the oxidation of toluene.

Large quantities of 1,2-diphenylethane are formed in acid media in the absence of molecular oxygen. This is due to the acid-catalysed conversion of the corresponding cyclohexadienyl radical into a benzyl radical:



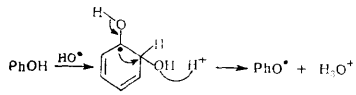
The cyclohexadienyl radical formed by the interaction of HO· with phenylacetic acid behaves similarly:



The radical (III) has been recorded in strongly acid media by electron spin resonance, and the radical (II) in less acid media.

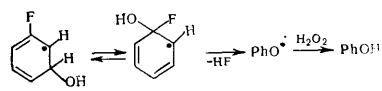
The acid-catalysed fragmentation of cyclohexadienyl radicals is a general phenomenon. Investigation of the reactions of anisole, acetanilide, fluorobenzene, and certain substituted phenols in the Ti^{3+}–H_2O_2 system showed that the adduct of HO· and phenol is recorded by e.s.r. only at pH > 1: in more acid media this adduct is not recorded, but the spectrum of the phenoxy-radical C_6H_5O· is clearly developed. Cyclohexadienyl radicals corresponding to the other benzene derivatives studied were not recorded at all in acid media[23].

These facts are explained by fragmentation of the radicals in acid media:



This last reaction is confirmed also by the pulse radiolysis of phenol in aqueous solutions[35]: the absorption spectrum of the adduct of HO· with phenol (λ_{max} = 330 nm) and the spectrum of the phenoxy-radical (400 nm) are recorded. At 20°C the adduct decomposes with a rate constant of 5000 s^{-1}, while phenoxyl accumulates at the same rate. The rate of conversion of the adduct into phenoxyl is substantially dependent on the pH and the temperature.

The above fragmentation of cyclohexadienyl radicals explains the formation of phenol when such compounds as fluorobenzene are oxidised by Fenton's reagent[23]:



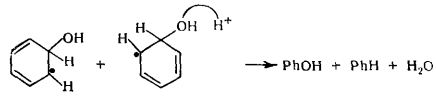
The fact that metal ions (Fe^{2+}, Fe^{3+}, Ti^{3+}) are not responsible for the influence of pH on the composition of the products is proved by results for the hydroxylation of toluene by hydrogen peroxide exposed to ultraviolet radiation[24]. Table 2 shows that the yield of cresols increases with pH, and that this effect is not due to the action of ions.

Table 2.

pH	5.4	3.0	2.0	1.0	0.2
Relative yield of cresols	10	4.2	2.5	0.9	trace

It is interesting that in strongly acidic media the yield of hydroxy-derivatives of anisole is far smaller than the yield of phenol from benzene under the same conditions[24]. The adduct of HO· with benzene is obviously more stable in acid media than is its adduct with anisole. This is confirmed by the clear e.s.r. spectra of C_6H_6O·H in the Ti^{3+} + H_2O_2 system[19], whereas the corresponding adduct of anisole is not recorded by e.s.r.[23]

Variation in pH affects the molar proportions of biphenyl and phenol produced by the ultraviolet irradiation of the C_6H_6 + H_2O_2 system (Table 3).[24] The relative increase in the yield of phenol can be explained by the fact that, in acid media, most of the phenol is formed by disproportionation, which is facilitated by hydrogen ions:



Thus the influence of pH on the composition of the products conforms to the same rules in oxidation by Fenton's reagent and in hydrogen peroxide exposed to ultraviolet radiation.

Table 3.

pH	5.5	3.0	2.0	0.5
[PhPh]/[PhOH]	0.5	0.4	0.23	0.02

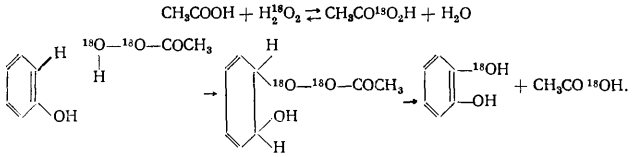
Metal ions (Fe^{3+} and Cu^{2+}) may play an important part in oxidation by Fenton's reagent, since their reactions with organic radicals are well known[36,37]. Additions of Cu^{2+} and F^- ions to Fenton's reagent have been made in the oxidation of anisole, and the effect on the yield of phenols has been examined. The yield is increased by the addition of copper ions, but fluoride ions lower the yield, since they form a stable complex with the Fe^{3+} ions which would have oxidised cyclohexadienyl radicals to phenols.

Important parameters of the species which attacks the benzene ring are the distribution of isomeric products which are formed and the relative reactivities of monosubstituted benzene derivatives and benzene itself towards this species. For example, most monosubstituted benzenes are more reactive than benzene itself towards the phenyl radical, independently of the polar character of the substituent[38]. The sequence of reactivities with Fenton's reagent is[22]

$$PhOCH_3 : PhH : PhCl : PhNO_2 = 6.35 : 1 : 0.55 : 0.14$$

This reactivity series differs from the order for phenylation[38], and indicates that the HO· species is electrophilic. The above reactivity sequence is maintained with hydrogen peroxide exposed to ultraviolet radiation.

The electrophilic nature of the HO· radical is confirmed by the distribution of isomeric phenolic products resulting from the oxidation of substituted benzenes. Table 4 shows that substituents of the first kind orient the group HO· mainly *ortho* and *para*, which is typical of electrophilic substitutions in the benzene series. Not only the HO· radical but also peroxy-acids (peracetic and trifluoroperacetic acids) may act as electrophilic agents[25,26]. Thus the oxidation of phenol by hydrogen peroxide in the presence of acetic acid and $H_2{}^{18}O_2$ yields catechol[25]:



Oxygen is incorporated into the catechol from the oxidant: free hydroxy-radicals are not formed in the reaction.

The action of Fenton's reagent involves attack by the radical HO· as has been noted many times. Several workers have recently obtained e.s.r. spectra of this radical in systems which act similarly to Fenton's

reagent. Table 5 lists the characteristics of the e.s.r. spectra and the conditions under which they have been obtained. It shows that the $Ti^{3+} + H_2O_2$ system generates HO· radicals in concentrations sufficient for detection by this method. The e.s.r. spectrum of the HO· radical differs from that of $HO_2^·$. The $Ce^{4+} + H_2O_2$ system produces solely $HO_2^·$ radicals by the reactions

$$Ce^{4+} + H_2O_2 \rightarrow Ce^{3+} + H^+ + HO_2^·$$
$$Ce^{4+} + HO_2^· \rightarrow Ce^{3+} + H^+ + O_2$$

and is considerably less effective than Fenton's reagent in the hydroxylation of benzene. From this Norman and Smith [18] concluded that $HO_2^·$ radicals are less reactive than HO· towards aromatic systems. However, Coppinger had shown [16] that the $HO_2^·$ radical is able to attack the benzene ring quite effectively.

Table 4. Distribution of isomers in the hydroxylation of substituted benzenes by Fenton's reagent.

Compound	Conditions	Phenols, %			Ref.
		ortho	*meta*	*para*	
Toluene	$Fe^{2+} + H_2O_2$, N_2	55.5	15.0	29.5	24

Many experimental results indicate nevertheless that the principal active species in oxidation by Fenton's reagent is the radical HO·. This is confirmed by the distribution of isomeric phenolic products, by the reactivity sequence of substituted benzenes towards Fenton's reagent, by the similarity with reactions with hydrogen peroxide exposed to ultraviolet radiation, and by the direct recording of the e.s.r. spectra in systems analogous to Fenton's reagent. However, recent e.s.r. studies of such systems as $Ti^{3+} + H_2O_2$ under flow conditions have shown that the e.s.r. signals originate, not from free HO· or $HO_2^·$ radicals but from their complexes with compounds of quadrivalent titanium [45]. It is probable that complexes of this type may also be hydroxylating species, acting as electrophilic agents.

III. MECHANISM OF RADIOLYTIC HYDROXYLATION

Many studies have been made of the hydroxylation of aromatic compounds under the influence of various kinds of radiation—the photochemical oxidation of benzene in aqueous solution on exposure to a mercury lamp [49,50], the oxidation of phenols under the same conditions [51–54], the photolysis of benzene in the gas phase on ultraviolet irradiation [55–59], and the oxidation of benzene and phenol in aqueous solution subject to ultrasonic vibrations [60]—but most of the investigations have used more penetrating, harder radiations—the oxidation of benzene to phenol by the action of neutrons and α-particles [61] and in aqueous solution by the action of X-rays [62–65]. The radiolysis of aromatic compounds in aqueous solution has been effected in many cases by means of cobalt-60 γ-rays [60–101]: studies have been made of the oxidation of benzene [66–92], toluene [93], naphthalene [95], chlorobenzene [97], nitrobenzene [101], anisole [100], *p*-nitrophenol [98] and benzoic acid [99].

In aqueous solution at room temperature, in the absence of oxygen and metal ions, the oxidation of aromatic compounds is effected by products of the radiolysis of water—H_2O_2, HO·, and $HO_2^·$—independently of the type of radiation employed [62,63,68]. The yields of phenols are low, 2.64–2.94 mM kr^{-1}. [67,68] In the presence of oxygen, however, the yield of phenol from benzene increases to G = 2 mol./100 eV. [68] It was first established in 1955 [49,68] that the addition of iron ions (Fe^{2+} or Fe^{3+}) to the aqueous solution increases the yield of phenol, which under certain conditions (oxygen pressure of 10 atm) may reach 6 mol./100 eV. [68] Raising the temperature from 20° to 220°C with the addition of iron ions enables phenol to be obtained from benzene in a yield of 0.035 M with a ratio of water to benzene of 32 : 1. [68] Resins containing both phenolic derivatives and polyphenylenes are formed together with the phenol. After the termination of exposure the reaction develops autocatalytically, and the authors assume that at high temperatures the oxidation of benzene is a branched chain process [68].

Exposure of a solution of benzene to X-rays in the absence of oxygen yields phenol and biphenyl, but in the presence of oxygen hydrogen peroxide and dialdehydes are also obtained [63,64]. Phenol and muconaldehyde are formed in parallel and in equal quantities [64]: G_{ph} = 1.8 and G_{dial} = 1.5.

Before considering the mechanism of the hydroxylation of aromatic compounds in the radiolysis of aqueous solutions, we must discuss the mechanism of the radiolysis of such systems as H_2O–O_2 and H_2O–O_2–Fe^{2+}–Fe^{3+}, since the facts given above make it clear that oxygen and iron ions play a very important part in the oxidation of aromatic compounds in radiolytic systems.

Analysis of the steady states arising in the radiolysis of water and their dependence on various input parameters has shown that the experimental results can be described correctly on the hypothesis that an excited species—an

exciton (ext)—takes part in the radiation-chemical process [102]. In contrast to earlier schemes [103], therefore, the mechanism of the radiolysis of the H_2O–O_2 system involves the reactions [102]

$$H_2O \rightsquigarrow H_2,\ H_2O_2,\ ext,\ H \quad (1)$$
$$ext + O_2 \rightarrow H_3O_3 \quad (2)$$
$$ext + H_2O_2 \rightarrow H_2O + 2HO^{\cdot} \quad (3)$$
$$ext \rightarrow H_2O \quad (4)$$
$$H_3O_3 + H_2O_2 \rightarrow H_2O + O_2 + H_2O_2 \quad (5)$$
$$HO^{\cdot} + H_2O_2 \rightarrow H_2O + HO_2^{\cdot} \quad (6)$$
$$HO^{\cdot} + H_2 \rightarrow H_2O + H \quad (7)$$
$$2HO_2^{\cdot} \rightarrow H_2O_2 + O_2 \quad (8)$$
$$H + O_2 \rightarrow HO_2^{\cdot} \quad (9)$$
$$HO_2^{\cdot} \rightleftarrows H^+ + O_2^- \quad (10)$$
$$O_2^- + H_2O_2 \rightarrow O_2 + HO^{\cdot} + HO^- \quad (11)$$

The above mechanism provides a good quantitative description of the radiolysis of solutions of oxygen at pH 0–6.5. The mechanism of the process at higher pH-values probably differs significantly, owing to the conversion of hydrogen atoms and excitons in alkaline medium into solvated electrons:

$$H + OH^- \rightarrow e_{aq}^- + H_2O \quad (12)$$
$$ext + HO^- \rightarrow e_{aq}^- + HO^{\cdot} \quad (13)$$

A solvated electron is extremely effective in breaking down hydrogen peroxide with formation of the radical-ion O_2^- by the reaction

$$e_{aq}^- + O_2 \rightarrow O_2^- \quad (14)$$

In solutions of Fe^{2+} and Fe^{3+} in sulphuric and perchloric acids saturated with hydrogen and oxygen under pressure the radiation efficiencies of oxidation are extremely high, reaching 100 mol./100 eV under optimum conditions [104,105]. This is evidently due to the chain character of oxidation. The radiolysis of such solutions involves the reactions [102]

$$H_2O \overset{\gamma}{\rightsquigarrow} H,\ \dot{O}H,\ H_2O_2,\ H_2 \quad (0)$$
$$HO^{\cdot} + H_2 \rightarrow H_2O + H \quad (7)$$
$$Fe^{2+} + HO^{\cdot} \rightarrow Fe^{3+} + HO^- \quad (15)$$
$$H + O_2 \rightarrow HO_2^{\cdot} \quad (9)$$
$$Fe^{2+} + HO_2^{\cdot} + H^+ \rightarrow Fe^{3+} + H_2O_2 \quad (16)$$
$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + HO^- + HO^{\cdot} \quad (17)$$
$$Fe^{3+} + H \rightarrow Fe^{2+} + H^+ \quad (18)$$
$$HO_2^{\cdot} \rightleftarrows H^+ + O_2^- \quad (10)$$
$$Fe^{3+} + O_2^- \rightarrow Fe^{2+} + O_2 \quad (19)$$

The cycle formed by reactions (7), (9), (16), and (17) regenerates a certain quantity of HO· radicals, which lays the foundation for development of a chain process. Chain termination takes place by reactions (15), (18), and (19). The conditions for chain propagation are determined by the relation between the reactions involving the growth and the termination of chains. Under certain conditions reaction (16) should be replaced by reaction (8).

Great progress has been made during recent years in the study of radiation processes in aqueous solutions, this being due in considerable measure to the successful application of pulse radiolysis, which permits determination of the absolute rate constants of many reactions involving intermediate products of radiolysis and their characterisation from the absorption spectra recorded during radiolysis [106–112].

When discussing the mechanism of the radiation hydroxylation of aromatic compounds we have repeatedly required a knowledge of the rate constants of the elementary reactions in the radiolysis of aqueous solutions. Rate constants for several primary reactions are therefore listed in Table 6. Thus the radiolysis of water and aqueous solutions involves formation of the radicals HO· and $HO_2^{\cdot}$, which in principle can be hydroxylating agents in the water–aromatic compound system. In the first stage of hydroxylation, as in the action of Fenton's reagent, the HO· radical "adheres" to the benzene ring [29,34,64].

Table 6. Rate constants of elementary reactions in the radiolysis of aqueous solutions (20–25 °C).

Reaction	Rate constant, $M^{-1}\,s^{-1}$	Ref.
$H + O_2$	$(0.53 \div 2.6)\cdot 10^{10}$	113
$H + Fe^{3+}$	$9.0\cdot 10^7$	114
$H + e_{aq}^-$	$2.5\cdot 10^{10}$	115
$HO^{\cdot} + Fe^{2+}$	$2.6\cdot 10^8$	118
$HO_2^{\cdot} + Fe^{3+}$ (0.5 M H_2SO_4)	$7.3\cdot 10^5$	108
$HO_2^{\cdot} + Cu^{2+}$ (pH 2,3)	$1.5\cdot 10^7$	109
$HO_2^{\cdot} + HO_2^{\cdot}$ (pH $\leqslant 3$)	$(1.9 \div 2.7)\cdot 10^8$	111, 116
$O_2^- + O_2^-$ (pH $\geqslant 5$)	$(1.35 \div 1.70)\cdot 10^7$	111
$e_{aq}^- + O_2$	$1.9\cdot 10^{10}$	117
$e_{aq}^- + N_2O$	$9.0\cdot 10^9$	117
$HO^{\cdot} + H_2O_2$	$4.5\cdot 10^7$	118

This reaction has been investigated with many benzene derivatives by pulse radiolysis with recording of the absorption spectra of the cyclohexadienyl radicals [29,34,117–129]. Table 7 gives the spectra of these radicals and the rate constants for reaction between the HO· radical and the aromatic compounds.

Table 7. Rate constants of reaction between HO· and C_6H_5X, and absorption spectra of cyclohexadienyl radicals $C_6H_5X(^{\cdot}OH)$.

The reactivities of substituted benzenes towards HO· have been compared under the same conditions as for the reaction of this radical with *p*-nitrosodimethylaniline. The

rate constants $k_{(HO^{\cdot} + C_6H_5X)}$ have been calculated, as well as the ratios

$$\frac{k_{(HO+C_6H_5X)}}{k_{(HO+C_6H_6)}} = \gamma^{120}.$$

A linear dependence of $\lg\gamma$ on σ_p and σ_m has been obtained for deactivating substituents X and a similar dependence of $\lg\gamma$ on σ_p for other substituents X. The coefficient ρ in the Hammett equation has been calculated as 0.41. The correlation of $\lg\gamma$ with the Hammett σ-parameter and the negative value of ρ confirm the electrophilic character of the radical $HO^{\cdot}$. However, a significant defect of this work [120] is the lack of an analysis of the isomeric phenols, so that σ is compared with the total phenol concentrations, not with the quantities of *para*- and *meta*-isomers formed.

In the absence of oxygen and iron ions the cyclohexadienyl radicals are able to react with the hydrocarbon C_6H_5X and with themselves. In the presence of oxygen and iron ions the radicals are consumed also by reactions with these additions. In acid media the unimolecular conversion of HOC_6H_5X into phenoxyl is also possible [121,122]:

$$HOC_6H_5X \xrightarrow{H^+} C_6H_5O^{\cdot} + H_2X^+$$

The mechanisms of the disproportionation of cyclohexadienyl radicals of type (I), their reaction with hydrocarbons, and also the unimolecular transformation of the radicals in acid media have been discussed in sufficient detail in Section II, and particular features of radiolytic systems have no significant influence on the mechanisms of the above processes.

The pulse radiolysis method has enabled the rates of disproportionation of radicals (I) and of their reaction with oxygen to be measured under identical conditions, and the effect of substituents X on these rates to be established [125]. The values of these rate constants in Table 8 have been used to correlate the quantities

$$\alpha = \frac{k_{(HO^{\cdot}C_6H_5X+O_2)}}{k_{(HO^{\cdot}C_6H_5+O_2)}} \quad \beta = \frac{k_{(2HO^{\cdot}C_6H_5X)}}{k_{(2HO^{\cdot}C_6H_5)}}$$

with the Hammett σ-parameters for the *meta*- and *para*-positions. Good linearity was obtained, and the coefficients in the Hammett equation were calculated as $\rho_\alpha = -1.0$ and $\rho_\beta = -0.75$. [125] Thus electron-donor substituents X tend to increase the rate of reaction of the radicals with molecular oxygen and with one another, whereas electron-acceptor substituents retard these reactions.

In the absence of oxygen a radical of type (I) may be oxidised to phenol by radicals ($HO^{\cdot}$, $HO_2^{\cdot}$) or by Fe^{3+} (Cu^{2+}) ions:

$$I + HO^{\cdot} \rightarrow XC_6H_4OH + H_2O \quad (20)$$

$$I + Fe^{+3} \rightarrow XC_6H_4OH + Fe^{2+} + H^+ \quad (21)$$

The rate constant of reaction (21) has been estimated as $k_{Fe^{3+} + HO^{\cdot}C_6H_6} = 7000\ M^{-1}\ s^{-1}$ at room temperature on the basis of the kinetic scheme set up for the oxidation of benzene in aqueous solutions in the presence of Fe^{2+} ions (0.001 M) on exposure to γ-rays. [76] The occurrence of reaction (21) is confirmed by a study of the effect of the concentration of potassium hexacyanoferrate(III) on the yield of hydroxybenzoic acids in the radiation hydroxylation of benzoic acid in aqueous solution in the presence of nitrous oxide [99]

$$(HOC_6H_5COOH)^{\cdot} + Fe(CN)_6^{3-} \rightarrow HOC_6H_4COOH + Fe(CN)_6^{4-} + H^+.$$

The rate constant (7000) of reaction (21) is much smaller than that of the reaction between the radical (I) and molecular oxygen (Table 8): i.e. addition of oxygen to the radical (I) is more rapid than the transfer of an electron by reaction (21).

Table 8. Effect of substituent X on rate of reaction of cyclohexadienyl radicals $HO^{\cdot}C_6H_5X$ (I) with oxygen and with each other.

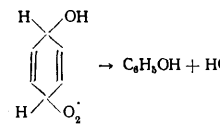
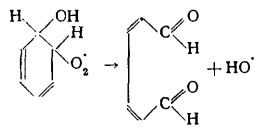
CH_3	390	3.85	3.0
C_2H_5	555	4.2	3.6

A radical of type (II) ($HO.C_6H_5.XO_2^{\cdot}$) differs from cyclohexadienyl radicals (I) in absorbing at shorter wavelengths [34]. Such radicals are able to decompose by the unimolecular reactions (22) and (23) to form phenol and dialdehydes respectively [78,79]:

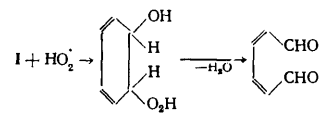


$$\rightarrow C_6H_5OH + HO_2^{\cdot} \quad (22)$$



(23)

Reaction (23) was first proposed by Kartasheva and Pikaev [78]. These workers have since shown that, in the radiolysis of benzene in aqueous solution containing iron ions and oxygen, the ratio $k_{22}/k_{23} = 1.4$. Muconaldehyde can be formed not only by reaction (23) but also by the reaction



(24)

Kartasheva and Pikaev [80] consider that, in the oxidation of benzene, the radical (II) may be involved in the reaction

$$O_2^{\cdot}C_6H_6OH + Fe^{2+} + H^+ \rightarrow HOOC_6H_6OH + Fe^{3+} \quad (25)$$

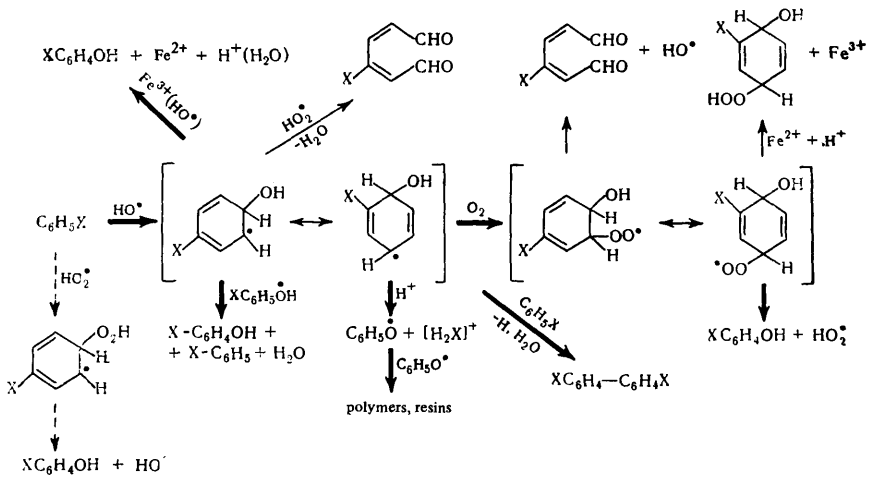
They give the ratios $k_{25}/k_{22} = 6300\ M^{-1}$ and also $k_{25}/k_{23} = 9000\ M^{-1}$: i.e. with 0.001 M Fe^{2+} the rate of reaction (25) will exceed those of reactions (22) and (23) by factors of 6 and 9 respectively. The hydroperoxide formed by reaction (25) may react in two ways:

$$HOOC_6H_6OH \rightarrow HO^{\cdot} + \dot{O}C_6H_6OH \quad (26)$$

$$HOOC_6H_6OH + Fe^{2+} \rightarrow Fe^{3+} + HO^- + \dot{O}C_6H_6OH \quad (27)$$

According to these workers [80] $k_{27}/k_{26} = 5900\ M^{-1}$.

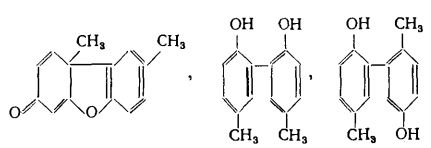
Scheme 1



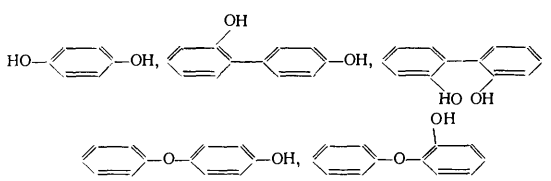
Every possible reaction in the radiation-chemical hydroxylation of benzene and its derivatives is shown in Scheme 1. Reliably demonstrated reactions of molecules and radicals are indicated by thick arrows; reactions which have been introduced into kinetic schemes, and are characterised by the constants of relatively reliably demonstrated processes, are denoted by ordinary arrows; and finally hypothetical reactions [75] are indicated by broken arrows.

Let us consider in greater detail the formation and reactions of phenoxy-radicals. As already noted [35], in acid media the adduct of the radical HO· with phenol is converted to phenoxyl with the elimination of water. The radicals $HOC_6H_4O^{\cdot}$ and $^{-}OC_6H_4O^{\cdot}$ (λ_{max} = 415 and 425 nm respectively) are recorded in the pulse radiolysis of quinol; they are formed from the adduct of HO· and quinol with a rate constant of $(4.6–8.8) \times 10^4$ s^{-1}. [122]

Phenoxy-radicals interact with one another. At 20°C the radicals $HOC_6H_4O^{\cdot}$ react with a rate constant of 1.09×10^9 M^{-1} s^{-1} to form quinone and quinol (disproportionation); [122] and tolyloxy-radicals $CH_3C_6H_4O^{\cdot}$ dimerise with a rate constant of 6.5×10^9 M^{-1} s^{-1}. [119] The recombination of tolyloxy-radicals has been proved [52] to yield dimers of the three types



The compounds



have been detected among the products of the photolysis of phenol [54].

It is very important to examine the effect of the reaction conditions—presence or absence of oxygen, addition of nitrous oxide, etc.—on the distribution of phenolic isomers in the radiation-chemical oxidation of substituted benzenes. Table 9 gives the distribution of isomeric phenols formed by the γ-irradiation of dilute aqueous solutions of benzoic acid, nitrobenzene, and anisole, and includes for comparison the distribution of isomers resulting from the hydroxylation of these compounds by Fenton's reagent.

Table 9. Distribution of isomeric phenols on γ-irradiation of dilute aqueous solutions of substituted benzenes at room temperature.

Compound	Conditions	Isomers			Ref.
		ortho	*meta*	*para*	
C_6H_5COOH	N_2O, $K_3Fe(CN)_6$	29	12	59	99
$C_6H_5NO_2$	air	50	31	19	101
$C_6H_5NO_2$	0.02 M N_2O	40	21	39	101
$C_6H_5NO_2$	0.014 M N_2O + 0.00023 M O_2, Fenton's reagent	51	31	18	110
$C_6H_5NO_2$	0.00023 M O_2	24	30	46	22
$C_6H_5OCH_3$	0.02 M N_2O	37	0	63	100
$C_6H_5OCH_3$	Fenton's reagent	80	0	20	100
$C_6H_5OCH_3$		81	1	18	24

Table 9 shows that the distribution of isomers varies with the conditions of hydroxylation: the distribution obtained on exposure in an atmosphere of nitrous oxide coincides with that obtained with Fenton's reagent, since the same species—the HO· radical—is the hydroxylating agent in this case. In the presence of nitrous oxide the reaction

$$e_{aq}^{-} + N_2O \rightarrow HO^{-} + N_2 + HO^{\cdot}$$

takes place with $k = 9 \times 10^9$ M^{-1} s^{-1} (Table 6). In an atmosphere of oxygen or air the reaction

$$e_{aq}^{-} + O_2 \rightarrow O_2^{-} \xrightarrow{H^+} HO_2^{\cdot}$$

occurs with $k = 1.9 \times 10^{10}$ M^{-1} s^{-1} (Table 6), and in my view the main hydroxylating species is now the $HO_2^{\cdot}$ radical, which produces a change in the distribution of isomers. Both radicals—HO· and $HO_2^{\cdot}$—operate in the presence of nitrous oxide and oxygen, since the reactions of the solvated electron with oxygen and with nitrous oxide are competitive. The hydroxylation of naphthalene at 55 to 120°C (on γ-irradiation) yields a little 2-naphthol (7–10%) at low temperatures, but with rise in temperature the

quantity increases to 75% (at 170°C), which is evidently due to a change in the relative proportions of HO· and $HO_2^·$ radicals with rise in temperature [95]. Thus the distribution of phenolic isomers in radiation hydroxylation indicates that two radicals—HO· and $HO_2^·$—may be active species.

The radiation oxidation of benzene and toluene in the presence of iron and copper ions at 100–200°C is especially interesting [84–94]. Iron(II) sulphate ensures a high yield of phenol (2.5% on the initial benzene) both with and without irradiation. On catalysis by the Fe^{3+} ion phenol is formed in considerable quantities only above 180°C. When copper(II) sulphate is used the yield of phenol is equally high (up to 3.7% on the initial benzene) with and without irradiation. Iron and copper chlorides are less active catalysts than are the sulphates [86,87]. The quantity of phenol formed is greatly diminished by addition of the anions Cl^- and SO_4^{2-}, but increasing the concentration of copper(II) sulphate from 0.0001 M to 0.01 M at 198°C increases the yield of phenol. Although phenol is the main reaction product, small quantities ($\sim 10^{-4}$ M) of such compounds as benzene diols, maleic, acetic, and formic acids, acetone, and acetaldehyde are also formed [90]. The oxidation of toluene under similar conditions (1 ml of toluene in 15 ml of an aqueous solution of an iron or a copper salt under 30 atm of oxygen at 100 to 200°C) yields $(2.5–4.0) \times 10^{-4}$ M benzaldehyde, $(0.2–2.1) \times 10^{-5}$ M benzyl alcohol, $\sim 0.5 \times 10^{-5}$ M benzoic acid, and up to 0.4×10^{-5} M cresols [93].

Study of oxygen transfer by means of ^{18}O showed that oxygen is incorporated into phenol both from water and from the gas phase [91]. Isotopic analysis of the phenol formed from an equimolecular mixture of benzene and hexadeuterobenzene gave $k_H/k_D = 1.2$. The small isotope effect suggests that detachment of a hydrogen atom from benzene occurs to a slight extent in the limiting step. On the basis of experimental results and published data Japanese investigators have suggested a mechanism for the oxidation of benzene and toluene, transferring without reservation to higher temperatures (180–200°C) a scheme adopted for radiation oxidation at room temperature. At high temperatures the reaction

$$HO^·C_6H_5X + O_2 \rightarrow HOC_6H_5XO_2^· \rightarrow HOC_6H_4X + HO_2^·$$

is most probably able to occur in a single step without formation of a peroxy-radical of type (II). Iron and copper ions act at high temperatures as initiators of oxidation, since they generate radicals by the reactions

$$Fe^{2+} + O_2 \rightarrow Fe^{3+} + O_2^- \xrightarrow{H^+} HO_2^· \quad (28)$$

$$Fe^{3+} + H_2O \rightarrow Fe^{2+} + H^+ + HO^· \quad (29)$$

The possible occurrence of reaction (29) has been shown by several workers [130,131]. Japanese authors attribute to iron ions also the role of stabilisers of peroxy-radicals (II), but even the existence of these radicals at high temperatures is doubtful.

The inhibiting action of chloride ions is explained by the reaction

$$Cl^- + HO^· \rightarrow Cl^· + HO^- \quad (30)$$

the rate constant of which is 1.8×10^8 M^{-1} s^{-1} at pH 2 and 25°C, increasing in 0.8 *N* sulphuric acid by a factor of 8. [118] The rate constant for the reaction between the radical HO· and benzene is 4.3×10^9 M^{-1} s^{-1}, and if the temperature variation of this constant is assumed to be the same as that of k_{30}, the reactions of HO· with benzene and with the chloride ion may compete with one another at high temperatures.

Japanese authors consider the oxidation of benzene and toluene to be a branched chain process. On the basis of published results [132] they suggest the scheme of branching

$$PhO^· + PhH \rightarrow PhOH + Ph^· \quad (31)$$
$$Ph^· + O_2 \rightarrow PhO_2^·$$
$$PhO_2^· + PhH \rightarrow PhOOH + Ph^·$$
$$PhO_2H + Fe^{3+} \rightarrow PhO_2^· + Fe^{2+} + H^+$$
$$PhO_2H + Fe^{2+} \rightarrow PhO^· + Fe^{3+} + HO^-$$
$$PhO_2H \rightarrow PhO^· + HO^·$$

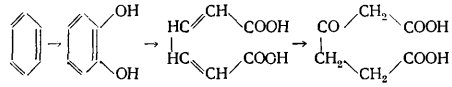
There are several grave objections to this scheme. Reaction (31) cannot occur at an appreciable rate, since the $C_6H_5O^·$ radical is relatively inactive, while the carbon–hydrogen bond in benzene is stable. This reaction is endothermic (17 kcal $mole^{-1}$) and is unable to compete successfully with such reactions of the phenoxy-radical as oxidation or addition to benzene. The hydroperoxide C_6H_5OOH does not exist as a molecular compound (especially at high temperatures), and therefore all reactions involving it are irrelevant. The mechanism of the acceleration of the oxidation of benzene in the presence of iron and copper ions will be considered in detail in Section IV dealing with the catalytic oxidation of aromatic compounds.

With regard to the part played by iron (copper) ions in radiation hydroxylation in aqueous solution, the addition of iron ions at room temperature ensures that a certain quantity of the hydroxylating agent (HO· radicals) is regenerated (reactions 16 and 17). The oxidised form of the ion (Fe^{3+} or Cu^{2+}) oxidises radicals of type (I) to phenol. At high temperatures the metal ions also initiate oxidation, since they generate HO· and $HO_2^·$ radicals by reaction with oxygen. At high concentrations of Fe^{2+} ions inhibition of the oxidation of benzene may become possible, since $k_{Fe^{2+} + HO^·} = 2.6 \times 10^8$ (Table 6), while other results indicate that $k_{HO^· + C_6H_6}/k_{HO^· + Fe^{2+}} = 3.2$ at 25°C. [133,134]

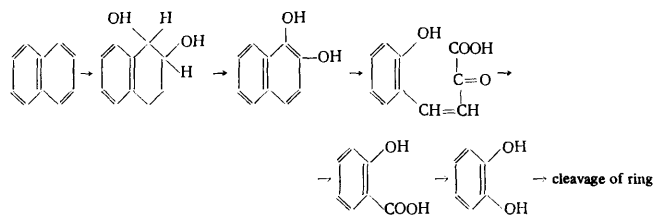
IV. CATALYTIC HYDROXYLATION

A. Enzymatic Hydroxylation of Aromatic Compounds

As already noted, micro-organisms are able to assimilate aromatic compounds, converting them into *o*- and *p*-benzenediols and then cleaving the ring to give aliphatic acids [3,135]. The oxidation of benzene yields catechol, and phenol and *cis-cis*-muconic acid accumulate [136]. Benzene oxidase has been extracted from cells grown on benzene, which it transforms according to the scheme [137]



Cultures of five different micro-organisms break down naphthalene as follows [138]:



A detailed account of the mechanism of the microbiological oxidation of aromatic and heterocyclic compounds has been published [139], but the first, most decisive stage of oxidation—hydroxylation of the aromatic ring—is not entirely understood. This stage usually involves active catalysis by enzymes, which transfer oxygen to the reaction product. Table 10 gives some examples of the hydroxylation of aromatic compounds by means of enzymes.

Table 10.

Substrate	Enzyme	Reaction product	Ref.
Salicylic acid	peroxidase + dihydroxyfumaric acid	2,4-dihydroxybenzoic acid	146
Phenylalanine	tyrosinase	tyrosine	146
3,4-Xylenol	tyrosinase	4,5-dimethylcatechol	142

In the above cases oxygen is incorporated into the hydroxy-group from molecular oxygen—not from water or hydrogen peroxide [140,142]—and the new hydroxy-group enters the *ortho*-position relative to orienting substituents of the first kind in the benzene ring. The oxygen molecule is a weak oxidant, since oxidation must involve rupture of the strong bond between the oxygen atoms, which are bound to one another by one two-electron bond and two three-electron bonds [sic]. The addition of two electrons to the oxygen molecule, as occurs on reduction to O_2^{2-} or H_2O_2, weakens the bond between the oxygen atoms. This function of reductants for the oxygen molecule is performed by metal ions, which are inevitably present in redox enzymes (Table 11). [143]

Table 11.

Metal-containing enzyme	No. of metal ions per enzyme mol.
Peroxidase	1 Fe
Tyrosinase	3-4 Cu
Catalase	4 Fe
Cytochrome oxidase	2 Fe + 2 Cu

The activation of molecular oxygen is not the only function of metal ions [144]: they may also stabilise structures, initiate chain processes, form catalytic units having qualitatively new catalytic functions, etc.

We shall consider below mechanisms of the activation of molecular oxygen and the schemes of the hydroxylation of aromatic systems which are known for peroxidases and tyrosinase [141]. Iron(II) and copper(I) ions allow the O–O bond to be ruptured by a mechanism involving reduction of the first pair of electrons. The ferrous ion combines with oxygen to form a perferryl ion FeO_2^{2+}, in which the bond between the oxygen atoms is less stable than in molecular oxygen, since electrons pass from iron to the oxygen.

Evidence of the existence of an intermediate perferryl ion has been obtained in work [144–148] on the kinetics of the oxidation of Fe^{2+} by oxygen, which is represented by the equations

$$Fe^{2+} + O_2 \rightleftarrows FeO_2^{2+}$$

$$FeO_2^{2+} + Fe^{2+} + H_2O \rightarrow Fe^{3+}OOH + Fe^{2+}OH$$

The bond in the perferryl ion may be broken with the formation of a ferryl ion FeO^{2+}. Bray and Gorin [149], from kinetic data for the reaction

$$2Fe^{3+} + H_2O_2 \rightleftarrows Fe^{2+} + FeO^{2+} + H_2O$$

suggested the existence of this ion in inorganic reactions.

There is evidence that FeO^{2+} or a similar ion of the same degree of oxidation may be present in biological systems [150]. The $FeOOH^{2+}$ ion, like the $FeOH^{2+}$ ion, is well known in inorganic chemistry from its charge-transfer spectra in solutions containing H_2O_2 and Fe^{3+}. Thus enzymes may contain iron ions of different degrees of oxidation:

$FeOOH^{2+}$ or $FeOH^{2+}$ (iron 5) – complex I,
FeO^{2+} (iron 4) – complex II,
FeO_2^{2+} – complex III,

Chance [151] showed that catalase reacts with hydrogen peroxide to form the complex (I), which reacts further with hydrogen peroxide to form molecular oxygen and water. One-electron reduction of the complex (I) yields the ferryl ion (complex II):

$$FeOOH^{2+} + H^+ + e \rightarrow FeO^{2+} + H_2O.$$

In the case of peroxidases complex (I) acts as a one-electron oxidant, the most probable mechanism being

$$Fe^{3+} + H_2O_2 \rightarrow FeOOH^{2+} + H^+$$

$$FeOOH^{2+} \xrightarrow[-H_2O]{H} FeO^{2+}$$

$$FeO^{2+} + PhH \rightarrow PhOFe^+ + H^+$$

$$PhOFe^+ + H^+ \rightarrow PhOH + Fe^{2+}$$

The hydroxylating species is the ferryl ion (complex II).

Copper is able to form complexes analogous to complexes (I)–(III) of iron-containing enzymes. It is present in tyrosinase as the univalent ion [152]; direct reaction of molecular oxygen yields the percupryl ion CuO_2^+, the analogue of complex (III) in iron-containing enzymes. The percupryl ion is then reduced to the complex (II) (the cupryl ion), which hydroxylates the benzene ring by transferring one of the atoms of the oxygen molecule to the substrate. Such a process is typical of enzymes which have been termed "oxidases of mixed function". [153] The mechanism of the action of tyrosinase is represented by the scheme [141]

$$Cu^+ + O_2 \rightleftarrows CuO_2^+ \quad \text{or} \quad Cu^+O_2Cu^+$$

$$CuO_2^+ + 2e + 2H^+ \rightarrow CuO^+ + H_2O$$

$$CuO^+ + PhH \rightarrow PhOCu^+ + H^+$$

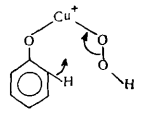
$$PhOCu^+ + H^+ \rightarrow PhOH + Cu^+$$

Evidence of the existence of the cupryl ion in tyrosinase has been obtained from the denaturation of the enzyme by acid and from kinetic investigations [154].

B. Models of Hydroxylase Biocatalysts and the Mechanism of Their Action

The detailed mechanism of the action of hydroxylases can be elucidated by means of models. Konecny, Havinga, and others [155–159] studied models of complex (I). Hydrogen

peroxide and the cupric ion hydroxylate benzene and sodium benzoate to phenol and salicylic acid respectively [155]. Studies have been made [156–159] of the copper-catalysed hydroxylation of phenols and aniline in the presence of amines. This model resembles tyrosinase: both the model and tyrosinase contain copper and hydroxylate in the *ortho*-position. A mechanism was proposed [156] in which the oxidant was hydrogen peroxide formed by the successive oxidation of certain reaction products. The Cu^{2+} ion, phenol, and the peroxide form the complex (I), which directs hydroxylation to the *ortho*-position. The Cu^{2+} ion is acting here as an acid catalyst, polarising the O–O bond so that it is cleaved with the formation of ions, the pair of electrons remaining on the oxygen near the copper atom. The action of the copper ion in this reaction resembles that of the two protons in acid-catalysed oxidations by hydrogen peroxide [160]. Complex (I) containing copper



like the iron-containing complex (I), may take part in free-radical reactions. It was suggested [156] that the hydroxylating agent in the copper–amine–phenol system was the OH^+ ion, formed by the breakdown of complex (I) and acting as an electrophilic agent. It will be shown below that this is incorrect.

Oxidative coupling of phenols is possible in the presence of amine–copper catalysts, e.g. [161]

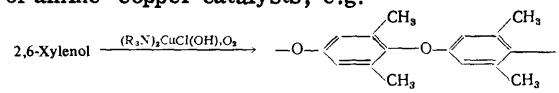


Table 12 gives the results of a study of models of peroxidases which hydroxylate aromatic compounds [162–165].

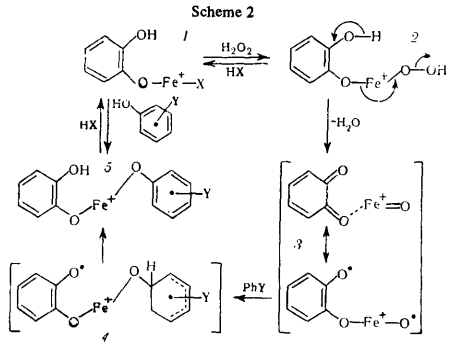
Table 12. Hydroxylation by systems (Fe^{3+}–H_2O_2–benzenediol) simulating peroxidases.

System	Substrate	Distribution of phenols			Ref.
		ortho	*meta*	*para*	
Fe^{3+} — H_2O_2 — Catechol	anisole	64	3	33	162
Catechol	nitrobenzene	48	26	26	164
Catechol	chlorobenzene	45	15	40	164
Fe^{3+} — H_2O_2 — Quinol	anisole	65	5	35	162

From a comparison of the resulting distribution of isomeric phenols with that obtained by the action of Fenton's reagent (Table 4) and a detailed kinetic investigation of hydroxylation involving the Fe^{3+}–H_2O_2–catechol system [163,164] it can be confidently stated that neither the radical HO· nor the radical $HO_2^·$ is the hydroxylating species in this case: hydroxylation occurs by the mechanism of Scheme 2. [164]

In this mechanism the overall rate of the process is limited by the formation of complexes *2* and *3*. The latter complex is a hybrid of all possible states of the metal, which explains its stability. It reacts as a radical, giving a distribution of isomeric phenols which is typical of radical attack on an aromatic ring. The ligands used to make complex *3* capable of hydroxylation were catechol, quinol, 3,4-dihydroxybenzoic acid, 3-methoxycatechol, etc. Phenol, ascorbic acid, and benzoquinone exhibit less catalytic activity or none at all, owing to the instability of the complex *3* when the above ligands are used. The interaction of form *3* with organic solvents involving removal of a hydrogen atom explains the inhibiting effect of the latter on hydroxylation.

Scheme 2



The relation between the above system and the action of such enzymes as peroxidase and catalase is that, according to George [166,167], the oxygen atom is bound to iron in the same way in these enzymes as in form *3*. In peroxidase and catalase this form is evidently stabilised by porphyrins having redox characteristics closely similar to those of catechol.

Table 13. Hydroxylation by systems (containing molecular oxygen) simulating oxidases.

System containing O_2	Substrate	Distribution of phenols, %			Ref.
		ortho	*meta*	*para*	
Fe^{2+} + EDTA + ascorbic acid	anisole	43	18	39	17
Fe^{2+} + 2,4,5-triamino-6-hydroxypyrimidine	anisole	49	13	38	169
$TiCl_3$	acetanilide	35	32	33	171
Sn^{2+}/HPO_4^{2-}	acetanilide	36	35	29	33
Fe^{2+} + 2-mercaptobenzoic acid	acetanilide	57	3	40	175
Fe^{2+} + 2-mercaptobenzoic acid	toluene	61	13	26	175
Microsome + NADP	toluene	59	13	28	175

Several enzymes (tyrosinase, etc.) act as "mixed-function oxidases", [153] which are characterised by the transfer of an oxygen atom from molecular oxygen to a substrate RH in conformity with the equation [168]

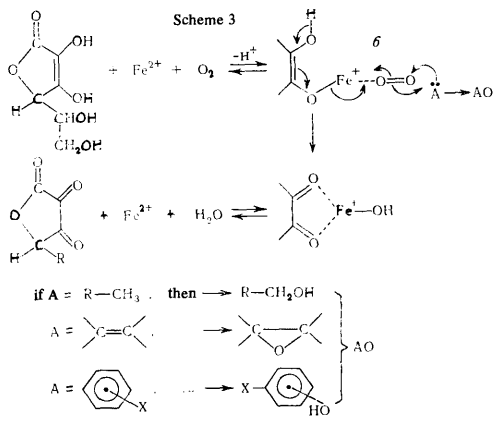
$$RH + DH_2 + O_2 \rightarrow ROH + D + H_2O$$

where DH_2 is a hydrogen donor. Such oxidases hydroxylate aromatic compounds to phenols, oxidise aliphatic compounds to alcohols, and epoxidise ethylenic compounds, which immediately excludes the radical HO· as a possible agent in their action. Several systems have been investigated which might be regarded as models of mixed-function oxidases [17,39,169–175]. These models help to answer the questions how molecular oxygen is activated,

how electrons are transferred to the oxygen molecule, and how this transfer is connected with hydroxylation of the substrate [176]. We shall first consider results (summarised in Table 13) for the hydroxylation of aromatic compounds by molecular oxygen in which such model systems are involved.

Table 13 shows that, for several substrates, the distribution of isomeric phenols differs from that for hydroxylation by Fenton's reagent (Table 4): i.e. the radical HO· is not in this case the hydroxylating species. Several papers have shown that hydrogen peroxide is not an intermediate product which might be formed and be responsible for hydroxylation [39,167,174]. Hence a special mechanism of hydroxylation is applicable to these models. The hydroxylating species in the O_2–$TiCl_3$–acetanilide system was assumed [171] to be the $HO_2^{\cdot}$ radical, which is less electrophilic than HO·, and will therefore give a distribution of isomeric phenols characteristic of nuclear attack by radicals. However, with other systems (e.g. O_2–Sn^{2+}–HPO_4^{2-}), which not only hydroxylate aromatic compounds but also oxidise aliphatic compounds, the $HO_2^{\cdot}$ radical cannot be accepted as the attacking species. Therefore several workers [39,170,174] suggest a mechanism consisting essentially in the reduction of molecular oxygen by metal ions to a so called "oxenoid" capable of transferring an oxygen atom to the substrate mostly by an electrophilic mechanism. According to Hamilton [170] the model of a mixed-function oxidase (Fe^{2+} + O_2 + ascorbic acid) acts by the mechanism of Scheme 3.

Scheme 3



According to Scheme 3 the oxidising agent is the complex *6*, where the function of the iron ion is to combine with the reducing agent and oxygen, transmitting electrons to the latter in the transition state. The iron ion enables a singlet oxygen atom to be transferred from the bound oxygen molecule to the substrate in such a way that intermediate diradicals are unnecessary. If a triplet oxygen atom were transferred, the process would be less advantageous energetically owing to the formation of a triplet reaction product, which would be less stable than a singlet product. Simultaneous transfer of the proton of ascorbic acid to the complex with molecular oxygen and transfer of electrons by means of the iron ion probably occur in complex *6*, leading to oxidation of the complex ascorbate and reduction and stabilisation of the oxygen atom not transferred to the substrate. But the other oxygen atom, having six electrons (hence analogous to carbenes CR_2 and nitrenes NR, which also have six electrons around the carbon or nitrogen and are very reactive), is incorporated into the substrate. This way a four-electron exchange is accomplished with minimum movement of nuclei.

There are in general two principal ways in which "oxene" :Ö: can act as an oxidant: (1) four-electron reduction of molecular oxygen and two-electron oxidation of the substrate take place in a single step:

$$DH_2 \cdot A \cdot O_2 \rightarrow D \cdot AO \cdot H_2O$$

(2) the same act can occur in two steps:

$$DH_2 \cdot A \cdot O_2 \rightarrow DO \cdot A \cdot H_2O$$
$$DO \cdot A \cdot H_2O \rightarrow D \cdot AO \cdot H_2O$$

In these schemes DH_2 represents the reduced form either of the enzyme or of the coenzyme, and AO the product of reaction between the substrate A and oxygen. Study of model systems shows [170] that both mechanisms are possible.

C. Mechanism of the Oxidation of Benzene to Phenol catalysed by Iron and Copper Ions in Aqueous Solution at 180–220°C

Studies of oxidation in the presence of copper and iron ions in aqueous solution have been made on the conversion of benzene into phenol at 180–220°C, [177–183] of phenol into catechol and quinol at 110°C, [184] and of ethylbenzene [185]. However, a detailed investigation of the kinetics and the mechanism of such catalysed oxidation has been made only on benzene [177–183]. Oxygen at 35–50 atm was used to oxidise benzene dissolved in water. In the absence of copper and iron ions no oxidation is observed in aqueous solution at 180–200°C, but in the presence of these ions benzene is oxidised to phenol, whose accumulation is clearly autocatalytic in character [177–187]. Phenol is an intermediate product in the reaction, which is proved by experiments in which phenol is introduced into the initial oxidising mixture. Resins and small quantities of compounds of low-molecular weight—acetone, acetaldehyde, acetic acid, etc.—are formed from phenol.

The introduction of small quantities of phenol into the initial mixture accelerates the oxidation of benzene in aqueous solution, whereas in hydrocarbon media phenol inhibits oxidation. It has been shown convincingly [180] that the phenol undergoing oxidation is responsible for the autocatalysis in the accumulation of phenol from benzene.

The valency state of the iron ions changes during the reaction: if Fe^{3+} ions are introduced into the initial aqueous solution of benzene, Fe^{2+} ions appear during the reaction; and conversely. All kinetic rules are very similar for catalysis by copper and by iron ions [177,178]: with increase in the benzene concentration the maximum reaction velocity passes through a maximum, while the maximum phenol concentration increases linearly. With increase in the catalyst concentration W_{max} passes through a maximum, while the maximum phenol concentration increases in the case of copper ions. The reaction velocity decreases with increase in the hydrogen-ion concentration. Under optimum conditions the yield of phenol is 57% based on the benzene consumed.

The mechanism of the oxidation of benzene is closely connected with that of the oxidation of phenol and the valency changes undergone by the catalytic ions. A detailed study was therefore made [181] of the mechanism of

the oxidation of phenol by oxygen catalysed by iron ions. This showed that the simultaneous occurrence of three modes of oxidation of phenol—by Fe^{3+} ions, by molecular oxygen, and by free radicals—in sulphuric acid solution at 200°C. The following mechanism was proposed for the oxidation of phenol in the presence of iron ions in aqueous solution:

$$PhOH + O_2 \rightarrow PhO^{\cdot} + HO_2^{\cdot} \qquad (0')$$

$$PhOH \overset{K_0}{\rightleftarrows} PhO^- + H_3O^+$$

$$PhO^- + O_2 \rightarrow PhO^{\cdot} + O_2^- \qquad (0'')$$

$$PhO^- + Fe^{3+} \rightarrow PhO^{\cdot} + Fe^{2+} \qquad (1')$$

Free radicals are formed in the oxidation of Fe^{2+} ions by the reactions [145–148,186,187]

$$Fe^{2+} + O_2 \rightarrow Fe^{3+} + O_2^- \qquad (2')$$

$$Fe^{2+}\,aq \overset{K_0}{\rightleftarrows} FeOH^+ + H^+$$

$$FeOH^+ + O_2 \rightarrow FeOH^{2+} + O_2^- \qquad (2'')$$

$$H^+ + O_2^- \rightarrow HO_2^{\cdot}$$

$$HO_2^{\cdot} + Fe^{2+} \rightarrow HO_2^- + Fe^{3+}$$

$$HO_2^- + H^+ \rightleftarrows H_2O_2$$

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + HO^{\cdot} + HO^-$$

The resulting radicals $HO^{\cdot}$ and $HO_2^{\cdot}$, which are indistinguishable kinetically and will henceforward be denoted by $r^{\cdot}$, react with Fe^{2+} and phenol:

$$Fe^{2+} + HO^{\cdot} \rightarrow Fe^{3+} + OH^- \qquad (3)$$

$$PhOH + r^{\cdot} \rightarrow PhO^{\cdot} + rH \qquad (4)$$

The resulting phenoxy-radicals either recombine or are oxidised to products [52,54,119,122].

Comparison of the above scheme with experiment showed that the rate of oxidation of Fe^{2+} by oxygen was

$$4\,[Fe^{2+}]\,[O_2]\,(k_{2'} + k_{2''}K_2[H^+]^{-1}),$$

and the overall rate of oxidation of phenol

$$W = (2k_0[O_2] + k_1[Fe^{3+}] + k_4[r^{\cdot}])[PhOH]_0,$$

where

$$k_0 = k_{0'} + k_{0''}K_0[H^+]^{-1}, \quad k_1 = k_{1'}[H^+]^{-1}.$$

Experimental results obtained at 200°C were used to determine the values of $k_{0'}$, $k_{0''}K_0$, $k_{2'} + k_{2''}K_2$, and $k_{1'}$, and to estimate the proportions of the three reactions in the total consumption of phenol.

Benzene when present reacts with the radicals $HO^{\cdot}$ and $HO_2^{\cdot}$ to form phenol:

$$C_6H_6 + HO^{\cdot} \xrightarrow{O_2} PhOH + HO_2^{\cdot}$$

$$C_6H_6 + HO_2^{\cdot} \rightarrow PhOH + HO^{\cdot}$$

The relative part played by each radical in the hydroxylation of benzene cannot be determined from the experimental results. However, it is clear that the catalytic oxidation of benzene in aqueous solution at 180–220°C is a coupled autocatalytic radical-ion oxidation of benzene and phenol involving short chains (4–6 steps). This conclusion was reached after a detailed study of the mechanism of oxidation of the phenol formed from benzene and an estimate of the contributions of the different reactions to the total formation of radicals in the system [182,183]. This estimate showed that, in the initial stages of the process, iron (or copper) ions act as initiators for the oxidation of benzene, forming radicals by reaction with oxygen (2′ and 2″). When the process has developed, the oxidation of phenol by oxygen (reactions 0′ and 0″) begins to play the main part in the generation of free radicals. Thus the role of accelerator of the reaction passes to phenol, while the metal ions may merely promote conversion of the radical $HO_2^{\cdot}$ into $HO^{\cdot}$.

V. HYDROXYLATION OF AROMATIC COMPOUNDS ON OXIDATION TOGETHER WITH ALCOHOLS AND HYDROCARBONS

The oxidation of hydrocarbons involves the accumulation of peroxides, which decompose with the formation of radicals. It may therefore be expected that aromatic compounds will undergo hydroxylation in the presence of easily oxidisable hydrocarbons and alcohols. Emanuel' and Denisov [188,189] were the first to demonstrate the fundamental possibility of oxidising liquid benzene to phenol under pressure at temperatures below the critical point (288°C), and discovered that such additives as cyclohexane and cyclohexanone (2 vol.%) could initiate the oxidation of benzene. The introduction of these compounds, which undergo oxidation by a chain mechanism, accelerates significantly the accumulation of phenol from benzene, but the oxidation of benzene remains self-inhibiting and cannot be conducted to high degrees of conversion.

Considerable rates of accumulation of phenol from benzene can be achieved by increasing the proportion of easily oxidisable substance. Thus when benzene is oxidised together with cyclohexane (10–20 mole %) in air (60 atm) at 220–250°C the rate of accumulation of phenol is $\sim 10^{-5}$ M s^{-1}. [190–192]. A kinetic study of the combined oxidation of benzene with cyclohexane, cyclohexanol, and cyclohexanone showed that autocatalysis in the oxidation of benzene was due to the autocatalytic oxidation of the additives [190–192]. In this case the developed reaction comprises the combined oxidation of cyclohexane and cyclohexanone and of benzene and phenol. The reaction remains self-inhibiting, owing to the inhibiting effects of benzene and of the resins formed from phenol. Other additives—methyl- and ethyl-cyclohexane, toluene, and *p*-xylene—may also exert an inhibiting action. Attempts to stimulate the oxidation of benzene by readily oxidisable organic additives have been undertaken also in the catalysed oxidation of benzene in aqueous solution [179]: the oxidation in aqueous copper(II) sulphate solution (0.125 M) at an oxygen pressure of 35 atm and 180°C is accelerated by the addition of cyclohexane and cyclohexanone (2 vol.% based on the benzene), whereas similar additions of cyclohexanol, propan-2-ol, cumene, and cyclohexene lengthen the induction period in the formation of phenol from benzene. Japanese workers [193] have made a systematic investigation of the simultaneous oxidation of benzene and toluene with the addition of ethylbenzene, cumene, cyclohexane, cyclohexene, n-hexane, t-butyl alcohol, propan-2-ol, and ethanol in solutions of iron(II) sulphate under 30 atm of oxygen at 180°C. They established that small additions of all the compounds diminish the yield of phenol from benzene and of benzaldehyde from toluene, but the yield of these products is increased by increasing the proportion by volume of the additives.

In all the above investigations the simultaneous oxidation of benzene and the additives was accompanied by hydroxylation of the benzene. However, several workers have found [194–196] that the addition of aromatic compounds diminishes the rate of oxidation of the other component, and phenolic products are not observed. Phenol is formed by the combined oxidation of benzene and a readily oxidisable additive only at sufficiently high temperatures—at 180–200°C in aqueous solution and at 220–250°C in

organic media. At lower temperatures phenol is not formed, and benzene either behaves as an inhibitor of oxidation [196] or simply changes the dielectric properties of the medium [197].

The kinetics and the mechanism of the hydroxylation of aromatic compounds have been studied when oxidised together with alcohols [198–204]. The combined oxidation of benzene and of the phenol formed from it by oxygen in aqueous solution has been established at 180–240°C; [198] a detailed study of the kinetics of the process showed that phenol was directly involved in the oxidation of benzene. To establish the character of the oxidation of benzene to phenol in aqueous solution it is important to compare the rates of oxidation of the two compounds under similar conditions. For this purpose the oxidation of benzene at 200°C was investigated on a sample which had initially been primed with phenol at its kinetically equilibrium concentration under these conditions. The rate of consumption of phenol was then equal to its rate of formation so long as there was no significant decrease in the benzene concentration. The rate of oxidation of benzene was 4.5×10^{-5} M s^{-1}, whereas the rate of oxidation of phenol at the kinetically equilibrium concentration but in the complete absence of benzene was 1.9×10^{-5} M s^{-1} under otherwise similar conditions. Thus the rate of oxidation of benzene is more than double that of phenol under analogous conditions, which indicates that the oxidation of benzene is a chain reaction. A detailed kinetic investigation of the oxidation of phenol by oxygen in phosphoric-acid solution (pH 1.55) supported the reaction mechanism [197,200]

$$\mathrm{PhOH} + \mathrm{O_2} \rightarrow \mathrm{PhO^{\cdot}} + \mathrm{HO_2^{\cdot}} \qquad (0')$$

$$\mathrm{PhOH} \rightleftarrows \mathrm{PhO^-} + \mathrm{H^+}$$

$$\mathrm{PhO^-} + \mathrm{O_2} \rightarrow \mathrm{PhO^{\cdot}} + \mathrm{O_2^-} \qquad (0'')$$

$$\mathrm{O_2^-} + \mathrm{H^+} \rightleftarrows \mathrm{HO_2^{\cdot}}$$

$$\mathrm{PhOH} + \mathrm{HO_2^{\cdot}} \rightarrow \mathrm{PhO^{\cdot}} + \mathrm{H_2O_2} \qquad (1)$$

$$\mathrm{PhOH} + \mathrm{H_2O_2} \rightarrow \mathrm{PhO^{\cdot}} + \mathrm{H_2O} + \mathrm{HO^{\cdot}} \qquad (2)$$

$$\mathrm{PhOH} + \mathrm{HO^{\cdot}} \rightarrow \mathrm{PhO^{\cdot}} + \mathrm{H_2O} \qquad (3)$$

$$\mathrm{PhO^{\cdot}} + \mathrm{PhO^{\cdot}} \rightarrow \mathrm{Products}\ .$$

Comparison of this scheme with the experimental relations enabled the rate constants of reactions (0′), (0″), and (2) to be evaluated as (in $M^{-1} s^{-1}$) $k_{0'} = 4.9 \times 10^8 \exp(-25\,600/RT)$, $k_{0''} = 3.5 \times 10^{12} \exp(-17\,000/RT)$, and $k_2 = 7.3 \times 10^{10} \exp(-23\,700/RT)$. The phenoxide ion reacts with oxygen at 200°C with a rate constant exceeding the rate constant of reaction (0′) by a factor of 10^7, but in acid media the two reactions occur at comparable rates, since the concentration of phenoxide ions is very small. The oxidation of phenol by oxygen is accompanied by the formation of $HO_2^{\cdot}$ radicals and hydrogen peroxide, which then reacts with the phenol. The rate constants of reactions (0′) and (2) can be used to calculate kinetically the equilibrium concentrations of hydrogen peroxide, and compare the results with the experimental values. Such a comparison has been made at 157° and 180°C, and shows good agreement between experimental and calculated quantities of hydrogen peroxide, which supports the above mechanism.

The radicals $OH^{\cdot}$ and $OH_2^{\cdot}$, formed by the oxidation of phenol, hydroxylate benzene. Whereas the hydroxylating power of the former radical is well known, the similar part played by $HO_2^{\cdot}$ in the combined oxidation of aliphatic alcohols and aromatic compounds has been demonstrated quite recently [201–204]. For this purpose benzene was introduced into two systems—comprising hydrogen peroxide and an initiator together with water and with methanol and molecular oxygen—in which $HO_2^{\cdot}$ radicals are generated continuously but no $HO^{\cdot}$ radicals are formed [201]. Under these conditions $HO_2^{\cdot}$ is formed by the reaction of initiator radicals and peroxy-radicals of methanol $RO_2^{\cdot}$ with hydrogen peroxide. Evidence has been obtained [205,206] of the rapid exchange $R^1OO^{\cdot} + R^2OOH \rightarrow R^1OOH + R^2OO^{\cdot}$. The radicals $RO_2^{\cdot}$ in the oxidisable alcohol exchanged for $HO_2^{\cdot}$ in the hydrogen peroxide formed, the degree of this substitution depending on the ratio of the rate constants $k_{RO_2^{\cdot} + H_2O_2}/k_{HO_2^{\cdot} + RH}$. At 30°C, for example, 0.11 to 0.47 M ROOH is sufficient for complete exchange of peroxy-radicals with the hydroperoxide during oxidation of the hydrocarbon [207]. It is therefore most likely that at 110–220°C there will be complete exchange of peroxy-radicals with hydrogen peroxide taken in the same concentrations, for the H–O bonds to be broken have almost the same strength in the hydroperoxides as in hydrogen peroxide.

In the presence of an initiator and hydrogen peroxide, phenol is formed from benzene both in water (in an atmosphere of argon) and in oxidisable methanol (in oxygen). Phenol is formed only by the reaction of benzene with free radicals: in the absence of an initiator hydrogen peroxide does not hydroxylate benzene under the experimental conditions, since no appreciable decomposition of the peroxide with the formation of $HO^{\cdot}$ radicals takes place. Therefore the formation of phenol from benzene in the systems—H_2O–H_2O_2—initiator and CH_3OH–H_2O_2–initiator–O_2—must be regarded as proof of hydroxylation by the radical $HO_2^{\cdot}$. Kinetic study of the combined initiated oxidation of methanol and benzene showed that the initial rate of accumulation of phenol $W_0^{C_6H_5OH}$ is directly proportional to the square root of the initial concentration of the initiator: i.e. it increases linearly with the concentration of free radicals in the system. Three types of free radicals—those from the initiator, $\diagdown\!\!\diagup C(OH)OO^{\cdot}$, and $HO_2^{\cdot}$—are present in the oxidisable alcohol (the concentration of $\diagdown\!\!\diagup C(OH)^{\cdot}$ radicals is very small in the presence of molecular oxygen and they can be ignored). Experiments in water showed that in the presence of hydrogen peroxide an initiator does not ensure the hydroxylation of benzene: i.e. the initiator radicals are not involved in hydroxylation. In methanol undergoing oxidation, therefore, benzene can be hydroxylated by $\diagdown\!\!\diagup C(OH)OO^{\cdot}$ and $HO_2^{\cdot}$ radicals. Experiments in methanol with different initial concentrations of hydrogen peroxide showed that this factor has hardly any effect on $W_0^{C_6H_5OH}$: i.e. benzene is hydroxylated either by both peroxy-radicals or by $HO_2^{\cdot}$ alone. The hydroxylation of benzene in the H_2O–H_2O_2–initiator system, in which $\diagdown\!\!\diagup C(OH)OO^{\cdot}$ radicals are in general absent, again proves that $HO_2^{\cdot}$ is able to hydroxylate benzene. Thus the hydroxylating power of the $HO_2^{\cdot}$ radical has been demonstrated.

The oxidation of alcohols involves the formation of hydrogen peroxide, which may yield $HO_2^{\cdot}$ radicals by reaction with the peroxy-radicals of the alcohol. Hydroxylation of benzene can therefore be expected when it is oxidised in the presence of alcohols. In fact phenol is formed in all cases of such oxidation in air at 50 atm and 200°C. [202,204] Its rate of accumulation shows a well defined autocatalytic character.

In order to obtain quantitative parameters a study was made of the initiated oxidation of mixtures of alcohols and benzene at 145°C. Measurements were made of the initial rates of accumulation of phenol $W_0^{C_6H_5OH}$ and of

the total oxidation products of the alcohol W_0^{alc}. The initial stages of oxidation of an alcohol mixed with the benzene were shown [201] to be described by the equation for chain reactions with quadratic termination:

$$W_0^{alc} = (k_2/\sqrt{k_6})_{alc}[R-OH]_0\sqrt{W_i},$$

where $[ROH]_0$ is the initial alcohol concentration, k_2 the rate constant of chain growth, k_6 the termination rate constant, and W_i the rate of initiation. The oxidation of benzene was characterised by the parameter $(k_2/k_6^{1/2})_b$, calculated by means of the equation

$$W_0^{PhOH} = (k_2/\sqrt{k_6})_b[C_6H_6]_0\sqrt{W_i}.$$

Table 14. Initiated oxidation of benzene–alcohol mixtures in air at 50 atm and 145°C in the presence of 0.054 M t-butyl peroxide ($W_i = 1.18 \times 10^{-5}$ M s^{-1}).

Alcohol	M	Benzene, M	$10^4 W_0^{alc}$, M s^{-1}	$10^3(k_2/k_6^{1/2})_{alc}$	$10^6 W_0^{C_6H_5OH}$, M s^{-1}	$10^{-4}(k_2/k_6^{1/2})_b$	No. of steps
Propan-2-ol	9.15	3.35	5.80	18.4	3.84	3.32	49
Ethanol	13.7	2.25	1.80	3.80	1.70	2.20	15
Methanol	19.7	2.25	1.82	2.70	0.47	0.61	15
t-Butyl alcohol	8.5	2.25	0.16		0.10		1—2

Experimental results for the initiated oxidation of mixtures of benzene and alcohols are given in Table 14, from which it follows that the rate of accumulation of phenol is a maximum for the initiated oxidation of benzene in propan-2-ol.

The oxidation of mixtures of propan-2-ol and benzene or toluene has been studied at 110–150°C. Rates of initiation were calculated for various temperatures by means of the equation $W_i = k_i[TBP]_0$, where TBP represents t-butyl peroxide and $k_i = 4.4 \times 10^{14}\exp(-35\,000/RT)$ s^{-1}. [207, 208] The initial rates of accumulation of phenol, benzaldehyde + benzyl alcohol, cresols, and acetone were used to calculate the rate constant ratios $k_2/k_6^{1/2}$ for benzene, toluene at the methyl group, cresols, and propan-2-ol: for a toluene–propan-2-ol mixture

$$(k_2/\sqrt{k_6})_{i\text{-PrOH}} = 1.30 \cdot 10^4 \exp(-11000/RT),$$
$$(k_2/\sqrt{k_6})\ \text{at}\ CH_3 = 3.20 \cdot 10^2 \exp(-9600)/RT),$$
$$(k_2/\sqrt{k_6})_{\text{cresols}} = 17.8\exp(-9100/RT),\ M^{-1/2}\,s^{-1/2}.$$

and for a benzene–propan-2-ol mixture

$$(k_2/\sqrt{k_6})_{i\text{-PrOH}} = 2.40 \cdot 10^3 \exp(-9800/RT),$$
$$(k_2/\sqrt{k_6})_b = 4.25 \cdot 10^2 \exp(-11700/RT),\ M^{-1/2}\,s^{-1/2}.$$

The hydroxylation of monosubstituted benzene derivatives in the course of the initiated oxidation of propan-2-ol has been studied at 137°C in air at 50 atm. The experimental results are listed in Table 15.

