Polyphosphoric Acids and Their Ammonium Salts

L.V.Kubasova

This review examines the most important results of studies in the field of the chemistry of polyphosphoric acids and their ammonium salts. The chief physicochemical properties and characteristics of these compounds are described. Particular attention is paid to the problem of the preparation of condensed ammonium phosphates by both industrial and laboratory methods. The bibliography contains 113 references.

CONTENTS

1. Introduction 1
2. Chemistry of polyphosphoric acids 1
3. Chemistry and technology of dehydrated ammonium phosphates 4

1. INTRODUCTION

Ammonium phosphates are of considerable scientific and practical importance. Since they are compounds containing two of the most important plant nutrient elements—nitrogen and phosphorus—the various ammonium ortho-, pyro-, poly-, and metaphosphates can be used as nitrogen–phosphorus fertilisers, and some can be used as feedstuffs in animal husbandry and as technical salts. With respect to the total concentration of nutrient elements, the poly- and metaphosphates are more concentrated than the salts of orthophosphoric acid—monoammonium and diammonium phosphates. Agricultural-chemical experiments have shown that the phosphorus and nitrogen are just as effective in ammonium polyphosphates as in other water-soluble fertilisers. The high concentration of nutrients gives the polyphosphates a number of economic and agricultural-technical advantages and provides promising possibilities for their utilisation as highly effective concentrated fertilisers, but the technology of these compounds has been insufficiently developed. The extensive development of the electrothermal production of phosphorus and "thermal" phosphoric acids, and also the production of polyphosphoric acids by the evaporation of "extraction" phosphoric acid, are raising the problem of the conversion of these materials into various forms of concentrated fertilisers and technical salts.

Despite the urgency of the problem, published data on the chemistry and technology of dehydrated ammonium phosphates have not been reviewed. The present review therefore deals with the most important results of the studies of recent years in the field of the preparation and study of the properties of ammonium poly- and metaphosphates. The problems of the structural chemistry of the phosphates are not examined in detail, since this subject has been dealt with in depth in the monograph by van Wazer[1] and in reviews by Khodakov[2], Thilo[3], Britske and coworkers[4], and others.

2. CHEMISTRY OF POLYPHOSPHORIC ACIDS

As early as 1910, Balareff[5] noted that in the two-component $H_2O-P_2O_5$ system in the range of high concentrations of phosphorus(V) oxide (>72.4%), solutions consisting of a mixture of various phosphoric acids begin to form. This was one of the first suggestions that in this concentration range the 100% orthophosphoric acid formed does

not simply mix with the excess of phosphorus(V) oxide, but that a large quantity of other condensed forms of phosphate anions is gradually formed in the solution.

After the establishment of the existence of a large number of polymeric phosphates, the attention of research workers was drawn to the development of analytical methods for their separation and quantitative determination in the presence of one another. It was established that classical analytical methods based on precipitation make it possible to separate only the first three members of the homologous series of polyphosphates[6-8]. The concentration of all other polyphosphates was determined from the difference between the total concentration of phosphorus in the phosphate mixture and the phosphorus present in the ortho-, pyro-, and tripolyphosphates. This was attributed to the fact that the polymeric phosphate homologues have extremely similar chemical properties and tend to undergo hydrolysis to orthophosphate, so that attempts to separate them by precipitation are unsuccessful.

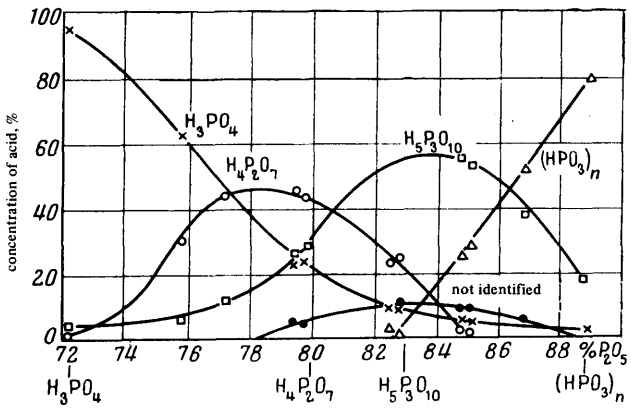

Figure 1. Composition of concentrated phosphoric acids.

Using the available analytical methods, Durgin and coworkers[9] established that phosphoric acids at high concentrations consist of mixtures of ortho-, pyro-, tripoly-, and other acids with different degrees of condensation. Later, Bell[10] detected regular features in the dependence of the production of a given phosphoric acid on the concentration of phosphorus(V) oxide in the solution (Fig. 1), namely that at concentrations in the range 72.4–85% P_2O_5 the solution always contains ortho- and pyrophosphoric acids, and in the range 72.4–88.7% P_2O_5 it also contains tripolyphosphoric acid $H_5P_3O_{10}$ in addition to these two acids. At a concentration greater than 83%, metaphosphoric acid appears in the polymeric form $(HPO_3)_n$.

Paper chromatography[11-15] has proved more successful for the separation of polyphosphate chains. Using this method, Huhti and Gartaganis[16] studied the compositions of phosphoric acids in the range 68.8–86.3% P_2O_5 and gave quantitative information on the concentration of phosphoric acids with different degrees of polymerisation in the mixture (Table 1). Unfortunately, even this most accurate method of polyphosphate analysis does not yet make it possible to separate polyphosphoric acids containing more than nine phosphorus atoms in the chain, so that the compositions of the acids with ratio $H_2O/P_2O_5 < 1.5$ have not yet been fully established. An interesting feature is that the author cited confirmed the previously noted observation[17] that liquid phosphoric acid with the theoretical composition of pure orthophosphoric acid (72.4% P_2O_5) contains 12.7% pyrophosphoric acid, the first detectable quantities of which begin to appear at 68.9% P_2O_5, and the composition of 100% orthophosphoric acid is achieved only on crystallisation.

Simon[18] considers that the rearrangement leading to partial condensation with the formation of free water and pyrophosphoric acid according to the equation

$$3H_3PO_4 \rightleftarrows H_4P_2O_7 + [H_3O]^+ + [H_2PO_4]^-,$$

takes place as a result of interaction within the three-dimensional structure and is associated with the presence of a large number of covalent bonds between hydrogen and oxygen atoms.

Table 1. Compositions of liquid polyphosphoric acids (according to Huhti and Gartaganis[16]).

Total P_2O_5 concentration	Ortho-	Pyro-	Tri-	Tetra-	Penta-	Hexa-	Hepta-	Octa-	Nona-	$(HPO_3)_n$
68.80	100	—	—	—	—	—	—	—	—	—
69.81	97.85	2.15	—	—	—	—	—	—	—	—
74.26	67.78	29.54	2.67	—	—	—	—	—	—	—
75.97	48.93	41.76	8.23	0.08	—	—	—	—	—	—
78.02	26.91	49.30	16.85	5.33	1.60	—	—	—	—	—
79.45	16.73	43.29	22.09	10.69	4.48	1.92	0.80	—	—	—
81.60	8.06	27.01	22.28	16.99	11.00	5.78	3.72	2.31	1.55	1.28
86.26	1.54	2.97	3.31	5.16	5.32	5.54	3.51	3.30	3.30	66.03

At the same time, studies of liquid phosphoric acids indicated that a definite molar ratio H_2O/P_2O_5 always corresponds to the same molar composition of the solution, which consists of a mixture of phosphoric acids with different degrees of condensation. This suggested that a given liquid polyphosphoric acid molecular composition expresses an equilibrium state between different structural units, molecules and molecular ions, which in the time taken for equilibrium to be established may break down and be re-formed repeatedly. There are many examples in organic chemistry of the rearrangement of molecular structures. This phenomenon for various processes has been studied in detail from the chemical viewpoint; in addition, a mathematical treatment of the molecular weight distribution in the intermediate compounds formed has been carried out[19] and has found extensive application for the description of unionised molecules as the Flory distribution function.

van Wazer and coworkers, following Flory, extended the theory of rearrangement to polyelectrolytes, that is ionised molecules such as those of the polyphosphoric acids, and derived an equation which makes it possible, for any given molar ratio H_2O/P_2O_5, to calculate the distribution of chains of different length[20]. It should be noted that recent work has shown that it is possible to carry out a more accurate quantitative analysis of polyphosphate compounds by means of computers.

Of the large numbers of known phosphoric acids, only a few have been identified and isolated in crystalline form. These are orthophosphoric acid hemihydrate ($H_3PO_4 \cdot 0.5H_2O$) and orthophosphoric (H_3PO_4), pyrophosphoric ($H_4P_2O_7$), and tetraphosphoric ($H_6P_4O_{13}$) acids. Other polyphosphoric acids have been obtained in the form of mixtures of acids

with different degrees of condensation, and form a series of compounds ranging from syrupy liquids, which crystallise slowly when kept, to amorphous glasses. The Americans Striplin and coworkers[21] of the TVA established the range of concentrations (75–76% P_2O_5) in which polyphosphoric acids are always produced in the form of syrupy liquids and do not crystallise on prolonged storage; in their opinion, this is due to the existence of a simple eutectic with the neighbouring region of the solutions, which have a strong tendency to undergo supercooling.

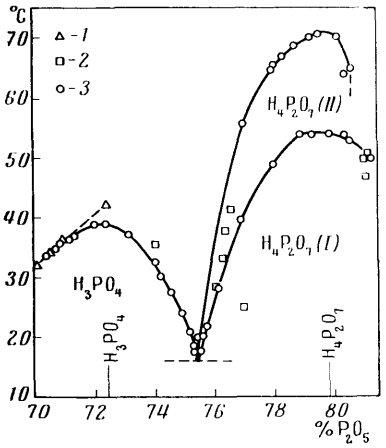

Figure 2. Fusion diagram of the $H_3PO_4-H_4P_2O_7$ system according to Refs. 23 (*1*), 24 (*2*), and 22 (*3*).

This suggestion was later confirmed by their colleague Wakefield and coworkers[22] in a study of phase changes in the $H_3PO_4-H_4P_2O_7$ system. The determination of the melting points of these acids, and the diagram constructed by the authors cited on the basis of the results obtained, show clearly the formation of a eutectic (16°) at a concentration of 75.4% P_2O_5 in phosphoric acid (Fig. 2). Moreover, the authors cited established the existence of two crystalline forms of pyrophosphoric acid, denoted (I) and (II). The ordinary metastable form (I) melts at 54.3°; the second form (II), the existence of which was confirmed by X-ray diffraction studies, melts at a higher temperature (71.5°). This form can be obtained by gradually heating the acid in form (I) above 54°, without stirring. All the acid, with the exception of a few crystals, melts, but further increase in temperature (from 60° to melting point) leads to the opposite phenomenon—all the liquid phase solidifies. The pyrophosphoric acid (II) obtained in this way is stable at room temperature. Transformation of one form of pyrophosphoric acid into the other in the solid phase was not observed. These results indicate that the melting point of 61° for pyrophosphoric acid, established in 1902 by Giran[25] and generally accepted since then reflects the melting point of a mixture of its two modifications.

In parallel with the study of the chemical compositions of polyphosphoric acids, a number of authors have determined the physical properties of these compounds. Particular attention has been paid to the study of such physicochemical characteristics as density and viscosity[9,26], a knowledge of which is very important for the industrial development of polyphosphoric acid production.

The experimental data on the density of thermal phosphoric acids over a wide range of concentrations have been treated mathematically and represented in the form of the equation given below, which makes it possible to find the temperature dependence of the density for acids at different concentrations

$$d = (0.7102 + 0.1617c) - (11.7 \cdot 10^{-4} - 6.00 \cdot 10^{-6}c)t,$$

where d is the density, g ml^{-1}; c the concentration (wt. % P_2O_5); and t the temperature, °C.

Workers from Monsanto[27] recommend a slightly simplified form of the equation for the concentration dependence of the density of the condensed acids

$$d = 0.0167(\%P_2O_5) + 0.66$$

for concentrations of phosphorus(V) oxide in the acid from 50% to 95%.

The viscosity of polyphosphoric acids was determined by Durgin and coworkers[9] in the range 71.8–77.1% P_2O_5 and by Kondratenko and Fedorchenko[28] in the range 65.2–74.6% P_2O_5. The results made it possible to establish the temperature dependence of the viscosity for a wide range of polyphosphoric acids as far as the azeotropic composition containing 92.4% P_2O_5.

Similar studies of the physicochemical properties of polyphosphoric acids obtained by the extraction method were carried out by Mal'tseva and coworkers[29,30], who were able to determine a number of thermochemical constants characterising the dilution of polyphosphoric acids; this is of considerable importance in the technology of polyphosphoric acids.

The industrial production of highly concentrated phosphoric acids is now carried out on the basis of the electrothermal process for the preparation of phosphorus and its oxidation, and on the basis of the production of extraction phosphoric acid.

Despite the fact that vacuum-evaporation, spraying, and other apparatus making it possible to increase the concentration of extraction phosphoric acids to 70% P_2O_5 [31-33] has been developed and introduced, the production of polyphosphoric acids by this method has not until recently found extensive industrial application. This is because the concentrated phosphoric acids obtained in this way in most instances are contaminated by traces of sulphuric acid, sesquioxides of iron and aluminium, etc.

In most instances, the direct method of preparing polyphosphoric acids in the electrothermal production of phosphorus is used. The production of polyphosphoric acid on a pilot-plant scale was first carried out by the TVA and in Japan[34,35]. The production scheme was as follows. The phosphorus(V) oxide vapour leaving the phosphorus combustion chamber was cooled to 460° and passed to an absorption tower, irrigated at 210–220° with concentrated 85% phosphoric acid. This high concentration of acid used for irrigation was necessary to obtain the maximal degree of absorption of phosphorus(V) oxide (99%). The concentration of acid leaving the tower was 87% P_2O_5. The proposed scheme required very rigorous observation of the temperature conditions of the absorption and the concentration of the absorbent. To avoid these technological difficulties, the same authors later proposed a new scheme for the production of polyphosphoric acid containing 76% P_2O_5,[20,36,37] according to which oxides of phosphorus containing small quantities of metaphosphoric acid at 600° were passed to a hydrating apparatus irrigated with water and dilute orthophosphoric acid. The resulting polyphosphoric acid was passed through a cooling channel into a

collector, and the unabsorbed phosphorus oxides in the form of a mist were trapped in an electrostatic filter or in a packed tower. Phosphoric acids at this concentration are extremely aggressive towards most metals, and the aggressive character increases considerably with increase in temperature to several hundred degrees, so that most of the apparatus (combustion chamber, hydration towers) had to be made of graphite or lined with acid-resistant brick.

Recently, the TVA has built a number of new plants for the production of polyphosphoric acid with increased concentration (~ 80% P_2O_5), [38] in which the old graphite equipment has been replaced by new stainless steel equipment.

In the Research Institute for Fertilisers and Insectofungicides, Postnikov and coworkers [39] have developed a new scheme for the preparation of thermal concentrated phosphoric acids (103–110% H_3PO_4). The authors rejected the old designs of plant with linings and changed to unlined metal equipment with water-cooled walls to remove the excess of heat and protect the metal from corrosion.

A number of authors have suggested a method involving the repeated rectification of a mixture of phosphoric acids and organic solvents to increase the concentration of these acids [40,41]. Recent work has shown that the best results are obtained by using such solvents as n-butanol, cyclopentanol, cyclohexanol, and 3-methylbutanol, which make it possible to reach a concentration of phosphorus(V) oxide in the acids equal to 77.8–93.8%. This method has not yet found extensive industrial application and is used only when necessary to prepare small quantities of concentrated polyphosphoric acid.

For preparative purposes, polyphosphoric acids can be obtained from the corresponding sodium polyphosphates by means of ion exchange resins in the H-form [42-47] or by adding phosphorus(V) oxide to pure orthophosphoric acid [16].

3. CHEMISTRY AND TECHNOLOGY OF DEHYDRATED AMMONIUM PHOSPHATES

The first papers on the chemistry of the salts of the above polyphosphoric acids appeared more than one hundred years ago. Graham [48], Fleitmann and Henneberg [49], Tammann [50], and a number of other workers developed methods of preparation and described a number of properties of polymeric phosphates of sodium and to a smaller extent potassium. Since inorganic chemical theory at that time was not well developed and sufficiently reliable analytical and physicochemical methods of study were not available, the authors cited made a number of errors in the nomenclature of the condensed phosphates, and this acted as a source of confusion and incorrect ideas regarding the structures of some of these compounds.

A systematic detailed study of the methods of preparation, properties, and structures of various oxygen compounds of phosphorus was undertaken about the middle of the twentieth century. Important work on the structural chemistry of the dehydrated phosphates and their classification and systematisation has been carried out by van Wazer, Thilo, Britske, and Khodakov and coworkers.

The large amount of physicochemical data obtained in the study of dehydrated phosphates, and a number of theoretical generalisations, have led these authors to the conclusion that there exist homologous series of phosphates, from the monomers to the higher members of the series, formed by the sharing of oxygen atoms between the structural units, each of which consists of a tetrahedral group of four oxygen atoms around a central phosphorus atom. Several different structural types can be distinguished in the polymeric phosphates, depending on the way in which the individual PO_4 tetrahedra are joined by the oxygen atoms shared by neighbouring tetrahedra, that is depending on the number of oxygen atoms corresponding to each PO_4 tetrahedron.

Polyphosphates —a homologous series of salts, the anions of which consist of PO_4 tetrahedra joined to one another by oxygen atoms in continuous chains of different length.

Metaphosphates $(MPO_3)_n$ are phosphates with anions having a ring structure.

Branched or network phosphates are compounds containing a greater or smaller number of "quaternary" phosphorus atoms, joined to other phosphorus atoms through three oxygen atoms. Van Wazer considers that there are several forms of structural block (point of branching, central and terminal groups) from which all these types of dehydrated phosphate can be constructed by different relative arrangements. By combining all these structural blocks in the most varied ways, it is possible to obtain a wide variety of hypothetical formulae for the condensed phosphates. The total number of structures formed in this way, however, does not always agree with the number actually existing, since the possibility of existence of a given structure is determined by steric factors (the strain in the P–O–P bonds, the size of the valency angles, etc.).