The mechanism of the oxidation of alcohols has now been thoroughly investigated [209]. The primary oxidation products are hydroperoxides, which break down into hydrogen peroxide, and carbonyl-containing compounds—acetone, formaldehyde, and acetaldehyde from propan-2-ol, methanol, and ethanol respectively. Hydrogen peroxide accumulates in considerable concentrations in the oxidation of secondary and primary alcohols, the quantity depending on the nature of the alcohol. In fact, in benzene–alcohol mixtures with the same conditions of initiation at 145°C, the quantity of hydrogen peroxide and its rate of accumulation increase in the sequence—methanol < < ethanol < propan-2-ol. Peroxy-radicals react with hydrogen peroxide to form hydroperoxy-radicals. Thus $HO_2^\cdot$ radicals are formed in mixtures of alcohols with benzene and its derivatives as a consequence of a series of reactions such as

$$\text{Initiator} \xrightarrow{k_i} r^\cdot \xrightarrow{RH} rH + R^\cdot \qquad ROOH \rightarrow H_2O_2 + \text{>C=O}$$
$$R^\cdot + O_2 \rightarrow RO_2^\cdot \qquad RO_2^\cdot + H_2O_2 \rightarrow HO_2^\cdot + ROOH$$
$$RO_2^\cdot + RH \rightarrow ROOH + R^\cdot \qquad HO_2^\cdot + RH \rightarrow H_2O_2 + R^\cdot \text{ etc.}$$

These radicals hydroxylate the aromatic compounds and react with one another:

$$XC_6H_5 + HO_2^\cdot \rightarrow XC_6H_4OH + HO^\cdot \qquad 2\,HO_2^\cdot \rightarrow H_2O_2 + O_2.$$

Table 15. Initiated oxidation of propan-2-ol (70 ml) mixed with monosubstituted benzenes (30 ml) at 137°C in the presence of 0.108 M di-t-butyl peroxide.

C_6H_5X	$[C_6H_5X]_0$, M	Length of chain	$10^2(k_2/k_6^{1/2})_{alc}$	$10^4(k_2/k_6^{1/2})_{ar}$	$10^4(k_2/k_6^{1/2})_{ar}$	
					ortho	*m + p*
C_6H_6	3.36	50	1.44	2.51	—	—
$C_6H_5CH_3$	2.82	53	2.09	2.24	1.12	1.12
C_6H_5Cl	3.11	64	2.14	3.43	1.48	1.94
$C_6H_5NO_2$	2.94	12	0.39	0.83	0.42	0.41
C_6H_5OH	0.50	3	0.11	—	—	—

At later stages the $HO_2^\cdot$ radicals react with the phenols which are formed, and both the latter and the resins which accumulate from them tend to inhibit oxidation [202].

The concentration of $HO_2^\cdot$ radicals in alcohol–benzene mixtures is $(\alpha W_i/k_6)^{1/2}$, where α represents the completeness of exchange of $RO_2^\cdot$ for $HO_2^\cdot$ radicals. Thus with the same initiation the concentration depends on α and k_6. The constant k_6 is greatly influenced by the medium [197], and α by the ease of oxidation of the alcohol. The combined effect of these factors is that the $HO_2^\cdot$ concentration, and hence the rate of hydroxylation of aromatic compounds $W = k_2^{ar}[XC_6H_5]_0[HO_2^\cdot]$, increase in the sequence—methanol < ethanol < propan-2-ol—corresponding to the ease of oxidation of the alcohols. Table 15 show that, in propan-2-ol undergoing oxidation, all monosubstituted benzenes are hydroxylated with formation of the corresponding phenols. The isomeric distribution of the resulting substituted phenols differs substantially from that obtained on hydroxylation by Fenton's reagent (Table 16). This indicates that in the present systems the benzene ring is attacked not by the $HO^\cdot$ radical, as with Fenton's reagent, but by another species—the $HO_2^\cdot$ radical.

---o0o---

A detailed examination of the mechanisms of the hydroxylation of aromatic compounds shows that various species can act as hydroxylating agents depending on the conditions—the $HO^\cdot$ radical (Fenton's reagent and radiolytic systems), the $HO_2^\cdot$ radical (catalytic conversion of benzene into phenol at high temperatures, the combined oxidation of aromatic compounds together with alcohols and hydrocarbons, and also perhaps in radiolysis at high temperatures), and complexes of iron-containing enzymes with oxygen. In many papers different mechanisms are

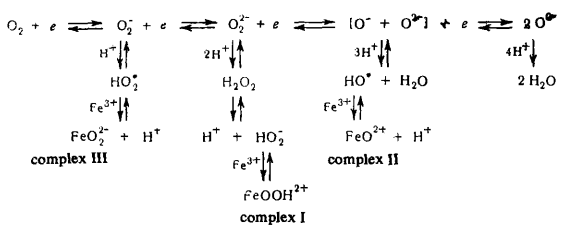
often sharply contrasted with one another; however, we shall attempt to show the relation between them by systematically examining the reduction of an oxygen molecule and the fate of the resulting intermediate species in the presence of ions of variable valency, e.g. iron. Scheme 4 shows the stepwise reduction of an oxygen molecule and the formation of every possible hydroxylating species.

Table 16. Distribution of isomers in the hydroxylation of benzene derivatives in propan-2-ol undergoing oxidation and by means of Fenton's reagent.

XC_6H_5	Combined oxidation of benzene and propan-2-ol			Fenton's reagent			Ref.
	ortho	*meta*	*para*	*ortho*	*meta*	*para*	
$C_6H_5CH_3$	50	25	25	55.5	15.0	29.5	24
		meta—para					
C_6H_5Cl	43	57		42	29	29	22
$C_6H_5NO_2$	51	49		24	30	46	22

According to George [167] the oxidising power of oxygen varies with the stage at which oxidation terminates. If molecular oxygen is reduced to the superoxide anion, and the latter is unable to react further, oxygen is a weak oxidising agent. A higher degree of oxidation is achieved when the superoxide ion combines with a proton to form $HO_2^{\cdot}$. In the reduction of hydrogen peroxide oxygen behaves as an oxidant of medium strength, approximately the same as Fe^{3+}. [176] In the presence of Fe^{3+} ions (or Ti^{4+}, etc.) $HO^{\cdot}$ and $HO_2^{\cdot}$ radicals are able to form complexes with the metals, and thus become stabilised. The ferryl ion FeO^{2+} can be regarded as an $HO^{\cdot}$ radical stabilised by the Fe^{3+} ion. Scheme 4 shows the possible hydroxylating agents and their modes of interconversion.

Scheme 4



A very important aspect of the hydroxylation of aromatic compounds is the nature of the attack on the ring. Although the $HO^{\cdot}$ radical attacks the ring by an electrophilic mechanism, as indicated by the distribution of isomers produced by Fenton's reagent and in radiolytic systems, the $HO_2^{\cdot}$ radical will give a distribution of isomers which is more typical of radical substitution in the benzene ring. Very contradictory results are obtained for the distribution of isomeric hydroxylation products with model systems of mixed-function peroxidases and oxidases and with the enzymes themselves. However, this discrepancy can be eliminated when it is remembered that the agents which attack the benzene ring in these cases are able to react in different forms—as radicals and as ions of different signs. Hamilton considers [170] that the character of the attack on the benzene ring, and hence the distribution of isomers, may change with model systems from radical to electrophilic and even to nucleophilic. It all depends on which state—ionic or radical—predominates with the given hydroxylating species. This state depends on the type of metal and especially on the ligand surrounding it. For example, hydroxylation by means of Fe^{2+}–mercaptobenzoic acid–O_2 yields a distribution of isomers which is characteristic of electrophilic reactions; the same distribution of isomers is obtained by the hydroxylation of toluene in the toluene–t-butyl hydroperoxide–$AlCl_3$ system [210], in which the benzene ring is attacked by the t-butyloxonium cation $[(CH_3)_3COH_2]^+$ by a definitely electrophilic mechanism. However, replacement of the ligand in the Fe^{2+}–EDTA–ascorbic acid–O_2 system produces a sharp change in the distribution of isomers, since the nature of the attacking species changes. There are in general many forms of the attacking complex in the latter case, so that it is necessary to consider the state of the complex as a whole and to know which form is the most significant, for this form will determine the character of the attack on the benzene ring.

We note in conclusion that the study of hydroxylation mechanisms is especially valuable in biochemistry, since reactions of this type occur widely in biological systems. Work during recent years has shown that the mechanism of free oxidations, which play a part in temperature control and several specific metabolic functions, such as the formation of metabolites by oxidation, the detoxication of poisonous compounds, etc., consists in hydroxylation of the substrate [211]. The most widespread is hydroxylation accomplished by a special respiratory chain comprising enzymes of free [non-phosphorylating] oxidation. This system is present in liver microsomes, where foreign compounds and several natural metabolites are converted into non-toxic polar products, the initial stage in these transformations being hydroxylation of the molecule.

Comparison of the Activities of Catalysts for Heterogeneous Catalytic Reactions

A.V.Sagalovich and A.L.Klyachko-Gurvich

The existing methods for comparing catalytic activities in terms of various parameters of the kinetic equation and the Arrhenius equation are discussed. A criterion is proposed for estimating the reliability of the results obtained by these methods. The conditions for and limits of their applicability have been defined.
The bibliography includes 157 references.

5. Comparison of the activities of catalysts in terms of the temperature at which the degree of conversion or the reaction rate has a specified value 587
6. Comparison of the activities of catalysts in terms of activation energy 589

1. REACTION RATE AS A MEASURE OF CATALYTIC ACTIVITY

Despite its wide employment in studies on catalysis, the term "catalytic activity" is exceptionally indeterminate, since various kinetic parameters are used, and not always justifiably, as a measure of activity. In some reports it is actually not stated at all what is meant by this term. To accord with the significance of the phenomenon of catalysis, the change in the rate of chemical reaction as the result of the introduction of the catalyst into the system should be adopted as a measure of catalytic activity[1]. Since the rate of the non-catalysed process is usually negligibly small compared with the catalysed rate, the rate of reaction in the presence of the catalyst may be regarded as an accurate measure of activity[1-4].

We shall define the rate of a heterogeneous catalytic reaction as a change in the number of reactant or product molecules per unit time per unit catalyst surface. On the basis of this definition, we shall examine the expressions for the rate of reaction in reactors with stationary catalyst beds. Under steady-state conditions in an ideal-mixing flow reactor (a gradient-free reactor, in particular a stirred flow reactor), the rate of reaction is constant both with respect to time and over the entire catalyst surface. If the amount of substance i changes by ΔN_i moles in a stream of reaction mixture passing through a catalyst bed with a surface area S during a time t, the rate of reaction is

$$v = \pm \frac{\Delta N_i}{St}, \qquad (1)$$

where the sign depends on whether the substance i is formed or consumed. When the rate of reaction is expressed in terms of various components of the reaction mixture, account must be taken of the stoichiometric coefficients. In a static ideal-mixing reactor, the rate of reaction is the same at each instant over the entire surface but varies with time. Therefore the rate at a given time is

$$v = \pm \frac{1}{S}\frac{dN_i}{dt}. \qquad (2)$$

In an ideal plug flow reactor under steady state conditions, the rate of reaction varies along the catalyst bed but remains constant with respect to time for each section of the bed. Therefore for an infinitely thin bed with a surface area dS, at right angles to the axis of the reactor, the rate is

$$v = \pm \frac{1}{t}\frac{dN_i}{dS}. \qquad (3)$$

For a flow reactor, the amount of substance is usually expressed in terms of the number of moles passing through the cross-section of the reactor per unit time: $N' = N/t$. Then Eqn. (3) becomes[5,6]

$$v = \pm \frac{dN_i'}{dS}.$$

The rate equations (1)–(3) can be formulated in terms of other variables. For example, for an ideal plug flow reactor,

$$v = \pm \frac{dN_i}{t\,dS} = \frac{N_0}{t}\frac{d\alpha}{dS} = \frac{N_0}{ts\rho}\frac{d\alpha}{dw} = \frac{N_0}{ts\rho\sigma}\frac{d\alpha}{dl}, \qquad (4)$$

where α is the degree of conversion, N_0 is the number of moles of the starting materials supplied to the reactor during a time t, $\pm N_i = N_0 d\alpha$, s and ρ are respectively the specific surface and the bulk density of the catalyst, σ is the cross-sectional area, and dl and dw are the length and the volume of a catalyst bed with a surface area dS. If the contact time $\tau = w/u$ is employed as a variable for a reaction without a change in the number of molecules, w being the volume of the catalyst bed and u the volume of gas passing through the cross-section of the bed per unit time, Eqn. (4) becomes

$$v = \frac{N_0}{ts\rho}\frac{d\alpha}{dw} = \frac{N_0}{ts\rho u}\frac{d\alpha}{d\tau} = \frac{P_0}{RTs\rho}\frac{d\alpha}{d\tau}, \qquad (5)$$

where $N_0/t = P_0 u/RT$ and P_0 is a constant pressure of the starting material at the inlet to the reactor. An analogous expression for the rate of reaction in terms of the contact time may be written for an ideal-mixing flow reactor:

$$v = \pm \frac{\Delta N_i}{tS} = \frac{N_0\alpha}{ts\rho w} = \frac{P_0}{RTs\rho}\frac{\alpha}{\tau}. \qquad (6)$$

In a reaction involving a change in the number of molecules, the flow rate u becomes a function of the degree of

conversion and the contact time τ in the flow reactor is determined by highly complex formulae, which depend on the form of kinetic equation[7]. Here one can employ as a variable in the rate equation[8] the quantity $\tau' = w/u_0$, where u_0 is the volume of gas passing into the reactor per unit time.

Our definition of the rate of reaction is not unique. Apart from the area of the catalyst surface[5,6,9,10], the rate of reaction may be referred to its unit weight[11], unit volume[12,13], or the length of the bed[14]. It is also possible to refer the rate to the surface area of the active phase or to the number of its active centres if these quantities are known†. The above definitions involve the number of moles of the substance in the numerator and can be readily interconverted on multiplication by appropriate constants. The definition of the rate of reaction in terms of the concentration of the substance[15-17] instead of its amount is not universal and is applicable only to reactions at constant volume, when the concentration varies only due to the reaction and not due to a change in the volume of the system system[10,18,19].

By definition, the rate of reaction v is the rate per unit catalyst surface. However, in the literature the rate of reaction is usually defined as the quantity v' calculated from the experimental data (the observed rate), which refers to a catalyst with a surface area S and the rate of reaction $v = v'/S$ is called the specific rate. We may note that the possible heterogeneity of the surface does not preclude the assignment of the observed rate v' to unit surface, since v characterises the average activity of 1 m^2 of the surface area of the given catalyst. Although in the vast majority of cases the observed rate of reaction on solid catalysts is proportional to their amount[20], it is useful to verify this experimentally. Such a test[21-24] confirms the validity of the definition of the activity of catalysts, since, if the experimental conditions are chosen erroneously, the above proportionality may not in fact obtain. For example, it will not hold for very long contact times in a flow reactor, when a linear relation is obtained between the yield of products per unit time and the rate of supply of the starting material, as has in fact been observed[25,26]. In this case the yield corresponds to equilibrium[27] and is attained on part of the catalyst bed, while the remainder is inactive.

In this review we shall not consider the experimental methods for the determination of the rate of reaction. The problem of the choice of experimental conditions to ensure that the observed rate of reaction characterises the activity of the catalyst has been most fully examined by Boreskov[1,20,28] and also by Dowden and Bridger[29], Germain[3], and de Mourgues[30]. The rate of reaction must be measured under isothermal conditions with the catalyst surface in a steady state and in the absence of an effect of heat and mass transfer processes, i.e. in the kinetic region‡. For a reversible reaction, the rate of the process in one direction only must serve as a measure of activity and not the observed rate, which is equal to the difference between the rates in the forward and reverse directions.

The rate of reaction in the presence of a given catalyst depends on temperature and the concentrations (or pressures) of the reactants and products and also extraneous substances. By virtue of this dependence, the rates for different catalysts can be compared only at the same temperature and pressure and for the same composition of the reaction mixture. Despite this, one sometimes encounters in the literature comparisons where the relevant mixture composition is not stated[31]. The relative activities of a series of catalysts found for the same composition of the reaction mixture may be altered for a different composition owing to varying forms of the kinetic equations valid for these catalysts.

In a gradient-free reactor the rate of reaction is calculated from data for a single experiment by Eqn. (6). It is more difficult to satisfy the conditions of a constant composition of the reaction mixture. It is incorrect to compare the rates of reaction for the same composition and rate of supply of the mixture of starting materials as is sometimes done[32-34]. This is because under such standard conditions the mixture compositions in the system differ owing to the different activities of the catalysts. Identical compositions of the reaction mixture can be achieved by varying the degree of conversion, the rate of supply of the starting materials, the composition of the mixture of starting materials supplied, or the amount of the catalyst as was done by Dzis'ko and coworkers[35-37]. It is also possible to find the kinetic equation for each catalyst and to use it to calculate the rate of reaction for a particular composition of the reaction mixture[38].

In integral reactors it is impossible to measure the rate of reaction but it can be found by the graphical differentiation of the kinetic curve. It can also be calculated from the differential kinetic equation by substituting specified concentrations of the reactants and the rate constant obtained by verifying the integral equation[39]. When the reaction is carried out in an "adsorption layer"[22,31,40,41], the condition of a constant composition of reaction mixture must be replaced by the condition of identical surface concentrations.

A special case of the comparison of catalysts in terms of the rate of reaction for a constant composition of the reaction mixture is the comparison based on the "initial rate", i.e. the rate at the start of the reaction when the concentration of reaction products is zero. Naturally, the concentrations of starting materials in such a comparison must be the same. The initial section of the "degree of conversion–time" (duration of contact) kinetic curve can never be measured directly and therefore the initial rate can only be found by extrapolation. The minimum degree of conversion determined experimentally depends on the accuracy of the analytical method and other conditions. The extrapolation is performed on the assumption that near the zero time the same kinetic law holds as in the region of conversions accessible to experiment.

The method of initial rates is usually employed when the experimental curve has a linear section which on extension passes through the origin of coordinates[24,30,42-45]. A linear section, i.e. a constant reaction rate, is characteristic of the initial part of the kinetic curve described by equations of the Langmuir–Hinshelwood type or by power functions without product inhibition, which in the region of low conversions can be approximated by the equation for zero-order kinetics[46]. Evidently the wider is the region

† The assignment of the rate of reaction to unit surface may be purely formal if the entire surface is not active, which sometimes happens for a catalyst with a large surface area or when the surface area of the active phase of the catalyst is unknown. In some cases the very concept of the catalyst surface is without significance (zeolites). We have adopted the definition of the reaction rate which is most widely used in the Russian literature.

‡ For industrial processes in the diffusion region, a quantitative comparison of the activities of catalysts is impossible; one can only compare the yields of products under specified conditions.

under which a constant reaction rate is observed under these conditions (up to 50% [44] and 60% [45] conversion), the lower is the accuracy needed to demonstrate it. If the accuracy of the analysis does not allow the attainment of the region which may be linear, the use of a tangent to the curve, as in the work of Wade et al.[47], involves large errors. When the reaction kinetics at moderate conversions permit the assumption of a linear section, interpolation formulae and in particular Newton's formula [48,49] may be recommended for extrapolation of the curve.

The application of the method of initial rates to reactions inhibited by products is open to objection (Kiperman [50] and Boudart [51]), since the kinetic equation $v = kC_i^n/C_j^m$, where C_i and C_j are respectively the concentrations of the reactant and the product, is not converted into the equation for zero-order kinetics in the region of low conversions [46]. The slope of the curve described by this equation is infinite at $t = 0$ and extrapolation of the curve is pointless.

There exists the opposite view [52,53] that the initial rate may be determined independently of the form of the kinetic equation, since a power function with inhibition cannot describe the region of low conversions where reaction products are virtually absent. Indeed the rate of reaction in the initial instant cannot be infinite. However, as already stated, a linear section must be always obtained to determine the initial rate. Without this, the absence of product inhibition cannot be assumed, since sometimes it already has an appreciable influence for conversions not exceeding 1% [51].

A flow reactor with a small amount of catalyst, which allows experiments at low conversions and which is called a differential reactor [54-56], is frequently used to determine the initial rate. As in a stirred flow reactor, the rate is calculated by Eqn. (6), i.e. the slight changes in the rate in a thin catalyst bed are neglected. As stated above, the constancy of the rate at low conversions depends not only on the type of reactor and the experimental conditions but also on the type of kinetic equation. Nevertheless, sometimes this problem is not discussed and only the maximum degree of conversion is reported [57]. In determinations of the rate of reaction at moderate and high product concentrations with the aid of the differential reactor [23,56,58,59], the type of kinetic equation does not play any role. In this region the determination of the rate does not involve an extrapolation.

2. COMPARISON OF CATALYST ACTIVITIES IN TERMS OF THE REACTION RATE CONSTANT

We shall formulate in a general form the dependence of the reaction rate on temperature and the concentrations of the reaction mixture components:

$$v = f(T, C_i, C_j).$$

As a rule, for heterogeneous catalytic reactions the multiplier $k(T)$, which depends only on temperature but not on pressure or the composition of the reaction mixture, may be taken outside the function f:

$$v = k(T)\varphi(T, C_i, C_j).$$

In particular, this possibility is illustrated by the review [60] of kinetic equations for catalytic gas-phase reactions investigated in flow reactors. By analogy with the kinetics of simple single-stage reactions, the multiplier $k(T)$ can be conventionally [61] referred to as the reaction rate constant.

For simple reactions, the rate constant is the proportionality coefficient between the rate of reaction and a power function of reactant concentrations only. For heterogeneous catalytic processes, the function φ is usually more complex. Fractional and negative power exponents and variation with product concentration and with temperature are typical. The rate constant in equations with several constants (for example in equations of the Langmuir–Hinshelwood type) is not equal to the rate for unit concentrations of the reaction mixture components. Only in single-term power equations can the rate constant for a multistage process be formally treated like the rate constants for simple reactions.

If in the presence of a series of catalysts a process obeys the same kinetic law, the relative reaction rates will be unchanged for different compositions of the reaction mixtures but equal rate constant ratios. It is then convenient to characterise the activity of the catalyst in terms of the rate constant. However, identical rate laws are usually found only for catalysts of similar types and therefore the method of comparing activities in terms of rate constants is not universal.

The identity of the equation implies the equality of the reaction orders with respect to each substance and for equations with several constants it implies in addition the equality of all the constants which cannot be taken outside the function φ. These are, for example, the adsorption coefficients in Balandin's equation [14], which may differ sharply both for the same catalyst of different temperatures and for catalysts of different chemical types [62,63]. Evidently, because of this difference, the result of comparing catalysts in terms of the rate constants of Balandin's equation, for example as in the work of Balandin and Teteni [62], can be actually directly opposed to the result of comparing them in terms of the rate of reaction for a specified reaction mixture composition. Likewise the constant α in Frost's equation can be used as a measure of activity only if the second constants of the equation β are equal, which has been observed [64,65] for catalysts of the same chemical composition subjected to different preliminary treatments.

Sometimes the constant taken outside the function φ can be represented by a fairly complex expression. For example, in first-order reactions investigated in a pulse microreactor, the adsorption equilibrium constant K and a constant k, which is in fact referred to as the reaction rate constant, may be isolated from this overall constant [66]. In this case the product kK is a measure of the activity [67]. The activation energy is also found from the temperature variation of the logarithm of the product kK. [67]

Usually it is assumed that, when different rate laws apply, it is impossible to compare the activities of catalysts in terms of reaction rate constants because these have different dimensions [61]. However, identical dimensions are necessary but not sufficient. Thus, in the equations $v = k$ and $v = kC_A/C_B$, the rate constants have the same dimensions but their ratio is not equal to the ratio of the reaction rates, which depends on the composition of the reaction mixture.

In the case of different power equations, the catalytic activities are sometimes compared [68] in terms of the rate constants, since these are equal to the rates of reaction at unit concentrations (or pressures). Such a comparison refers of course only to a single composition of the reaction mixture and essentially does not differ in any way from the comparison based on the reaction rates. Similar examples can also be found in the studies of homogeneous reactions [69-71]. Apart from unit concentrations, other

compositions of the reaction mixture are sometimes employed[70,71]. Suppose, for example, that the process takes place in the presence of two catalysts according to the equations

$$v_1 = k_1 C_A,\ v_2 = k_2 C_A C_B.$$

Then

$$\frac{v_1}{v_2} = \frac{k_1 C_A}{k_2 C_A C_B} = \frac{k_1}{k_2 C_B},$$

and the activities of the catalyst at a specified concentration of the substance B may be characterised by the rate constants, having multiplied k_2 or divided k_1 by C_B.

The method of comparing activities analysed above, which arose as a result of the work of a number of investigators, is widely employed. The catalysts are compared in terms of the rate of reaction[24,35-38,42-45,56,58,59] and, when the kinetic equations are identical, in terms of the rate constant[65,72-76]. For example, we shall consider the work of Shcheglov et al.[77], who determined the activities of metals in the Fourth Period in the synthesis of ammonia in a flow-circulation reactor. Because of the identity of the kinetic equations for iron catalysts, their activities were compared in terms of the rate constants. Since the equations for other metals were different, the rates of reaction for similar compositions of the gaseous mixture were adopted as a measure of their activity. In those cases where, by virtue of the large difference between the activities it was impossible to obtain comparable data (the catalysts operated in different temperature ranges), the reaction rates were extrapolated by the Arrhenius equation to temperatures at which measurements are impossible.

However, parameters of the kinetic equation and the Arrhenius equation other than the reaction rate or the rate constant are frequently employed as a measure of activity. We shall consider the most widely used of these methods for characterising activity. As will be shown below, many of these are ambiguous and may lead to serious misunderstanding. As in the discussion of the rate constants, the agreement with the results of comparing catalysts in terms of the reaction rates for the same composition of the reaction mixture will be adopted as a criterion of the reliability of the results which they yield.

3. COMPARISON OF CATALYST ACTIVITIES IN TERMS OF THE DEGREE OF CONVERSION

In studies on catalysts, the degree of conversion α, i.e. the amount of substance which has reacted or the yield of products referred to unit amounts of the catalysts, are frequently employed as a measure of activity. The comparison is carried out at a fixed temperature, initial mixture composition, and time in a static reactor or for a fixed duration of contact in a flow reactor§. Under these conditions and in the absence of side reactions, the degree of conversion is proportional to the yield of products. The wide use of the degree of conversion as a measure of catalytic activity can be explained by the ease of its experimental determination. However, one can point to causes which lead to erroneous conclusions and frequently vitiate the results of such investigations.

§ For reactions involving a change in the number of moles, the duration of contact $\tau = \omega/u$ is not usually calculated and therefore the conversions are compared for the same value of w/u_0, i.e. for different values of τ.

A very common error is the assignment of the degree of conversion to a unit amount of the catalyst[78-82]. α is proportional to the amount of catalyst only for zero-order reactions. The proportionality obtains also in the region of low conversions for reactions whose kinetics can be treated approximately as zero-order under these conditions. In all other cases, a change in the amount of catalyst, for example in its surface area, does not entail a proportional change in the degree of conversion. To demonstrate this, we shall consider a plot of α against time (duration of contact) for reactors of different types. Usually this relation is described by a kinetic curve with saturation[83]. The limit to which α tends is independent of the catalyst and is equal to the equilibrium yield for reversible reactions and to total conversion for irreversible reactions¶.

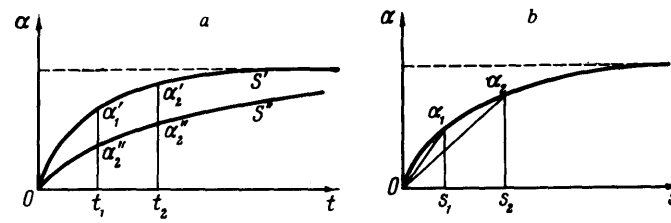

Figure 1. Variation of the degree of conversion with the amount of catalyst: *a*) static reactor; *b*) flow reactor, u_0 = const.

In a static reactor, there is a specific curve relating α to time for each catalyst sample (Fig. 1*a*). For two such curves, the S_1/S_2 ratio is constant and the $(\alpha_1/\alpha_2)_t$ ratio varies with time, since these curves reach the same limit at different rates. Under these conditions for an arbitrarily chosen time, both α/S and the ratio of such quantities for two samples vary along each curve, i.e. $(\alpha_1/S_1)_t \neq (\alpha_2/S_2)_t$. Naturally, the quantity α/S, which depends on the amount of the catalyst, cannot serve as a measure of its activity.

In a flow reactor, it is impossible to determine the variation of α with S or u_0 for a constant contact time, since a change in either of these quantities leads to a change in τ. On the other hand, when S and u_0 are varied simultaneously in such a way that τ remains constant, then α does not vary either. Therefore it is possible to investigate the variation of α with S or u_0 only keeping u_0 or S constant but not τ. The variation of α with $1/u_0$ for two samples of the same catalyst has the same form as the $\alpha - t$ plot for a static reactor (Fig. 1*a*). If the amount of catalyst is varied for a constant rate of supply (of the reactants), the curve shown in Fig. 1*b* is obtained. It is readily seen that in both cases α increases more slowly than S despite the fact that the contact time also increases. Two different catalysts are usually compared for a constant u_0 and volume of the bed. The degree of conversion obtained in such experiments qualitatively characterises the activities of the catalyst volumes employed but it cannot be adjusted for any other volume or any other surface area.

¶ The limiting non-equilibrium yield sometimes observed may be due to the inhibition of the reaction by its products.

In a gradient-free reactor the degree of conversion is proportional to the observed reaction rate and can be referred to a unit amount of the catalyst. However, it would be erroneous to assume that the degrees of conversion obtained for constant rates of supply and compositions of the mixture at the inlet to the reactor may serve as a reliable characteristic of the activity. An increase in the amount of catalyst under these conditions leads to an increase of the observed reaction rate and degree of conversion, i.e. to a change in the composition of the reaction mixture. This in turn entails a decrease of the reaction rate and causes a breakdown of the proportionality between the observed rate and the degree of conversion, on the one hand, and the amount of catalyst, on the other. Therefore comparison of catalysts in terms of the values of α/S is equivalent to the comparison of the reaction rates for different compositions of the reaction mixture.

One can point to examples of unjustified conclusions arrived at by referring α to a unit amount of the catalyst. Tetenyi et al.[84] used a flow reactor to study the activity in three reactions of nickel obtained by different procedures. The conclusion that it had different specific activities was based on a comparison of the amount of unreacted starting material referred to unit catalyst surface. The specific surface of the catalysts varied from 0.5 to 39.3 $m^2 g^{-1}$, i.e. by a factor of 80. Since zero order kinetics were not observed for the reactions investigated, the change in the amount of reactant for identical catalyst samples should be less than the change in surface area, if a constant specific activity is postulated. Indeed the maximum difference between the amounts of starting materials which have reacted is a factor of 12. After referring the conversion to unit surface, catalysts with larger surface areas proved to be "less active". This result provides no information about the constancy or variability of the specific activity of nickel obtained in different ways.

Specific surfaces and activities of $Ni-Al_2O_3$ catalysts according to Swift et al.[85]

Catalyst	Ni, %	$S_{sp\ Ni}$, m^2 g cat.	Activity, % conversion	
			per g of cat.	per m^2 of Ni
$Ni-\eta-Al_2O_3$	6.48	0.58	16.0	27.6
$Ni-\gamma-Al_2O_3$	6.00	1.24	25.0	20.2

Similar objections can be made to a comparison of the activities of two catalysts with the same contents of nickel deposited on η- and γ-Al_2O_3 in the dehydrogenation of cyclohexane[85]. The activity is characterised by the degree of conversion of cyclohexane per gram of catalyst at a constant flow rate through the reactor. The Table shows that the surface area of the active phase in the $Ni-\gamma-Al_2O_3$ catalyst was twice as great, while the degree of conversion of cyclohexane in its presence was higher by a factor of 1.5. After referring α to unit surface of nickel, this catalyst proved to be "less active". To account for the different effects of carriers, the authors investigated their structures and put forward a number of hypotheses. However, the method of comparison which they chose does not allow a decision as to whether there really is a difference between the specific activities of the catalysts investigated.

Unfortunately similar misunderstandings are still encountered fairly frequently on studies of heterogeneous catalysis[86-89].

The lack of proportionality between the degree of conversion and the amount of catalyst is a serious obstacle to the employment of α as a measure of catalytic activity. Naturally, one can point to certain specific problems concerning one particular catalyst, where it is sufficient to know the degree of conversion without referring it to unit catalyst surface. For example, these include tests for the reproducibility of the activity and for the absence of diffusion-dependent inhibition[89], the choice of regeneration conditions[90], the study of the effect of poisons[91] or extraneous substances[92,93], etc. A qualitative comparison of the change in product yield during the experiment and a physical property of the catalyst[94,95] may be accepted, provided that the specific surface remains unaltered in the experiment. However, none of these cases have a direct bearing on the problem of comparing the activities of different catalysts.

As a result of the absence of a proportionality between the degree of conversion and the amount of catalyst, the experimentally determined value of α characterises only the activity of the amount of catalyst employed in the experiment. In a static reactor, it is possible to compare the degrees of conversion obtained during the same period in the presence of different catalysts provided that samples are employed for which the quantitative measure of activity is the same. In a flow reactor samples are also sometimes chosen for which the surface area[96,97], the number of elementary zeolite cells[98], etc. are the same; the comparison is performed at a constant rate of supply. However, owing to differences between the volumes of the catalysts, the comparison in this case involves different contact times.

We shall now point to another cause of the unreliability of characterising catalytic activity with the aid of α determined using an integral reactor. We shall suppose that the amount of catalyst need not be taken into account, since the degrees of conversion during equal periods have been determined for samples with the same quantitative measures of activity, for example the surface area of the active phase. Under this condition, it is also possible to obtain erroneous results, since the ratio of the degrees of conversion is not equal to the ratio of the reaction rates for the same composition of the reaction mixture.

Suppose that in Fig. 2*a* curves I and II refer to two different catalysts taken in identical amounts and catalysing a single process at the same rate. The ratio α_1/α_2, i.e. the ratio of the tangents of the angles ψ_1 and ψ_2, differs appreciably in magnitude from the ratio of the tangents of the angles ψ_3 and ψ_4 defining the slopes of the curves for the mixture composition corresponding to α_1:

$$\left(\frac{\alpha_2}{\alpha_1}\right)_t = \frac{\tan\psi_2}{\tan\psi_1} < \frac{\tan\psi_4}{\tan\psi_3} = \left(\frac{v_2}{v_1}\right)_{\alpha_1},$$

because $\psi_4 > \psi_2$ and $\psi_3 < \psi_1$. Thus the degree of conversion cannot serve as a quantitative characteristic of activity. On the other hand, if the kinetic equations for two catalysts are different, comparison in terms of α can also yield a qualitatively incorrect result. In Fig. 2*b*, α for the upper curve is larger, while the initial rate is also higher but subsequently becomes lower than for the lower curve. If the $\alpha - t$ kinetic curves for two catalysts intersect, the same pattern as in Fig. 2*b* is repeated up to the point of intersection. At the point of intersection the degree of conversion is the same but the rates of reaction are different. In a comparison of the catalysts in terms

of α, the form of the kinetic equation is usually unknown. Therefore there is always a risk that an incorrect result will be obtained, since the equations may be different not only for catalysts of similar composition but even for the same catalyst when the composition of the reaction mixture is changed, as was observed, for example, by Kiperman and coworkers[99,100].

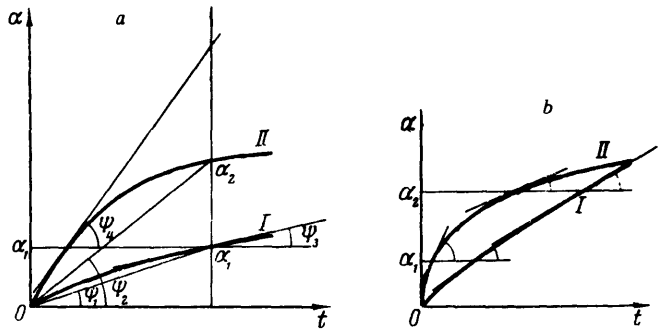

Figure 2. Comparison of the activities of two catalysts in terms of the degree of conversion and reaction rate: *a*) $\alpha_2/\alpha_1 < (v_2/v_1)_{\alpha_1}$; *b*) $v_2 > v_1$ for $\alpha = \alpha_1$ and $v_2 < v_1$ for $\alpha = \alpha_2$.

Thus the method of comparing catalyst activities in terms of degrees of conversion or product yields must be treated with considerable caution. The errors associated with the application of this method are still being encountered in studies on heterogeneous catalysis, although the risk of such errors has been pointed out repeatedly[75,101,102]. Dixon and Webb have reported[103] that, in contrast to heterogeneous catalysis, in the field of enzymatic catalysis comparison of the changes in concentration over a specified period has been completely abandoned in recent years and the method of initial rates is mainly employed.

4. COMPARISON OF THE ACTIVITIES OF CATALYSTS IN TERMS OF THE TIME REQUIRED FOR THE ATTAINMENT OF A GIVEN DEGREE OF CONVERSION

The possibility of a quantitative comparison of catalytic activities in integral reactors without determining the type of kinetic equation, which is provided by the time required for the attainment of a specified degree of conversion as a measure of activity[102], is extremely attractive. It is possible to show[104] that, for $2\alpha - t$ curves described by the same equation, the rate constant ratio is equal to the reciprocal of the ratio of the times required for the attainment of a specified degree of conversion of the starting material when its initial concentrations are the same:

$$\frac{k'}{k''} = \frac{t''_\alpha}{t'_\alpha}. \qquad (7)$$

Therefore the quantity $1/t_\alpha$ is referred to a unit amount of the catalysts[22,105] and is used as a quantitative characteristic of activity. It is evident from Eqn. (7) that the ratio of the quantities t_α for two catalysts is independent of the degree of conversion chosen arbitrarily for comparison in the range of mixture compositions where a single kinetic equation holds (Fig. 3*a*).

For a flow reactor, the contact time w/u_0 [106,107] or the proportional quantities $1/u_0$, G/u_0, [102] Su_0, or G^*/u_0 [108], where G and G^* are the weights of the catalyst and the active phase respectively, etc., are employed instead of time.† Depending on the factor used, different activities are obtained. For the same degree of conversion, the values of $1/u_0$ are proportional to the rate constants corresponding to the total amount of catalyst taken for the reaction, the values of S/u_0 are proportional to the rate constants referred to unit catalyst surface, etc.

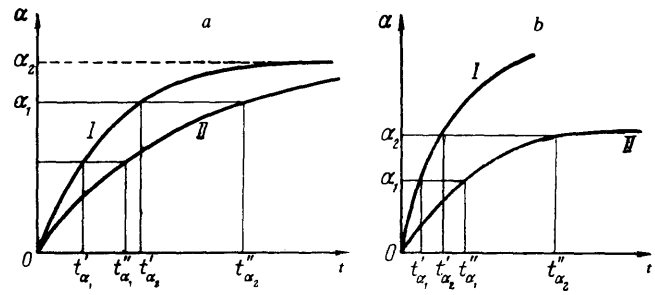

Figure 3. Time required for the attainment of a specified degree of conversion: *a*) $t'_{\alpha_1}/t''_{\alpha_1} = t'_{\alpha_2}/t''_{\alpha_2} = \text{const.}$; *b*) $t'_{\alpha_1}/t''_{\alpha_1} \neq t'_{\alpha_2}/t''_{\alpha_2}$.

Comparison of catalysts in terms of the time required to attain the same degree of conversion is restricted by the same condition as the comparison in terms of rate constants—it is permissible only when the kinetic equations are identical. We may recall that, for an equation with several constants, identity implies the equality of all the constants other than the rate constant. However, if the equation is known, the rate constant is also known and there is no need to replace it by t_α. It is possible to verify the identity of the kinetic equations by a graphical method without determining their form. For this purpose, it is sufficient to superimpose the kinetic curves (Fig. 3*a*) by altering the scale along the abscissa. The constancy of the ratios of t_α for different α can also serve to confirm the identity of the equations. Without such a test, there is always a risk that the equations are different and the method of comparing the activities is inapplicable.

An impression might be created that, regardless of the type of kinetic equation, a higher activity is always associated with a shorter time to attain a specified percentage conversion. That this view is erroneous can be demonstrated with the aid of Fig. 2*b* already examined: t_α for the upper curve is smaller, while the rate of reaction (the slope of the curve) is initially higher and then lower than for the lower curve. If the $\alpha - t$ curves intersect, then at the point of intersection the rates are different while t_α is the same. Thus for different kinetic

† w/u_0 is more correctly called the reciprocal of the space velocity.

equations, comparison of catalysts in terms of the values of $1/t_\alpha$ may be incorrect.

For a reversible reaction investigated at the same temperature in the presence of different catalysts, the same degree of conversion implies also the same degree of deviation from equilibrium and therefore the effect of the reverse reaction on the observed rate of the process will also be the same. The derivation of Eqn. (7), obtained for an irreversible reaction[104], can be extended to this case. For this purpose, it is convenient to employ the criterion of the effect of the reverse reaction γ proposed by Kiperman and Gadzhi-Kasumov[109]. The observed rate of the reverse reaction is

$$v = \vec{k}\vec{\varphi}(C_i)\gamma,$$

where $\vec{k}$ and $\vec{\varphi}(C_i)$ are respectively the rate constant and a function of the concentrations of the reaction mixture components for the forward reaction; γ depends on the degree of departure from equilibrium y. The latter is determined as a fraction of the yield of reaction products relative to the equilibrium value. For the same degree of conversion and an unchanged equilibrium yield, the values of y and γ will also be the same, i.e. Eqn. (7) will hold for a reversible reaction occurring in the presence of two catalysts according to an identical kinetic law.

If the $\alpha - t$ curves have been obtained for the same catalyst at different temperatures, the temperature variation of $1/t_\alpha$ is used to determine the apparent activation energy[41,110,111]. This is valid either when the equilibrium yield in the temperature range investigated is almost constant or for large departures from equilibrium. In the same cases, when the equilibrium yield varies with temperature, an identical degree of conversion is associated with different degrees of deviation from equilibrium and consequently with different values of γ. Then the ratio t'_α/t''_α at two temperatures depends on the value of α (Fig. 3*b*) and cannot be used to calculate the activation energy. The constancy of the activation energy for different α can indicate both[111] the absence of an effect by the reverse reaction and the identity of the kinetic equation in the given temperature range.

5. COMPARISON OF THE ACTIVITIES OF CATALYSTS IN TERMS OF THE TEMPERATURE AT WHICH THE DEGREE OF CONVERSION OR THE REACTION RATE HAS A SPECIFIED VALUE

We shall consider in turn the different variants of the methods for comparing catalysts in terms of the reciprocals of the temperatures at which a particular degree of conversion or reaction rate is attained. The temperature of the onset of reaction[110] is the most indeterminate characteristic of the activity. The experimentally observed onset of reaction depends on the sensitivity of the analytical method and, since it is a quantity lying at the limit of sensitivity, its determination is inaccurate. The possible errors are compounded by the fact that in the region of low conversions a small change in α usually corresponds to a considerable change in temperature. Comparison of the temperatures corresponding to complete conversion is open to similar objections[112].

Therefore it is best to compare the temperatures T_α at which the same degree of conversion is attained in a specified time (the contact time) [113-120] for constant initial concentrations. However, this method has a number of disadvantages associated with the indeterminacy of the degree of conversion as a measure of activity. T_α depends on the amount of catalyst and it is impossible to take into account this relation. Moreover, for integral reactors T_α is not always the temperature at which the catalysts have the same activity because, owing to different forms of the kinetic equation, the same value of α for a constant τ may correspond to different reaction rates.

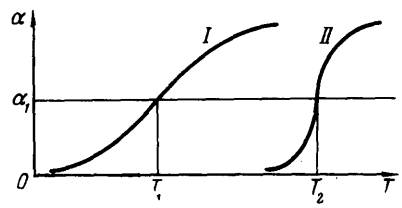

Figure 4. Temperature variation of the degree of conversion.

The variation of α with T for a constant τ is represented by S-shaped curves (Fig. 4, curve *I*)[113,117-120], which are displaced when the rate of supply of the starting material or the amount of catalyst is altered[121]. Takeuchi et al.[120] observed such a sharp increase of α at a specified temperature (curve II) that this temperature was no longer dependent on the amount of catalyst. Therefore they regarded it as a specific characteristic of the catalyst, although the phenomenon might have been associated with the non-isothermal experimental conditions.

In work with reactors allowing the determination of the rate of reaction in a single experiment, the activity is characterised by the temperature T_v, at which the rate of the reaction has a specified value[30,122-125]. Naturally, the comparison must be made for a constant reaction mixture composition. An attempt to employ this method was made by Rubanik et al.[123] in a stirred flow reactor. Deciding against extrapolation of the reaction rate, they adopted as a measure of activity the "temperature at which the same reaction rate, referred to unit catalyst surface, is attained" for constant concentrations of the reactants in the system. However, in fact this characteristic of the activity was not obtained. The surface areas of the catalysts differed at most by a factor of 15. The experiments were performed at a constant volume of the catalyst bed, flow rate, and composition of the gas mixture at the inlet to the reactor. Under these conditions, an identical observed reaction rate v' would imply a constant concentration of all the substances in the system. However, the temperatures were not compared for the same value of v' but for the same value of v'/S, which corresponded to different values of v' and consequently to different compositions of the reaction mixture.

It is possible to avoid the need to allow for surface areas, using catalyst samples for which these areas are the same. It is also possible to achieve the same mixture composition in the reactor for identical values of v'/S by altering the flow rate or the composition of the mixture supplied. The above difficulty of allowing for the amount of catalyst is obviated when the rate of reaction is determined in a differential flow reactor. A constant mixture composition at the inlet and a sufficiently low degree of

of conversion at all temperatures ensure an approximately identical composition of the reaction mixture. This permits a comparison of the temperatures at which the values of $v = v'/S$ are identical.

However, even in the most rigorous variant the reciprocal of the temperature cannot serve as a quantitative criterion of activity in place of the reaction rate, since these quantities are not proportional. In order to justify the use of T_v as a qualitative characteristic of activity, we shall consider the temperature variation of the reaction rate. If for a particular process the same single-term kinetic equation of a power function type holds over a range of temperatures and the Arrhenius law is valid, then

$$v = k\varphi(C_i) = k_0 e^{-E/RT}\varphi(C_i). \quad (8)$$

In this case the temperature variation of the rate constant for a positive activation energy is represented by a rising S-shaped curve. Evidently for a constant composition of the reaction mixture, the $v-T$ plot is also S-shaped. Its specific form is determined by the relative values of k_0, E, and the function φ for specified concentrations. In practice such curves can be readily obtained in a differential flow reactor.

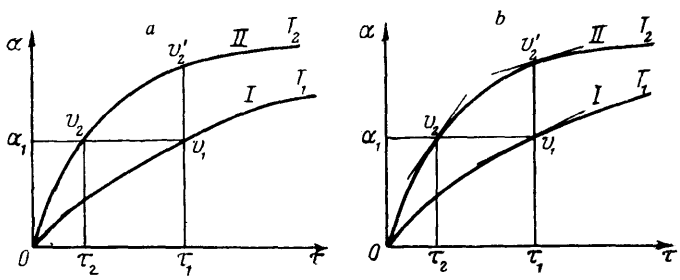

Figure 5. Temperature variation of the reaction rate: *a*) stirred flow reactor; *b*) flow reactor.

In a gradient-free reactor, for a constant contact time and mixture composition at the inlet, the rate of reaction calculated by Eqn. (6) can also only increase with temperature. Suppose that, when the temperature is raised from T_1 to T_2 and α = const., i.e. $\varphi(C_i)$ = const., the rate of reaction increases from v_1 to v_2 (Fig. 5*a*) and the entire curve II lies above curve I, since by our hypothesis they are described by a single equation and cannot intersect. We then increase t_2 to $t_2' = t_1$. The reaction rate v_2' will be higher than v_1, since $\alpha_2' > \alpha_1$.

In contrast to gradient-free reactors, in integral reactors for constant initial concentrations and times (durations of contact) the reaction rate can both increase with temperature and pass through a maximum. Fig. 5*b* shows that $\alpha_2' > \alpha_1$ but $v_2' < v_1$.

Hitherto we have assumed that a single-term power equation holds over a range of temperatures and the activation energy is positive. However, the kinetic equation can contain, apart from the rate constant for the forward reaction, also other constants which depend on temperature (the adsorption coefficients and the rate constants for elementary stages or the reverse reaction). Then both the degree of conversion and the rate of reaction in any reactor are bound to increase with temperature.

Reactions are known with a maximum rate (hydrogenation of olefins[126] and benzene[127]) and degree of conversion (synthesis of ammonia[128]) with respect to temperature. Therefore, for a comparison of catalysts both in terms of T_v and T_α, it is necessary to investigate the variation of v or α with T over a wide temperature range.

The $v-T$ curves for different catalysts may intersect. It has been frequently pointed out[129-131] that temperature is unsuitable as a criterion of activity for different activation energies, since catalysts may be classified as identical or different depending on the rate of reaction chosen arbitrarily for the comparison. There is a risk of arriving at an incorrect result when each catalyst is characterised by a single value of T_v. But if one considers two intersecting curves, the dependence of the result of the comparison on an arbitrarily chosen value of v cannot serve as evidence against the use of T_v as a criterion of activity. The temperature at which the reaction rates are compared is after all chosen just as arbitrarily. At the same time the comparison in terms of T_v yields the same activity series as the comparison in terms of reaction rates at the same temperature, provided that both temperatures and both reaction rates lie on one side of the point of intersection (Fig. 6). Indeed $v_1 > v_2$ and $T_1 < T_2$ but $v_1^* < v_2^*$ and $T_1^* > T_2^*$. When several curves intersect, a more complex pattern may be obtained. Therefore T_v should not be used for the comparison of catalysts with similar activities, particularly since T_v is a less sensitive characteristic than v because of the exponential relation between v and T.

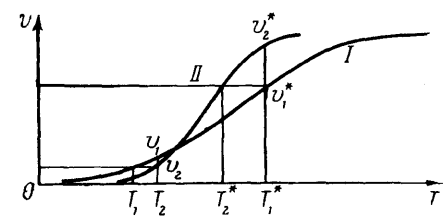

Figure 6. Comparison of the activities of two catalysts in terms of T_v and v.

Thus comparison of catalysts in terms of T_v may yield the correct series of their activities but not their relative values. At the same time the reliability of the results of the comparison in terms of T_α is extremely doubtful, particularly if the differences between the activities are not very great[116] or are absent[132], the $\alpha-T$ curves are not quoted, and there are no data concerning the identity of the kinetic equations.

The use of T_v as a measure of activity is quite justified when a direct comparison of the rates of reaction is impossible because of the different temperature ranges in which the catalysts were used[30]. De Mourgues[30] has mentioned that a comparison of the T_v "yields less quantitative information but is more valid, since it is based on actual and not extrapolated results". This view is shared also by other investigators[125,131,133], although essentially temperature as a measure of activity has no advantages over reaction rates. There may be doubts about the actual values of the extrapolated rate ratios but not about the order of activities based on them.

6. COMPARISON OF THE ACTIVITIES OF CATALYSTS IN TERMS OF ACTIVATION ENERGY

In order to correlate the activities of catalysts with their physical properties, it is extremely desirable to have a characteristic of the activity which depends on the least possible number of process parameters. We shall examine the possibility of using as a kinetic correlation parameter the activation energy—a quantity which is not only independent of the amount of catalyst and the concentrations of the reactants and products but is also constant over a range of temperatures. Although the catalyst reduces the activation energy for the reaction, a reduced value of E cannot be regarded as evidence of higher activity. This method of characterising activity is restricted by a number of conditions. In the first place these are the conditions analogous to those restricting the use of rate constants: (1) if the kinetic equation involves several constants varying with temperature, the activation energy found from the logarithms of the rate constant does not fully reflect the temperature variation of the rate of reaction[1] and cannot therefore replace it as a measure of activity; (2) if different equations hold for different catalysts, then, as shown above, the rate constants cannot serve as a measure of activity and therefore the activation energy is also unsuitable for the purpose of comparison.

Comparison of catalysts in terms of activation energies is possible only when the kinetic equations, with a single temperature-dependent constant, are identical. Eqn. (8) shows that, by virtue of the exponential relation between v and E, the activation energy as well as temperature can serve only as a qualitative characteristic of activity and is less sensitive than the reaction rate.

The last limitation of the method of comparing catalysts in terms of activation energies, which has been frequently pointed out[101,131,134,135], is the necessity to take into account the pre-exponential factor k_0.

Its variability for different catalysts leads to an ambiguous relation between k and E. Indeed, for the same E and different k_0, the activities of catalysts expressed by the rate constants will be different at all temperatures. When E and k_0 vary in parallel (the compensation effect), the linear Arrhenius plots should intersect. Then the activation energy, which is constant over the entire range of temperatures, cannot reflect the reversal of the relative activities at the point of intersection (Fig. 7).

The Arrhenius plot always shows whether the straight lines intersect in the temperature range investigated and whether they can intersect beyond it. The rate constants must then of course be referred to a unit amount of the catalyst.

Thus, for a comparison of catalysts with the aid of activation energies, it is necessary to analyse the relative positions of the linear Arrhenius plots, just as for a comparison in terms of T_V it is necessary to examine the curves relating v to T. Bearing in mind all possible cases of a simultaneous variation of E and k_0 for two catalysts discussed in the literature[136,137], we conclude that the activation energy cannot characterise the activity for parallel or intersecting straight lines when the point of intersection lies in the temperature range investigated or to the right of it.

Thus taking into account the limitations discussed above, the activation energy may be used as a qualitative characteristic of activity. But for the calculation of E, it is necessary to determine initially the rate constant or the rate of reaction over a range of temperatures, which makes it possible to characterise the activity incomparably more accurately without resorting to the activation energy.

The activation energy is employed as a measure of activity mainly in studies dealing with the elucidation of the role of the electronic factor in catalysis. Examples may be found in the reviews of Baker and Jenkins[138] and Schwab[139,140]. When additives are introduced into catalysts (semiconductors or metals deposited on semiconductors), the parallel changes in their activity and electrical properties are compared. The activation energy is determined as a rule from the temperature variation of the initial rate. For equations with a single constant which varies with temperature,

$$\left(\frac{\partial \ln v}{\partial T}\right)_{C_i} = \frac{d \ln k}{d},$$

i.e. when the composition of the gas phase remains unchanged, the apparent activation energy may be determined from the rate of reaction[141,142]. Then, in order to compare the catalysts in terms of the activation energies, account must be taken, instead of k_0, of the variation of v_0—the rate of reaction extrapolated to an infinite temperature. Since for a single-term power equation

$$\lg v = \lg k - \sum n_i \lg C_i,$$

the difference between the $\lg v_0$ is equal to the difference between the $\lg k_0$ when the equations for two catalysts are identical, and the $\lg v - 1/T$ and $\lg k - 1/T$ straight lines intersect at the same temperature.

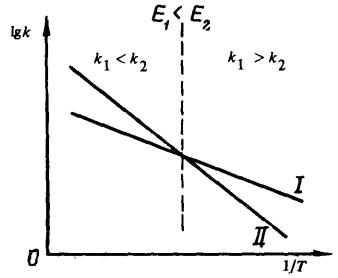

Figure 7. Activation energy as a measure of the activity when linear Arrhenius plots intersect.

When the reaction order changes over a range of temperatures, the activation energies calculated from the rates of reaction[143-145] as well as from the rate constants lose their significance. Therefore it is not surprising that the values of E found for the hydrogenation of benzene on the $Ni-Al_2O_3$ catalyst from the initial rates under the conditions of a variable reaction order and from the rate constants in an equation of the Langmuir–Hinshelwood type are markedly different (16 and 28 kcal mole^{-1}) [143]. There is no reason to regard either of the above quantities as the activation energy for the reaction.

Comparison of catalysts in terms of activation energies is usually not reliable, since it is made without allowance for all the above conditions. The retention of the identical form of the kinetic equation on introduction of an additive into the semiconductor has not been verified[146,147] although the mechanism and processes of semiconductor catalysts may alter under the influence of very small amounts of

impurities. For example, according to the data of Bielanski et al.[68], when 0.1 at. % of iron is added to nickel oxide, the overall order of the CO oxidation reaction changes from first to zero. The change in E is discussed without taking into account the possible change in the pre-exponential factor[146]. Schwab has reported in some papers[148,149] that there is a linear relation between E and k_0 and the temperature corresponding to equal rates for all the catalysts lies above the working range. On the other hand, in other studies this has not been verified[147] or confirmed[148], but E is nevertheless regarded as a characteristic of the activity.

It is clear from the foregoing that it is more desirable to estimate the catalytic activity with the aid of rate constants or reaction rates and the activation energy should be correlated as an energy characteristic of the surface with the activation energy for electrical conduction, electron work function, etc.[74,105]. In correlations of this kind, the variation of k_0 does not play any role, while the remaining limitations remain in force. Teichner[150] concluded that the correlation of the activity with the catalyst properties is best based on the true and not the apparent activation energy, since the change in E on introduction of an additive may be caused by a change in surface coverage and reaction order. The constancy of the reaction order is of course a necessary condition for the comparison of the values of E in the presence of different catalysts but this need not be a zero order and the use of the true activation energy is not necessary.

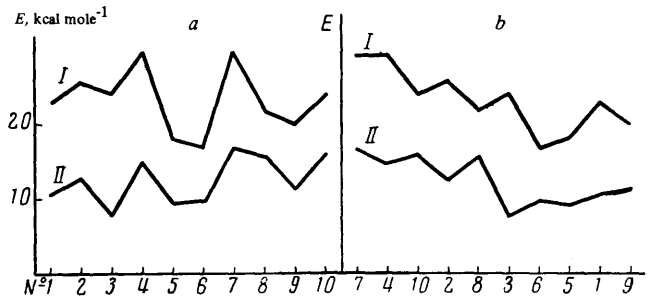

Figure 8. Variation of the activation energy for the dehydrogenation of cyclohexane (curve *1*) and isopropyl alcohol (curve *2*) with the number of the catalyst: a) according to the data of Firth and Holland[152]: *b*) when the order of the catalysts is altered.

The correlation should not be based on the variation with the number of the catalyst arbitrarily assigned by the investigator[84,151,153]. For example, the parallel variation of the activation energies for the dehydrogenation of isopropyl alcohol and cyclohexane in the presence of a series of nickel specimens prepared in different ways[151] can be readily transformed into the opposite variation when the numbers of the catalysts are transposed (Fig. 8).

---oOo---

Thus we have seen that catalytic activity should be characterised in terms of the reaction rates under rigorously defined conditions. The use for this purpose of other quantities is possible if it is known that the result of their comparison agrees quantitatively or at least qualitatively with the result of a comparison of the rates of reaction at the same temperature and for the same concentrations of all the substances which affect the rate. When this criterion is fulfilled, activity may be characterised, apart from the parameters of the kinetic equation and the Arrhenius equation discussed above, by any other quantity, for example, the rate of evolution of heat when the reaction is performed in a microcalorimeter[152].

Recently attempts have been made to employ correlation analysis for a comparison of the activities of catalysts with their properties. The reaction parameter is the linear relation between free energies yields a general characteristic of the activity of the catalyst for a series of compounds undergoing the same reaction[153,154]. As for the rate constant, its use is restricted by the condition that the kinetic equations must be identical.

We must emphasise that for an accurate expression of catalytic activity, it is sufficient to determine the reaction rates and the knowledge of the mechanism and kinetics of the process does not by itself play a role. Another problem is that in integral reactors the study of kinetics is necessary for the calculation of the reaction rates, while in gradient-free reactors the kinetic equation can be conveniently used to determine the rate of reaction for a specified composition of the reaction mixture. Thus the obligatory need to study the kinetics in order to estimate catalytic activity, which is frequently pointed out[101,137], is valid only for integral reactors.

The aim of a study of catalytic activity can be either practical (the choice of the optimum catalyst and the optimisation of the process) or theoretical (the elucidation of the relation with composition, structure, and physical properties of the catalyst)[3]. In both cases a comparison of the reaction rates is necessary but not sufficient. For the first aim to be achieved, it is in addition important to know the activity of each catalyst under its optimum conditions[155-157,159] and then to decide for which of them the process is more economical.

Attempts are usually made to achieve the second aim by correlating the activity with the properties of the catalyst as a solid. The variation of the reaction rate with concentrations and temperature makes it impossible to characterise the activity also as a property of the solid. "One can speak rigorously only of the catalytic activity characteristic of the entire system, including the catalyst and the reaction mixture"[1]. Therefore the activity should be characterised by a set of reaction rates over a wide range of concentrations and temperatures. Comparison of the activities under one particular set of conditions is insufficient for correlations with the properties of the catalyst as a solid.

In theoretical studies on catalysts, de Mourgues[30] recommends that the simplest reactions be chosen as models. For complex processes, i.e. when several reactions take place simultaneously, the rate of the main reaction or the overall rate of the process may be adopted as a measure of activity.

In conclusion we may note that in the present review the authors endeavoured to describe the present state of the problem and not its history. The review does not pretend to be complete and the choice of specific examples, the aim of which was to make them typical, may inevitably prove to be arbitrary.

Absorption Spectra of Organic Dyes Containing Two Chromophores

A.I.Kiprianov

The Review begins with consideration of the absorption spectra of dyes whose molecules contain non-conjugated (isolated) chromophores. The major portion of the Review, however, is devoted to the spectra of dyes having two conjugated chromophores. According to the view adopted until recently the interaction of conjugated chromophores is apparent in a displacement of the absorption band to longer wavelengths and in an increase in its intensity. The Reviewer and his coworkers have recently established that this view is valid only for the particular case of conjugated chromophores which absorb similar light quanta and lie on the same straight line.

If the light quanta absorbed by the conjugated chromophores are very different, the chromophores do not interact. If the conjugated chromophores are at an angle, their absorption bands do not merge into a single band: on the contrary, they either split or move apart. The intensities of the two new bands are then determined by the angle between the interacting chromophores.

The spectra of bis-dyes which illustrate these principles are examined, and an elementary theory is given for the interaction of conjugated chromophores. A list of 61 references is included.

The concept of colour carriers (chromophores) and of groups of atoms that intensify the colour (auxochromes), which was introduced by Witt into the chemistry of colouring matters almost a century ago, has retained its value until the present time, although we now give a different content to these terms. The name *chromophore* is now applied to a system of conjugated single and double bonds whose presence in sufficient length causes the absorption of visible light even in hydrocarbon molecules. *Auxochromes* are atoms or groups of atoms containing delocalised electron pairs (electron donors—NH_2, NR_2, OH, O^-) and negative [sic] groups of atoms (electron acceptors—NO_2, $CO:NR_2^+$). Auxochromes are located at the ends of the conjugated chain of the dye molecules: donors supply their electrons to the chain of conjugation; acceptors withdraw them.

In the present Review we shall for brevity apply the term *chromophore* to the whole part of the dye molecule which is responsible for its colour, i.e. to the actual chromophore together with the auxochromes (Aux). Thus, when discussing how electronic interaction of two chromophores is revealed in the absorption spectra, we shall have in mind the mutual influence of two systems A and B, both of which absorb visible light, linked together through a series of conjugated or non-conjugated covalent bonds C (Fig. 1) into a single molecule of a bis-dye.

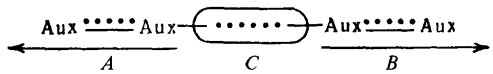

Figure 1.

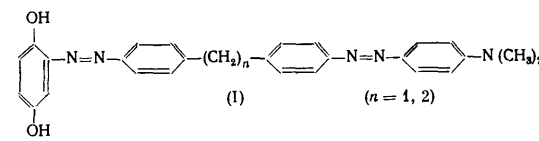
We shall not be concerned in this Review with the synthesis of the compounds discussed, which can easily be found in the papers cited.

Very many dyes containing two chromophores have been described in the periodical and patent literature, among them the immense group of bisazo-dyes. Unfortunately, only a few such compounds have been examined spectrographically.

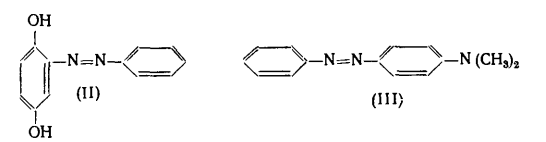
Two chromophores which are separated from each other by saturated groups of atoms ($CH_2.CH_2$, $CH_2.O$, CH_2, etc.) absorb light additively. The absorption spectrum of the solution of such a dye is almost identical with that of a solution of equimolecular proportions of the two corresponding component dyes (parent dyes)[1]. Isolated chromophores absorb light independently of one another: they do not influence each other.

This has been shown by Brode and his coworkers on bisazo-dyes. The absorption curve of the unsymmetrical bisazo-dye (I)



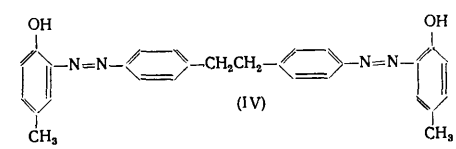
(I) ($n = 1, 2$)

coincides with that of an equimolecular mixture of the two parent monoazo-dyes (II) and (III) [2]



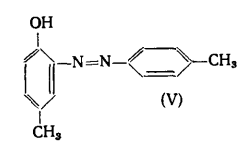
(II) (III)

The spectrum of the symmetrical bisazo-dye (IV)



(IV)

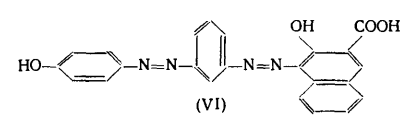
is indistinguishable from that of dye (V)



(V)

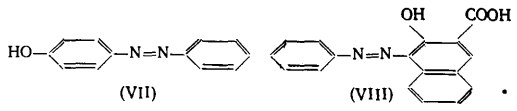
at double the concentration [3].

According to Funkhouser and Brode[4] two chromophoric systems are isolated when linked together through *meta*-positions in a benzene ring: the absorption curve of the bisazo-dye (VI)



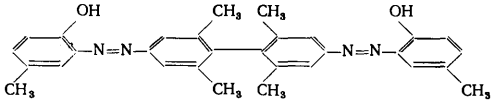
(VI)

is identical with the curve of a mixture of the dyes (VII) and (VIII)



(VII) (VIII)

Isolation of the two azo-chromophores in bisazo-dyes obtained from benzidine derivatives may be due to steric hindrance between the biphenyl rings: the absorption spectrum of the bisazo-dye (IX)

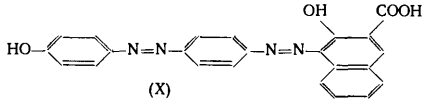


does not differ from that of the bisazo-dye (IV) [5].

All that has been said about the spectra of bisazo-dyes containing isolated chromophores applies also to bis-dyes of other classes—bismerocyanines[6], bisazomethines[7], etc.

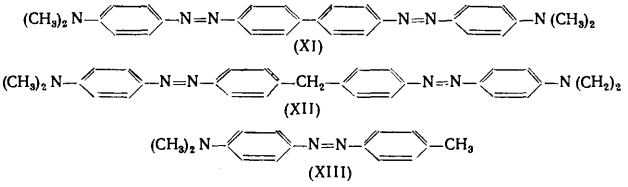
We shall not deal in this Review with the vast number of papers by the eminent Soviet scientist V. A. Izmail'skii, in which he showed that an intense colour can arise also when two auxochromes (donor and acceptor of electrons), present in the same molecule, are isolated from each other by saturated groups of atoms. This type of coloration is observed only in the solid state and in concentrated solutions. It is due not to intramolecular electron transitions but to intermolecular exo-interactions of donor and acceptor groups, and is explained by the formation of complexes with partial transfer of charge. If two chromophores in a dye molecule are not isolated from each other, but are in some measure conjugated, the absorption spectrum usually differs markedly from those of the component dyes. According to ideas current until recently the interaction of conjugated chromophores is shown by a shift in the absorption band to longer wavelengths and in an increase in the intensity of absorption[8].

Brode and his coworkers showed, for example, that the bisazo-dye (X)



(X)

in which the arylazo-groups are interlinked through a *para*-phenylene ring, absorb considerably further towards the red end of the spectrum and more strongly than the isomer (VI), in which the same chromophores are joined in the *meta*-position[4]. Fig. 2 shows the absorption curves† of two symmetrical bisazo-dyes (XI) and (XII) and also of the corresponding component dye (XIII) (at double the concentration). Here, too, a bathochromic shift in the band due to dye (XI) is clearly evident in comparison with the bands of dyes (XII) and (XIII), which show close similarity[3].



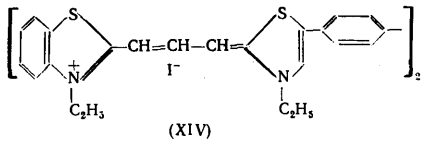
(XI)

(XII)

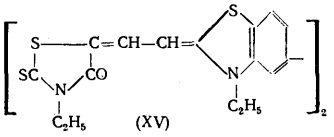
(XIII)

† Here and subsequently absorption curves and maxima are given for alcoholic solutions, where no solvent is specially mentioned.

A similar deepening of colour has been observed in symmetrical biscyanines (XIV) [9] and bismerocyanines (XV) [10]



(XIV)



(XV)

in comparison with the corresponding mono-dyes.

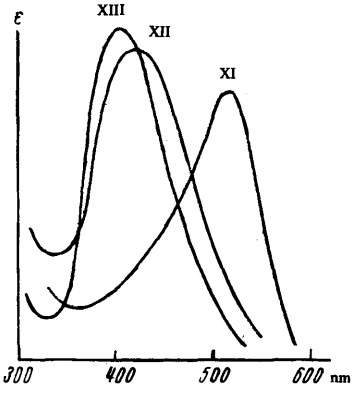


Figure 2.

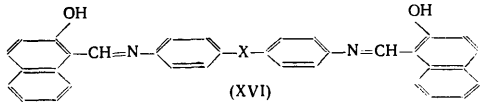
The effect of the nature of the bridge X on the degree of conjugation between azomethine chromophores has been investigated on bisazomethines of formula (XVI) [11]



(XVI)

Table 1.

X	Abs. max., nm	$10^{-4}\varepsilon$	X	Abs. max., nm	$10^{-4}\varepsilon$
CH_2	345	2.86	S	358	3.70
O	350	3.60	NH	413	4.83

Such conjugation is apparent in a displacement of the absorption maximum (abs. max.) and an increase in molecular extinction. Table 1 shows that oxygen, sulphur, and nitrogen atoms, with their lone pairs of electrons, do not have an isolating effect like that of the methylene group. However, the effect of conjugation through bridges of this type is relatively small in bisazomethines, as well as in bisazo-dyes[12,13] and in biscyanines[14].

We shall not cite other published examples of the interaction of bound chromophoric systems. The view held until recent years was that two conjugated chromophores in a dye molecule lose their individuality, delocalise into one conjugated system, and absorb light as a single chromophore having a longer conjugated chain. As a result the absorption bands corresponding to each individual chromophore merge to form a single more intense band displaced to lower frequencies[15].

Table 2.

Biscyanines	Abs. max., nm
 (XVII)	422 563
 (XVIII)	581 522
Component cyanines	**Abs. max., nm**
 (XVIIa)	420
 (XVIIb)	558
 (XVIIIa)	562
 (XVIIIb)	558

It has been found recently, however, that this view is valid only for the particular case in which the conjugated chromophores when separated (in the parent dyes) absorb closely similar light quanta, and also when these chromophores lie on the same straight line (Fig. 1). If the quanta absorbed by the two chromophores differ greatly, the chromophores do not interact at all, even when conjugated with each other. If the conjugated chromophores do not lie on a straight line, but are inclined at an angle, their absorption bands do not merge into a single band, but on the contrary split or move apart. The intensities of the two new bands will then depend on the angle between the interacting chromophores. We shall now discuss these previously unknown phenomena.

In 1964 Kiprianov and Mushkalo[16] synthesised six biscyanine dyes in which the nitrogen atom of the thiazole ring of one cyanine was covalently bound to the benzothiazole ring of a second cyanine. Two biscyanines of this type—dyes (XVII) and (XVIII)—are given as examples in Table 2. The absorption spectra of each of the six biscyanines of this series contained two intense bands. It would naturally be assumed that the maxima of these bands would approximate in some measure to those of the corresponding parent dyes, which were also prepared (e.g. XVIIa and XVIIb in Table 2). However, comparison of the absorption maxima of the biscyanines with those of the corresponding parent dyes led to an unexpected result.

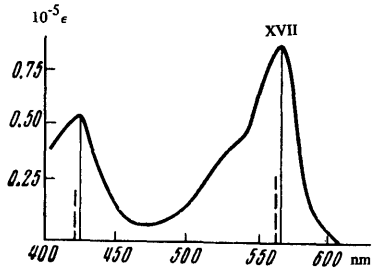


Figure 3.

With biscyanines in which the two chromophoric chains differed in length, e.g. (XVII), the maxima on the absorption curve (Fig. 3) almost coincided with those of the corresponding component dyes (XVIIa) and (XVIIb) (these maxima are indicated by the broken lines in Fig. 3). This implies that the chromophores in such biscyanines do not interact, although they are conjugated.

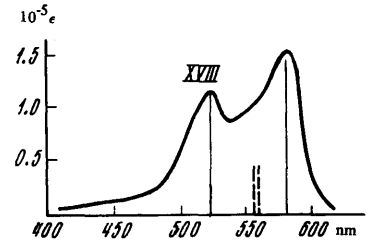

Figure 4.

With biscyanines which contain two chromophores of the same length, e.g. (XVIII), on the other hand, the maxima on the curve (Fig. 4) differed markedly from the absorption maxima of their component dyes (denoted by broken lines). The shorter-wavelength maximum of the biscyanine was shifted to still shorter wavelengths, and the longer-wavelength maximum to still longer wavelengths, than in the component dyes. Thus the chromophores in biscyanines with polymethine chains of the same length interact. The interaction, however, does not lead to coalescence of the absorption bands but to their

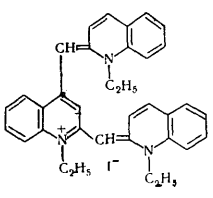
moving apart (or resolution, as has since been shown with biscyanines of symmetrical structure).

Despite the paucity of experimental results these workers[16] permitted themselves the conclusion that the interaction of two conjugated chromophores depends on the light quanta which each chromophore absorbs separately. If the quanta differ greatly, the chromophores do not interact. If the quanta differ little, the chromophores interact in such a way that the frequency absorbed by one chromophore increases, while that absorbed by the other decreases, the absorption bands moving apart. The authors mention the theory of perturbations and its application to electronic spectra[17].

Kiprianov and Dyadyusha[18] examine the physical nature of these phenomena, starting to a first approximation from the principles of classical wave mechanics. Two conjugated chromophores are two coupled oscillators, analogous e.g. to two loosely connected pendulums. If such pendulums differ in length, they have little influence on each other, and each oscillates at its characteristic frequency. But if the pendulums have the same or similar lengths, they interact, which is apparent in a change in their vibration frequency. When isolated from each other, the pendulums oscillated at frequency ν; now that they are coupled, they are able to oscillate only at the two new frequencies $\nu - e$ and $\nu + e$. In one case oscillations of the pendulums are in phase; in the other case they are of opposite phase.

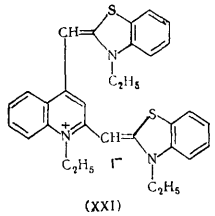
Electrons oscillate in the conjugated chromophores of bis-dyes. If the vibration frequencies of the electrons in the isolated chromophores are the same or similar, the conjugation of such chromophores should result in their vibration and absorption of light at two new frequencies, one higher and the other lower than the original frequency.

Two cases are known of the observation by other workers of analogous phenomena to those observed by Kiprianov and Mushkalo above. In 1953 Shibata[19] prepared the distyryl dye (XIX) and the corresponding two monostyryl dyes (XIXa) and (XIXb) (Table 3). He took no notice of the fact that the bands corresponding to the monostyryl derivatives had moved apart in the spectrum of the distyryl compound. Perhaps this was because such separation was inconsistent with his quantum-mechanical calculations.



(XX)

Abs. max. 615, 480 nm (550, 520 nm)

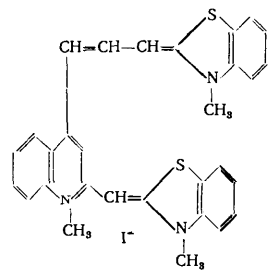


(XXI)

Abs. max 547, 450 nm (509, 480 nm)

Still earlier Brooker and Smith[20] had noted something similar in the spectra of the two biscyanines (XX) and (XXI). With both dyes the two absorption maxima were farther apart than those of the corresponding monocyanines (indicated in parentheses). The authors tried to explain why the longer-wavelength bands of their dyes had shifted towards the red end of the spectrum, but the displacement of the shorter-wavelength bands in the opposite direction remained incomprehensible to them.

Kiprianov and Mushkalo showed[21] that the parting of the absorption bands in the spectra of Brooker and Smith's biscyanines was due to the same cause as in the spectra of the biscyanines which they themselves had described[16]. While it is true that the two chromophoric chains in (XX) and (XXI) differ in length and that the absorption maxima of the corresponding component dyes do not coincide, it must be borne in mind that conjugation of the chromophores, including the common methine groups, is far stronger here than in Kiprianov and Mushkalo's bis-dyes. In fact it was found that in the spectra of dyes of the same type, but with a still greater difference in length between the chromophoric chains, e.g. in the spectrum of the biscyanine (XXII)



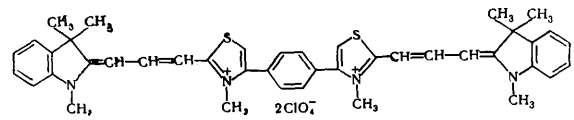
(XXII)

Table 3.

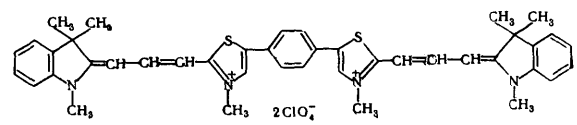
Distryl dye	Abs. max., nm	Monostyryl dye	Abs. max., nm
 (XIX)	500 570	 (XIXa)  (XIXb)	527 546

there is hardly any separation of the absorption maxima relative to those of the component dyes.

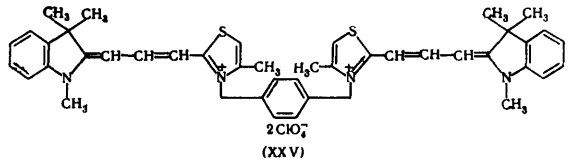
The biscyanines in which the separation of absorption bands due to conjugated chromophores was discovered proved to be a convenient subject for studying the new phenomenon. This applies especially to symmetrical biscyanines, in which the bands due to the two identical component dyes do not move apart but are resolved.



(XXIII)



(XXIV)



(XXV)

have been synthesised[22]. Figs. 5–7 show their absorption curves (full lines) and those of the corresponding parent monocyanines (XXIIIa)–(XXVa) (broken curves). The curves for (XXIII) and (XXIIIa) (Fig. 5) have the same shape and the same position of the maxima, differing only in intensity. The chromophores in the molecule (XXIII) are not formally conjugated, and hardly interact at all. In contrast, curves (XXIV) and (XXIVa) in Fig. 6 are completely different: here the chromophores are conjugated, so that the band of the parent cyanine is split in the spectrum of the biscyanine into two new bands of different intensities. Interaction between the chromophores is observed also in the biscyanine (XXV) (Fig. 7), but it is far weaker, and the two bands have moved apart less.

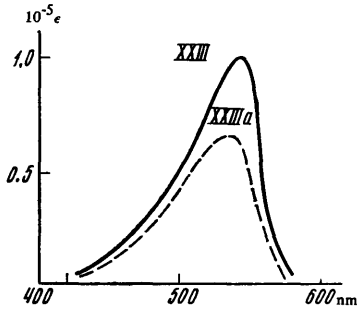


Figure 5.

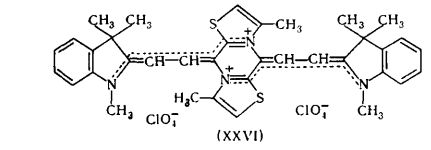
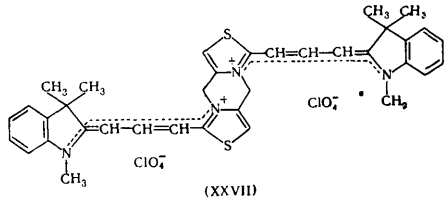
It has been shown[23] how different are the spectra of biscyanines with conjugated and non-conjugated chromophores by the synthesis of two biscarbocyanines (XXVI) and (XXVII)

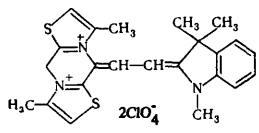


(XXVI)

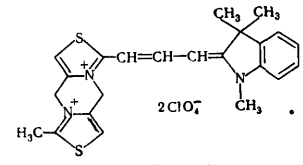


(XXVII)

of generally similar structure together with the corresponding parent cyanines (XXVIa) and (XXVIIa)



(XXVIa)



(XXVIIa)

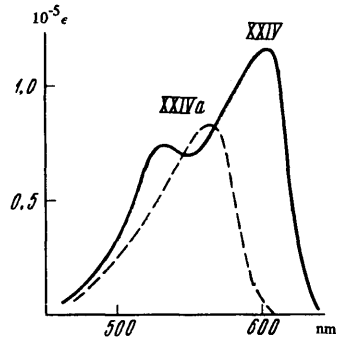


Figure 6.

The chromophoric chains in the bis-dyes are shown as broken lines in the structural formulae. They are conjugated in the first of these biscyanines, but separated by methylene groups in the second biscyanine.

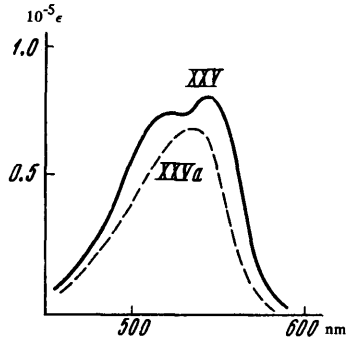

Figure 7.

Fig. 8 shows the absorption curve of the biscyanine (XXVI) and the absorption maximum of the component cyanine (XXVIa) (broken curve). This is a typical picture of strongly interacting chromophores: the absorption bands of the cyanine (XXVIa) (maximum at 552 nm) are split into two mutually remote bands (maxima at 490 and 642 nm).

Fig. 9 shows that the absorption curves of the biscyanine (XXVII) and the component cyanine (XXVIIa) are very similar in shape, with only one band of almost double

the intensity in the biscyanine. Both indicate absence of interaction between the chromophores, but the biscyanine maximum is displaced 19 nm to longer wavelengths. Consequently the methylene group does not completely isolate the chromophores in this case, some mutual influence being preserved.

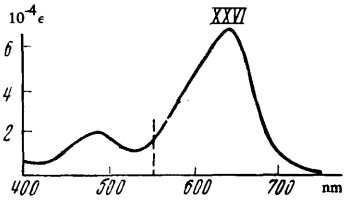

Figure 8.

It must be supposed that the degree of interaction of the chromophores in bis-dyes is defined by the increase in separation or the resolution of their absorption bands. If we denote by Δ_1 the difference between the absorption maxima of the two component dyes and by Δ_2 the difference between the maxima of the two bands of the bis-dye, the degree of interaction of the chromophores in the latter should be measured by $\Delta = \Delta_2 - \Delta_1$. In the case of bis-dyes of symmetrical structure $\Delta_1 = 0$ and $\Delta = \Delta_2$.

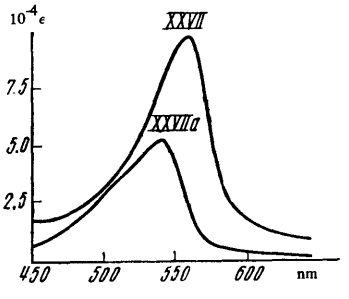

Figure 9.

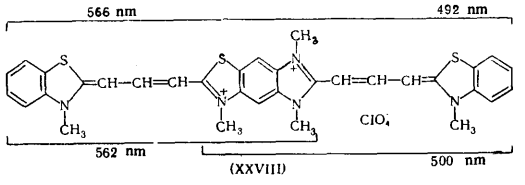
In order to elucidate the factors determining the degree of interaction of chromophores in biscyanines, a series of nine dyes of the type (XXVIII)

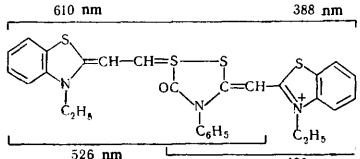


(XXVIII)

and the corresponding parent monocyanines were prepared[24,25]. Above the formula of the bis-dye (XXVIII) are indicated the maxima of its two absorption bands, and below the formula those of the component monocyanines. In the present case the maxima move apart by $\Delta = 12$ nm. Both central and terminal heterocycles were varied in biscyanines of this type, the corresponding Δ values being determined each time.

This work confirmed the correlation already mentioned between the increase Δ in the separation of the absorption maxima of the chromophores in the biscyanines and the difference Δ_1 in the maxima of the component cyanines: the smaller is Δ_1 the larger is Δ. The mutual withdrawal of the bands is largest in symmetrical biscyanines. The interaction of the chromophores is influenced also by the mobility (degree of delocalisation) of the π-electrons in the polymethine chromophore: the more delocalised are these electrons, the more strongly the chromophores interact‡. However, there is yet another important factor influencing the increased separation of absorption bands in dyes having conjugated chromophores. It can be termed "the degree of conjugation of the chromophores", a name which has not yet been fully defined.

An example of bis-dyes with a high degree of conjugation between the chromophores is provided by the trinuclear rhodacyanines[27]. Spectroscopic investigation[21] of the dye (XXIX)

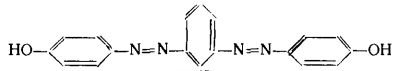


(XXIX)

showed that, despite the very large difference between the maxima of the two component dyes of this rhodacyanine ($\Delta_1 = 87$ nm) and the absence of formal conjugation between the polymethine chains, the mutual withdrawal Δ of the maxima reaches 135 nm. The probable reason for such strong interaction of the chromophores through the rhodanine ring is that this ring is present in both component dyes. Investigation of a series of analogous trinuclear cyanines (bismerocyanines) shows[28] very considerable withdrawal of the absorption bands in all of them, which is also larger the smaller the difference between the maxima of the component dyes.

Hitherto we have been considering the resolution of absorption bands in biscyanine dyes. However, this phenomenon should be common to bis-dyes of all classes. It seemed surprising that it had not been noted in any of the many known bisazo-dyes. It was therefore of especial interest to study, more carefully than had been done previously, at least the simplest members of this immense group of colorants. In 1968 the two bisazo-dyes (XXX) and (XXXI)

(XXX)



(XXXI)

were investigated spectroscopically[29].

Fig. 10 shows the absorption curves of the bisazo-dye (XXX) and of the component dye *p*-hydroxyazobenzene (XXXa). These curves were obtained in alcohol alone (full curves) and with added alkali (broken curves). In both solvents we observe the long known pattern: the

‡ The degree of delocalisation of π-electrons in unsymmetrical cyanines is determined by their deviation[26].

bands of the bis-dye are displaced to longer wavelengths, especially in the alkaline solution§. No splitting of the band is seen in the bisazo-dye (XXX).

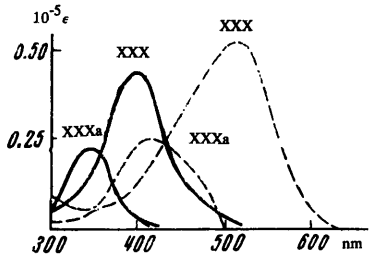


Figure 10.

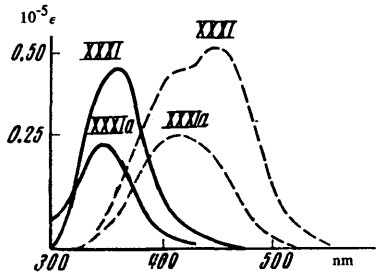

Figure 11.

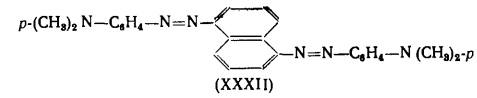
The absorption curves of the bisazo-dye (XXXI) in neutral and alkaline alcoholic solutions are at first glance unexpected (Fig. 11). Here the two azo-groups are linked through the *meta*-position of a benzene ring, so that formally they are not conjugated. Nevertheless, the absorption band of the bisazo-dye (XXXI) is displaced towards the red end of the spectrum with respect to that of the component dye (XXXa)¶, and in alkaline solution there is even appreciable resolution into two bands. It has also been shown in several other experiments—dyes (XLIII), (XLVII), (LVI), and (LVII)—that the interaction of chromophores linked through the *meta*-positions of a benzene ring is weak but not entirely absent. The situation is probably similar to that observed with rhodacyanine dyes. As we shall see later, the absence of band splitting in the bisazo-dye (XXX) and its presence in (XXXI) are connected with the linear structure of the former molecule and the angular structure of the latter.

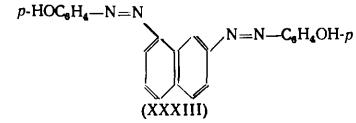
§ Delocalisation of π-electrons is greater in dye anions and cations than in the unionised molecules[26].

¶ Although Brode had stated[4] that azo-chromophores in *meta*-positions do not influence each other.

The interaction of two azo-chromophores has been studied also in the bisazo-dyes from naphthylene-1,5-diamine (XXXII) and from naphthylene-1,7-diamine (XXXIII)[30]



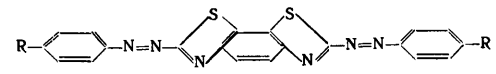
(XXXII)



(XXXIII)

Contrary to earlier results[31], no conjugation has been detected between the azo-chromophores in the spectrum of the bisazo-dye (XXXII). On the other hand, the chromophores are conjugated in (XXXIII), as is seen from the distinct splitting of the absorption band (angular molecular structure).

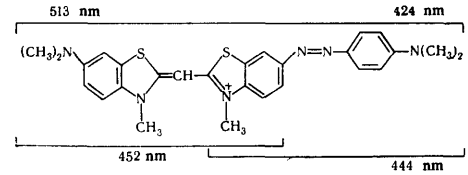
Two bisazo-dyes have been prepared from thiazolobenzothiazolediamine—(XXXIV) and (XXXV)[32]



(XXXIV: R=OH) (XXXV: R=N(CH3)2)

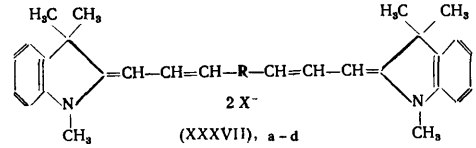
Both these symmetrical bisazo-dyes show, in neutral alcoholic solution and still better in alkaline (XXXIV) or acid (XXXV) solutions, the splitting of the absorption band of their component dyes which is typical of conjugated bis-dyes.

The interaction of a polymethine chromophore with an azo-chromophore has been studied[33] in azo-cyanine dyes. Here, too, maximum interaction was observed in dyes where the two component dyes absorbed similar light quanta, e.g. (XXXVI)



(XXXVI)

Very interesting results on the band intensities of dyes containing two conjugated chromophores were obtained[34,35] from an investigation of the spectra of biscyanines synthesised from isomeric dimethylthiazolobenzothiazoles. Four isomeric bistrimethinecyanines (XXXVII)



(XXXVII), a–d

were obtained, in which the central ring R was one of the fused systems (a)–(d) (Fig. 12), as well as several other symmetrical biscyanines and distyryl derivatives containing the same ring systems (a)–(d). The absorption curves of the biscyanines (XXXVIIa–d) are reproduced in Fig. 13.

The spectrum of the biscyanine (XXXVIIa) was found to contain two bands *a* and *a'* of almost equal intensity; with (XXXVIIb) the intensity of the shorter-wavelength band *b'* fell, whereas the longer-wavelength band *b* increased sharply in intensity; the shorter-wavelength band *c'* of the biscyanine (XXXVIIc) was hardly noticeable;

and finally (XXXVIId) exhibited only a strong longer-wavelength band *d*, while the shorter-wavelength band had almost disappeared†. Comparison of the structural formulae of these biscyanines (XXXVIIa–d), taking into account X-ray data on the thiacyanines [38,39], clearly reveals a correlation between the intensity ratio of the two bands of each biscyanine and the angle between the directions of its polymethine chromophores (from one auxochrome to the other). This angle is smallest (80°) in the isomer (XXXVIIa) (Fig. 14); it is 180°, i.e. a maximum, in (XXXVIId), whose molecule is centrosymmetric.

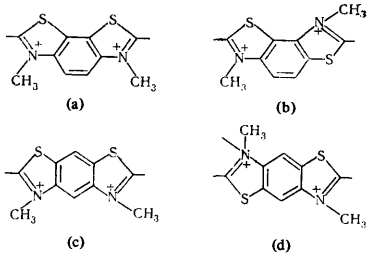


Figure 12.

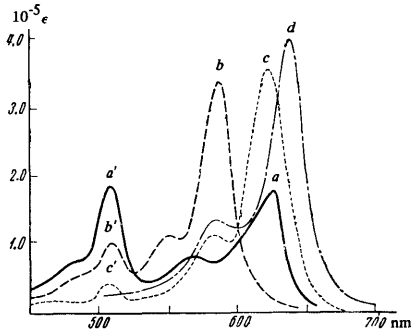

Figure 13.

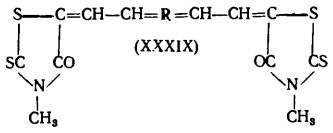
The intensity ratio of the two bands in the biscyanine (XXXVIIa) remains almost unchanged with increase in the length of its chromophoric chains. In the distyryl dye (XXXVIII)

(XXXVIII)

containing the same central ring (R = a), however, the intensity of the longer-wavelength band, in contrast to the biscyanine (XXXVIIa), is almost double that of the shorter-wavelength band (Fig. 15). In fact, the angle between the chromophoric chains is far larger in (XXXVIII) than in (XXXVIIa) (Fig. 16).

† Inflexions on the short-wavelength portion of the absorption curves, in the present case in the range 550–600 nm, are characteristic of most cyanine dyes and are due to vibrational transitions [36]. This origin of such inflexions has recently been proved by the luminescence spectra at low temperatures [37].

Investigation of the spectra of the bismerocyanines (XXXIX)



(XXXIX)

where R represents one of the ring systems (a)–(c) (see above) revealed the same dependence of the intensities of the absorption bands on the angles between the chromophores [40].

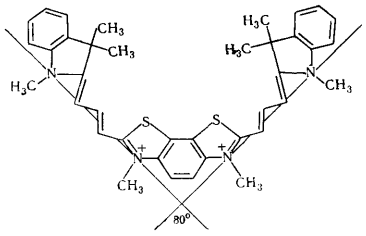


Figure 14.

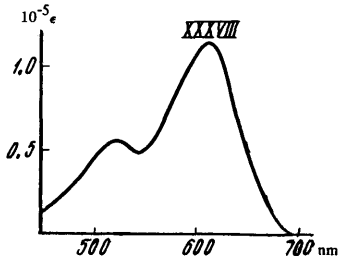

Figure 15.

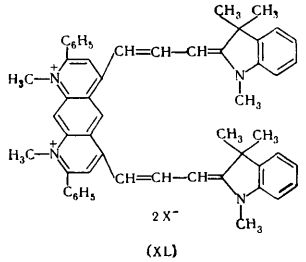
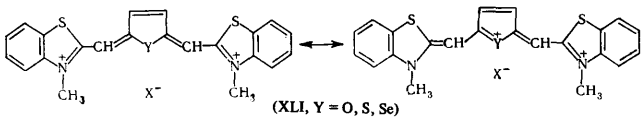
In 1968 it proved possible to synthesise [41] the first biscyanine (XL) in which the directions of the chromophoric chains formed an acute angle



(XL)

In conformity with expectation the shorter-wavelength band of this dye was considerably more intense than the longer-wavelength band (Fig. 17). Since then simpler bis-dyes have been obtained with acute angles between the chromophores—see (XLII) and (XLVI).

Unusual bis-dyes of general formula (XLI)



(XLI, Y = O, S, Se)

have recently been described[42]. Fig. 18 shows that two bands—a more intense longer-wavelength band with a fine structure and a weaker shorter-wavelength band—are present in the absorption spectra of all three compounds.

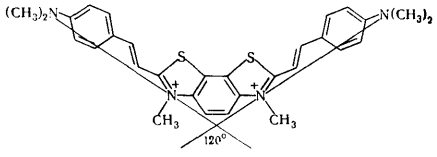


Figure 16.

This corresponds to obtuse angles between the chromophores. The intensity ratio of the two bands indicates that the selenophen derivative has the largest angle and the furan derivative the smallest: this was to be expected. Similar observations have been made[43] on biscyanines obtained from dimethyloxazolobenzoxazole and dimethylthiazolobenzothiazole.

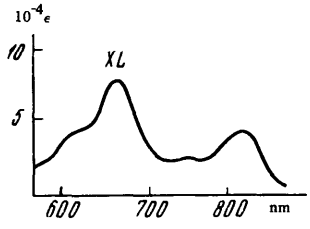

Figure 17.

The experimental results discussed in this Review leave no doubt that the intensity ratio of the two absorption bands which appear on electronic interaction between two combined chromophores is determined by the angle between the chromophores in space‡.

The elementary theory of the interaction of chromophores (Kiprianov and Dyadyusha[18,44]) is consistent with this generalisation. The oscillations of a positive or a negative charge excited in the chromophores by the alternating electric field of a light wave are equivalent to vibrations of a dipole. Because of the repulsion of like charges, the excitation of oscillations in which the like charges in chromophores joined at the ends come together (*a* and *d* in Fig. 19) requires more energy than with the opposite phase relationship (*b* and *c*). The former corresponds to high-frequency or short-wavelength absorption bands, the latter to low-frequency or long-wavelength bands.

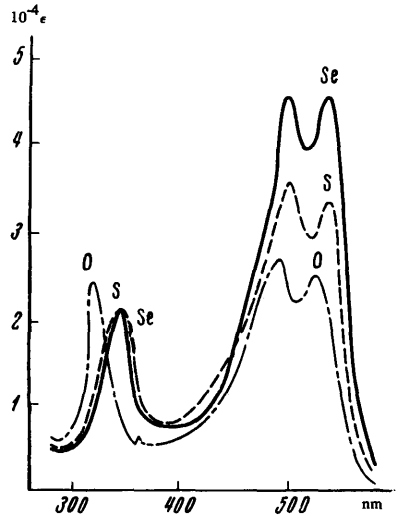

Figure 18.

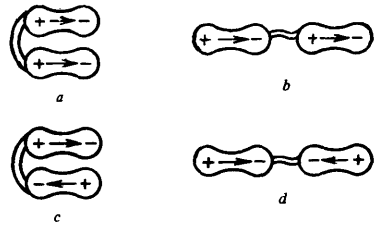

Figure 19.

If the angle between the chromophores is either 0 or 180°, the oscillations depicted as *a* and *b* (Fig. 19) are equivalent to vibrations of a dipole having double the charge. They interact strongly with the field of the light wave. With oscillations of types *c* and *d*, on the other hand, the aggregate dipole remains unchanged, and these vibrations cannot be actively involved in the absorption of light. With the chromophores arranged parallel (angle 0°), therefore, only the short-wavelength band can be intense. If, however, one chromophore constitutes a prolongation of the other (angle 180°), only the long-wavelength band can be intense. With intermediate angles between the chromophores (Fig. 20) both absorption bands should be observed, with the short-wavelength band more intense at acute angles, and the long-wavelength band at obtuse angles.

It is desirable that models for study of a new phenomenon should be as simple as possible. In the case of

‡ At least in bis-dyes of symmetrical structure. The intensities of the component dyes must also be taken into account in the case of unsymmetrical bis-dyes.

dyes having two linked chromophores this condition was met by bishemicyanines. A considerable number of dyes of this group have been reported in the patent literature[45], but their absorption spectra have not been investigated.

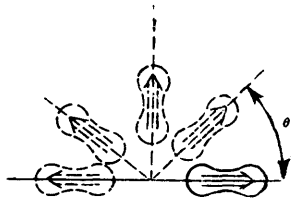

Figure 20.

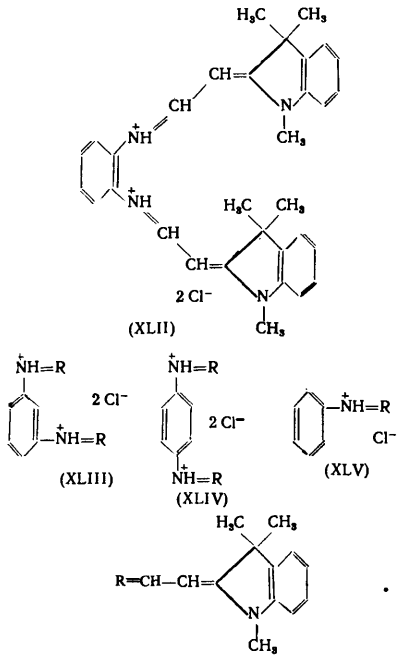
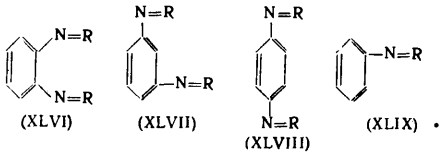
Kiprianov and Buryak[46] determined the absorption curves of three simple isomeric bishemicyanines (XLII)–(XLIV) and also that of the component hemicyanine (XLV). We give the structure of the first of these dyes in full, and the other structures in abridged form:



These dyes are converted by alkali into the corresponding bases (XLVI)–(XLIX)



The absorption curves of these bases show (Fig. 21) that the chromophores interact in every case. In the spectrum of the *ortho*-derivative (XLVI) the band of the component base (XLIX) is split into two new bands, of which the shorter-wavelength band is by far the more intense. This intensity relationship was to be expected, since the two chromophores should form an acute angle in this *o*-phenylenediamine derivative.

No splitting of the band due to the component hemicyanine is observed in the spectrum of the base (XLVII) (a derivative of *m*-phenylenediamine). However, the chromophores do interact, as is evident from the shift in the band to longer wavelengths.

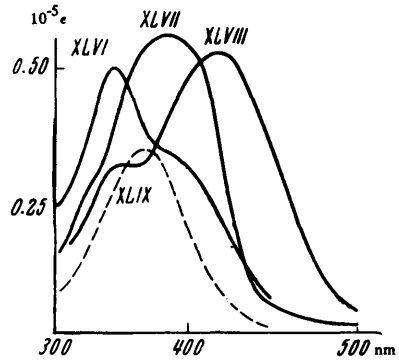


Figure 21.

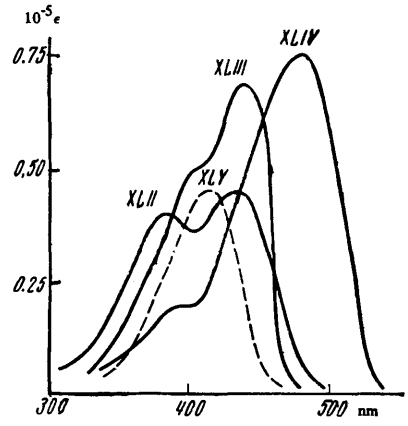

Figure 22.

In the base (XLVIII) the chromophores are conjugated, but they are arranged in diametrically opposed directions. Here an intense long-wavelength band would be expected with disappearance of the short-wavelength band. Nevertheless, although the former is strong, we see also a weak but distinct short-wavelength band. It is probable that not all the equilibrium conformations of this molecule have a centrosymmetric structure§.

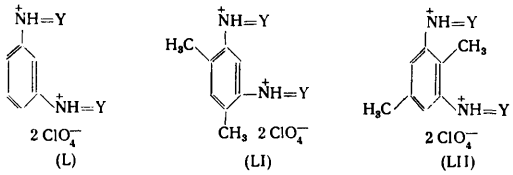
Fig. 22 shows the absorption spectra of the bishemicyanines themselves (XLII)–(XLIV) and of the hemicyanine (XLV). As usual, the absorption bands of the salts

§ Like the dimethyl ether of quinol, in which the dipole moment differs from zero.

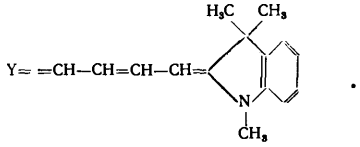
are more intense than those of the bases, and are displaced towards the red end of the spectrum. The absorption curves underwent interesting changes on passing from the bases to the salts. The longer-wavelength band—not the shorter-wavelength band—is more intense in the spectrum of the *ortho*-derivative (XLII) in contrast to the spectrum of the base (XLVI). The appearance of like cationic charges on the nitrogen atoms pushed the latter apart. The absorption curve of the *meta*-derivative (XLIII) exhibits not only a general shift in the band to longer wavelengths but also a distinct splitting with the formation of a shorter-wavelength maximum, in spite of the absence of formal conjugation. The absorption curve of the *para*-derivative (XLIV) resembles that of the corresponding base (XLVIII).

The spectra of bishemicyanines revealed steric effects on the introduction of methyl groups *ortho* to the chromophoric chains. These effects are readily evident in the methyl and dimethyl derivatives of the bishemicyanines just described[47], but they become especially strong as the polymethine chromophores become longer. Let us give a few examples[48].

m-Phenylenediamine and its dimethyl derivatives have been used to prepare the bishemicyanines (L)–(LII)



where



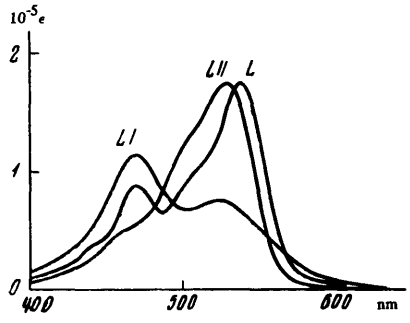


Figure 23.

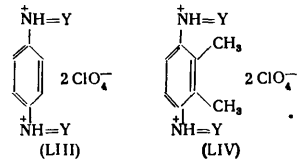
From Fig. 23 it can be seen how the volume of the methyl groups affects the angle between the chromophores. The intensities of the absorption bands indicate that, as was to be expected, this angle is obtuse in the bishemicyanine (L). The introduction of two methyl groups into positions 4 and 6 of the benzene ring (bishemicyanine LI) forces the chromophoric chains together and makes the angle between them acute. But if a methyl group is placed between the chromophores (dye LII), the angle between them increases almost to 180°.

Similar changes in angle between the chromophores under the influence of adjacent methyl groups are observed also in the bishemicyanine from *p*-phenylenediamine (LIII) and its dimethyl analogue (LIV)



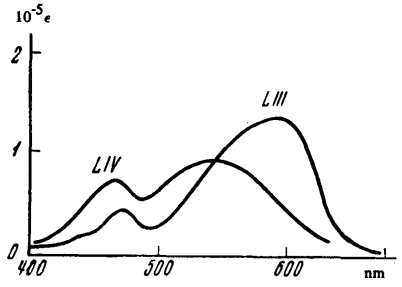


Figure 24.

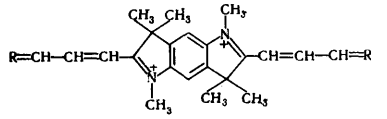
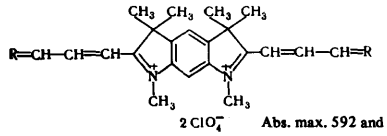
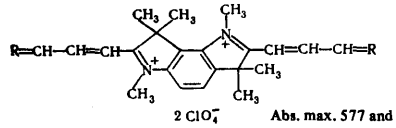
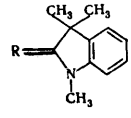
The chromophores in (LIII) lie in opposite directions (cf. preceding footnote §). This is apparent in the spectrum (Fig. 24) as an intense long-wavelength band and a weakly defined short-wavelength band. Two methyl groups introduced into positions 2 and 3 in the benzene ring (bishemicyanine LIV) reduce this angle almost to a right-angle (two maxima of almost equal intensity).

We have already noted—dyes (XXXI) and (XLIII)—that spectral interaction of two chromophores is observed when they are linked not only through the *ortho*- and *para*-positions of a benzene ring but also through the *meta*-position. A special investigation has been made of this last case[49]. Three symmetrical biscyanines (LV)–(LVII)



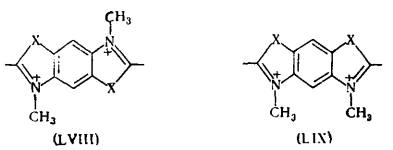






were prepared from isomeric dimethyldiazaindacene derivatives. Mutual separation of the absorption bands is observed with all three bis-dyes, but its value Δ, representing the degree of interaction of the combined chromophores, is 139 nm in (LV), in which the chromophoric chains are conjugated through the *para*-position of the benzene ring, whereas it is 77 and 74 nm, i.e. only half, in the biscyanines (LVI) and (LVII), where the same chains are combined through the *meta*-position.

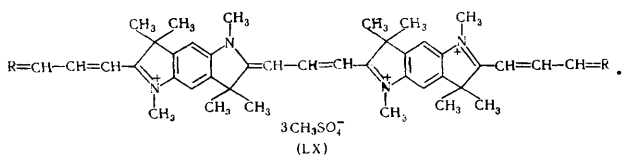
In the analogous biscyanines containing fused thiazolobenzothiazole or oxazolobenzoxazole rings as central nucleus the structures (LVIII) and (LIX)



(LVIII) (LIX)

(where X = S, O) show little difference in mutual separation of the bands. In these dyes, however, conjugation can be accomplished not only through the nitrogen atoms but also through the sulphur or oxygen atoms.

In concluding this survey we note that it has recently proved possible[50] to synthesise the first triscyanine dye (LX)



(LX)

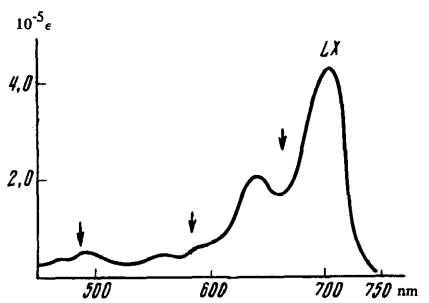


Figure 25.

Fig. 25 shows that the absorption curve of this dye in nitromethane contains bands corresponding to three electronic transitions (indicated by arrows).

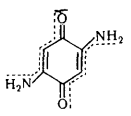
From all that has been stated concerning the interaction of conjugated chromophores it must be concluded that a cautious approach is necessary to the use of spectral methods to determine the structure of organic compounds. In the infrared and nuclear magnetic resonance spectra each group of atoms is represented by a band or region of characteristic absorption, so that these methods are extremely valuable for the determination of structure. But the attempts of many chemists to establish such characteristic frequencies in electronic spectra, e.g. for substituents in aromatic and heterocyclic ring systems, have been unsuccessful. For the most part conjugated chromophores do not absorb at all in the spectral region in which the isolated chromophores absorb. It was therefore supposed that on conjugation the individual chromophores merge into a single longer chromophore, which absorbs at longer wavelengths. We now know that the situation is more complicated, and that the conjugation of two chromophores results in the formation of two new absorption bands, for each of which both interacting chromophores are responsible.

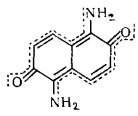
This interaction of chromophores has been discussed in the quantum theory of the spectra of organic compounds[16,51]. The probable reason why it has not been observed hitherto in the spectra of simple conjugated systems, e.g. the absorption spectra of aromatic hydrocarbons and polyenes, is that such spectra are too complicated, consisting of a large number of closely spaced bands. However, the splitting of bands has been observed by Davydov in the spectra of molecular crystals of naphthalene and anthracene at low temperatures, when the bands are especially narrow, and has been brilliantly explained by him (Davydov splitting)[52,53]. It must also be borne in mind that, according to London's theory, electrical interaction between oscillators in molecules should be greater the stronger the oscillators and the longer the longest wavelengths of absorption bands due to the molecule. Consequently resonance interactions should be more clearly developed between dye molecules than between aromatic hydrocarbon molecules containing conjugated systems of the same length[54]. Earlier spectroscopic investigations on bisazo-dyes have not resulted in the discovery of splitting of their absorption bands, for the dyes studied mostly had linear molecules, in which splitting should not have been observed. Furthermore—probably the most important reason—the absorption bands of azo-dyes are broad, overlapping, and devoid of distinct maxima. It is not surprising that cyanine dyes, with their narrow and intense absorption bands, provided greater success.

As early as 1944 Förster[55,56] used the interaction of π-electron systems to explain the absorption bands of dimeric cyanine dyes, which lay at shorter wavelengths than the bands due to the monomers. The chromophores were arranged parallel to each other in the molecules of these dimers. Recently Kuhn[57] has shown that, in monomolecular layers of simple cyanine dyes deposited on a glass surface in such a way that the chromophoric chains of two neighbouring molecules A and B are contiguous, the chromophores begin to interact as coupled oscillators. As a result, the absorption band of dye A is displaced in one direction, and that due to dye B in the other, so that the bands move apart.

Whether in Davydov's molecular crystals, in dimers of cyanines, or in Kuhn's monolayers of dyes, the interacting molecules only approach one another, but do not form covalent bonds. Recently, however, Dähne has shown[58] that the deep and intense colour of certain aromatic and heterocyclic compounds, including Indigo Blue, Indanthren Blue, and Alizarin, can be regarded as resulting from the interaction of two electronic oscillators bound covalently into a single cyclic system

(coupling effect). This has been shown especially convincingly for red 2,5-diamino-*p*-benzoquinone (LXI) and blue 1,5-diamino-2,6-naphthaquinone (LXII)





336 and 488 nm 321 and 581 nm

Absorption maxima in $(CH_3)_2SO$

(LXI) (LXII)

which, according to Dähne, are doubly bound merocyanine molecules. This has been confirmed by appropriate quantum-mechanical calculations of the absorption maxima of these compounds, investigation of their ultraviolet and nuclear magnetic resonance spectra, and X-ray examination of the crystals [59-61].

Nevertheless, as is evident from the present review, it is only by investigating the spectra of bis-dyes in which the two component dye molecules are combined into a single open conjugated chain that we were able to establish that not all combined chromophoric systems interact spectroscopically, but only those which absorb similar quanta of light energy, that the intensities of the two absorption bands of a bis-dye can be used to estimate the direction of its chromophores in space, that these directions are easily changed by steric and electronic factors, etc.

The investigation of bis-dyes having conjugated chromophores has opened a new chapter in the theory of colour and constitution.

Thermochemical Constants of $A^{III}B^{V}$ Compound Semiconductors, and Approximate Methods of Calculation

L.I.Marina and A.Ya.Nashel'skii

Published data on the phase diagrams and on the nature of melts in the A^{III}–B^{V} system and on the thermochemical constants of $A^{III}B^{V}$ semiconducting compounds are reviewed. Approximate methods of calculating thermochemical constants are suggested: they are based on summing the constants of the elemental semiconductors whose atomic weights add up to the molecular weight of the compound. 128 references.

I. INTRODUCTION

$A^{III}B^{V}$ compounds, composed of elements of Groups III and V of the Periodic Table, have recently attracted a great deal of attention from physicists, chemists, and device technologists because of their semiconductor properties [1]. The properties of $A^{III}B^{V}$ compounds have increased our understanding of semiconductors, and have given rise to new applications in different branches of electronics: in semiconductor electronics (by virtue of the properties of their crystal lattice), in molecular electronics (by making possible new solid-state circuits), and in quantum electronics (which relies on quantum phenomena within the atoms and molecules of the material).

A knowledge of the thermochemical properties of $A^{III}B^{V}$ compounds (or III–V compounds) is essential to the full understanding of their nature and properties, and also for the development of apparatus and techniques for preparing these compounds and for producing devices from them. The constants which must be known to solve the first problem include the enthalpy and entropy of formation of the compound, the free energy of the formation reaction, the heat of atomisation, the absolute entropy, etc. The second and the third problem cannot be solved without a knowledge of the phase diagrams of the individual components and of the compound, of the vapour pressure of the volatile component at the melting point, of the specific heat, heat of melting, etc.

Many of the above constants have been determined experimentally for the compounds which can be prepared relatively easily. Some of these compounds, however, have high melting points and high vapour pressures of the volatile component at their melting point: most of the physicochemical constants which are available for these compounds were obtained by calculation and are only tentative. In many cases data are altogether lacking.

This review attempts to systematise the thermochemistry of III–V compounds by a critical discussion of published methods of evaluating physicochemical constants by approximate calculations.

II. PHASE DIAGRAMS AND NATURE OF MELTS IN A^{III}–B^{V} SYSTEMS

With the exception of boron-containing systems, the phase diagrams of A^{III}–B^{V} systems (plotted as T against x, where T is temperature and x is the composition in at.%) are all of the same type [2]. They all include one congruently melting compound (of 1:1 atomic composition) whose melting point is much higher than the melting points of the components (Fig. 1). The eutectic on the side of the A^{III} component is degenerate. The other eutectic, on the right-hand side of the diagram, usually lies at high concentrations of the B^{V} component. An analysis of these phase diagrams suggests that only the compound can have semiconductor properties in these binary systems.

As the atomic weight of the component atoms increases, the shape of the phase diagram for the binary system changes, indicating a change in the type of interaction between the elements. In the heaviest systems the phase diagrams no longer show a 1:1 compound (see, for example, the rare earth element–bismuth systems). The new compounds have neither a tetrahedral structure nor semiconductor properties.

The semiconducting phases in the binary systems belong to the type known as linear phases, in which the solubility of the components is very low. Mironov and Borisova [15] have discussed deviations from stoichiometry in the III–V semiconductors and the methods used to study these deviations.

Thermodynamic arguments based on the free-energy curves for the crystal and the melt in a binary system which forms a compound semiconductor have shown that the maximum melting point (the distectic point) of the compound does not coincide with the stoichiometric composition. The phase diagram of the binary system in the region of the compound takes the form shown in Fig. 2. Crystals grown from a melt lying in the composition region *3* contain an excess of component B, those grown from region *1* contain an excess of component A. A crystal of exactly stoichiometric composition can be grown only from a melt of composition *Q*.

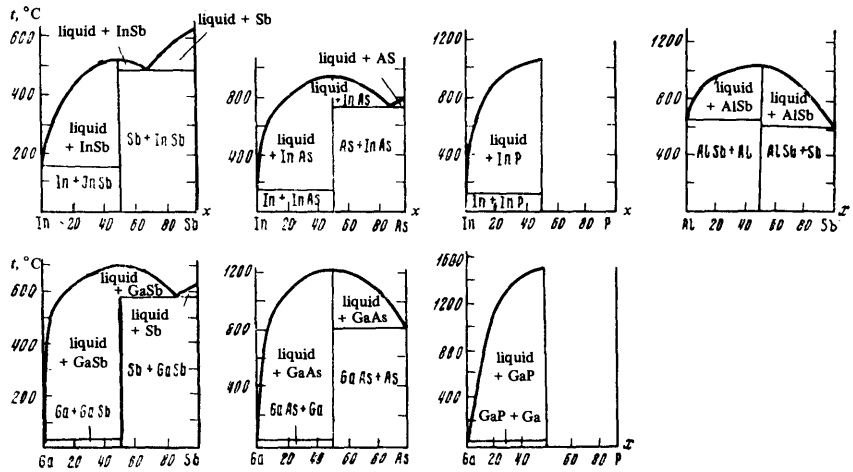

Figure 1. Phase diagrams of some $A^{III}-B^{V}$ systems in $T-x$ coordinates: In–Sb,[3,4] In–As,[5,6] In–P,[6,7] Al–Sb,[8,9] Ga–Sb,[10,11] Ga–As,[6,11] Ga–P.[12,14]

However, in most III–V compounds the deviations from stoichiometry arising from the solubility of an excess of the components in the compound are not detectable by precision X-ray, chemical, or mass-spectroscopic analyses. $A^{III}B^{V}$ semiconductors can be prepared with such a low concentration of current carriers (under conditions leading to mutual compensation of impurities and native defects) that the presence of a stoichiometric excess of one of the components is inconceivable. GaAs and GaSb are exceptional in this respect: a shift of their maximum melting point towards the gallium-rich side has been detected by an indirect method [16,17].

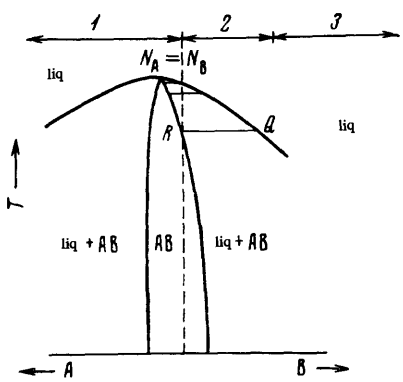

Figure 2. Part of the phase diagram in the region of the compound semiconductor, illustrating the deviation of the maximum melting point from the stoichiometric composition [15].

The most likely source of deviations from stoichiometry in III–V compounds are lattice defects and impurity atoms. The latter can displace normal atoms from lattice sites or, if they are not too large, they can reside in interstitial sites. In either case, the conductivity type of the compound is affected. Atom displacements (or substitutions) in the lattice of a III–V compound can produce point defects of various types: vacancies at the normal lattice sites, interstitial atoms surrounded by four atoms of the same kind or of the opposite kind, and the substitution of atoms of one kind by atoms of the other kind [18].

These structural defects appear to be the only mechanism by which the composition of III–V compounds can deviate from stoichiometry. Many attempts at inducing non-stoichiometry by adding an excess of one of the components to the melt, by diffusion of the vapour of the volatile component into the solid compound, or by other methods, were unsuccessful. The conclusion, which is extremely important in the technology of III–V compounds, is that small variations in the composition of the melts used to grow single crystals of the compounds have a negligible effect on the physical properties of the crystals.

Equilibrium in the A–B systems involves four phases: component A(sol), component B(vap), a solution of component A(liq) in B(liq), and the compound AB(sol). This equilibrium corresponds to a quaternary point in the $p-T-x$ diagram (where p is pressure) at the intersection of four lines characterising the corresponding three-phase equilibria [19]. In unstable III–V compounds the quaternary point lies in the region of low pressures, at temperatures close to the melting point of component A, and consequently at low concentrations of component B in solution.

An analysis of all possible phase equilibria indicates that, for all practical purposes, the most important equilibrium is

$$AB(sol) \rightleftharpoons \text{solution of B in A(liq)} \rightleftharpoons B(vap) \ .$$

Three-phase equilibria in binary systems are monovariant ($v = 3$, $F = 1$). Hence, this equilibrium is described on a $p-T-x$ diagram by a curve terminated at one end by the quadruple point and at the other end in one of a number of ways [20,21], depending on the type of interaction between the components A and B.

The binary phase diagram for an involatile (A) and a volatile (B) component which react to give a semiconducting

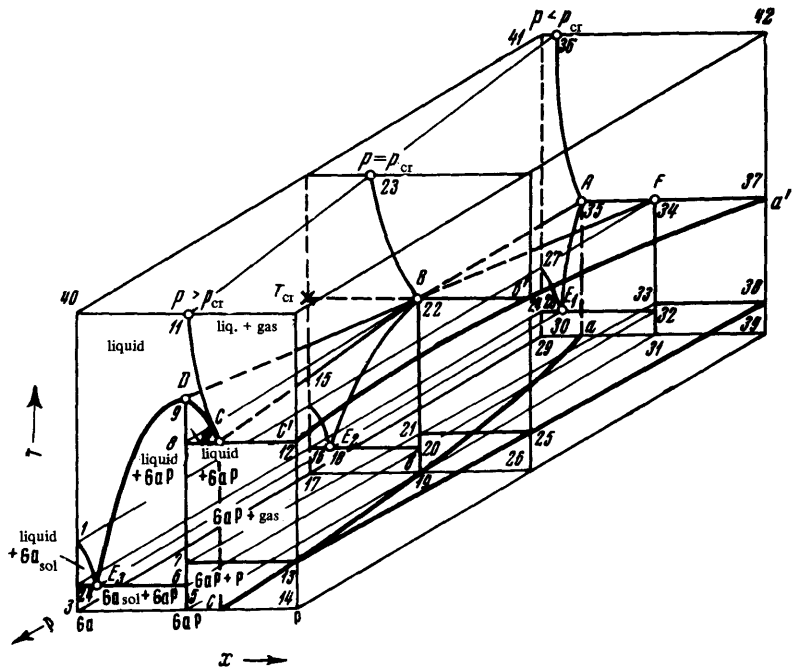

Figure 3. Hypothetical three-dimensional phase diagram for the gallium–phosphorus system [12].

compound at low pressures is of the peritectic type. Unstable compound semiconductors are almost completely dissociated below the melting point when heated under normal conditions, and therefore their liquidus curve does not show a maximum.

However, when the pressure is raised, the regions of the phase diagram are displaced towards the point where the liquid phase composition is the same as that of the compound, and the solid phase begins to take part in the transformations [22,23]. On further raising the pressure the peritectic phase diagram is converted into a phase diagram with a normal maximum [24].

The transition from one type of phase diagram to the other under the influence of external pressure is illustrated by the hypothetical three-dimensional phase diagram for the Ga–GaP system shown in Fig. 3. The diagram includes the following regions and equilibrium lines:

Two-phase regions: *1–2–3–18–30–27–28–16–15–1* (melt + Ga crystals); *2–3–5–6–20–16–17–19–31–32–28–29* (GaP crystals + Ga crystals); *5–7–13–14–26–19–21–25–38–39–31–32* (GaP crystals + P crystals); *6–4–9–6–20–32–34–22–35–30–18–4* (melt + GaP crystals); *9–22–10–8* (melt + GaP crystals).

Single-phase region: *40–41–36–28–11–10–9–41–27–30–35–36* (melt).

Two-phase equilibrium lines: *BD* (GaP crystals + melt); *a′b′c′* gives the temperature variation of the vapour pressure of liquid P; *1–15–27* gives the pressure dependence of the melting point of Ga; *13–25–38* gives the temperature dependence of the vapour pressure of solid P.

Three-phase equilibrium lines: *ABC* (melt + GaP crystals + vapour); $E_1E_2E_3$ (melt + GaP crystals + P crystals); *BF* (melt + GaP crystals + vapour). *B* is the point corresponding to the four-phase equilibrium (melt + GaP crystals + liquid P + P vapour).

The three-phase equilibrium of interest (compound AB(sol)–solution of component B in A(liq)–component B(vap)) is shown by the line *CBA* in the three-dimensional diagram (see Fig. 3). The projections of this line are shown on the three coordinate planes: *cba* on plane p–x, $c'b'a'$ on plane p–T, and E_3D on plane T–x.

Fig. 4 shows a series of consecutive isobaric sections of the three-dimensional phase diagram, drawn by Folberth [25] to demonstrate the shift of the point representing the three-phase equilibrium line on the T–x plane (points *1–5* in Fig. 4*a*–4*e*) caused by an increase of pressure. The point goes through a maximum (Fig. 4*f*).

Wagner [26] has discussed the general case of equilibrium between liquid and solid phases in a binary system containing a compound. The liquidus curve (Eqn. (1)) was derived without making allowance for the temperature dependence of the energy of mixing ω ($\omega = \omega_{AB} - (\omega_{AA} + \omega_{BB})/2$, where ω_{AB}, ω_{AA}, and ω_{BB} are the interaction energies between unlike and like atoms) or for the difference in specific heat between the solid and the liquid phase of the compound:

$$\omega = \frac{RT}{2(x-0.5)^2}\left[\ln\frac{1}{4x(1-x)} - \frac{\Delta S_f}{R}\left(\frac{T_f}{T}-1\right)\right], \qquad (1)$$

where ΔS_f and T_f are the entropy and the temperature of fusion of the compound, x is the atom fraction of component B in the melt, and R is the gas constant.

Eqn. (1) was applied to InSb and GaSb by Schottky and Bever [27], who postulated that melts of these compounds are regular solutions with an entropy of melting equal to the ideal entropy of mixing. Experimentally, gallium antimonide melts were found to behave like ideal solutions whereas indium antimonide melts gave negative deviations from ideality.

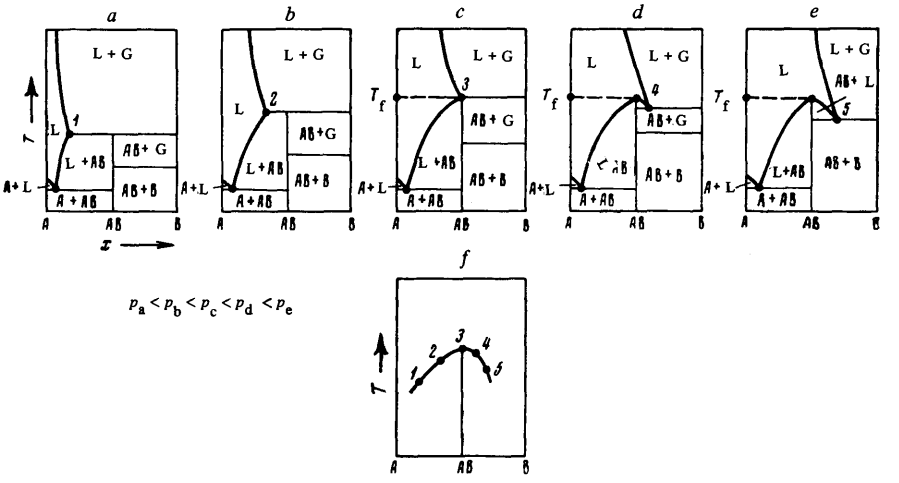

Figure 4. Isobaric sections of the phase diagram for a binary system consisting of an involatile component A and a volatile component B and forming a semiconducting compound AB: *a*)–*e*) isobaric sections; *f*) projections of the three-phase equilibrium point (AB_{sol}–solution of B in Aliq–B_{gas}) on the T–x plane (liquidus line).[25]

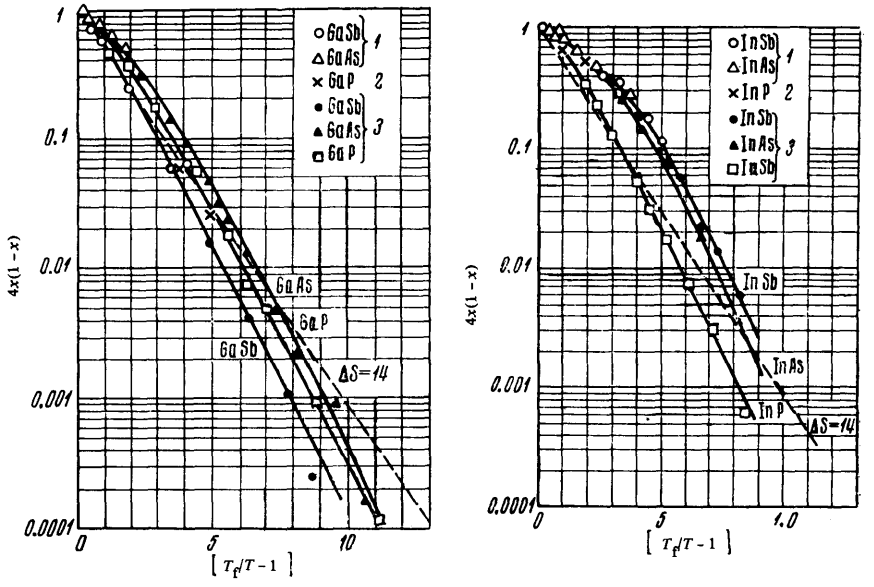

Figure 5. Dimensionless plots of the solubility of GaSb, GaAs, GaP, InSb, InAs, and InP: *1*) after Ref. 11; *2*) after Ref. 14; *3*) after Ref. 13.

Wieland[28] used regular solution theory to interpret data on the vapour pressure of III–V compounds:

$$p^{1/4} = p_0^{1/4} \cdot \exp[\omega(1-x)^2/RT] \text{ atm}, \quad (2)$$

where p is the pressure of tetra-atomic molecules of the volatile component B^V over a melt of A^{III} containing an atom fraction x of component B, and p_0 is the pressure of the same molecules over the pure liquid component B at the given temperature. In practice, Eqn. (2) is difficult to apply to the determination of the equilibrium pressure of component B over melts of approximately stoichiometric composition because of the lack of reliable vapour pressure data for the pure liquid components B (such as phosphorus, arsenic, etc.) whose vapour pressure is high at high temperatures.

According to Hall[13], $A^{III}B^V$ melts behave as ideal solutions at low temperatures. In this case $\omega = 0$, and plots of $\ln 4x(1-x)$ against $(T_f/T - 1)$ are linear for all systems, with a slope of $\Delta S_f/R$. All the plots are found to have approximately the same slope (Fig. 5), corresponding to an entropy of fusion of $\Delta S_f^* = 14$ cal mole^{-1} deg^{-1} for the ideal solution.

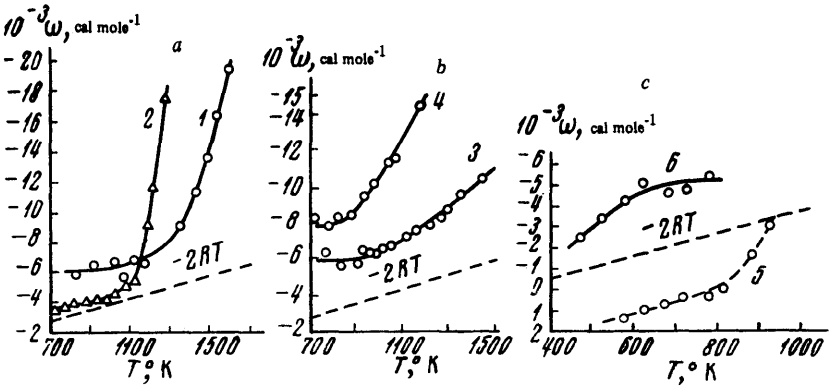

Figure 6. Variation of the energy of mixing with temperature, calculated from experimental liquidus data for A^{III}–B^{V} systems [29,30]: *1*) Ga–P, *2*) In–P, *3*) Ga–As, *4*) In–As, *5*) Ga–Sb, *6*) In–Sb.

A thermodynamic analysis of the liquidus curves for the systems formed by gallium and indium with phosphorus, arsenic, and antimony, based on Eqn. (1), has yielded the energies of mixing of those systems [29,30]. The values (Fig. 6) were found to be a function of temperature and of the concentration of the melt: hence, these systems cannot be treated as regular solutions. In all systems the energy of mixing tends towards zero as the concentration of the Group V element decreases. With the exception of the Ga–Sb system, the calculated energies of mixing are smaller than $-2RT$, pointing to a strong interaction between unlike atoms and confirming the theoretical conclusion of Pines and Kamenetskaya [31,32] that compound formation should occur in systems for which $\omega < -2RT$.

The Ga–Sb system differs from all the others [30] in having an energy of mixing more positive than $-2RT$ over the whole range of temperatures (see Fig. 6*c*), and therefore also of compositions: its value lies in the range 0–2 kcal mole^{-1}. This observation lends support to Schottky and Bever's statement [27] that gallium–antimony melts can be treated as ideal solutions. The bond in liquid gallium antimonide has a greater proportion of metallic character than in any other III–V compound [33]. This phenomenon may be responsible for the anomalous thermodynamic properties of the material.

The temperature dependence of the energy of mixing obtained in the above work [29,30] is inconsistent with the results of Thurmond [34], who found a linear dependence for the Ga—As and Ga—P systems, the quantity ω changing sign as it passes through zero. This may be due to an incorrect choice of entropies of melting by Thurmond [34]: there is serious disagreement on the entropies of melting of GaAs and GaP among different workers.

III. TEMPERATURE, HEAT, AND ENTROPY OF MELTING

The melting points of most of the antimonides and arsenides are quite accurately known; conflicting data have been published for some of the phosphides, and the values for most of the nitrides are purely tentative.

The melting points of the III–V semiconductor compounds, listed in Table 1, show a correlation with the position of the components in the Periodic Table. The melting points of the compounds decrease as the molecular weight increases. Vigdorovich and coworkers [47] have pointed out that the rule [48,49], according to which the melting points of elements with a covalent type of bond increases as the shortest interatomic distance in the crystal lattice decreases, applies also to III–V compounds (see Fig. 7). Only aluminium and gallium antimonides fall outside the linear relationship.

Table 1. Melting points (°C) of III–V compounds.

*Cubic modification; **under equilibrium vapour pressure of the volatile component; ***under 4 atm nitrogen pressure.

In most cases, the thermodynamic characteristics of the melting of III–V compounds have been obtained by indirect calculations. Experimental and calculated values of the heat and entropy of melting of semiconductor compounds are given in Tables 2 and 4.

Glazov and Krestovnikov [50] measured the heat of melting of a number of III–V compounds, and showed that this parameter decreases when the cation or the anion are replaced by a heavier atom, in the following sequence: AlSb → GaSb → InSb and GaAs → InAs.

Melekh and Semenkovich [51] proposed an approximate method of calculating the entropies and heats of melting of compound semiconductors, based on the formula [36]

$$\Delta S_f = \sum S_{f,el.} + S_{mix}, \qquad (3)$$

where ΔS_f is the entropy of fusion of the alloy, $S_{f,el}$ is the entropy of fusion of the constituent elements, and S_{mix}

is the entropy of mixing of the alloy, calculated from the formula

$$S_{mix} = R(N_1 \cdot \ln N_1 + N_2 \cdot \ln N_2)$$

where R is the gas constant and N_1 and N_2 are the atom fractions of the elements in the binary alloy.

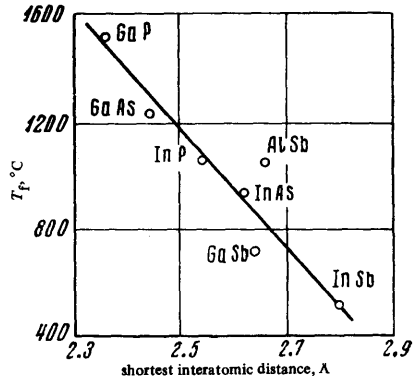

Figure 7. Melting point of some III–V compounds as a function of the shortest A^{III}–B^{V} distance in the crystal lattice [49].

Table 2. Experimental and calculated heats of fusion (kcal mole^{-1}) of some III–V compounds.

*Calculated.

The same workers [51] have shown that the approximate calculation of ΔS_f by formula (3) is justified if the behaviour of the compound semiconductor at the melting point is of the semiconductor–metal type (III–V compounds, germanium, silicon, etc.). If, on the other hand, the behaviour is of the semiconductor–semiconductor type (tellurides, selenides, etc.), the term for the entropy of mixing should be omitted in formula (3). Conversely, a good agreement between the experimentally determined value of ΔS_f for a compound semiconductor and the value given by formula (3) is a convincing argument for assigning the compound to the semiconductor–metal melting type (in which a completely disordered solution is formed in the liquid state, with considerable weakening of the chemical bond). An experimental value much lower than the value given by formula (3) indicates melting of the semiconductor–semiconductor type.

It was pointed out above, in the discussion of the phase diagrams of A^{III}–B^{V} systems, that the interaction between the constituent elements of the compound depends on the atomic weight of the elements. III–V compounds and Group IV elemental semiconductors are isoelectronic analogues: they belong to the same crystal-chemical group of diamond-like semiconductors and they have similar bond types and energy spectra. Hence, many thermochemical constants of the III–V compounds can be evaluated by summing the constants for the elemental semiconductors whose atomic weights add up approximately to the molecular weight of the compound semiconductor.

Table 3. Molecular weights of III–V compounds and corresponding sums of the atomic weights of elemental Group IV semiconductors.

III–V compounds		Elemental semiconductors	
Formula	Molecular weight	Elements	Sum of atomic weights
BN	24.8	2C	24.0
AlN	40.98	C+Si	40.1
GaN	83.72	C+Ge	84.6
InN	128.76	C+α-Sn	130.7
BP	41 82	Si+C	40.1
AlP	57.98	2Si	56.18
GaP	100.7	Si+Ge	100.7
InP	145.7	2Ge	145.2
BAs	85.3	Ge+C	84.6
AlAs	101.9	Ge+Si	100.7
GaAs	144.6	2Ge	145.2
InAs	189.7	Ge+α-Sn	191.3
BSb	132.6	α-Sn+C	130.7
AlSb	148.7	α-Sn+Si	146.8
GaSb	191.4	α-Sn+Ge	191.3
InSb	236.4	2α—Sn	237.4

The molecular weights of the III–V compound semiconductors and the sums of the atomic weights of their corresponding elemental semiconductors from Group IV of the Periodic Table are listed in Table 3.