On the basis of a calculation of the total number of bonds in a given phosphate, van Wazer [51] proposed a method for calculating the formulae of phosphates of different structural types, according to which chain phosphates can be described by the formulae $M_{n+2}P_nO_{3n+1}$ and $M_nH_2P_nO_{3n+1}$, where n is the degree of condensation. Ring phosphates have the formula $M_nP_nO_{3n}$. As $n \to \infty$, the general formula of the chain polyphosphates $M_{n+2}P_nO_{3n+1}$ approaches that corresponding to the metaphosphate composition $(MPO_3)_n$, so that the last formula is the limiting formula for both chain and ring phosphates. Thus the term "metaphosphate", covering a wide range of polymeric phosphates with the composition $(MPO_3)_n$ with both chain and cyclic structures, still appears in the literature.

Despite the fact that various physicochemical methods for the study of polymeric compounds are now known and widely employed (paper chromatography, infrared spectroscopy, X-ray diffraction), the determination of the structures and molecular weights of various condensed phosphates presents considerable difficulty.

Nuclear magnetic resonance (NMR) has proved extremely effective for the qualitative determination of the compositions of mixtures of various phosphates and the investigation of their structures. The use of this method became possible because the resonance peaks in the NMR spectra of phosphates result from the presence, in the phosphate anions, of the so-called central and terminal groups, the concept of which was introduced by van Wazer. It has been established that a central group in a chain is equivalent to a central group in a ring, and also that terminal groups exhibit identical bond characteristics, irrespective of the chain length [52-54].

The NMR spectra of the anions of chain phosphates, given in Fig. 3, show clearly the change in the character of the spectrum with change in the ratio of terminal and central groups in the anion. Thus the spectrum of the pyrophosphate reflects the presence of only terminal

groups, whereas the spectrum of tripolyphosphate reveals a central group in addition. It can readily be seen that in the spectrum of the tripolyphosphate the peak of the terminal group is split to form a doublet, and the peak of the central group is a triplet. This is not accidental, but is related to the nature of the bonds in the terminal and central groups in the tripolyphosphate: each terminal group is joined to one central group, and each central PO_4 group to two terminal groups.

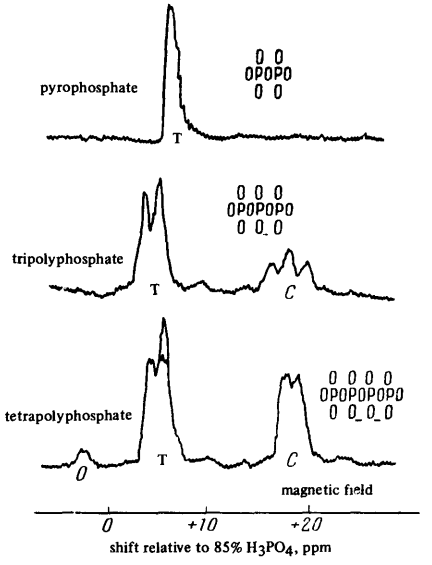

Figure 3. NMR spectra of polyphosphate anions; T—peaks due to terminal groups; C—peaks due to central groups; O—peaks due to orthophosphate.

The NMR spectrum of the tetrapolyphosphate anion in a solution of crystalline ammonium tetrapolyphosphate reflects the presence of terminal and central groups; the peaks reflecting these groups are split to form doublets, proving that this anion has a linear structure.

A characteristic feature is that the ratio of terminal to central groups can be estimated by comparing the areas under the corresponding peaks (2 : 1 for the tripolyphosphate and 2 : 2 for the tetrapolyphosphate).

All the NMR spectra of different metaphosphate specimens showed the presence of exclusively central groups, proving conclusively the original structure of the metaphosphate anions.

Unfortunately, the NMR method has not yet been sufficiently fully developed for the quantitative analytical determination of mixtures of phosphates.

The existence of "inorganic rings" with six members (trimetaphosphates) and eight members (tetrametaphosphates) has suggested the possible production of different steric configurations in these compounds, analogous to that observed in the chemistry of organic cyclic compounds (cyclohexane, decalin, etc.).

The most detailed studies from the viewpoint of stereochemistry have been made for only two ammonium salts, the trimetaphosphate $(NH_4)_3P_3O_9$ and the tetrametaphosphate $(NH_4)_4P_2O_{12}$, which are comparatively stable in aqueous solution and do not undergo immediate hydrolysis. It has been found that the molecules of these compounds can in fact exist in two different geometric configurations: the boat form (a) and the chair form (b) (Fig. 4).

Figure 4. Configuration of the molecules of ammonium tri- and tetrametaphosphates: *a*) boat form; *b*) chair form.

As a consequence of the difference in various physical and chemical properties of these geometric isomers, it is comparatively easy, by fractional crystallisation or paper chromatography, to separate their mixtures and identify each of the forms for more detailed study. Thus Romers and coworkers[55] made an X-ray diffraction study of one of the isolated isomers of ammonium tetrametaphosphate, with the chair conformation. They were able to establish the presence of regular PO_4 tetrahedra in the metaphosphate anions; the phosphorus atoms are not situated at the centres but are displaced away from the oxygen atoms common to two tetrahedra. The authors cited attributed this to the influence of hydrogen bonds between the unshared oxygen atoms of the PO_4 groups and the nitrogen atoms of the ammonium ions. This explanation has been disputed by van Wazer, since the displacement of the phosphorus atoms may be due to the presence of negative charges on the unshared oxygen atoms as a consequence of the ionisation of the phosphate anion.

This is only one of many examples indicating that many problems of the stereochemistry of condensed phosphates are still unsolved (methods for proving spatial configurations, and their separation), and for various extremely interesting problems, such as the presence of a conformation or the interconversion of rings etc., there is almost no published information.

The possibility of extensive and varied applications of polymeric phosphates in the national economy has drawn the attention of research workers to not only the chemistry but also the technology of these compounds. Attempts have been made to find simpler and more rational methods for their preparation. Phosphates with polymeric compositions were first prepared not by neutralising the corresponding polyphosphoric acids but by the thermal dehydration of acid salts of orthophosphoric acid:

$$n\,MH_2PO_4 \rightarrow (n-1)\,H_2O + M_nH_2P_nO_{3n+1},$$

and for this reason they have been called dehydrated phosphates.

This comparatively simple method has found extensive application for the preparation of polyphosphates of sodium, potassium, lithium, and other elements, namely those for which the acid orthophosphates do not undergo any changes other than removal of water of constitution in the temperature range of dehydration. These compounds have been studied in most detail. (The results of studies published up to 1956 have been reviewed by van Wazer in the first volume of the monograph "Phosphorus and its Compounds".)

There is very little information on the ammonium salts of polyphosphoric acids. This is apparently due to the fact that the method of thermal dehydration, widely employed in practice for the preparation of poly- and metaphosphates, cannot be used for the ammonium salts, since with increase in temperature, ammonium hydrogen orthophosphates decompose with the liberation of ammonia before dehydration takes place.

In 1955, Thilo and Grunze[56] investigated the thermal dissociation of monoammonium phosphate in order to study the reaction products with maximal degree of dehydration. They showed that the decomposition of monoammonium phosphate on heating takes place in stages according to the reactions

$$NH_4H_2PO_4 \xrightarrow[\text{up to } 140^\circ]{-NH_3} NH_4H_2PO_4 + H_3PO_4 + NH_3$$

$$NH_4H_2PO_4 \xrightarrow[140-190^\circ]{-NH_3;\ -H_2O} (NH_4)_n H_2P_nO_{3n+1};\ (NH_4, H)_{n+2}P_nO_{3n+1}$$

$$(NH_4)_n H_2P_nO_{3n+1} \xrightarrow{} H_{n+2}P_nO_{3n+1}$$

$$(NH_4)_n H_2P_nO_{3n+1} \xrightarrow[200-300^\circ]{} (NH_4PO_3)_n$$

$$(NH_4PO_3)_n \xrightarrow[300^\circ]{-NH_3} (HPO_3)_n$$

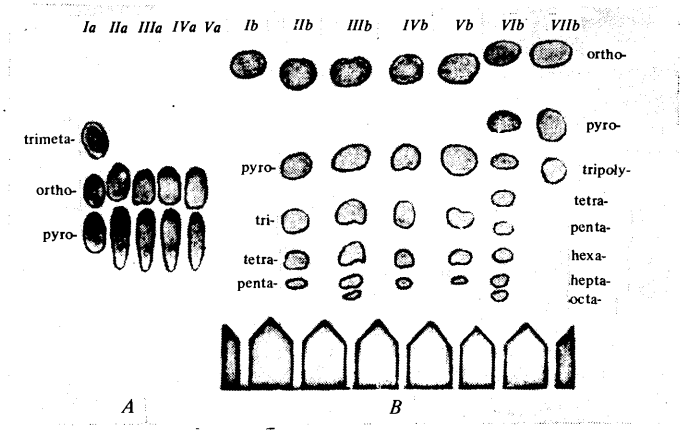

Figure 5. Paper chromatogram for the products of the dehydration of $NH_4H_2PO_4$ (*A*—chromatography in ammoniacal solution; *B*—chromatography in acid solution); *Ia*) mixture of standards (trimeta-, ortho-, and pyrophosphates), *Ib*) $NH_4H_2PO_4$ after heating for 24 h at 140°, *II*–*VII a* and *b*) products of the dehydration of $NH_4H_2PO_4$ at 150, 160, 170, 200, 230, and 250° (for 24 h).

From this it follows that the dehydration of monoammonium phosphate, which begins at ~ 140°, is accompanied by the liberation of ammonia. Using paper chromatography to analyse the dehydration products, Thilo and Grunze established that in the range 140–190° a mixture of oligophosphates with the composition $(NH_4)_nH_2P_nO_{3n+1}$, with degree of condensation n in the range 1–5, is formed. On further heating, the greater part of the mixture is converted, with loss of ammonia, into polyphosphoric acids with higher molecular weight, and a very small fraction is converted into a water-insoluble macromolecular crystalline ammonium polyphosphate (Fig. 5). Above 300°, this salt also is unstable, and decomposes with the liberation of ammonia to form polyphosphoric acid.

Analogous phenomena were observed by Japanese workers in a study of the possibility of preparing ammonium polyphosphates by the thermal degradation of acid ammonium salts of orthophosphoric acid. Unlike Thilo, Kobayashi[57] was able, not merely qualitatively, to characterise the dehydration of monoammonium phosphate at various temperatures from 175° to 300° ± 5° with heating for different periods of time (maximal duration of dehydration 25 h). Data on the ratios of pyro- and tripolyphosphates and phosphates with higher molecular weight, and also on the quantity of undehydrated orthophosphate, were obtained by ion exchange chromatography on Dowex-1-X8 resin (KCl solutions with different concentrations were used as eluant). It was established that even at 300°, dehydration is not complete, and the final product contains from 15% to 5% P_2O_5 in the ortho-form, relative to its total concentration, depending on the duration of heating. Increase in the duration of heating at any temperature leads to more complete dehydration, but the relationships for the formation of pyro- and tripolyphosphates and other dehydrated forms of phosphate are different. At 175, 200, and 225°, a general tendency for the dehydrated forms of the phosphates to increase with increase in the duration of dehydration is observed, whereas at higher temperatures (260 and 300°), at definite stages of the dehydration, the quantity of pyro- and tripolyphosphates formed reaches a maximum and then gradually decreases, with a corresponding increase in the quantity of polyphosphates with higher molecular weight.

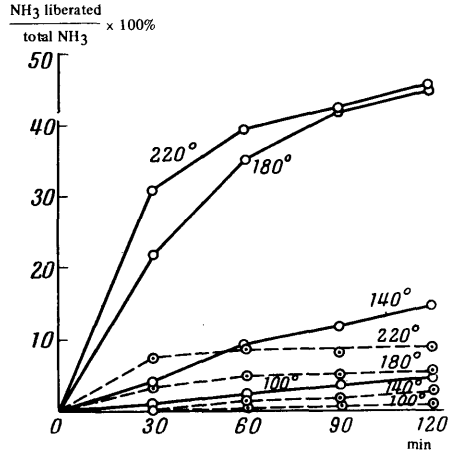

Figure 6. Dependence of the liberation of ammonia on the time for which diammonium phosphate and ammonium polyphosphate are heated at various temperatures: continuous lines—diammonium phosphate; broken line—polyphosphate.

The chemical compositions of the products show that in fact the dehydration of monoammonium orthophosphates is accompanied by appreciable loss of ammonia; the concentration of ammonia gradually decreases from 16% at 175° to 11% at 300° (heating for 25). The formation of acidic ammonium polyphosphates ($NH_4 < H$) is also confirmed by the fact that solutions of the specimens studied had an acidic reaction (pH 2.5–4.0).

It should be noted that the ammonium polyphosphates themselves decompose with the liberation of ammonia with much greater difficulty than the original salts of orthophosphoric acid[58]. This is clearly confirmed by data obtained in a study of thermal dissociation up to 220° over a period of 2 h for diammonium phosphate and ammonium polyphosphate with an average degree of condensation n = 7–8 (Fig. 6). Above 140°, diammonium hydrogen phosphate is converted into a mixture containing varying quantities of diammonium pyrophosphate and triammonium tripolyphosphate[59].

To obtain ammonium phosphates with the maximal degree of dehydration, corresponding to the chemical composition $(NH_4PO_3)_n$, Vol'fkovich and Kubasova[60] proposed a method for the thermal dehydration of ammonium hydrogen orthophosphates under a pressure of gaseous ammonia.

The use of gaseous ammonia in the dehydration made it possible to find conditions in which the pressure of ammonia vapour during the decomposition is balanced by the ammonia pressure created above the original salt, and the dehydration proceeds without the loss of ammonia (at an approximately constant molar ratio NH_3/P_2O_5), with a continuously increasing degree of dehydration, that is with a decrease in the molar ratio H_2O/P_2O_5 in the dehydration products. The greater part of the water of constitution is removed from monoammonium orthophosphate in the range 275–325°, after which the rate of dehydration decreases; the composition of the products approaches that of macromolecular polyphosphates of the type $(NH_4PO_3)_n$.

Unfortunately, the production of ammonium polyphosphates by thermal dehydration must at present be regarded as a preparative method, since all the experiments were carried out in laboratory apparatus by batch methods. The pilot-plant or industrial introduction of this method of preparation requires the development of equipment which would make possible a continuous process.

Recently, Kobayashi[61] described a study of the kinetics of formation of condensed ammonium phosphates in a continuous process involving the reaction of thermal phosphoric acid with ammonia. The experimental assembly is illustrated in Fig. 7. The starting materials (phosphoric acid and ammonia) were introduced into the first reaction vessel, which was heated by external and internal heaters to 230° or 250°, after which phosphoric acid, previously heated to 100° by heat exchange with steam leaving the reaction vessel, was introduced into the reaction vessel. Contact between the phosphoric acid and the liquid in the reaction vessel led to intensive volatilisation with the removal of a large proportion of the water, leaving a salt melt in the reaction vessel. With mixing (rate of stirring 200 rev min^{-1}) the phosphoric acid reacts with ammonia (simultaneous ammonium salt formation and dehydration), as a result of which the level of liquid in the reaction vessel increases and the product is removed continuously from the reaction vessel through an outlet.

For $(NH_4)H_2PO_4$ heated in a batch process, the rates of formation of the individual salts (r_2 for pyrophosphate, r_3 for tripolyphosphate, and r_m for the average polyphosphate) were calculated by substituting the apparent rates of formation in the reaction rate equation derived on the basis of the known mechanism of complex formation. The following values were obtained for the range 230–250°: $r_2 = 2 \times 10^{-2} - 1 \times 10^{-3}$ mole min^{-1}, $r_3 = 5 \times 10^{-3}$ mole min^{-1}, and $r_m = 1 \times 10^{-3} - 1 \times 10^{-4}$ mole min^{-1}.

The rates of the reaction between phosphoric acid and ammonia were determined from the kinetic equation applicable to continuous processes in bulk apparatus. In these experiments it was established that the concentration of condensed phosphates in the final product decreases with increase in the input of starting materials. The reaction rate increases, however. Thus for example at a reaction temperature of 250°, increase in the input of phosphoric acid by increasing the concentration from 30% to 50% (calculated as P_2O_5) increases the reaction rate from 0.385 kg h^{-1} $litre^{-1}$ to 0.651 kg h^{-1} $litre^{-1}$.

The products contained 10–12% nitrogen and 62–67% P_2O_5 and had an acidic reaction. For this reason, the treatment with ammonia was repeated. The condensed phosphates obtained in this way contained 13–15% nitrogen and 65% P_2O_5. The degree of conversion of $(NH_4)H_2PO_4$ into $(NH_4 + H)_{n+2}P_nO_{3n+1}$ (where n = 2–10) was 60–80%.

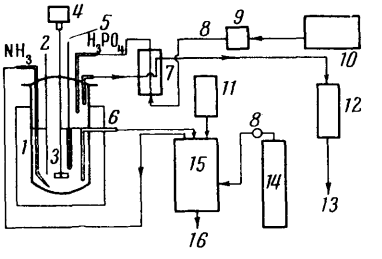

Figure 7. Diagram of the laboratory apparatus for the preparation of condensed ammonium phosphates[61]: *1*) external heater; *2*) thermistor; *3*) first reaction vessel; *4*) motor with stirrer; *5*) heating element; *6*) removal of product; *7*) heat exchanger; *8*) flow meter; *9*) pump; *10*) phosphoric acid tank; *11*) vessel for added salts; *12*) cooler; *13*) water; *14*) ammonia cylinder; *15*) second reaction vessel for repeated treatment with ammonia; *16*) final product.

The experiments showed that the ammonium polyphosphate obtained can be mixed with a number of salts containing various nutrient elements, for example with potassium chloride during the repetition of the treatment with ammonia, and this is of interest for the preparation of complex fertilisers.

Various dehydrated ammonium phosphates can also be prepared by ion exchange from solutions of the polymeric phosphates of other cations, followed by treatment of the polyphosphoric acid solutions with ammonia and precipitation of the crystalline salts with ethanol or acetone[62,63].