Table 4. Experimental and calculated entropies of melting (cal mole^{-1} deg^{-1}) of III–V compounds.

A^{III}	B^{V} P	Ref.	As	Ref.	Sb	Ref.

*Calculated by adding the entropies of melting of the elemental semiconductors.
**Calculated by the method of Melekh and Semenkovich [51].

Table 4 gives the experimental and the calculated entropies of melting of the III–V compound semiconductors. The calculated values were obtained either by adding the entropies of melting of the appropriate elemental semiconductors or by means of Eqn. (3). [51]

IV. STANDARD ENTROPY

Very few data on the entropy and other thermochemical constants of III–V compounds have been published, and most of the published values are computed.

Table 5. Absolute standard entropies of Group III and V elements of the Periodic Table (cal mole^{-1} deg^{-1}), after Kubaschewski and Evans [36].

Element	S^0_{298}	Element	S^0_{298}
$B_{(sol)}$	1.07	$As_{(sol)}$	8.40
$Al_{(sol)}$	6.77	$Sb_{(sol)}$	10.50
$Ga_{(sol)}$	9.80	$C_{(sol)}$	1.36
$In_{(sol)}$	13.98	$Si_{(sol)}$	4.53
$N_{2(g)}$	22.80	$Ge_{(sol)}$	7.43
$P_{(sol)}$	10.60	α-$S_{(sol)}$	10.46

The method of calculating standard entropies for III–V compounds is described by Kubaschewski and Evans [36], who deal particularly with AlN, AlSb, and GaN. Their calculation is based on experimental data on equilibrium constants and on heats of formation, and also on the standard entropies of the component elements (Table 5).

Table 6. Shortest distances (Å) between atoms in III–V compound semiconductor lattices of the sphalerite type [18].

A^{III}	B^V			
	N	P	As	Sb
B	1.58	1.97	2.06	—
Al	—	2.36	2.43	2.64
Ga	—	2.36	2.44	2.66
In	—	2.54	2.62	2.80

They use the equations

$$\Delta G^0_{298} = -298\,R\ln K_p \qquad (4)$$

$$\Delta S^0_{298} = {}^1/_{298}(\Delta H^0_{298} - \Delta G^0_{298}) \qquad (5)$$

$$S^0_{298} = \Delta S^0_{298}(A^{III}B^V) + S^0_{298}(A^{III}) + S^0_{298}(B^V), \qquad (6)$$

where ΔG°_{298} is the free energy of formation of the compound, ΔH°_{298} is the enthalpy of formation of the compound, ΔS°_{298} is the entropy of formation, and S°_{298}, $S^\circ_{298}(A^{III})$, $S^\circ_{298}(B^V)$ are the standard entropies of the compound and of the constituent elements. R is the gas constant and K_p is the equilibrium constant of the formation reaction at pressure p.

The standard absolute entropies of III–V compounds can be calculated also from X-ray diffraction data. Renner [40] evaluated the entropies of inorganic compounds by means of the formula [57]

$$S^0_{298} = 1.5\,R\ln A + R\ln V - 1.5\,R\ln T_f + 12.5 \qquad (7)$$

where S°_{298} is the mean atomic entropy (cal mole^{-1} deg^{-1}), A is the mean atomic weight of the compound, T_f is the melting point of the compound (deg K), V is the mean atomic volume, which can be equated to a^3 (where a is the lattice constant, see Table 7). In the case of III–V compounds, Renner [40] subtracts a correction of 5 cal mole^{-1} deg^{-1} from the value given by Eqn. (7).

Table 7. Lattice constants (Å) of III–V compounds crystallising in the sphalerite structure.

A^{III}	B^V							
	N	Ref.	P	Ref.	As	Ref.	Sb	Ref.
B	3.615	35	4.537	59	4.777	60	—	
Al	—		5.451		5.620		6.095	
Ga	—		5.450	60	5.653	61	6.140	62
In	—		5.869		6.058	61	6.479	

The lattice constants of III–V compound semiconductors which crystallise in the sphalerite structure can be calculated [58] by multiplying the shortest interatomic distance (Table 6) by the conversion factor [18] 2.31. The values obtained in this way (no literature reference) are compared in Table 7 with the experimentally determined lattice constants of the III–V compounds.

Table 8. Standard absolute entropies of III–V compounds (cal mole^{-1} deg^{-1}).

Compound	Experimental value	Ref.	Calc. by adding the entropies of the elemental semiconductors*		Calc. from Eqn.(7), with negative correction of 5 cal mole^{-1} deg^{-1}**	
			Value	Discrepancy from experiment	Value	Discrepancy from experiment

*Calculated from data of Tables 3 and 5.
**Calculated from data of Table 7.
The melting points assumed in the calculations are: GaP, 1795; InP, 1330; GaAs, 1510; InAs, 1216; AlSb, 1343; GaSb, 976; InSb, 798°K.

We have calculated the standard absolute entropies of III–V compounds by adding the standard absolute entropies of the appropriate Group IV semiconductors, and we have obtained satisfactory agreement with experimental data. As Table 8 shows, the agreement is better than can be achieved using Eqn. (7).

V. SPECIFIC HEAT

Experimental measurements of specific heat are available only for a few III–V compounds. Thus, Kochetkova and Rezukhina [67] obtained the specific heat of GaSb between 20 and 700° by calorimetric measurements.

Table 9. Specific heat equations of III–V compounds (cal mole^{-1} deg^{-1}) calculated from data obtained from Eqns. (8)–(10).

A^{III}	B^{V}			
	N	P	As	Sb
Al	—	—	$9.004+3\cdot10^{-3}T$	$10.310+4\cdot10^{-3}T$
Ga	$8.122+3\cdot10^{-3}T$	$10.180+2.47\cdot10^{-3}T$*	$10.028+3\cdot10^{-3}T$	$10.668+4\cdot10^{-3}T$
In	$9.863+3\cdot10^{-3}T$	$10.180+4\cdot10^{-3}T$	$10.530+4\cdot10^{-3}T$	$11.804+2\cdot10^{-3}T$

*A correction [73] has been applied to the equation previously accepted [42,47].

Nachtrieb and Clement [68], using a similar method, obtained the following values for the mean specific heat of InSb: 0.052, 0.056, 0.062, 0.062 cal g^{-1} deg^{-1} (or 12.3, 13.2, 14.7, 14.7 cal mole^{-1} deg^{-1}) for the temperature intervals 20–90, 90–170, 170–350, and 350–500° respectively. The low-temperature specific heats of GaP and InP have been measured [66] between 40 and 300°K. Piesbergen [69] determined the temperature dependence of the specific heat of a number of III–V compound semiconductors from data on their Debye characteristic temperature. High-temperature thermodynamic quantities are difficult to calculate, because of the lack of adequate specific heat data. Hence, approximate methods of computation of the specific heat of III–V compounds are very valuable.

Table 10. Specific heat equations for Group IV semiconductors [74].

Element	Specific heat equation	Temp. range, °K
α-Sn	$5.05+4.80\cdot10^{-3}T$	273—504
C	$2.162+3.059\cdot10^{-3}T-1.303\cdot10^{5}\cdot T^{-2}$	273—1313
Si	$5.74+0.617\cdot10^{-3}T-1.01\cdot10^{5}T^{-2}$	273—1174
Ge	$5.94+0.90\cdot10^{-3}T-0.59\cdot10^{5}\cdot T^{-2}$	273—713

Attempts to apply the additivity rule to the temperature dependence of the specific heats of the constituent elements have not been successful, because the specific heat equations for the relatively low-melting components [36,57] are not valid at the higher temperatures of interest for high-melting compounds.

If the melting point is known, an equation for the temperature dependence of the specific heat can be obtained by Kelly's method [70], which assumes a linear variation of specific heat between room temperature and the temperature of the first phase transition. In addition, the following assumptions are made:

1. The molecular specific heat of the compound at room temperature is additive in terms of the atomic specific heats, as required by the rule of Dulong and Petit, and equals 12.6 cal mole^{-1} deg^{-1}. [71]

2. The specific heat of the compound at its melting point is 14.5 cal mole^{-1} deg^{-1}, by analogy with the atomic specific heat of many inorganic compounds at their melting point [36].

Table 12. Comparison of experimental and calculated standard specific heats of III–V compound semiconductors (cal mole^{-1} deg^{-1}).

The precision of Kelly's specific heat equation can be improved by using Landiya's equation

$$C_p=(C_{v,at}+\alpha_{at}T^{3/2})\cdot n, \tag{8}$$

to calculate the specific heat C_p of the compound at constant pressure, where n is the number of atoms in one molecule of the compound, $C_{v,at}$ is the atomic specific heat at constant volume, α_{at} is the atomic thermal expansion coefficient. The quantities $C_{v,at}$ and α_{at} can be calculated by the equations

$$C_{v,at.}=6.6-\frac{a}{b+k(T-b)} \tag{9}$$

and

$$\alpha_{at.}=\frac{1.24}{T_f}(C_{v,at}^{298})^2\cdot10^{-3}, \tag{10}$$

where T_f is the melting point of the compound and $C_{v,at}^{298}$ is the atomic specific heat at constant volume, obtained

Table 11. Specific heat equations for III–V compound semiconductors, obtained by adding the specific heat equations of the elemental Group IV semiconductors.

A^{III}	B^{V}			
	N	P	As	Sb

Al	$7.902+3.676\cdot10^{-3}T-2.313\cdot10^{5}T^{-2}$	$11.480+1.234\cdot10^{-3}T-2.020\cdot10^{5}T^{-2}$	$11.680+1.520\cdot10^{-3}T-1.60\cdot10^{5}T^{-2}$	$10.790+5.417\cdot10^{-3}T-1.010\cdot10^{5}T^{-2}$
Ga	$8.102+3.959\cdot10^{-3}T-1.893\cdot10^{5}T^{-2}$	$11.680+1.52\cdot10^{-3}T-1.60\cdot10^{5}T^{-2}$	$11.880+1.80\cdot10^{-3}T-1.18\cdot10^{5}T^{-2}$	$10.990+5.70\cdot10^{-3}T-0.590\cdot10^{5}T^{-2}$
In	$7.212+7.859\cdot10^{-3}T-1.303\cdot10^{5}T^{-2}$	$9.24+4.54\cdot10^{-3}T$	$10.990+5.70\cdot10^{-3}T-0.59\cdot10^{5}T^{-2}$	$10.10+9.60\cdot10^{-3}T$

from Eqn. (9) by putting $T = 298°K$. The coefficients a, b, and k in Eqn. (9) take the following values for a compound which dissociates with evolution of a volatile component:

$$a = \frac{4400}{S^0_{298}};\quad b = 298;\quad k = \frac{(2200 - 149 \cdot S^0_{298})}{(5070 - 149 \cdot S^0_{298})}$$

The specific heat values calculated for 298°K and T_f are then used to obtain a linear equation for the temperature dependence of the specific heat, valid between 298°K and T_f. The results are summarised in Table 9.

If the thermodynamic data needed to obtain a specific heat equation for III–V compounds as a function of temperature by the above method are not available, the equation can be produced by summing the specific heat equations for the corresponding elemental semiconductors (see Table 3).

The specific heat equations for the elemental semiconductors of Group IV are listed in Table 10: the specific heat equations for III–V compounds deduced from those data are given in Table 11.

As Table 12 shows, the specific heats of III–V compounds calculated by Landiya's method agree satisfactorily with experimental values. Results fully adequate for approximate calculations are obtained also by adding the specific heat equations of the appropriate elemental semiconductors of Group IV (see Table 12).

VI. ENTHALPY AND FREE ENERGY OF FORMATION AND HEAT OF ATOMISATION OF $A^{III}B^{V}$ COMPOUNDS

The enthalpy of formation of a compound is one of its most important parameters, and is related to many of its physicochemical characteristics. Very few experimental determinations of the enthalpy of III–V compounds have been reported, particularly for compounds which tend to dissociate.

The enthalpy of formation of InSb has been determined fairly accurately by tin calorimetry [27,76], by direct fusion [77], by the e.m.f. method, and by fusion in a bomb calorimeter [81,82]. The enthalpy of GaSb has been measured calorimetrically [27] and by the e.m.f. method [80,83].

The enthalpy of dissociating compounds is difficult to measure experimentally. For InAs the problem has been solved using colorimetric [27,80] and mass-spectrometric [84,85] techniques. Values of the enthalpy of formation of GaAs have been obtained from mass-spectrometric experiments [86], from thermochemical studies of transport reactions involving the compound [87], and by the e.m.f. method [80].

The enthalpy of formation of InP has been obtained from the temperature dependence of the dissociation pressure [88,89], mass-spectrometrically [86], and also by fusion [82] and combustion in a bomb calorimeter [90]. The enthalpy of formation of GaP was first determined [91] from the temperature dependence of the dissociation pressure of the compound. Johnston [92] obtained a different value under similar conditions. Data from combustion experiments in a bomb calorimeter have been reported [90]. More recent work on the enthalpy of formation of GaP has relied on the e.m.f. method [93,94] and on calorimetric measurements [95]. The enthalpy of formation of BP has been measured calorimetrically by the reaction between the compound and gaseous F_2 to give BF_3. [96]

Renner [40] computed the enthalpies of formation of III–V compounds from reactions of the type

$$A^{III}_{(liq)} + \frac{1}{n} B^{V}_{n(g)} \rightleftarrows A^{III}B^{V}_{(g)}$$

using published values of the latent heat of fusion, enthalpy of dissociation, and specific heat of the elements [36,57].

The free energies of formation ΔG°_{298} of the compounds can be calculated from their enthalpies ΔH°_{298} and entropies ΔS°_{298} of formation:

$$\Delta G^\circ_{298} = \Delta H^\circ_{298} - T\Delta S^\circ_{298} \text{ kcal mole}^{-1} \qquad (11)$$

Table 13. Enthalpies of formation of III–V compounds, kcal mole^{-1}.

*Calculated from the reaction between BP and F_2.

For a III–V compound whose vapour phase consists almost exclusively of the component B^V, the free energy ΔG°_T at a given temperature can be calculated from the experimentally observed dissociation pressure at the room temperature:

$$\Delta G^\circ_T = -\frac{RT}{x} \ln p_{B_xV} \qquad (12)$$

where p_{B_xV} is the dissociation pressure of the compound at temperature T.

Table 13 lists the enthalpies of formation of III–V compounds, measured experimentally or calculated by Eqns. (11) and (12).

The heat of atomisation is an important parameter which reflects the strength of the chemical bond in a semiconducting compound and therefore shows good correlation with its electrical and thermochemical properties [109,110].

Table 14. Heat of atomisation (kcal mole^{-1}) of A^{III} and B^V elements and of Group IV semiconductors.

Moser and Pearson [110] have considered three idealised bond formation schemes in III–V compounds. The atoms of elements in the IIIB subgroup have three electrons with an s^2p^1 configuration in their outer unfilled shell. The atoms of elements in the VB subgroup have five electrons with the s^2p^3 configuration. When a covalent bond is formed, the Group V atom gives up one electron to the Group III atom, producing a V^+ and a III^- ion with four valence electrons each. The electrons take up the sp^3 configuration, forming tetrahedral bonds of the diamond type. However, the atoms also experience an electrostatic attraction. In the case of a neutral (atomic) bond [111], all the atoms retain their valence electrons, and the charge on all the atoms is the same. In the case of an ionic bond, three electrons are transferred from the A^{III} to the B^V atom, and III^{3+} and V^{3-} ions with filled spherical shells are formed.

Folberth [25] has shown that the bond in III–V compounds is covalent, with a significant proportion of ionic character. Because of the additional effect of the ionic contribution to the bond, III–V compounds have a higher bond strength than the Group IV elements [10].

Various empirical and theoretical methods of evaluating the degree of ionicity and the effective charges are discussed in review articles by Madelung [113], Hilsum and Rose-Innes [18], and also in papers by Suchet [114] and Syrkin and coworkers [115]. Sirota and coworkers [116–118] have derived the effective charges and the ionic contributions to the bond energies for aluminium, gallium, and indium phosphides, arsenides, and antimonides from electron density maps.

The heat of atomisation $\Delta H^\circ_{at}{}^{AB}$ is the sum of the enthalpy of formation of the compound from its atoms ($\Delta H^\circ_{298}{}^{AB}$) and of the heats of transformation of the components to the gaseous state ($\Delta H^\circ_g{}^{,A}$ and $\Delta H^\circ_g{}^{,B}$):

$$\Delta H^{\circ,AB}_{at.} = \Delta H^{\circ,AB}_{298} + \Delta H^{\circ,A}_{g} + \Delta H^{\circ,B}_{g} \quad . \qquad (13)$$

Since the heat of atomisation is known experimentally to be an insensitive function of temperature [109] and does not need to be reduced to a standard state, it can be evaluated by the additive method used above to calculate various thermochemical constants (latent heat of fusion, entropy, and specific heat): in this case, from a summation of ΔH°_{at} values for the elemental semiconductors. The data required for the calculation are given in Table 14.

Table 15. Heat of atomisation (kcal mole^{-1}) of III–V compounds.

Compound	Experimental		Obtained by adding ΔH°_{at} values for elemental semiconductors		Difference, %
	$-\Delta H^\circ_{298}$; AB	$-\Delta H^\circ_{at}$; AB	Sum of ΔH°_{at} for C, Si, Ge, and α-Sn	$-\Delta H^\circ_{at}$; AB

AlP	—	—	2 Si	178.0	—
GaP	24.4[94]	165.6	Si + Ge	167.4	+1.1
InP	22.3[107]	155.7	2 Ge	156.8	+0.7
BAs	—	—	Ge + C	216.4	—
AlAs	—	—	Ge + Si	167.4	—
GaAs	17.7[107]	152.7	2 Ge	156.8	+2.6
InAs	14.8[97]	151.0	Ge + α-Sn	148.4	−1.7
BSb	—	—	α-Sn + C	208.0	—
AlSb	—	—	α-Sn + Si	159.4	—
GaSb	9.9[97]	137.9	α-Sn + Ge	148.0	+7.5
InSb	8.2[79]	128.4	2 α-Sn	140.0	+9.0

Experimental and calculated values of the heat of atomisation of III–V compound semiconductors are compared in Table 15. It is evident from this Table that the difference between the experimental values and those calculated additively does not exceed 11%, with a mean deviation of 5.3%. This degree of accuracy is fully adequate for many approximate calculations.

VII. VAPOUR PRESSURE

Reliable data on the vapour pressure of the volatile components over III–V compounds tending to dissociate are essential to the design of rational methods of synthesis and crystal growth for these compounds. The measurement of vapour pressure in these systems has some unusual features.

Phase equilibria in two-component systems are more complex than the corresponding equilibria in one-component systems: hence, it becomes more difficult to measure the saturated vapour pressure p and also to estimate the reliability of the results. For a solid or a liquid sample in equilibrium with the vapour of the volatile component the number of degrees of freedom given by Gibbs' phase rule is two, i.e. $p = f(T, x)$. For solids this conclusion applies at temperatures below the solidus line, for liquids above the liquidus line of the phase diagram. As a special case, the sample can have the stoichiometric composition, and in this case the system is monovariant, i.e. $p = f(T)$.

If a solid sample is heated above the solidus line, or a liquid sample is cooled below the liquidus line, a third phase appears. In a system of this type, for which a detailed analysis was given by Vigdorovich and Nashel'skii [122], the number of degrees of freedom is one, i.e. $p = f(T)$ at $x = \text{const}$ or $p = f(x)$ at $T = \text{const}$. In the special case of a stoichiometric solid and a stoichiometric liquid an additional constraint is present and the system becomes invariant, and a unique vapour pressure of the volatile component can be measured at the melting point.

The gas-phase composition varies from point to point if the temperature of the sample is not uniform, since molecular dissociation processes (under the influence of temperature) and atomic association processes (under the influence of pressure) take place in the gas phase in opposite directions [88]. Hence, calculations by the Mendeleev–Clapeyron equation are difficult to apply, since they involve the molecular weight of the vapour phase. Furthermore, the measurement of vapour pressure for compound semiconductors which undergo dissociation presents a number of experimental difficulties, including the need to work at high temperatures and pressures and the aggressive nature of the vapours and the melts towards most commonly used container materials. Nashel'skii [123] has reviewed experimental methods of measuring the vapour pressure of dissociating semiconductor compounds, including III–V compounds.

If the experimental difficulties prove insurmountable, the vapour pressure of III–V compound semiconductors can be estimated from thermochemical data by means of Eqn. (12), Many workers have carried out calculations of this type [40,42,49,73]. The temperature dependence of the vapour pressure of the volatile component is usually reported in the form of plots of $\lg p_{B_x^V}$ against $1/T$ (Fig. 8), or in the form of an equation of the type

$$\lg p_{B_x^V} = -\frac{A}{T} + B \quad . \qquad (14)$$

Values of the A and B coefficients of Eqn. (14) for arsenides and phosphides are given in Table 16.

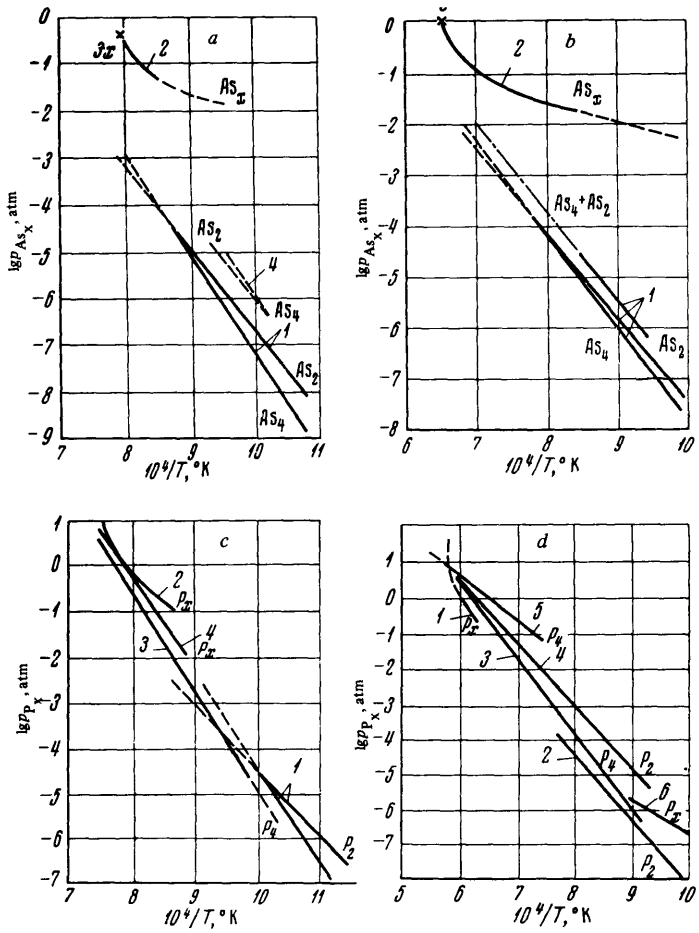

Figure 8. Dissociation pressure of some III–V compounds: (*a*) indium arsenide and (*b*) gallium arsenide [*1*) Ref. 84, 86; *2*) Ref. 44; *3*) equilibrium vapour pressure of arsenic at the melting point of the compound; *4*) Ref. 40]; (*c*) indium phosphide [*1*) Ref. 84, 86; *2*) Ref. 92; *3*) Ref. 44; *4*) Ref. 88, 89]; (*d*) gallium phosphide [*1*) Ref. 44; *2*) Ref. 92; *3*) and *4*) Ref. 73; *5*) Ref. 91; *6*) Ref. 127].

The dissociation pressure of InSb and GaSb is very low [84,86]. The vapour pressure of Sb and InSb over InSb has been measured [125] by an effusion method, with radioactive isotopes. The vapour pressure of Sb over GaSb samples of different composition has been measured [126] by the "dew-point" method.

Table 16. Experimental values of the temperature dependence of the dissociation pressure of III–V arsenides and phosphides (atm).

Compound	Molecular composition of vapour	Numerical values of constants in Eqn.(14)		Temp. range, °K		Equilibrium pressure of the B^V component at the melting point of the compound	
		A	B				
InAs	As_2	18.840	24.00	911—1195	109	0.33	11
	As_4	22.725	27.25				
GaAs	As_2	17.340	9.86	950—1200	109	0.9	11
	As_4	19.320	24.66			~1.0	44
InP	P_2	14.850	10.32	775—900	109	~21	44
		21.300	16.84				
	P_4	23.000	21.00	973—1318	89	~40	88
		19.200	13.80	1123—1243	88		
GaP	P_2	13.650	6.90	973—1073	127	~20	12
		18.870	13.60	1054—1278	92	~35	44
	P_4	12.510	8.167	1350—1678	91		

All the thermochemical data relating to III–V compound semiconductors indicate a gradual variation with the molecular weight of the compound. The lattice parameter, specific heat, and standard entropy increase with molecular weight in an isoelectronic series. Conversely, the melting point, heat of fusion, entropy of fusion, enthalpy of formation, and heat of atomisation decrease with increase of molecular weight in an isoelectronic series.

These changes are consistent with the changes in the nature and strength of the chemical bond [124,128] in III–V compounds expected from the position of their constituent elements in the Periodic Table.

Liquid Lasers Based on Lanthanide Complexes

I.M.Batyaev

The review deals with the chemical problems concerning the use of neodymium, europium, gadolinium, and terbium complexes in liquid lasers. The equilibria arising in solutions are briefly examined. The principal liquid laser systems have been analysed. The systems can be divided into two types: chelate systems with transfer of absorbed energy from the ligand molecule to the lanthanide ion (these include europium, gadolinium, and terbium complexes) and systems based on neodymium complexes in inorganic solvents. The latter are distinguished by enhanced stability to the action of light and are at present the most promising for the preparation of liquid lasers.
The effect of solvents and structure of the complexes on the laser properties of the systems is also discussed. The bibliography includes 109 references.

VII.	The structure of the complexes and its relation to luminescence	627

I. INTRODUCTION

The lanthanide elements have been used successfully to make lasers comparatively long ago. So far the laser effect produced by crystals and glasses has been obtained for the following lanthanides: praseodymium, neodymium, samarium, europium, gadolinium, terbium, dysprosium, holmium, erbium, thulium, and ytterbium[1-5]. During the last ten years, several multicomponent liquid systems with laser properties were obtained on the basis of lanthanide complexes.

The formation of lasers based on liquid systems constitutes a major and complicated problem in the development of which the work of both physicists and chemists is combined. Advances in studies in this field depend entirely on their joint efforts. Some of the problems can be solved by physicists and others by chemists.

The first class of problems, which are in principle solved by physicists and therefore may be arbitrarily called "physical", may be said to include problems such as the methods for the design of lasers under different operating conditions, a number of experimental and theoretical problems concerning the development and formation of active media based on organic and inorganic materials, and the choice of resonators, optical pumping systems, and optical shutters.

Usually physicists investigate the fundamental characteristics of lasers: the pumping rate, emission intensity, efficiency, and also the spectroscopic and time characteristics of laser emission. The study of the angular divergence of the emission plays a significant role. Some of these problems have been formulated and examined by a number of workers[6-17]. Certain other information concerning technical applications of solid lasers may be found in the monograph of Mikaelyan et al[18].

All the physicochemical processes associated with the study of the structure of complex multicomponent systems employed as liquid lasers may be included in the second class of problems which we have arbitrarily called "chemical". These are problems solved by methods of classical physical chemistry: the thermodynamics of the formation of the complexes and also the study of the rates of chemical reactions.

The range of problems associated with the study of the structures of the complexes formed and their spectroscopic properties over a wide range of the electromagnetic vibration spectrum is no less important. Finally, it is also possible to formulate a further series of problems connected with the investigation of the interaction between radiation and matter.

In view of the large number of problems which must be solved in the making of liquid lasers, we shall consider only some of them. For example, the choice of solvents and their chemical purification, the choice of complex-forming ligands and aprotic acids which improve the properties of the laser systems, and the preparation and selection of compounds in the form of which lanthanides may be introduced into the solvent can be classified as chemical problems.

The requirements which must be met by complex liquid laser systems are dictated by their own properties, i.e. a sufficiently high concentration of active molecules, optical homogeneity of the system, and its stability with respect to light are required. These "physical" requirements themselves have a profound physicochemical basis and need the most far reaching and thorough physicochemical study.

For example, the problem of solubility is one of the most complex. The point is that in multicomponent systems in which the number of components is greater than 4-5 the introduction of each new component improving the optical properties of the system is extremely difficult. This applies in particular to inorganic systems which at this stage appear to be more promising for the formation of liquid lasers.

For example, the inorganic systems include those containing various oxide halides and a wide variety of aprotic acids. The absence of a single quantitative theory of solubility precludes a reliable theoretical prediction of the solubilities of specific lanthanide compounds in various solvents. In the preparation of liquid lasers with fairly high lanthanide concentrations, experimental

data must be employed in each individual case. Very rigorous requirements must be met by the optical homogeneity and transparency of the laser systems, particularly at the emission wavelength, which in turn entails a need for very careful purification of the components.

However, even the most thorough initial purification of the compounds used to prepare the laser liquids does not always yield satisfactory results, since the occurrence of reactions and the formation of side products are possible in the course of the preparation. The side products greatly influence the optical properties of the laser liquid prepared. Therefore the multicomponent liquid systems obtained must be often additionally purified without impairing the laser properties of the system.

The stability of lasers to the action of light also constitutes a very important problem, which concerns the interaction between radiation and matter, involving the stability of solvates and complex species.

The principal components of liquid laser systems are lanthanides, complex-forming ligands, and solvents. We shall attempt to estimate the effect of the system components on the properties of liquid lasers.

II. PRINCIPAL LANTHANIDE ELEMENTS ON WHICH LIQUID LASERS ARE BASED

So far a laser effect in solutions has been obtained for four lanthanides: europium, neodymium, terbium, and gadolinium. The laser systems based on these lanthanides must be immediately subdivided according to the type of "operation" of the lasers. Whereas the systems based on europium, gadolinium, and terbium operate according to the so called "six level" mechanism with transfer of absorbed pumping energy from the ligand to the lanthanide ion, the system based on neodymium gives rise to a laser effect based on a four-level mechanism. In this connection the role played by each component of the laser system as well as the requirements which must be met by the system components will be different.

III. THE NATURE OF THE EQUILIBRIA IN LASER SYSTEMS

In order to prepare new liquid laser systems, detailed studies of their thermodynamic properties are required—these include the types of equilibria occurring in the solutions and the changes in the equilibria when the temperature is altered during the pumping process. The temperature range can be varied within wide limits. We may note that the equilibria arising in such systems can be divided into three types:

1. Solvation equilibria which characterise the interaction of neodymium, europium, gadolinium, and terbium with solvent molecules.
2. Equilibria involved in the formation of complexes by lanthanide ions with various organic and inorganic ligands present in the laser systems.
3. Processes where both types of equilibria can be involved in complex formation.

Lanthanide ions interact in solution with both solvent molecules and with the ligands. In these processes, involving competition between solvation and complex formation, the chemical processes can follow largely one of three pathways, depending on the stability of the complexes formed.

In the formation of a laser system an attempt should be made to ensure that the solvent molecules are displaced from the inner sphere of the complex, since the solvent molecules usually include CH_2 and OH groups, which have a high vibration frequency promoting the leakage of energy in radiationless transitions. A complex of this kind should have a stable inner sphere and the solvent molecules should be in the outer sphere.

The distribution of ligands in the inner sphere obeys the coordination laws but the distribution of molecules in the outer sphere may not in fact be subject to these laws and may be determined statistically. The most complete information about the stability of the solvate complexes of lanthanides formed in different solvents may be provided by the thermodynamic functions for the solvation processes, but few data are available for such functions in non-aqueous solvents[19,20].

Another no less important aspect of the study of laser effects is the coordination number of the lanthanides and the structure and symmetry type of the complexes formed. At the present time much attention is being devoted to them[21].

IV. THE COORDINATION NUMBER OF LANTHANIDES AND THE SYMMETRY TYPE OF SOME OF THEIR COMPLEXES

In the study of the competitive complex formation account must be taken of the variable coordination numbers of lanthanides. In certain early investigations, a coordination number of six was attributed to lanthanides[22-24]. Later studies showed that the coordination number of lanthanides is variable. At the beginning of the lanthanide series the coordination number is 9, but, starting with erbium, it decreases to six[26,27]. Table 1 gives a compilation of studies in which various investigators demonstrated particular coordination numbers of lanthanides using different methods. It is noteworthy that the coordination numbers attributed to a particular lanthanide in solutions should strictly speaking be determined in these solutions. However, many investigators refer to the coordination number determined by the X-ray diffraction analysis of solid lanthanide[26,27]. Such assignment of the lanthanide coordination number to solutions is risky and invalid although in some cases the method is justified.

The coordination number, symmetry, and point group determined by X-ray structure analysis of the crystals sometimes help in the elucidation of the structure of the solvate–ligand complexes formed in the solutions. Table 1 therefore includes, together with the coordination numbers of lanthanides obtained in solutions, certain incomplete data concerning the determination of the coordination numbers in solid salts. Probably solutions with a high salt concentration, close to saturation, bear a marked analogy to the structure of the crystalline compounds. In dilute strong electrolyte solutions, the coordination number and symmetry type of the solvate complex depends mainly on the structure of the solvent surrounding the metal ion. The ligands in the outer coordination sphere have a weaker effect on the solvate complex. A change of solvent leads to a change in the coordination number and the symmetry of the solvate complex[31,33,38]. With increase of ligand concentration and its incorporation into the inner sphere of the lanthanide ion, the coordination number and the symmetry of the solvate structure also change.

In this respect the work of Lugina and Davidenko[34,35] is most instructive and correct. They compared the absorption spectra of the aqueous solutions and the solid hydrates of lanthanide chlorides, bromides, perchlorates, and bromates in order to obtain data on the structure of the lanthanides (neodymium, erbium, and europium) aquo-ions. In particular, it was shown that, together with the dominant form of the $Nd(H_2O)_9^{3+}$ aquo-ion with D_{3h} symmetry, aquo-ions having different structures are also present in the solution.

It has been shown[35] that at higher KSCN and LiCl concentrations, reaching respectively 10 and 14 M, structures with a coordination number of 9 and D_{3h} symmetry, structures with a coordination number of 8, and several structures with equivalent and non-equivalent positions of the ligands coexist.

The spectroscopic method proved extremely fruitful for the comparison of the structures of neodymium complexes with β-diketones in crystals and solutions[36].

Table 1. Coordination numbers of lanthanides determined in various systems.

* Note: A = acetylacetone residue; B = benzoylacetone residue; TTA = thenoyltrifluoroacetone residue; TBP = tri-s-butyl phosphate.

Comparison of the reflection spectra of crystalline neodymium acetylacetonates and benzoylacetonates and the absorption spectra of methanol and aqueous methanol solutions of neodymium complexes with acetylacetone and benzoylacetone with different stoichiometric compositions showed that the $Nd(AA)_3$ and $Nd(BA)_3$ complexes exist in solution with two solvent molecules in the inner coordination sphere.

As data accumulate on the crystal structures of the lanthanide complexes with various organic ligands, they may be employed to investigate the structures of the solutions by spectroscopic methods[44-47].

NMR and X-ray diffraction structure analyses of the solutions are also used to establish the structures of the solvate-ligand complexes[37,41-43]. Nowadays X-ray diffraction structure analysis of liquids is being employed with increasing success for the elucidation of the structural characteristics of the immediate environment of cations in aqueous solutions[48,49].

The data in Table 1 permit certain preliminary conclusions. The coordination number of lanthanum, cerium, praseodymium, neodymium, and gadolinium is 9 or 8, while coordination numbers of 8 and 7 are characteristic of europium. Starting with erbium, the coordination number of lanthanides decreases to 6.

The coordination numbers of lanthanides and the symmetry type of their solvate-ligand complexes are influenced primarily both by the structure of the solvent molecules and that of the ligand molecules coordinated in the inner sphere. In the determination of the composition of the inner-sphere lanthanide complexes, one should bear

in mind the variable coordination numbers listed in Table 1. We may note that a study has also been made where a lanthanide coordination number of six was demonstrated by a derivative plot method[29].

V. PRINCIPAL LIQUID LASER SYSTEMS

The principal data on liquid laser systems are compiled in Table 2. Their analysis permits the following conclusions. While the number of lanthanides used in the preparation of liquid lasers is comparatively small, the number of complex-forming ligands employed for this purpose is fairly large.

A considerable proportion of these ligands have similar properties owing to the mechanism of operation of the laser system. Two laser mechanisms may constitute a kind of barrier, which permits the classification and characterisation of the complexes formed in various solvents.

The majority of laser systems are based on complexes with various β-diketones. These systems involve a single common mechanism in which energy is absorbed by the organic components of the molecule with its subsequent transfer to europium or terbium.

The first eight complexes have approximately the same structure in which the central metal atom is surrounded by four ligands occupying eight coordination sites. Thus the inner sphere of such complexes is completely saturated and all the solvent molecules have been displaced to the outer sphere. According to their structure, these are the usual chelate compounds characteristic of β-diketones.

The study of the luminescence spectra of the octacoordinate europium chelates with the general formula $EuL_4.P$ (where P = piperidine and L is one of the following three β-diketones: benzoylacetone, dibenzoylmethane, or benzoyltrifluoroacetone) led to the conclusion that, among the europium chelates, only the octacoordinate chelates exhibit a laser effect[56]. The following mixtures were employed as solvents: (1) the standard alcoholic solvent (SAS)—a 3 : 1 ethanol–methanol mixture; (2) the dimethylformamide solvent—a 4 : 1 mixture of the standard alcoholic solvent and dimethylformamide (DMF); (3) the nitrile solvent—a 1 : 1 : 1 mixture of acetonitrile, propionitrile, and butyronitrile.

It has been established that chelates with D_4, C_4, and D_2 symmetries are the most effective for the preparation of lasers. The chelates investigated are quite stable with respect to high-intensity radiation pulses. Their chemical stability is determined by the ligand, the solvent, and the concentration of the solution. The chemical structure of the coordinated β-diketones also plays a considerable role.

It is extremely instructive that, out of nine halogeno-substituted derivatives of benzoyltrifluoroacetone (*ortho*-, *meta*-, and *para*-fluoro-, -chloro-, and -bromo-derivatives), only the *ortho*-substituted derivatives can give rise to laser effects in the form of the compounds EuL_4. .DMA. The *ortho*-chloro-compound has the lowest pumping threshold[58].

The ninth and tenth complex (Table 2) are distinguished by the fact that the metal atom in them is coordination-unsaturated. One or two free sites, available to the solvent (acetonitrile or dioxan) molecules, remain in the inner sphere. In the eleventh complex, that of neodymium with pentafluoropropionic acid and *o*-phenanthroline, the variable coordination number of neodymium (which is eight or nine) suggests that the solvent molecules (dimethyl sulphoxide) coordinated to the metal are present in the inner sphere.

The twelfth system, based on neodymium oxide dissolved in selenyl chloride with added aprotic acids, differs somewhat in its physicochemical properties from the systems enumerated above. It is one of the first systems consisting entirely of inorganic components and exhibiting enhanced light stability. Its laser properties are comparable to those of the best specimens of solid systems based on $Nd^{3+}:CaWO_4$ crystals and glasses[63,64].

Analysis of the luminescent properties of this system shows that its structure is closer to that of neodymium crystals in calcium tungstate than to the glasses.

We shall now attempt to describe the chemical reactions occurring when Nd_2O_3 and $NdCl_3$ are dissolved in the $SeOCl_2-SnCl_4$ solvent using the results of certain studies on this problem[65-68]. The reactions occurring in the solvent itself can be described by the following stepwise equilibria:

$$SnCl_4 + 2SeOCl_2 = SnCl_6^{2-} + 2SeOCl^+, \quad (1)$$

$$SbCl_5 + SeOCl_2 = SbCl_6^- + SeOCl^+, \quad (2)$$

$$Nd_2O_3 + 6SeOCl^+ = 2Nd^{3+}_{(solvate)} + 3SeOCl_2 + 3SeO_2. \quad (3)$$

The overall reaction involving the dissolution of neodymium oxide in the $SeOCl_2-SnCl_4$ binary solvent, quoted by Brecher and French[69], can be represented as follows:

$$Nd_2O_3 + 3SnCl_4 + 3SeOCl_2 = 2Nd^{3+}_{(solvate)} + 3SnCl_6^{2-} + 3SeO_2. \quad (4)$$

In these equations the $Nd^{3+}_{(solvate)}$ ion is equivalent to the solvated ion with several selenyl chloride molecules, which are coordinated in the inner sphere with formation of $Nd(SeOCl_2)_n^{3+}$; the $SnCl_6^{2-}$ anions or those of other aprotic acids are coordinated in the outer sphere. The independence of the electronic absorption spectra of neodymium in the visible region of the chemical structure of the aprotic acid may be regarded as indirect evidence that the aprotic acids are combined only in the outer sphere of the solvated neodymium ion. The most intense neodymium absorption bands at 0.53, 0.74, 0.80, and 0.86 nm, corresponding to the $^4G_{5/2}$, $^2G_{7/2}$, $^4S_{3/2}$, $^4F_{1/2}$, $^2H_{9/2}$, $^4F_{5/2}$, and $^4F_{3/2}$ transitions, remain unchanged. Consequently in solution the electrically neutral neodymium complex should have the structure $[Nd(SeOCl_2)n]_2(SnCl_6)_3$. A detailed elucidation of the complex formation processes and the structures of the compounds formed in solution requires further investigation.

Selenium dioxide formed on dissolution of neodymium oxide must be carefully filtered off, since its presence can constitute a serious obstacle to the occurrence of a laser effect[65].

It is noteworthy that, when neodymium chloride is dissolved, the solutions do not contain selenium dioxide particles. The solubility of $NdCl_3$ in pure selenium oxide chloride is limited, but in the $SeOCl_2-SnCl_4$ two-component solvent neodymium chloride dissolves fairly readily. In this case too the final compounds in the oxide chloride solution are probably the solvate–ligand neodymium complexes of the type $Nd(SeOCl_2)_x(SnCl_6)_y^{(3-2y)-}$.

Heller[68] employed lanthanide chlorides obtained by vacuum drying in hydrogen chloride vapour. These compounds usually contain 1–2.5% of water. Traces of water have a marked effect on the luminescence lifetime of the inorganic system, reducing it to 20–30 μs. It is impossible to achieve a laser effect in such systems[65]. Therefore, in order to obtain anhydrous lanthanide chlorides, it is necessary to employ more effective drying conditions[70] or an attempt must be made to separate water and hydrogen chloride vapours during the preparation of the laser system.

The principal equations of the preparative method for the making of laser solutions were described by Heller[67]. Usually the mixture obtained is coloured brown owing to the the presence of selenium monochloride (Se_2Cl_2):

$$2SeOCl_2 = SeO_2 + SeCl_4, \quad (5)$$

$$2SeCl_4 = Se_2Cl_2 + 3Cl_2, \quad (6)$$

$$Se_2Cl_2 = 2Se + Cl_2. \quad (7)$$

The presence of selenium monochloride may be avoided by oxidation with $KClO_3$.

The chlorine and chlorine dioxide vapours are removed by vacuum treatment. The role of $SbCl_5$ as an aprotic acid improving the solubility of neodymium oxide is analogous to that of $SnCl_4$.

Information about the laser effect of neodymium in a binary phosphorus oxide chloride–aprotic acid system was published almost simultaneously in several papers[72-80]. The principal data for these systems are presented in the Tables and are numbered 12–20. We may note that $BeCl_2$, $ZnBr_2$, $CdCl_2$, $HgCl_2$, BCl_3, BBr_3, $AlBr_3$, $AlCl_3$, $GaCl_3$, $GaBr_3$, $LnCl_3$, $SnBr_4$, $TiBr_4$, $ZrCl_4$, $ZrBr_4$, $AsCl_3$, $NbCl_5$, and $SbCl_5$ as well as the solvents $SOCl_2$ and CCl_4 have also been used in these systems.

Systematic studies by a group of investigators[80-83] suggest that liquid lasers based on phosphorus oxide chloride are more effective than systems based on selenium chloride. There exists also another view, namely that the systems are equivalent in their effectiveness[69].

The dissolution of neodymium oxides and chlorides in a phosphorus oxide chloride–aprotic acid binary solvent resembles in some of its features the dissolution in $SeOCl_2$. The chemical reaction between the binary solvent and neodymium oxide can be represented schematically as follows[69,84,85].

$$Nd_2O_3+3SnCl_4+6POCl_3 = 2Na^{3+}Nd^{3+}_{(solvate)}+3SnCl_6^{2-}+3P_2O_3Cl_4\,. \qquad (8)$$

Here $Nd_{(solvate)}$ is the solvated neodymium ion surrounded by several $POCl_3$ molecules. The study of the structure of this solvate complex and also of its thermodynamic equilibrium with the surrounding medium is of direct theoretical and practical interest for the improvement of the properties of liquid luminescent systems.

Various neodymium compounds have been employed[84,85] to prepare liquid luminescent systems. Most reproducible results were obtained for the $Nd_2O_3-SnCl_4-POCl_3$ system.

The absorption and luminescence spectra of neodymium led to the conclusion that the similarity of the spectra of solutions obtained under different conditions is due to the presence of the same type of immediate environment of the activator in the solution. In the neodymium solvate complex the first coordination sphere consists of $POCl_3$ molecules coordinated to neodymium via oxygen[86]. It is sufficiently stable to form identical luminescence centres in several versions of the solution which the present author investigated, this being reflected in a similarity of the spectra. The existence of a fairly stable solvate shell has been confirmed by Antipenko et al.[85], who showed the occurrence of energy transfer between lanthanide ions in the $POCl_3-SnCl_4$ system.

Different workers suggest a wide variety of metal halides as aprotic acids[63-83]. Aprotic acids play an important role in the enhancement of the effectiveness of luminescence [quantum yield of luminescence (Ed. of Translation)]. This does not involve merely an improvement of the solubility of neodymium salts; for example, when neodymium perchlorate was employed[75], the metal concentration in solution was fairly high, since the perchlorate is readily soluble in $POCl_3$, but the luminescence intensity of the $POCl_3-Nd(ClO_4)_3$ solution was low. The luminescence of the same solutions increases abruptly by a factor of five when small amounts of aprotic acids are added.

The present author explains the increase of the effectiveness of the luminescence by the association of chloride anions with the aprotic acid. The most effective aprotic acids are $SnCl_4$, $SbCl_5$, $TiCl_4$, $TaCl_5$, and $HfCl_4$. The behaviour of these compounds in $POCl_3$ has already been partially investigated; thus the following equilibrium (equilibrium constant K) has been suggested for the reaction of $SbCl_5$ and $POCl_3$:[87]

$$Cl_5SbOPCl_3 \rightleftharpoons SbCl_6^- + POCl_2^+\,, \qquad (9)$$

where $K = 4\times10^{-6}$. For the next reaction stage,

$$SbCl_6^- + POCl_3 \rightleftharpoons Cl_5SbOPCl_3 + Cl^-; \qquad (10)$$

K not exceeding 10^{-9}. The mobilities obtained from conductimetric data are more characteristic of non-solvated ions.

VI. SOLVENTS

The principal physicochemical information about the nature of the solvents is presented in Table 3. The number of solvents in which laser effects of lanthanide ions have been observed is small.

All the solvents can be arbitrarily divided into two groups. Proton-containing organic compounds may be included in the first group and aprotic solvents in the second. On introduction of binary solvents such as metal oxide halide–aprotic acid, the number of solvents which can be used to obtain laser systems will increase.

It is noteworthy that three-component solvents of the type $POCl_3-SOCl_2$–aprotic acid have already appeared[81]. The addition of $SOCl_2$, carbon tetrachloride, and certain other components tends to extend the region of the liquid state and to stabilise neodymium solutions while the luminescent and laser characteristics are retained[81].

Thus multicomponent liquid laser systems, the individual components of which will successfully supplement one another in creating the optimum operating characteristics of the system, will probably be employed in the future. The use of a number of components in the test system is reasonable, since none of the solvents usually has the entire set of the necessary properties. All this applies equally to proton-containing organic solvents and to aprotic solvents[89,90].

An attempt has been made[90] to assess the prospects for the application of various solvents in liquid laser systems. Hydrogen-bonded organic solvents have been mainly examined. Analysis of the physicochemical properties of solvents makes it possible to find ways for the selection of the most effective solvents in broad outline only.

VII. THE STRUCTURE OF THE COMPLEXES AND ITS RELATION TO LUMINESCENCE

An excited lanthanide ion, for example a neodymium ion, can lose its energy via two main mechanisms. One may assume that the first mechanism whereby the energy of the excited neodymium ion is dissipated is a direct transfer to the surrounding medium via vibrations. The mechanism of this type of transfer has been studied by different investigators on various models[63,91,92].

In the second case account must be taken of the high neodymium concentration as a result of which self-quenching of neodymium occurs[93] owing to an energy jump between adjacent neodymium atoms[94]. It is suggested that the radiationless energy transfer from neodymium and other lanthanides is analogous to the processes occurring in organic compounds[95-97] and also in inorganic ions[98-102].

Table 3. Solvents.

Name and structural formula	M	Dielectric constant ε	M.p.-b.p., °C	n_D	d, g cm^{-3}	κ, Ω^{-1} cm^{-1}	η, cP	References
CH_3OH	32.04	32.63	−97.47÷64.56	1.3286 at 15°	0.78675	$1.5\cdot10^{-9}$	0.5445	88
C_2H_5OH	46.086	24.3	−117.3÷78.327	1.3594	0.78506	$1.35\cdot10^{-9}$	1.078	88
Standard alcoholic solvent, 3:1 C_2H_5OH-CH_3OH								
Acetonitrile CH_3CN	41.052	37.5 at 20°	−45.72÷81.60	1.34163	0.77683	10^{-8}	0.3448 at 30°	89
Dioxan $C_4H_8O_2$	88.1	2.209	11.7÷108.8	1.42436	1.03375 at 20°	$5\cdot10^{-15}$	1.439	89
Dimethylformamide	73.01	36.71	−61÷153.0	1.4294	0.9443 at 25°	$2\cdot10^{-7}$	0.796	89
Propyl alcohol solvent−2:5.6:0.8 dimethylformamide-ethyl alcohol-propyl alcohol	60.09	19.7 at 25°	−127÷97.2	1.3873	0.80753 at 15°	$5\cdot10^{-8}$	2.18 at 20°	88
Dimethyl sulphoxide $(CH_3)_2SO$	78.13	48.9	18.2÷189		1.100	$3\cdot10^{-3}$	2.473 at 20°	89
Selenyl chloride	165.9	46.2 at 20°	8.5÷168	2.64 at 25°	2.44 at 25°	$2.5\cdot10^{-5}$		87, 88
Phosphorus oxide chloride $POCl_3$	153.33	13.9	1.25÷105.8	1.460	1.648	$2\cdot10^{-8}$	1.018	87

The main conclusions which may be drawn from these studies reduce to the condition that the solution should not contain light atoms with a high bond vibrational energy for example hydrogen atoms or at any rate these atoms should not be linked directly by chemical bonds to atoms coordinated to the lanthanides.

The studies of Heller and Lempicki confirm these postulates in broad outline.

Earlier experiments in organic solutions showed that the removal of quenching elements from the intervening spaces between excited ions and vibrating adjacent molecules rapidly increases the luminescence quantum yield[103]. An aqueous neodymium chloride solution may be adopted as a standard solution with the specified minimum quantum yield. The replacement of an aqueous solution by a deuterated solution increases the luminescence factor fivefold. The replacement of water by a solvent such as dimethyl sulphoxide, in which the solvating oxygen atoms are not linked to hydrogen atoms, increases the luminescence intensity by a factor of 10 and the quantum yield rises almost by two powers of 10 compared with aqueous solutions; on the other hand, deuteration increases further the luminescence yield by a factor of three. From this standpoint, organic halogeno-derivatives are the most suitable compounds, since they do not contain atoms lighter than carbon.

Therefore it is also not surprising that the most effective luminescent systems proved to be those in inorganic solvents, of the type $Nd^{3+}-SeOCl_2$−aprotic acid or $Nd^{3+}-POCl_3$−aprotic acid; the quantum yield for the first system is sometimes higher than the luminescence yield in aqueous solutions.

Table 4 presents the principal characteristic vibration frequencies of groups of atoms in the solvent and ligand which in solvation and complex formation processes may be in the immediate vicinity of the central atom with a specified energy store[104-106].

Table 4. Characteristic bond vibration frequencies in various components of laser systems.

Compound	Bond	Absorption region, cm^{-1}	References
Primary alcohols	O−H	3650—3590	104
Primary alcohols	C−H	1050	104

"	$TiCl_6^{2-}$	463	106

The smallest distances between the excited lanthanide levels for Nd^{3+} ($^4F_{3/2}-{}^4I_{15/2}$) Eu^{3+} ($^5D_0 \rightarrow {}^7F_6$), and Tb^{3+} ($^5D_4-{}^5F_5$) are respectively 5500, 12500, and 18300 cm^{-1} [107,108], while the bond vibrational energies in phosphoryl and selenyl groups, tin tetrachloride, and antimony pentafluoride are much lower. The stretching vibrational energies of the O−H and C−H bonds are much closer to the energy differences between the excited levels in lanthanide ions.

The study of lanthanide complexes in aprotic solvents led to the development of new views on their structure and also made it possible to discover a relation between the dissipation of energy from the excited ions to the surrounding medium as a function of the type of bond. These concepts were used initially by a group of investigators for polyphosphoric acids which had been subjected to extensive chlorination and fluorination[86]. Extensive chlorination of polyphosphoric acids leads to the occurrence in solutions of non-bridged structures isolated from the surrounding medium by halogen atoms. Important additional information is provided by studies on the vibrational spectra, which showed that in aprotic solvents lanthanide ions are surrounded by oxygen atoms. These investigations also led to the discovery that unchanged metal halide molecules are absent from the solutions.

The determination of the crystal field parameters and the study of the vibronic spectra made possible a number of conclusions concerning the immediate environment of lanthanide ions in solvents such as H_3PO_4, $SeOCl_2-SnCl_4$, $H_2SeO_3-POCl_3$, and $POCl_3-SnCl_4$. These data show that the ion has C_{4V} symmetry with some distortion. The immediate environment of the ion consists of P—O groups or, less probably, [109].

In conclusion one must emphasise that the discovery of liquid luminescent and laser systems based on inorganic solvents with heavy atoms gives rise to the hope for a rapid development and application of these systems as lasers, which will not be inferior in their properties to solid lasers. One should also bear in mind liquid laser systems based on organic solutions of lanthanide chelates. The studies in this field are still far from completion.

The Chemistry of New Atoms†

V.N.Gol'danskii and V.G.Firsov

The physicochemical interaction of hydrogen-like positronium and muonium atomic systems, in which the proton is replaced by a positron or a μ^+-meson, and mesonic atoms containing a μ^-- or a π^--meson instead of an electron have been examined. The nuclear-physical methods for the investigation of processes involving the new atoms have yielded information which significantly supplements that available from the usual research techniques.
The bibliography includes 123 references.

I. INTRODUCTION

The last two decades have been distinguished by the appearance and development of a new research field intermediate between the physics of elementary particles and chemistry. It concerns the chemistry of "new atoms" in which either an electron or a proton is replaced by another negatively or positively charged elementary particle.

Atoms in which there is a negative meson instead of one of the electrons are called mesonic atoms. On forming a chemical bond with other "ordinary" atoms, mesonic atoms can form also the so called mesonic molecules.

The most thoroughly investigated examples of new atoms of this type are the μ- and π-mesonic atoms. They will be the only ones considered in the appropriate sections of the present review.

However, in principle, there is also a possibility of the existence of K-mesonic atoms and new atoms in which instead of an electron there is a negative hyperon, an antiproton, or an antihyperon.

The radius of the nth Bohr orbital is $a_n = \hbar^2 n^2/\mu Z e^2$, in which $\mu = Am_N m/(m + Am_N)$ is the reduced mass, m the mass of the particle in the orbital, m_N the mass of the nucleon, A the mass number of the nucleus, and Z its charge.

Therefore the radii of the first Bohr orbitals of the hydrogen-like μ- and π-mesonic atoms are respectively about $2.5 \times 10^{-11}/Z$ cm and $1.9 \times 10^{-11}/Z$ cm, which are closer to nuclear rather than atomic dimensions. This is

† In the compilation of this review data known to the authors by 1st March 1970 were employed.

even more true of the K-meson, antiproton, and hyperon atoms (for example $a_1 \simeq 5 \times 10^{-13}$ cm for K-mesonic sodium and $a_1 \simeq 2.7 \times 10^{-13}$ cm for antiproton-sodium). As a result, the effective charge of the nucleus of the mesonic atom or an even heavier new atom of this type is z only for large values of n, of the order of $n \simeq \sqrt{m/m_0}$ (m_0 is the mass of the electron), and decreases by unity when the particle replacing the electron passes to the first orbitals.

Atoms in which the proton is replaced by another positive particle are named after the particle with the ending "onium". The penetration of any positive particle into the nucleus is hindered by electrostatic repulsion which can be counteracted only by attraction due to nuclear forces. Therefore, for the lightest positive particles (leptons), i.e. the positron and μ^+-meson, which do not enter into nuclear interactions, atoms of the "onium" type are possible only without a nucleonic nucleus, the positive leptons replacing the sole nucleon (the proton). An atom comprising a positron and an electron is called positronium (Ps) and an atom comprising a μ^+-meson and an electron is called muonium (Mu). Both positronium and muonium may be regarded as light hydrogen isotopes, positronium being the lightest of all the new atoms—it is at the same time the only atom altogether without a nucleus. Indeed, since both constituent particles of positronium have equal masses, the centre of gravity about which they both rotate does not approach either of them (such a particle would have played the role of a nucleus) but is located exactly in the centre.

A nuclear proton can be replaced also by a positively charged hyperon just as a neutron can be replaced by neutral hyperon. This gives rise to the so called hypernuclei and the corresponding hyperatoms. However, the structure of the electron shells of hyperatoms and their chemical properties hardly differ from those of the atoms with the same nuclear charge and therefore hyperatoms are not usually included among the "new atoms".

All the new atoms are unstable. The upper limits to the lifetimes of atoms with charged μ- or π-mesons are the intrinsic lifetimes of these particles in a vacuum ($\tau_\mu \simeq 2.2 \times 10^{-6}$ s, $\tau_\pi \simeq 2.5 \times 10^{-8}$ s) in relation to the decomposition processes $\mu^\pm \rightarrow e^\pm + \nu(\tilde{\nu}) + \tilde{\nu}_\mu/(\nu_\mu)$ and $\pi^\pm \rightarrow \mu^\pm + \nu_\mu(\tilde{\nu}_\mu)$ (ν is a neutrino and $\tilde{\nu}$ an antineutrino).

Each of the constituent particles of positronium is itself stable but, being a particle and an antiparticle, the electron and positron annihilate one another with emission of gamma-quanta, which is the reason for the instability of positronium and its very short lifetime (10^{-7}–10^{-10} s in a vacuum).

From the chemist's point of view, the main interest of the study of new atoms consists in the fact that chemical and crystalline environments influence their lifetimes and various characteristics of their destruction.

The first stage of studies in the chemistry of new atoms is the elucidation of the laws governing such influence and the verification of how specified changes in the chemical or crystal structure of the substance or the changes established in independent experiments influence the fate of new atoms.

The second stage of such investigations of the greatest importance to chemistry, in which chemistry assumes the role of a "consumer", is the determination of new structural-chemical data on the kinetics and mechanism of chemical processes based on the observation of particular characteristics in the formation, transformation, and destruction of new atoms.

At present, the mesochemical studies on μ- and π-mesonic atoms and muonium are still in the first stage, while the work on the physical chemistry of the positron and positronium have already passed to the second stage and has begun to yield new information of general importance to chemistry.

II. POSITRONIUM

1. General Characteristics of the Annihilation of Positrons and the Physical Properties of Positronium

The annihilation of positrons and the formation and destruction of positronium have been described in monographs[1,2], reports at the 1965 Conference in Detroit (USA),[3] compilation tables[4], many reviews[5–18] and articles containing an extensive bibliography (see, for example, Refs. 19 and 20), and about 400 original papers. The aim of the present review is not to give any sort of complete list of literature on this problem and we shall confine ourselves to the description of the general information of the greatest significance to chemists, concentrating attention on the latest work.

The positron, predicted theoretically by Dirac and discovered in 1932 by Anderson, is the antiparticle of the electron having the same mass ($m_0c^2 = 0.511$ Mev) and the opposite positive electrical charge ($e = 4.8 \times 10^{-10}$ CGSE). The hitherto unknown mutual annihilation process was first observed for the positron (e^+) and the electron (e^-); the process is characteristic of the interaction of particles and antiparticles in general and in the present case is accompanied by the emission of γ-quanta. The annihilation on collision between an electron and a positron can involve the emission of either two or in rare cases (probability 1/373) of three γ-quanta. One-quantum or quantumless annihilation require the participation of a third body and their probabilities are altogether low.

In laboratory experiments positrons are obtained from radioactive isotopes, for example sodium-22 or copper-64, which emit positrons with a maximum energy of several hundred keV. The positrons emitted by the sources initially behave like electrons—they are retarded expending their energy on the ionisation and excitation of the surrounding molecules. Up to energies of several tens of electron-volts, the role of annihilation is negligibly small and almost all the positrons "survive" until the attainment of the above low energies and are only then annihilated. By virtue of the possibility of recording the annihilation quanta, the positron is, as it were, a labelled electron the fate of which, from its appearance in the substance until its destruction by annihilation, can be followed. According to Dirac, the 2γ-annihilation cross-section for the positron and electron moving relative to one another at a velocity $v \ll c$ ($c = 3 \times 10^{10}$ cm s^{-1}) is

$$\sigma_D = \pi r_0^2 \frac{c}{v} = \pi \left(\frac{e^2}{m_0c^2}\right)^2 \cdot \frac{c}{v} \simeq 7.4 \cdot 10^{-15} \cdot \frac{1}{v} \text{ cm}^2 . \qquad (1)$$

There exist three principal variants of the annihilation, each of which can be isolated experimentally and each provides certain specific information about the properties of the medium in which the annihilation takes place.

The first pathway involves the annihilation in free or quasi-free (i.e. without the involvement of the ionic framework) collisions of positrons with electrons. If the two particles were at rest at the instant of mutual annihilation, then the two annihilation quanta would have absolutely identical energies (equal to m_0c_2) and the angle of their divergence would be exactly 180°. The experimentally

observed negligible deviations of the energies (by several electron-volts) and angles (by several milliradians) from the above values permit a direct recording of the count distribution of the conductivity and valence electrons which annihilate the positrons (their penetration to the region of the inner atomic orbitals is prevented by the Coulombic repulsion by the nucleus) and the observation of the anisotropy of such distribution relative to particular specified directions in crystals and molecules and the changes in it during phase transitions.

Another annihilation pathway is via the formation of combined states of the positron with neutral molecules (e^+M) or with anions (e^+A^-). From a theoretical standpoint, the structure and analysis of the wave functions of molecules of the type e^+H^- or, what amounts to the same thing, positronium hydride PsH, are of interest[20]. One cannot rule out the possibility of the formation of a completely new type of chemical bond of the kind He$-e^+-$He. The formation of a virtual or combined level of the e^+M system (as a result of the polarisation by the positron of the electron cloud of the atom or molecule) leads to a characteristic "resonance annihilation" phenomenon the cross-section of which is sometimes tens and hundreds of times greater than the Dirac σ_D. There is also a possibility of the formation of collective (polaron) states of the positron or bonds between the positron and lattice defects in ionic crystals. Of the problems which are not considered in a monograph by one of the present authors[1], we shall mention here only the model of the optical positron[21] and new experimental methods, based on it, for the determination of a parameter of great importance for structural chemistry—the effective charges of the anions (atoms of Group VII and VI elements) from data for the angular correlation between the annihilation quanta[22] and the lifetimes of positrons[23] in ionic media.

We shall also mention recent interesting observations[24] which established a very marked influence of even low concentrations of F-centres in KCl (approximately 3×10^{-4} of the number of regular Cl^- sites) on the type of angular correlation of the annihilation γ-quanta and thereby again demonstrating the high sensitivity of positron methods to any kind of breakdown in the regularity of crystal lattice structures.

The third pathway for the annihilation of positrons—via the formation of positronium atoms—is of greatest interest for a wide range of problems in modern physical chemistry and is in fact considered below.

The possibility of the existence of combined states of the electron–positron system was postulated in 1934,[25] the name "positronium" was proposed for the electron–positron atom in 1945,[26] and the chemical symbol Ps was put forward in 1959.[27] The existence of positronium was demonstrated experimentally by Deutsch in 1951.[28] The mass of positronium is 920 times smaller than the mass of the hydrogen atom but its reduced mass $\mu_{Ps} = m_0/2$ is only twice as small as the reduced mass of the hydrogen atom $\mu_H \simeq m_{i0}$. Accordingly the ionisation potential of positronium in the ground (1s) state $V = e^4\mu z^2/2\hbar^2 n^2$ ($\mu = m_{i0}/2$, $z = 1$, and $n = 1$) is twice as small as the value for hydrogen and amounts to $V_{Ps} \simeq 6.77$ eV. The distance between the positive and negative charges, which in the case of hydrogen is defined as the radius of the first Bohr orbital, is twice as large in positronium and is close to 1.06 Å (when $n = 1$). In the present case this distance is, however, not the radius but the diameter of the atom.

There exist two ground states (1S; $n = 1$) of positronium—the triplet state $^TPs(^3S_1)$ or orthopositronium o-Ps with parallel spins of e^- and e^+ and the singlet state $^SPs(^1S_0)$ or parapositronium p-Ps with antiparallel spins of e^- and e^+. The total moment of o-Ps is $J_T = 1$ and in this case three substates are possible, differing in the magnetic quantum numbers: $m = +1$, 0, or -1. For p-Ps, $J_S = 0$ and $m = 0$. Correspondingly, the statistical weight $2J_T + 1$ of o-Ps is three times larger than for p-Ps and in the formation of positronium o-Ps arises in 75% of cases and p-Ps in only 25% of cases.

In accordance with various selection rules, p-Ps is annihilated with the emission of two γ-quanta and o-Ps with the emission of three γ-quanta. As a result, the intrinsic lifetime of singlet positronium is much shorter than that of triplet positronium. The lifetime of p-Ps in a vacuum is

$$\tau_S^0 = 2\frac{\hbar^2}{m_0e^2}\cdot\frac{1}{cr_0^2} = 1.25\cdot 10^{-10}\text{s}. \qquad (2)$$

while that of o-Ps is higher by a factor $9\pi/4(\pi^2 - 9)(\hbar c/e^2) = 1115$ and amounts to $\tau_T^0 = 1.4 \times 10^{-7}$ s.

As a result of the hyperfine splitting of the 1S state of positronium, the energy of o-Ps exceeds that of p-Ps by an amount

$$\Delta W = {}^TW - {}^SW = \frac{7}{12}\left(\frac{e^2}{\hbar c}\right)^4 m_0c^2 = 8.4\cdot 10^{-4}\text{ eV} \qquad (3)$$

(to within the so called radiation corrections).

In fairly strong external magnetic fields, a "good" quantum number is no longer the total moment of positronium J but m, the states with $m = 0$ and $J = 1$ and with $m = 0$ and $J = 0$ are mixed, and the contribution by the 2γ-annihilation of positronium increases (in a vacuum) from 25 to 50%. External fields alter the energies of the sublevels with $m = 0$, increasing the energy for the state with $m = 0$ and $J = 1$ and correspondingly decreasing it for the state with $m = 0$ and $J = 0$ by $\Delta W(1 + x^2)^{1/2}/2$, where $x = (2e\hbar/m_0c)(H/\Delta W) = 2.75 \times 10^{-2} H$ (kilogauss), but do not affect the energies of the $m = \pm 1$ states. An additional decrease of the probability of the 3γ-annihilation of triplet positronium can arise due to the magnetic dipole transitions ($m = \pm 1$) $\rightarrow$ ($m = 0$) in a high-frequency electromagnetic field at the resonance frequency

$$\nu = \frac{\Delta W}{2\hbar}[\sqrt{1 + x^2} - 1].$$

For fields of about 10 kG, the frequency $\nu \simeq 3000$ MHz, so that the experiments on the quenching of the 3γ-annihilation of positronium by a high frequency field, which were carried out for the first time by Deutsch[29] and made it possible to determine with high accuracy ΔW, were the first experiments on the microwave spectroscopy of positronium.

2. General Chemical Properties of Positronium. The Quenching of Positronium. Principal Differences between Positronium and Hydrogen

Positronium, which is the lightest hydrogen-like atom and constitutes a model free radical, is also a kind of labelled atom, the properties, the lifetime, and the mechanism of the destruction of which greatly depend on the properties of the surrounding medium. The short intrinsic lifetime of orthopositronium makes it possible to use this time as a convenient standard in the investigation of rapid reactions involving atoms of the hydrogen type and to observe and study the role of diffusion and quantum (tunnel effect) factors in the kinetics of such reactions.

As a rule the duration of chemical reactions in which positronium is involved lies within the limits between the characteristic lifetimes of the long-lived form (ortho-positronium, 10^{-9} s in the condensed phase, 10^{-7}–10^{-8} s in gases, $\tau_T^0 = 1.4 \times 10^{-7}$ s in a vacuum) and of the short-lived form (parapositronium, $\tau_S^0 = 1.25 \times 10^{-10}$ s). Therefore a decrease of the lifetime (the quenching of positronium) constitutes in the first place the quenching of orthopositronium, the replacement of the annihilation of the positron in the ^{T}Ps state by other types of annihilation.

The processes involving positronium which lead to the quenching of ^{T}Ps include the following: (1) annihilation by "foreign" electrons at the instant of collision between Ps and other atoms or molecules—the so called "pick-off" annihilation; (2) ortho-para conversion in the interaction with paramagnetic species, for example $^T\mathrm{Ps}(\uparrow\downarrow) + \dot{\mathrm{N}}\mathrm{O}(\downarrow) \rightarrow {}^S\mathrm{Ps}(\uparrow\downarrow) + \dot{\mathrm{N}}\mathrm{O}(\uparrow)$; (3) substitution reactions, for example, $\mathrm{Ps} + \mathrm{Cl}_2 \rightarrow \mathrm{PsCl} + \mathrm{Cl}$; (4) addition reactions, for example, $\mathrm{Ps} + (\mathrm{CF}_3)_2\dot{\mathrm{N}}\mathrm{O} \rightarrow (\mathrm{CF}_3)_2\mathrm{NOPs}$, as a result of which the positron is brought into the field of many electrons, as in pick-off annihilation; (5) oxidation reactions, for example, $^T\mathrm{Ps} + \mathrm{Fe}^{3+} \rightarrow e^+ + \mathrm{Fe}^{2+}$, which lead to the formation of a rapidly destroyed free positron.

In substitution, addition, and oxidation reactions, positronium behaves as a chemical analogue of hydrogen. However, because of the very great difference between the masses of hydrogen and positronium, there are many differences in the structure of their compounds, the energies of their formation, and the kinetics of their chemical reactions.

While an HA molecule (A is any atom) should be regarded as a two-centre molecule, its analogue PsA = e^+A^- is better characterised as a one-centre molecule, namely as an A atom with mixed electron and positron clouds. This is markedly reflected in the bond energy—for example, while the A_2 bond energy is close to 4.5 eV, the energy for HPs is estimated as 0.657 eV [20] and for Ps_2 as 0.11 eV.[30] The stability of any PsA molecule must be lower than that of HA if only because, with increase of the reduced mass μ of the molecule, the energy of the zero-point vibrations, from which the dissociation energy is reckoned, must increase. In principle $\hbar\omega_0 \propto 1/\sqrt{\mu}$, but in fact that ratio $(\hbar\omega_0)_{PsA}/(\hbar\omega_0)_{HA}$ probably never reaches the value

$$\sqrt{\frac{\mu_{PsA}}{\mu_{HA}}} \simeq \sqrt{\frac{m_H}{m_{Ps}}} \simeq 30 .$$

Nevertheless any reaction involving the substitution of H by Ps, $HA + Ps \rightarrow PsA + H$, is probably endothermic.

As stated above, the ionisation potential of the H atom is twice as high as for Ps. Therefore in the gas phase the oxidation of positronium by hydrogen is a highly exothermic process: $H^+ + Ps \rightarrow H + e^+ + 6.8$ eV. Since however the heat of hydration (and in general the heat of solvation) of the proton, which is close to 11 eV, is much higher than for the positron (one can assume arbitrarily that this heat is 1.5–2 eV, as for the electron), the oxidation of positronium by hydrogen in aqueous solution is endothermic and hardly occurs to an appreciable extent: $H^+_{aq} + Ps_{aq} \rightarrow H_{aq} + e^+_{aq}$ (~ 2.5 eV). The electron affinity of the hydrogen atom (0.75 eV) also exceeds the analogous quantity for positronium (estimated [31,32] as ~ 0.20 eV).

In comparing the rates of reaction of hydrogen and positronium, one should bear in mind not only the difference between the heats (the heat of an endothermic reaction is equal to its minimum possible activation energy), the pre-exponential factors (the thermal velocity of Ps atoms is about 30 times higher than that of H), and the diffusion coefficients, which reach $D \simeq 3 \times 10^{-4}$ cm^2 s^{-1} for Ps in various solvents (Becquerel [1], Chapter VII), but also the possibility of tunnel transitions within a particle as light as positronium under conditions where such transitions are virtually ruled out for H atoms. We obtained in our investigations [33,34] the temperature T_{tun} below which tunnel transitions predominate exponentially over the Arrhenius (over-the-barrier) transitions: $T_{tun} = (\hbar/k\pi d)\sqrt{E/\mu}$, where k is the Boltzmann constant, μ the reduced mass of the tunnelling system, d the width of the potential barrier, and E its height. For free positronium, the temperature T_{tun} is approximately 30 times higher than for H atoms and sometimes amounts to hundreds of degrees. Therefore in gas-phase reactions of positronium, a non-activation tunnel mechanism is extremely likely.

The appearance of a tunnel effect is not the sole expression of the wave properties of positronium associated with its low mass and consequently with its high De Broglie wavelength. For a thermal positronium atom at room temperature, $\lambda\!\!\!^{-} \simeq 9$ Å, so that the cross-sections for processes involving positronium can reach in principle $4\pi\lambda\!\!\!^{-2} \simeq 10^{-13}$ cm^2.

Yet another kinetic difference between the reactions of hydrogen and positronium, due to the unusually low mass of the latter, consists in the fact that the electron transitions between positronium and another atom cannot be regarded as adiabatic, without a change in the distance between the positron and the nucleus of the other atom.

Finally the low mass of positronium leads to an unusual form of the excitation functions for its endothermic substitution reactions ($Ps + AB \rightarrow APs + B$), which differ appreciably from those for H atoms, but are close to the excitation functions for dissociative electron capture ($\bar{e} + AB \rightarrow A\bar{e} + B$). The cross-sections for the above reactions of Ps and an electron have a sharp maximum directly at the threshold and the maximum cross-section is very sensitive to the threshold energy and provides a method for its determination. When the energy increases above the threshold value by an AB vibration quantum, the substitution cross-section decreases sharply [35].

The above factors make it difficult to transfer directly the results of positron studies to reactions of hydrogen atoms, but they give rise to the possibility of many specific applications of the positron method in chemistry, which will be described below.

3. The Probability of the Formation of Positronium and Its Inhibition Processes

One of the principal characteristics of the annihilation of positrons is the probability P of the formation of positronium. The simplest estimate of this quantity is provided by the so called Ore model [36] illustrated in Fig. 1. Here V denotes the ionisation potential of the molecules of the medium and E the excitation energy for their first electronic level. As long as the kinetic energy of positrons exceeds E and particularly V, the energy expenditure on ionisation and excitation predominates. On the other hand, when the energy of positrons is lower than $V - 6.8$ eV, the formation of positronium is simply

impossible on energy grounds. The range of positron energies between E (upper limit) and $V - 6.8$ eV (lower limit), in which the dominant positron interaction process is the formation of Ps, is called the Ore gap. For a rectangular spectrum of retarded positrons, the Ore model gives $6.8/V > P > [E - (V - 6.8)]/E$, which holds fairly well for simple gaseous systems. For example, for argon $V = 15.8$ eV and $E = 11.6$ eV, whence $0.43 > P > 0.22$, while experiment gives $P = 0.30$.

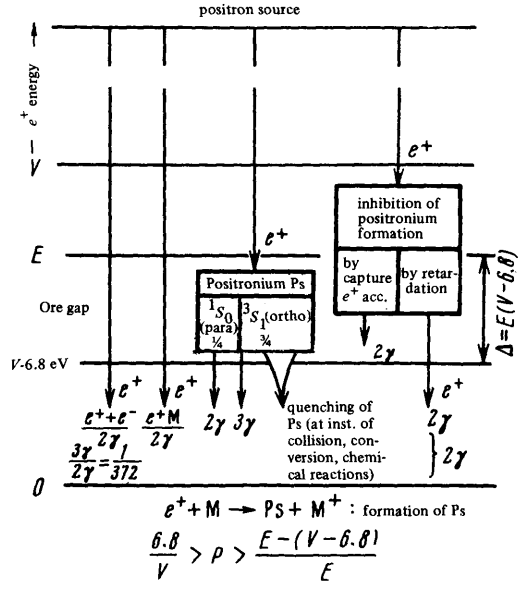

Figure 1. A schematic representation of the processes involving the formation and destruction of positronium, illustrating the Ore model and possible deviations from it.

In the condensed phase predictions based on the Ore model must be appreciably modified if only because account must be taken of the affinity of the medium for electrons, positrons, and positronium atoms. However, even without these complicating factors, the situation may alter (even in gases) in consequence of various inhibition processes, which lower the probability of the formation of positronium (Fig. 1). These are the capture of positrons, competing with the formation of positronium and with the elastic retardation of positrons (resulting in their slow passage through the Ore gap), which altogether removes positrons "from play", and non-elastic retardation of positrons, which rapidly brings them below the Ore split into the region of low energies, where positronium is no longer formed.

Both types of inhibition—by capture (capture inhibitors) and retardation (retardation inhibitors)—may be due to the medium itself in which the annihilation is investigated (auto-inhibition) and to different additives (inhibition by impurities) at varying concentrations.

The foregoing shows that the observation of changes in the probability of the formation of positronium and the study of various processes involving the inhibition of such formation can yield information about the various ways in which positrons are captured (for example, capture from a complex with annihilation: $e^+ + AB \rightarrow ABe^+ \rightarrow 2\gamma$, or capture with dissociation: $e^+ + AB \rightarrow A + Be^+ \rightarrow 2\gamma$), about their non-elastic retardation, and about the excitation of the electronic, vibrational, and rotational levels of the inhibitor molecules. An additional source of information comes from the increase of the probability of the formation of positronium when static external electric fields are applied, because the field accelerating positrons can return to the Ore gap some positrons with an energy less than $V - 6.8$ eV. The combination of such accelerating effects of the field and the loss of positron energy in elastic and non-elastic collisions is comparatively readily susceptible to calculation and can serve as a basis for the estimation of the cross-sections for different types of interaction involving positrons.

Thus different ways become available for obtaining data about the competition between the ionisation of molecules, their electronic excitation, and the capture of electrons by positrons with energies of the order of several electron-volts and about the relative contributions of the cross-sections for the elastic and non-elastic scattering and the capture of positrons.

When applied to the gas phase, the relevant field of study has been called by Massey "positronics" [37] and constitutes a useful addition to gaseous electronics. In the condensed phase positronic research techniques are applicable also under conditions where the corresponding data are altogether lacking even for electrons. In this connection, one of the most interesting problems is, for example, the study of the changes in the nature of the retardation of positrons on passing from a gas to a liquid and further to a solid, as a result of the appearance of collective interactions.

4. Principal Experimental Methods in Positronium Chemistry

According to the foregoing, the main subject of observations in experiments with positronium is two characteristics of the annihilation of positrons: (a) the probability of the formation of positronium, the decrease of which is caused by various inhibition processes, and (b) the rate of destruction of positronium atoms in various interactions with molecules, atoms, radicals, etc. owing to all possible positronium quenching processes.

For laboratory isotope sources of the usual power (up to several hundred millicuries), the steady-state concentrations of positrons or any products of the combination of positrons with electrons, anions, and molecules, do not exceed several units per cm^3. Clearly there can be no question of any classical methods for the observations of chemical reactions involving positronium—it is necessary to employ the experimental techniques of nuclear physics whereby the fate of each individual positronium atom can be followed.

Different arrangements for the measurements are presented in Fig. 2. The top figure shows a triple collision scheme, in which orthopositronium annihilation acts with emission of three γ-quanta incident on $C1$, $C2$, and $C3$ grids, are recorded. A disadvantage of this method consists in the fact that the counting rate $C_{3\gamma}$ of the γ-coincidences is proportional to the product of two variable factors—the probability P of the formation of positronium (the fraction of orthopositronium $I_2 = 3P/4$) and the probability of its spontaneous annihilation (with emission of three γ-quanta), which is $\omega_{3\gamma} = \tau_2/\tau_T^0$, where τ_2 is the

actual lifetime of orthopositronium in the substance, shortened relative to $\tau_T^0 = 1.4 \times 10^{-7}$ s in consequence of various quenching processes. Therefore the decrease of $C_{3\gamma} \propto I_2\tau_2/\tau_T^0$ may be due to both the quenching of positronium (τ_2 decreases) and the inhibition of its formation ($I_2 = 3P/4$ decreases), whereas it is in fact desirable to separate the contributions by these two types of interactions.

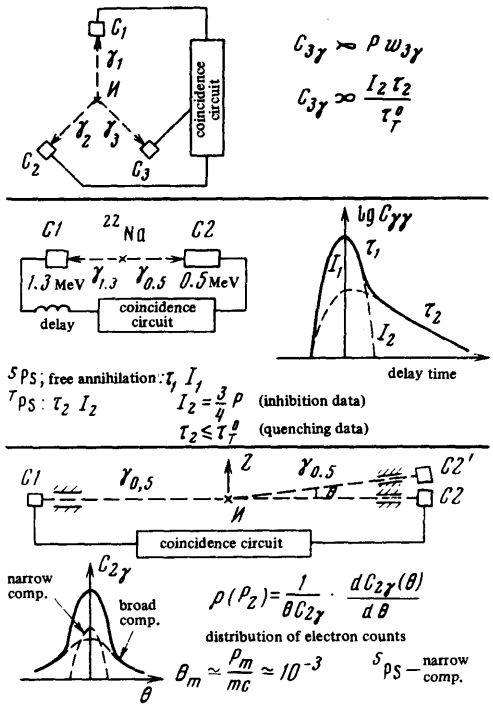

Figure 2. Schematic representation of different procedures for the observation of the fundamental characteristics of the annihilation of positrons. Upper figure—recording of 3γ-coincidences; middle figure—recording of the time spectrum of delayed $\gamma\gamma$-coincidences; lower figure—recording of the angular correlation of the annihilation γ-quanta.

The greatest variety of information is provided by observations of the time spectrum of the annihilation of positrons (the central part of Fig. 2) with the aid of delayed coincidence circuits. The coincidences $C_{\gamma\gamma}$ of the 1.3 MeV nuclear γ-quantum (C1 counter), emitted almost simultaneously with the ejection of a positron from a ^{22}Na nucleus, with the 0.5 MeV γ-quantum (C2 counter) emitted in the 2γ-annihilation of this positron, are recorded. In the simplest case the spectrum consists of two components[38]. The short-lived component with a lifetime τ_1 and a relative intensity I_1 is due to the annihilation of the positron in quasi-free collisions with electrons and in parapositronium and the long-lived component (τ_2, $I_2 = 1 - I_1$) is due to the annihilation of the positrons forming the triplet orthopositronium. The usual order of magnitude of the τ_i in the condensed phase amounts to a fraction of a nanosecond for τ_1 and several nanoseconds for τ_2. In the gas phase τ_2 increases as the pressure is reduced, tending to τ_T^0.

The improvement of the resolving capacity of coincidence circuits made it possible to determine finer details of the time spectra of the annihilation of positrons. Thus four sections of such spectra were observed in the gas phase[39]: an "instantaneous" peak (τ_p) due to the annihilation of parapositronium and the destruction of positrons above the Ore gap, followed by a "shoulder" whose length is inversely proportional to the gas pressure (treated as the lifetime of positrons between emission below the Ore gap and capture), and then sections corresponding to the exponential destruction of positrons with the characteristic annihilation times τ_1 (quasi-free and resonance annihilation) and τ_2 (orthopositronium) (see Fig. 3).

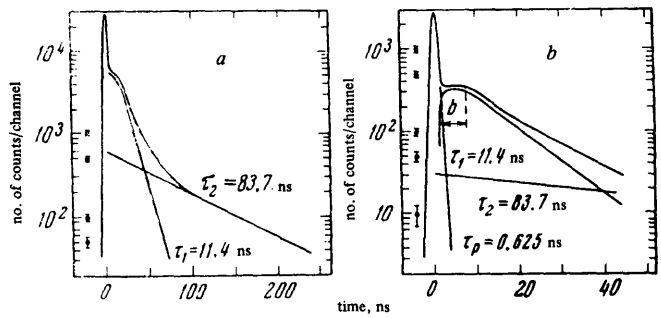

Figure 3. Curves for the distribution of the annihilation of positrons in pure argon with respect to time[39]: *a*) argon pressure 17.2 atm, duration of experiment 1223 min, $\tau_1 = 11.4$ ns, $\tau_2 = 83.7$ ns; b) argon pressure 16.8 atm, duration of experiments 928 min; *b*) width of "shoulder" $\tau_1 = 11.4$ ns, $\tau_2 = 83.7$ ns, $\tau_p = 0.625$ ns—limiting "instantaneous time" accessible to measurement, obtained by the extrapolation of the lifetime of singlet positronium.

For glycerol and many polymers (polyethylene, Teflon, and others) a third component, intermediate between τ_1 and τ_2, was also noted; it is treated here as an effect of annihilation in quasi-free e^+e^- collisions[40].

Finally, in powdered oxides (Al_2O_3, MgO, SiO_2, etc.) the presence of two characteristic long lifetimes—not only τ_2 (several nanoseconds), which is usual for a condensed phase, but also τ_3 (many tens of nanoseconds, up to $\tau_T^0 = 1.4 \times 10^{-7}$ s), caused by the spontaneous annihilation of orthopositronium atoms during their diffusion between the oxide particles, has been established[41-43].

The time method makes it possible to separate clearly the quenching of positronium and the inhibition of its formation. In the simplest case of "pure" inhibition, the intensity of the long-lived component I_2 decreases without further decrease of the slope of its "tail" characterising its lifetime τ_2.

On the other hand, in the case of "pure" quenching, τ_2 falls but I_2 remains unchanged. Two examples taken from Gol'danskii et al.[44], illustrating inhibition and quenching, are presented in Fig. 4, where the distance between two adjacent points in the spectra corresponds to approximately 0.1 ns. Fig. 4*a* illustrates the inhibition of the formation of positronium in benzene by added iodobenzene—probably as a result of positron capture by the iodobenzene—and

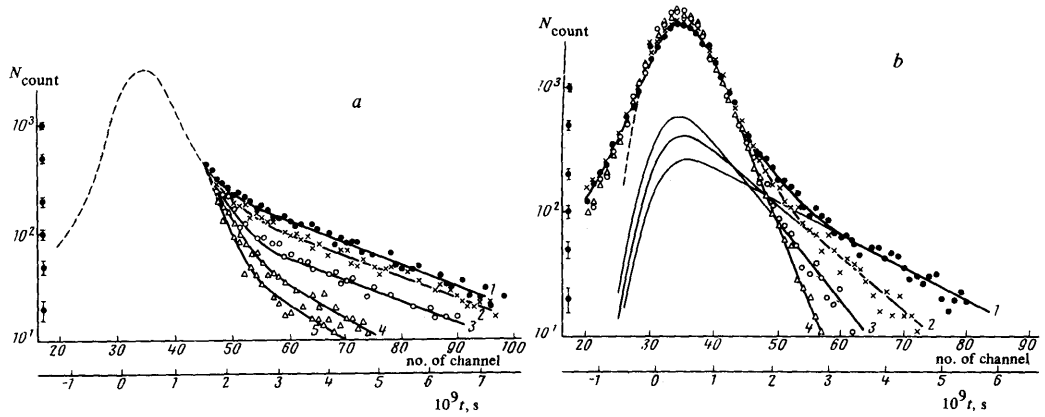

Figure 4. Positron annihilation spectra. *a*: 1) benzene; 2)–4) solutions of iodobenzene in benzene [2) 0.004 M; 3) 0.02 M; 4) 0.34 M]; 5) iodobenzene. *b*: 1) water; 2)–4) aqueous solutions of $K_2Cr_2O_7$ [2) 0.005 M; 3) 0.015 M; 4) 0.025 M]. Power of ^{22}Na source 10 μc.

Fig. 4*b* illustrates the quenching of orthopositronium in aqueous solution by a powerful oxidising agent ($K_2Cr_2O_7$).

The third main experimental method for the investigation of the annihilation of positrons—the observation of correlation curves, i.e. the relations between the counting rate $C_{2\gamma}$ of the coincidence of two 0.5 MeV annihilation γ-quanta and the angle θ, equal to the difference between 180° and the angle between the directions at which the two quanta are emitted—is illustrated schematically in the lower part of Fig. 2. Differentiation ($dC_{2\gamma}/d\theta$) makes it possible to determine the count distribution function for the electrons in the substance. The narrowest component at the angular distribution of the coincidence counting rate $C_{2\gamma}(\theta)$ on the complex correlation curve corresponds to the annihilation of singlet parapositronium. Therefore, by dividing the correlation curves for a series of numerous experiments into narrow and broad components, one can obtain important information, in addition to that from the annihilation time spectra about the chemical reactions of positronium, namely, the contributions by various types of quenching of positronium may be separated. Indeed pick-off annihilation of orthopositronium, as well as the formation of its chemical compounds or oxidation to a positron, correspond to the annihilation of positrons by valence electrons, the kinetic energy of which (T_e) amounts to several electron-volts. Correspondingly, the width of the correlation curves $\Delta\theta \propto \sqrt{T_e/mc^2}$ amounts under these conditions to several milliradians. Nevertheless the ortho-para conversion and subsequent 2γ-annihilation of the slow ^{S}Ps atoms contribute to the correlation curves a central narrow peak near $\theta = 0$, the width of which is about 1 milliradian (the so called narrow component with an intensity I_N). An example of the combination of the time and correlation methods is provided by Fig. 5, where data for aqueous solutions of two manganese salts are presented—the paramagnetic converter $MnSO_4$ and the diamagnetic oxidant $KMnO_4$.[45] The addition of these two salts shortens τ_2, i.e. they behave as quenching agents for positronium. However, the ortho-para converter increases at the same time the intensity of the narrow component of the correlation curve by $\Delta I_N = 15\%$, while the oxidant decreases its intensity by $\Delta I_N = -7\%$, since not only triplet but also singlet positronium is oxidised. The possibility of detecting the oxidation of singlet positronium demonstrates the applicability of positron methods to the observation of reactions occurring over periods as short as 10^{-10} s. A clear confirmation of this possibility is also provided by recent observations of the changes in the intensity of the narrow component ΔI_N for aqueous solution of the $CoCl_2.6H_2O$ converter, the $CuCl_2.2H_2O$ oxidant, and their mixtures[46]. In accordance with the kinetic equations taking into account the oxidation of ^{S}Ps among other processes, the changes in ΔI_N for mixed Co^{2+}–Cu^{2+} solutions are by no means additive relative to the analogous data for Co^{2+} and Cu^{2+} separately (Fig. 6).

The combination of various experimental techniques, supplemented by the variation of a number of parameters (composition, temperature, concentration of additives, and viscosity for liquid systems and composition, temperature, and pressure for gaseous systems) over a wide range makes it possible to verify and analyse in detail different versions of kinetic equations and to determine the kinetic constants for elementary chemical reactions involving positronium.

5. Examples of Information of General Chemical Importance Obtained from Observations on the Annihilation of Positrons

Using various methods described above, the investigators in a number of countries (USSR; USA—Berko, Brandt, Celitans, Lee, McGervey, Tao, and others; Canada—Bell, Hogg, Pohl, and others; France—Paulin and others; India—Thosar and others; Italy—Germagnoli and others; Australia—Green; Norway—Trumpy, etc.) observed fairly numerous examples of all classes of chemical reactions of positronium‡.

Our task is not, however, the description of the chemistry of positronium itself; this new atom is of interest to us as a means of obtaining information of

‡ In the present review we have examined only the reactions of positronium and not the annihilation of slow positrons in general. This is the only reason why we have not mentioned here I. Ya. Dekhtyar, V. L. Fedov, and others (the USSR), de Benedetti, Stewart, Roellig, and others (USA), Massey, Osman, and others (England), Zappa, Colombino, Ferranti, and others (Italy), etc.

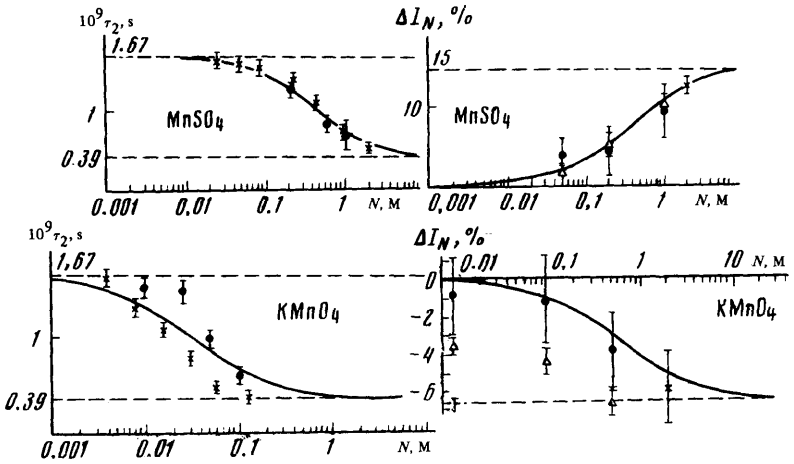

Figure 5. Variation of the lifetime of positrons (τ_2) (on the left) and of the intensity of the narrow component of the correlation curves (ΔI_N) (on the right) in the annihilation of positrons in aqueous solutions of an ortho–para converter ($MnSO_4$; upper figure) and an oxidant ($KMnO_4$; lower figure) as a function of the concentration of additives[1,45]. Power of ^{64}Cu or ^{22}Na source in the experiments on angular correlations—tens of millicuries or several millicuries respectively.

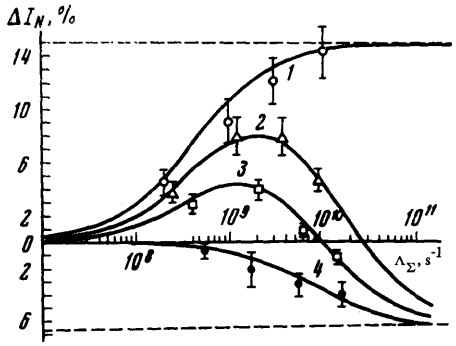

Figure 6. Variation of the intensity of the narrow component of correlation curves in an aqueous solution of converter ($CoCl_2$) and oxidant ($CuCl_2$) salts as a function of the overall rate of conversion and oxidation. Curves *1*–*4* correspond to the contributions by conversion to the overall rates of quenching, which is 100, 80, 50, and 0% respectively, the quenching rate constants being k_{conv} $(2.0 \pm 0.3) \times 10^9$ litre mole^{-1} s^{-1} and $k_{ox} = (5.4 \pm 0.4) \times 10^9$ litre mole^{-1} s^{-1}.

general chemical interest. We shall now consider examples of such information.

In the gas phase the rate of conversion quenching of positronium may serve as a fairly sensitive measure of the concentration of paramagnetic centres—quenching agents. For example, the rate constant for the quenching of positronium by paramagnetic nitric oxide NO, determined by various methods (from annihilation time spectra[28], an increase in the counting rate of the 2γ-coincidences[47], and a decrease in the counting rate of the 3γ-coincidences[48]), amounts to $(1-4) \times 10^{-10}$ cm^3 s^{-1}.

The latest value obtained from observations of the narrowing of the correlation curves is $(2.1 \pm 0.5) \times 10^{-10}$ cm^3 s^{-1}.[49] Adopting this value and assuming that the observation of a change in the counting rate of coincidences by 1% is a real effect, we obtain $n \simeq 10^{13}-10^{14}$ cm^{-3} (at room temperature; with increase of temperature, the sensitivity of the method is unchanged if $\sigma_{conv}v$ = const. and increases when σ_{conv} = const.) as the lower limit of the concentration of the paramagnetic centres recorded in the gas phase by the positron method.

The conversion of positronium includes in all probability the formation of the positronium–converter complex as the first stage. The positronium annihilated in such a complex does not give rise to the narrow component of the correlation curves characteristic of the destruction of free thermalised parapositronium. Therefore the correlation method makes it possible to establish whether the positronium–converter complex became stabilised in new collisions before annihilation or whether the complex decomposed with ortho–para conversion. By varying the concentration of the converter and the overall gas pressure, it is possible to determine on this basis the lifetimes of various positronium complexes; this is important also for other gas-phase reactions. The complexes formed on collision between positronium and NO are very unstable—even at a gas pressure of hundreds of atmospheres they decompose before collision with gas molecules. However, more complicated excited complexes, of the kind of $PsNO_2^*$ or $(CF_3)_2NOPs^*$, which have a larger number of degrees of freedom, have been shown experimentally[50] [for example, by measurement of the correlation curves in argon or oxygen at 30–150 atm with the addition of $5 \times 10^{-4}-0.8$ atm of $(CF_3)_2NO$] to survive for about $(1-2) \times 10^{-12}$ s and to have sufficient time to transfer their excitation energy in new collisions.

We shall now turn to the liquid phase. In the discussion of the mechanism of oxidation–reduction reactions in solutions, the problem of whether an electron is transferred from the reductant to the oxidant by a long-range tunnel transition or via the formation of an intermediate oxidant–reduction complex has been frequently discussed.

In the study of the kinetics of the chemical reduction of anions, Frumkin and coworkers[51] rejected the hypothesis of a long-range tunnel effect. An analogous conclusion was arrived at also on the basis of the comparison of the rate constants for the reactions of hydrogen and positronium atoms with Fe^{2+} and Fe^{3+}, the results of which are presented below (the constants are listed in litre mole^{-1} s^{-1}):

Acceptor	(Ac)	H	Ps	$\frac{k_{Ps}}{k_H}$
$Ac + Fe^{2+}$ →	$[FeAc]^{2+}$	$2 \cdot 10^{7}$ [52]	$2 \cdot 10^{9}$ [54]	100
$Ac + Fe^{3+}$ →	oxidation	$9 \cdot 10^{7}$ [53]	$1.2 \cdot 10^{10}$ [54]	130

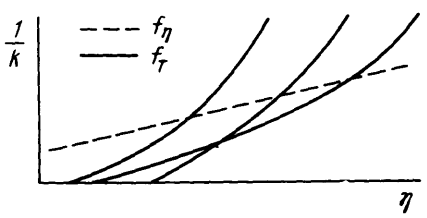

Figure 7. Variation of the reciprocal of the rate constant for the quenching of positronium in the mixed diffusion–kinetic region ($1/k$) with the viscosity of the solution η.[18,55] Dashed straight line—variation of f_η at a constant temperature and a variable solvent composition. Continuous curves—variation of f_T at a constant solvent composition and a variable temperature.

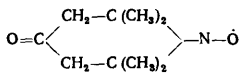
Radiation-chemical studies have shown that the reaction between H and Fe^{2+} proceeds via an intermediate complex, but the mechanism of the reaction between H and Fe^{3+} requires explanation. The fact that the rate of reaction of positronium, which is almost 1000 times lighter, with both Fe^{2+} and Fe^{3+} exceeds to approximately the same extent (by two powers of ten) the rate of reaction of hydrogen suggests that the mechanism of both reactions (with Fe^{2+} and Fe^{3+}) is the same. If a tunnel effect obtained in the second case, there would be no reason to expect such a sharp difference between the rates of the reactions of Ps and H with Fe^{3+}.

Another example of the use of positronium for the investigation of the mechanism of reactions in the liquid phase concerns the development of a method whereby the role of diffusion and kinetic factors can be distinguished[55]. This method, which has been applied to the quenching of positronium, can be readily extended to any other system, which would be of considerable importance to the study of the kinetics of liquid-phase reactions[56].

The method is based on the idea that the viscosity η of a solvent, in which the quenching of positronium by different free radicals [for example, diphenylpicrylhydrazyl (DPPH) $(C_6H_5)_2N-N-C_6H_2(NO_2)_3$ or 2,2,6,6-tetramethyl-4-oxopiperidine 1-oxide



(TMOPO)] takes place, is varied into waves. The viscosity is first increased by altering the composition of the solvent at a constant temperature T_0, for example by adding to water small amounts of glycerol, and then by reducing the temperature ($T < T_0$) for an unchanged composition of the solvent. Under these conditions, the reciprocal of the rate constant for the quenching of positronium ($1/k$) varies as follows:

$$\frac{1}{k} = f_\eta = \frac{\eta}{b}\left(\frac{1}{T_0} + \frac{a'}{\eta\sqrt{T_0}\,P} \cdot e^{E/RT_0}\right)$$

or

$$\frac{1}{k} = f_T = \frac{\eta}{b}\left(\frac{1}{T} + \frac{a}{\eta\sqrt{TP}} e_{E/RT}\right), \qquad (4)$$

where the activation energy E and the solvent parameters b and P are constant and a and a' are very similar. The experiments were carried out in octanol between −12° and 130°C, in ethyl ether between −90° and 25°C, and in cyclohexanol–acetone and water–glycerol mixtures at room temperature. The first type of variation of η is indicated in Fig. 7 by the linear function (dashed straight line) $1/k = f_\eta(\eta)$ while the second type of variation is more pronounced [$1/k = f_T(\eta)$] and is represented by continuous lines. By comparing $f_\eta(\eta)$ and $f_T(\eta)$ and also the slopes of the plots of $\ln k$ and $\ln(1/\eta)$ against $1/T$, it is possible to estimate the activation energy for the quenching of positronium by radicals despite its extemely low value ($E \simeq 1$ kcal mole^{-1}), against the background of the diffusion activation energy $E \simeq 2-6$ kcal mole^{-1}.

To complete the range of examples of the chemical applications of the positronium method in the liquid phase, we shall consider its use in the investigation of the structure of the coordination sphere of the complexes of paramagnetic ions (Co^{2+}) and electron-accepting oxidant ions (Fe^{3+}) in aqueous, alcoholic, and aqueous-alcoholic solutions.

In the first experiments of this kind, the results of which are presented in Fig. 8, the rate of quenching of positronium by the paramagnetic salt $CoCl_2$ (as a result of ortho–para conversion) was compared with the rate of reaction of this salt with TMOPO and DPPH radicals. The quenching was observed from the shortening of τ_2 and the reaction of $CoCl_2$ with the radicals from the broadening of the lines of the radicals in the ESR spectra. The observations were made in propanol, water, and their mixtures of various compositions. A change in solvent composition entails a rearrangement of the structure of the outer coordination sphere of the Co^{2+} complex—the tetrahedral (blue) form $Co(H_2O)_2Cl_2$ characteristics of the alcohol is transformed in water into the octahedral form $[Co(H_2O)_3]\cdot Cl_2$. In this example delocalised unpaired electrons, smeared over the coordination sphere of the complex and concentrated mainly at Cl^- ions in the pure alcohol and at the oxygen atom of the hydroxy-groups in water (the main part of the spin density is of course localised at the Co^{2+} ions themselves, "screened" from positronium by the ligand environment), behave as a quenching agent for positronium (or an agent interacting with radicals). In the mixed solvents the formation of hydrogen bonds between water and the alcohol and also the steric hindrance

due to the propyl radicals in the coordination sphere make the delocalised electron least accessible and retard the reaction of $CoCl_2$ with positronium and other radicals. Fig. 8 shows that under these conditions positronium is in fact the most sensitive detector of changes in the spin density of the delocalised unpaired electron—on passing from propanol and water to their mixtures, the rate of the paramagnetic quenching of positronium falls by a factor of several tens.

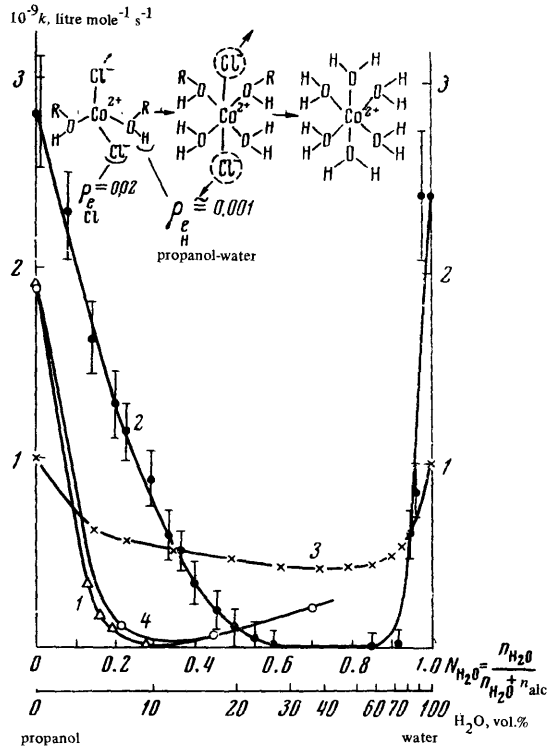


Figure 8. Variation of the rate of reactions of positronium and free DPPH and TMOPO free radicals with the composition of propanol–water mixtures[1,18,57]: 1) concentration of the tetrahedral (blue) form of the complex; sum of concentrations 4.5×10^{-2} M; 2) rate of reaction of Ps with $CoCl_2$ (0.4 M); 3) rate of reaction of TMOPO with $CoCl_2$ (6×10^{-2} M); 4) rate of reaction of DPPH with $CoCl_2$ (4.3×10^{-2} M).

Subsequent experiments on the quenching of positronium by the $FeCl_3$ oxidant in various alcoholic solutions[58] showed that positronium is extremely sensitive also to the delocalisation responsible for the oxidising effect of the Fe^{3+} acceptor orbital.

The observations of a sharp increase in the rate of reaction of positronium with other radicals when solutions are frozen, for example in octanol and benzene[18,59], are very remarkable and hitherto unexplained. For example, the rate of reaction of Ps with TMOPO in frozen octanol at −20°C is higher by a factor of almost 30 than in the liquid at −12°C, i.e. 3 degC above the melting point. These results may indicate both an increase in the rate of diffusion of Ps atoms in the solid phase and the presence of interaction mechanisms specific to the solid state, which operate in the liquid to a much lesser extent and which may play a role not only in the reactions of positronium but in solid-phase reactions in general.

The interpretation of the majority of the data concerning the formation and destruction of positronium in the solid phase is based on the so called "free volume model" examined for the first time by Wallace[60] and developed to the greatest extent by Brandt and coworkers (see, for example, Refs. 61 and 62).

The term "free volume" is applied to all vacancies, defects, and traps and all irregularities in the structure of the crystal lattice where Ps atoms may be located. In the simplest version of the free volume model[60], positronium is distributed in the interstices—a potential well with a periodic inner and exponentially decaying outer wave functions. We have the following quantity normalised to unity:

$$\Psi^2_{\text{outer}} = \frac{k^2/\alpha}{\alpha + \frac{2m_0 u}{\hbar^2} a + \frac{k^2}{\alpha}}, \qquad (5)$$

where

$$\alpha = \frac{\sqrt{2m_0(u-E)}}{\hbar}, \quad k = \frac{\sqrt{2m_0 E}}{\hbar},$$

u is the depth of the well, a its radius, and E the energy of the level occupied by positronium. With decrease of the radius of the well a, i.e. of the free volume, Ψ^2_{outer} increases, which implies an increase in the overlapping of the wave function of positronium with the electron clouds of the surrounding molecules, an increase in pick-off annihilation, and a decrease of τ^2.

In principle it is clear that the changes in free volume must influence not only the lifetime (τ_2) of the Ps atoms in the traps, but also the very probability of the formation of positronium $P = (4/3)I_2$.

Among the factors which may lead to changes in free volume and hence may influence τ_2 and I_2, one must mention in the first place a change in temperature, the contraction of solids, fusion, and various phase transitions[1,62,63].

Having analysed the data for three groups of substances, namely (a) liquids and amorphous materials, (b) polymers, and (c) crystals, Thosar and coworkers[64], concluded that, within the limits of each group, the increase of τ_2 is accompanied by a decrease of I_2, and they obtained the following semiempirical relation:

$$\frac{4}{3} I_2 = a \cdot \frac{1 + \ln \tau_2/\tau_1}{b + \ln \tau_2/\tau_1}, \qquad (6)$$

where

$$a = K\frac{V_f}{v_0}, \quad b = \frac{v_1}{v_0}, \quad \tau_2 = \tau_1 \exp\left(\frac{v - v_1}{v_0 - v}\right),$$

V_f is the overall free volume, and K a constant (Fig. 9).

The significance of Eqn. (6) is that the free volume v corresponding to one positronium atom may vary from $v_{\min} = v_1$ (here $\tau_2 = \tau_1$) to $v_{\max} \to v_0$ (here $\tau_0 \to \infty$) and correspondingly $K = V_f/v$ is in the range $K(v_f/v_0) \leqslant P \leqslant K(V_f/v_1)$. Expressing I_2 as a percentage and τ_2 in nanoseconds, the authors[64] quote the following values of the parameters a and b: $a = 23$ and $b = 0.01$ for liquids, $a = 16$ and $b = 0.01$ for polymers, and $a = 4.5$ and $b = 0.01$ for crystals.

Owing to the different values of the parameter a for the above three groups of substances, the transition from one group to another may involve a change in τ_2 and I_2 in the same direction, for example, in the fusion of naphthalene (the dashed curve N in Fig. 9) or in the crystal–glass transition for Marlex-50 polyethylene (the dot–dash curve M in Fig. 9), where both τ_2 and I_2 increase.

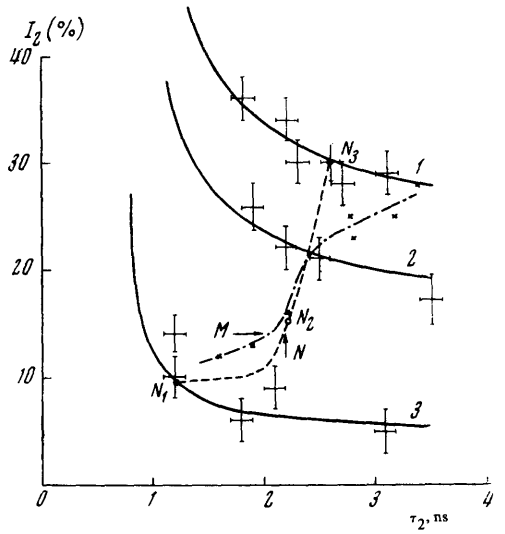

Figure 9. $I_2-\tau_2$ correlation curves for liquid and amorphous materials, polymers, and crystals[64]: 1) liquids and amorphous materials (fused quartz, polystyrene, isopropyl alcohol, liquid naphthalene, benzene, and cyclo-octatetraene); 2) polymers [poly(vinyl chloride), polyethylene, poly(methyl methacrylate), Teflon]; 3) crystals (phenanthrene, naphthalene, stilbene, polyoxymethylene, and Sb_4O_6). N—heating and fusion curve for naphthalene (30 to 80.2°C); M—heating (between −196° and 142°C) and glass-formation curve (−20°C) for crystalline Marlex-50 polyethylene.

The factors which influence the probability of the formation of positronium in solids and its lifetime include also radiation effects and therefore their study must be regarded as one of the promising applications of positron methods.

The after-effects of radiation which may influence the annihilation of positrons are extremely various—they include the appearance of all possible radiation-induced effects (the possibility of the study of which by annihilation methods has been examined[65]), the generation of F-centres to which the annihilation of positrons proved to be extremely sensitive[24], the formation of ions and paramagnetic centres, etc.

The first experiments on the influence of radiation on the characteristics of the annihilation of positrons were performed as early as 1957–1958.[56] Subsequently it was shown that, as a result of the irradiation of solid anthracene with neutrons, positronium begins to form, as in liquid anthracene and in contrast to non-irradiated crystals, both τ_2 and I_2 increasing with radiation dose[67], although τ_2 does not in fact reach the value characteristic of liquid anthracene.

The wide variety of the effects of radiation is shown, for example, by the fact that, following the γ-irradiation of Teflon, the opposite behaviour is observed—τ_2 and I_2 decrease with radiation dose[68,69], which has been attributed to the increase of the degree of crystallinity of Teflon on irradiation and the quenching of positronium by the free radicals formed.

Indeed it has been shown[65] that the variation of τ_2 in the γ-irradiation of Teflon is correlated with the radical concentration determined by ESR. At the same time, according to the data of Indian investigators, the breakdown of the microcrystals and the increase of the proportions of low-density amorphous regions in irradiated polyethylene lead to an increase of τ_2,[70] while the rupture of benzene rings in polystyrene on neutron irradiation leads to a decrease of I_2,[71] since the formation of positronium in compounds of this kind is in fact mainly localised at aromatic rings.

Recently the positron method was applied in Japan (Tabata and coworkers[19,72]) in observations on radiation-induced solid-phase polymerisation of a number of monomers (acrylonitrile, methacrylonitrile, acetaldehyde, N-vinylcarbazole, and dimethyl and diethyl itaconates).

A number of factors influencing the formation and destruction of positronium arise in the course of polymerisation. As the polymeric chain grows, the number of defects and dislocations in the crystalline monomer increases—the systems of monomeric units contract after polymerisation. All these factors are responsible for a general increase in free volume, which alone would lead to an increase of τ_2. At the same time, the presence of terminal active centres (usually paramagnetic) of the growing polymeric chains at the free volume boundaries is responsible for a multiplicity of ways in which positronium can be destroyed and thus shortens its lifetime—together with pick-off annihilation there is the possibility of ortho–para conversion and positronium capture. Ultimately fairly different types of relation between τ_2 and I_2 may arise. With increase of radiation dose D from 5 to 20 Mrad, a correlation similar to that described by Thosar et al.[64] is observed for N-vinylcarbazole—initially τ_2 increases and I_2 falls and then (starting with $D \simeq 13$ Mrad) the opposite variation is observed, τ_2 decreasing and I_2 increasing. On the other hand, in dimethyl itaconate an increase of the degree of polymerisation is accompanied by an appreciable increase of the probability of the formation of positronium (Fig. 10), while τ_2 remains almost constant.

Apart from radiation-induced polymerisation, the positron method has recently been applied for the first time to another kinetic problem in polymer chemistry, namely in the study of the ageing of poly(vinyl chloride) due to thermal oxidation[73]. Prolonged heating of this polymer leads to a sharp reduction of τ_2, while I_2 increases with temperature. In the vicinity of the phase transition of the polymer at 195°C, τ_2 passes through a minimum ($\tau_2^0/\tau_2 \simeq 3$) and I_2 passes through a very sharp maximum ($I_2/I_2^0 \simeq 2$, where τ_2^0 and I_2^0 correspond to room temperature). The decrease of τ_2 was compared with the accumulation of free radicals detected by ESR and with the weight loss by the polymer owing to the elimination of HCl. The clear correlation between the above quantities has been interpreted[73] as confirmation of the mechanism of the quenching of positronium by combination with radicals or double bonds, or by ortho–para conversion, or finally by the interaction of Ps with HCl or HCl_2^-.

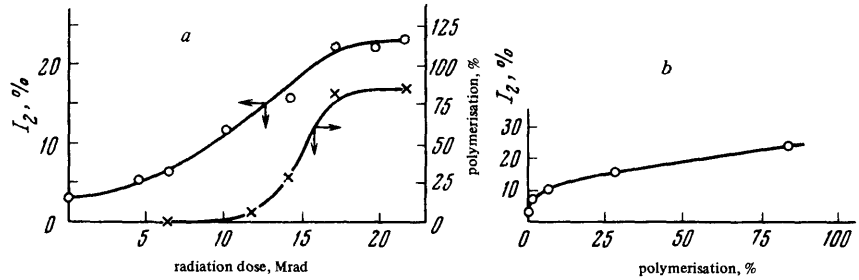

Figure 10. *a*) Variation of I_2 (%) and percentage polymerisation with radiation dose (^{60}Co γ-radiation) in the radiation-induced solid-phase polymerisation of dimethyl itaconate[69]; *b*) variation of I_2 with percentage polymerisation of dimethyl itaconate[69].

Thus the first, not altogether fully defined possibilities of the new chemical applications of positron methods have been outlined, namely in observations on the kinetics of solid-phase reactions accompanied by marked changes in the structure of the solid.

6. Characteristics of the Annihilation of Positrons in Porous Media

In conclusion of the section on positronium, we shall consider the most interesting observations on the characteristics of the annihilation of positrons in highly dispersed media and the wide variety of prospects for the employment of the results of these observations.

As already mentioned, in the study of the positron annihilation spectra in powdered oxides (Al_2O_3, MgO, SiO_2), Paulin and Ambrosino[41] observed two long-lived components—with a lifetime τ_2 of the order of several nanoseconds, characteristic of pick-off annihilation in the solid, and τ_3 of the order of several tens of nanoseconds, up to $\tau_T^0 = 1.4 \times 10^{-7}$ s. With increase of the degree of dispersion of the powders, i.e. with increase of the proportion of free volume $v_f/v = (\rho_0 - \rho)/\rho_0$ (ρ_0 is the density of the monolithic substance and ρ its density), an increase was observed in the intensity of the most long-lived component I_3 owing to the decrease of the contribution by the pick-off component I_2. An example is provided by Table 1.

The τ_3 component arises as follows. The positrons retarded in the porous solid can ultimately form Ps atoms. Part of these atoms undergo pick-off annihilation in the solid itself, while others emerge into the free volume between the particles. The probability of the capture of such atoms on impact against the surface of the particles is very low—they are much more likely to undergo repeated reflection (albedo) being ultimately destroyed in the pore volume (in flight)—either by pick-off annihilation in the pores filled with gas or in consequence of spontaneous annihilation. The relative contributions of these two processes may be assessed from the fact that the value of τ_3, reaching 140 ns in a vacuum, decreases by a factor of 2 when experiments with SiO_2 are performed in air or oxygen at the normal pressure.

Brandt and Paulin[42] calculated from the data of Paulin and Ambrosino[41] the characteristics of the diffusion of Ps atoms in the particles of solid oxides—the diffusion coefficients in the range between $D = (5.8 \pm 1.9) \times 10^{-5}$ (SiO_2) and $D = (1.4 \pm 0.7) \times 10^{-3}$ (MgO) cm^2 s^{-1}, the activation energy for diffusion $E = 700 \pm 370$ cal mole^{-1}, and the overall paths traversed before annihilation $\lambda = \sqrt{2D\tau}$ (46 ± 7 Å in SiO_2 and 270 ± 80 Å in MgO—for orthopositronium). Apart from the powdered oxides enumerated above, Bartenev et al.[43] observed the τ_3 component also in powdered BeO but not in the sintered oxide. Observations on the angular correlation of the annihilation quanta demonstrated the presence of a narrow component in BeO, MgO, SiO_2, and Al_2O_3 powders and its absence in monolithic specimens of these oxides. One cannot rule out the possibility that the results of the above investigations[41-43] explain the high probability of 3γ-annihilations in certain alkali metal halides and particularly in BeO and MgO, discovered and investigated by Italian workers[74,75] (see also Refs. 1 and 63), which for a long time appeared to be a puzzling anomaly. In all probability, these findings are not due to the molecular properties of the materials investigated but to their high degree of dispersion—indeed the entire anomaly in the counting rate of the 3γ-coincidences for MgO disappeared on passing to single crystals[76].

Table 1. Characteristics of the annihilation of positrons in highly dispersed oxide powders.

Substance	Specific surface m^2 g^{-1}	ρ, g cm^{-3}	τ_2, ns	I_2, %	τ_3, ns	I_3, %
SiO_2	50	0.3	1.77±0.2	28±2	140±4	4±0.5
SiO_2	180	0.06	1.89±0.2	10.7±0.8	142±3	11.6±1

The extension of the range of substances investigated by positron methods in a highly dispersed state constitutes an urgent problem. Possibly the formation of positronium in fine-pored specimens will be detected also in substances where its existence has been hitherto ruled out—for example, metals.

Other consequences of the above studies[41-43] are also of interest—the observations of the reactions of positronium with atoms and molecules adsorbed on surfaces or

filling adsorbent pores and the development of positron methods for the investigation of the physical chemistry of surface phenomena, adsorption, and heterogeneous catalysis are promising.

The probability of the capture of hydrogen atoms (ϵ_H) on impact against various surfaces is known to vary within extremely wide limits—from $\epsilon_H = 10^{-4}-10^{-5}$ for SiO_2 to $\epsilon_H \simeq 1$ for graphite and $ZnO.Cr_2O_3$.[77] Moreover, ϵ_H depends markedly on temperature: $\epsilon_H \propto \exp(-E/RT)$, where $E = 9000-13\,000$ cal mole^{-1}.

There is reason to expect similar relations also for positronium and comparison of data for positronium, with its exceptionally low mass and large de Broglie wavelength, and hydrogen is of particular interest.

The interest becomes even greater in connection with the recent theoretical demonstration by Kagan[78] that a neutron can also give rise to a long-lived bound state in porous substances: the porous medium behaves as a kind of "sponge" which sorbs neutrons into a bound state with a binding energy of the order of 10^{-7} eV and a characteristic lifetime, which reaches tens and hundreds of seconds at the helium temperature.

The annihilation spectra of positrons in silica gel, alumina gel, and aluminosilicate catalyst specimens of moderate porosity, having specific surfaces in the range 130–230 m^2 g^{-1} and an average pore radius of about 40 Å, were recently compared[79] at a number of points on the water desorption isotherm at room temperature. As long as the water vapour pressure p is close to the saturated vapour pressure p_S ($p/p_S \gtrsim 0.3$), the τ_3 component in the time spectra is altogether absent, since the pore volume is entirely filled by liquid water. On the other hand, in the region of low values of p/p_S, corresponding to a more or less depleted monolayer of physically adsorbed water, a correlation was noted between the catalytic activity of the specimens in the dealkylation of cumene (i.e. the strength of the Brönsted acid centres) and the values of τ_3. For catalytically inactive silica gel and alumina gel, the desorption of water with decrease of p/p_S hardly affected τ_3, while for the aluminosilicate catalyst τ_3 decreased appreciably under these conditions, apparently due to the reaction $H^+ + Ps \rightarrow H + e^+$, which is energetically possible only for non-hydrated protons weakly bound to the surface of the pore, i.e. only for strong proton acid centres. The effect of the desorption of water on τ_3 in the region of low values of p/p_S for catalyst specimens containing sodium cations was much weaker and the values of τ_3 themselves were higher. Indeed the reaction $Na^+ + Ps \rightarrow Na + e^+$ is endothermic ($Q = -1.63$ eV) and therefore it could not play an appreciable role. Thus a change in the probability of the capture of positronium ϵ_{Ps} as a function of the state of the surfaces of adsorbents and catalysts was demonstrated[79].

The observation of the annihilation of positrons in porous materials in an atmosphere of different gases is frequently more convenient than experiments with the gases themselves—the volume of the highly dispersed system necessary for the effective retardation of positrons is much smaller than for pure gases and the positronium atoms traversing the labyrinth between the grains of the highly dispersed powders do not leave the field covered by the counters recording the annihilation γ-quanta up to the very instant of annihilation.

These advantages were fully reflected in the work of Chuang and Tao[80], who observed the annihilation of positrons in iodine and carbon tetrachloride adsorbed on silica gel. In our remark in subsection 4 that a decrease of I_2 for a constant value of τ_2 corresponds to "pure" inhibition of the formation of positronium and a decrease of τ_2 for a constant I_2 corresponds to its "pure" quenching, we simplified the situation somewhat.

If fast positronium atoms enter into an endothermic threshold reaction, which is possible only up to their retardation and "thermalisation" and leads to instantaneous annihilation, the annihilation spectrum shows an additional component with a short lifetime virtually indistinguishable from τ_1. The conversion of some of the orthopositronium atoms into this component is detected as a decrease of I_2—in other words the quenching of fast Ps atoms is recorded as apparent inhibition. This type of apparent inhibition, due to the reaction $Ps + Cl_2 \rightarrow PsCl + Cl$, was in fact observed by Tao[81] after the addition of chlorine to argon. The possibility of distinguishing true quenching agents and inhibitors on the basis of their influence on annihilation in the adsorbed state has been demonstrated[80]. The authors[80] believe that the adsorption of the quenching agent on the surface of silica gel alters significantly the potential for the interaction of Ps with the surface or, using the terminology adopted above, by increasing the probability of the capture of positronium ϵ_{Ps} it thereby shortens τ_3. At the same time the adsorption of the quenching agent should lower also the value of I_3, since the presence of the quenching agent on the surface of the adsorbent reduces the probability of the liberation of Ps atoms from the bulk of the silica gel globules into pores. Both these effects, the decrease of τ_3 and I_3 with increasing amount of the adsorbed substance, have been observed for iodine, which is therefore believed[80] to be a true quenching agent for positronium. Different results have been obtained for the "pseudoinhibitor" carbon tetrachloride—over a wide range of its concentrations (up to the saturation of a monolayer on the surface of silica gel), I_3 decreased, while τ_3 remained unchanged. This implies that the presence of carbon tetrachloride on the silica gel surface does not increase ϵ_{Ps}.

The total experimental data obtained by Paulin and Ambrosino[41] and subsequent investigators for the annihilation of positrons in porous media and also the relevant theoretical considerations indicate the possibility of creating effective highly dispersed positronium sources (it must be stressed that these are in fact positronium sources and not simply positron sources), which are particularly promising for the study of chemical reactions in gases over a wide range of temperatures and pressures.

III. MUONIUM

1. The Nuclear-physical Characteristic of the μ^+-Meson and Muonium

Muonium (atomic system consisting of a μ^+-meson as the central nucleus and an electron) is a hydrogen-like atom—a model light analogue of atomic hydrogen. The μ^+-meson (an elementary particle) (mass 206.76 $m_e \simeq \frac{1}{9} m_p$; lifetime with respect to the decomposition into a positron, a neutrino, and an antineutrino 2.2×10^{-6} s; spin 1/2; magnetic moment 8.89 nuclear magnetons) arises in the decomposition of π^+-mesons formed in charged-particle accelerators as a result of nuclear reactions above the meson generation threshold. It is significant that in the decomposition of π^+-mesons in flight the resulting μ^+-mesons are fully polarised longitudinally in consequence of the non-conservation of parity in the $\pi\mu e$ decomposition,

i.e. the spin of the ejected μ^+-meson is oriented in opposition to the direction of its motion. The ejection of the position in the μe decomposition ($\mu^+ \rightarrow e^+ + \nu + \tilde{\nu}$) takes place preferentially in the direction of the spin of the meson and there is a steric asymmetry with the impulse of the positron.

In the theory of the two-component neutrino[82-84], the asymmetry coefficient c, defined as the ratio of the difference between the "forward" and "reverse" decompositions (along and in opposition to the initial direction of the spin of the μ^+-meson) to their sum, averaged over the entire energy spectrum of the decomposition positrons, is 1/3 (polarisation $P = 1$) for fully polarised μ^+-mesons. The change in the polarisation of μ^+-mesons in the medium as a function of the experimental conditions is a characteristic of the interactions with matter.

When the meson is retarded to velocities of the order of that of atomic electrons of the medium, a charge-transfer stage ensues, which is completed by the capture of an electron and the formation of a stable μ^+e^- atomic system, i.e. a muonium atom (ionisation potential 13.539 eV, Bohr radius 0.532 Å, mass $207.76m_e$). Since the initial direction of the spin of the μ^+-meson is arbitrary, the formation of muonium with parallel and antiparallel orientations of the meson and electron spins is equally probable (the $^3S_1$, $m = 1$ triplet state with a population of 1/2 and superposition of the $^1S_0$, $m = 0$ and $^3S_1$, $m = 0$ states with populations of 1/4 in each case). In the first case the spin of the μ^+-meson in the absence of external perturbations retains its initial polarisation in the course of the lifetime of the meson; in the second case there are harmonic oscillations between the (1,0) and (0,0) states, the frequency of which (ω_0) is determined by the hyperfine splitting energy ΔW ($\omega_0 = \Delta W/\hbar = 2.804 \times 10^{10}$ s^{-1}). Thus in a period of the order of about 10^{-10} s the para-state of muonium undergoes irreversible depolarisation and the overall asymmetry coefficient decreases to the level of 1/2 of the initial value. Processes involving the exchange of electrons having opposite spins with the medium (conversion) can lead to further depolarisation of the μ^+-meson down to zero.

We may note that the "thermalisation" time of the μ^+-meson in condensed media and gases at a pressure greater than 50 atm does not exceed $10^{-12}-10^{-13}$ s, which is significantly less than the characteristic depolarisation time ($1/\omega_0$). Consequently depolarisation during the retardation time is insignificant; repeated charge transfers in the inhibition of the meson do not lead to a change of its spin and the probability of the formation of the ortho- or para-state of muonium depends only on the last electron capture step.

In fairly strong longitudinal (in the direction of the spin of the μ^+-meson) external magnetic fields, the interaction of the magnetic moments of the meson and the electron in the muonium atom disappears; both populated states (+1/2, +1/2 and 1/2, −1/2) retain the initial polarisation of the μ^+-meson. A critical condition for which the magnetic energy of muonium in the external magnetic field is equal to the hyperfine splitting energy is that $H_0 = \Delta W/2(\mu_e - \mu_\mu) = 1585$ G. Since ΔW depends on the cube of the distance between the interacting magnetic moments [$\Delta W = f(r^{-3})$], it is clear that H_0 is extremely sensitive to changes in the distribution of electron density in the molecule incorporating muonium. The last factor allows an additional identification of the form in which muonium is present in the medium. In transverse magnetic fields there is a Larmor precession of the spin (or a system of spins) with a frequency determined by the magnetic moment and the spin. Since the magnetic moment in the triplet state of muonium is determined largely by the magnetic moment of the electron and the spin is unity, the precession frequencies of the μ^+-meson and triplet muonium differ by a factor of about 103 and can be readily distinguished experimentally.

A typical apparatus for the measurement of the asymmetry coefficient for the angular distribution of μe-decomposition positrons (Fig. 11*a*) incorporates two telescopes comprising two scintillation counters, each recording the passage of charged particles. The arrest of a μ^+-meson by the target *5* is recorded by the counters *1* and *2* in the absence of coincidences with the counters *2* and *3*, giving rise to a "start" pulse signal. In the decomposition of a μ^+-meson on the target, positrons are recorded by the counters *3* and *4*, giving rise to a "stop" signal in the absence of coincidences with the counters *2* and *3*. The pulses produced according to the $12\overline{23}$ and $34\overline{23}$ scheme control the operation of the time–amplitude converter.

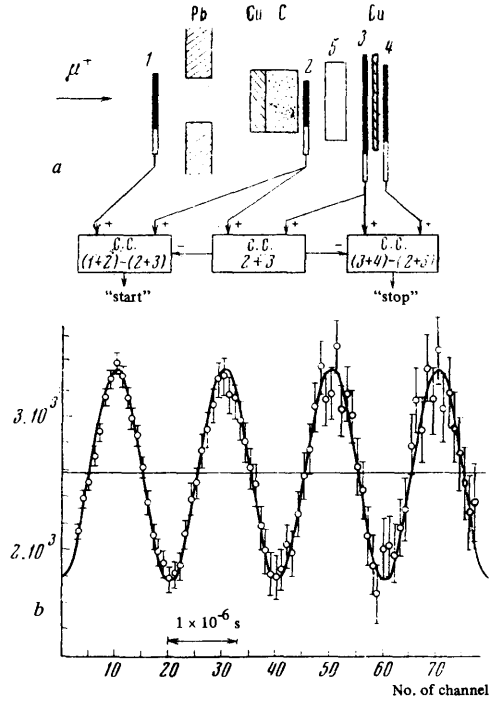

Figure 11. *a*) A typical arrangement of the apparatus for the measurement of the asymmetry coefficient for the angular distribution of μe decomposition positrons [1)–4) scintillation counters; 5) target; C. C.—coincidence circuits]. The magnetic coils are not shown in the Figure. *b*) The precession curve in bromoform. The numbers of readings in the channels are corrected for the background and the exponential decomposition of μ^+-mesons.

The latter transforms the time interval between the pulses into a variable amplitude signal recorded by a multichannel analyser. The use of a transverse magnetic field of the required strength leads to the modulation of the exponential decomposition curve for the Larmor precession of the μ^+-meson or triplet muonium. After the correction of experimental data for the random coincidence background and the decomposition of the μ^+-meson, a

typical precession curve has the form shown in Fig. 11*b* (in this case the magnetic field strength was 50 G and the precession period about 1.5×10^{-6} s).

2. Physicochemical Principles of the Interactions of Muonium

a. Kinetic scheme. Calculation of the rate constants for the chemical reactions of muonium. In the majority of cases the behaviour of muonium (Mu) described is complicated by its involvement as a hydrogen-like atom in chemical reactions with the molecules of the medium, with formation of fairly strong chemical bonds in a manner analogous to the reactions of atomic hydrogen. In view of their wide occurrence, the reactions of atomic hydrogen have been investigated in detail by chemical kinetic methods in the course of several decades (see, for example, the relevant fundamental monographs[85,86]).

The incorporation of muonium in the molecule after chemical reaction alters fundamentally the factors governing its depolarisation in the medium[87,88]. In the reaction with an unsaturated covalent compound (for example, $C_8H_{18} + H \rightarrow H_2 + C_8H_{17}^{\cdot}$; the dot designates the unpaired electron of the radical product), which is typical for atomic hydrogen, the hydrogen atom enters into the composition of a molecule with a closed diamagnetic shell, where the electron spins are compensated in pairs. A similar reaction involving muonium has the same consequences. Thus the magnetic field created by electrons at the point where the μ^+-meson is located in the molecule is zero. Under these conditions, there is no coupling of the magnetic moments of the meson and the electron and depolarisation by the above process does not occur. However, the interaction with the magnetic moments of the adjacent nuclei of the molecule is possible, provided of course that the latter are not even–even. Under real conditions, allowance for the rotational states of molecules, in particular for gases and liquids, leads to a virtually negligible contribution by depolarisation factors to the formation of the diamagnetic electron shell; for solids, this depolarisation mechanism can play an appreciable role only when $r \lesssim 1$ Å.

It is significant that the Larmor precession for muonium incorporated in the molecule occurs at a frequency corresponding to a free μ^+-meson. Indeed the absence of magnetic interactions between the meson and the electrons of the diamagnetic shell of the molecule corresponds to an independent interaction of the magnetic moment of the μ^+-meson with the external field. This factor resolves the apparent contradiction in the earlier experimental studies, where the search for the precession of triplet muonium was unsuccessful, but the precession of the spin of the μ^+-meson was observed[89,90].

Thus the involvement of muonium in the composition of a diamagnetic molecule leads to the "freezing" of the depolarisation processes at a level which depends on the rate of reaction of muonium with the medium. For a fairly short characteristic time of the chemical reaction τ, the para-state of muonium (Mu^S) is involved in the process, which prevents depolarisation when $\tau \ll 1/\omega_0$; then precession at the frequency of the free μ^+-meson (the meson component) has the maximum amplitude. With increase of τ, there is a possibility of partial or complete depolarisation of Mu^S; the probability of the reaction of triplet muonium (Mu^T) and Mu^S which has retained its polarisation corresponds to the observation of the meson precession with an amplitude depending on the value of τ. Finally, for large values of τ (for example, $\tau > \tau_{\mu^+}$), the absence of chemical interactions makes it possible to observe the precession of the frequency of triplet muonium (the muonium component). Consequently, a qualitative treatment yields the relation between the rate of the chemical reaction of muonium and the experimental polarisation at the corresponding (meson or muonium) frequency. We may note that, in the absence of conductivity electrons, the conversion exchange is appreciably suppressed, since it apparently requires an energy expenditure on the scale of the triplet excitation energy of molecules and for covalent compounds the rate of such exchange does not exceed the rate of decomposition of the μ^+-meson.

We shall now formulate the characteristics of the muonium method for the investigation of chemical processes. Firstly, one of the characteristic conditions associated with the specific features of the experimental method is the presence throughout the bulk of the test substance only of single muonium atoms. Thus the reaction kinetics are studied in the initial stage when there are no complications associated with the formation and accumulation of secondary reaction products in the bulk phase. Secondly, the use of nuclear-physical constants as independent time standards permits the determination of the absolute rate constants for a wide range of fast reactions. Thirdly, the observation of the behaviour of the spin and the magnetic moment of the μ^+-meson allows the study of the factors determining the spin interactions during the process or at steady state, which is one of the unique characteristics of the method. Fourthly, the typical independence of the recording method of the external experimental parameters significantly increases the scope of the investigation; in particular, the method becomes universally applicable to various states of aggregation of matter.

From the standpoint of the experimental characteristics associated with the method (the observation of the meson and muonium precession frequencies in an external magnetic field), it is desirable to classify in appropriate groups the products obtained as a result of the reaction. We shall include in the first group molecules which incorporate muonium and have a diamagnetic electron shell; the second group includes reaction products with an unpaired electron (radicals). In the absence of an effect of the magnetic moments of the surrounding nuclei, the products of the first group are observed at the meson frequency. We may note that, in the reaction of muonium with a molecule having different substituents, parallel pathways are possible, but, since the molecular products are indistinguishable in terms of experimental technique (in the concrete example of the interaction of muonium with chloroform, MuH and MuCl are formed, the precession occurring at the meson frequency in both cases), the probability of the formation of the sum of the molecular products is determined. In the formation of radical products incorporating muonium (for example in the reaction involving addition to a multiple bond: $Mu + H_2C = CH_2 \rightarrow H_2MuC-CH_2^{\cdot}$), the interaction of the magnetic moments of the μ^+-meson and the unpaired electron (complicated by the change of the average effective distances and the nature of the delocalisation of the electron in the molecule) persists. In this case there is no precession at the meson frequency, but the "latent" polarisation may be determined either from its restoration in longitudinal magnetic fields in consequence of a change in H_0 or from the competition between various reactions of muonium in

homogeneous mixtures of compounds (the method of competing acceptors).

We shall now consider a kinetic scheme for the reactions of muonium with matter[88,91]. The time interval between the individual steps involving the entry of a μ^+-meson into the space occupied by the test compound is much longer than its lifetime. Consequently the number of mesons in the system is unity (the time interval between the decomposition of a μ^+-meson and the entry of the next particle is insignificant, since no processes occur during this interval) and the statistical conditions for a steady state are fulfilled; the rates of appearance and loss of reaction intermediates are then equal. In the general case it is necessary to take into account the following competing processes: reactions with formations of molecular and radical products, reactions involving conversion spin exchange with the electrons of the molecules of the medium, irreversible depolarisation of Mu^S in consequence of spin flip, and the decomposition of the μ^+-meson. We may note that any chemical reactions of a depolarised muonium atom (Mu^D) naturally yield products with an isotropic angular distribution of decomposition positrons. The interaction of muonium with hydrogen-containing compounds can be formulated schematically as follows:

$$\begin{aligned}
&(1).\ Mu^T\ (Mu^S) + RH \xrightarrow{k_1} MuH + R^{\cdot}\ ,\\
&(2).\ Mu^T\ (Mu^S) + RH \xrightarrow{k_2} RMuH^{\cdot}\ ,\\
&(3).\ Mu^T\ (Mu^S) + RH \xrightarrow{k_3} Mu^S\ (Mu^T) + RH\ , \qquad (1)\\
&(4).\ Mu^S \xrightarrow{k_4} Mu^D\\
&(5).\ Mu^T\ (Mu^S, MuH, RMuH^{\cdot}, Mu^D) \xrightarrow{k_5} e^+ + \nu + \tilde{\nu}\ .
\end{aligned}$$

By fitting the function $\exp(-\lambda t)$ to the average polarisation of Mu^S ($1/\omega_0 t.\sin\omega_0 t$), we find the depolarisation rate constant $k_4 = \frac{2}{\pi}\omega_0$; the decomposition rate constant is $k_5 = 1/\tau_{\mu^+}$.