A number of papers describing the properties of condensed ammonium phosphates, prepared by ion exchange, have been published[64,65]. Unfortunately, some contain inaccurate data, since they describe not the pure salts but their mixtures. Ammonium pyro- and tripolyphosphates have been most fully characterised in a review by Frazier[66], who described the methods of preparation and the crystallographic properties of six pyrophosphates: $(NH_4)_2H_2P_2O_7$ (monoclinic and orthorhombic), $(NH_4)_3HP_2O_7$, $(NH_4)_3HP_2O_7.H_2O$, $(NH_4)_4P_2O_7$, $(NH_4)_4P_2O_7.H_2O$, and six tripolyphosphates: $(NH_4)_3H_2P_3O_{10}$, $(NH_4)_3H_2P_3O_{10}.H_2O$, $(NH_4)_4HP_3O_{10}$, $(NH_4)_9H(P_3O_{10})_2.2H_2O$, $(NH_4)_5P_3O_{10}.H_2O$, and $(NH_4)_5P_3O_{10}.2H_2O$. All these salts were prepared from recrystallised reagents or obtained as solid phases in the

determination of solubility according to Farr and Fleming[67] in the $NH_3-H_4P_2O_7-H_2O$ and $NH_3-H_5P_3O_{10}-H_2O$ systems. To obtain reliable results, the authors cited prepared the original condensed ammonium phosphates by three methods. The passage of solutions of $Na_4P_2O_7$ or $Na_5P_3O_{10}$ through Amberlite IR-120 resin which had been treated with acid gave solutions of the corresponding acids, which were immediately treated with ammonia and evaporated in a vacuum. To prevent hydrolysis, all these operations were carried out below 10°.

Ammonium tripolyphosphates were prepared by fractional crystallisation of the products obtained by treating thermal superphosphoric acid (79–82% P_2O_5) with ammonia. $(NH_4)_5P_3O_{10}\cdot H_2O$ was purified by recrystallising eight times. Other tripolyphosphates were obtained by lowering the pH of solutions of this salt with Amberlite IR-120 resin and then treating the eluate with ethanol. The salt frequently separated in the form of an oily liquid; a seed crystal was added to bring about crystallisation.

Ammonium pyrophosphate $(NH_4)_4P_2O_7$ was prepared by treating aqueous solutions or suspensions of calcium ammonium pyrophosphates with ammonium fluoride. This salt was recrystallised and used for the preparation of more acidic ammonium pyrophosphates.

A recently published paper by French workers[68] on the isolation of a new ammonium salt with mixed orthophosphate and pyrophosphate anions $(NH_4)_2H_5(PO_4,P_2O_7)$, with melting point 93° ± 1°, is of interest. According to the authors cited, this acidic ammonium phosphate is a new compound and should not be regarded as an intermediate product of the thermal dehydration of the orthophosphate with formation of the pyrophosphate.

Frazier[66], and later other workers[69], paid particular attention to the problems of the stability of ammonium pyro- and tripolyphosphates; this is of direct interest in the study of the possibility of using condensed ammonium phosphates as highly concentrated liquid and solid nitrogen-phosphorus fertilisers. Thus it has been established that tetrasubstituted ammonium pyrophosphate, unlike the analogous potassium and lithium salts, does not condense in the presence of acetic anhydride at room temperature, but at higher temperatures it forms a mixture of linear phosphates[70]. The solubility of ammonium pyro- and tripolyphosphates and the phase changes in the $NH_3-H_4P_2O_7-H_2O$ and $NH_3-H_5P_3O_{10}-H_2O$ systems were studied by Farr and coworkers[71].

Ion exchange has been used to isolate not only ammonium polyphosphates with a chain structure, but also ammonium salts with the metaphosphate composition containing phosphate ions with ring structures—ammonium trimeta- and tetrametaphosphates; this is attributed to the stability of trimeta- and tetrametaphosphoric acids in aqueous solutions. It has been established[73] that ammonium trimetaphosphate is stable as far as 100°, but on further heating at 120–180° it undergoes hydrolysis, absorbing moisture from the atmosphere, and is converted into a mixture of acidic "oligophosphates" with the composition $(NH_4)_nH_2P_nO_{3n+1}$. Above 180° these compounds also decompose with the liberation of ammonia, with the formation of polyphosphoric acids containing traces of macromolecular ammonium polyphosphate.

Chromatographic analysis (Fig. 8) showed that the thermal dissociation of ammonium tetrametaphosphate takes place analogously only if the salt is heated gradually over a prolonged time interval. If the heating is rapid, over a period of 2–3 h, a macromolecular crystalline ammonium polyphosphate containing an anion with a chain structure is formed.

The properties of crystalline ammonium polyphosphate with the composition $(NH_4)_{n+2}P_nO_{3n+1}$, where n ~ 50 or more, have been described[66]. This salt was prepared from the product obtained by treating superphosphoric acid (83–84% P_2O_5) with ammonia, by crystallisation as the transparent ammonium polyphosphate gel dissolved. The crystals, when washed with acetone and dried in air, are stable at room temperature and remain crystallographically unchanged when heated at 105° for 48 h. This polyphosphate does not show a great similarity to Madrell's or Kurrol's salts as far as optical properties are concerned. Its infrared spectrum is similar to that of Kurrol's salt and is quite unlike that of metaphosphates containing phosphate anions with a cyclic structure.

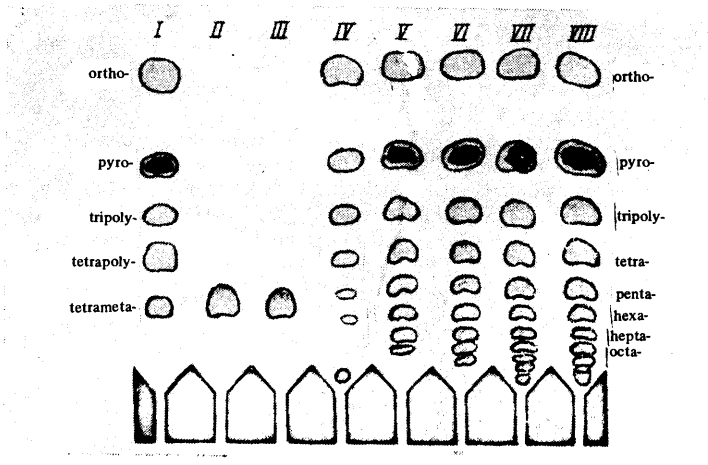

Figure 8. Paper chromatogram for the products obtained by heating ammonium tetrametaphosphate. Bands: *I*) standards (ortho-, pyro-, tripoly-, tetrapoly-, and tetrametaphosphates); *II*) $(NH_4)_4P_4O_{12}$; *III – VIII*) products obtained by heating $(NH_4)_4P_4O_{12}$ for 24 h at 100, 150, 200, 250, and 280°.

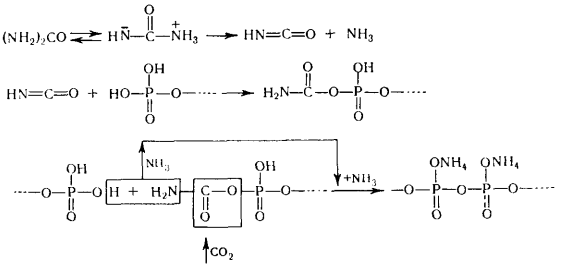
In recent years a number of papers reflecting the search for new methods for the preparation of ammonium polyphosphates from various phosphoric acids, including the use of urea as nitrogen-containing reagent, have been published. Phosphoric acids react with urea in solution and in the melt to give complex compounds—urea phosphates $(NH_2)_2CO.H_3PO_4$.[74–76] Japanese workers have established that reaction between phosphoric acid and urea begins at temperatures close to the decomposition temperature of urea with the formation of ammonium polyphosphate[77–79]. The authors cited paid particular attention to the influence of temperature, the concentration of the original phosphoric acids, and the quantitative component ratios, on the composition and properties of the compounds obtained. As original phosphoric acids they chose liquid polyphosphoric acids, containing 71.2–87.8% P_2O_5. The quantities of urea taken for the reaction were calculated from the given ratios $(NH_2)_2CO:P_2O_5$, equal to 1–4. It was found that the reaction of the polyphosphoric acids with urea in the ratio $P_2O_5:(NH_2)_2CO = 1:2$ even at 80° gives a sufficiently high yield of ammonium polyphosphates, although part of the urea remains unreacted (up to 14.6%

with acid containing 71.2% P_2O_5 and about 4% with acid containing 87.8% P_2O_5).

The reaction proceeds to the greatest extent at 140° – 160°. The isocyanuric acid liberated, in the opinion of the authors cited, indicates that the following reaction mechanism is most probable:



The small quantities of isocyanuric acid present can be readily removed by filtration, and the ammonium polyphosphate formed is removed from the solution by adding ethanol. The results in Table 2 show that the quantity of unreacted urea and isocyanuric acid liberated depends chiefly on the quantitative original component ratios.

Table 2. Compositions and qualitative ratios of the products of the reaction of polyphosphoric acids and urea at 140°.

Basic data on the reaction	Concn. of P_2O_5 in the original polyphosphoric acid, wt.%

The condensation mechanism of formation of ammonium polyphosphates has been proved by infrared spectroscopy [80,81]. All the polyphosphates obtained in this way contained anions with a chain structure. The average length of the chains in the anions was determined by potentiometric titration of the weakly acidic terminal OH groups. The quantitative ratio of phosphate anions with different degrees of condensation was established chromatographically. Phosphoric acid (61–69% P_2O_5) gave ammonium polyphosphates with a relatively short chain, and polyphosphoric acid (80–88% P_2O_5) gave compounds with a much longer chain.

The formation of condensed phosphates when monoammonium phosphate and urea are heated together (110–120°) was established by Vol'fkovich and coworkers [82], who made a physicochemical study of the production of nitrogen–phosphorus fertilisers from polyphosphoric acids and and intermediate product of the preparation of urea.

Industrial methods for the preparation of ammonium polyphosphates are based on the treatment with ammonia, a reaction which has been well studied for orthophosphoric acid. To increase the extent of the reaction of ammonia with the polyphosphoric acids, many authors have proposed that the process be carried out, as in Soviet work, under a pressure of gaseous ammonia [83-87]. Thus Getsinger and coworkers studied the reaction of ammonia with polyphosphoric acid containing 76% P_2O_5, under an ammonia pressure of 0.7–21 atm at 170–230°.

The neutralisation was carried out in a stainless steel reaction vessel with turbine stirrer. The reaction is very exothermic, so that to prevent decomposition of the final products, some of the heat of the reaction was removed by circulating water. The ammonium polyphosphates were obtained in the molten state. To improve the physical properties and in particular to decrease the hygroscopic character of the polyphosphates, the melt was granulated. Analysis of the final products showed that they consist of a mixture of ammonium polyphosphates with different degrees of dehydration, the chief components being monoammonium orthophosphate and the neutral and acidic ammonium pyrophosphates $(NH_4)_4P_2O_7$ and $(NH_4)_3HP_2O_7.H_2O$. The composition of the products varied from 16-61-0† to 18-69-0, depending on the conditions of treatment with ammonia (temperature, pressure, and duration of interaction of the reagents).

To develop technological conditions for the production of ammonium polyphosphates, experiments were carried out on a pilot-plant assembly with thermal phosphoric acid (77% P_2O_5) and highly concentrated extraction phosphoric acid (72% P_2O_5). [88] The treatment of the phosphoric acids with gaseous ammonia was carried out in an autoclave similar to that described earlier, at an automatically controlled pressure of 1.75–2.5 atm. The ammonium polyphosphate melt removed from the reaction vessel at 190° was passed to a horizontal two-roller mixer-granulator, in which it was simultaneously cooled to 60–100°, depending on the concentration of phosphoric acid used. The final solid product contained 14–15% N and 59–61% P_2O_5 (total), of which 40–50% P_2O_5 was in the dehydrated form.

According to a patent of Hignett and Getsinger [89], ammonium polyphosphates are obtained in the form of a solidified melt from gaseous ammonia and polyphosphoric acid (74–85% P_2O_5) or concentrated extraction acid (65–75% P_2O_5) at a pressure of 0.7–7 atm and 173–196°. The product was a mixture $(NH_4 + H)_{n+2}P_nO_{3n+1}$, with n = 2–10, containing 16% N and 61% P_2O_5.

In recent years, laboratory experiments have been carried out in the USSR, in the Samoilov Fertiliser Research Institute, on the preparation of solid ammonium polyphosphate by the treatment of polyphosphoric acids with ammonia without pressure, and it has been shown that it is possible in principle to obtain a product with good physical properties [90].

The TVA has developed on the laboratory scale a two-stage process [91] for the preparation of ammonium polyphosphate from extraction phosphoric acid (containing 55% P_2O_5) by neutralisation at an elevated temperature (121–155°). To prevent solidification of the ammonium polyphosphate melt, the temperature in the second neutralisation vessel was kept at an even higher level (~ 246°). The melt, containing ~ 50% phosphate in the polyphosphate form, was transferred to a screw granulator together with the recycle. The final product contained 11–12% N and 63–59% P_2O_5.

The direct reaction of phosphorus(V) oxide with ammonia might be of interest for the preparation of ammonium phosphates with the maximal degree of dehydration.

† Conventional symbols for the composition of the fertilisers: 16% N; 61% P_2O_5; and 0% K_2O.

This reaction has been known for a long time and has been studied by many workers[92-96]. It has been established that, irrespective of the conditions of the reaction, the production of (P–O–P) bonds and the production of (P–NH–P) bonds in the final products are equally probable, and this leads to the formation of a mixture of nitrogen-phosphorus compounds with different compositions, such as: diamidopyrophosphoric acid $P_2O_3(NH_2)_2(OH)_2$, diammonium monoamidophosphate $P_2O_3(ONH_4)_2(NH_2)(OH)$, or the ammonium salt of a polyphosphoric acid in which the phosphorus atoms are joined not only through oxygen atoms but also through imido-groups (NH).

Thus ammonium poly- or metaphosphates have not yet been obtained in the $P_2O_5-NH_3$ system. The formation of dehydrated ammonium phosphates of this kind should be expected in the $NH_3-P_2O_5-H_2O$ system.

A thermodynamic calculation by Britske and Dunaev[92] confirmed the possibility of obtaining ammonium poly- and metaphosphates in acceptable yield by the gaseous-phase reaction of phosphorus(V) oxide, ammonia, and water vapour; the formation of phosphates containing imido- and amido-groups is not excluded. The characteristics and composition of the products obtained in this ternary system depend not only on the $NH_3 : P_2O_5 : H_2O$ ratio, temperature, and duration of the interaction between the components, but also on a number of other factors, including the order in which the components are introduced.

A continuous process for the preparation of dehydrated ammonium phosphates in stages, carried out on a pilot-plant assembly by Stinson and coworkers[97], is apparently of technological interest. Phosphorus is burned in a stainless steel vessel at 370–405°. The phosphorus(V) oxide vapour produced is directed by means of a stream of dry air to a reaction vessel in which the first stage—the reaction of the phosphorus(V) oxide with gaseous ammonia—is carried out at 400–540°. Change in the temperature of the reaction within the range indicated, and the quantity of air used, had no influence on the properties of the intermediate products. These consisted of a mixture of various amido- or imido-derivatives of phosphoric acids with different degrees of dehydration. To obtain the final product with the metaphosphate composition, the second stage was carried out; this involved the treatment of the resulting mixture of intermediate products with steam in a rotating drum. This high-temperature hydrolysis leads finally to the formation of a product exhibiting good physical properties, in that it is relatively non-hygroscopic and is readily granulated. 70–75% of this product consisted of macromolecular ammonium polyphosphate $(NH_4PO_3)_n$ containing 16–19% nitrogen and 74–79% phosphorus(V) oxide. The remaining fraction of the product consisted of complex nitrogen-phosphorus compounds, the nature of which was not studied. From the equations for the reactions which may take place in the process, however:

$$P_4O_{10} + 4NH_3 = 2PN(OH)_2 + 2H_2O$$
$$PN(OH)_2 + H_2O = NH_4PO_3$$
$$PN(OH)_2 + NH_3 = PN(OH)ONH_4$$

the authors cited conclude that 10–15% consisted of $PN(OH)ONH_4$ and 10–20% of $PN(OH)_2$. Vol'fkovich and coworkers[98,99] in the Scientific Research Institute for Fertilisers and Insectofungicides and Moscow State University carried out laboratory studies on the preparation of phosphamic compounds from P_2O_5 and NH_3 in order to produce fertilisers not bound by soils.

Japanese workers[100-103] have also studied nitrogen-phosphorus compounds formed in the $P_4O_{10}-NH_3$ and $P_4O_{10}-NH_3-H_2O$ systems. They established that equilibrium mixtures of low-molecular forms of ammonium polyphosphates $(NH_4 + H)_{n+2}P_nO_{3n+1}$ are obtained by the reaction of phosphorus(V) oxide with ammonia (or ammonium orthophosphate) in the presence of a small calculated quantity of water at comparatively low temperatures, up to 150–180°. Increase in temperature and the pressure of ammonia in the reaction vessel leads to the formation of condensed vitreous phosphates. Thus at 300–450° and an ammonia pressure of ~ 30 atm the composition of the reaction products is close to the metaphosphate composition: 16–18% NH_3 and 62–67% P_2O_5.

The authors cited confirmed that ammonium polyphosphates containing imido-groups are obtained when insufficient water vapour is present in the system. In this instance, increase in temperature leads to the production of vitreous forms of dehydrated phosphates, in which only 70–75% of the total nitrogen is present in the ammonium form, the remaining fraction being present as amido- or imido-groups.

The ammonium polyphosphates obtained by various methods are at present used not only as solid but also as liquid nitrogen-phosphorus fertilisers[36]. Dissolution of ammonium polyphosphate in water gives a liquid fertiliser with the composition 10-34-0, which is the same as that obtained by treating superphosphoric acid with ammonia. Thermal orthophosphoric acid, however, gives liquid nitrogen-phosphorus fertilisers with a lower concentration of nutrients (8-24-0).[104] According to Young[105], liquid fertilisers are obtained by dissolving ammonium polyphosphates in water or aqueous ammonia.

Since superphosphoric acid containing 76% P_2O_5 is a comparatively expensive product and is produced in insufficient quantities, it was proposed that liquid nitrogen-phosphorus fertilisers be produced from a mixture of acids: extraction phosphoric acid and a superphosphoric acid solution which had been treated with ammonia[106]. Moreover, the addition of polyphosphoric acid to orthophosphoric acid prevents the precipitation of impurities which usually separate when the latter is treated with ammonia. The introduction of potassium-containing components into the liquid nitrogen-phosphorus fertilisers makes it possible to obtain complex NPK-fertilisers with varied compositions[107,108].