Using the method of steady states, we obtain expressions relating the rate constants for reactions (1)–(5) to the experimental asymmetry coefficients c_1', c_2', and c_3' determined under various conditions:

$$\frac{2k_5 + 2(k_1+k_2)[RH]}{k_4}\cdot\frac{1}{1+\dfrac{2k_3[RH]}{(k_1+k_2)[RH]+k_5}} = \frac{c_1'}{fc-c_1'}\ , \qquad (2)$$

$$\frac{k_1[RH]}{k_2[RH]+k_5+\dfrac{k_4}{2+\dfrac{k_4}{(k_1+k_2)[RH]+2k_3[RH]+k_5}}} = \frac{c_2'}{fc-c_2'}\ , \qquad (3)$$

$$\frac{k_2[RH]+k_5}{k_1[RH]+\dfrac{k_4}{2+\dfrac{k_4}{(k_1+k_2)[RH]+2k_3[RH]+k_5}}} = \frac{c_3'}{fc-c_3'}\ , \qquad (4)$$

where f is the degree of polarisation of the initial beam of μ^+-mesons, which depends on the kinematic conditions of the formation of the meson beam in accelerators. Formula (2) corresponds to the case where the depolarisation of the μ^+-meson is due solely to reaction (4) and characterises the overall reactivity of the compound via all reaction pathways. Formulae (3) and (4) are applicable to experiments by the precession method in transverse magnetic fields and describe the meson and muonium components respectively. We may note that, for reaction rates comparable to ω_0, the inaccuracy of the approximation employed for the average polarisation of Mu^S limits the applicability of the formulae. In this case it is necessary to take into account the oscillatory nature of the depolarisation of Mu^S when reactions (3) and (5) are neglected owing to their small contributions[92].

The statistical accuracy of the determination of the absolute rate constants for the reactions of muonium depends on the magnitude and accuracy of the determination of the asymmetry (polarisation) coefficients. The current experimental techniques ensure an accuracy in the determination of the reaction rate constants for a pure compound reaching under favourable conditions 10–20%.

Table 2. Rate constants for the reactions of muonium.

Compound	Formula	k_1	k_2
Cyclohexane	C_6H_{12}	$(2.4\pm0.2)\cdot10^9$	—
Methanol	CH_3OH	$(5.6\pm1.1)\cdot10^8$	—
Octane	C_8H_{18}	$(2.9\pm0.4)\cdot10^9$	—
Chloroform	$CHCl_3$	$(4.2\pm1.4)\cdot10^9$	—
Benzene	C_6H_6	$(3.0\pm1.1)\cdot10^8$	$(3.1\pm0.4)\cdot10^9$
Bromoform	$CHBr_3$	$(1.1\pm0.2)\cdot10^{10}$	—
Diphenylpicrylhydrazyl (DPPH)		$(7.6\pm2.2)\cdot10^{10}$	

With a correct choice of the second solution component, the method of competing acceptors makes it possible to obtain the maximum accuracy in all necessary cases; moreover, this method allows the detection, from the results of the measurements of the meson frequency, of radical product formation processes.

b. Experimental data for a number of compounds. We shall examine one specific example[92,93] the determination of the absolute rate constants for the reaction of muonium by the method of competing acceptors. In order to observe the precession in a transverse magnetic field at the meson frequency, measurements were made of the asymmetry coefficients for individual substances (listed in Table 2) and their binary solutions. Some of the data obtained for the variation of the asymmetry coefficient with the concentration of the substance in solution are presented in Fig. 12. We may note that for heterogeneous mixtures, where the competition between parallel reactions is appreciably suppressed, or in the absence of chemical interactions, the dependence of the asymmetry coefficient on the concentration of the mixture components should be linear, while for competing acceptors the form of the analogous relation is determined by the ratio of the overall (via pathways involving the formation of both molecular and radical products) reactivities of the compounds. The curve for $C_6H_6-CHBr_3$ is typical in this sense (Fig. 12*a*).

The form of the curve for the $C_6H_6-CH_3OH$ mixture is important (Fig. 12*b*)—despite the lower asymmetry coefficient at the meson frequency for benzene, the overall consumption of muonium in the interaction with benzene is higher than in the interaction with methanol, which leads to a deviation of the curve relating the asymmetry coefficient to concentrations towards smaller values. This is evidence of the predominance of the "latent" polarisation due to the radical pathway of the reaction of muonium with benzene involving the formation of $C_6H_6Mu^{\cdot}$.

Quantitative calculation for the system as a whole yielded the reaction rate constants (in litre $mole^{-1}$ s^{-1}) listed in Table 2. These data may be used to calculate the

rate constants for the corresponding reactions of atomic hydrogen, provided that the activation energies for the processes are known (see below).

c. Gas-phase reactions of muonium. The study of the reactions of muonium in the gas phase is of considerable interest, since it permits a direct comparison with the gas-phase kinetics involving atomic hydrogen.

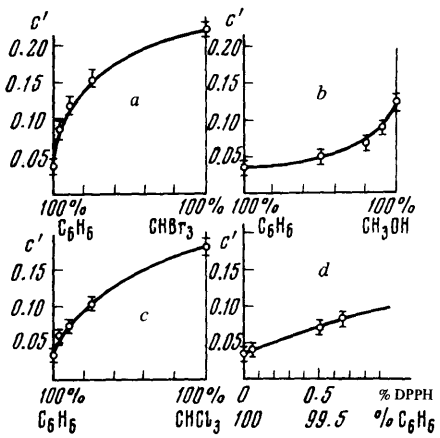

Figure 12. Variation of the asymmetry coefficients at the meson frequency with the concentration of the solution components (in mole %): *a*) $C_6H_6-CHBr_3$; *b*) $C_6H_6-CH_3OH$; *c*) $C_6H_6-CHCl_3$; *a*) C_6H_6–DPPH.

The presence of an inert buffer gas, which is necessary for the retardation of μ^+-mesons, permits the use of low concentrations of the test substance, i.e. a significant reduction of the rate of reaction, and the usual kinetic curves for the decrease in the amount of muonium with time at a given acceptor concentration may be studied. Calculation of the reaction rate constants is in this case trivial—the characteristic time of depolarisation (equivalent to the decrease of the concentration of muonium) is equal to the duration of the chemical reaction and is inversely proportional to the rate of reaction (V) with the acceptor at a concentration [Ac]:

$$\tau = \frac{1}{V} = \frac{1}{k\,[\mathrm{Ac}]} \quad . \qquad (5)$$

The calculations quoted below are based on the experimental data of Hughes and coworkers[94,95]. The inert buffer gas employed was carefully purified argon under a pressure of about 50 atm to which small admixtures of the test compounds (NO, O_2, NO_2, C_2H_4, H_2, N_2, etc.) were added. As an example, Fig. 13 presents the variation of the muonium depolarisation factor with time for various concentrations of ethylene at room temperature. The linear relation between the rate of depolarisation and the concentration of ethylene, which is evident from Fig. 13 (compare curves *1* and *2*), is evidence that the rate-limiting stage of the process is the formation of the radical $C_2H_4Mu^{\cdot}$, in which the depolarisation of the μ^+-meson takes place owing to the exchange interactions of the unpaired electron.

Standard kinetic treatment of the data in Fig. 13 leads to the characteristic times for the decrease of the polarisation of muonium (by a factor e) $\tau = (8.4 \pm 2.2) \times 10^{-6}$ s (curve *1*) and $\tau = (2.7_5 \pm 0.7) \times 10^{-6}$ s (curve *2*). The corresponding reaction rate constants $k = (1.7_5 \pm 0.4_5) \times 10^9$ litre mole^{-1} s^{-1} and $k = (1.4 \pm 0.4) \times 10^9$ litre mole^{-1} s^{-1} agree within the limits of experimental error. By combining the data, we have

$$K(\mathrm{Mu} + C_2H_4) = (1.6 \pm 0.3) \cdot 10^9 \text{ litre mole}^{-1}\,\text{s}^{-1}\,.$$

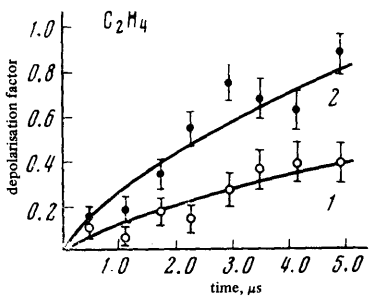

Figure 13. Kinetic curves for the decrease of polarisation (increase of the depolarisation factor) for muonium with time in the reaction with ethylene (according to Mobley et al.[94]): 1) $[C_2H_4] = 4.1 \times 10^{16}$ mol. cm^{-3}; 2) $[C_2H_4] = 15.8 \times 10^{16}$ mol. cm^{-3}.

The calculation for the analogous reaction of atomic hydrogen (according to collision theory, the rate constant ratio is about 3; in view of the low activation energies for the reactions of H and Mu with C_2H_4, it is not necessary to allow for the difference between them) yields the

$$k(\mathrm{H} + C_2H_4) = (5.3 \pm 1.0) \cdot 10^8 \text{ litre mole}^{-1}\,\text{s}^{-1},$$

in satisfactory agreement with the literature data[96,97] for the kinetics of the gas-phase reaction of H with C_2H_4 at 18°C, which gave

$$K(\mathrm{H} + C_2H_4) = (5.1 \div 7.5) \cdot 10^8 \text{ litre mole}^{-1}\,\text{s}^{-1}.$$

Experiments in longitudinal magnetic fields[95] showed that the strength of the critical magnetic field for NO and O_2 is consistent with the value of H_0 for the free muonium atom, confirming thereby the hypothesis of the dominant role of conversion processes in reactions with the given compounds. At the same time the critical field for C_2H_4 is significantly weaker (about 100 G), which is evidence of an increase of the effective distance between the meson and the unpaired electron as a result of the formation of the ethyl radical $C_2H_4Mu^{\cdot}$.

d. Temperature variation of the rates of the reactions of muonium. The activation energy for the process is one of the most important criteria of the reactivity of compounds. Having determined by the method described above the rate constants for the reactions at different temperatures, it is possible to obtain with an adequate statistical accuracy (which depends, in particular, on the width of the temperature range) the principal parameters of the chemical reactions of muonium

(the pre-exponential factor, the steric factor, and the activation energy).

Similar measurements have been made[98] for the substances listed in Table 3. Particular attention has been devoted to the phase transition point. For organic compounds, the continuous variation of the asymmetry coefficient during the change in the state of aggregation permitted the determination of the activation energies for the corresponding reactions of muonium. It is striking that, for the compounds investigated, the activation energies are low and do not exceed 1.5 kcal mole^{-1}. It is probably necessary to take into account the possible decrease of the activation energies for substitution reactions involving atoms with a smaller mass[99].

Table 3. Activation energies for the reactions of muonium.

Compound	Temp. range, °K	E, kcal mole^{-1}
C_6H_{12}	303÷77	1410±50
C_6H_5Br	303÷80	970±80
$CHBr_3$	303÷77	⩾670±50
H_2O (liq.)	363÷273	135±320
H_2O (solid)	273÷77	10±30

The abrupt change of the asymmetry coefficient for the water–ice phase transition (Fig. 14), corresponding to a decrease of the reaction rate constant by two powers of 10, is of interest. The interpretation of this effect must be related to the presence of hydrogen bonds in the crystal structure of ice[100]. When the temperature is reduced during the crystallisation of ice, a closed-coordination system of hydrogen bonds is formed, which gives rise to a sharp decrease of the rate of the process on transition to the crystal structure. In this case the free muonium atom in the ideal ice lattice migrates in the crystal owing to the impossibility of stabilisation by addition to hydrogen bonds. The evident conclusion is that muonium may be identified in ice, which has in fact been demonstrated[101]. The absence (within the limits of experimental error) of an activation barrier in the reaction of muonium with water and ice is also consistent with the specific nature of the process involving addition to the hydrogen bond.

The problem of barrier tunnelling interaction of muonium is of interest. Estimates based on a number of studies[33,94] showed that the temperature limit at which the rates of activation and tunnel processes become comparable may be reached at 30–70°K for muonium (for E = 1000–2000 cal mole^{-1} and an effective half-width of the activation barrier of 2–3 Å). Comparison with the analogous data for positronium, muonium, and atomic hydrogen will probably allow a solution of this theoretically important problem.

3. Reactions of Muonium with Unsaturated Compounds

a. Ratio of the rate constants for the formation of molecular and radical products. The interactions of muonium, like those of atomic hydrogen, with aromatic and other unsaturated compounds can occur, as already stated, by parallel pathways—substitution reactions with the removal of an atom and the formation of a diamagnetic molecule incorporating muonium and addition to a multiple bond with formation of a radical. The effect of the functional groups and substituents in the molecule and the role of factors involving the conjugation of different types of bonds were discovered in the study of the variation of the reaction rate constants associated with a successive logical alteration of molecular structure.

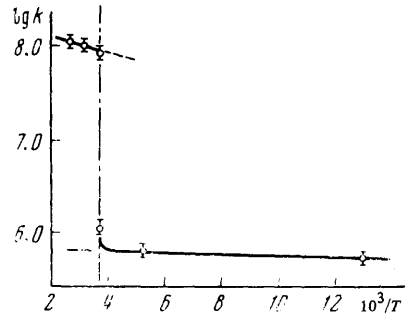

Figure 14. Temperature variation of the rate constant for the reaction of muonium with H_2O; the dot–dash line represents the temperature of the water–ice phase transition.

Table 4. Ratio of the rate constants for the reactions of muonium with methyl-substituted (in the ring) benzene derivatives.

Compound	k_2/k_1	$k_1\times10^{-9}$	$k_2\times10^{-9}$
C_6H_6	10.5±4.2	0.30±0.11	3.1±0.4
$C_6H_5CH_3$	3.3±1.0	0.77±0.20	2.5±0.7
$C_6H_4(CH_3)_2$	2.7±0.8	0.82±0.23	2.5±0.8
$C_6H_3(CH_3)_3$	2.3±0.6	1.03±0.22	2.4±0.7
$C_6H_2(CH_3)_4$	2.2±0.6	1.08±0.24	2.3±0.7
$C_6(CH_3)_6$	0.84±0.26	1.85±0.34	1.5±0.5

We shall examine, for example, the results[92] for two homologous series—for the successive methylation of the benzene ring and for the successive introduction of methyl groups into a side chain. In the first case (Fig. 15*a*) the polarisation increases relatively slightly up to the introduction of four methyl groups [as in durene (tetramethylbenzene)] but there is a subsequent increase of the asymmetry coefficient for hexamethylbenzene associated with the screening of the ring by CH_3 groups. These data indicate that the reaction involving the addition of muonium to the multiple bond predominates even under the conditions of partial screening of the benzene ring. It is significant that the polarisation for hexamethylbenzene is nevertheless appreciably less than for saturated compounds (octane and cyclohexane). One may suppose that this difference is caused by the attack of muonium in the plane of the benzene ring with formation of a π-complex. Quantitative calculation yields the reaction rate constants (litre mole^{-1} s^{-1}) listed in Table 4.

We may note that the overall reaction rate constants hardly change in this series, but there is a redistribution of the reactivity of the molecule with respect to parallel reaction pathways.

The analogous relations for normal (unbranched) alkylbenzenes are of a different type (Fig. 15*b* and Table 5). With increase of the length of the side chain, there is a monotonic increase of the asymmetry coefficient and an equivalent increase of the rate constant for the formation of molecular products. This change corresponds to the absence of a redistribution among parallel reaction pathways. This result is of very general importance, since it indicates the independence of the interactions of muonium with aromatic rings and the side chains when the chain length is sufficiently long (more than two carbon atoms).

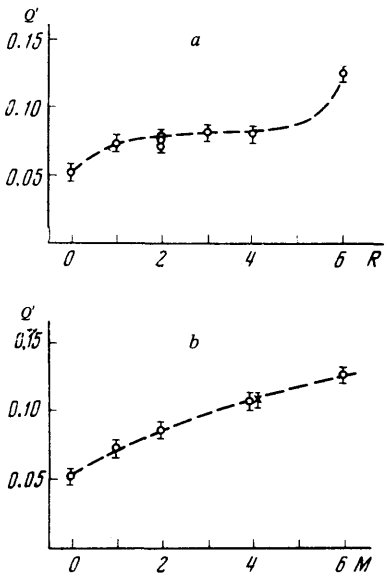

Figure 15. Variation of the asymmetry coefficient with the number of methyl groups R in the benzene ring (*a*) and with the number of carbon atoms (M) in the side chain of n-alkylbenzenes (*b*); X = $C_6H_5CH(C_2H_5)C_3H_7$.

The hypothesis that in many cases the interaction does not take place with the molecule as a whole but with individual fragments is confirmed by the experiment with 3-phenylhexane for which the reaction rate constants agree for the analogous values for n-butylbenzene (Table 5).

Many other results confirming the probable future value of this research technique for the investigation of the relation between the reactivity of the molecule and its chemical structure are quoted in the literature[92,93,102].

b. The restoration of polarisation in longitudinal magnetic fields. The effect of external magnetic fields on the polarisation of the μe decomposition when muonium interacts with unsaturated compounds revealed the presence[103-105] of as a rule two polarisation components. The first component, which is independent of the strength of the transverse magnetic field, is due to a substitution reaction with formation of diamagnetic molecular products containing muonium. The second component depends on the longitudinal magnetic field; however, both the initial (at $H \simeq 0$) polarisation and the critical magnetic field strength are not consistent with the hypothesis of a simple Paschen–Back effect associated with the prevention of depolarisation owing to the uncoupling of the magnetic moments of the μ^+-meson and the electron in a free (isolated) muonium atom.

Table 5. Ratio of the rate constants for the reactions of muonium with alkylbenzenes.

Compound	$(k_1+k_2)\times10^{-9}$	k_2/k_1	$k_1\times10^{-9}$
C_6H_6	3.4±0.3	10.5±4.2	0.30±0.11
$C_6H_5CH_3$	3.3±0.4	3.3±1.0	0.77±0.20
$C_6H_5C_2H_5$	3.6±0.8	2.4±0.8	1.05±0.30
$C_6H_5C_4H_9$	4.3±0.9	1.4±0.3	1.8±0.6
$C_6H_5C_6H_{13}$	5.7±1.0	0.78±0.22	3.2±0.7
$C_6H_5CH(C_2H_5)C_3H_7$	4.3±0.9	1.4±0.3	1.8±0.6

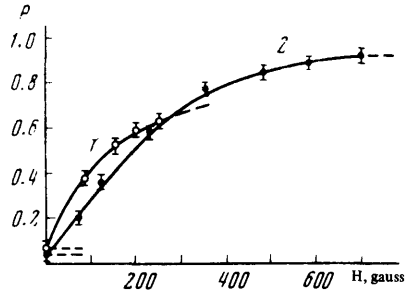

Figure 16. Variation of polarisation with longitudinal magnetic field strength. The lower dashed lines correspond to polarisation in a transverse magnetic field: 1) benzene; 2) naphthalene.

In these cases when a muonium atom adds to a multiple bond forming a radical with an unpaired electron, a complex system of spin interactions of the magnetic moments of the delocalised (in the general case) electron, the μ^+- meson, and the adjacent nuclei (protons) in the molecule is achieved and leads to depolarisation. The latter is removed when the strength of the longitudinal magnetic field corresponds to a change in the average effective distance between the meson and the delocalised electron in the molecule, the limiting asymptotic value of the polarisation corresponding to the overall rate of interaction via the molecular (component independence of the transverse magnetic field strength) and radical reaction pathways.

We shall consider as an example the results obtained[106] for the restoration of polarisation in crystalline benzene (−196°C) and naphthalene (30°C) specimens. The reason for the use of a solid phase is that molecular rotation during the period of observation may lead to an averaging of the interactions of the magnetic moments[87]. If the moment of inertia of the molecule is sufficiently high, the rotation during a period of the order of the lifetime of the μ^+-meson can be of course neglected. Fig. 16 shows that the polarisation is restored along curves with different parameters and there are differences between both the asymptotic limits to which the polarisation tends with increasing field strength and between the critical magnetic field strengths. Using the overall values for the reactivity

of benzene obtained by the method of competing acceptors, we find that at $-196°C$, $P = 0.79 \pm 0.03$, which is in satisfactory agreement with the asymptotic limit (Fig. 16). The estimates based on the difference between the reactivities of benzene and naphthalene in reactions involving addition to a multiple bond[86,106] show that, within the limits of the accuracy of the measurements, the asymptotic polarisation limit for naphthalene should be unity, in agreement with experimental data.

The difference between the critical magnetic field strengths (86 ± 6 G for benzene and 168 ± 11 G for naphthalene) is qualitatively consistent with the hypothesis concerning the effect of quaternary carbon atoms on the distribution of the probability density of the unpaired electron in the $C_{10}H_8Mu^{\cdot}$ radical. Quantitative analysis of the results requires detailed quantum-chemical calculations. Adopting the very rough approximation that the nature of the interaction of the magnetic moments of the μ^+-meson and the electron in the radical is the same as in the muonium atom and depends only on the average effective distance (r_{eff}), we obtain $r_{eff} = 1.40 \pm 0.03$ Å for benzene and $r_{eff} = 1.12 \pm 0.02$ Å for naphthalene. Without carrying out a specific physical interpretation of these values, we shall only point out the high experimental (but not computational) accuracy of the determination of r_{eff}.

4. Other Types of Interaction of Muonium

Like atomic hydrogen, the free muonium atom can also enter into redox reactions with variable-valence ions involving electron transfer (for example, $Mu + Fe^{3+} \rightarrow \mu^+ + Fe^{2+}$). However, these reactions are less specific for muonium, since, firstly, the indeterminacy of the further behaviour of the meson (or of the system in which it is incorporated) remains, secondly, the interaction with a solvent, which is inevitably present, becomes important, and, thirdly, the role of conversion exchange is much more pronounced for paramagnetic species.

Certain experiments on Cu^{2+}, Fe^{2+}, and Fe^{3+} ions[93] showed that the accuracy of the determination of the rate constants for the reactions of muonium in these cases is low and there is only a qualitative correspondence with the analogous reactions of atomic hydrogen investigated in the radiation chemistry of aqueous solutions[107]. The study of redox reactions with ions in solution is most promising for processes involving positronium, since there is for the latter a specific relation between the lifetime and the change in electronic state.

Conversion exchange is most important for compounds with unpaired electrons (NO, O_2, etc.). Despite the high rates of chemical reactions with these compounds, conversion exchange involving them predominates and the cross-sections for the processes are close to the gas-kinetic collision factors[94].

Interesting possibilities arise in the study of diamagnetic molecules incorporating muonium under conditions where there is a relation between the magnetic moments of the μ^+-meson and of an adjacent nucleus. Precession in a magnetic field which is not strong enough to uncouple the magnetic moments of the meson and the nucleus should be determined by the overall magnetic moment and the spin of the system. In particular, as a result of the vector addition of the magnetic moments and the spins of the proton and meson, the precession frequency in the transverse field for certain states of the MuH molecule should be 0.343 and the asymmetry coefficient should be half of the corresponding value for the precession of the μ^+-meson incorporated in the molecule. This constitutes the basis of one of the possible ways of identifying individual products[91] formed in the reactions of muonium with matter.

Among other aspects of the application of the μ^+-meson and muonium, we may mention the study of their interactions with a crystal lattice, which is of interest for the physics of solids and semiconductors. The slow (of the order of several microseconds) depolarisation effect during the time of observation found for a number of substances (B_4C, LiH, etc.[90,108]) is significant in the study of the spin–lattice relaxation of a polarised ion, of crystal structures, and of the role of local magnetic fields. In semiconductors[109,110] the introduction of alloying additives and also a change of temperature revealed a complete spectrum of polarisation changes as a function of the concentration of charge carriers in the specimen. Identification of the precession of triplet muonium in germanium single crystals at 77°K demonstrated[110] a low contribution by the exchange interaction with the electrons of the medium under the given conditions. The role of possible conversion exchange processes involving the lattice anions has been elucidated for the single crystals of a number of alkali metal halides[111,112]. The study of crystal lattice defects demonstrated that the latter are appreciable but do not alter the overall nature of the observed phenomena.

IV. MESONIC ATOMS

A number of very interesting effects are observed in the study of the effect of chemical structure on the atomic capture of μ^-- and π^--mesons in various substances. Negatively charged mesons retarded in a given medium are ultimately captured by atomic orbitals forming mesonic atoms in which they play the role of "heavy electrons". Initially the capture takes place usually in orbitals with high quantum numbers ($n = 10-15$) and then, as a result of a series of cascade transitions with emission of mesonic X-rays, the meson reaches the ground energy state in the inner $K(1s)$ shell of the given atom. As already stated, the radii of a mesonic atom orbital are close to nuclear dimensions and the atom of mesohydrogen, for example, behaves as a single electrically neutral particle. It can approach various nuclei and interact with them without the interference normally caused by the electrostatic repulsion between the nucleus and the proton. In particular mesonic hydrogen can behave as a kind of catalyst of the cold mesonuclear synthesis of helium from hydrogen[113].

In the capture of a μ^--meson, there arises both a characteristic mesonic X-ray emission spectrum and the lifetime of the μ^--meson in the 1s shell changes as a function of the atomic number z of the nucleus. By studying these factors in various compounds, it was possible to establish the probability of the atomic capture of μ^--mesons by individual components.

Theoretical hypotheses concerning the additivity of capture in a multicomponent system give rise to the expression (the Fermi–Teller z law)

$$W_i = \frac{n_i z_i}{\Sigma n_i z_i} \quad ,$$

where W is the probability of the capture of the μ^--meson, n the concentration of the atoms of the ith component, and z the atomic number. Numerous experiments showed that this relation does not constitute the rule but is a rare exception—it holds satisfactorily only for metallic alloys.

A detailed study[114] of the probabilities of the atomic capture of μ^--mesons in a number of oxides ($z = 4-82$) led to the conclusion that the ratio of the capture probabilities per nucleus of the given element $[W(z)]_\mu$ and oxygen $[W(0)]_\mu$ varies periodically. The experimental relation $[W(z)/W(0)]_\mu = f(z)$ is plotted in Fig. 17.

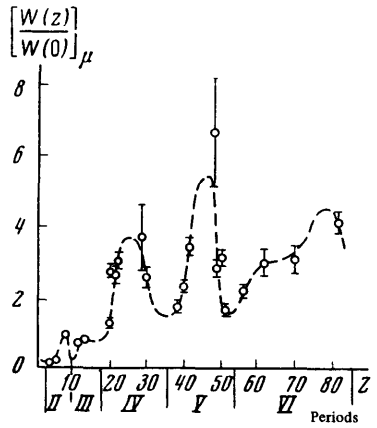

Figure 17. The ratio of the probabilities of the atomic capture of μ^--mesons in oxides. $W(z)$ and $W(0)$—probabilities of meson capture per nucleus z and per oxygen nucleus respectively.

Such periodicity is quite unexpected in terms of the concepts concerning the capture of mesons directly by atomic orbitals. However, it can be satisfactorily explained within the framework of the "model of large mesonic molecules"[115], according to which the mesons are initially captured by generalised mesonic molecular levels, the quantum numbers of which are so large that they correspond to the usual atomic dimensions (about 10^{-8} cm), despite the fact that the linear scale of mesonic atoms is smaller by a factor of 200 compared with the usual atoms. Thus the μ^--meson is located in an asymmetric double potential well (Fig. 18). The probability of the transfer of the meson to lower levels of one or other atom in cascade transitions to the region where the mesonic levels of the two atoms are separated depends on the properties of the electron shells of both. Clearly the periodicity of the structure of the outer shells of one of the atoms while that of the other remains unchanged (in the given case of oxides, this is oxygen) may lead to the appearance of a periodic variation of the probability ratio $[W(z)/W(0)]_\mu$.

The ratios of the probability of the capture of μ^--mesons by atomic orbitals are equivalent to the ratio of the effective atomic dimensions in complicated compounds. Thus there is a possibility of investigating the distribution of electron density in molecules, i.e. of a quantitative experimental determination of the amount of ionic character (covalence) of chemical bonds in polyatomic compounds.

The model of large mesonic molecules has been applied also to relations governing the capture of slow π^--mesons in mixtures and in chemical compounds involving hydrogen. In hydrogen such capture is accompanied by a charge-transfer reaction:

$$\pi^- + p \rightarrow \pi^0 + n$$

(the capture takes place partly according to the mechanism $\pi^- + p \rightarrow \gamma + n$) and the resulting slow π^0-meson decomposes after about 10^{-16} s into two γ-quanta moving apart at an angle of 180°C. In the capture of π^--mesons in complex nuclei, there is no charge transfer or the second process indicated above; in this case the capture of π^--mesons is accompanied by the ejection of numerous nucleons ("star"). Therefore the determination of the yield of π^--mesons, for example, by recording the coincidences due to the 2γ-quanta, constitutes a reliable criterion for the determination of the fraction of π^--mesons captured in complex systems by hydrogen atoms.

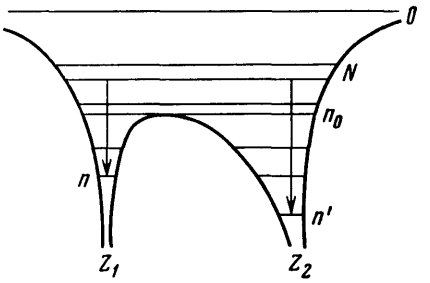

Figure 18. Schematic representation of the meson levels in an asymmetric diatomic molecule z_1z_2. The levels above n_0 are common mesomolecular levels; the mesonic atomic levels z_1 and z_2 are shown below.

It has been shown in a series of studies[116-118] that the ratio of the probabilities of the capture of slow π^--mesons by protons and nuclei with a charge Z differs sharply for simple mixtures and chemical compounds (Z and H). Whereas for $Z_m + (H_2)_n$ mixtures the ratio is $[W(H)/W(Z)]_\pi \simeq 2n/mz$, in binary compounds of analogous composition the ratio is smaller by a factor Z^2. For example in the $N_2 + 2H_2$ gas mixture the probability of the capture of π^--mesons by hydrogen is 30%, while in hydrazine (N_2H_4) the probability is reduced almost to 1/200. The finding that $[W(H)/W(Z)]_\pi$ depends on the nature of the chemical bond is even more interesting. Thus for ethylene (C_2H_4) $[W(H)/W(Z)]_\pi$ is higher than for acetylene (C_2H_2) by a factor of 2.5 and not 2. Thus fine differences between the $H_2C{=}CH{-}H$ and $HC{-}C{\equiv}H$ bonds are shown in the capture of π^--mesons, and are probably reflected in a slightly higher C–H bond energy in acetylene compared with ethylene.

We may note that the method applied provides a sensitive criterion for the determination of the difference between hydrogen involved in exchange interactions (in the molecule) and free hydrogen[119], which is very useful for the elucidation of many problems in structural chemistry, kinetics, and catalysis of chemical reactions. In particular, such problems may include the kinetics and catalysis of reactions of the type $Z + H_2 \rightarrow Z_mH_n$, the nature and kinetics of adsorption, sorption, and chemisorption phenomena, the role of water of crystallisation in compounds, the structure of ice at low temperatures, and the nature of hydrogen bonds.

As an illustration, one may point to the lower probability of the capture of π^--mesons by hydrogen in titanium hydrides[120] compared with the theoretical values, which is

probably due to the characteristics of the hydrogen bond in pseudohydrides. Although the nature of the hydrogen bond with the metal in compounds of this kind has not been finally elucidated, it has been suggested that in pseudohydrides the hydrogen is partly involved in chemical interactions and partly ionised and exists in the form of a proton gas[121]. Since only chemically combined hydrogen is involved in the capture of π^--mesons, it is reasonable to expect a lower probability of their capture in pseudohydrides compared with the usual hydrogen-containing compounds. Thus the result obtained confirms the above hypothesis: it is also possible to estimate the fraction of ionised hydrogen (protons) in pseudohydrides. Experiments on the problem of the spatial and temporal delocalisation (this problem has been considered theoretically by Blyumenfel'd et al.[122]) of π^--mesons among systems comprising several identical ZH groups in symmetrical compounds of the type $R(ZH)_q$,[120] and also on the problems of the determination of the amounts of ionic character of O–H bonds in various oxygen-containing acids, are being carried out. A number of interesting data concerning the intensity ratio of π^--mesonic X-ray emission lines associated with changes in chemical structure have been obtained[123].

At the present time both the development of theoretical concepts and of the techniques of mesochemical experiments are far from complete. Nevertheless, comparison of the experimental probabilities of meson capture with theoretical estimates already yields very interesting data. So far, experiments with μ^-- and π^-- mesonic atoms reduce as a rule to the study of the effect of the known properties of various compounds on the catpure characteristics. The converse problem now arises in nuclear chemistry—the employment of the properties of mesoatomic systems to obtain hitherto unknown characteristics of chemical bonds, i.e. the problem of creating mesochemical research methods.

---o0o---

The scope of studies with the aid of elementary particles constitutes, as a whole, a novel set of nuclear-physical methods which may prove suitable for the solution of many physicochemical problems. The principal aim of this review was to outline the range of problems where these methods yield information of interest for chemical research. Undoubtedly further expansion of studies in this field will reveal other important aspects of the application of the chemistry of new atoms.

The Heterogeneity of Natural Lignin

O.P.Grushnikov and N.N.Shorygina

The results of investigations of the molecular-weight distribution of lignin in the delignification of wood by various methods, modern ideas on the distribution of lignin in cell walls of plant tissues, and the presence of bonding between the lignin and the carbohydrate components are critically examined. The results obtained in the course of these investigations show that natural lignin evidently consists of two main components which differ in molecular weight, in their localisation in the cell walls of the plant tissues, in the nature and number of the bonds with the carbohydrate components of the wood, and also in the topochemical models at the time of delignification.
The present review is the first attempt to survey the results relating to the problem of the heterogeneity of natural lignin. There is a bibliography of 143 references.

CONTENTS

I. Introduction 657

IV. Some aspects of the heterogeneity of natural lignin 663
V. The heterogeneity of lignin in relation to its bonding with the other components of plant tissue 665

I. INTRODUCTION

The problem of the homogeneity or heterogeneity of natural (that is, not isolated from plant tissue) lignin is of both theoretical and practical interest. The establishment of homogeneity or heterogeneity of natural lignin is undoubtedly a necessary prerequisite for solving the problem of the nature and number of lignocarbohydrate bonds in plant tissues. As is well known, this problem is of considerable interest and is now attracting the attention of investigators both in the USSR and abroad. Furthermore, the importance of information about the homogeneity or heterogeneity of lignin is also apparent in the development of rational industrial processes for the delignification of vegetable raw materials.

At the same time the complexity of the solution of this problem is primarily due to the fact that wood chemistry does not yet have a method for isolating lignin from lignified plant tissues which does not involve the use of acids, alkalis, or mechanical action, which change natural lignin to a greater or lesser extent. However, despite this the intensive development of the physical chemistry of lignin which began in the middle of the 1950s and was linked with progress in the physical chemistry of polymers which had benefitted by a series of promising methods of investigation, led to the obtaining of a considerable number of results relating to this problem. These results concerned the mechanisms observable in the isolation of lignin from wood by various methods, the distribution of lignin in the cell walls of plant tissues, the nature of the bonds between lignin and carbohydrate constituents and various other questions. The generalisation of these results allows a representation of the present state of the problem of the heterogeneity of natural lignin to be compiled.

In conclusion we note that the results examined in the present review mainly relate to the lignin of coniferous species, which have been investigated most.

II. MOLECULAR WEIGHTS OF PREPARATIONS OF LIGNIN ISOLATED AT SUCCESSIVE STAGES OF THE DELIGNIFICATION OF WOOD

The results of the investigations [1-12] on the fractionation of lignosulphonates isolated as a result of the sulphite digestion of wood, made in the 1940s and 1950s, showed that these preparations had a considerable polydispersity. McCarthy and coworkers [13] made the first attempt to connect the change in molecular weight of the lignosulphonates isolated with the degree of delignification of the wood. They subjected wood flour from *Tsuga*, spruce, and maple to treatment with $NaHSO_3$–H_2SO_3 solutions at 135°C for various intervals of time. It was found that for coniferous woods (*Tsuga* and spruce) the molecular weights of the soluble lignosulphonates isolated as a result of brief (30 min) digestions amount to ~ 2000–4000 (diffusion method). On increasing the duration of the digestion the molecular weight of the lignosulphonates increases as the delignification of the wood proceeds, reaching the maximal value of ~ 11 000 at almost complete delignification (4 to 5 h digestion). Longer digestion reduced the molecular weight to a minimal value of ~ 5000 and, for *Tsuga*, then led to a further increase. The investigators associated these maximal and minimal values of the molecular weights of the lignosulphonates with the action of three processes which occur simultaneously during the sulphite digestion but at different rates: (a) the hydrolysis of hydrolysable bonds in the polymeric lignin; (b) the differential diffusion of soluble lignosulphonates from the wood tissue, with the finer fragments diffusing first; and (c) the irreversible autocondensation of the macromolecules of the lignosulphonates.

A serious drawback of the method used by these investigators is that the dissolution of the lignin is cumulative, so that each fraction contains not only the material dissolved during the given interval of the treatment but also products from the degradation of the lignosulphonates

which had been transferred to the solution in earlier stages of the digestion. The interpretation of these results is hindered by the fact that the main heterogeneous reaction is accompanied by a homogeneous reaction in which the lignosulphonate that has already dissolved undergoes various chemical changes.

Felicetta and McCarthy [14] attempted to improve the cumulative method considered above by "incremental" delignification, in which the wood is treated with the digestion solution in several successive stages. After each stage the residue is separated and subjected to further treatment. They delignified *Tsuga* wood by five successive treatments with $NaHSO_3$–H_2SO_3 solutions, each of which was continued for ~15 h at 130°C. An increased dissolution of the lignin was brought about by increasing the concentration of free SO_2 after each stage except the first (pH of digestion: 4.8, 4.8, 3.4, 2.5, and 2.1). The molecular weights of the lignosulphonates increased from 3400 to 30 000 (diffusion method) in the first four digestions. The final sulphite treatment led to the isolation of a lignosulphonate with molecular weight 20500.

Table 1. Characteristics of the fractions of dioxan-lignin isolated as a result of four successive extractions of spruce wood [15].

Fraction	Yield, % of Klason lignin		Contents, %		M_w	D_A, $cm^2 s^{-1}$	E_{280}, litre $cm^{-1} g^{-1}$	dn/dc, $ml\ g^{-1}$	$\bar{v}$, $ml\ g^{-1}$
	not purified	purified	OCH_3	carbohydrates					
1	18.1	12.7	15.4	0.03	4300	$1.77 \cdot 10^{-6}$	19.8	0.113	0.703
2	25.0	17.0	15.5	0.02	7400	$1.22 \cdot 10^{-6}$	20.8	0.116	0.712
3	21.0	16.2	15.9	0.03	33000	$0.775 \cdot 10^{-6}$	22.1	0.124	0.693
4	17.6	12.9	15.5	0.03	85000	$0.55 \cdot 10^{-6}$	23.3	0.135	0.701

Rezanowich and coworkers [15] observed a similar tendency to an increase in the molecular weight of the lignin preparations with progress in the delignification of wood during four successive extractions of white spruce sawdust with aqueous dioxan containing a little hydrochloric acid, by Pepper's method [16]. The dioxan-lignin fractions obtained contained methoxyl groups and carbohydrate impurities which showed ultraviolet absorption at 280 mμm (E_{280}), an increase in the refractive index increment (dn/dc), characteristic viscosity, diffusion constant (D_A), partial specific volume ($\bar{v}$), and molecular weight (M_w), determined by sedimentation equilibrium in an ultracentrifuge (Table 1). These results show the homogeneity of the dioxan-lignin fractions in respect of the content of methoxyl groups and carbohydrate impurities, and also of the partial specific volumes. Nevertheless, with increase in the molecular weight of the fractions there is a small but definite increase in the ultraviolet light absorption and in dn/dc. Rezanowich and coworkers [15] consider that these changes in dn/dc and E_{280} are probably connected with differences in the chemical structure of the fractions, and these in turn may be due to the heterogeneity of the lignin in the wood. For example, the dioxan-lignin fractions which are extracted later can contain a greater proportion of biphenyl bonds which could explain the higher molecular weights and refractive index increment observable for these preparations. On the other hand, the chemical changes which accompany the changes in dn/dc and E_{280} can be the result of the prolonged acidolysis of the last fractions, which can also lead to an increase in their molecular weight, owing to polymerisation. Although their results cannot be interpreted with certainty, the investigators assume that slight structural heterogeneity of the dioxan-lignins extractible from spruce wood is superimposed on their polydispersity over a wide range of molecular weights.

Yean and coworkers [17] isolated five lignosulphonate fractions as a result of the successive extraction of spruce wood flour with an acid sulphite solution. The weight-mean molecular weights of the resulting preparations, determined by sedimentation equilibrium in the ultracentrifuge and by light scattering, ranged from 5000 to 130000, increasing with quantity of lignin extracted from the wood. The ratio M_w/M_n, calculated on the basis of the weight distribution, was 3.1, which shows the appreciable polydispersity of the lignosulphonates isolated in sulphite digestion of spruce wood. This polydispersity is confirmed by the experimental separation of one of the fractions with molecular weight 95 200 by dialysis through membranes with successively increasing pore dimensions as a result of which nine subfractions with molecular weights from 37 000 to 1 270 000 were obtained.

Arlt and Schuerch [18] investigated four fractions of ethanol-lignin, isolated by successive extraction of spruce wood with 0.2 *N* HCl (gas) in an anhydrous mixture (4 : 1) of chloroform and ethanol at 60°C according to a method developed earlier [19]. Table 2 gives some results from this investigation; they relate to ether-insoluble fractions of the ethanol-lignin which had dissolved in chloroform, after their purification from carbohydrates.

Table 2. Characteristics of the fractions of ethanol-lignin isolated as a result of four successive extractions of spruce wood [18].

Fraction	Yield, % of Klason lignin*	Contents, %					Molecular weight (cryoscopic, in ethylene carbonate
		C	H	OCH_3	OC_2H_5	OH_{phen}

*Calculated by us from published results [18,19].

Successive treatments of lignified material with a mixture (1 : 4) of nitric acid (specific gravity 1.4) and 96% ethanol at the boiling point was proposed by Kürschner and Hoffer [20,21] as a method for the delignification of wood. On the basis of the results of an analytical investigation of the fractions obtained by the fractional precipitation of nitrolignin from the combined reaction solutions after several successive digestions of a single portion of spruce wood, Kürschner [22] concluded that the nitrolignin isolated in alcoholic nitration is a homogeneous product. This conclusion met with objections from Fuchs [23], who, by starting from the premise of the heterogeneity of the lignin in the wood, assumed that it could not be homogeneous in its derivative, nitrolignin. On the basis of the results of a chromatographic examination of the nitrolignin isolated from the combined reaction solutions after several successive digestions of a single portion of spruce wood under the conditions of the Kürschner method,

Chuksanova and coworkers[24] concluded that it was heterogeneous: the fractions obtained differed significantly in molecular weight. A more detailed investigation, made by Grushnikov and Shorygina[25], showed that the nitrolignins isolated after each of the successive digestions of spruce wood under the conditions of this method are similar as regards both elemental analyses and functional groups, and also spectroscopically. Nevertheless the molecular weight of nitrolignin isolated after the first nitration is about half that of the nitrolignins isolated after subsequent digestions[26]. Table 3 gives some of the results of this investigation.

Table 3. Characteristics of nitrolignins isolated as a result of successive nitric acid digestions of spruce wood[25,26].

Nitrolignin isolated after nitration	Yield, % of Komarov lignin	Contents, %		Contents, moles per C_6–C_3				Molecular weight (ebullioscopic, in absolute dioxan)
		C	H	NO_2	OCH_3	OC_2H_5	O_2 (COOH)

3	10.9	50.38	5.07	0.68	0.89	0.20	0.32	3190
4	5.5	50.17	4.95	0.74	0.92	0.16	0.26	—

Each of the above methods of wood delignification suffers from a significant drawback, the possibility of irreversible changes occurring in the undissolved lignin during the repeated operations of filtration and washing needed to separate the residue from the digestion solutions. A special hazard is the sorption of molecular oxygen, which in repeat heating can facilitate an increase in the molecular weight of the preparations isolated, due to the polymerisation of the lignin.

These drawbacks are eliminated in continuous digestion, in which the wood is treated in a specially constructed autoclave in a continuous stream of digestion liquid at the temperature and pressure corresponding to the standard digestion conditions. Continuous digestion allows the dissolved material to be constantly removed from the autoclave without being subjected to the further action of the digestion solution and it also ensures the absence of contact between the wood being digested and the atmosphere, thus eliminating the possibility of secondary changes in the lignin.

Yean and Goring[27] undertook the acid sulphite digestion (135°C; total SO_2 concentration ~6%) of spruce sawdust by a continuous process. Six specimens of digestion liquid, representing the soluble material at successive stages of the wood delignification process, were withdrawn. The lignosulphonates isolated from these specimens were freed from low-molecular-weight impurities by dialysis and from non-dialysable polysaccharides by electrophoresis-convection. The purified lignosulphonates were analogous in the contents of sulphur and methoxy-groups and also in ultraviolet light absorption (E_{280}) and refractive index increment (dn/dc) (Table 4). However, the mean molecular weight (M_w) increased from 9700 to 143 000 (sedimentation equilibrium in an ultracentrifuge) as the wood was delignified. To investigate the possibility of the condensation of the lignin during treatment with acid hydrogen sulphite solution, two of the fractions isolated were subjected to repeat digestions under various conditions. In every instance degradation of the lignin was observed†. These results were thought by Yean and Goring to show that in acid sulphite digestion polymerisation of lignin either does not occur or is completed in the early stages of the digestion.

Table 4. Characteristics of the fractions of lignosulphonate isolated at various stages of acid sulphite digestion[27].

Fraction	Degree of delignification, %	Contents, %		M_w	E_{280}, litre $cm^{-1} g^{-1}$	dn/ds, ml g^{-1}
		OCH_3	S			
1	13.3	13.6	4.7	9700	12.1	0.189
2	34.2	13.4	4.8	22 900	12.4	0.191
3	49.7	12.5	4.4	39 000	12.6	0.181
4	65.1	14.0	4.7	75 400	12.9	0.192
5	79.0	13.8	4.9	100 000	13.2	0.197
6	92.5	14.0	5.7	143 000	13.9	0.198

The results of these investigations showed that ~40% of the lignosulphonate isolated from spruce wood as a result of acid sulphite digestion is capable of being dialysed and consequently has a molecular weight of < 5000. The remaining 60% has a molecular weight in the range from 9700 to 143 000. This molecular weight distribution enabled the investigators to postulate the existence of two types of lignin in spruce wood: low- and high-molecular-weight types and it was suggested that they were localised in different parts of the cell wall of the fibre. To check this assumption Yean and Goring[29] investigated lignosulphonates isolated from morphologically different parts of the wood structure. The differencs between sapwood and heartwood, earlywood and latewood, compressionwood, tensionwood, and ordinary wood were investigated. However, no significant differences in molecular weight were observed between the lignosulphonates isolated on the basis of which it could be concluded that the wide range of molecular weights observed earlier was unconnected with the morphological differences investigated. It was assumed that the results obtained could be explained on in molecular weight of the lignins localised in the material of the middle plate and in the secondary wall, or on the basis of the assumption that in the parts of the wood structure investigated lignins with different molecular weights are homogeneously mixed at the molecular level.

Yean and Goring[30] made a hydrogen sulphite digestion (153°C, pH 4) of spruce wood sawdust by a continuous process. Four specimens with approximately the same weight percentage of lignin were withdrawn during the digestion. The lignosulphonates isolated were purified by dialysis and moving boundary electrophoresis and were then analogous in the contents of methoxyl groups

†According to Reznikov's results[28] even relatively mild chemical action (acid treatment at ⩾ 100°C) of both the lignins isolated and the lignin in wood leads to the condensation of the macromolecules in the solid phase. In this connection Reznikov assumes that from the results on the molecular weights of preparations of lignin isolated from acid medium it is impossible to obtain even approximate ideas of the molecular weight of the lignin in the wood.

and sulphur, ultraviolet absorption (E_{280}), refractive index increment (dn/dc), and also infrared spectra (Table 5). Simultaneously the weighed mean molecular weight (M_w) increased from 10 000 (sedimentation equilibrium in an ultracentrifuge) for the first fraction to 77 000 for the final fraction.

Table 5. Characteristics of the fractions of lignosulphonate isolated at various stages of the hydrogen sulphite digestion of spruce wood[30].

Fraction	Degree of delignification, %	Contents, %		M_w	E_{280}, litre $cm^{-1}\,g^{-1}$	dn/dc, ml g^{-1}
		OCH_3	S			
1	8.3	11.8	6.2	10 000	13.3	0.185
2	26.6	12.8	5.6	13 600	12.1	0.181
3	43.1	12.9	5.2	31 000	12.8	0.191
4	54.9	12.6	5.5	77 000	14.1	0.198

A similar tendency for an increase in the molecular weights of lignin fractions during the course of the delignification of wood was also observed in continuous kraft digestion[31]. Some results are given in Table 6.

Table 6. Characteristics of the fraction of kraft lignin isolated at different stages of the kraft digestion of spruce wood[31].

Fraction	Degree of delignification, %	Contents, %			M_w	E_{280}, litre $cm^{-1}\,g^{-1}$	dn/dc, ml g^{-1}
		carbohydrates	OCH_3	S			
1	5.5	22	12.1	2.5	1780	20.5	0.191
2	17.2	9	11.2	2.1	11 700	18.8	0.188
3	31.0	16	12.5	1.7	13 100	18.4	0.211
4	45.0	11	12.2	1.5	15 500	18.5	0.211
5	60.0	14	13.1	2.1	32 800	19.0	0.190
6	75.0	12	12.5	1.5	30 900	18.8	0.201
7	88.0	3	11.8	1.7	51 000	17.2	0.197

As the results show, seven fractions representing different stages of the delignification of spruce wood had analogous methoxy-group contents, ultraviolet absorption (E_{280}), and refractive index increment (dn/dc), but their weight mean molecular weights (M_w) increased from 1800 (sedimentation equilibrium in an ultracentrifuge) for the first fraction to 51 000 for the final fraction. Gel filtration on Sephadexes showed the considerable polydispersity of the fractions isolated.

The authors consider that the above results for acid sulphite[27], hydrogen sulphite[30], and kraft[31] digestions of spruce wood by continuous processes have shown that the different processes used for the dissolution of wood lignin do not alter its structural properties to any great extent, as is shown by the similarity in orders of magnitude of the methoxy-group content, ultraviolet absorption, and refractive index increment for lignosulphonates obtained as a result of acid sulphite and hydrogen sulphite digestions and also for kraft lignins (Table 7). In a comparison of lignosulphonates isolated as a result of the acid sulphite and hydrogen sulphite digestions their similar molecular weights at similar degrees of delignification of the wood is noteworthy. In comparison with the lignosulphonates, the kraft lignins have a lower molecular weight than the lignosulphonates, which is attributed to the more rapid degradation of the lignin in the kraft digestion. This regularity can be readily observed in Fig. 1, which shows the change in the molecular weight of the lignin preparations isolated during the course of the wood delignification.

Table 7. Mean value of the content of OCH_3 groups, absorption of ultraviolet light (E_{280}), and refractive index increment (dn/dc) for lignin derivatives isolated as a result of three different digestion processes.

Process	Content of OCH_3 groups, %	E_{280}, litre $cm^{-1}\,g^{-1}$	dn/dc, ml g^{-1}
Acid sulphite (Ref.27)	13.6 (±0.4)	12.8 (±0.5)	0.191 (±0.004)
Hydrogen sulphite (Ref.30)	12.5 (±0.4)	13.1 (±0.6)	0.189 (±0.006)
Kraft (Ref.31)	12.2 (±0.4)	18.7 (±1.6)	0.198 (±0.008)

Brown and coworkers[32,33] investigated the isolation of lignin from liquidambar and spruce woods with the aid of brown rot fungus. Lignin preparations were obtained by extracting the wood with dimethylformamide at successive stages of increased enzymatic removal of carbohydrates: 10.5, 27.1, 47.1, 59.5, 77.2, 80.5, 92.6, 97.7, and 100%.

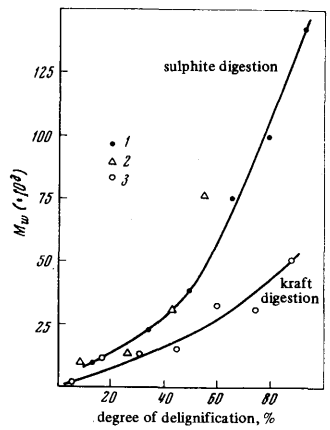

Figure 1. Variation of the molecular weights of the lignin preparations isolated by different methods with the degree of delignification of spruce wood[27,30,31]: *1*) acid sulphite digestion; *2*) hydrogen sulphite digestion; *3*) kraft digestion.

The separation of the resulting extracts on Sephadex G-50 led to the formation of three fractions (1) with molecular weight > 14 000; (2) with molecular weight from ~ 3000 to ~ 14 000; and (3) with molecular weight from 100 to ~ 3000. It was shown that as the proportion of carbohydrates removed increased, the relative quantity of lignin eluted from fraction 1 rose and the amount of lignin eluted from fraction 3 decreased. The relative

amount of lignin eluted from fraction 2 remained approximately constant at all stages of the carbohydrate removal. The observed increase in the ratio of high-molecular-weight to low-molecular-weight components as the carbohydrates are gradually removed was thought to show that wood lignin consists of at least two main components, which differ considerably in molecular weight and are localised in different parts of the cell walls of the fibres.

As regards the lignins isolated from plant tissue, their heterogeneity in molecular weight was shown by gel-filtration of lignin from mechanical grinding [34,35] and of alkali lignins [36], by fractionated dioxan-lignins [37,38] and by Brauns "native" lignin [39], by sulphite [40] and kraft [41] digestions of periodate lignin, and by many other investigations, consideration of which is not the task of the present review.

Hence the above results from studies of the molecular weight distribution of lignin during the delignification of wood by various methods (various digestion procedures, enzymatic isolation) has allowed us to pose the question of the existence of two types of natural lignin, which differ considerably in molecular weight. However, before examining the arguments for and against this hypothesis we must briefly characterise contemporary ideas about the distribution of lignin in the cell walls of plant tissue.

III. DISTRIBUTION OF LIGNIN IN THE CELL WALLS OF PLANT TISSUES

According to contemporary ideas concerning the anatomical structure of wood from coniferous species, the cell walls of moulded tracheids consist of two ontogenetically different structural parts: primary and secondary walls. The primary wall, which is the external sheath of the cell, plays an important part in the period of surface growth, whereas the secondary wall is formed after surface growth ceases. In turn the secondary wall consists of three layers with different optical properties (Figs. 2 and 3). In addition to the morphological subdivisions shown in Figs. 2 and 3, there are indications [46] of the existence of the so-called "warty layer", which covers the tertiary wall at the side of the lumen.

One of the first attempts to investigate the quantitative distribution of lignin in the cell wall was made by Ritter [47]. With the aim of removing the carbohydrate components, he treated 3 mm sections of wood with sulphuric acid according to the standard Klason method for determining lignin and found that middle lamella lignin and cell wall lignin could be distinguished in wood: the former retains the initial wood structure after removal of carbohydrates but the second is structureless. A mechanical separation of the lignin residue thus obtained showed that ~ 75% of the wood lignin is localised in the middle lamella, and ~ 25% in the cell wall and that the lignins localised in these two sites of the plant tissue differ significantly in the methoxy-group content (Table 8). Although the low methoxy-group content shows that the purity of the preparations is insufficient the fact that they are isolated under similar conditions and at the same time differ so much in the methoxy-group content is thought to show a significant difference between the middle lamella lignin and the cell-wall lignin.

On taking into account the volume occupied by the middle lamella in the wood tissue, Ritter was doubtful about the reliability of the values he had obtained which characterise the quantitative distribution of the lignin. The results obtained during this investigation enabled Ritter [48] to conclude that only half of all the wood lignin is localised in the middle lamella. However, in 1934 Ritter [49] confirmed his initial conclusion that the main mass of the lignin is localised in the middle lamella. Subsequently, this conclusion was confirmed in an investigation made by Harlow[50].

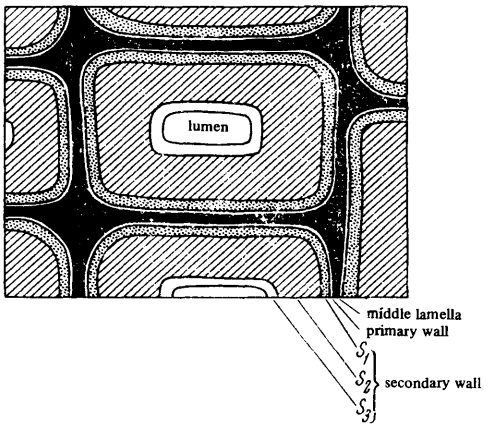

Figure 2. Transverse section of moulded tracheids of wood from coniferales species [42-44]. On the diagram are marked: the middle lamella or intercellular substance; the primary wall; the secondary wall, consisting of three layers: outer or external (S_1), middle or central (S_2), and internal (S_3); the lumen or cell cavity of the fibre.

The results obtained by Ritter and Harlow are evidently connected with the incomplete separation of the two types of lignin, since the mechanical method used for the separation is extremely imperfect, and also with the incomplete removal of carbohydrates, which is evident from the low concentration of methoxy-groups in the lignin preparations mentioned above.

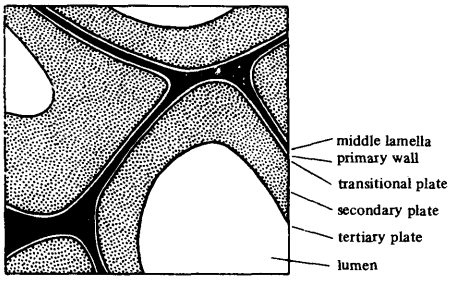

Figure 3. Transverse section of moulded tracheids of coniferales species [45].

Bailey [51,52] used a micromanipulator to separate 0.5 mg of the middle lamella from Douglas fir wood and found that the preparation isolated contained lignin 71, pentosans 14, cellulose 4%. Lange [53], using an ultraviolet microscope,

calculated that the weight concentration of lignin in the secondary cell wall amounted to 10–20%, and that in the middle lamella to 60–90%. The mean values obtained from 50 measurements were 16 and 73% respectively, and he suggested a gradual decrease in the lignin concentration from the middle lamella to the lumen. A series of investigations [54–56] showed that the distribution of lignin in the cell wall was more uniform than according to Lange's suggestion. The results of electron microscope investigations [57–59] of preparations of wood from which the carbohydrate components had been removed by various chemical treatments or by the action of enzymes showed that the distribution of lignin in the secondary cell wall is non-uniform; the lignin concentration is higher in the inner layer (S_3) close to the lumen and in the outer layer (S_1) adjacent to the primary wall.

Table 8. Distribution of lignin between the secondary cell wall and the material of the middle lamella [47].

Characteristic being studied	Red alder			Cuban white pine		
	secondary cell wall	material of middle lamella	total quantity	secondary cell wall	material of middle lamella	total quantity
Lignin, % of wood	7.3	19.5	26.8	6.9	23.4	30.3
Lignin, % of total lignin in wood	27.3	72.7	—	22.7	77.3	—
Methoxyl groups in Lignin, %	4.8	13.6	—	4.3	10.8	—

Investigations into the distribution of lignin in cell walls of plant tissues, published up to 1963, were examined in detail in the reviews of Northcote [60], and of Milyutina and Sergeeva [61].

The problem of the quantitative distribution of lignin in cell walls of plant tissues was critically examined by Berlyn and Mark [62], who emphasised that the results of Bailey and Lange are diametrically opposed to those of Ritter. Noting that the volume of the fractions of the middle lamella and primary-wall substances make up only 10–12% of the volume of the plant tissue, Berlyn and Mark calculated that even if this region consisted entirely of lignin it could not contain more than 40% of the total wood lignin. This surmise found experimental confirmation during an investigation by Goring and coworkers [63]. The method they employed was a combination of ultraviolet microscopy and densitometric analysis of negatives obtained by ultraviolet photomicrography. A special detailed examination of this method [64] showed that its use was well-founded, since when certain experimental conditions are satisfied the method enables the concentration of lignin in the various parts of the cell wall to be determined with sufficient accuracy. Furthermore, it is noteworthy that these investigators [63] calculated the concentration of lignin in the secondary wall by two methods: (1) on the basis of the relative ultraviolet absorption and the volumes of the fractions of different parts of the cell wall, and (2) directly from the absorption in the ultraviolet, using the Lambert–Beer law. The values obtained by the two methods showed good agreement, which also shows the reliability of their method.

Table 9 gives some results obtained by Goring and coworkers and shows that the middle lamella material is more lignified than that of the secondary wall, but despite this it contains only an insignificant proportion of the total lignin of spruce wood.

Table 9. Distribution of lignin in spruce tracheids [63].

Wood	Morphological differentiation*	Relative absorption of UV	Total fraction, %	Lignin, % of total lignin in wood	Lignin concn., g per g wood
Early	SW	1	87.4	72.1	0.225
	ML (r) (t)	2.21	8.7	15.8	0.497
	ML (cc)	3.77	3.9	12.1	0.848
Late	SW	1	93.7	81.7	0.222
	ML (r) (t)	2.7	4.1	9.7	0.60
	ML (cc)	4.5	2.2	8.6	1.0

*SW = secondary wood; ML middle lamella; r radial direction; t tangential direction; cc cell corner.

Scott and Goring [65] also used ultraviolet microscopy in conjunction with densitometric analysis of the ultraviolet photomicrographs obtained in investigating the concentration of lignin in the S_3 layer of wood of coniferous species.

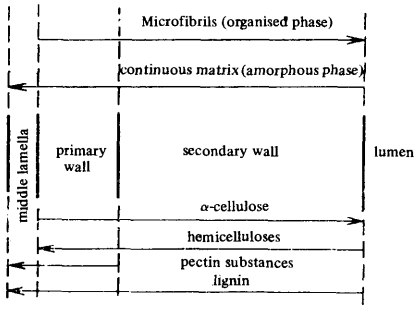

Figure 4. Distribution of the constituents of moulded cell walls. The arrows show the direction of the increase in the relative concentrations of the individual components [60].

Their results showed that in trunk wood a uniform distribution of the lignin in the secondary wall is usually observed. On the other hand, in the wood of the branches a high concentration of lignin in the S_3 layer is often observed.

Hence the above results show convincingly that the distribution of lignin in the cell walls of plant tissues is

non-uniform, and it is interesting to note that according to the results of several investigators [66-69] non-uniformity is also observed in the distribution of the carbohydrate components (hemicelluloses and cellulose) of plant tissue.

In ending the examination of the problems associated with the distribution of lignin in the cell walls of plant tissues, it is noteworthy that according to Northcote's views [60] the cell wall can be regarded as a two-phase system consisting of microfibrils immobilised in a continuous matrix. The microfibrils are concentrated close to the lumen and their density falls in the direction towards the outer parts of the cell, where the other phase prevails. Northcote proposed the following classification of the material of the cell wall:

1. Continuous matrix: (a) pectin substances; (b) lignin; (c) possibly, polysaccharides of the hemicellulose group.

2. Microfibrils: (a) polysaccharides containing glucose (cellulose); (b) polysaccharide (polysaccharides) containing xylose; (c) a polysaccharide (polysaccharides) containing mannose; (d) possibly, polysaccharides of the hemicellulose group.

The scheme presented in Fig. 4 is a representation of the distribution of the various components of the cell wall of plant tissue.

In conclusion, we must note that in comparison with coniferous woods the wood of deciduous species exhibits a more complex anatomical structure and also differs in the nature of the distribution of the lignin in the plant tissue [70].

IV. SOME ASPECTS OF THE HETEROGENEITY OF NATURAL LIGNIN

As stated above, the results obtained during experiments on the delignification of wood, allowed the problem of the existence of two types of natural lignin differing significantly in molecular weight to be settled. However, the solution of the problem of the homogeneity or heterogeneity of lignin not isolated from plant tissue is hindered by the impossibility of an unambiguous interpretation of the results examined in Section II. This is primarily because the use of acids or alkalis during the wood delignification processes considered above leads to more or less significant changes (on the one hand, hydrolytic; on the other, condensation) in the natural lignin, which change its structure significantly [28]. It is now impossible to speak with complete certainty about the absence of depolymerisation or condensation changes in the lignin even in its enzymatic isolation from the wood [33], which is the mildest method of those examined in Section II. Hence the heterogeneity, according to molecular weight, of the lignins isolated from wood by various methods may be due to the heterogeneity of the natural lignin or may be secondary, being the consequence of condensation or hydrolysis of the lignin during isolation.

In this connection other aspects of the problem of the heterogeneity of natural lignin which are of some interest and which can assist in presenting a more complete, even if more complex, picture of the contemporary state of this problem must be considered.

The non-uniformity of the distribution of lignin in plant tissue, considered in Section III, enabled certain investigators [27,30,33] to suggest the localisation of lignins with different molecular weights in different parts of the cell walls of wood tissue. The arguments of these investigators were based on a series of propositions.

According to contemporary ideas [71-74] the first traces of lignification are observed in the primary wall in the cell corners, then the process of accumulation and deposition of the lignin is extended to the middle lamella and throughout the entire primary wall, subsequently into the corners of the middle lamella of the cell, and finally, into the secondary wall (layers S_1, S_2, and S_3, successively, see Fig. 2). Starting from this, it is logical to suggest that the molecular weight of the lignin will be greatest at those parts of the cell wall, where the concentration of the lignin precursors is highest and consequently the degree of condensation polymerisation is increased. Such parts of the cell wall are the primary wall and the middle lamella.

At the same time, according to Cowling's results [75], obtained in the enzymatic isolation of lignin with brown rot fungus, the micro-organisms initially occupy the lumens of the cells of the wood tissue. It is logical to assume that in this connection the enzymatic "digestion" of carbohydrates takes place gradually in the direction of the middle lamella and consequently the lignin in the earlier stages of the enzymatic decomposition of the wood is extracted from the secondary layer and in the later stages from the middle lamella. Such a sequence of enzymatic action is shown by several investigators [45,76,77]. On this basis, Brown and coworkers [33] assumed that the low-molecular-weight lignin extracted in the initial stages of the enzymatic removal of carbohydrates is extracted from the middle lamella. The stated distribution of lignins with different molecular weights in the cell walls will favour a gradient in the size of the spaces between the microfibrils and the distances between the cellulose macromolecules in the amorphous regions from the central plate substance through the secondary wall to the lumen [53]. The electron microscope studies mentioned above [57-59] showed that the greatest density of lignin is observed in the middle lamella, the primary wall, and the S_3 layer. In the S_2 layer of the secondary wall the lignin exists as a branched three-dimensional lattice which immobilises the carbohydrate chains, which exhibit crystal structures. Furthermore all the investigators noted an obvious orientation of the lignin in the S_1 layer.

Finally, as a result of the investigation of the path of penetration of various liquids into wood and of the influence on this process of morphological factors, Wardrop and Davies [78] found that after penetration into the lumens of the cells the reagents used diffuse through the cell walls so that the middle lamella and especially the regions of the cell angles of the middle lamellas are the last parts which react with these agents. In the digestion of wood the path of penetration of the digestion solutions stayed the same but the rate of passage was greatly increased. These results give a basis for suggesting that low-molecular-weight lignin isolated at different stages of the delignification of wood by different methods (see Section II) is localised in the secondary wall, but the high-molecular-weight lignin is localised in the middle lamella.

A special investigation of the topochemistry of the delignification of spruce wood during industrial digestions showed the following regularities [79]. In the early stages of kraft and acid sulphite digestions the lignin is preferentially removed from the secondary cell wall. After ~50% delignification the lignin of the middle lamella is rapidly dissolved, leaving the residual lignin in the secondary wall. In the neutral sulphite digestion the removal of lignin from the secondary cell wall and middle lamella proceeds with approximately the same rates up to 50% delignification. Approximately analogous topochemical models of delignification were observed in kraft and neutral sulphite diges-

tions of birch wood [74]; in the early stages of the digestions preferential delignification of the secondary walls of the fibres and vessels. It is interesting to note that the sequence of the delignification of the various morphological parts of the cell wall of both spruce [79] and birch [74] wood in the order of the digestion processes used is: SW > > ML(cc) > ML(r)(t) (for symbols see Table 9), opposite to that examined above for the deposition of lignin during the lignification of plant tissue.

According to some results [74,79], the above morphological differences in the rate of delignification are not connected with the diffusion of the active reagent into the cell wall or with the diffusion of lignin macromolecules from the cell walls, but are due evidently to the different stability of the lignins to the actions of the digestion solutions. Were the morphological structure of the cell the main factor affecting the rate of delignification, it could be expected that the sudden breakdown of the wood structure (for example, as a result of the compression treatment of the wood at high temperature) leads to a considerable change in the rate of delignification. However, as the investigations of Yean and coworkers [80] have shown, preliminary treatment of spruce and birch sawdusts at pressures up to 35 155 kgf cm^{-2} and temperatures up to 200°C hardly altered the rate of delignification. Analogous results were obtained by Kleinert [81], who showed that preliminary compression of the wood had no effect on the absorption of SO_2 nor on the delignification in sulphite and kraft digestions. These results show that since the changes in the morphological structure of the cells have no significant effect on the rate of delignification of wood, the rate-determining factor for the dissolution of lignin in the various morphological parts of the cell wall is not its accessibility but the chemical structure of the lignins in these regions, which also determines their different degree of stability to the action of digestion solutions.

The mathematical model for the degradation of a three-dimensional gel developed by Szabo and Goring [82], applied to the delignification of spruce wood in kraft and acid sulphite digestions is thought [82] to confirm this assumption. In their calculations Szabo and Goring started from the assumption that the degradation of a three-dimensional gel is a reversible process in relation to trifunctional polycondensation, the theory of which was propounded by Flory [83]. According to this theory, the polycondensation of monomers which contain more than two functional groups leads to the formation of a three-dimensional lattice polymer. A characteristic feature of the three-dimensional polycondensation is the sudden formation of an infinite lattice observable at the point of gel formation. After this a high-molecular-weight three-dimensional lattice polymer (the so-called "gel-component") and a low-molecular-weight soluble product (the so-called sol-component) are present in the system, but a sharp separation into these components is not observed: the particles of the sol enclose the infinite lattice of the gel. With further condensation the amount and molecular weight of the sol component decrease as a result of the selective addition of its coarser and more complex particles to the infinite lattice of the gel-component, According to the model developed by Szabo and Goring, in the degradation of the three-dimensional gel initially low-molecular weight fragments are formed, which are distinct from the infinite lattice of the gel owing to the breaking of the intramolecular transverse bonds. In the later stages of the degradation the gel will "break up" and give coarser fragments of soluble lignin. In this model Szabo and Goring started from the assumption of the presence of two structurally different gels, one of which corresponds to the secondary wall lignin, the other to the lignin of the central lamella. The quantities predicted on the basis of the model developed by Szabo and Goring agree well with the experimentally obtained topochemical model of the delignification of spruce wood [79] and also with the molecular weight distribution of lignin in its isolation in acid sulphite [27] and kraft [31] digestions of spruce wood.

An analogous condensation was proposed by Elton [84] on the basis of a kinetic investigation of the delignification of wood of the loblolly pine during neutral sulphite digestion. As a result of the investigations it was found that 8–11% of the lignin is removed at an appreciably greater rate than the remaining lignin. This difference in the rate of delignification in the initial and subsequent periods of digestion was explained primarily on the basis of the molecular weight distribution of the lignin in the wood, and also on the basis of the diffusion of the reaction product and the physical availability of the lignin in the plant tissue. Elton assumed that the low-molecular-weight lignin dissolves slowly after sulphidation, and the rate of delignification in the initial digestion period is determined by the rate of sulphitation. On the other hand, for the dissolution of the remaining high-molecular-weight lignin its hydrolysis to finer fragments is necessary, which also determines the rate of delignification in the subsequent period of digestion.

In ending our examination of the problems associated with the topochemical delignification of wood during industrial digestions mention must be made of the work of Jayme and Torgersen [85], who investigated the topochemical delignification in sulphite and sulphate digestions. Their ultraviolet microscopical investigation into the partial delignification of spruce wood showed that in the sulphite digestion (loss of 27.5% of the initial lignin) the concentration of lignin in the secondary cell wall hardly altered and almost all the dissolved lignin was removed from the middle lamella. The delignification began with the material of the middle lamella and proceeded in the direction of the lumen. In sulphate digestion (removal of 29.8% of the initial lignin) a considerable proportion of the lignin was removed from both the secondary wall and from the middle lamella. The delignification in this instance began simultaneously from the middle lamella and the lumen.

In the present review we have not spent time on an examination of the occasionally contradictory results of the early investigations on the topochemistry of the delignification of wood [78,86–97]. However, a comparison of only two late investigations in this field (Goring and coworkers [79] and Jayme and Torgersen [85]) who used the same method but arrived at different conclusions shows that this problem requires further experiments to be made.

In conclusion, it is interesting to trace the evolution of Goring's opinions on the heterogeneity of natural lignin. On the basis of investigations of the molecular weight distribution of the lignins isolated during acid sulphite [27] and bisulphite [30] digestions, he suggested the presence in spruce wood of two types of lignin: low-molecular and high-molecular-weight, localised in different parts of the cell wall. Later experiments [79] on the topochemistry of the delignification of spruce wood, which showed that in the early stages of sulphite and kraft digestions there is preferential delignification of the secondary wall, allowed Goring [98] to suggest that the low-molecular-weight lignin is localised in the secondary wall. Finally, the theory of the degradation of a three-dimensional gel, developed by Szabo and Goring [82] led them to the conclusion that low-

molecular-weight lignin, which, dissolves in the early stages of the digestion, is formed as the result of the degradation of both lignin gel localised in the secondary wall and also the lignin gel of the middle lamella. They assume that instead of low- and high-molecular weight lignins we must speak of the structurally different lignin of the secondary wall and the lignin of the middle lamella.

V. HETEROGENEITY OF LIGNIN IN RELATION TO ITS BONDING WITH THE OTHER COMPONENTS OF PLANT TISSUE

In conclusion yet another aspect of the problem of the heterogeneity of natural lignin must be mentioned, one which is connected with the existence of lignocarbohydrate bonds in plant tissues [99].

In 1958 Aaltio [100,101] published the results of an extensive investigation of the type of bonding of lignin with other components of plant tissue. He undertook a series of nine butanol digestions of aspen wood. Fine sawdust, previously extracted with acetone was digested with neutral buffered butanol–water mixture for 4 h at 158°C. Each successive digestion was carried out on the residue from the previous one. The solubility of the wood was traced by analysis of the insoluble residues and digestion solutions. Table 10 gives some of the results of the investigations.

Table 10. Some results obtained in successive digestions of aspen wood with buffered aqueous butanol [100].

Digestion No.	Ratio of dissolved lignin to dissolved pentosane-uronids	OCH_3 groups in dissolved lignin, %		Digestion No.	Ratio of dissolved lignin to dissolved pentosane-uronids	OCH_3 groups in dissolved lignin, %	
		found	calculated			found	calculated
1	1.05	21.4	21.7	6	0.59	—	15.3
2	0.75	—	21.3	7	0.55	15.0	15.0
3	0.77	20.1	20.2	8	0.54	—	15.0
4	0.73	—	21.4	9	0.55	14.9	12.0
5	0.74	17.9	17.9				

The results led Aaltio to the conclusion that aspen wood consists partly of homogeneous ligno-carbohydrate complexes. According to his interpretation, during the first five digestions there is a gradual action of the digestion solution on the middle lamella, which leads to the separation of a highly methoxylated lignin and pentosan uronides in the ratio ~ 0.75. After dissolution of all the middle lamella defibrisation of the material takes place and in subsequent digestions the secondary cell wall is subjected to the action of the digestion solution. This leads to the separation of lowly methoxylated lignin and pentosan uronides again in a constant ratio (~ 0.55), which, however, differs from the ratio found for the dissolution of the middle lamella. It is noteworthy that according to Aaltio, the greater part of the lignin in the complex isolated from the middle lamella is in the free state and does not have chemical bonds with the carbohydrate components. This assumption of Aaltio agrees with the conclusions of other investigators.

Thus, according to Björkman's ideas [102], the lignin in the growing plant tissues can be divided into two fractions in respect of its bonding with hemicelluloses. One fraction has a very small number of bonds with hemicelluloses or none at all and in all probability is localised in the middle lamella. This fraction is isolated under mild conditions and corresponds to the lignin of mechanical grinding obtained by Björkman's method. The other fraction is firmly linked with hemicelluloses and can be isolated by more severe methods. This fraction corresponds with the lignocarbohydrate complex obtainable by the Björkman method. The ratio between these fractions is ~1:1. On the basis of experiments on the fractionation of hydroxyethylated wood (previously ground in a ball mill) dissolved in dimethylformamide, Brownell and West [103] also concluded that approximately three-quarters of all the lignin in wood is chemically bound with carbohydrates. About one-quarter of the lignin can be easily separated from the carbohydrates. They assume that this fraction is not linked with the carbohydrates by a hydrogen bond although it is quite possible to assume that these bonds are broken at the time the wood is ground in the ball mill. As a result of an investigation involving oxidation of wood with hydrogen peroxide, Berlin [104] concluded that the lignin localised in the middle lamella is of higher molecular weight and is chemically unconnected with the polysaccharides. Tishchenko [105] concluded, on the basis of results on the stepwise ozonation of spruce wood in ethyl acetate, that in spruce there are both lignin unconnected chemically with carbohydrates (not less than 43% of all the lignin) and lignin thus connected.

It is interesting to note that in 1934 Boyarkin [106] made a microchemical examination of the sclerin-chemical fibres using two widely known colour reactions: phloroglucinol and the Mäule reaction. As a result of this, he found the presence of different microchemical reactions at different elements of the lignified tissues. Thus a characteristic reaction with phloroglucinol + conc. H_2SO_4 is shown only by the primary walls of neighbouring cells with intercell substance between them, whereas the Mäule reaction is characteristic only for the secondary cell wall‡. These results enabled him to suggest the existence in the lignified tissue of two components of lignin, designated respectively as "F" and "M". Later Bardinskaya [112] found that alkaline extraction of lignified material alters the microchemical reaction significantly: after extraction with alkali (0.5 *N* NaOH) the vessels which had retained their form were not stained by phloroglucinol + H_2SO_4. Evidently this is because the alkali extracts that part of the lignin which is responsible for the phloroglucinol reaction of the lignified fibres. On the basis of this a scheme for the isolation of both components of the lignin was proposed; it involved the alkaline extraction of the plant material, previously extracted with alcohol–benzene mixture (isolation of component "F") and then the acid hydrolysis of the residue (isolation of component "M"). The fractions obtained were quite different in elementary and functional composition (Table 11).

According to Bardinskaya [116], fraction "F" is the most "mobile" part of the lignin, less firmly connected with the other components of the cell wall. The remaining part of the lignin (fraction "M") is evidently more strongly

‡It has been repeatedly suggested [107-111] that this difference in the colours in the microreactions on the lignin is because some of the histochemical reactions (including that of phloroglucinol) are characteristic for the guacyl residues of the lignin and the second group (including the Mäule reaction) for the syringyl residues.

bound to the polysaccharides components of the cell wall and therefore is not extracted by alkali under the conditions employed. Bardinskaya assumes that the two fractions also differ in molecular weight. In addition it has been suggested [117,118] that there is the possibility of the existence of different paths of biosynthesis for the two components of the lignin. Later Furst [119] investigated differential conduction systems and the dynamics of the accumulation of lignin in the elements of the xylem at various stages of the development of leaves of certain types of onion from the moment of germination of the seed up to 4–6 month seedlings. He showed that the "F" component is formed earlier than "M" lignin, and if the "F" component starts to be deposited at the side of the middle lamella and primary wall, then the component "M" is mainly deposited on the inner (at the side of the cavity) envelopes of the leaf tracheids.

Table 11. Characteristics of the lignin fractions isolated from sugar beet stalks [114,115].

Fraction	Yield of lignin, % of initial raw material	Present, %				Yield of aromatic aldehydes after nitrobenzene oxidation of the lignin, % of lignin
		C	H	N	OCH_3	
Lignin "F"	0.59	57.32	6.62	3.71	14.05	6.0
Lignin "M"	7.25	58.32	6.02	0.9	18.46	4.8

The hypothesis of the existence of two types of lignin received confirmation as a result of Lüdtke's chemical investigation [120] of the best fibres of various plants. According to his results, these lignins are distinguished in localisation in the cell wall of the plant. The major fraction of the lignin is localised in the middle lamella; the second fraction, which makes up 10–30% of all the lignin, is localised in the primary and secondary cell walls and is chemically bound with carbohydrate material. These fractions differ somewhat in elemental composition and content of OCH_3 groups.

In conclusion, mention must be made of the results of an investigation by Matsukura and Sakakibara, published recently [121]. They isolated from the wood of the spruce (*Picea jezoensis*), ground in a vibromill, the mechanically ground lignin (MGL) and lignin-carbohydrate complex (LHC) (by extraction with dimethylsulphoxide) according to Björkman's method. The MCL and LHC and the residue were subjected to ethanolysis and also to oxidation by $KMnO_4$ or nitrobenzene in alkaline medium. The quantity of degradation products was found by gas chromatography.

The oxidation of LHC by permanganate led to the production of a very small quantity of degradation products: 1.78% (reckoning from the lignin in the LHC) veratric acid, 0.46% isohemipinic, and 0.25% dehydrodiveratric acid. As a result of the ethanolysis of LHC, monomeric products were obtain in good yield: guacylacetone, methyl vanyloyl ketone, and 2-ethoxy-1-guacylpropan-1-one. From these results it was concluded that bonds of the arylglycerol β-aryl ethers type predominate in the lignin present in the LHC.

The oxidation of the wood residue with permanganate led to the production of the same acids in good yields: 9.88, 3.46, and 3.43% on the lignin; at the same time as a result of ethanolysis only insignificant amounts of the monomeric "Hibbert ketones" were obtained. These results are thought to show the presence in the wood residue of a large quantity of condensed chains of lignin. The results of alkaline nitrobenzene oxidation of all three specimens showed small but distinguishable differences between them.

Matsukura and Sakakibara assume that the above results convincingly show the heterogeneity of the chemical structure of the lignin. According to the results obtained the LMP isolated by the Björkman method exhibits a structure intermediate between the other two preparations and in this connection they think that it cannot be regarded as a model for all the lignin of wood.

---o0o---

The investigations of the last 10–15 years which we have considered above enable us to acknowledge to the first approximation the presence in plant tissue of two types of lignin, which differ in molecular weight, in localisation in the cell wall, in bonding with other components of the plant tissue, and also in the topochemical behaviour in the different processes for the digestion of wood.

The results of these investigation confirm the hypotheses, repeatedly expressed earlier, concerning the heterogeneity of natural lignin. Here we must first note Klason's hypothesis [122–124] concerning the existence in spruce wood of α- and β-lignins. He formulated this hypothesis on the basis of experiments on the precipitation with 2-naphthylamine hydrochloride of the lignosulphonic acid obtainable in the sulphite digestion of wood. Later Holmberg and Wintzell [125] and also Hibbert and coworkers [126] reported the presence of two fractions in alkali lignin which could be isolated from black alkali after the soda digestion of spruce wood. Proof of the heterogeneity of natural lignin is also provided by the results of the fractionation of a series of preparations that have been isolated: formic acid lignin isolated from birch wood [127], ethanol-lignin from wood [128–130], acetic acid [131] and butanol-lignins [132–135], isolated from various wood species; lignin isolated by hydrogenolysis of maple wood [130,136], lignins extracted from oat and wheat straw by methylcellolsolve + HCl [137]; lignins isolated from bamboo [138] and aspen [139,140] woods by a hydrotropic method, and also enzymatically isolated lignins [141]. Finally, mention must be made of the hypothesis of Purves [142], who assumed that the molecular weight and the ratio of the "free" and "combined" lignins in the plants can vary not only with the type of plant but also with growth and the growing conditions. These investigations have been partly considered in Lebedev's review [143].

As regards the practical recommendations [74,79] which can be made from the existence of different types of natural lignin, clearly of most importance would be the finding of a delignifying agent which exhibits specific action towards the middle lamella, which probably consists mainly of lignin. This would lead to the obtaining of a fibrous mass in very high yield which could then either be used as such or be subjected to further delignification for obtaining a desired type of fibre.

Catalytic Disproportionation of Unsaturated Hydrocarbons

M.L.Khidekel', A.D.Shebaldova, and I.V.Kalechits

The review considers the data at present available on the disproportionation reaction† of olefins. The practical value of this versatile reaction, which opens up new pathways for synthesis of a wide variety of unsaturated hydrocarbons, is noted. The applications of the reaction to dienes and acetylenes are also considered.
Studies using various heterogeneous disproportionation catalysts have been described, together with simple process parameters (catalyst activity, temperature, pressure, etc).
Much attention has been devoted to the applications of homogeneous catalytic systems in the disproportionation of olefins and to the characteristics which distinguish them from heterogeneous catalysts. Problems concerned with the reaction mechanism and its stereochemical features are discussed.
The bibliography includes 92 references.

I. INTRODUCTION

The most important and interesting reactions in organic chemistry discovered in the last decade undoubtedly include the disproportionation of olefins. This reaction apparently constitutes a new field in the chemistry of unsaturated compounds.

According to the first patent data [1-4] and more detailed subsequent studies [5,6], acyclic olefins can be converted in the presence of catalysts into higher and lower homologues:

$$\underset{50\%}{2\,RCH{=}CHR'} \rightleftarrows \underset{25\%}{RCH{=}CHR} + \underset{25\%}{R'CH{=}CHR'}.$$

The olefins with a smaller and larger number of carbon atoms (compared with the initial substance) are formed in almost equal molar amounts. The degree of conversion is limited by the thermodynamic equilibrium.

The new catalytic reaction immediately attracted attention, which led initially to the publication (starting in 1964) of numerous patents dealing with the search for the best disproportionation catalysts, the development of suitable conditions for the process, and its practical applications.

The considerable interest in the disproportionation of olefins is due to the versatility of this reaction and the consequent increase in the number of methods for the chemical processing of unsaturated hydrocarbons.

Some of these possibilities will be mentioned here. The disproportionation reaction constitutes an extremely effective means for the preparation of olefins with various structures, many of which serve as the starting material in many manufacturing processes. For example, the disproportionation of propene leads to the preparation of very pure ethylene and straight-chain butenes—olefins which are used in the large-scale manufacture of various valuable products (polyethylene, vinyl chloride, styrene, ethylene oxide, butadiene, butyl alcohols, and others).

The disproportionation of straight-chain butenes yields straight-chain pentenes—the starting material for the synthesis of isoprene. For the synthesis of olefinic hydrocarbons, disproportionation is particularly promising because many types of the initial olefinic raw material can be provided by the petrochemical industry.

An unusual feature of the reaction is the mutual disproportionation of two molecules of different olefins. In particular, if one of the olefins is ethylene, the reaction (the so called ethenolysis) makes it possible to convert olefins with an inner multiple bond into α-olefins [6-8].

The application of disproportionation to cyclo-olefins merits particular attention, since it provides a new synthesis of macrocycles [9-11]. Mutual disproportionation of cyclic and alicyclic mono-olefins leads to the formation of diolefins [12,13].

It is noteworthy that the disproportionation reaction is not characteristic solely of mono-olefins. Recently the disproportionation of dienes [14] and alkynes [15] was discovered. It is also likely that olefins with other than alkyl substituents can also be disproportionated, as shown by the disproportionation of stilbene [16]. All these findings suggest that the disproportionation process has general applicability and is characteristic of all unsaturated compounds.

An important feature of the reaction is the high purity of the products obtained, which could hardly be achieved by any other method of synthesis (especially with higher olefins).

A fundamentally new stage in the development of the disproportionation reaction has been the use of homogeneous catalytic systems [17-24], which exhibit an unusually high selectivity and stereospecificity. An industrial application of the disproportionation reaction has been achieved comparatively rapidly, particularly in the conversion of propene into ethylene and straight-chain butenes [25-27]. The first industrial apparatus for this process, which also included a system for the further conversion of straight-chain butenes into butadiene, was first used in Canada in 1966‡. The annual production

†In addition to the term "disproportionation", the terms "dismutation" and "metathesis" are also employed.

‡The process was patented by the Phillips Petroleum Co. under the name "Triolefin Process". [28]

from the apparatus with respect to the raw material (obtained from pyrolitic gas) was 31500 tonnes, the output of ethylene being 9000 tonnes and that of straight-chain butenes 22 700 tonnes[27]. Thus the problem of the utilisation of propene (the principal side product in the manufacture of ethylene), the demand for which lags behind its supply in the world markets[29], can be partially solved.

One can also point to other applications of the reaction which show promise for industry. For example, mixtures of ethylene and but-2-ene (disproportionation products of propene) can be usefully alkylated with isobutane[30,31]. The alkylated products thus obtained have a higher octane number than the alkylation products based on propene.

A combination of the cracking of petroleum raw material with olefin disproportionation and dehydrogenation processes and also with the isomerisation and polymerisation of olefins has been proposed in a number of studies[3, 32-35].

Thus the disproportionation of unsaturated hydrocarbons opens up new and interesting possibilities not only for preparative chemistry but also for chemical industry.

At the present time there are no publications in the USSR literature giving a systematic and general account of the advances in the disproportionation of olefinic compounds§. The aim of the present review is to fill this gap.

II. HETEROGENEOUS CATALYSTS FOR THE DISPROPORTIONATION OF OLEFINS

The range of metals whose compounds provide the basis of heterogeneous catalysts for the disproportionation of olefins was comparatively small until recently: these were mainly molybdenum, tungsten, and rhenium; the list has been appreciably expanded only in recent years, the following metals having been introduced: rhodium, iridium, osmium, ruthenium, niobium, tantalum, tellurium, lanthanum, thorium, vanadium, and tin.

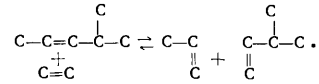
The most common catalysts are molybdenum, tungsten, and rhenium oxides deposited on alumina or silica gel. Among these the cobalt–molybdenum catalysts are outstanding because of their effectiveness, availability, and relative cheapness[1-8,37-57]. Their molybdenum oxide content is usually 1–15% (mainly 12–14%) and that of cobalt oxide is 1–5% (the optimum content is 2.5–3.5%). These catalysts are active over a very wide range of temperatures: from 20° to 400°C (the optimum range is 90 to 260°C); the pressure can vary from atmospheric to 140 atm. An industrial cobalt–molybdenum catalyst (11% MoO_3, 3.4% CoO, and 85.6% Al_2O_3)[5] showed a very high efficiency: for example at 205°C and a pressure of 32 atm, the conversion of propene supplied at a weight rate of 3.5–4.4 kg h^{-1} reached 42.4%, the selectivity being greater than 94%.

A chromium–molybdenum catalyst on alumina with somewhat better properties than the cobalt–molybdenum catalysts was proposed quite recently[52].

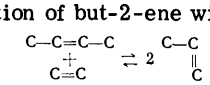
Tungsten oxide (usually 3% WO_3) also exhibits a high disproportionating activity[4,37,43-50,53-55]; however, this catalyst is effective at higher temperatures than the molybdenum catalyst (250–550°). Thus the maximum degree of conversion of propene (44.8%) in the presence of tungsten oxide is attained only at 427°C.[44,53] The use of tungsten oxide on silica gel for the synthesis of 2-methylbut-2-ene (the starting material in the synthesis of isoprene) by the disproportionation of a mixture of isobutene with but-2-ene or propene has been described[55]. For an isobutene conversion of 35%, the isopentene content in the C_5 fraction was 92–97% (450°C and 21 atm).

After the molybdenum and tungsten oxides, catalysts based on rhenium oxide (1–20% Re_2O_7) began to be employed[8,47-51,56-66]. They rapidly gained recognition owing to their activity, high selectivity, and resistance to catalytic poisons. Moreover, with rhenium catalysts it proved possible to carry out the reaction under milder conditions than on MoO_3 and WO_3: 20–100°C and atmospheric pressure. But-1-ene is converted into ethylene and hex-3-ene with a selectivity of 95.5% at a temperature as low as 25°C, the conversion being 38%.[64]

Rhenium catalysts yielded excellent results in ethenolysis[8,64]; in particular, 3-methylbut-1-ene and propene were obtained from 4-methylpent-2-ene and ethylene in 93% yield for a 94% conversion of the initial higher olefin (25–140°C and atmospheric pressure)[64]:



The disproportionation of but-2-ene with ethylene,



under the same conditions gives a 100% yield of propene (the conversion with respect to but-2-ene is 55%).

The disproportionation of readily polymerised secondary and tertiary olefins with alkyl and aryl substituents has been achieved in the presence of Re_2O_7/Al_2O_3.[65,66]

Apart from the molybdenum, tungsten, and rhenium oxides mentioned above, the carbonyls of these metals deposited in an amount of 5–10% on alumina are also employed as catalysts for the disproportionation of olefins[5,35,45,67]. The carbonyl catalysts are active at fairly low temperatures (100–150°C) and are particularly effective in the disproportionation of higher olefins. The dependence of the activity on the nature of the metal is the same as for the oxides, i.e. $Mo(CO)_6$ and $Re(CO)_{10}$ show the highest activity. For example, whereas the conversion of but-1-ene in the presence of $Mo(CO)_6/Al_2O_3$ (120°C and 35 atm) is 10% and that of pent-1-ene 60%, in the presence of $W(CO)_6/Al_2O_3$ the conversions of these olefins are 7 and 44% respectively[5].

Attempts were made to use alumina, silica gel, and aluminosilicates promoted with molybdenum and tungsten sulphides (2–10%) for the disproportionation of C_3–C_{20} olefins[49,68]. However, these catalysts proved to be relatively inactive over a fairly wide temperature range (65–535°C) (for example, the conversion of propene did not exceed 1.3%).[68]

Among catalysts including other metals in their composition, those with lanthanum, rhodium, iridium, osmium, and tin oxides on alumina are known[69]. They all exhibit very low disproportionating activity (for example, the maximum conversion of propene at 350°C was achieved in the presence of RhO_3 but amounted to only 6%). According to patent data[70-73], the disproportionation catalysts are also promoted by tantalum, tellurium, niobium, ruthenium, vanadium, and thorium (mainly as the oxides). Niobium, tantalum, and tellurium oxides proved to be the most effective among these. However, a quantitative comparison of the activities of these catalysts is difficult because of the differences in the test conditions.

§During the preparation of this paper, Bailey's review was published[36].

Recently it was discovered [74,75] that olefins are appreciably disproportionated on alumina alone. The conversion of propene in this process was 0.1–8.5% depending on temperature; a higher conversion was achieved at 400°C and atmospheric pressure, the selectivity being 12% with respect to ethylene and 58% with respect to straight-chain butenes.

The disproportionation reaction is probably very common in catalysis and accompanies many processes involving the formation or conversion of olefins in the presence of alumina. In particular, it has been shown [75] that disproportionation takes place in the dehydration of isopropyl alcohol [76] and also probably under the conditions of ethylene hydropolymerisation [77].

The principal parameters which determine the course of the olefin disproportionation reaction are catalyst activity, temperature, and contact time. Pressure apparently does not play a significant role (the reaction takes place without a change in volume); it has an effect only in consequence of a change in the density of the gases. The effect of these factors on the conversion and selectivity has been investigated in greatest detail for the disproportionation of propene [5,25,31,52,53,67,78,79] in connection with the development of the optimum conditions for the industrial process.

The kinetics of the disproportionation of propene on WO_3/Al_2O_3 (in a pilot plant) were examined [80] and it was shown that the reaction is between an adsorbed propene molecule and one from the gas phase (or physically adsorbed—Rideal's model). The rate of the process is limited by the rate of collision between the molecule and the catalyst surface. The apparent propene disproportionation energy is 21.6 kcal mole^{-1}.

However, the results obtained in a recent study [81] for the initial rate of the disproportionation of propene (in the presence of the cobalt–molybdenum catalyst) support another mechanism: the reaction takes place between two propene molecules adsorbed on the surface of the catalyst (the Langmuir–Hinshelwood model).

A thermodynamic calculation has been carried out on the disproportionation of propene and the equilibrium constants have been determined in the range 50–300°C. [82]

The activity of disproportionation catalysts, like that of catalysts in other processes, is determined mainly by the nature of the metal and the type of carrier; in addition, promoting additives, the method of preparation of the catalyst, and catalytic poisons have a considerable influence.

As already mentioned, transition metal (tungsten, molybdenum, and rhenium) compounds are best catalysts for the disproportionation of olefins. Cobalt [5,78], alkali and alkaline earth metals [6,41–44,49] and also compounds of Group VIII metals [49] have been recommended as promoting additives to oxide catalysts. Side reactions (isomerisation, coke formation, etc.) are mainly suppressed in their presence.

A general method for enhancing the activity of disproportionation catalysts consists in their preliminary activation by gases at 300–900°C (nitrogen, hydrogen, oxygen, carbon dioxide, carbon monoxide, helium, and dry air) followed by treatment with an inert gas (mainly nitrogen). Thus the conversion of straight-chain pentene after treatment of WO_3/SiO_2 with carbon monoxide increased by 36.5%. [43] The effect of preliminary treatment on the activity of disproportionation catalysts has been confirmed by infrared spectroscopy [79] [for $Mo(CO_6)/Al_2O_3$]. The effectiveness of the catalysts, in particular a rhenium catalyst, depends to some extent on the polarity of the solvent in which the oxide is dissolved for subsequent impregnation of the carrier [60]. When dioxan, methanol, and water were used, the degree of disproportionation of but-1-ene was 31.5, 29, and 24.6% respectively with molar selectivities in relation to $C_2 + C_6$ olefins of 95, 93, and 78.2%.

To improve the activity of the solid oxide catalysts, it is recommended that [72] they be treated in a hydrocarbon solution by the hydrides of organic derivatives of Group I, II, or III metals (for example with triethylaluminium).

Alumina, silica gel, and aluminosilicates were mainly employed as carriers, and less frequently aluminium, magnesium, titanium, zirconium, and calcium phosphates [31,70] and magnesium [4], thorium, and zirconium oxides [70]. The oxides of Group IV elements were employed for rhenium catalysts [58,59,62] and it was found that in the presence of Re_2O_7/SnO_2 the conversion of but-2-ene was higher by a factor of 10 compared with Re_2O_7/Al_2O_3 (other conditions being equal) [62]. One cannot rule out the possibility that carriers comprising the oxides of Group IV elements themselves catalyse the disproportionation reaction.

The conversion of olefins increases by 5–10% and the period of constant activity of the catalyst is doubled when the alumina carrier is first treated with a 0.001–10 N solution of an organic or inorganic acid (mainly hydrochloric and acetic acids) [45,48,51,63,67,69].

The problem of the effect of catalytic poisons on the activity of heterogeneous disproportionation catalysts is very important. The majority of different types of olefinic starting materials are obtained by pyrolysis or thermal cracking and contain numerous admixtures which deactivate the catalysts (water, hydrogen sulphide, oxygen and its compounds, and also alkynes and alkadienes). The presence of water or sulphur compounds in the starting material rapidly reduces the conversion of the olefins. For example, when propene is saturated with water, its conversion in the presence of WO_3/SiO_2 is reduced in 1 h to 10% and in the presence of sulphur dioxide to 16%, while hydrogen sulphide completely deactivates the catalyst [53]. The elimination of water and sulphur compounds under industrial conditions can be successfully achieved using molecular sieves [25].

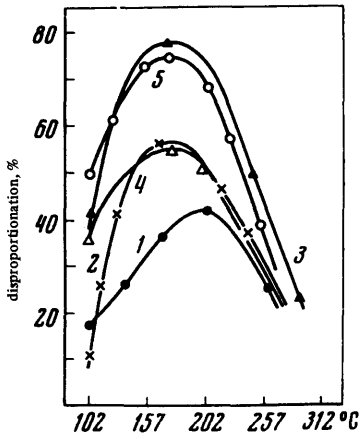
Alkynes and alkadienes, which form coke and polymer deposits on the catalysts, are also powerful catalytic poisons [43]. In this case the activity of the catalyst can be restored only by regeneration. The yield of coke is reduced by the addition of 2–4% of cobalt oxide to molybdenum oxide [5]. In addition, the olefinic starting materials may be subjected to preliminary purification, designed to remove acetylenes and dienes, by selective hydrogenation on industrial palladised catalysts [25].

Disproportionation in the presence of 10–60% of hydrogen is recommended as a method which eliminates the necessity for a careful preliminary removal of alkadienes from alkenes; at the same time the activity and the useful life of the catalyst increase appreciably [49].

The resistance of the catalyst to poisons increases with process temperature; however, as will be shown below, high-temperature conditions are undesirable for many reasons.

The presence in the olefinic starting material of paraffinic and cycloparaffinic hydrocarbons does not affect the reaction and therefore they can be used as inert diluents [5,43,48,53,69]. Thus a change in the concentration of propene in the starting material from 60 to 99% (the residue was propane) did not affect its conversion. This is very important, since there is then no need to concentrate the olefins before their disproportionation.

The effect of process temperature on the degree of conversion of olefins was investigated in the disproportionation of propene [5,25,52,53,82], straight-chain butenes [5,6], straight-chain pentenes [5], hex-1-ene [5], oct-1-ene [5] and other olefins [48,51,68]. In all cases the temperature dependence of their conversion is described by a curve with a maximum, which is typical of reactions the rate of which is limited by an equilibrium (see Figure).



Effect of temperature on the degree of disproportionation of olefins: 1) propene; 2) but-1-ene; 3) pent-1-ene; 3) hex-1-ene; 5) oct-1-ene.

Optimum temperatures correspond to the majority of the most favourable combinations of degree of conversion and selectivity, since after the attainment of the temperature of the onset of isomerisation and cracking, the efficiency begins to decrease rapidly. Thus, when the temperature is increased from 95° to 205°C ($CoO.MoO_3.Al_2O_3$ catalyst, pressure 32 atm), the conversion of propene increases from 17.9 to 42.6%. According to a thermodynamic calculation [82], a further increase of temperature should lead to increased conversion. Nevertheless, above 200°C the conversion fell to 14.6% (at 300°C), in all probability due to side processes and deactivation of the catalyst. The best combination of degree of conversion and selectivity for propene is achieved at 163°C.

Thermodynamically the disproportionation process is independent of pressure. [82] However, experimental data [5,43,52,53] show that an increase of pressure favours the process to some extent. Probably this effect may be explained by an increase of the concentration of the olefin on the catalyst surface, which in turn leads to an increase of the rate of reaction. It has also been noted that [43] a decrease of pressure (below 10 atm) in the disproportionation of higher olefins promotes the formation of products with a more branched chain than in the initial substances. In certain cases (particularly in the presence of MoO_3) an increase of pressure was accompanied by an increase in coke formation [43]. A pressure below 40 atm is usually optimum (for example, in the disproportion of propene it is 32 atm).

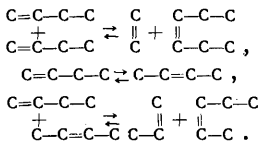
The space velocity at which the stream of starting material is supplied varies within wide limits probably only in the case of propene (between 10 and 130 kg h^{-1}) and does not influence appreciably the degree of conversion [25]. However, a further increase of space velocity (> 180 h^{-1}) leads to some decrease of the conversion of propene [52]. In the disproportionation of higher olefins, the rate of supply of the olefinic starting material plays an important role in determining the possibility of isomerisation, which usually becomes very appreciable at low flow rates of the starting material and almost disappears at high flow rates.

The contact time is related to pressure and space velocity and also depends on temperature and the activity of the catalyst. It can vary from 0.1 s to 120 min, the optimum time recommended being 0.1–60 s.

The main factor which precludes a 100% yield of the required products in the disproportionation of olefins is undesirable side reactions (isomerisation, cracking, polymerisation, condensation, and others), which inevitably occur to some extent on heterogeneous catalysts. However, by careful choice of conditions, the majority of side processes may be suppressed to an extremely insignificant level ensuring thereby a higher selectivity and conversion. The only reaction which cannot be completely eliminated is isomerisation.

It is noteworthy that the isomerising activity of the catalyst decreases more rapidly than its disproportionating activity [6]. Probably this is evidence that both reactions occur at different catalyst active centres. On this basis, isomerisation may be to a large extent suppressed by poisoning the acid regions of the catalyst (which are responsible for its isomerising capacity) by adding small amounts of alkali and alkaline earth metals [6,7,41–49], the effectiveness of the alkali metal ions increasing in the sequence sodium < potassium < rubidium < caesium [41]. When the catalyst is cautiously poisoned and appropriate conditions are chosen, it is possible to control the isomerisation reaction and to obtain pure olefins with a high degree of selectivity.

With this idea in mind, a detailed study was made of the disproportionation of straight-chain butenes [6], which can lead both to ethylene and hex-3-ene (from but-1-ene) and to propene and straight-chain pentenes (from but-2-ene):



By varying the reaction temperature, the rate of supply of but-1-ene, and the amount of sodium in the catalyst, it was possible to find the optimum conditions for both the disproportionation reaction (the formation of $C_2 + C_6$ olefins) and for isomerisation (the formation of $C_3 + C_5$ olefins). The highest selectivity with respect to $C_2 + C_6$ olefins (90.7%) was achieved in the presence of a cobalt–molybdenum catalyst treated with a 0.2 *N* solution of $NaHCO_3$ (140°C). An increase of temperature and a decrease of the rate of supply of but-1-ene promote its isomerisation to but-2-ene and hence an increase in the yield of $C_3 + C_5$ products.

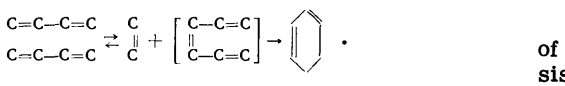
One of the important advantages of the olefins disproportionation process is the purity of the products. If one starts with a pure starting material, then theoretically pure alkenes should be obtained. However, in practice the reaction products are usually contaminated by impurities from various sources (the starting material and the regenerating gas), which are retained on the catalyst and are liberated in the subsequent working period. Moreover, another source of impurities is side reactions accompanying the disproportionation (isomerisation, cracking, hydrogenation, hydrogen transfer).

Nevertheless, the experience gained on an industrial apparatus for the disproportionation of propene has convincingly demonstrated that the majority of the sources of impurities can be controlled to some extent, so that the propene conversion products (ethylene and straight-chain butenes) do not require additional purification (the purity of of commerical ethylene, for example, can be easily raised to 99.9%).[25]

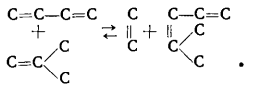
Not only mono-olefins but also dienes undergo the disproportionation reaction[14]. So far only heterogeneous catalysts for the process are known. In particular tungsten oxide deposited on silica gel (7% WO_3) with a small amount of sodium (0.19% Na_2O) catalyses at 538°C and atmospheric pressure the disproportionation of buta-1,3-diene, penta-1,3-diene, and also mixtures of these dienes with mono-olefins (propene, butenes).

The conversion of dienes (the cleavage of butadiene by *trans*-but-2-ene) in the presence of this catalyst reached 39% in the best case, but mostly did not exceed 10%. The selectivity in relation to the desired products was 46–100%. The reaction is complicated by the oligomerisation of the dienes in the presence of a tungsten catalyst (the amount of dimers in individual experiments reached 32%).

An interesting observation of the formation of cyclohexadiene (instead of the expected hexatriene) was made in the disproportionation of buta-1,3-diene:

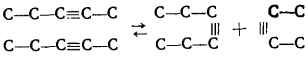


The disproportionation of dienes together with mono-olefins (a process similar to ethenolysis) makes it possible to obtain with a high degree of selectivity a new mono-olefin and a diene. For example, ethylene and 4-methylpenta-1,3-diene was obtained with 100% selectivity from buta-1,3-diene and isobutene:



Thus the disproportionation of dienes opens up vast possibilities both for preparative synthesis and for the industrial manufacture of valuable diene hydrocarbons of different structures.

The wide variety of disproportionation reactions of unsaturated hydrocarbons is also shown by the fact that these reactions are undergone by alkynes[15]. The formation of homologues was noted in many catalytic and thermal reactions of alkynes¶, but the experimental proof of disproportionation was obtained only recently for pent-2-yne[15]. The catalyst was tungsten oxide on silica gel. When the reaction was performed in a stream of cyclohexane at 350°C and at atmospheric pressure, pent-2-yne was converted with an overall yield of 44% into but-2-yne and hex-3-yne (molar ratio 1–1.2) and also a polymer. The selectivity with respect to the alkynes is 53%.



The first experiments on the disproportionation of alkynes left no doubt that this reaction, like that in the series of alkenes, constitutes a new means for the synthesis of a wide variety of acetylene homologues.

Summarising the applications of heterogeneous disproportionation catalysts, one must emphasise some of their advantages, such as relatively ready availability, the possibility of employment for a wide range of olefins (C_3–C_{40}, regardless of the position of the multiple bond and the degree of chain branching), and also a very favourable olefin: catalyst ratio (between 1000 : 1 and 1 : 1).

At the same time mention must be made of some important disadvantages of heterogeneous disproportionation. These include in the first place inadequate process selectivity. This applies in particular to higher olefins, the disproportionation products of which must be regarded as the result of two competing processes: double bond migration, and disproportionation. The reaction is apparently sufficiently selective only for the special case of the disproportionation of propene to ethylene and straight-chain butenes.

In addition, in the presence of heterogeneous catalysts the disproportionation usually takes place at elevated temperatures and pressures, which gives rise to certain disadvantages in the technological formulation of the process. Finally, another negative feature is the lack of continuity in the disproportionation process using heterogeneous catalysts owing to the comparatively extensive coke deposition on them during operation (up to 20%).

III. HOMOGENEOUS DISPROPORTIONATION OF OLEFINS

The disproportionation of olefinic hydrocarbons is one of the catalytic processes for which homogeneous catalysis by complex compounds has only just begun to be employed. Nevertheless, the few available data[17–24] on this problem indicate a wide scope of homogeneous disproportionations, primarily in the solution of applied problems involving the synthesis of various olefins. At the same time, the use of homogeneous catalysts makes it possible to obtain more profound information about the reaction mechanism.

The homogeneous catalysts at present available, which are capable of catalysing the disproportionation of olefins, are largely based on tungsten and molybdenum complexes.

The study of homogeneous disproportionation was begun by Calderon and coworkers[17–19], who reported the disproportionation of olefins in the presence of a new catalytic system (for this reaction), consisting of tungsten hexachloride, ethylaluminium dichloride and ethyl alcohol, using benzene as the solvent. A much less active catalyst was obtained without ethyl alcohol. None of the systems component alone is an active catalyst of the disproportionation or migration of the C=C bond (under the process conditions). The aluminium : tungsten ratio can be varied within wide limits, but best results were obtained for a 4 : 1 ratio. The $WCl_6 + C_2H_5AlCl_2 + C_2H_5OH$ catalytic system proved very effective in the disproportionation of C_4 and higher olefins with a non-terminal double bond. The reaction was achieved at room temperature and atmospheric pressure; equilibrium was established extremely rapidly (in seconds).

The selectivity of the homogeneous disproportionation proved to be very high. Thus in the case of pent-2-ene, but-2-ene, and hex-3-ene, it reached 99.6%.

A relative disadvantage of the $WCl_6 + C_2H_5AlCl_2 + C_2H_5OH$ catalytic system is slight oligomerisation of olefins, which was found to depend on the position of the double bond in the alkene and decreased in the sequence but-2-ene > alk-2-ene > alk-3-ene > alk-6-ene. The solvent (benzene) was alkylated to a very slight extent. There was also some loss of activity of the catalyst with time.

¶The disproportionation of acetylene has been postulated in its photolysis[83].

The binary catalytic system comprising tungsten hexachloride and n-butyl-lithium is free from all these disadvantages [20], the second component playing the role of a reducing and alkylating agent for WCl_6. Neither tungsten hexachloride nor n-butyl-lithium gives rise separately to olefin reactions, i.e. any anionic (due to C_4H_9Li) or cationic (due to WCl_6) processes can be completely ruled out. The new homogeneous catalyst proved to more be selective. For example, pent-2-ene was converted with 100% selectivity into but-2-ene and hex-3-ene regardless of the degree of conversion.

However, in contrast to the preceding homogeneous system, where the olefin : WCl_6 ratio could reach 10 000, the catalyst with n-butyl-lithium was sufficiently effective only for olefin : WCl_6 ratios not exceeding 100 (the optimum ratio was 50).

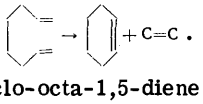
The dependence of catalyst activity on the Li/W ratio has not so far been explained. It was found that the system catalyses effectively the disproportionation of pent-2-ene only for a 2 : 1 ratio of these metals.

The attempts to replace the n-butyl group by isomeric groups were unsuccessful. The conversion of pent-2-ene decreased in the series n-butyl > s-butyl > t-butyl and after 15 min of reaction, amounted to 15, 4, and 0% respectively.

Recently reports have been published [21-24] about yet another type of homogeneous catalytic system for the disproportionation of olefins—the nitrosyl complexes $L_2Cl_2(NO)_2M$ (where M = Mo or W and L = Ph_3P, C_5H_5N, PH_3PO, and others) treated with alkylaluminium chlorides in chlorobenzene. Like the previous homogeneous catalysts, these systems are effective at a low temperature (0–50°C).

The activity of the nitrosyl catalytic complex depends on the nature of the metal and the ligand [21,23]. Tungsten-containing catalysts are less active than the analogous molybdenum compounds. The $(C_5H_5N)_2Cl_2(NO)_2Mo$ complexes showed the highest selectivity. In addition to the disproportionation reaction the systems including ethylaluminium dichloride as a co-catalyst catalyse also the isomerisation reaction, which greatly reduces the process selectivity. The most active catalyst was obtained with methylaluminium sesquichloride.

It should be noted that the effectiveness of the homogeneous disproportionation in the presence of nitrosyl complexes is as a whole much lower than in the presence of the systems with tungsten hexachloride indicated above. However, nitrosyl-containing catalysts are very effective in the disproportionation of $\alpha\omega$-dienes and cyclic olefins with ethylene [23]. Thus octa-1,7-diene undergoes intramolecular disproportionation with formation of cyclohexene as the main product:



The ethenolysis of cyclo-octa-1,5-diene leads to the formation of deca-1,5,9-triene.

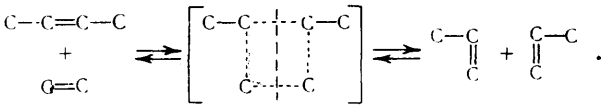
The kinetics of the homogeneous disproportionation of pent-2-ene were investigated, using the nitrosyl complexes described above [24]. The order of the reaction, which is unity with respect to the catalyst and variable with respect to the olefin, was determined: at a low olefin concentration the order is closer to 2, while at very high concentrations it approaches unity. The activation energy was found to be 6.6 kcal $mole^{-1}$.

Comparison of the results of applying catalytic systems of various types in the disproportionation of olefins makes it possible to define clearly the advantages of homogeneous over heterogeneous catalysts. The most important of these are milder process conditions combined with a high efficiency, selectivity, and stereospecificity (this feature is discussed in the last section of the review) and relative simplicity of action, which makes it possible to establish the most significant features of the kinetics and mechanism of the reaction.

Hence the urgent necessity to continue the search for complex catalytic systems for homogeneous disproportionation of olefins is quite evident.

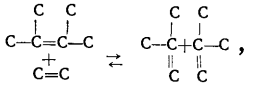
IV. MECHANISM OF DISPROPORTIONATION

The mechanism of both heterogeneous and homogeneous disproportionations of olefins is essentially based on the concept of the coordination of unsaturated ligands (olefins) with transition metals. The first considerations in relation to the mechanism of the reaction concern its occurrence in the presence of heterogeneous catalysts. Banks and Bailey [5] and then Bradshaw and coworkers [6] put forward the hypothesis that the intermediate stage in the disproportionation of olefins involves the formation of a four-membered ring—"quasicyclobutane". The reaction carried out by Bradshaw and coworkers [6], which is the reverse of the disproportionation of propene, i.e. the ethenolysis of but-2-ene ($CoO–MoO_3$ catalyst), may be regarded as confirming to some extent this hypothesis. They suggested, in accordance with the mechanism involving the formation of quasicyclobutane, that the only reaction product is propene:



A further development of the hypotheses concerning the disproportionation mechanism may be found in the work of Mol and coworkers [84,85], who suggested the formation of 1,2-dimethylcyclobutadiene (in the case of propene) as an intermediate. They also believe that the intermediate is formed as a result of the adsorption of two olefin molecules on the catalyst surface.

Quite recently Crain [7] questioned Mol's hypothesis of the formation of cyclobutadiene π-bonds by the transfer of four hydrogen atoms from two olefin molecules to the catalyst surface. He based his criticism on the ethenolysis of 2,3-dimethylbut-2-ene,

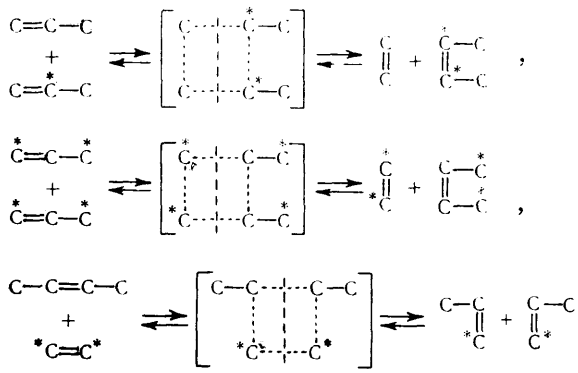


the product of which is isobutene, whereas according to Mol's hypothesis of the migration of hydrogen atoms to the catalyst the process should lead to methylbutenes, propene, and straight-chain butenes. Nevertheless, no traces of these substances were found in the ethenolysis products.

Important evidence in favour of the disproportionation mechanism involving the formation of an intermediate four-membered surface ring was provided by the study of the reaction using radioactive olefins [75,85-88].

In the disproportionation of [2-^{14}C] propene in the presence of Re_2O_7/Al_2O_3 [83] or in the presence of alumina alone [75], it was found that among the products only the straight-chain butenes exhibit specific radioactivity and that it is twice as high as for the initial propene. In the

case of propene with the extreme carbon atoms labelled, i.e. [1,3-^{14}C]propene, both reaction products, i.e. ethylene and straight-chain butenes, proved to be radioactive. Moreover, in the ethenolysis of but-2-ene using radioactive ethylene, propene containing radioactive carbon was isolated. The result described could have been obtained for the following disproportionation mechanism:



The mechanism of the disproportionation of propene in the presence of a cobalt–molybdenum catalyst was also investigated with the aid of radioactive carbon, attention being concentrated on the isomerisation reaction [87,88]. The results of these experiments confirmed the validity of the four-centre mechanism. Clark and Cook [88] note that at low temperatures (60°C) in the reaction involving [1-^{14}C]propene radioactivity was detected only in ethylene; [2-^{14}C]propene gave rise to radioactive butene. However, at an elevated temperature (100–160°C) the disproportionation of [1-^{14}C]propene yields two radioactive products —ethylene and butene, which the authors believe can be explained by the isomerisation of [1-^{14}C]propene to [3-^{14}C]propene. The apparent activation energy for disproportionation is 7.7 kcal mole^{-1} and for isomerisation 17.3 kcal mole^{-1}. On the other hand, the authors do not rule out the possibility of the formation at high temperatures of two adsorbed π-allyl complexes in the disproportionation of which the radioactive atom will enter ethylene and butene with equal probability.

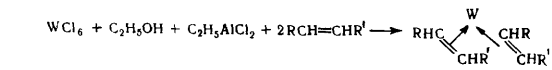
Banks and Bailey [86] postulated that the four-centre mechanism is common to various reactions of olefins (disproportionation, isomerisation, polymerisation, etc.), the reaction pathway depending on the ability of the catalyst to promote the migration of hydrogen atoms. In particular, disproportionation takes place when olefin molecules are adsorbed with formation of a four-centre complex, the desorption involving the dissociation of two opposite bonds without the migration of hydrogen.

The results of numerous experiments on the disproportionation of mono-olefins with a wide variety of structures [6–8] and also diolefins [14] and acetylenes [15] agree satisfactorily with the hypothesis of the formation of an intermediate surface cyclobutane and constitute an additional argument in favour of the "quasicyclobutane" mechanism.

Thus it is possible to exclude the "linear" mechanism of the disproportionation of olefins [90] according to which radioactive ethylene and but-1-ene should be formed from [2-^{14}C]propene:

Homogeneous disproportionation yields much more complete information about the reaction mechanism. In their discussion of the mechanism of homogeneous disproportionation, Calderon and coworkers [17–19] also began with the hypothesis of an intermediate four-membered cyclic compound as the transition state and the possibility of its formation was considered wholly using the hypothesis of the coordination of olefins to transition metals. According to the concept of these authors, the disproportionation of olefins consists of three consecutive stages; the formation of a bisolefin–metal complex, transalkylidenation, and finally exchange of the olefins in the complex.

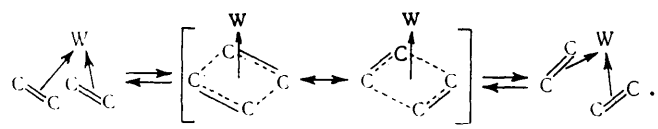
The first reaction stage, i.e. the formation of the bisolefin complex with tungsten, probably includes as an initial stage the reaction of tungsten(VI) with $C_2H_5AlCl_2$ in the presence of the free olefin, which leads to the reduction of tungsten(VI) to tungsten(IV):



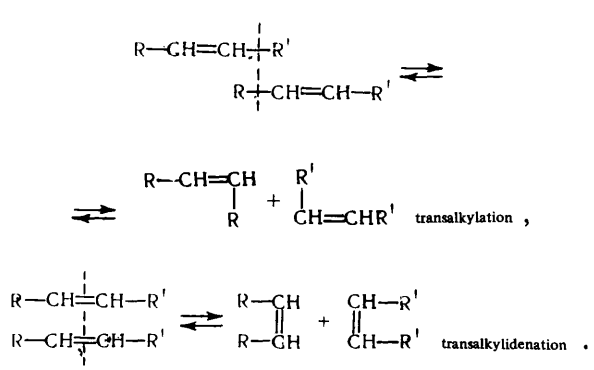
(The capacity of organoaluminium compounds to reduce transition metal halides is well known.)

Next tungsten(IV) is coordinated to two molecules of the olefinic ligand in the *cis*-configuration with formation of a bisolefin complex. The olefin bonds in the latter may be delocalised, as in the analogous structure of norbornadienetungsten tetracarbonyl. It is suggested that two olefin molecules form a four-membered ring—the square base of a tetragonal pyramid with the tungsten atom at the apex. The positions of the remaining ligands have not so far been determined. Nor is the role of ethanol in the catalytic reaction clear.

The next stage is transalkylidenation, consisting in the dissociation of the double bonds weakened by the coordination of the olefin to the metal [tungsten(IV)] and the formation of new multiple bonds:

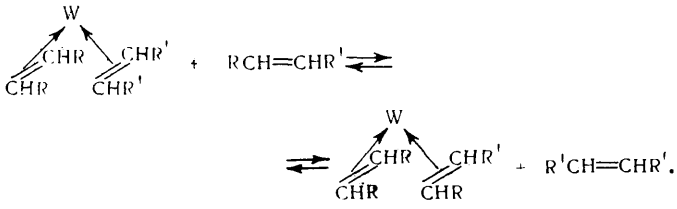


The transalkyledination mechanism, i.e. the exchange of alkylidene and not alkyl groups in disproportionation, was proved experimentally in experiments with deuterated olefins [18,19]:



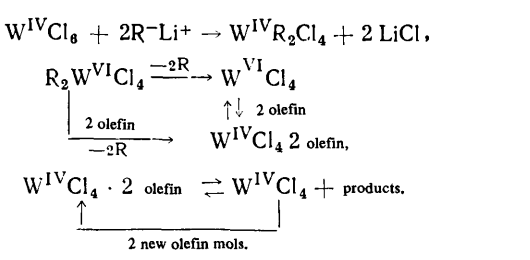
The isotope composition of the products agrees only with the four-centre mechanism.

Finally, the last reaction step—the exchange of the olefinic ligands in the coordination complex—alternates with the preceding stage—transalkylidenation:



The high rate of homogeneous disproportionation can be explained only by a very high rate of the last stage, i.e. the exchange of olefinic ligands. Examples of fast exchange reactions involving certain complexes of olefins with metals are known [91,92]. Thus the replacement of ethylene in Zeise's salt $K[(CH_2{=}CH_2)PICl_3].H_2O$ by other olefinic ligands is very rapid [91,93].

The work of Wang and Menapace[20] on a catalytic system comprising tungsten hexachloride and n-butyl-lithium constitutes further confirmation of the role of coordination interaction in the olefin disproportionation mechanism. Their reaction mechanism includes the substitution of two chlorine atoms in tungsten hexachloride by two alkyl groups, the subsequent mono- or bi-molecular reduction of tungsten(VI) to tungsten(IV), and the coordination of the latter to two pent-2-ene molecules:



The formation of the reaction products from the intermediate coordination complex $W^{IV}Cl_4.2$olefin and the regeneration of the catalyst can be explained using the concepts of Calderon and coworkers [18,19].

Some information concerning the reaction mechanism can be obtained from the analysis of the results reported recently by Kotari and Tatsuma [92], who found that the WCl_6–ethylaluminium dichloride catalytic system can catalyse both alkylation and disproportionation reactions depending on the way in which the process is carried out. If the catalyst is prepared first (in toluene) and then the olefin (pent-2-ene) is added, toluene is rapidly alkylated. When pent-2-ene is added to toluene, then tungsten hexachloride, and finally ethylaluminium dichloride, disproportion mainly takes place. The authors suggested that the catalytically active complex contains reduced tungsten [tungsten(IV)] coordinated to the solvent and aluminium via chlorine bridges. The "quasicyclobutane–tungsten" complex can be converted into a catalytically inactive state by the action of toluene.

It is noteworthy that recently data have been published showing the possibility that homogeneous disproportionation can be interpreted in terms of a non-concerted mechanism including an oxidative addition stage. Thus in a study of the valence isomerisation of cubane catalysed by rhodium compounds, Cassar et al. [94] concluded that the reaction proceeds via a non-concerted oxidative addition mechanism and suggested that the mechanism for a number of reactions, including the disproportionation reaction, might be revised appropriately.

V. STEREOCHEMICAL CHARACTERISTICS OF THE REACTION

The stereochemistry of heterogeneous disproportionation has been hardly investigated; some observations concerning the relative amounts of the *trans*- and *cis*-forms of the reaction products were made only in the disproportionation of C_3–C_5 olefins in the presence of a molybdenum oxide catalyst [5]. Moreover, in a few studies the amounts of *cis*- and *trans*-isomers were fixed. It is therefore at present impossible to arrive at any conclusion concerning the stereoselectivity of heterogeneous disproportionation catalysts.

The stereospecificity of homogeneous catalytic systems is much more pronounced. The stereochemistry of homogeneous disproportionation was investigated using complex catalysts based on tungsten [19,20] and also nitrosyl complexes of molybdenum [22].

Initially, it was found [19] that in the disproportionation of pentene and hexenes (with an internal double bond) in the presence of the WCl_6–$C_2H_5AlCl_2$ + C_2H_5OH catalytic system *trans*-*cis*-products are formed in the proportions predicted by thermodynamics. The final proportions of the isomers are then independent of the *trans*/*cis* ratio in the initial olefins.

The stereochemistry of homogeneous disproportionation was investigated in greater detail [20] in the presence of the WCl_6 + C_4H_9Li complex catalyst, using pure *cis*- and *trans*-isomers of pent-2-ene and also their mixture as the initial olefins. The results of this investigation differ from those of the previous studies. It was found that the ratio of the isomers in the reaction products depends to some extent on the *trans*–*cis* distribution in the initial olefins. The latter factor also determines the degree of conversion of the olefins. The *trans*-isomer reacts much more slowly than the *cis*-isomer or the mixture of the two isomers.

The stereospecificity of the catalyst is fairly high; for example, in the disproportionation of a mixture consisting of 46% of *trans*- and 54% of *cis*-isomers of pent-2-ene the final *trans*/*cis* ratio for but-2-ene was 4.2, which corresponds to 81% of the *trans*-form.

All these findings were fairly convincingly explained on the hypothesis of the formation of an intermediate bisolefin complex [20]. Thus the lower reactivity of *trans*-pent-2-ene compared with the *cis*-isomer is evidently due to the steric hindrance arising in the coordination of *trans*-olefins to the metal.

The discrepancy between the results obtained in the presence of different catalysts for the dependence of the *trans*/*cis* ratio in the reaction products on the stereochemical composition of the initial olefin can probably be explained by additional stereoisomerisation, which may occur owing to cationic aluminium-containing fragments.

Among homogeneous catalysts, nitrosylmolybdenum complexes $(C_5H_5N)_2Mo(NO)_2Cl_2.C_2H_5AlCl_2$ showed the highest stereoselectivity, as demonstrated by the conversion of pent-2-ene into but-2-ene and hex-3-ene [22]. The ratios of the *trans*- and *cis*-isomers of all three olefins reached the equilibrium values regardless of the isomeric nature of the initial pent-2-ene. However, it was found that in the early stages of the reaction the ratio of the isomers is appreciably determined by that in the initial olefin.

Interesting correlations were established between the total concentration of *cis*-olefins in the reaction mixture and the degree of conversion. The rate of disproportionation and the rate of stereoisomerisation were found to

decrease simultaneously, which is apparently evidence of a close relation between these processes and of their occurrence in the presence of the same catalyst.

To account for the above finding, the bisolefin–metal model for the intermediate complex has been successfully employed[22].

---o0o---

It is not difficult to predict that in the near future new homogeneous systems catalysing the disproportionation of unsaturated hydrocarbons will be found. One can also expect that homogeneous catalysis will make it possible to solve many problems of the practical application of the reaction. The elucidation of the mechanism of the action of homogeneous disproportionation catalysts will promote the application of theoretical concepts in the chemistry of complex compounds to catalytic problems.

At the same time one should expect further advances in the selection and modification of heterogeneous catalysts for the disproportionation of olefins.

Polycondensation Reactions of Fluorinated Organic Compounds

R.M.Gitina, E.L.Zaitseva, and A.Ya.Yakubovich (deceased)

The review deals with the principal advances in the synthesis and investigation of the properties of polycondensation of fluoro-polymers. In many cases the properties of the fluoro-polymers have been compared with those of their non-fluorinated analogues. The applications of the polymers are also described briefly.
The bibliography includes 138 references.

I. INTRODUCTION

The study of organofluorine polymers and low-molecular-weight compounds of this class began to develop comparatively recently—during the 1940's. The scope of the chemistry of fluorinated macromolecular compounds was of course limited mainly by the relatively low level of development of the chemistry of fluorinated low-molecular-weight compounds. This was responsible for the fact that until recently (until the 1950's) the principal methods for the synthesis of fluoro-polymers consisted in the polymerisation of the relatively readily available fluorinated olefins, which yielded polyperfluoroalkylenes. Polymerisation fluoro-polymers, particularly polytetrafluoroethylene (Teflon), which is the most important member of this class, have found a firm place among modern polymeric materials employed under severe operating conditions.

By virtue of the considerable advances in organofluorine chemistry in recent years, many aspects of this field, which were either impossible or difficult to achieve, have become more or less commonplace, in particular methods for the synthesis and the study of the properties or organic perfluoro-compounds and polyfluorinated compounds with a wide variety of functional groups have been developed on a large scale [1]. This led to the expansion of studies on the synthesis and properties of fluorinated polymers obtained by methods for the polycondensation of bi- and poly-functional monomers. The application of the polycondensation methods of synthesis to fluoro-polymers led to a much greater variety of the structures of macromolecules and thus to the development of new essential materials.

Much attention has been devoted to problems of the synthesis of polymerisation fluoro-polymers, their properties, and applications; the present review gives the first systematic account of polycondensation fluoro-polymers. It covers the original literature (including patents) up to the end of 1969 and deals with fundamental work on the synthesis and properties of polycondensation fluoro-polymers containing fluorine atoms in the main macromolecular chain and those obtained on the basis of bifunctional derivatives of 2,2-diphenylperfluoropropane.

II. FLUORINE-CONTAINING POLYESTERS AND POLYTHIOESTERS

Fluorine-containing polyethers are mainly obtained by the polymerisation of epoxyfluoroalkanes. In contrast, polyesters are synthesised by the polycondensation method.

The first fluorine-containing aliphatic polyesters were described in 1952. [2] At the present time fluorine-containing aliphatic, alkylene, aromatic, and fully aromatic polyesters are known. Depending on which component contains fluorine, polyesters can be divided into two types: (1) polyesters from fluorinated dicarboxylic acids and non-fluorinated diols; (2) polyesters from fluorinated dicarboxylic acids and fluorinated diols; (3) polyesters from non-fluorinated dicarboxylic acids and fluorinated diols. Table 1 lists the fluorine-containing polyesters described in the literature and some of their properties.

Aliphatic polyesters of the first type were obtained by the direct esterification of glycols by perfluoroalkanedicarboxylic acids [2,3]:

$$HO(CH_2)_m OH + HOOC(CF_2)_p COOH \xrightarrow{-H_2O} [-O(CH_2)_m OCO(CF_2)_p CO-]_n,$$

and also by the reaction of the silver salts of these acids with $\alpha\omega$-di-iodoalkanes [3]. The polyesters synthesised by the second method have lower viscosities than those obtained by direct esterification.

Data have also been published on the synthesis of fluorine-containing polythioesters by the reaction of pentane-1,5-dithiol and perfluoroglutaric acid dianhydride [4] and also by the reaction of hexane-1,6-dithiol with polyfluorochlorohexanedicarboxylic acid [5]. Aliphatic polyesters of the second type can be obtained by the reaction with tetrahydroperfluoroalkane-$\alpha\omega$-diols of both perfluoroalkanedicarboxylic acids in the presence of zinc chloride as a catalyst [6,7] and their dianhydrides [8]; however, these polyesters have a low molecular weight. Polyesters with a high molecular weight can be obtained using acid dichlorides [6,7], since fluorinated diols are acidic compounds and are esterified with difficulty.

It is noteworthy that polyesters obtained from perfluoroalkanedicarboxylic acids are hydrolysed much faster than their non-fluorinated analogues [3,8] and therefore they have not found practical applications [7]. The enhanced

*Here and henceworth the following abbreviations are employed: sol. = soluble; M = molecular weight; $T_{brittle}$, T_g, T_{soft}, T_{decomp}, and T_f are the embrittlement, glass, softening, and decomposition temperatures and the melting point respectively; cryst. = crystalline; amorph. = amorphous; DMFA = dimethylformamide; DMAA = dimethylacetamide; DMSO = dimethyl sulphoxide.

reactivity of the carboxyl carbon atom in these compounds to nucleophilic attack by water molecules is undoubtedly associated with the marked electron-acceptor influence of the perfluoromethylene chain.

The introduction of methylene groups between the carboxyl carbon atom and the perfluoroalkylene chain of the acidic component stabilises the polyesters with respect to hydrolysis [7].

Mixed polyesters obtained from perfluoroglutaric acid and hexafluoropentanediol, containing 2–5 mole % of non-fluorinated diacids or diols such ethylene glycol or 1,2-di(hydroxymethyl)carborane, were described in a recent patent [9]. These polymers are viscous liquids, and it has been suggested that after vulcanisation they can be employed as chemically stable elastomers.

Aliphatic polyesters of the third type have been investigated in greatest detail [6 10–14]. One of the examples of these polyesters, poly(hexafluoro-1,5-pentylene adipate)

$$[-OCH_2(CF_2)_3CH_2OCO(CH_2)_4CO-]_n,$$

has found industrial application in the manufacture of a special oil- and frost-resistant rubber. Although the thermal stability of the latter is not in fact very high, its capacity to retain elastic properties at fairly low temperatures is of some value. The working temperature range for this rubber is between −50° and 150°C. [15] Its degradation has been investigated [16–18].

In contrast to polyesters of the first and second types, some of the polyesters of the third type considered here, for example poly(hexafluoropentylene adipate), have fairly high molecular weights (about 20000)†. Such polyesters have been obtained by the reaction of fluorinated diols with aliphatic acid dichlorides; on the other hand, esterification with acids or their diethyl esters led only to low-molecular-weight polyesters.

All the aliphatic fluorine-containing polyesters synthesised are viscous liquids and rubber- or wax-like substances, many of which are insoluble in the usual organic solvents. It is suggested that the solubility of the polyesters falls with increasing total content of fluorine atoms in the molecule regardless of whether they are in the main or side chain [6].

A rubber-like vulcanised product based on the polyester from 4-oxa-2,2,3,3,5,5,6,6-octafluoroheptane-1,7-diol and adipic acid dichloride, which can be employed at low temperatures, has been described in an American patent [11]. Its embrittlement temperature is −58°C.

$$[-OCH_2(CF_2)_2O(CF_2)_2CH_2OCO(CH_2)_4CO-]_n.$$

In order to enhance the thermal stability while retaining an adequate flexibility of the macromolecule, polyesters containing aromatic units together with perfluoromethylene groups have been synthesised by the polycondensation of hexafluoropentanediol with derivatives of terephthalic [19], isophthalic [18,20], phthalic [18], and p-pentyloxyisophthalic [20] acids and also di-(p-carboxyphenyl) ether and 1,5-di-(p-carboxyphenoxy)pentane [18]. The polymers described in a British patent [19] have been suggested as thermostable casting resins and varnishes.

The possible mechanisms of the degradation of fluorine-containing polyesters have been discussed [18].

Mixed aromatic polyperfluoroalkylene esters, obtained by the joint polycondensation of hexafluoropentanediol with the dichlorides of isophthalic [12] and terephthalic acids [13], have also been described. It has been shown [12] that, following the introduction of 50 mole % of isophthaloyl units into the poly(hexafluoropentylene adipate) chain, the glass temperature of the polymer increases from −57° to −31°C and the rate of crystallisation falls appreciably. The introduction into the polymer chain of up to 30 mole % of terephthaloyl units hardly increases the glass temperature of the polymer (−62° and −60°C for the homopolymer and the copolymer), but the thermal stability increases slightly: the weight losses in a vacuum over a period of

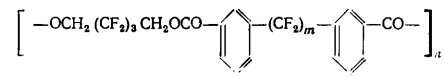
†The molecular weight was determined by measuring the viscosity of the melt by Flory's method and the characteristic constants of the equation relating the viscosity of the melts to the molecular weight of the polymer were found by titrating the terminal groups [6]. Subsequently the viscosities of the solutions of the polymers in chloroform were employed for this purpose [12]. The light-scattering method and measurements of the viscosity of dilute solutions of the polymer have also been employed [14] to determine the molecular weight.

2 h at 250°C are 32.6 and 26.65% for the homopolymer and the copolymer respectively[13].

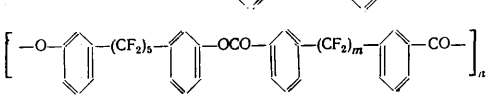
The polycarbonates obtained by the treatment with phosgene of a mixture of hexafluoropentanediol (80 to 95 mole %) and 2,2-di-(*p*-hydroxyphenyl)propane (20 to 5 mole %) have useful physical and chemical characteristics and are more readily worked into sheets and fibres than the corresponding non-fluorinated analogues[21].

In the 1960's hexafluoro-2,2-di-(*p*-hydroxyphenyl)-propane was employed as the fluorine-containing diol component for the synthesis of polyesters[22,29], polycarbonates[22,30], and polythiocarbonates[31]. Polyesters based on this diol and the dichlorides of isophthalic, terephthalic, and biphenyl-4,4′-dicarboxylic acids[22-29] and also polyesters based on trifluoromethyldi-(*p*-hydroxyphenyl)phenylmethane and the dichlorides of isophthalic and terephthalic acids[26,27] exhibit an enhanced stability with respect to thermal and thermo-oxidative degradation. Thus the temperatures of the onset of decomposition in nitrogen (data obtained by dynamic thermogravimetric analysis) of polyterephthalates obtained from the fluorine-containing diols hexafluoro-2,2-di-(*p*-hydroxyphenyl)-propane and trifluoromethyldi-(*p*-hydroxyphenyl)phenylmethane (438° and 446°C respectively) are higher than for the polyterephthalate obtained from 2,2-di-(*p*-hydroxyphenyl)propane (397°C).[27] On heating in air for 1 h at 400°C, these polymers lose 16.2, 11.5, and 26.3% of their weight respectively[32]. According to Ref. 29, sheet materials and aeroengine tubes made from polyesters and polycarbonates based on hexafluoro-2,2-di-(*p*-hydroxyphenyl)propane retain their characteristics after heating at 258°C for seven days.