Determination of the solubility of various dehydrated forms of ammonium phosphates has confirmed that it is possible to obtain ammonium polyphosphates in a form which is insoluble in water but soluble in ammonium citrate and citric acid solutions; this is of interest for the preparation of concentrated nitrogen-phosphorus fertilisers with different solubilities and mobilities in soil[109,110]. It was noted that structural factors play a part in the change in the solubility of the polyphosphates. Macromolecular crystalline polyphosphates were almost insoluble in water, whereas the amorphous compounds dissolved extensively and fairly rapidly in water. It was established that in the production of a given polyphosphate structure, a particularly important role is played by such factors as the stabilisation of various crystal lattices, the rearrangement of molecules, etc.[111] Sufficiently detailed theoretical studies of this problem have not yet been made, however, and the accumulated experimental data on the influence of various factors on the production of nitrogen-phosphorus polymeric compounds with a given solubility are not used in technology.

Practical disadvantages of most dehydrated ammonium phosphates as fertilisers are that the molar ratio of nitrogen to phosphorus does not correspond to the requirements of a large number of soils and agricultural crops, and also the hygroscopic nature of many of these salts. Many workers have therefore proposed that they be used in mixed

and liquid fertilisers. A number of proposals have been aimed at improving the physical properties by granulation and the introduction of conditioning additives.

The rapid development of sources of electrical energy, the increase in natural gas and petroleum resources, and the considerable progress in the field of high-temperature reactions, particularly electrothermal reactions, reactions in cyclones and plasma, etc., are enabling research workers to introduce new and more rational schemes for the production of highly concentrated phosphoric acid and macromolecular condensed phosphates[112,113]. In turn, the industrial development of thermal reactions for processing phosphates and preparing polymeric phosphates requires detailed physicochemical studies using the latest instrumental methods of analysis in order to elucidate the chemistry of the process and to determine the optimal conditions for carrying it out.

In conclusion, we may express the hope that the chemistry of polyphosphoric acids and dehydrated ammonium phosphates will attract the attention of a wider circle of research chemists, and that the results of their work will find varied application in various branches of the national economy, particularly in the field of concentrated and complex fertilisers.

Three-component Complex Organometallic Catalysts

V.P.Mardykin, A.M.Antipova, and P.N.Gaponik

The review deals with the literature and patent publications on the polymerisation of olefinic hydrocarbons and some of their derivatives. The mechanism of the action and the specificity of catalytic systems containing mainly ethers and amines are discussed. A small section dealing with systems based on the ether complexes of aluminium alkyls is included. The bibliography includes 236 references.

CONTENTS

1. Introduction 13
2. Polymerisation of α-olefins 13
3. Polymerisation of diene hydrocarbons 16
4. Polymerisation and copolymerisation of other monomers 18
5. Catalytic systems based on the ether complexes of organoaluminium compounds 18

I. INTRODUCTION

Catalytic systems based on organometallic compounds (and among them the Ziegler–Natta catalysts) have found wide application in the polymerisation of olefinic and diene hydrocarbons. Together with a high activity, these catalysts in many cases exhibit the so called stereospecificity, i.e. polymers with a definite microstructure (isotactic, syndiotactic, and *cis*- and *trans*-isomeric structures) are obtained in their presence. In order to enhance the specificity of the action of Ziegler–Natta catalysts, i.e. in order to increase the yield of structures which have the most valuable physical and mechanical properties in practice, a number of three-component catalysts have been proposed.

By introducing a third component, the molecular weight of the polymer is regulated and one attains increased rates of polymerisation and an improvement in heat exchange, the sticking of the polymer to the reactor walls, the shaft, and the blades of the stirrer is eliminated, and less dangerous components can be employed[1-9]. The third component increases the selectivity of the catalytic system in the dimerisation of α-olefins[10-12] and the cyclo-oligomerisation of dienes[13,14]. Moreover, the modified systems may prove to be the most suitable for the polymerisation of monomers containing a heteroatom in the substituent[8]. Finally, the modification of Ziegler catalysts is one of the methods helping to elucidate the details of the mechanism and nature of stereospecific polymerisation.

Certain problems associated with the effect of the modification of organometallic catalysts by various compounds[9,15-24], including nucleophilic[25-36] and electrophilic[9,29] substances and aromatic hydrocarbons[29,34,37], and also with the application of complexes of these compounds with one of the components of the catalytic system[28,38-43], have been described in the literature. Data are also available on the effect of admixtures in the catalyst, solvent, and the monomer on the polymerisation process[9,44-52]. However, the extensive experimental data accumulated hitherto have not been described systematically in the review literature and we therefore attempted to fill this gap. The present review deals with systems containing organic compounds as the third component.

2. POLYMERISATION OF α-OLEFINS

In the polymerisation of α-olefins, electron-donating compounds have found the widest application as modifying additives: ethers[1-4,53-59], esters[59-61], amines[62-66], sulphides[67,68], phosphines[69], and certain other O-, N-, S-, and P-containing compounds[70-80]. Solvents or their mixtures are frequently employed for this purpose[9,81]; particular mention should be made of the use of non-fractionated hydrocarbons as solvents[5].

The published data indicate the complex nature of the effect of additives both on the activity and the stereospecificity of the catalyst and on the molecular weight of the resulting polymers[33,35,82-85]. Investigators have frequently approached the consideration of the mechanism of the action of additives from different standpoints and contradictory views exist[25,34,39,86]. The contradictions are aggravated also by the fact that the estimation of the effect of the modification is not made under identical experimental conditions (different amounts of the additive, different order of introduction of the components, etc.).

Razuvaev and coworkers showed that, in the polymerisation of propene in the presence of the $TiCl_3-Al(C_2H_5)_3$ catalyst, the amount of additives introduced has a significant influence on the activity of the catalyst and the molecular weight of the polymer[29,37,86-88]. It has been found[87] that, for the ratio Al : Ti = 3 : 1, an increase in the ratio amine : $TiCl_3$ to 1 entails a sharp increase (by a factor of 2–3) of the molecular weight of the polymer (while the yield remains as usual). These results led the authors to the conclusion that the complexes formed prevent chain termination but do not affect the chain propagation stage. The decrease of the molecular weight of the polymer and its yield observed on increasing the amine : $TiCl_3$ ratio above the equimolar value is accounted for by the binding of the excess amine by $Al(C_2H_5)_3$. An appreciable effect of the order of introduction of the components on the experimental results was not observed. The effect of dioxan, diphenyl sulphide, and pyridine, the amounts of which were varied in the range of the ratio additive : $TiCl_3$ between zero and unity, is fully analogous to the effect of amines but in the presence of dioxan and pyridine there was an appreciable increase in the rate of the process[86].

Under these conditions, the stereospecificity of the catalyst changed insignificantly.

The addition of aromatic hydrocarbons with electron-donating properties[89] has an effect which does not differ in principle from that of other nucleophilic compounds[29,37]. Small amounts of aromatic compounds (benzene, naphthalene, anthracene, diphenyl, styrene) accelerate the polymerisation of propene, while large amounts inhibit it. The compounds can be arranged in the following series in terms of their promoting effect:

benzene ≃ toluene < ethylbenzene ~ isopropylbenzene < *o*-xylene < styrene < tetrahydronaphthalene < mesitylene < anthracene,

which agrees with their sequence in terms of decreasing ionisation potential[37].

Unsaturated aliphatic and alicyclic hydrocarbon can also serve as activators[90-94], but dienes frequently behave as effective polymerisation inhibitors[93,94]. Medvedev and coworkers[93] established that unsaturated compounds can be arranged in the following series in terms of their capacity to reduce the rate of polymerisation of ethylene:

butadiene > isoprene > styrene, isobutene > α-methylstyrene

Minsker[95] explains the effect of the modification of Ziegler–Natta catalysts by a number of polar compounds (amines, ethers, sulphides) in the following way. The reacting monomer molecules are subjected simultaneously to the action of two components of opposed types—the electron-donating ($TiCl_3$) and electron-accepting (AlR_3) components. Therefore, with increase in the amount of the additive, the rate-limiting role may pass from one stage to another (for example, from the electron-accepting to the electron-donating stage and conversely). As a result the additive can behave as a promoting agent at one concentration and as an inhibitor at another.

Vesely[96] found that tributylamine increases the molecular weight of the polymer but does not affect the rate of polymerisation of propene in the presence of the $TiCl_3$–$Al(C_2H_5)_3$ system. In this case the effect of the amine is due to its adsorption on the catalytic centres. As a result of this, the protected active centre cannot be reactivated by extraneous compounds (impurities, the solvent). A number of O-, N-, and S-containing compounds have been investigated in an analogous process[97]. It was found that, when the donor forms a stable complex with AlR_3, the decrease of the concentration of AlR_3, which is capable of giving rise to an active centre on the surface, may be inferred from the decrease of the rate of polymerisation. At a high concentration of the aluminium alkyl small amounts of electron donors increase the rate of polymerisation, while at a low concentration they decrease it. The effect of additives depends on the order of addition of the catalyst components.

Subsequently Ambrož and Hamřik[94,98] reported that electron donors capable of forming 'onium salts behave as promoting agents for catalysts with a low specific surface. For example, tributylamine increased the rate of polymerisation of propene by a factor of 2. At the same time there was an increase in the fraction of isotactic polypropylene and the yield of the amorphous fraction fell. In addition, Kodama and Atarasi[8] observed an increase of the melting point and the density of the polypropylene obtained using the $TiCl_3$–$Al(C_2H_5)_3$–ether (amine) system compared with the polymer synthesised in the presence of the two-component system. The promoting effect of the substances which they investigated varied as a function of their amount, passing through a maximum in all cases.

In order to elucidate the effect of amines in polymerisation on the $TiCl_3$–aluminium alkyl system, Milovskaya and Dolgopol'skaya[99] investigated the distribution of triethylamine between the principal components of the catalyst in the absence of the monomer. It was established that the organoaluminium compound in the complex with the amine is inactive in the polymerisation reaction. When all the components are introduced simultaneously, the amine reacts preferentially with the aluminium alkyl and not with $TiCl_3$. The authors believe that the increase of the molecular weight of the polymer in the presence of amines is due to the formation of a stable complex with the primary aluminium alkyl present in the solution and capable of displacing the polymer chain from the catalytic surface. A similar explanation of the decrease of the activity and the increase of the stereospecificity of the $TiCl_3$–$Al(C_2H_5)_3$ catalyst in the presence of $SeOCl_2$ was put forward by Soga et al.[100]

The mechanism of the action of electron-donating compounds was treated in a different way by Pirogov and Chirkov[39], who assumed that $TiCl_3$ is a fairly strong aprotic acid participating in the double composition reaction

$$TiCl_3 + AlR_3 \cdot D \rightleftarrows TiCl_3 \cdot D + AlR_3 .$$

According to the authors, three-component systems contain not less than five compounds: $TiCl_3$, AlR_3, $TiCl_3$.D, AlR_3.D, and D, their relative amounts varying during the experiment and affecting the activity and the stereospecificity of the catalyst. The activation energy for modified systems is higher than for the $TiCl_3$–AlR_3 two-component system: the values of E_{act} (in kcal mole^{-1}) are 14 for the addition of ether, 19.5 for diphenylamine, 20 for pyridine, and 23 for diethylamine, while in the absence of additives E_{act} is 11.6 kcal mole^{-1}. Thus E_{act} increases with the basicity of the donor. If both compounds are employed as complexes with a Lewis base, the systems are inactive.

The findings of Pirogov and Chirkov are confirmed by other results[28,101]. The occurrence of the reaction involving the exchange coordination of the aluminium alkyl to the donor is proved, according to Pomogailo, Matkovskii, and coworkers, by the fact that the system $VCl_4.2C_5H_5N$–$(iso\text{-}C_4H_9)_2AlCl$ is more active than $VCl_4.2C_5H_5N$–$Al(iso\text{-}C_4H_9)_3$. Since the stability of the complexes of the same ligand is determined by the strength of the Lewis acid, which for organoaluminium compounds varies in the series[102]

$$AlR_3 < R_2AlCl < RAlCl_2 < AlCl_3,$$

it follows that, in the displacement of free VCl_4 from the complex $VCl_4.2C_5H_5N$, di-isobutylaluminium chloride has proved more active than tri-isobutylaluminium.

The authors explain the greater stability of the three-component systems with respect to time compared to two-component systems by the coordination of the amine to the aluminium alkyl. The latter is also a factor which increases the molecular weight of polyethylene.

The studies by Boor[34,82,103,104] on the effect of amines on the polymerisation of propene under the influence of the Ziegler–Natta catalyst and $TiCl_3$–$Zn(C_2H_5)_2$ merits serious attention. The author attributes the fundamental role in the stereospecificity of the catalyst to the nature of the surface of the heterogeneous phase. It is suggested that the active centres are "exposed" titanium atoms and that on the $TiCl_3$ surface isolated centres of various stereospecificities exist. The latter is due to the different ways in which chlorine atoms surround the titanium atoms located in different parts of the crystal (at the corners, on the edges, and on the faces). This imparts to the centres

different capacities for coordinating α-olefin molecules. On the basis of experimental data [82,104], the effect of triethylamine on the rate of polymerisation, the isotactic properties, and the molecular weight of the polymer can be represented schematically in the following way (Fig. 1).

In the region *A* the growth of stereospecificity and the decrease of conversion are due to the binding of non-stereospecific centres, which are most exposed and accessible and also the most "acidic"; in the region *B* the constancy of the stereospecificity and the increase of the conversion are due to the increase of the activity of the remaining more stereospecific centres following the adsorption of the amine next to them (at a chlorine atom); in the region *C*, at high amine concentrations, the constancy of the stereospecificity and the decrease of conversion are caused by the deactivation of the stereospecific centres.

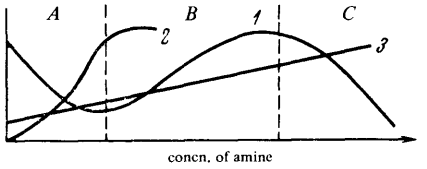

Figure 1. Variation of the degree of conversion (1), the stereospecificity of the catalyst (2), and the molecular weight of polypropylene (3) with the concentration of the amine.

Boor [34,103] divides electron-donating substances into two groups in terms of the nature of their influence. The first group combines substances which decrease the number of active centres as a result of coordination to "exposed" titanium atoms. They always increase the degree of crystallinity, the precise increase depending on the nature of the donor (Lewis bases, azulenes, aromatic compounds and olefins) and its concentration. The second group includes compounds which lower the conversion at low concentrations in consequence of the binding of the active centres and at high concentrations activate the centres (certain aliphatic and heterocyclic amines, phosphines, and azulenes). The results of thermometric titration of catalytic systems by electron donors show that, with substances of the first group, heat is not evolved while in the presence of substances of the second group the heat (exothermic) corresponds to the effectiveness of the donor as an activator of polymerisation. It must be emphasised that Boor believes that the mechanism of the activation process involves the adsorption of the amines on the surface chlorine atoms and not titanium atoms, the main role being attributed in fact to adsorption and not to coordination, since amines with large molecules (tri-n-octylamine) also activate the catalyst, i.e. the steric factor is not very important.

It has been shown in a number of studies [32,105-110] that the two-component system $TiCl_3-C_2H_5AlX_2$, which is inactive in the polymerisation of propene, becomes stereospecific following the introduction of electron-donating additives [111]. Amines, amides, ethers, 'onium salts, phosphines, and sulphides have been investigated as active additives [32,105,110]. Using *NNN'N'N"N"*-hexamethylphosphoramide (HMPA), Coover [110] showed that the rate of polymerisation of propene and the stereospecificity of the catalyst are a maximum when the HMPA: $C_2H_5AlX_2$ ratio is 0.6–0.7. Polymerisation does not occur both in the absence of HMPA and when it is present in excess of the equimolar amount. The same type of behaviour is characteristic of all strong bases, while in the case of weak bases the system is active whatever the amount of the electron donor [109].

According to the literature [105,108,109,111,112], the stereospecificity of the $TiCl_3-C_2H_5AlX_2-D$ system is analogous to the stereospecificity of the $TiCl_3-(C_2H_5)_2AlX$ system. These results are due to the disproportionation (dismutation) reaction of $C_2H_5AlX_2$ in the presence of Lewis bases with formation of free $(C_2H_5)_2AlX$, which gives rise to active centres:

$$2RAlX_2 + D \rightarrow R_2AlX + AlX_3 \cdot D.$$

The occurrence of this reaction has been confirmed by cryoscopic measurements and the isolation of R_2AlX from the reaction products [108]. Ikegami et al. [113], who investigated the reaction of $(C_2H_5)_3Al_2Cl_3$ [i.e. of $(C_2H_5)_2AlCl$ and $C_2H_5AlCl_2$] with an electron donor (pyridine and dibutyl ether) and also the polymerisation of propene on $TiCl_3-(C_2H_5)_3Al_2Cl_3-D$, arrived at the same conclusion.

However, Coover [32] pointed out that the mechanism of the formation of active centres is more complex than the one discussed above and cannot be reduced solely to the reactions of the individual components. He quotes experimental data in support of this assertion [33]. Thus many compounds with high complex-forming capacity (dioxan and tetrahydrofuran) are ineffective in the polymerisation of propene when combined with $TiCl_3$ and $RAlX_2$. Infrared spectroscopy failed to reveal appreciable amounts of $(C_2H_5)_2AlCl$ in benzene solutions of $C_2H_5AlCl_2$ and HMPA.

It is believed [110] that the donor forms a complex with alkylaluminium dihalide of a type such that the active centre contains a hydrocarbon bridge. On the other hand, in the absence of a third component a dimeric structure with a halide bridge is produced:

It is noteworthy that the system β-$TiCl_3-C_2H_5AlCl_2-$HMPA is more stereospecific than the systems β-$TiCl_3-Al(C_2H_5)_3$ and β-$TiCl_3-(C_2H_5)_2AlCl$. [32,114] With increase of the stereospecificity of the catalyst, the molecular weight distribution of the polypropylene becomes narrower. In general the third component in many cases promotes a narrower molecular weight distribution [114-116].

In contrast to $TiCl_3-AlR_3-D$ systems, the activity of which increases with the basicity of the donor [$C_5H_5N > N(CH_3)_3 > N(C_2H_5)_3$], in systems with $RAlX_2$ the opposite relation is observed [32,107]: the activity of the catalytic system decreases in the series

$$N(C_4H_9)_3 > [N(CH_3)_2]_3PO \sim P(C_4H_9)_3 > (C_4H_9)_2O > (C_4H_9)_2S > C_4H_9I.$$

In a later study [98] other results were obtained for the system $TiCl_4-Al(C_2H_5)_3$, indicating the absence of a direct relation between the electron-donating properties of the additives and their effect on the polymerisation of propenes. In the presence of the system $TiCl_3-(C_2H_5)_3 \cdot Al_2Cl_3-$ether (amine), with increase of the chain length in the ether group the rate of polymerisation of propene increases, the molecular weight of the polymer rises

somewhat, and the stereospecificity of the catalyst falls[57]. The system $VCl_4-(C_2H_5)_2AlCl$ is also sensitive to the effect of the donating capacity of the Lewis base, the activity and stereospecificity of the system increasing as the strength of the Lewis base diminishes[117].

The favourable effect of Lewis bases is attributed to their capacity to increase the degree of dissociation of associated aluminium alkyls[102], which promotes the formation of active centres[107,112,118,119].

In the polymerisation of ethylene in the presence of the system $TiCl_4-LiC_4H_9$–phenetole, it was found[120] that the yield–phenetole concentration and molecular weight–phenetole concentration curves have maxima at a phenetole : Li ratio of unity. Since the above relations show a parallel variation, it was concluded that the lifetime of active centres increases while their number remains constant. An analogous observation was made for the system $VCl_4.2VP-(C_4H_9)_2AlCl-SnCl_4$ (VP = 2-vinylpyridine): the change in the rate of polymerisation and correspondingly of the molecular weight also indicates an increase of the polymerisation rate constant or the lifetime of the catalytic centre[121].

Schindler[122] established different effects of electron donors as a function of the initial ratio of the principal components of the $TiCl_4-(C_2H_5)_2AlCl-D$ catalyst. For the system with Al : Ti = 1.5, an increase of the concentration of D leads only to deactivation, while for the system with Al : Ti = 5 deactivation is observed at low donor concentration, but at high concentration the activity increases. These results are explained by invoking the existence of centres with different activities and containing Ti^{3+} and Ti^{4+}. Deactivation takes place as a result of the binding of the more acidic centres containing Ti^{4+}. According to Schindler, the increase of activity is not caused by the binding of the aluminium alkyl but by the coordination of the donor to the centre containing Ti^{3+}, as in Boor's hypotheses[103].

Table 1. Effect of the order of introduction of the components on the activity of the catalyst.

Order of addition	Monomer	Yield of polymer, g	References
$TiCl_3$—$Al(C_2H_5)_3$	propene	170*	125
$Al(C_2H_5)_3$-pyridine-$TiCl_3$	ditto	172*	125
$TiCl_3$-pyridine-$Al(C_2H_5)_3$	»	250*	125
$TiCl_4$—LiC_4H_9	ethylene	4.00	120
$TiCl_4$-phenetole-LiC_4H_9	ditto	5.25	120
LiC_4H_9—$TiCl_4$	»	1.10	120
LiC_4H_9-phenetole-$TiCl_4$	»	3.50	120
Pyridine-VCl_4-anisole-(iso-C_4H_9)$_2$AlCl	propene	0.00	117
Anisole-VCl_4-(iso-C_4H_9)$_2$AlCl-pyridine	ditto	0.9	117

*The yield is given in grammes per gramme of catalyst.

The activity of catalytic systems depends on the order of introduction of the components[117,120,123]. When anisole is added to the product of the reaction of VCl_4 and R_2AlCl, a catalyst with a lower stereospecificity is formed than following the addition of R_2AlCl to VCl_4 + anisole or of VCl_4 to R_2AlCl + anisole[117]. These results suggest that the electron donors are active components of the catalyst.

A number of workers established experimentally that it is best to introduce the catalyst components in the following sequence: the transition metal compound, the donor, and the metal alkyl (Table 1).

Having investigated the polymerisation of propene in the presence of the system $VCl_4-(C_2H_5)_2AlCl-D$, Natta et al.[124] arrived at the conclusion that the effect of anisole, the most effective of all the donors investigated (anisole, furan, isopropyl ether, diethyl ether, thiophen, pyridine, and triethylamine), is associated with its coordination both to the transition metal compound and to the organometallic compound:

$$VCl_4 + D \rightarrow VCl_4 \cdot D,$$
$$2\,(C_2H_5)_2AlCl + 2D \rightleftarrows 2\,(C_2H_5)_2AlCl \cdot D.$$

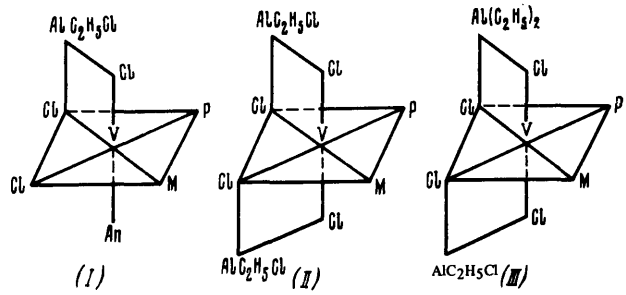

Figure 2. The structure of stereospecifically active vanadium(III) complexes in the presence (I) and absence (II and III) of anisole; P—growing molecule; M—complexed monomer; An—molecule of anisole or another Lewis base[124].

It is assumed that only free $(C_2H_5)_2AlCl$ is capable of alkylating VCl_4 or VCl_4.D. The catalytically active vanadium compound is formed by the reaction

$$(C_2H_5)_2VCl_2 \rightarrow C_2H_5VCl_2 + C_2H_5^{\cdot} \quad \text{or} \quad (C_2H_5)_2VCl_2 \cdot D \rightarrow C_2H_5VCl_2 \cdot D + C_2H_5^{\cdot}.$$

Complexes of six-coordinate V^{3+}, constituting one of the structures presented in Fig. 2, are suggested as stereospecifically active centres.

3. POLYMERISATION OF DIENE HYDROCARBONS

The polymerisation of diene hydrocarbons in the presence of Ziegler catalysts using electron-donating additives (amines, ethers, thiophen, etc.) has been described in a number of patents[126–142]. Thus it has been suggested that butadiene be polymerised at 10–50° with a $TiCl_3I-AlR_3-D$ catalyst, whereby it is possible to obtain polymers containing more than 80% of *cis*-1,4-units. The molar ratio of the catalyst components is 1 : 1.5 : 1.5.[137] As with α-olefins, the introduction of an electron donor accelerates the polymerisation[133], and regulates the molecular weight[138]. In many cases the content of the gel fraction and of cyclisation products is reduced[143]. When three-component systems are employed, the preferential formation of *cis*-1,4-,[132,139] *trans*-1,4-[138] or 1,2-structures[129,130] is achieved.

Following the introduction of ethers into the $TiI_4-Al(iso\text{-}C_4H_9)_3$ system, Dolgoplosk and coworkers[144] observed a change in the polymer microstructure: a decrease of the content of *cis*-1,4-units and hence an increase of the content of *trans*-1,4-units; the content of

1,2-units remained constant. The ethers can be arranged in the following series in terms of their effect:

dimethyl ether > ethyl methyl ether > diethyl ether > dibutyl ether,

i.e. the effect of the ether decreases with increase in the length of the hydrocarbon group and follows the decrease of the tendency towards complex formation. Therefore, in order to obtain a polymer with a high content of *cis*-1,4-units, one adds di-isopropyl ether [83,140], the electron-donating capacity of which is probably reduced owing to the steric factor. It has been noted that in the presence of electron donors the molecular weight of the polymers falls [145]. The introduction of an excess of dimethyl ether in relation to the aluminium alkyl causes a complete reversal of the microstructure with formation of a crystalline *trans*-1,4-polymer [23].

The effectiveness of sulphides as well as ethers decreases with increase in the length of the hydrocarbon group: $(C_2H_5)_2S > (C_4H_9)_2S > (C_8H_{17})_2S$. Tetrahydrofuran has a powerful effect [146]. Only compounds with a greatly reduced activity (thiophen, diphenyl sulphide, and diphenyl ether) have no influence on the chain microstructure and the polymerisation kinetics.

It is noteworthy that, when the polymerisation of isoprene is performed in diethyl ether, dioxan, aniline, dimethylaniline, and pyridine, a polymer is not formed [147]. However, in di-isopropyl ether there is a possibility of the formation of *cis*-1,4-polybutadiene [141].

The system comprising $TiCl_4$, AlI_3, and $AlHCl_2$ leads to *cis*-1,4-polybutadiene when it contains an ether or an amine in an amount equimolar with that of $AlHCl_2$. With increase of the amount of the electron donor, the content of the *trans*-units rises owing to a decrease from the content of the *cis*-units, i.e. the additives have the same effect as in the TiI_4-AlR_3 system. Analogous results were obtained in the polymerisation of isoprene under the influence of $TiCl_4-AlHCl_2.O(C_2H_5)_2$. Systems containing trimethylamine exhibit high stereospecificity [23].

The introduction of β-naphthylphenylamine into the $TiCl_4-Al(C_2H_5)_3$ system makes it possible to obtain polyisoprene not containing a gel [118]. The rate of polymerisation and the degree of conversion depend in this case on the order of introduction of the catalyst components.

The simultaneous addition of two donors (an ether and an amine) is interesting [148]. The introduction of an amine into the polymerisation system together with an ether leads in some cases to a considerable acceleration of the process. At the same time the content of the gel diminishes but the molecular weight and the polymer structure remain constant. The presence of an amine and an ether makes it possible to alter the relative amounts of the principal catalyst components without risk of increasing the content of the gel or of retarding the polymerisation.

Systems consisting of $CoCl_2$ complexes with pyridine or an alcohol in combination with R_2AlCl exhibit high stereospecificity [149-152]. It has been established that the addition of ethers, amines, and sulphides to a cobalt catalyst leads to a sharp change in the structure of the polydiene chain and a decrease of the rate of polymerisation and the molecular weight of the polymer [145]. The addition of AlR_3 has a similar influence [153-155]. The opposite effect is obtained in those cases where small amounts of water, alcohols, $AlCl_3$, $RAlCl_2$, Br_2, and other compounds are introduced [155-157]. It has been shown [154] that the complex formed from cobalt halides and $(C_2H_5)_2AlCl$ is active. There is then no oxidation-reduction interaction between the catalyst components. On the other hand, in the presence of AlR_3 cobalt is reduced to the metal with simultaneous formation of R_2AlCl and other substances. The above negative effects are associated with this reduction. In a treatment from a single standpoint of all these phenomena, Vinogradov, Dolgoplosk, and coworkers [158] start from the known fact that R_2AlCl solutions form AlR_3 under the influence of electron donors. Thus the effect of donors is analogous to that of AlR_3 additives.

On the other hand, when catalytic systems based on $CoCl_2-RAlCl_2$ [108,109,159] and $CoCl_2-AlCl_3$ [160] are employed, small amounts of donors are essential for the preparation of the *cis*-polymer, since in this case Lewis bases bind free $AlCl_3$ and suppress cationic polymerisation. Judging from the change in the degree of unsaturation of the polymer, anisole and thiophen are the most effective. Nitrogen-containing compounds (pyridine, diphenylamine, dimethylaniline) proved to be unduly powerful donors for this system; they break down the catalytic complex with formation of $CoCl_2$.

Electron-donating additives have the same influence on the homogeneous $CoCl_2.2D-(C_2H_5)_2AlCl$ system (D = pyridine or acetylacetone) [36,161] as on the heterogeneous system [145]. However, in the case of the homogeneous system the observed decrease of the molecular weight of the polymer is associated with the participation of free donors in the chain-transfer reaction [161]. This view is confirmed by the fact that an increase of the concentration of the aluminium alkyl leads to an increase of both the degree of polymerisation and the catalyst activity. An increase of the concentration of the aluminium component should lead to a decrease of the concentration of the free Lewis base. If at the same time there is an increase of the molecular weight, it follows that it is in fact the free donors which influence the chain growth limitation reaction. As already mentioned [162], the $R_2AlCl-CoCl_2.2C_5H_5N$ system is active in the preparation of the *cis*-1,4-polymer of butadiene only in the presence of water or other electron-accepting substances.

The most complete data on the kinetics of this reaction have been presented by Karchevskaya et al. [163] Water not only accelerates the polymerisation and increases the molecular weight but, after the attainment of the optimum concentration, the excess water breaks down the active centres and reduces the rate of polymerisation, but the molecular weight continues to grow. This complex effect of water is due to its dual nature, i.e. its electron-accepting and electron-donating properties.

Kinetic data for the systems $CoCl_2.2C_5H_5N-(C_2H_5)_2.AlCl-A$ (A = $AlCl_3$, $SnCl_4$, or $C_2H_5AlCl_2$) have been presented [164]. When $C_2H_5AlCl_2$ is introduced, the rate of polymerisation increases and reaches a maximum for the equimolar $(C_2H_5)_2AlCl : C_2H_5AlCl_2$ ratio. Further increase of the amount of $C_2H_5AlCl_2$ leads to the appearance of an introduction period, which is a maximum in the absence of $(C_2H_5)_2AlCl$. The molecular weight increases continuously with the amount of additive and is a maximum when the aluminium component is completely replaced by $C_2H_5AlCl_2$.

In the absence of additives, the rate of the process is low; only an oligomer was obtained: the authors suggest that the aluminium component participates in the formation of active centres and also in the decomposition of these centres and chain transfer.

Recently it has been established [165,166] that the addition to the catalytic system of halogenohydrocarbons containing two and more halogen atoms (for example CH_2Br_2 and CH_2Cl_2) increases the activity of the catalyst and makes it possible to obtain a high yield of polyisoprene containing 97-98% of *cis*-1,4-units.

4. POLYMERISATION AND COPOLYMERISATION OF OTHER MONOMERS

The effect of a large number of organic compounds containing a heteroatom on the polymerisation of styrene in the presence of $TiCl_4-Al(C_2H_5)_3$ has been investigated. It has been found that only thiophen and furan increase the stereospecificity of the system (the conversion of styrene then diminishes). Many substances (halogenobenzenes, di-n-hexyl ether, and triphenylphosphine) reduce the yield of polystyrene without affecting its structure. On the other hand, most of the compounds eliminate the stereospecificity of the catalyst, diminishing or increasing the conversion of styrene. The effect of additives reduces to binding the substances responsible for non-stereospecific cationic polymerisation. The inhibiting effect of additives is shown particularly clearly at the high concentrations employed in the study quoted above. In the polymerisation of styrene in the presence of β-$TiCl_3-Al(C_2H_5)_3$ and β-$TiCl_3-(C_2H_5)_2AlCl$ an increase of the rate of formation of the isotactic polymer is observed when straight-chain dipropyl, dibutyl, and dihexyl ethers and triethylamine are introduced up to a donor : aluminium component ratio of unity[35]. Further addition of the donor leads to a sharp decrease in the rate of polymerisation.

The effectiveness of the substances investigated decreases in the sequence

$$(n\text{-}C_6H_{13})_2O > (n\text{-}C_4H_9)_2O > (n\text{-}C_3H_7)_2O > (C_2H_5)_3N.$$

In the polymerisation of acetylene under the influence of $TiCl_4-Al(iso\text{-}C_4H_9)_3-D$, the addition of dioxan (0.05–0.1 mole per mole of $TiCl_4$) or triethylamine (0.1–0.3 mole per mole of $TiCl_4$) increases the yield of polyacetylene only when the Al : Ti ratio is less than the optimum value (for the two-component system); in other cases the additives sharply inhibit polymerisation[26].

Catalysts modified by Lewis bases are used for the polymerisation of iodo-derivatives of α-olefins in which the carbon–iodine bond is remote from the double bond[168]. The polymerisation of fluorine-containing monomers[169], symmetrical dichloroethylene[170], and vinylidene chloride[171] in the presence of similar systems has been described.

The introduction of tetrahydrofuran, triethylamine, pyridine, and diethyl ether alters sharply the activity and nature of the $Ti(OC_4H_9)_3-C_2H_5AlCl_2$ catalytic system in the copolymerisation of ethylene with vinyl chloride[172], which is evident from the change in the composition and yield of the copolymer (Table 2). On the other hand, anisole and thiophen do not have a significant influence on the activity of the system, while acetylacetone, triphenylphosphine, and dipyridyl inhibit polymerisation. According to infrared spectroscopic data, the copolymer obtained in the presence of anisole and thiophen is identical with the product synthesised without a donor and is predominantly a block copolymer. On the other hand, the spectra of the copolymers obtained in the presence of tetrahydrofuran, triethylamine, pyridine, and diethyl ether are analogous to the spectrum of the copolymer synthesised in the presence of $B(C_4H_9)_3$–t-butyl peroxide by a radical mechanism[173]. In the absence of tetrahydrofuran the composition of the copolymer is constant and the yield depends on the Al : Ti ratio.

Isotactic and syndiotactic poly(vinyl chloride) is obtained in the presence of the three component system transition metal (Ti, V, Zr, Fe, or Ni) chloride–$Al(C_2H_5)_3$–D.[174–178] In the absence of a Lewis base the polymerisation of vinyl chloride under the influence of $VOCl_3-Al(iso\text{-}C_4H_9)_3$ is slow. In the presence of ethyl acetate effective polymerisation takes place at −30°C. The authors adduce evidence for the suggested radical mechanism for this process[179].

The copolymerisation of ethylene and butadiene[180–182] and ethylene and α-olefins[183–189] in the presence of three-component catalysts has been described. Under these conditions, the third component not only promotes an increased yield but also improves the physical and mechanical properties of the copolymers. The electron-donating component is then introduced as a complex with a transition metal halide[189] and more rarely with an aluminium alkyl[180].

Table 2. Copolymerisation of ethylene with vinyl chloride*.