Fluorine-containing polyesters based on the dichloride of 2,2-di-(*p*-carboxyphenyl)hexafluoropropane, which are distinguished by enhanced thermal stability, elasticity, and solubility, have also been described[27,28]. The synthesis of polyesters from *m*-derivatives of αω-diphenylperfluoroalkanes was reported in 1969.[33] Polyesters of the type



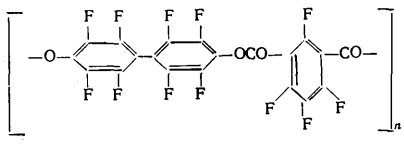
and



were obtained by the polycondensation of the dichlorides of -di-(*m*-carboxyphenyl)perfluoroalkanes with hexafluoropentanediol or αω-di-(*m*-hydroxyphenyl)perfluoropentane.

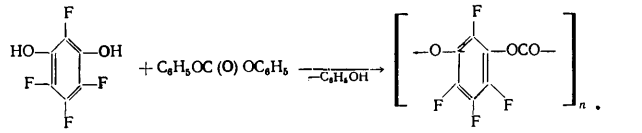
A polycarbonate based on αω-di-(*m*-hydroxyphenyl)-perfluoropentane has also been described[33]. The polymers synthesised in the same investigation have fairly low glass temperatures (16–45°C) and are elastomers above room temperature.

One of the attempts to modify the properties of polyesters consisted in their synthesis from aromatic perfluoro-compounds. A patent has been taken out[34] for high-molecular-weight polyesters which are resistant to thermal and thermo-oxidative degradation and which were synthesised by the interfacial polycondensation of octafluoro-4,4′-dihydroxybiphenyl with the dichlorides of tetrafluoroisophthalic and tetrafluoroterephthalic acids:



A similar polymer, consisting of a fluorinated analogue of Lavsan [a variety of nylon produced in the USSR (Ed. of Translation)] was obtained by the polycondensation of dimethyl tetrafluoroterephthalate and ethylene glycol; it differs little in its properties from Lavsan[35].

A patent[36] describes aromatic polyfluorocarbonates obtained by the polycondensation of tetrafluorophenylene bischloroformates with perfluorinated aromatic diols or 2,2-di-(*p*-hydroxyphenyl)propane. Poly(tetrafluoro-*m*-phenylene carbonate) was also synthesised by the polycondensation in the melt of tetrafluororesorcinol with diphenyl carbonate:



These polymers are suitable for the manufacture of articles designed for use at high temperatures.

III. FLUORINE-CONTAINING POLYAMIDE POLYMERS

1. Polyamides

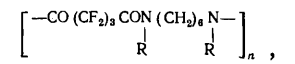
The development of the chemistry of fluorine-containing polyamides was stimulated by the endeavour to synthesise a fluorinated analogue of nylon for the manufacture of fire-resistant fibres[37]. Like polyesters, fluorine-containing polyamides can be divided into three types. The polyamides and some of their properties are listed in Table 2.

Aliphatic fluorine-containing polyamides were first described in patents at the beginning of the 1950's.[2,38] Polyamides of all three of the above types were obtained by the polycondensation of the diethyl esters or the dichlorides of alkane- and perfluoroalkane-dicarboxylic acids with hexamethylene- and 2,2,3,3,4,4,5,5-octafluorohexamethylene-1,6-diamine[38]. It proved possible to synthesise by this method only polyamides of the first type with a molecular weight (10000) sufficient for the preparation from them of fibre-forming materials:

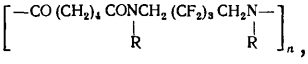
The fibres made from these polyamides have a high strength and density and are suitable for the manufacture of heavy fire-resistant fabrics. Analogous results were obtained in another study[39].

Later it was shown that, when solutions of diethyl perfluoroadipate are mixed with hexamethylenediamine, a low-molecular-weight polyamide is formed even in the cold, but its further polycondensation on heating in nitrogen or *in vacuo* is accompanied by degradation[40].

Fluorine-containing *N*-alkyl-substituted polyamides of the first type,



were synthesised by the polycondensation of secondary aliphatic diamines with dimethyl perfluoroglutarate, polyamides with the highest molecular weights being obtained from *NN′*-dimethyl and *NN′*-dimethyl-hexamethylenediamines. *N*-Substituted polyamides of the third type,



with a moderate molecular weight (degree of polymerisation 20–50%) could be obtained only from acid dichlorides, the reaction being carried out in a boiling inert solvent or in the presence of pyridine [41].

It was found that polyamides of the first type, like polyesters obtained from perfluoroalkanedicarboxylic acids, are hydrolysed very readily, the tendency towards hydrolysis decreasing somewhat with increasing dimensions of the substituent at the nitrogen atom [41].

It is noteworthy that chlorine-containing polyamides cannot be obtained by the polycondensation of hexamethylene- and octafluorohexamethylenediammonium salts of perfluoroadipic acid in the melt, since the salts decompose below the melting point. The attempts to achieve their polycondensation in the solid state at a temperature close to the melting point also failed to yield the expected results [39,40].

Although fluorine-containing diamines do not in fact form salts with weak acids owing to their low basicity, polyamides of the third type could nevertheless be obtained by heating the diamines with adipic acid [40,41].

In order to synthesise fluorine-containing polyamides of the first type, some investigators attempted to employ the methods of interfacial polycondensation using aliphatic [40,42,43] and aromatic [40] diamines and dichlorides of perfluoroalkanedicarboxylic acids. However, the polyamides obtained in this way proved to have low molecular weights. There is no doubt that the reason for the failure of these syntheses is the very ready hydrolysability of the dichlorides of perfluoroalkanedicarboxylic acids.

The high acylating capacity and volatility of such dichlorides made it possible to achieve the synthesis of fluorine-containing polyamides of the first type by a gas-phase polycondensation at the liquid–gas interface. High-molecular-weight fluorine-containing polyamides were obtained by passing the vapour of the dichloride of perfluoroadipic acid in a stream of nitrogen through aqueous solutions of aliphatic and aromatic diamines at 90–100°C. [40–46]

Attempts have been made to employ irreversible low-temperature polycondensation in amide solutions for the synthesis of fluorine-containing polyamides [47–49]. However, the aromatic polyperfluoroglutaramides obtained from the dichloride of perfluoroglutaric acid and benzidine or 3,3′-dihydroxybenzene in dimethylacetamide had very low molecular weights. Probably this is a consequence of the appreciably high rates of the competing reactions of dimethylacetamide with both the initial dichloride [50] and with the final acid chloride groups of the oligomers, resulting in chain termination.

A number of polyamides obtained from bifunctional derivatives of $\alpha\omega$-diphenylperfluoroalkanes have also been described. A thesis [51] mentions a high-melting polyamide made from hexamethylenediamine and 1,2-di-(*p*-carboxyphenyl)perfluoroethane. Mixed polyamides of this type with adipic or sebacic acid have been used to prepare thermostable fibres.

Recent patents [52,53] describe the synthesis of high-molecular-weight polyamides from *pp*′-dicarboxy- and *pp*′-diamino-derivatives of 2,2-diphenylhexafluoropropane. These polyamides are high-melting film-forming polymers with a comparatively high solubility.

Data on polyoxyamides and polyamides, obtained from derivatives of $\alpha\omega$-diphenylperfluoroalkanes and 2,2-diphenylperfluoropropane are presented in Table 2 and in Section IV, 2. A polyamide with aromatic perfluoro-units was obtained by heating octafluorobenzidine with pyromellitic dianhydride [54].

There has been only one study on the synthesis of fluorinated polyureas [55]. The polymers were obtained by the interfacial polycondensation of octafluorohexamethylenediamine with a number of di-isocyanates (hexamethylene, diphenylmethane, and toluylene di-isocyanates):

$$H_2NCH_2(CF_2)_4CH_2NH_2 + OCNRNCO \rightarrow [-NHCH_2(CF_2)_4CH_2NHCONHRNHCO-]_n .$$

The polymers synthesised had a low molecular weight and a relatively low thermal stability (decomposition temperature 215°C). [55]

2. Polyhydrazides

The possibility of obtaining low-molecular-weight fluorine-containing polyhydrazides from the dihydrazides and dichlorides of perfluoroalkane-dicarboxylic acids was first suggested by Brown in 1964 [61,62] (see Section IV, 2):

$$H_2NHNOC(CF_2)_mCONHNH_2 + ClOC(CF_2)_mCOCl \xrightarrow{-HCl} [-CONHNHCO(CF_2)_m-]_n .$$

High-molecular-weight aromatic poly(perfluoroalkylenebenzenedicarboxylic acid hydrazides) were synthesised by low-temperature polycondensation in amide solvents:

However, it was not possible to obtain high-molecular-weight fluorine-containing polyhydrazides by this method using the dichlorides of perfluoroalkanedicarboxylic acids. In order to avoid the chain termination of the macromolecules due to the considerable rate of reaction of the dichlorides of the strong perfluoroalkanedicarboxylic acids with the amide solvents, the dichlorides of aromatic acids were employed as the acid component and the dihydrazides of perfluoroalkanedicarboxylic acids as the diamine component (Table 3).

Aromatic poly(perfluoroalkylenebenzenedicarboxylic acid hydrazides) are amorphous polymers very readily soluble in the usual organic solvents; their softening temperatures are in the range 190–210°C and the temperatures of the onset of vigorous decomposition in air are between 250° and 300°C.

Polyisophthaloperfluoroglutarohydrazide, as well as polyisophthalohydrazide, form metal derivatives with zinc, nickel, and mercury salts.

Data on polyhydrazides based on 1,5-di-(*p*-carboxyphenyl)perfluoropentane [57] and 2,2-di-(*p*-carboxyphenyl)-perfluoropropane [63] are given in Table 3 and in Section IV, 2.

Fluorine-containing polyhydrazides are not of independent importance and are used as intermediates in the synthesis of certain polyazoles; the possibility of the cyclisation of fluorine-containing polyhydrazides into poly-1,3,4-oxadiazoles is discussed in Section IV, 2.

Fluorinated polymers obtained by the polycondensation of the dihydrazide of perfluorosuberic acid with isophthalaldehyde and terephthalaldehyde ($\eta_{inh} \simeq 0.1$) have also been described [64]:

3. Polyurethanes

Fluorine-containing polyurethanes were first obtained in 1954 by heating hexafluoropentanediol with hexamethylene, toluylene, and octafluorotetramethylene di-isocyanates at 150°C.[65] These polyurethanes have been suggested as thermostable coatings. The fluorine-containing polyurethanes described in the literature and some of their properties are presented in Table 4.

Many polyurethanes containing fluorine in both the diol and in the di-isocyanate components of the molecule, including aromatic perfluoropolyurethanes have been described[66,67]. They were synthesised from fluorine-containing compounds in two ways: (1) by the reaction of di-isocyanates with diols (in solution and in the melt) and (2) by the reaction of diamines with bischloroformates (in solution under the conditions of interfacial polycondensation). For example, the synthesis of poly-[(*N*-hexafluorotrimethylene)hexafluoropentamethylene

dicarbamate] was achieved by heating hexafluorotrimethylene di-isocyanate with hexafluoropentanediol in ethyl acetate in the presence of triethylamine:

$$OCN(CF_2)_3NCO + HOCH_2(CF_2)_3CH_2OH \rightarrow [-NH(CF_2)_3NHC(O)OCH_2(CF_2)_3CH_2OCO-]_n \xrightarrow{H_2O} HOOCCF_2COOH + H_2NCOOCH_2(CF_2)_3CH_2OCONH_2 .$$

This polyurethane is readily hydrolysed in air to hexafluoropentylene dicarbamate. On heating in the absence of moisture at 80–90°C, the polyurethane splits off hydrogen fluoride and is apparently converted into the polymer $[-N{=}CFCF_2CF{=}NCOOCH_2(CF_2)_3CH_2OCO-]_n$, which is somewhat more resistant to hydrolysis.

Polyurethanes in which a methylene group separates the perfluoroalkylene chain from the nitrogen atom, which some investigators believe makes them more resistant to hydrolysis, were synthesised by the reaction of fluorine-containing bischloroformates with diamines. Thus, on heating hexafluoropentamethylene bischloroformate with hexafluoropentamethylenediamine in ethyl acetate in the presence of pyridine, poly-[(*N*-hexafluoropentamethylene)-hexafluoropentamethylene dicarbamate] is formed:

$$ClOCOCH_2(CF_2)_3CH_2OCOCl + H_2NCH_2(CF_2)_3CH_2NH_2 \xrightarrow{-HCl} \rightarrow [-NHCH_2(CF_2)_3CH_2NHCOOCH_2(CF_2)_3CH_2OCO-]_n .$$

Under the conditions of interfacial polycondensation, the same reaction is accompanied by extensive hydrolysis of the bischloroformate. Unfortunately the authors do not quote experimental data for the hydrolytic stability for the polymer itself.

An aromatic perfluoropolyurethane was obtained by the reaction of tetrafluoro-*m*-phenylene di-isocyanate with tetrafluorohydroquinone in boiling xylene [66,67]. Among the fluorine-containing polyurethanes synthesised by Hollander and coworkers [66,67], the most thermostable is poly-[(*N*-tetrafluoro-*p*-phenylene)hexafluoropentamethylene dicarbamate], the decomposition temperature of which is about 300°C; other fluorine-containing polyurethanes decompose at about 200°C. [67]

The effect of fluorine atoms in the diol or di-isocyanate unit of the polymer on the properties of aliphatic polyurethanes was also investigated in other studies [68,69]. It was found, for example, that the polyurethane $[-NHCH_2(CF_2)_4CH_2NHCOO(CH_2)_6OCO-]_n$, containing in the di-isocyanate component a perfluoromethylene chain separated from the nitrogen atom by a methylene group, surpasses in its thermal stability the polyurethane $[-HN(CH_2)_6NHCOOCH_2(CF_2)_4CH_2OCO-]_n$ and a non-fluorinated analogue (weight losses *in vacuo* at 215°C over a period of 3.5 h about 1.5, 20, and 50% respectively). The first polyurethane is somewhat more resistant to the action of acids than the non-fluorinated polyurethane, but is inferior to it as regards resistance to the action of alkalis.

Polyurethanes based on fluorine-containing polyesters and polyethers with terminal hydroxy-groups [for example poly(hexafluoropentamethylene adipate), poly-hexafluoropentamethyleneformyl, etc.] and aromatic di-isocyanates or perfluorodi-isocyanates have also been

$p\text{-}C_6H_4(CH_2NH_2)_2$	$C(CF_3)_2(C_6H_4OCOCl\text{-}p)_2$	$\eta_{inh} = 0.40$	75
$CH_2(cis\text{-}C_6H_{10}NH_2\text{-}4)_2$	$C(CF_3)_2(C_6H_4OCOCl\text{-}p)_2$	$\eta_{inh} = 1.16$, $T_f = 210°C$	75
$p\text{-}C_6H_4[C(CH_3)_2NH_2]_2$	$C(CF_3)_2(C_6H_4OCOCl\text{-}p)_2$	$\eta_{inh} = 0.33$, $T_f = 200°C$	75

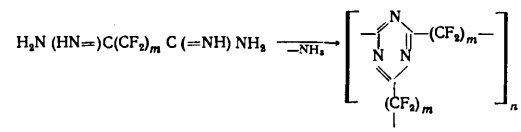
described. Polyurethanes obtained from polyperfluoroethers may find application as elastomers, coatings, adhesives, etc., i.e. whenever elasticity at low temperatures and high chemical stability are required [10,70,74].

A patent was published in 1968 describing the synthesis of high-molecular-weight polyurethanes based on the bischloroformate of 2,2-di-(4-hydroxyphenyl)hexafluoropropane and various diamines. It is suggested for the manufacture of light-resistant flexible sheets and crease-resistant fibres [75].

IV. FLUORINE-CONTAINING POLYAZOLES

1. Poly-1,3,5-triazines

The first examples of the class of polyperfluoroalkylene-heterocycles, namely polyperfluoroalkylene-1,3,5-triazines, were obtained towards the end of the 1950's and at the beginning of the 1960's by the homocondensation of the diamidines or imidines of perfluoroalkanecarboxylic acids and their copolycondensation with the monoamidines of perfluoroalkanecarboxylic acids [76-80]. Thus, on heating perfluoroadipodiamidine or perfluoroglutarimidine above the melting point, solid insoluble and infusible cross-linked polymers are formed:

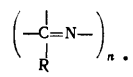


The use of mixtures of a diamidine (or imidine) with a monoamidine for polycondensation leads to the formation of partly cross-linked polymers, the degree of cross-linking and the properties of which depend on the molar ratios of the components and the length of their perfluoromethylene chain. The copolymers are either elastomeric materials with a low strength or they are rigid non-elastic

polymeric substances. All polyperfluorotriazines have a very high chemical stability and a high resistance to thermal and thermo-oxidative degradation. For example, the copolymers of perfluoroadipodiamidine or perfluoroglutarimidine with perfluorobutyramidine (1 : 1) are stable on heating in air at 350°C for about 72 h. Boiling in fuming nitric acid for 24 h leads only to a change of their colour from yellow to white.

The thermal degradation of polyperfluoroalkylenetriazines was investigated by a number of workers. It has been shown [81,82] that the activation energy for the degradation reactions of these polymers (homo- and co-polymers) is about 30–40 kcal mole^{-1} below 500°C, which is much less than the activation energy for the thermal decomposition of Teflon (about 80 kcal mole^{-1}); at about 500°C the rates of their decomposition are lower than that of Teflon.

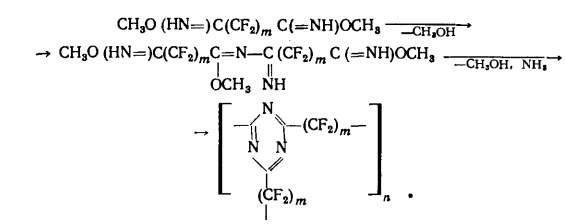
Other investigations [83] showed that the rate of degradation of polyperfluoroalkylenetriazines at 350–500°C *in vacuo* falls rapidly with increasing conversion up to 30% and then remains almost constant up to complete volatilisation of the polymer. While the rate of degradation in the initial stage is comparable with the rate of degradation of Teflon, in the second stage it is much lower. The authors suggest that the high rates of degradation in the initial stages are due to the amide groups, which are always present in the polymers. The decomposition of their amide groups results in the formation of water, which hydrolyses the triazine rings, and radicals, which cause their polymerisation with formation of a polyene structure:



After the amide groups have been consumed, the main degradative pathway reduces to the depolymerisation of the comparatively short perfluoroalkylene fragments of the macromolecule with chain transfer by the transalkylation of the triazine rings. The rates of these reactions are lower than the rate of depolymerisation of Teflon.

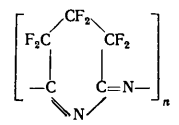
Since polyperfluoroalkylenetriazines were of greater interest as very promising elastomers [84], the efforts of many investigators were directed to the development of other methods for their synthesis, including methods for the synthesis of polytriazines with a linear structure.

Cross-linked polyperfluoroalkylenetriazines similar to those described above were obtained by the thermal homopolycondensation of dimethyl perfluoroglutarimidate and dimethyl perfluoroadipimidate and their "dimers": [85–87]



Later a similar conversion of dimethyl perfluoroglutarimidate into a cross-linked triazine polymer was also described in another study [88].

The trimerisation reaction of the dinitriles of perfluoroalkanedicarboxylic acids, the possibility of which in the presence of acid or alkaline catalysts and had been pointed out previously [79], was investigated. The homopolycyclisation of perfluoroglutarodinitrile under a high pressure (about 20 000 kgf cm^{-2}) in the presence of ammonia or secondary amines at 276°C leads to polytriazines. When the pressure is reduced, the formation of polymers with the structure [89]



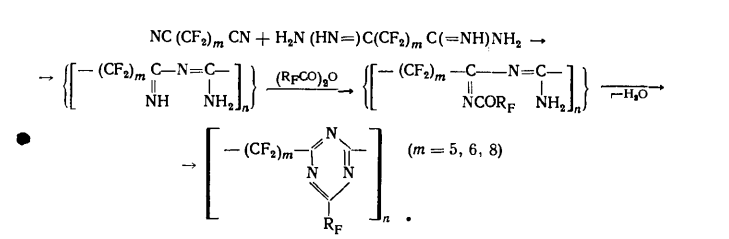
predominates.

A method for the preparation of cross-linked polytriazines by the polycyclisation of fluorine-containing dinitriles in the presence of metals (copper, iron, etc.) at 190°C has been described [90]. Polycondensation of perfluoroglutarodinitrile in the presence of metal oxides (Ag_2O, HgO, etc.) leads to a low-molecular-weight polymer (ηinh = 0.03) containing the group $-C=N-C=N-$. [91,92]

A method for the preparation of polytriazine by the thermal homopolycondensation or copolycondensation of perfluorodinitriles containing ether linkages [for example, 2,7-dicyano-3-oxaperfluoroheptane $NCCF(CF_3)O(CF_2)_4CN$ and 2,10-dicyano-3,9-dioxaperfluoroundecane $NCCF(CF_3)O(CF_2)_5OCF(CF_3)CN$] in the presence of ammonia has been patented. The cotrimerisation of the above dinitriles with diamidines derived from them or of diamidines with mononitriles (for example, with perfluoroacetonitrile and perfluoro-2-propoxypropionitrile) in an amount of 0.5–30% has also been described. In contrast to the polymers obtained from derivatives of perfluoroalkanedicarboxylic acids, these resins have satisfactory mechanical characteristics, which allows their use for the manufacture of mechanically strong articles [93,94].

A patent [95] proposes a method for the synthesis of perfluoroalkylenetriazines by heating at 50°C a mixture of perfluoroglutarothioamide with perfluorobutyronitrile in the presence of triethylamine.

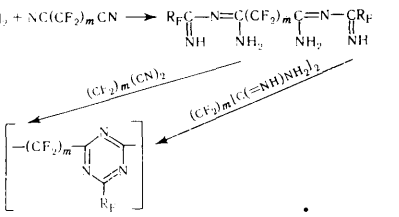
The first reports of the synthesis of linear polyperfluoroalkylenetriazines were published almost simultaneously by a number of investigators. According to the method proposed by Dorfman et al. [96] and by Griffin [97], the reaction of diamidines of perfluoroalkanedicarboxylic acids with dinitriles of perfluoroalkanedicarboxylic acids was used to synthesise initially at room temperature linear imidoylamidine polymers which, without isolation, were acylated and cyclodehydrated by anhydrides of perfluorocarboxylic acids to polyperfluoroalkylenetriazines:



This method was employed to synthesise from derivatives of perfluoroalkanedicarboxylic acids linear-high-molecular-weight polytriazines (degree of polymerisation about 300), which are soluble yellow rubberlike polymers with a glass temperature between −5 and −17°C and a decomposition temperature of about 420°C (differential thermal analysis).

The attempt [96] to obtain an imidoylamidine polymer by the reaction of dinitriles with ammonia without isolating the diamidines yielded only low-molecular-weight products.

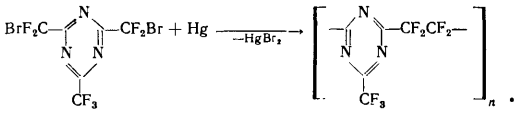
In another method [97,98] a stable intermediate bisimidoylamidine compound is initially obtained from a monoamidine and a dinitrile and isolated in the solid state; after purification it is refluxed in benzene with a diamidine or a dinitrile until the formation of a linear elastomer:



If the above processes are carried out without the isolation and purification of the intermediate, a gel is formed.

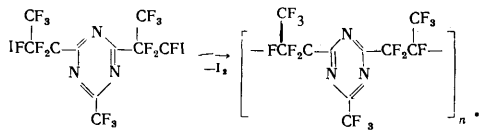
Methods have also been proposed for the preparation of polyperfluoroalkylenetriazines from monomers already containing triazine rings.

An interesting method has been described [91,97,99,100] for the preparation of a high-molecular-weight polytriazine from 2,4-di(bromodifluoromethyl)-6-trifluoromethyltriazine by heating it with mercury in evacuated tubes at 200°C (degree of polymerisation about 350):



An analogous polymer was obtained [100] by the same method from 2,4-di(difluoroiodomethyl)-6-difluoromethyltriazine. According to Griffin [97], the polymer exhibits elastic properties above 40°C. The author suggests that the glass temperature of this polymer may be reduced by introducing into the triazine rings of the macromolecules longer perfluoroalkyl substituents.

A polytriazine elastomer has been obtained by the radical polycondensation of di(iodoperfluoroalkyl)triazine under the influence of ultraviolet light:



The scope of this method is limited by the low availability of the initial di-iodide.

The thermal and chemical stabilities of linear high-molecular-weight polytriazines are comparable to the stability of cross-linked polymers but, as was expected, their mechanical strength proved to be much higher (the tensyl strength of linear polytriazine is 98 kgf cm^{-2} [97] against 7–35 kgf cm^{-2} [96] for cross-linked polymers).

The possibility of obtaining polytriazines from monomers containing triazine rings and cyanoperfluoroalkyl groups is considered in a brief report [90].

2. Other Polyazoles

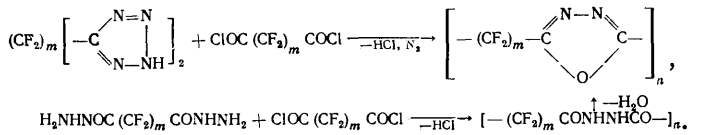
Simultaneously with the development of methods for the synthesis of linear polyperfluoroalkylene-1,2,3-triazines, the possibility of synthesising other high-molecular-weight linear polyperfluoroalkyleneazoles was investigated.

Numerous model perfluoroalkyl-substituted heterocyclic systems were obtained even earlier and it was established that their chemical and thermal stabilities are comparable to those of fluorinated triazine systems [80,101].

Towards the first half of the 1960's, methods of synthesising various high-molecular-weight linear polyazoles containing aliphatic and aromatic units in the macromolecular chain were already known. It was possible to postulate that the use of these methods for the synthesis of fluorine-containing polyazoles will make the latter more readily available than linear polytriazines.

Indeed, soon after the first publications on cross-linked polyfluoroalkylenetriazines, several communications appeared on the synthesis of other fluorine-containing polyazoles: poly-1,3,4-oxadiazoles, polybenzoxazoles, polybenzimidazoles, etc. These polyazoles were linear polymers with relatively low molecular weights.

The synthesis of polyperfluoroalkylene-1,3,4-oxadiazoles was achieved by two methods [61,62,102]; in the first method polyoxadiazoles were obtained by treating solutions of bistetrazoles in pyridine or acetonitrile with dichlorides of perfluoroalkanedicarboxylic acids:

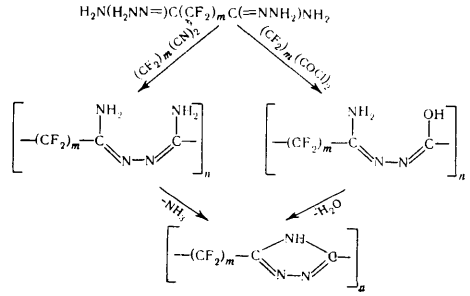


A polyoxadiazole (η_{inh} = 0.1), which behaves as an elastomer in the range 65–120°C and is inert at 100°C to the action of concentrated sulphuric and nitric acids, was synthesised in this way from perfluorohexane-1,6-bistetrazole and the dichloride of perfluorosuberic acid [61,62,102].

In the second method, polyhydrazides, which were subsequently converted into polyperfluoroalkyleneoxadiazoles, were obtained from the dihydrazides and dichlorides of perfluoroalkanedicarboxylic acids. The conditions for the preparation of the polyhydrazides and their cyclisation and also the characteristics of the polymers were not quoted [61,62] apart from the mention of a comparatively low molecular weight.

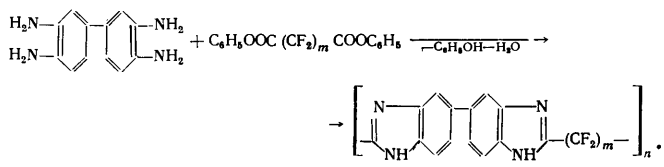
It is noteworthy that aromatic polyperfluoroalkylenehydrazides (see Section III, 2) do not undergo thermal cyclisation to polyoxadiazoles. Chemical cyclodehydration of these polyhydrazides with phosphorus oxychloride is accompanied by marked degradation and leads to low-molecular-weight compounds [48].

Two pathways for the preparation of polyperfluoroalkylene-1,2,4,4*H*-triazoles from perfluoroalkylenediacyldihydrazidines have been indicated [62]:



In the first method perfluoroalkylenediacyldihydrazidine reacts with a perfluoroalkylenedinitrile giving a polymer, which is converted into poly-1,2,4,4*H*-triazole with liberation of ammonia. In the second method perfluoroalkylenediacyldihydrazidine is acylated by the dichloride

of a perfluoroalkanedicarboxylic acid and the resulting polymer is dehydrated to poly-1,2,4,4*H*-triazole. These methods of synthesis of triazoles are similar to the modern methods for the synthesis of linear polyperfluoroalkylenetriazines from the diamidines of perfluoroalkanedicarboxylic acids (see Section IV, 1). In 1964 a number of investigators described almost simultaneously the synthesis of low-molecular-weight polyperfluoroalkylenebenzimidazoles by the polycondensation in the melt of 3,3-diaminobenzidine with the diphenyl esters of various perfluoroalkanedicarboxylic acids [103-105]:

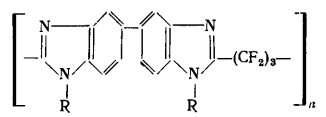


Contrary to expectation, these polymers proved to be inadequately thermostable and their degradation with liberation of hydrogen fluoride was observed in the polycondensation process itself in an atmosphere of argon below 250°C. [104,105] According to thermogravimetric data, the temperature of the onset of vigorous decomposition of polyperfluoroalkylbenzimidazoles in nitrogen does not exceed 300°C. [103] It has been noted [104] that polycondensation with perfluoroglutaric acid (at 220–250°C) leads to marked charring of the reaction mixture.

In the polycondensation of 3,3′-diaminobenzidine with both perfluoroglutaric acid and with its diphenyl ester, the evolution of not only hydrogen fluoride but also carbon dioxide was observed [106].

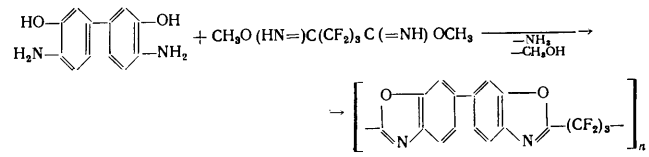
The comparatively low thermal stability of poly-2,2′-(perfluoroalkylene)-5,5′-dibenzimidazoles can be explained by a dehydrofluorination reaction, which is attributed mainly to the mobility of the hydrogen atoms in the imino-groups of the benzimidazole rings [104,107]. This hypothesis was confirmed to some extent by the appreciable increase of the decomposition temperatures of model *N*-methyl- and *N*-phenyl-substituted 2-perfluoroalkylbenzimidazoles ($T_{decomp} \simeq 390$–450°C) compared with unsubstituted 2-perfluoroalkylbenzimidazoles ($T_{decomp} \simeq 300$°C). [49,107]

N-Substituted fluorine-containing polybenzimidazoles were obtained by the polycondensation in the melt of 4,4′-di(methylamino)-3,3′-diaminobiphenyl and 4,4′-dianilino-3,3′-diaminobiphenyl with diphenyl perfluoroglutarate [49]:



The study of their thermal stability *in vacuo* and in air showed that only phenylation at nitrogen leads to some improvement of thermal stability: poly-(*NN*′-diphenyl-2,2′-perfluorotrimethylene-5,5′-dibenzimidazole) begins to decompose very slowly at about 350°C in air and *in vacuo*. The appreciable difference between the behaviour of model fluorine-containing benzimidazoles and the corresponding polymers can be explained by the presence in the latter of a relatively large number of terminal amino-groups as a result of their low molecular weight.

It was found useful to attempt the replacement of the imino-group in the ring by an oxygen atom, i.e. to obtain a benzoxazole structure. A low-molecular-weight poly-2,2′-perfluorotrimethylene-6,6′-dibenzoxazole was obtained by the polycondensation of 3,3′-dihydroxybenzidine with dimethyl bisiminoperfluoroglutarate in *N*-methylpyrrolidone at 190°C; its properties were not investigated [108]:

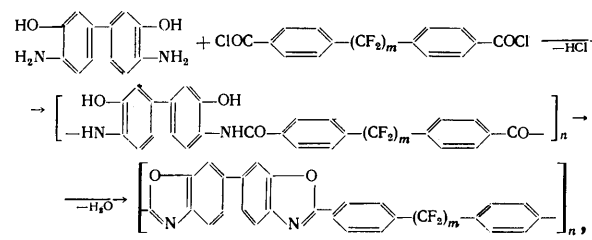


It follows from the above that fairly numerous attempts to achieve the synthesis of polyazoles with perfluoromethylene bridges in the chain from derivatives of perfluoroalkanedicarboxylic acids led only to low-molecular-weight polymers (with the exception of polytriazines).

High-molecular-weight linear polyperfluoroalkyleneazoles were obtained successfully for the first time from derivatives of $\alpha\omega$-diphenylperfluoroalkanes—monomers with functional groups of the type

where X = *p*-COCl, *m*-NH_2, etc., "screened" from the perfluoromethylene chain. In these compounds thermostable benzene rings serve as a "screen" [33,56-59,109].

Thus high-molecular-weight polybenzoxazoles were obtained by a two-stage synthesis from the dichlorides of $\alpha\omega$-di-(*p*-carboxyphenyl)perfluoroalkanes and 3,3′-dihydroxybenzidine via poly-*o*-hydroxyamides with their subsequent thermal cyclisation (250–300°C) in a vacuum or by chemical treatment (polyphosphoric acid, 200°C). [56,57,109] The polybenzoxazoles synthesised by the first method,



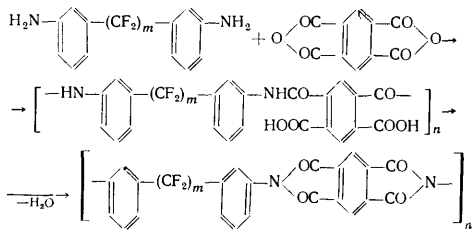
are insoluble, probably owing to partial cross-linking. On cyclisation under milder conditions in polyphosphoric acid, soluble polymers are formed ($\eta\log = 0.5$–1.3). However, under these conditions there is partial hydrolysis of CF_2 groups adjacent to the benzene rings.

High-molecular-weight soluble polybenzimidazoles ($\eta\log = 1.1$–1.6) were synthesised by the polycondensation in the melt of 3,3′-diaminobenzidine with diphenyl esters of $\alpha\omega$-di-(*p*-carboxyphenyl)perfluoroalkanes [56,57,109].

Polyperfluoroalkylene-1,3,4-oxadiazole was obtained by the condensation of the dihydrazide of 1,5-di-(*p*-carboxyphenyl)perfluoropentane with isophthaloyl chloride in hexamethylphosphoramide followed by cyclisation of the resulting polyhydrazide [57,109]. In contrast to the polyhydrazides obtained from derivatives of perfluoroalkanedicarboxylic acids [48], heat treatment of this polyhydrazide resulted in its conversion into a poly-1,3,4-oxadiazole.

High-molecular-weight polyperfluoroalkyleneimides have been synthesised by various investigators from

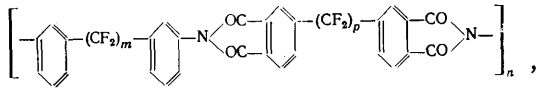
derivatives of αω-diphenylperfluoroalkanes in two ways—by a two-stage synthesis [33,57-59,109] and by polycondensation in the melt [33,58]:



Thus reaction of αω-di-(*m*-aminophenyl)perfluoroalkanes with pyromellitic dianhydride [57,109] and also of di-(*m*-aminophenyl) [33,58] and di-(*p*-aminophenyl) ethers [33,58,59] with the dianhydride of 1,3-di-(3′,4′-dicarboxyphenyl)perfluoropropane in dimethylacetamide yielded polyamides which were then cyclised to the corresponding polyimides either by heat treatment or by treatment with a mixture of acetic anhydride and pyridine [33,57,58,109]. The polyimides based on pyromellitic dianhydride are soluble only in concentrated nitric acid ($d = 1.5$), probably with decomposition ($\eta\log \simeq 0.3$); the polymers based on di(aminophenyl) ethers are sparingly soluble in dimethylacetamide ($\eta_{inh} = 0.56$ and 1.31 for *m*- and *p*-derivatives respectively), their softening temperatures lying in the range 190–240°C.

The variation of the glass temperature with the composition of the copolymers of di-(*p*-aminophenyl) ether with pyromellitic dianhydride and the dianhydride of 1,3-di-(3′,4′-dicarboxyphenyl)perfluoropropane has been investigated [59].

Polyimides containing fluorine atoms in both components ($\eta_{inh} = 0.5–1.7$, $M > 30\,000$),



where $m = 3$ or 5 and $p = 3$, 4, or 7, have been synthesised by the polycondensation in the melt of αω-di-(*m*-aminophenyl)perfluoroalkanes with the dianhydrides of αω-di-(3′,4′-dicarboxyphenyl)perfluoroalkanes [33,58]. The ready solubility of these polyimides in amide solvents and in chlorinated hydrocarbons and also the comparatively low softening temperatures (135–180°C), above which they behave as elastomers, are noteworthy.

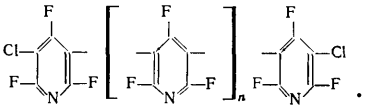
Polybenzoxazoles and polyimides form strong sheets [57,58].

Polyazoles based on derivatives of αω-diphenylperfluoroalkanes begin to decompose in air at about 350 to 400°C [57] (data derived from dynamic thermogravimetric analysis) and are thus somewhat inferior in their thermal stability in air to aromatic polyazoles.

All the above data show that the synthesis of aromatic polyperfluoroalkyleneazoles from derivatives of αω-diphenylperfluoroalkanes with different functional groups is the most general method for the preparation of linear high-molecular-weight polyperfluoroalkyleneazoles containing perfluoromethylene units in the main chain.

There exists also patent data concerning the synthesis of polyimides [60] and poly-1,3,4-oxadiazoles [63] with hexafluoropropyldiene bridges by a two-stage method. Polyazoles fluorinated in both components are distinguished by an unusually high solubility while retaining a high thermal stability: $T_{decomp} \simeq 460–475$°C; T_g (polyimide) ≃ ≃ 340°C.

Brief reports have been published recently on the use of aromatic polyfluoro-derivatives for the synthesis of fluorine-containing polyazoles. Thus poly-1,3,4-oxadiazole has been obtained from the dichloride of tetrafluoroterephthalic acid [35]. A patent [110] (see also Dine-Hart and Wright [54]) describes a synthesis of polypyromellitimides from *m*- and *p*-tetrafluorophenylenediamines, octafluorobenzidine, and pyromellitic dianhydride. Articles made from these polymers can be used for a long time at high temperatures. Polyperfluoropyridine ($n = 15–16$) has been obtained as a solid with m.p. 180–190°C by heating 3,5-dichlorotrifluoropyridine in dimethylformamide in the presence of activated copper [111]:

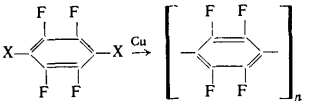


The above data on fluorinated polyazoles evidently show that studies not only on triazine polymers but also on other polyazoles are being vigorously pursued.

V. FLUORINE-CONTAINING POLYPHENYLENE POLYMERS

1. Polyphenylenes

A low-molecular-weight polyperfluoro-*p*-phenylene ($M \simeq 1700$, $T_{soft} > 360$°C) was first obtained in 1955 [112] by the Ullmann reaction in which 1,4-dibromo- or 1,4-di-iodo-tetrafluorobenzene was heated with activated copper powder. The use of 1,4-dichlorotetrafluorobenzene in this reaction leads to the same results [113]:



where X = Cl, Br, or I.

A polyperfluoro-*p*-phenylene with a relatively high molecular weight was synthesised by the decomposition of pentafluorophenylmagnesium bromide in boiling tetrahydrofuran (THF), the properties of the polymers formed depending on the temperature at which the initial organomagnesium compound had been obtained [114,115]. Thus if the latter was obtained at −30°C, a soluble polymer with $M \simeq 15\,000$ is formed, while the organomagnesium compound obtained at a higher temperature yields mainly an insoluble polymer. An insoluble polyperfluorophenylene infusible up to 360°C has also been obtained by the decomposition of pentafluorophenylmagnesium chloride [114,116]:

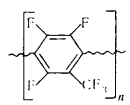
The predominantly *p*-phenylene structure of the polymer was confirmed by the isolation of perfluoroquaterphenyl from the reaction products [114]. A method for the preparation of polyperfluorophenylenes, probably with a *p*-phenylene structure, by decomposing perfluorophenylmagnesium

chloride in boiling tetrahydrofuran in the presence of decafluorobiphenyl, has been suggested in a patent [117]. In the presence of a tenfold excess of the organomagnesium compound, a polyphenylene with a degree of polymerisation of about 25 is obtained.

It is noteworthy that attempts to achieve the synthesis of a polyphenylene by the polycondensation of 1,4-dibromo- and 1,4-di-iodo-tetrafluorobenzene in the presence of sodium or zinc [112] and also by the decomposition of organolithium and organomagnesium compounds derived from 1,4-dibromo- and 4-bromo-tetrafluorobenzene [114] did not lead even to low-molecular-weight polymers of this type.

Polyperfluoro-*m*-phenylene was synthesised simultaneously by a number of workers [114,117-119] by heating 1,3-dibromo- or 1,3-dichlorotetrafluorobenzene with activated copper in decafluorobiphenyl or dimethylformamide and also in the absence of solvents; the reaction with the 1,3-dibromo-derivative leads to the formation of a polymer with a much higher molecular weight (up to about 16 000, $T_{soft} \simeq 300°C$) and requires lower temperatures. Polyperfluoro-*m*-phenylene is more soluble and melts at a lower temperature than polyperfluoro-*p*-phenylene. It is interesting that their thermal stabilities are approximately the same. According to Thrower and White [118], polyperfluoro-*m*-phenylene may prove to be more readily available than its non-fluorinated analogue because of the high reactivity of 1,3-dibromotetrafluorobenzene.

Low-molecular-weight polyperfluorophenylenes ($M \simeq 1500$, $T_{soft} \simeq 200°C$) containing simultaneously 1,3- and 1,4-phenylene units have also been described. They are obtained by the reaction of 1,3-tetrafluorophenylene-dimagnesium dibromide with decafluorobiphenyl (in molar proportions of 2 : 1) in boiling tetrahydrofuran [114]. High-molecular-weight polyperfluorotolylenes,



(M up to 200 000), have been synthesised by the decomposition of 2-heptafluorotolylmagnesium chloride in boiling tetrahydrofuran. They do not melt up to 300°C and their solubility in organic solvents is much higher than that of polyperfluorophenylenes [62,114,120].

High-molecular-weight polyperfluorophenylenes, like polyperfluorotolylenes, are stable in a vacuum up to about 600°C: under the conditions of oxidative degradation, they are less stable and begin to decompose vigorously at about 400°C. The thermal stability of polyperfluorophenylenes *in vacuo* is comparable with that of non-fluorinated polyphenylenes and poly(phenylene oxides), but is lower than the thermal stability of polytetrafluoroethylene.

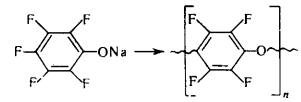
The resistance of polyperfluorophenylenes to thermo-oxidative degradation is inferior to that of the above polymers [62,114,115,121].

It has been noted that, when polyperfluorophenylenes are heated initially in a vacuum at 400°C, their resistance to oxidative degradation is greatly improved.

2. Polyphenylenes with Bridging Groups

Since polyperfluorophenylenes are fairly rigid systems, attempts have been made to improve their flexibility by introducing various atoms or groups of atoms, such as O, S, OCF_2, and others, between the phenyl rings.

a. Polyoxy(phenylenes). Polyoxy(perfluorophenylenes) were first obtained in 1958 by the thermal decomposition of alkali metal pentafluorophenoxides [122,123]:



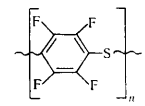
According to Pummer and Wall [123], the polymers are formed as a result of nucleophilic attack on the carbon atom adjacent to the fluorine atom by the growing phenoxide anion and they probably contain both 1,3- and 1,4-phenylene units.

The decomposition of pentafluorophenoxides is carried out in three ways: in the absence of solvents, in an aqueous medium, and in pentafluorophenol [123]. In the first two cases low-molecular-weight polymers are formed. A high-molecular-weight polymer ($M \simeq 12\,500$) has been obtained by heating an excess of sodium pentafluorophenoxide with pentafluorophenol. Polyoxy(perfluorophenylene) is a low-melting vitreous material ($T_{soft} > > 100°C$) soluble in the usual organic solvents: on heating *in vacuo* (260°C, 18 h), it becomes insoluble and acquires rubberlike properties in the temperature range 90 to 300°C. [114] Polyoxy(perfluorophenylene) is much less stable than its non-fluorinated analogue and polyperfluorophenylenes: on heating *in vacuo* for 30 min at 400°C it loses about 47–50% of its weight [114].

Aromatic polyesters with perfluoroisopropylidene units,

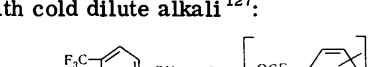
where (I) X = SO_2, T_g = 205°C, and T_f = 255°C and (II) X = CO and T_g = 175°C, have been obtained by the polycondensation of alkali metal phenoxide derivatives of 2,2-di-(*p*-hydroxyphenyl)perfluoropropane with di-(4-fluorophenyl) sulphone or 4,4'-difluorobenzophenone in aprotic solvents at 130–140°C. [124]

b. Polythioperfluorophenylenes. Low-molecular-weight polythioperfluorophenylenes,



have been synthesised in two ways [125]: by the reaction of hexafluorobenzene with sodium sulphide (the polymer has the 1,4-structure with a degree of polymerisation of about 10) and by the thermal decomposition of sodium pentafluorophenoxide. In contrast to polyoxyperfluorophenylene, polythioperfluorophenylene is insoluble in the usual organic solvents and does not melt up to about 300°C. [114] The thermal stability of polythioperfluorophenylene is lower than that of polythiophenylene. It begins to decompose vigorously below 400°C under the conditions of both thermal and thermo-oxidative degradation: the formation of a large residue indicates a significant role of chain-transfer reactions [126].

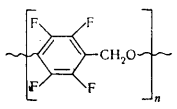
c. Polyoxybenzylenes and polythiobenzylenes. Poly-*o*- and poly-*p*-oxy-$\alpha\alpha$-difluorobenzylenes were first obtained by heating *o*- and *p*-trifluoromethylphenols with cold dilute alkali [127]:



According to the authors, this reaction proceeds via pseudoquinonoid structures, since *m*-trifluoromethylphenol, which is incapable of forming structures of this kind, is resistant to the action of aqueous alkali.

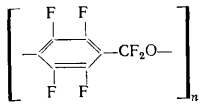
Poly-*p*-oxy-$\alpha\alpha$-difluorobenzylene has also been synthesised by the thermal dehydrofluorination of *p*-trifluoromethylphenol *in vacuo* at 900–950°C, the polymer being formed on the surface of a cold trap in the form of a weakly coloured film [128]. Poly-*p*-oxy-$\alpha\alpha$-difluorobenzylene is sparingly soluble in the usual organic solvents and is resistant to the action of concentrated alkalis.

Poly-oxy-2,3,5,6-tetrafluorobenzylene,



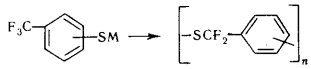
synthesised by refluxing 2,3,4,5,6-pentafluorobenzyl alcohol of 2,3,4,5,6-pentafluorobenzyl bromide with aqueous potassium hydroxide, has been described [129,130]; its melting point is 180–190°C. [130]

A third example of fluorine-containing polyoxybenzylenes is poly-*p*-oxy-perfluorobenzylene:



which was synthesised by a number of investigators by heating heptafluoro-*p*-cresol with aqueous bases at 100°C. [114,131,132] Later polyoxyperfluorobenzylene was obtained by the thermal dehydrofluorination of heptafluoro-*p*-cresol *in vacuo*. [128] The mechanism of the formation of the polymer was not elucidated by the authors. The maximum molecular weight of polyoxyperfluorobenzylene is about 3000–5000; it is soluble in the usual organic solvents and its softening temperature varies in the range 65–120°C depending on the molecular weight. Like polyoxyperfluorophenylene, polyoxyperfluorobenzylene gives rise on heating *in vacuo* at about 200°C to a polymer with elastic properties at temperatures above 100°C. The thermal stability of polyoxyperfluorobenzylene is approximately the same as that of polyoxyperfluorophenylene: the weight loss at 350°C in 1 h is 89%.

A method for the preparation of poly-*m*- and poly-*p*-thio-$\alpha\alpha$-difluorobenzylenes has been patented:

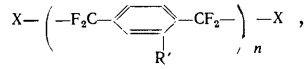


It involves heating Group I metal *m*- or *p*-($\alpha\alpha\alpha$-trifluoromethyl)thiophenoxides at 200°C for 5 days; the reaction may be carried out in pyridine solution. Poly-*m*-thiodifluorobenzylene (degree of polymerisation 12) melts at 285–310°C. [133]

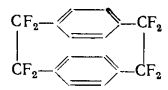
d. Poly-*p*-xylylenes. Poly-$\alpha\alpha\alpha'\alpha'$-tetrafluoroxylylene,

was first synthesised by the pyrolysis of $\alpha\alpha$-dibromo-$\alpha\alpha\alpha'\alpha'$-tetrafluoro-*p*-xylylene in a vacuum at 330°C in the presence of zinc in the form of an amorphous film on the surface of a trap cooled to −78°C; the conversion of the initial monomer into the polymer is about 8% and the softening temperature of the polymer is 380°C. The authors suggest that $\alpha\alpha\alpha\alpha$-tetrafluoro-*p*-quinodimethane, which is stable in the gas phase but polymerises rapidly in the liquid phase, is an intermediate in the reaction [134]. Other investigators believe [135] that the reaction can also proceed via the free biradicals $F_2CC_6H_4CF_2$.

High-temperature vacuum pyrolysis (700–950°C) of dihalides [136,137] and disulphones of the type [136,137],



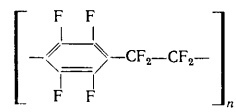
where $n = 1$ or 2, X = Cl, Br, or SO_2R (R is a small alkyl group), and R′ = H, Cl, or C_6H_5, and also of the cyclic dimer of $\alpha\alpha\alpha'\alpha'$-tetrafluoroxylylene [136,138],



has been recently used successfully in the synthesis of poly-$\alpha\alpha\alpha'\alpha'$-tetrafluoro-*p*-xylylenes. Strong transparent sheets have been obtained by this method from the disulphones and the dimer.

Poly-$\alpha\alpha\alpha'\alpha'$-tetrafluoroxylylene (m.p. about 500°C) is a highly crystalline insoluble polymer with a very high thermal stability; the mechanical properties of sheets of this polymer hardly change on heating in air for 3000 h at 250°C or 100 h at 300°C.

A method for the preparation of polyperfluoro-*p*-xylylene from the corresponding disulphone has also been patented [137]:



---o0o---

The new field of the chemistry of organofluorine compounds (polycondensation fluoropolymers) discussed in the present review is at present in the stage of establishment and development, the number of studies in this field increasing continuously: for example three-quarters of the relevant studies were published in the 1960's.

The interest in polycondensation fluoropolymers can be readily understood: in almost every class materials have been found with promising operational properties (high thermal stability, chemical stability, elasticity at low temperatures, etc.). Thus polyperfluoroalkylenetriazines have the highest thermal stability among the known elastomers, poly(hexafluoropentylene adipate) has found application in the preparation of special oil- and frost-resistant rubber, fluorine-containing polyurethanes based on polyperfluoroethers can be used as elastomers at low temperatures, etc.

At the same time one should note that the introduction of fluorine atoms does not always lead to the improvement of the properties of the polymer and in some cases a decrease of thermal and chemical stability, for example, has been observed as a function of the structure of the polymer. Unfortunately exhaustive data on the properties of polycondensation fluoropolymers are frequently lacking in the literature and therefore it is difficult to make a comparative analysis of fluoropolymers and their non-fluorinated analogues. Whenever possible, such a comparison has been made in the appropriate places in the text.

Polycondensation reactions of fluorine-containing compounds frequently lead to polymers with a lower molecular weight compared with their non-fluorinated analogues. This is due to the powerful electron-accepting influence of the fluorine atoms on the reactivity of the functional

groups. Recently definite progress has been achieved in the synthesis of polycondensation fluoropolymers—high-molecular-weight compounds of various classes which were previously regarded as unattainable—had been synthesised. Their synthesis became possible owing to the application of new methods of polycondensation and also the use of new types of fluorine-containing monomers.

The entire accumulated experience on the synthesis of fluoropolymers and the study of their properties show that further studies in this interesting series of still new polymers are justified.

The Photoelectric Effect at the Metal-Electrolyte Boundary

L.I.Korshunov, Ya.M.Zolotovitskii, and V.A.Benderskii

Photoelectrochemistry is a new branch of physical chemistry, with many applications in the study of boundary layer structure, the energetics of electrons in solutions, the mechanism of photoemission, and the kinetics of fast reactions in solutions initiated by solvated electrons. 110 references.

I. INTRODUCTION

The generation of photocurrents by illumination of the interface between an electrode and an electrolyte solution was first reported by Becquerel over 100 years ago[1]. However, the elementary acts involved in the electrode photoeffect have only recently been characterised by work done at Harwell (England)[2-4] and at the Chemical Physics and the Electrochemistry Institutes of the USSR Academy of Sciences[5-11].

According to current views, the following charge separation processes have to be considered when a metal-solution interface is illuminated: 1) photoemission of electrons from the metal into the electrolyte solution; 2) photoionisation of the surface donor-acceptor complexes which include the electrode as one component; 3) electrode reactions involving metastable species produced by the interaction of photoemitted electrons with the molecules of the medium; 4) electrode reactions involving the products of photochemical reactions in solution.

In real systems these processes usually overlap, and complicated experimental procedures are needed to resolve them.

This review is concerned with elementary, light-induced charge transfer processes at the metal-electrolyte boundary: a) in solutions which do not absorb in the spectral region used to excite the electrode, and b) in solutions of photochemically active redox systems, including a light-absorbing dye.

The electrode photoeffect has great theoretical and practical interest. Photo-emission from metals into electrolyte solutions offers a new approach to the study of the behaviour of low-energy electrons in condensed media. Its characteristics are directly determined by the structure of the interfacial boundary layer and by the physicochemical properties of the solution.

The photoelectrochemical method of detecting unstable species in solution is much more sensitive than alternative methods such as optical and radiation methods.

II. EXPERIMENTAL METHODS

The electrode photoeffect can be studied by three methods: with constant illumination, interrupted illumination, and pulse illumination. The relaxation methods are by far the more important, because they give both the magnitude and the kinetic constants of the photoeffect.

The photocurrent in an electrochemical cell exposed to steady light can be measured with a sensitive galvanometer[11] or a polarograph[13]. The success of the method depends on the purity of the reagents, since it is essential to avoid significant Faradaic currents in this work. Intermittent photocurrent is obtained by modulating the light supplied to the electrode. Barker[3] used a square-wave polarograph to measure intermittent photocurrents (f = 225 Hz). For sinusoidal modulation, the measuring equipment consists of a narrow-band amplifier tuned to the modulation frequency, followed by a synchronous detector[10]. The current-voltage curve for the photoeffect is plotted directly, by sweeping the voltage (Figs. 1 and 2). An apparatus has been described[14] in which the impedance of an electrochemical cell can be measured by sinusoidally modulating the illumination or by applying a small alternating voltage. The measurements of the components of the photoimpedance, proposed by Rotenberg and coworkers[15], has not yet been realised experimentally.

The pulse method was first applied by Berg[16]. One form[8] of the apparatus is shown in Fig. 3. The photopotential which appears across a standard resistor in series with the cell is displayed on a double-beam oscilloscope. The second channel of the oscilloscope is used to record the wave-form of the light pulse (Fig. 4).

Powerful light pulses in the visible and the ultraviolet region of the spectrum are obtained by means of mercury or xenon lamps. Lasers also are a convenient source of radiation[9,17].

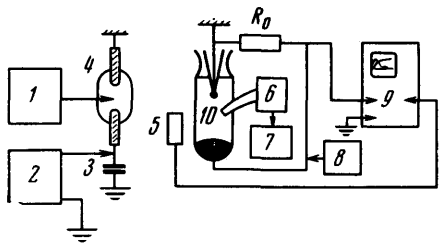

Figure 1. Pulse apparatus: *1*) firing circuit; *2*) condenser charging circuit; *3*) pulse condenser; *4*) flash lamp; *5*) synchronising photodiode; *6*) reference electrode; *7*) potentiometer for the working electrode; *8*) commutator circuit for measuring the capacity of the working electrode; *9*) oscilloscope; *10*) polarographic cell; R_0 is the standard resistor.

An analysis of the equivalent circuit of the cell shows that the measured signal $V_{ph}(t)$ is related to the photocurrent $I_{ph}(t)$ flowing through the interface by the expression

$$V_{ph}(t) = \exp(-t/RC) \int_0^t 1/C I_{ph}(t') \exp(t'/RC)\, dt' \qquad (1)$$

where t is time, R is the resistance of the circuit, and C is the capacity of the electrical double layer (~16 μF cm^{-2}).

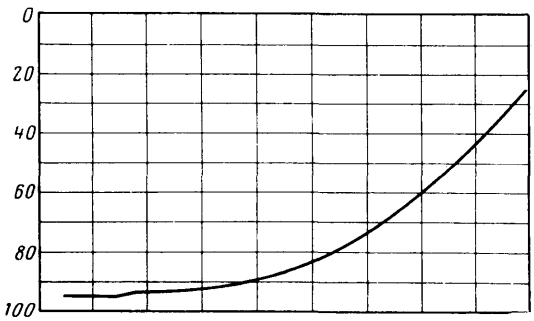

Figure 2. Plot of the photocurrent obtained by sweeping the potential. The potential is plotted horizontally and the photocurrent vertically.

For pulse measurements the standard resistance is chosen to give an RC value much greater than the duration of the pulse of photocurrent. In this case, $V_{ph}(t) = \int_0^t C^{-1} \cdot I_{ph}(t')dt'$, i.e. the measured photopotential is proportional to the charge transferred across the interface. With the dropping mercury electrode—a very convenient photocathode—the condition is satisfied by taking $R \geq 10^5$ ohm for pulse durations of 10^{-5}–10^{-3} s. The capacity, which must be known in order to calculate the charge, is measured by the commutator method[18].

Apparatus for intermittent illumination: *1*) DRSh-1000 lamp; *2*) quartz lens; *3*) chopper; *4*) Glan Nicol prism; *5*) quartz condenser; *6*) photodiode; *7*) photocathode; *8*) polarisable reference electrode; *9*) polarising circuit; *10*), *11*), *13*) V6-2 amplifiers; *12*) KZ-2 synchronous detector; *14*) chart recorder.

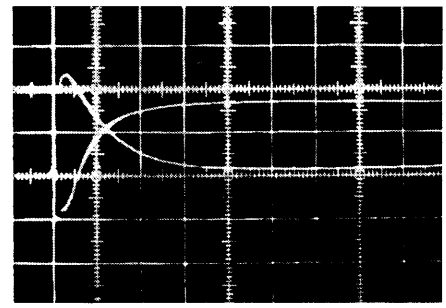

Figure 4. Oscillograms of the photoemission signal $V(t)$ (upper trace) and of the light pulse $L(t)$ (lower trace). Calibration: 200 μs cm^{-1} (horizontal axis) and 1 mV cm^{-1} (vertical axis).

In Delahay's differential method[19], the potential difference between two identical electrodes (one of which is kept in the dark while the other is exposed to a pulse of light) is measured. With modulated or steady illumination one usually measures the quantity $V_{ph}(t) = I_{ph}(t) \cdot R$. This regime corresponds to the condition $\omega_M RC \ll 1$, where ω_M is the modulation frequency. For a dropping electrode this condition is satisfied by $R \leq 500$ ohm and $\omega_M \leq 10^3$ Hz. An analysis of the measurement errors[20] has shown that in the steady illumination regime the error is usually 3–4%, as compared with 7–8% for pulses of 10^{-6}–10^{-7} s duration. The precision of the pulse method can be increased by using storage oscilloscopes and amplitude–time analysers for the microsecond range[21]. Stroboscopic light sources, including

pulsed gas lasers, are very important in studies of the relaxation phenomena associated with photoemission. They are used in conjunction with signal averaging devices [22].

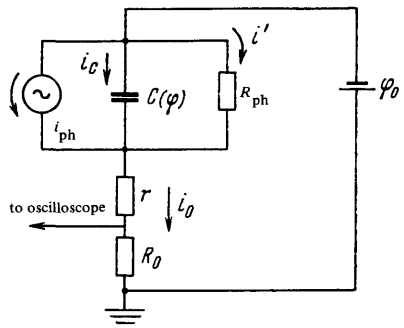

Figure 5. Equivalent circuit of the electrochemical cell during the passage of photocurrent.

Korshunov and coworkers [22] illuminated the electrode–solution interface with pulses from a nitrogen laser ($\lambda = 3371$ Å) of 20 ns duration at the 0.35 level. The time resolution of the apparatus was 10 ns. In order to avoid the slow ($10^{-7}-10^{-5}$ s) signal fluctuations due to electrocapillary effects, the dropping mercury electrode was replaced by an amalgamated gold wire ($s = 2.5 \times 10^{-3}$ cm^2). In order to match the signal to the input of the measuring apparatus, a standard resistance of 150 ohm was used. The time constant of the integrating circuit ($\sim 2 \times 10^{-5}$ s) allowed processes occurring over periods of $10^{-8}-10^{-5}$ s to be studied. The repetition frequency of the laser pulses was 50 Hz.

III. GENERAL ASPECTS OF PHOTOEMISSION INTO ELECTROLYTE SOLUTIONS AND IONISATION OF SURFACE DONOR–ACCEPTOR COMPLEXES

The concepts of cathodic photocurrent due to u.v. illumination of solutions of indifferent electrolytes, and of the emission of electrons from an electrode into a solution, are both due to Barker [2]. Earlier, pioneering work on the electrode photoeffect includes Heyrovsky's hypothesis [23-27] of the surface donor–acceptor complex and Berg's "hot electrode" concept [28-33]. Heyrovsky considered that the photocurrent is produced by ionisation of a surface donor–acceptor complex, consisting of the electrode on the one hand and the solvent or solute on the other hand. Absorption of a light quantum raises the complex to an excited state. The direction of the electron transfer (i.e. the sign of the photocurrent) depends on the relative positions of the energy levels of the complex, the energy level of the electrode being determined by the electrode potential φ. Heyrovsky's hypothesis was based on the observation of anodic photocurrents at $\varphi > \varphi_{z.c.}$, where $\varphi_{z.c.}$ is the potential at the point of zero charge, in solutions of organic molecules containing the functional group $-\underset{\underset{O}{\|}}{C}-\underset{\underset{X}{|}}{C}=$.

The formation of surface donor–acceptor complexes has since been confirmed for a number of compounds, but only at $\varphi > \varphi_{z.c.}$ [10].

According to Berg, the photoexcitation of electrons in the metal causes the electrolyte ions to be discharged at more positive potentials. The suggestion had been put forward earlier by Bowden [34], who had observed a decrease of hydrogen overvoltage at an illuminated electrode. However, since the relaxation time of the charge in the metal [35] is less than 10^{-16} s, this mechanism cannot be accepted.

Barker based his hypothesis on a detailed study of the spectral and current–voltage characteristics of the electrode photoeffect, because properties such as proportionality to the light intensity, short persistence, and the presence of a long-wave threshold can be explained by almost any model. We shall discuss the problem in some detail in the following paragraphs.

Photoemission from metals into electrolyte solutions can be treated as three distinct steps: a) interaction of a photon with the conduction electrons of the metal, causing an electron to pass through the potential barrier at the interface; b) thermalisation and solvation of the emitted electron in the solution medium; c) chemical and electrode reactions of the solvated electron, and of the products of its interaction with acceptor molecules present in solution.

The first step in photoemission is quite different from photoemission into a vacuum, because of the sharp drop in potential across the electrical double layer over distances of 10 Å or less (in concentrated solutions), and because of the Coulombic screening of the emitted electron with respect to the image forces.

The double layer at the interface affects the emission properties of the metal electrode, because the emitted electrons can tunnel through the dense part of the double layer, thus lowering the work function of the metal by an amount equal to the applied potential. The screening effect operates on the positive charge in the metal electrode produced by the emission of an electron, and is due to the ions in the electrical double layer. (The electron in the solution is screened much more slowly). According to Brodskii and Gurevich [6], this effect should result in the replacement of Fowler's parabolic law [36,37] by a "five-over-two" law of the form

$$I_0 = L\chi(\omega)(h\omega - h\omega_0 - e\varphi)^{5/2} \qquad (2)$$

where L is the light intensity, $\chi(\omega)$ is a function of the properties of the metal and of conditions of light absorption, h is Planck's constant, ω is the frequency of the incident light, ω_0 is the frequency of the long-wave limit of the photoeffect, e is the electronic charge, and φ is the potential of the electrode relative to the potential at the point of zero charge.

The second step in photoemission is the least well understood at the moment, because very little is known about the differential scattering cross-sections of low-energy electrons (0.5–3 eV) in condensed media. If we assume that the main scattering mechanism in water is dipole relaxation, the characteristic thermalisation time works out [38] to $10^{-12}-10^{-13}$ s. The time for the hydration of an electron, i.e. the time needed to convert it into a polaron state, is [38] $\sim 10^{-12}$ s.

The third step in photoemission concerns the behaviour of the electrons after thermalisation and hydration. Such electrons can be captured by acceptors in solution, or they can return to the electrode. The capture of a solvated electron by an acceptor is diffusion-controlled,

with a characteristic time of $10^{-6}-10^{-9}$ s depending on the concentration of the acceptor. The molecule containing a trapped electron can itself undergo homogeneous or heterogeneous (electrode) reactions; furthermore, the homogeneous reaction product can undergo further reaction at the electrode. Thus, the experimentally observed photocurrent depends, in general, on the emission current I_0, the diffusion current of electrons returning from the solution I_1, and the currents (I_{2i}) due to the electrode reactions of the species produced from the acceptor containing a trapped electron:

$$I = I_0 - I_1 + \sum_i I_{2i}$$

Various electron acceptors are added to the solution in order to minimise the reverse diffusion current I_1: these can be neutral (N_2O, CO, acrylonitrile), positively charged (H^+), or negatively charged (NO_3^-, NO_2^-, BrO_3^-, CN^-, SeO_3^-, TeO_4^-, etc.) [2,27].

Barker solved the steady-state problem for the simplest case (no side reactions) by the equivalent circuit method[3]. Sinusoidally modulated[39] and pulsed[20] illumination were treated separately. Solution of the non-stationary diffusion equation gives the following expression for the photocurrent produced by illumination for times longer than the times involved in the reverse current of solvated electrons and in electron capture by the acceptors (estimated to be less than 10^{-6} s):

$$I = L(t)\int_0^\infty f(x)\left\{1-\exp\left(-\sqrt{\frac{kc}{D_s}}\,x\right)\right\}dx \qquad (3)$$

Under these conditions, $I_0 = L(t)\int_0^\infty f(x)dx$, where $L(t)$ is the intensity of the exciting light, $f(x)$ is a function of the source of solvated electrons, x is the distance from the electrode, k is the rate constant of the reaction between the solvated electron and an acceptor molecule, c is the acceptor concentration, and D_S is the diffusion coefficient of the solvated electron.

In real systems, the emission current usually includes a component from the electrode reactions of the electron–acceptor complexes, and also of the products of their transformations in solution. These effects can distort the $I(\varphi)$ current–voltage characteristic, since the rate constant of the electrode reaction is (in general) a function of φ. However, if the electrode reactions of the products do not depend on φ in the region of interest, the current–voltage characteristic $I(\varphi)$ will be determined by $I_0(\varphi)$ and by the potential dependence of the source of solvated electrons.

This situation occurs for the acceptors N_2O and H_3O^+ (and for protons at $\varphi < -0.6$ V†), when the transfer of the second electron at the electrode–electrolyte interface involves the reduction of a hydroxyl radical or atomic hydrogen, and the emission current is simply doubled:

$$\begin{cases} N_2O + e_s^- \rightarrow N_2O^- \\ N_2O^- + H_2O \rightarrow N_2 + OH + OH^- \end{cases}$$

$$\begin{cases} H_3O^+ + e_s^- \rightarrow H + H_2O \\ H_{ad} + H_2O + e \rightarrow H_2 + OH^-, \end{cases}$$

where e_s is a solvated electron. N_2O and H_3O^+ have been used to investigate the detailed aspects of photoemission in solutions of electrolytes.

Some of the early workers[40,41], and also Heyrovsky[27], plotted their current–voltage and spectral measurements of the electrode photoeffect using ($\lg Q$, φ) and ($\lg Q$, $\hbar\omega$) co-ordinates, but Barker[3] and Delahay[17], who did not distinguish between photoemission into a vacuum and into a solution of electrolyte, used ($Q^{1/2}$, φ) and ($Q^{1/2}$, $\hbar\omega$) co-ordinates. (Here Q is the emitted charge). In both cases, the experimental results lay on a straight line over a limited region of potential. A more general law—the "five-over-two" law was first proposed[8,20] for the photoemission from mercury in the wave-length region 250–450 nm at potentials up to −0.7 V (relative to the point of zero charge) in acid solutions and up to −1.5 V (z.c.) in neutral or alkaline solutions containing nitrous oxide as an acceptor. It was shown that the current–voltage characteristics of the photoeffect "straighten out" when plotted in ($Q^{0.4}$, φ) co-ordinates‡ (Fig. 6). For solutions with different acceptor concentrations but constant ionic strength the straight lines intersect at one point on the potential axis.