Donor	Al:Ti	Yield, %	Vinyl chloride in copolymer, mole %	Type of copolymer	$[\eta]$**, dl g^{-1}
—	3.0	20.2	15.8	block	0.42
Tetrahydrofuran	3.0	31.6	86.8	non-regular	0.26
Triethylamine	3.0	24.0	86.1	ditto	0.24
Pyridine	3.0	22.5	89.3	»	0.30
Ether	3.0	11.1	79.5	»	0.26

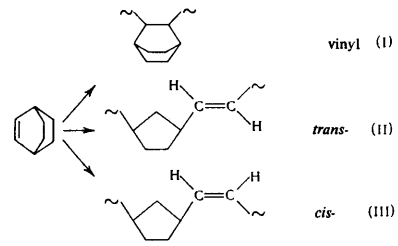
Thiophen	3.0	12.0	13.4	ditto	0.24
Dipyridyl	3.0	1.8	—	—	—
Acetylacetone	3.0	0	—	—	—
Triphenylphosphine	2.2	0	—	—	—

*Experimental conditions: 0.35 mole of ethylene, 0.35 mole of vinyl chloride, and 2.0×10^{-3} mole of $Ti(OC_4H_9)_3$; D : Ti = 1; 50 ml of n-heptane; temperature 50°C; duration of polymerisation 3 h.
**Measured in cyclohexanone solution at 30°C.

Lewis bases alter the mode of polymerisation of norbornene[190,191]. In the presence of the usual Ziegler catalyst norbornene is polymerised at the double bond with *trans*-ring opening, while in the presence of Lewis bases the polymerisation takes place only with *trans*- and *cis*-ring opening:



5. CATALYTIC SYSTEMS BASED ON THE ETHER COMPLEXES OF ORGANOALUMINIUM COMPOUNDS

In many studies it has been suggested that, instead of free aluminium alkyls or the addition of ethers to two-component catalysts, pre-synthesised ether complexes of aluminium alkyls be employed[1,38–42,136,142,192–202]. In some cases this leads to certain advantages; since in contrast to ether-free aluminium alkyls, the ether complexes are more convenient to prepare and handle[203] and can be obtained in the laboratory without particular difficulty[201,204–206].

Moreover, ether complexes in many cases promote the formation of polymers with valuable physical and mechanical properties. However, until recently little attention was devoted to the study of the properties of the ether complexes of organoaluminium compounds as catalysts, since it was believed[207] that ethers forming stable complexes with aluminium compounds deactivate the Ziegler–Natta systems.

The studies were mainly directed to the search for means of separating the ethers from the organometallic component. The results of the measurement of the heat of formation of triethylaluminium-ether complexes[208] suggested that the replacement of diethyl ether by an alkyl aryl ether will yield ether complexes from which ether can be readily eliminated by distillation and which can be employed as active components in catalytic systems by virtue of the presence of weakened Al ← O bonds. An inverse relation was found between the enthalpy of dissociation of the ether complexes and their polymerisation activity with respect to ethylene[41,209]. The catalyst is much less sensitive to the electron-donating capacity of the ether in the polymerisation of propene[34,202]. In this case even adducts of triethylaluminium with diethyl ether[196] and monoglyme[197] exhibit a high activity. Complexes of ethylaluminium dichloride with di-isopropyl, di-n-butyl, and di-isopentyl ethers are effective in the stereospecific polymerisation of propene[210].

It has been reported[42] that polyethylene obtained in the presence of systems with ether complexes is similar in some of its properties to the Ziegler polyethylene and, according to infrared spectroscopic data, does not contain methyl side groups[40,41].

The yield of polyethylene in the presence of the $TiCl_4$–$Al(C_2H_5)_3.C_6H_5OC_2H_5$ catalyst[202] depends on the Al : Ti ratio, but this dependence is not as pronounced as for the ether-free catalyst[211]. It is well known that the activity of the catalyst is higher when it is formed in the presence of the monomer. A similar effect is shown also for ether complexes[202]. In the presence of ether or the monomer, the molecules of which behave as ligands, the following complexes may be formed:

$$[TiCl_3]^+ \xrightarrow{ROR'} [TiCl_3]\ (I) \quad \text{or} \quad [TiCl_3]^+\ (II)$$

(I): $^{+}O(R)R'$; (II): $CH_2{=}CH_2$

As a result, further reaction between the components of the bimetallic complex $[TiCl_3]^+[Al(C_2H_5)_3Cl]^-$ is hindered, which leads to its deactivation. Then the Ti–C bond in compound (II) should be comparable in strength to the Ti ← O bond in compound (I). For ethylene, this is observed in the case of ethers containing an aryl group (weak nucleophilic agents). Depending on the monomer, different ethers cause deactivation.

Mardykin et al.[212] compared the effectiveness of ether complex systems with ether-free systems in the polymerisation of styrene. The corresponding results are presented in Table 3, from which it follows that the $TiCl_n$–$Al(C_2H_5)_3$.ether systems are active in the stereospecific polymerisation of styrene.

With the aid of the ether complexes of aluminium alkyls optically active poly-α-olefins have been obtained even from optically inactive olefins[217–219].

The ether complexes of aluminium alkyls are also active in the polymerisation of dienes (isoprene, butadiene, etc.), the ether complexes of tri-isobutylaluminium being most often used in such cases. In the presence of systems of this kind polyisoprene with the properties of natural rubber is obtained[142,198–200,220].

The polymerisation of penta-1,3-diene[219], hexa-1,3,5-triene[221], and other conjugated trienes[222] in the presence of ether complexes has been described.

Together with the ether complexes of aluminium alkyls, complexes of organoaluminium compounds with amines have been employed in the polymerisation of olefins[223] and organic sulphide complexes of aluminium alkyls have been employed in the polymerisation of dienes[224].

Table 3. Stereospecificity of the $TiCl_n$–AlR_3 (a) and $TiCl_n$–AlR_3.ether (b) systems in the polymerisation of styrene.

*Extraction with ethyl methyl ketone and in the remaining cases with acetone.

The copolymerisation of ethylene with nitrogen-containing monomers (acrylonitrile, diallylamine, etc.) previously bound in complexes with one of the components of the Ziegler catalyst is of considerable interest[225,226].

The above review of the applications of three-component systems shows that a positive effect is achieved by introducing into the Ziegler–Natta catalysts substances of different types: ethers, amines, phosphorus derivatives, sulphur derivatives, alcohols, water, salts, etc. Evidently the mechanism of the action of such a wide variety of reagents cannot be common to all of them. Moreover, the role of the third component must be considered in relation to a definite class of substances constituting the basis of the catalytic system. Until recently in the study of three-component systems the principal role was attributed to processes involving the chemisorption of electron-donating compounds on the active centres of the catalyst[29,82]. Admittedly, in most cases the third component was introduced to a complex already formed from the principal components (MX_n–ER_m; M = transition metal, X = halogen, and E = Al, Mg, Li, etc.). In these cases the effect of the donor is shown by virtue of its binding in a complex (or chemisorption on) already existing polymerisation centres.

The third component has a more profound specific effect when it interacts with one of the principal components of the catalyst before the formation of the catalytic complex proper. The complexes of the catalyst components formed under these conditions will behave differently in the chemical reaction and will yield products (some of which are active centres) differing from those obtained when free (non-complexed) components are employed.

Thus, together with chemisorption, in three-component systems account must be taken also of chemical reactions between all three components. One of the principal reactions in the formation of the catalytic complex is the alkylation and reduction of the transition metal compound:

$$AlR_3 + TiCl_4 \rightarrow RTiCl_3 + R_2AlCl;\ RTiCl_3 \rightarrow TiCl_3 + 1/2\,R_{(+H)} + 1/2\,R_{(-H)}.$$

Nucleophilic compounds accelerate this reaction [25,31,38,158]. If the Ti–C bond is assumed to be the active centre [227-231], the increase of the rate of alkylation of titanium will lead to an increase in the number of active centres and a corresponding acceleration of the polymerisation process. The electron donor coordinated to the catalytic complex losens the Ti–C bond by virtue of the increase of the electron density around the titanium atom and thereby facilitates the insertion of the monomer into the active centre [232]. Moreover, as the reaction between the components of the catalytic system proceeds, there is a possibility of the formation of new complexes, since certain reaction products are stronger Lewis bases. For example, in the $TiCl_4-AlR_3$ system these are R_2AlCl, $RAlCl_2$, and $AlCl_3$. As a result, the donor is transferred to the powerful new electron acceptors appearing in the system and new more stable complexes are formed: $R_2AlCl.D$, $RAlCl_2.D$, and $AlCl_3.D$. In turn, these complexes behave differently than the corresponding free compounds. Thus, under certain conditions, the complexes $R_2AlCl.D$ and $RAlCl_2.D$ disproportionate with formation of an additional amount of the initial organometallic component:

$$2R_2AlCl + D \rightarrow AlR_3 + RAlCl_2 \cdot D,$$
$$2RAlCl_2 + D \rightarrow R_2AlCl + AlCl_3 \cdot D \text{ etc.}$$

Consequently in the presence of the donor, the effective concentration of the organometallic component increases which, depending on its initial concentration, determines the effectiveness of the catalytic system. However, not all donors are capable of being transferred from one component to another. Some of these are irreversibly bound in complexes with the initial components and are cleaved:

$$RAlX_2 + R'OR'' \rightarrow RAlX_2 \cdot O\begin{matrix}R'\\R''\end{matrix} \rightarrow RAlX(OR') + R''X,$$

$$TiCl_4 + R'OR'' \rightarrow TiCl_4 \cdot O\begin{matrix}R'\\R''\end{matrix} \rightarrow TiCl_3OR' + R''Cl.$$

In the presence of $AlCl_3$ and other Lewis acids alkyl aryl ethers readily rearrange to alkylphenols [233]. Phenol and its alkyl derivatives have been detected [234] among the products of the reaction between $TiCl_4$ and $Al(C_3H_7)_3$. $.C_6H_5OCH_3$.

Electron donors reacting in the above manner deactivate (disrupt) the catalyst when present in equimolar amounts in relation to the main components. Only those donors which are not cleaved or are cleaved only to a slight extent exhibit a positive modification effect when present in large amounts.

In the latter case the degree of reduction of the transition metal and hence the activity of the catalytic system increase owing to the formation of alkoxy-derivatives, since the presence of RO groups in the $TiCl_4-(C_2H_5)_2AlCl$ system in amounts up to 25% greatly increases the degree of reduction of $TiCl_4$. [235] Systems containing alkoxy-derivatives of titanium proved to be more effective. The effect of small amounts of active substances such as alcohols and water should be treated similarly.

The complexity of the relation between the molecular weight of the polymer and the amount of the donor is due to the fact that the donor can (1) behave as a chain-transfer agent, (2) can form complexes with chain-transfer agents, (3) can alter the chain propagation rate constant or the lifetime of the active centre by forming complexes with the latter, and (4) can influence the molecular weight by altering the relative amounts and the activities of the main components.

The differences in the electron-donating capacity and the structure of additives are shown in the fact that they exhibit the same effect at unequal concentrations [236]. As a rule, small amounts of the donor increase and large amounts reduce the molecular weight of the polymer.

The stereospecificity of catalytic systems depends similarly on the content of the electron-donating compound. When a third component is introduced, the number and activity of the stereospecific and non-stereospecific centres change owing to both chemical reactions and adsorption processes.

Redox Reactions of Atoms and Radicals with Ions in Solution

E.T. Denisov

The reactions of hydrogen atoms and various radicals ($HO^{\cdot}$, $HO_2^{\cdot}$, $RO_2^{\cdot}$, $RO^{\cdot}$, $R^{\cdot}$, diphenylpicrylhydrazyl) in solution with cations and complexes of metals of variable valency and also with anions are surveyed, and their mechanism is discussed. The rate constants of these reactions are tabulated. A list of 130 references is included.

1. INTRODUCTION

For a long time research workers studying the changes undergone by free radicals concentrated their attention on reactions with molecules which involve substitution and addition. The reactions of radicals with metal ions—electron-transfer reactions—became a subject for quantitative investigation only in the 1960s. Whereas about 20 papers were published on this topic before 1960, the number of publications which appeared during the 1960s exceeded 100.

The enhanced interest taken by investigators in the reactions of free radicals with ions is due to the active part played by these processes in various chain and free-radical chemical reactions. Redox reactions of hydrogen atoms and hydroxy-radicals with various ions take place in photochemical and radiation-chemical systems[1]. The decomposition of hydrogen peroxide involves the formation of hydroxyl and hydroperoxy-radicals, which react with metal ions[2]. The introduction of ions of metals having variable valency into a system in which radical polymerisation is taking place leads to chain termination as a result of reactions between the metal ions and polymer macroradicals[3]. Reactions between peroxy-radicals and compounds of metals with variable valency play an important part in the catalytic liquid-phase oxidation of hydrocarbons[4]. Reactions between alkyl radicals and salts of heavy metals form the basis of various organic syntheses.

A free radical possesses an unpaired electron, and is able to oxidise a reducing ion by removing an electron from the latter, e.g. $Fe^{2+} + HO\cdot \rightarrow Fe^{3+} + HO^-$, but it is able also to reduce an oxidising ion, by donating its electron to the latter, e.g. $Fe^{3+} + H\cdot \rightarrow Fe^{2+} + H^+$.

The redox reactions of free radicals with ions are often very rapid. For example, the polyacrylamide radical reacts with ferric ions with a rate constant of the order of 10^3 M^{-1} s^{-1}; the hydrogen atom and hydroxyl and hydroperoxy-radicals react in water with ions of metals having variable valency with rate constants of the order of 10^8-10^{10} M^{-1} s^{-1}. The reactions of atoms and radicals with ions of metals having variable valency may have various mechanisms: in one case the radical replaces the solvent molecule in the inner coordination shell of the ion; in another case electron transfer takes place from the ion through the medium to the radical or conversely; and in a third case reaction of the radical with a ligand is followed by rearrangement of the electronic structure of the complex.

The reactions of atoms and radicals with ions and complexes are studied quantitatively by methods developed to measure the rate constants of rapid reactions[5]—flow methods (FM), the flash method (FP), pulse radiolysis (PR), and the inhibiting effect of a reactant on the chain reaction—but the most widely used is the method of competing reactions (MCR), which enables the ratio of the rate constants of two parallel reactions involving the same species (e.g. the hydrogen atom) to be determined from the composition of the products.

2. REACTIONS OF HYDROGEN ATOMS

The hydrogen atom is an active reducing agent, which reacts rapidly with oxidising ions:

$$H^{\cdot} + M^{n+1} \rightarrow H^+ + M^{n+}.$$

Such a reaction occurs either by addition of the hydrogen atom to one of the ligands with rearrangement of the electronic structure of the complex, e.g.

$$FeOH^{2+} + H^{\cdot} \rightarrow FeH_2O^{2+},$$
$$MnO_4^- + H^{\cdot} \rightarrow HMnO_4^- \rightleftharpoons H^+ + MnO_4^-,$$

or as a result of the transfer of an electron from the hydrogen atom to the central atom of the complex.

The rate constant for reaction of hydrogen atoms with ions of metals having variable valency is almost independent of the redox potential of the ion. For the ions Cu^{2+}, $Fe(CN)_6^{3-}$, Fe^{3+}, and Ag^+, for example, the redox potential and $\lg k(H\cdot + \text{ion})$ are respectively 0.15 and 7.77 (Cu^{2+}), 0.36 and 9.60 $[Fe(CN)_6]^{3-}$, 0.77 and 7.34 (Fe^{3+}), and 0.8 and 10 (Ag^+). The hydrogen atom reacts with MnO_4^- and Ag^+ with diffusion-controlled rate constants of the order of 10^{10} M^{-1} s^{-1}.

The hydrogen atom behaves as an oxidant on reaction with reducing ions. For example, hydrogen atoms oxidise I^- to I·, Fe^{2+} to Fe^{3+}, etc. The following mechanism has been suggested[6] for the oxidation of Fe^{2+} ions by hydrogen atoms:

$$H^{\cdot} + Fe^{2+} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} FeH^{2+}; \quad FeH^{2+} + H^+ \xrightarrow{k_2} Fe^{3+} + H_2.$$

Approximate values of the rate constants[6] are $k_1 \simeq 10^9$ and $k_{-1}/k_2 \simeq 0.02$. A different mechanism has been proposed[7] for the reaction of hydrogen atoms with I^-, according to which the hydrogen atom adds to a hydrogen ion with the formation of H^+_{2aq}, and this species oxidises the iodide ion:

$$H^\cdot + H^+_{aq} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} H^+_{2aq} \quad H^+_{2aq} + I^- \xrightarrow{k_2} H_2 + I^\cdot$$

where $k_1 \simeq 10^2 - 10^3$ M^{-1} s^{-1}.

Table 1 lists rate constants for the redox reactions of hydrogen atoms with various cations and anions. Where the method of competing reactions has been used, the competing compound is indicated. The hydrogen atoms were obtained radiochemically using an aqueous solution or by passing an electric discharge through hydrogen and then bubbling the H_2 + H· through an aqueous solution.

Table 1. Reactions of hydrogen atoms with ions in aqueous solution at room temperature (20–25°C).

3. OXIDATION OF IONS BY FREE HYDROXYL

The hydroxy-radical is a very active oxidant, rapidly oxidising not only cations of metals of variable valency (Fe^{2+}, Ce^{3+}, Tl^+) but also anions such as HCO^-_3, HSO^-_4, and NO^-_2.

The rate constant for oxidation of the Fe^{2+} ion by hydroxyl is 3×10^8 M^{-1} s^{-1}, which exceeds the rate of substitution of the water molecules in the inner coordination sphere of the $Fe(H_2O)^{2+}_6$ ion by factors of 10^2-10^3. Hence the oxidation of Fe^{2+}_{aq} does not involve entry of the hydroxyl into its inner coordination sphere. Two alternative mechanisms can be suggested for this process—electron transfer from Fe^{2+}_{aq} to HO· through the solvent or

abstraction by hydroxyl of a hydrogen atom from a water molecule in the inner coordination sphere of Fe^{2+}_{aq}:

$$HO^{\cdot} + Fe(H_2O)_6^{2+} \rightarrow H_2O + Fe(H_2O)_5OH^{2+}.$$

The $Fe(CN)_6^{4-}$ ion is oxidised by hydroxyl with a diffusion rate constant of $\sim 10^{10}$ M^{-1} s^{-1}; oxidation probably occurs by transfer of an electron from the complex ion to hydroxyl. The Cu^{2+} ion is oxidised by hydroxyl to tervalent copper.

The rate constant of the reaction between hydroxyl and the chloride ion depends on pH:

pH	0	1	2	3
lg$k$	9.60	8.60	7.60	7.20
$k/[H^+]$	$4\cdot10^9$	$4\cdot10^9$	$4\cdot10^9$	$1.6\cdot10^{10}$.

A possible explanation is that oxidation of Cl^- is accomplished by the reaction

$$HO^{\cdot} + HCl \rightarrow H_2O + Cl^{\cdot}.$$

A somewhat analogous reaction takes place in the oxidation of bromide ions, since here, too, k increases with the hydrogen-ion concentration:

pH	0	2	3	7
lg$k$	10.20	9.70	9.34	9.00 .

Oxidation of the iodide ion by hydroxyl is independent of pH:

$$I^- + HO^{\cdot} \rightarrow I^{\cdot} + HO^-.$$

Table 2 gives rate constants for the oxidation of ions by hydroxyl radicals, which were obtained photochemically and radiation-chemically. In most cases the method of competing reactions was used to measure the rate constants.

Measured rate constants quoted in different papers usually show good agreement. The mean logarithms of the rate constants are

$$\lg k\,(Fe^{2+} + HO^{\cdot}) = 8.47 \pm 0.04,\ \lg k\,(Fe(CN)_6^{4-} + HO^{\cdot}) = 9.85 \pm 0.28,$$

$$\lg k\,(Ce^{3+} + HO^{\cdot}) = 8.40 \pm 0.09,\ \lg k\,(I^- + HO^{\cdot}) = 9.75 \pm 0.25,\ \lg k\,(CO_3^{2-} + HO^{\cdot}) = 8.30 \pm 0.$$

The rate constant of the reaction ·OH + Ion is independent of the free energy of reaction:

Ion	Br^-	Ce^{3+}	Mn^{2+}	I^-	Fe^{2+}	$Fe(CN)_6^{4-}$
ΔG, kcal mole^{-1}	−3	−8	−10	−18	−26	−36
lg$k$	9.0	8.4	8.1	9.5	8.5	9.9 .

4. REACTIONS OF ALKYL AND ARYL RADICALS WITH SALTS OF METALS HAVING VARIABLE VALENCY

Reaction of the Type $R\cdot + MX_n \rightarrow RX + MX_{n-1}$

The Sandmeyer reaction—decomposition of ArN_2X under the influence of CuX—involves the intermediate formation of an aryl radical. This is evident if only from the formation of the aryl iodide by the reaction[76]

$$Ar\cdot + I_2 \rightarrow ArI + I\cdot$$

when the arenediazonium chloride is decomposed by copper(I) chloride in the presence of molecular iodine. Kochi proposed the following mechanism for this reaction[76]

$$ArN_2^+ + CuCl_2^- \rightleftharpoons ArN_2CuCl_2 ,$$
$$ArN_2CuCl_2 \rightarrow Ar\cdot + CuCl_2 + N_2 ,$$
$$Ar\cdot + CuCl_2 \rightarrow ArCl + CuCl .$$

The last stage involves oxidation of the aryl radical by copper(II) chloride occurring as a radical substitution.

A similar primary step occurs in the Meyerwein reaction, whose mechanism can be represented[76,77]

$$ArN_2^+ + CuCl_2^- \rightleftharpoons ArN_2CuCl_2 \rightarrow Ar\cdot + N_2 + CuCl_2 ,$$
$$Ar\cdot + CH_2{=}CHY \rightarrow ArCH_2\dot{C}HY \quad (I) ,$$
$$ArCH_2\dot{C}HY + CuCl_2 \rightarrow ArCH_2CHYCl + CuCl .$$

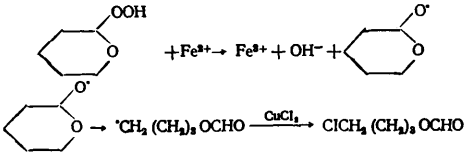
The final product $ArCH_2CHYCl$ is formed by oxidation of the radical(I) by copper(II) chloride. Addition of the aryl radical to the alkene is accompanied by the parallel reaction[77]

$$Ar\cdot + CuCl_2 \rightarrow ArCl + CuCl .$$

Occurrence of the reaction $R\cdot + CuCl_2 \rightarrow RCl + CuCl$ is indicated by the appearance of compounds containing chlorine when hydroperoxides are decomposed in aqueous solution by Fe^{2+} ions in the presence of copper(II) chloride. For example, methyl chloride is formed in the decomposition of t-butyl hydroperoxide as a result of the reactions[78]

$$(CH_3)_3COOH + Fe^{2+} \rightarrow (CH_3)_3CO\cdot + OH^- + Fe^{3+} ,$$
$$(CH_3)_3CO\cdot \rightarrow CH_3COCH_3 + \dot{C}H_3 ,$$
$$\dot{C}H_3 + CuCl_2 \rightarrow CH_3Cl + CuCl .$$

The decomposition of tetrahydropyran hydroperoxide is accompanied by the formation of $ClCH_2[CH_2]_3OCHO$ by the mechanism[78]



Similarly, the decomposition of tetrahydrofuran hydroperoxide yields $ClCH_2[CH_2]_2OCHO$ [79].

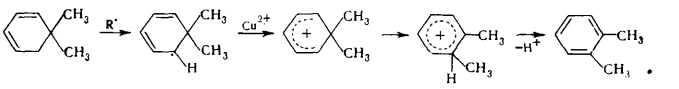
Reaction of the Type $R\cdot + M^{(n+1)+} \rightarrow R^+ + M^{n+}$

Alkyl radicals are oxidised by copper ions with formation of an alkene and an alcohol[80-82]. The carbonium ion is most probably the precursor or both products, and oxidation of the alkyl radical results from electron transfer from the radical to the copper(II) ion:

$$R\cdot + Cu^{2+} \rightarrow R^+ + Cu^{1+} ,$$
$$R^+ \rightarrow Alkene + H^+ ,$$
$$R^+ + H_2O \rightarrow ROH + H^+ .$$

In the oxidation of various radicals by copper ions the yield of alcohol is greater the more stable is the carbonium ion formed[80]: the ratio [Alcohol]/[Alkene] has the values 0.81, 3.4 and 9.1 for C_2H_5, s-C_4H_9, and t-C_4H_9 respectively, while the allyl radical is oxidised solely to the alcohol. This is consistent with the hypothesis of a carbonium ion as kinetically independent species formed in the oxidation of an alkyl radical.

Perhaps the most convincing evidence of formation of a carbonium ion is the formation of *o*-xylene from 5,5-dimethylcyclohexadiene in the presence of a peroxide (source of radicals) and copper ions[83]. This fact is explained by the following mechanism[83], involving formation of a carbonium ion:



The oxidation of alkyl radicals by copper ions is used for the preparation of certain unsaturated compounds: e.g. [82]

The thermal and photochemical decarboxylation of aliphatic (butyric, isobutyric) acids under the influence of cobalt(III) and cerium(IV) ions is accompanied by oxidation of alkyl radicals by these ions[84,85]. Evidence of this is provided by the formation of 2-methylpropene and an ester as a result of decarboxylation of pivalic acid (where $R\cdot = (CH_3)_3C\cdot$):

$$(RCOO)_3Co \rightarrow (RCOO)_2Co + RCO_2^\cdot ,$$
$$RCO_2^\cdot \rightarrow R\cdot + CO_2 ,$$
$$R\cdot + Co^{III} \rightleftarrows R'Co^{III} ,$$
$$R'Co^{III} \rightarrow R^+ + Co^{II} ,$$
$$(CH_3)_3C^+ \rightarrow (CH_3)_2C{=}CH_2 + H^+ ,$$
$$(CH_3)_3C^+ + RCOOH \rightarrow RCOOC(CH_3)_3 + H^+ .$$

In the decarboxylation of n-butyric acid the radical R· is converted mainly into RH, since the reaction $R\cdot + RCOOH \rightarrow RH + R'\cdot$ occurs more rapidly than the reaction $R\cdot + Co^{III}$ or $R\cdot + Ce^{IV}$. In the presence of copper ions, however, $n\text{-}C_3H_7\cdot$ is oxidised with the formation of propene and an ester[84,85]. Hence copper(II) ions react with alkyl radicals much more rapidly than do cobalt(III) and cerium(IV) ions, although the latter are stronger oxidants than are copper ions.

The oxidation of n-pentanol by cerium nitrate[86] gives an 11–15% yield of 2-methyloxolan. Formation of this compound can be explained by the mechanism

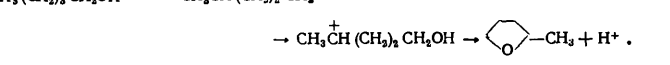


Table 3 lists rate constants for the oxidation of various alkyl radicals by copper complexes. The rate constants were measured by the method of competing reactions.

Reaction of the Type $R\cdot + M^{n+} \rightarrow R^- + M^{(n+1)+}$

Reducing ions (Ti^{3+}, V^{2+}, Cr^{2+}) are able to convert the methyl radical to the carbanion. This is proved by the

formation of DCH_3 from methyl radicals in the presence of metal ions in heavy water[82]:

$$CH_3^{\cdot} + M^{n+} \rightarrow CH_3^- + M^{(n+1)+},$$
$$CH_3^- + D_2O \rightarrow CH_3D + DO^-.$$

The experimental $[CH_4]/[CH_3D]$ ratio (methane is formed by the reaction $CH_3^{\cdot} + RH$) is lower the stronger the reductant: it has the values 2100, 32, 11, and 4.6 for Fe^{2+}, Ti^{3+}, V^{2+}, and Cr^{2+} respectively.

Table 3. Rate constants of $R^{\cdot} + CuL_4^{2+}$ reactions measured by MCR method in 1 : 1.5 CH_3CN-CH_3COOH at 25.5°C.[87]

Ion	Radical	lg*k*
$Cu(NCCH_3)_4^{2+}$	$CH_3CH_2CH_2CH_2^{\cdot}$	6.49
$Cu(C_{10}H_8N_2)^{2+}$	$CH_3CH_2CH_2CH_2^{\cdot}$	7.23
$Cu(NCCH_3)_4^{2+}$	$(CH_3)_3CCH_2^{\cdot}$	5.65
$Cu(C_{10}H_8N_2)^{2+}$	$(CH_3)_3CCH_2^{\cdot}$	4.40
$Cu(NCCH_3)_4^{2+}$	$C_6H_5CH_2CH_2^{\cdot}$	6.20
$Cu(C_{10}H_8N_2)^{2+}$	$C_6H_5CH_2CH_2^{\cdot}$	7.145
$Cu(NCCH_3)_4^{2+}$	p-$CH_3OC_6H_4CH_2CH_2^{\cdot}$	4.32
$Cu(C_{10}O_2N_2)^{2+}$	p-$CH_3OC_6H_4CH_2CH_2^{\cdot}$	6.48
$Cu(NCCH_3)_4^{2+}$	$(CH_3)_2CH^{\cdot}$	6.70

Complexes of the Type $(R{\cdot}M)^{n+}$

Kochi and Rust studied the decomposition of t-butyl hydroperoxide in aqueous solution, and found that the yield of ethane increased in the presence of ions of metals with variable valency[88]: the ratio $[C_2H_6]/[CH_4] = 0.33$ in the absence of ions, and increases to 0.95, 0.95, and 4.9 in the presence of Mn^{2+}, Co^{2+}, and Ni^{2+} respectively. The yield of ethane in the presence of Fe^{2+} decreases with increasing concentration of F^- ions, which form a complex with Fe^{2+}. A similar phenomenon is observed if ethyl radicals are generated in the solution[88]: the ratio $[C_4H_{10}]/[C_2H_6]$ has the values 0.27 in the absence of metal ions, 1.05 in the presence of Co^{2+}, and 1.17 in the presence of Ni^{2+}. This result was explained by complex formation:

$$R^{\cdot} + M^{n+} \rightleftharpoons (R^{\cdot}M)^{n+},$$
$$R^{\cdot} + (R \cdot M)^{n+} \rightarrow R{-}R + M^{n+},$$
$$2(R \cdot M)^{n+} \rightarrow R{-}R + 2M^{n+}.$$

The alkyl radical is less active in the complex; this lowers the yield of methane in the case of methyl radicals, and of ethane in the case of ethyl radicals.

A similar conclusion was reached by Brackman and his coworkers in a study of the products of the radiolysis of methanol[89]. In the absence of metal ions the oxidising radicals formed by radiolysis combine rapidly to give ethylene glycol: $2{\cdot}CH_2OH \rightarrow HOCH_2CH_2OH$. In the presence of metal ions formaldehyde is produced, its appearance being explained by complex formation:

$$^{\cdot}CH_2OH + M^{n+} \overset{K}{\rightleftharpoons} (\dot{M}CH_2OH)^{n+},$$
$$(\dot{M}CH_2OH)^{n+} + {}^{\cdot}CH_2OH \overset{k}{\rightarrow} CH_2O + CH_3OH + M^{n+}.$$

The products kK of these constants calculated from the experimental results at 30°C have the values:

Ion:	Mn^{2+}	Fe^{2+}	Co^{2+}	Ni^{2+}	Cu^{2+}	Zn^{2+}
kK:	0.043	0.124	4.87	3.13	15.6	0.215

5. REACTIONS OF MACRORADICALS WITH IONS OF METALS HAVING VARIABLE VALENCY

The introduction of ions of variable valency into a system in which radical polymerisation is occurring results in retardation of the chain polymerisation owing to the termination of chains by interaction between macroradicals and metal ions. Termination takes place both on oxidising ions (Fe^{3+}, Cu^{2+}, $CeOH^{3+}$) and on reducing ions (Cr^{2+}, V^{2+}, Ti^{3+}). The mechanism of chain polymerisation in the presence of inhibitor ions can be

Table 4. Rate constants for reactions of macroradicals with metal ions.

represented by the simple scheme (where M is the monomer [and Me the metal])

$$\text{Initiator} \rightarrow r^{\cdot} \xrightarrow{M} M^{\cdot},$$
$$M^{\cdot} + M \xrightarrow{k_p} M^{\cdot},$$
$$M^{\cdot} + M^{(n+1)+} \xrightarrow{k_x} M^{+} + M^{n+},$$
$$M^{+} + H_2O \rightarrow MOH + H^{+},$$
$$M^{+} \rightarrow \text{Alkene} + H^{+}.$$

The rate of polymerisation in this system is $w = k_p[M^{\cdot}][M] = k_p[M]w_i/k_x[Me^{(n+1)+}]$ (where w_i is the rate of initiation). Measurement of the rate of polymerisation at different ionic concentrations gives the ratio of the constants k_p/k_x, and values of k_x are calculated for known values of k_p (this method has been used for the k_x in Table 4).

If values of $\lg k$(Radical + Fe^{III}) are compared for H· (Table 1) and ~$CH_2CHCONH_2$ (Table 4), where Fe^{III} reacts in the forms Fe^{3+}, $FeOH^{2+}$, $FeCl^{2+}$, a linear relation is observed:

$$\lg k(\sim CH_2CHCONH_2) = -3.2 + 0.835 \lg k(H).$$

6. REACTIONS OF PEROXY-RADICALS WITH COMPOUNDS OF METALS HAVING VARIABLE VALENCY

Salts of metals with variable valency are widely used as catalysts for the liquid-phase oxidation of hydrocarbons. The primary reason for their accelerating action on oxidation is that they break down hydroperoxides to form free radicals, and thus ensure that a chain oxidation shall be rapid. In some cases, however, salts of metals having variable valency behave as inhibitors: they retard oxidation. This is due to the termination of chains as a consequence of reactions between peroxy-radicals and the lower-valency form of the catalyst[98]: e.g.

$$RO_2^{\cdot} + St_2Co \rightarrow St_2CoOH + R'{=}O,$$
$$RO_2^{\cdot} + St_2Mn \rightarrow St_2MnOH + R'{=}O.$$

The inhibiting effect of cobalt and manganese stearates on the oxidation of cyclohexane[93], α-pinene[99], synthin[100], n-octane[101], and n-decane[102] is observed only if the catalyst is added in sufficiently high concentration (when $k[St_2Co][RO_2^{\cdot}] > k_6[RO_2^{\cdot}]^2$) in the lower valency state (Co^{III} and Mn^{III} do not retard oxidation) and if it is added at the start of oxidation (when hydroperoxide is absent, and the catalyst does not take part in the initiation of chains). During the oxidation the retarding effect of the catalyst usually disappears, firstly because a hydroperoxide has appeared and the catalyst is involved in chain initiation, and secondly as a reaction of the type $RO_2^{\cdot}$ + Co^{II} → Mol. products + Co^{III} ceases to cause chain termination, for Co^{III} immediately reacts with an oxidation product of the hydrocarbon (alcohol, ketone, or aldehyde) to form a free radical. Thus during an oxidising process the reactions between peroxy-radicals and the catalyst are converted from chain-terminating steps into chain-propagating steps involving the catalyst. This explains also the influence of the catalyst on the composition of the oxidation products of the hydrocarbons cyclohexane[103], n-decane[102], and alkanes[104]. This aspect has been discussed in detail in a review[105] and in a monograph[4].

Critical phenomena characteristic of the inhibited oxidation of hydrocarbons[106] are observed also in catalysed oxidations. A detailed study of this phenomenon has been made by Gol'dberg and Obukhova on the oxidation of n-decane in the presence of a potassium–manganese catalyst[107-109]. When a mixture of potassium and manganese stearates is added to n-decane undergoing oxidation, more prolonged inhibition is observed than in the case of manganese stearate alone. The induction period is directly proportional to $[KSt.MnSt_2]^3$. This is explained by formation of the strongly inhibiting complex $3KSt.3MnSt_2$ [107]. Complex formation is proved by electron spin resonance. A critical phenomenon is observed on the introduction of the potassium–manganese catalyst into oxidised n-decane containing a hydroperoxide[108]. When the hydroperoxide content of the decane was less than 2.3 mole % (at 140°C), addition of the catalyst was found to halt the process; but when the hydroperoxide content exceeded this value, the reaction was rapidly accelerated. The occurrence of a critical hydroperoxide concentration in this system is due to the fact that the catalyst initiates chains by reacting with the hydroperoxide at a rate $k_i[St_2Mn][ROOH]$ and terminates chains[108] by the reaction of peroxy-radicals with the complex $3KSt.3MnSt_2$.

In the course of the catalytic oxidation of n-decane the process ceases after some time. A linear relation is observed between the catalyst and hydrocarbon concentrations at this point[109]: in other words, there is a critical ratio between the concentration of the K–Mn catalyst and that of the hydrocarbon in the catalysed oxidation of n-decane.

Hence reactions of peroxy-radicals with compounds of metals having variable valency play a very important part in the mechanism of catalysed liquid-phase oxidation.

In a hydrocarbon medium peroxy-radicals react rapidly with a salt of a metal with variable valency. The rate constant for the reaction of manganese stearate with the peroxy-radical $(CH_3)_2(CN)COO\cdot$ in chlorobenzene measured by a chemiluminescent method is[110]

$$k = 2.8 \cdot 10^8 \exp(-4800/RT)\ M^{-1}\,s^{-1}.$$

The rate constant for the reaction between cobalt(II) acetylacetonate and peroxy-radicals of styrene $C_6H_5CH(OO\cdot)CH_2\sim$ in chlorobenzene is[111]

$$k = 2.9 \cdot 10^9 \exp(-7800/RT)\ M^{-1}\,s^{-1}.$$

The peroxy-radical most probably adds to the cation of the salt of the metal with variable valency, and is then converted into stable molecular products. It has been established[112] that a ketone is formed by reaction of a secondary peroxy-radical with manganese stearate, so that we can write the mechanism

$$RO_2^{\cdot} + MnSt_2 \rightarrow ROO{-}MnSt_2 \rightarrow HOMnSt_2 + R'{=}O.$$

A different type of reaction takes place between the peroxy-radical and the metal complex if the latter contains a ligand having a labile O–H or N–H bond. In this case the peroxy-radical reacts with the ligand as with an ordinary inhibitor. When copper stearate and phenyl-2-naphthylamine are added together to n-decane undergoing oxidation, they cause prolonged inhibition of the reaction[113]; the amine inhibitor is consumed rapidly, but oxidation is inhibited for many hours after it has been exhausted. The explanation offered is that the amine forms with the copper stearate a complex which has a strongly inhibiting action by reacting rapidly with the peroxy-radicals:

$$R_1R_2NH + CuSt_2 \rightleftharpoons StH + StCu\dot{N}R_1R_2,$$
$$RO_2^{\cdot} + St_2Cu\dot{N}R_1R_2 \rightarrow \text{Mol.products}.$$

Study of the inhibiting action of hydroxyquinoline complexes of metals on the oxidation of ethylbenzene[114] has provided kinetic evidence of the reaction of a peroxy-radical with a ligand in the complex. It was established by a chemiluminescent method that, with excess of hydroxyquinoline in the system, chains were terminated by reaction between peroxy-radicals and the metal–hydroxyquinoline complex, whereas the duration of the inhibition was determined by the concentration of hydroxyquinoline OxH in the solution. This corresponds to the following mechanism of inhibition:

$$M^{n+} + OxH \rightleftharpoons MOxH^{n+},$$
$$RO_2^{\cdot} + MOxH^{n+} \rightarrow ROOH + MOx^{n+}.$$

It is interesting that free hydroxyquinoline has a very weak inhibiting effect on oxidation, whereas its complexes react rapidly with peroxy-radicals.

It has been established[115] that the oxidation of cumene is inhibited by the complex of cobalt with dimethylglyoxime DM of composition $Co(DM)_2pyCl$. In this case, too, the peroxy-radical probably reacts with an O–H bond of dimethylglyoxime in the complex.

In contrast to the peroxy-radicals from hydrocarbons, the hydroperoxy-radical $HO_2\cdot$ is able to react either as oxidant or as reductant with ions of variable valency[116]:

$$HO_2^{\cdot} + Fe^{2+} \rightarrow HO_2^{-} + Fe^{3+},$$
$$HO_2^{\cdot} + Fe^{3+} \rightarrow O_2 + H^+ + Fe^{2+}.$$

The hydroxyperoxy-radical formed in the oxidation of an alcohol possesses similar dual reactivity[117]. As a consequence, copper ions are ideal negative catalysts for the chain oxidation of alcohols, which they inhibit for an infinite time[117]. The usual inhibitors are consumed during oxidation, and inhibition ceases when the inhibitor is exhausted. Negative catalysis by copper ions in an alcohol undergoing oxidation is due to the reactions

$$>C(OH)OO\cdot + Cu^{2+} \rightarrow >C{=}O + O_2 + H^+ + Cu^{1+},$$
$$>C(OH)OO\cdot + Cu^{1+} \rightarrow >C(OH)OO^- + Cu^{2+},$$
$$>C(OH)OO\cdot + H^+ \rightleftharpoons >C(OH)OOH \rightleftharpoons >C{=}O + H_2O_2.$$

Table 5 lists rate constants for the reactions of peroxy-radicals with ions and complexes of metals of variable valency. The $HO_2\cdot$ + Ion rate constants were measured by the pulse radiolysis method, except in the case of the reaction $Cu^+ + HO_2\cdot$, whose rate constant was measured by a flow method[118]. The rate constants for the reactions of peroxy-radicals with metal complexes were determined by chemiluminescence methods[114,119], except in the cases of the $RO_2\cdot$ + $Co(acac)_2$ reaction, where the rate of consumption of Co^{II} was determined[107], and the $RO_2\cdot$ + Cu^{2+} reaction, where the rate constant was calculated from the dependence oxidation of the rate on the concentration of copper ions[117].

EDTA = $(-OOC)_2NCH_2CH_2N(COO^-)_2$; Oxin =

acac = $CH_3C(O^-)=CH-C(=O)CH_3$

7. OXIDATION OF FERROUS IONS BY DIPHENYLPICRYLHYDRAZYL

Several studies have been made of the oxidation of Fe^{2+} ions by diphenylpicrylhydrazyl[121–123]. In aqueous alcohol the rate constant of this bimolecular reaction is $2.7 \times 10^{11} \exp(-13\,500/RT)$ and $1.2 \times 10^8 \exp(-8100/RT)$ $M^{-1}\,s^{-1}$ for alcohol contents of 50%[125] and 80%[126] respectively.

It is assumed that a hydrogen atom is abstracted by the radical from a ligand (alcohol molecule)[125]:

$$R^{\cdot} + Fe(ROH)_n^{3+} \rightarrow RH + [Fe(ROH)_{n-1}RO]^{2+}.$$

8. REACTIONS OF OTHER RADICALS WITH IONS

Alkoxy-radicals are oxidants and react with reducing ions. When t-butyl hydroperoxide decomposes in the presence of reducing cations in solution, t-butyl alcohol is formed[128]. This indicates that the reaction

$$(CH_3)_3CO^{\cdot} + M^{n+} \rightarrow (CH_3)_3CO^{-} + M^{(n+1)+}$$

occurs in parallel with the breakdown of $(CH_3)_3CO\cdot$ into acetone and a methyl radical. Values of the [Alcohol]/-[Acetone] ratio are given below for various reducing ions[128]:

Ion	Ti^{3+}	Fe^{2+}	Cr^{3+}	V^{3+}	$Fe(CN)_6^{4-}$	S_4O_6
[Alcohol]/[Acetone]	0.59	1.0	4.26	1.0	9.0	19

Table 6. Oxidation of iron ions by diphenylpicrylhydrazyl.

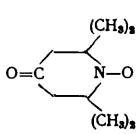
	n-C_4H_9OH 0.05 M $NaClO_4$	20	2.095	127

The reaction of the nitroxide radical



with iron ions has been studied[129]. In the presence of 0.1M HCl and 0.4M NaCl in water the rate constant is

$$k = 8.1 \cdot 10^{10} \exp(-7000/RT)\ M^{-1}\ s^{-1}\ .$$

The active radical $\cdot NO_3$ is a strong oxidant, and oxidises Ce^{3+} to Ce^{4+}. At 23 °C the rate constant of this reaction is $1.70 \times 10^6\ M^{-1}\ s^{-1}$, with $E = 1$ kcal mole^{-1}.[130]

---o0o---

Great success has been achieved by chemical kinetics during recent years in the quantitative investigation of rapid ion–radical reactions involving such species as H·, HO·, $HO_2\cdot$, and macroradicals. With few exceptions, however, the detailed mechanism of such reactions still remains obscure. An atom (a radical) may react with an ion after an intermediate stage involving substitution of a ligand in the inner coordination sphere, it may react with one of the ligands of the complex (by detaching an atom or adding to the ligand), or finally electron transfer may occur through the solvent. As is evident from the present Review, a conclusion can be reached in some cases, but in many cases the detailed mechanism of interaction between radicals and ions is obscure. A more profound understanding of the mechanism of these reactions will require elucidation of the effect of the solvent and of the ionic strength on ion–radical reactions. It is also important to know the activation energy of these reactions (in most cases the rate constants have been measured at a single temperature).

A very promising field of investigation is the formation of complexes between metal ions and free radicals. As yet such complex formation can be judged only from the changed composition of the products from radicals in the presence of ions. Such complexes are obviously short-lived labile structures. Some of them, of course, possess unusual reactivity for free radicals. Investigation of the reactions of such complexes, e.g. by a flow method, is of undoubted scientific interest.

Hardly any quantitative study has yet been made of the reactions of many radicals with ions of metals of variable valency. Such radicals include, for example, alkyl, phenyl, alkoxyl, carboxyl, and hydroxyalkyl radicals. The lack of quantitative data on the rate of these reactions does not permit assessment of their role or value in various transformations of organic compounds in the presence of ions.

Advances in the Chemistry of Aliphatic *N*-Nitrosamines

A.L.Fridman, F.M.Mukhametshin, and S.S.Novikov

The review gives for the first time a systematic account of the extensive literature data on the chemistry of aliphatic nitrosamines. A separate chapter summarises the work on the physical properties, structure, and spectra of *N*-nitroso-derivatives. The chemical behaviour of the nitrosamines is determined largely by the characteristics of the *p*-π-conjugation in the $\rangle\ddot{N}-\ddot{N}-O$ fragment. The principal chemical reactions of nitrosamines are treated from this standpoint: the denitrosation reaction, the formation of complexes, the cyclisation to sydnones and sydnoneimines, and the synthesis of lactams. In conclusion, certain aspects of the practical applications of nitrosamines are considered.
The bibliography includes 272 references.

V. Chemical properties	40
VI. Certain aspects of practical application	46

I. INTRODUCTION

N-Nitrosamines occupy an important place in the large class of nitroso-compounds. The reason for this is not only the high chemical reactivity of the nitroso-group but also the valuable products formed as a result of various reactions. It is sufficient to say that *N*-nitroso-compounds are widely used in the synthesis of diazo-derivatives and dialkylhydrazines, and are employed to prepare nitramines, sydnones, sydnoneimines, and complex compounds. The *N*-nitrosation reaction is closely related to the chemistry of carbonium ions. *N*-Nitrosamines are excellent objects for the investigation of *p*-π-conjugation, n-π^* and π-π^* transitions, and rotational isomerism.

Despite the large number of studies that have been made on nitrosamines and their theoretical and practical importance, we were unable to find any reviews on this field of chemistry. The existing reviews deal mainly with aromatic nitrosamines, or deal with highly specific problems [1-5].

The present review is the first attempt to fill this gap, and covers the fundamental studies on aliphatic nitrosamines up to 1968-1969.

The study of the chemistry of aliphatic nitrosamines began in 1863, when Geuther obtained *N*-nitrosodiethylamine by the reaction of diethylamine hydrochloride with sodium nitrite [6,7]. Subsequently the *N*-nitrosation reaction was employed by many investigators, who improved and developed it. A number of interesting studies on the chemistry of nitrosamines have been made by Soviet chemists. Significant advances in the understanding of the structure of nitrosamines were made in the 1950's and 1960's. During this period, many new reactions of nitrosamines were discovered.

II. NITROSATING AGENTS AND NITROSATION

It is believed that nitrosation is achieved by agents related to nitrous acid having the structure NOX, where X = OAlk, NO_2, NO_3, halogen, or OH_2^+. Depending on the experimental conditions, any member of this series may become the main nitrosating agent.

In the reaction of alkali metal nitrites with inorganic acid, nitrous acid is formed, its subsequent fate being determined by the reaction conditions. Thus two nitrous acid molecules can be converted via a stage involving "self-protonation" and nucleophilic attack by the nitrite ion into nitrogen trioxide, which is 6–10 times weaker than protonated nitrous acid [8,9]:

$$2HONO \rightleftarrows H_2\overset{+}{O}\cdot NO + NO_2^-,$$

$$H_2\overset{+}{O}\cdot NO + NO_2^- \rightleftarrows N_2O_3 + H_2O.$$

If a halide ion serves as the nucleophilic agent, nitrosyl halides are formed. This happens when the nitrosation is carried out in hydrogen halide solution [10,11].

In a highly acidic medium, nitrogen trioxide and nitrous acid cannot exist in a free form, and, for example in 70–80% sulphuric acid, are converted into the nitrosonium salt $NO^+HSO_4^-$. [12] Nitrosyl sulphate acid readily dissociates with formation of a nitrosonium cation [13]:

$$N_2O_3 + 3H_2SO_4 \rightarrow 2NO^+ + 3HSO_4^- + H_3O^+.$$

The nitrosonium cation is one of the most active nitrosating agents. Nitrosonium tetrafluoroborate is an interesting nitrosating substance [14]. Recently nitrosylsulphuric anhydride $HOSO_2ONO$ was proposed as an effective nitrosating compound [15].

Certain investigators [16] explain the nitrosating activity of nitrogen tetroxide by the existence of the latter in the nitrosyl nitrate form $NO.ONO_2$, which serves as a source of nitrosonium cations, like the nitrosonium salt of sulphuric acid already mentioned. The nitrosonium cation is present at high concentrations only at high acidities. In a weakly acidic medium or in the presence of an active nucleophilic agent, for example hydroxide ions, the nitrosonium cation is converted into nitrous acid and further into nitrite ions [13]:

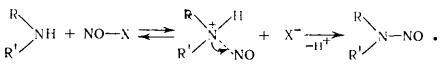
$$NO^+ + OH^- \rightleftarrows HNO_2 \rightleftarrows H^+ + NO_2^-.$$

At pH $\geqslant$ 7 the equilibrium in the reaction is completely displaced to the right.

Depending on changes in the acidity in the reaction zone, various nitrosating agents are present, which can be arranged in the following series in terms of increasing activity [11]: $NO.NO_2$, NOCl(Br, F), $NO.OH_2^+$, NO^+. Nitrous

acid and alkyl nitrites are absent from this series because free nitrous acid does not exhibit nitrosating activity [11]. In addition nitrous acid salts of primary and secondary amines have been described in a number of papers [17,18]. Alkyl nitrites are as a rule rarely recommended for *N*-nitrosation reactions.

In its simplest form the nitrosation of amines includes electrophilic attack by the nitrosating species on the lone pairs of sp^3 electrons of the nitrogen atom and subsequent deprotonation of the alkylnitrosimmonium cation [11]. In the case of secondary dialkylamines the reaction may be represented by the following scheme:



The amine participates in the reaction in a non-protonated form and therefore it is desirable to carry out the nitrosation of highly basic amines in a weakly acidic medium. Under these conditions, the comparatively inactive nitrogen trioxide or at best a nitrosyl halide will function as the nitrosating agent. With amines having a low electron density at the nitrogen atom, nitrogen trioxide proved to be less effective than the nitrosonium cation. This makes it necessary to carry out the reaction in a highly acidic medium.

Thus the acidity of the medium plays a dual role in the nitrosation of amines. Its increase enhances the concentration of the more powerful nitrosating agent ($H_2O^+.NO$, NO^+), but lowers the concentration of the active (non-protonated) form of the amines, i.e. the excess acid has an inhibiting effect, which is shown particularly clearly in the case of highly basic aliphatic amines. When the basicity of the amine is low, part of it may exist as the non-protonated species even in the presence of a considerable excess of the acid [11] and this species is in fact acted upon by the powerful nitrosating agent.

These factors must be taken into account in the nitrosation of various types of secondary amines.

III. METHODS OF SYNTHESIS OF *N*-NITROSAMINES

The methods of preparation of *N*-nitrosamines may be divided into three principal groups: 1) nitrosation of secondary amines in an acidic medium, which should include also the nitrosation of the hydrochlorides, hydrogen nitrates, and hydrogen sulphates of secondary amines by metal nitrites; 2) nitrosation with the aid of NOCl, N_2O_3, and N_2O_4; 3) nitrosation by cleaving tertiary amines. In addition, several methods of nitrosation have been described which are not of general importance at the present time.

1. Reaction of Alkali Metal Nitrites with Solutions of Amines in Acids

After the discovery of *N*-nitrosodialkylamines [6] the efforts of investigators were concentrated on the development of a convenient and reliable method for their synthesis. As early as 1865, Fischer found that, when dimethylamine hydrochloride acidified with sulphuric acid is treated with sodium nitrite in an aqueous medium, *N*-nitrosodimethylamine is formed in a high yield [19]. Subsequently acetic [20-25] or nitric [26-29] acid was employed in addition to sulphuric acid, but hydrochloric acid in fact found the widest application [30-51].

Various modifications of Fischer's method are distinguished by the procedures employed to isolate the desired products or by the temperature conditions. Nitrosamines have been extracted from the reaction medium by steam distillation [19,52-54], extraction by different solvents [20,21,30,37,50], and other methods [6,20,21,31-36]. Some investigators carried out the nitrosation reaction with cooling (usually to 0–5 °C), [20,27,36,40,41,45-51,55-58] while others heated the reaction mixture [6,22,31,36,38,52,54,59-61]. However, temperature is in fact an important factor in the reaction. In an acidic medium it is desirable to carry out the process at a low temperature to avoid denitrosation, which is acid-catalysed. If the acidity in the reaction zone is low, the process usually takes place at an elevated temperature [60,61], which has a favourable effect on the yield of the final product and reduces the duration of the reaction. It is not fortuitous that, in the synthesis of nitrosamines, many investigators treated secondary amine hydrochlorides with an excess of sodium or potassium nitrite at room or higher temperature without additional acidification [6,21,37,55,59,62-69].

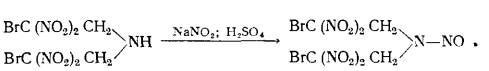
By virtue of its simplicity, nitrosation in an acidic medium has been more widely used than other methods [70-72]. The considerable range of applications of "acid" nitrosation is shown by its employment to synthesise many nitrosamines containing various substituents in the alkyl residue: aryl groups [23,35,36,39,57,63,73-75], halogens [21,59,76,77] and keto- [22,41,64], ester [32-34,62,78,79], carboxy- [37,40,45,50,56], hydroxy- [21,57,61,73], alkoxy- [20,53], nitrile [26,46-49,51,78,80], nitrate [27], sulphate [81], and nitro-groups [55]. Nitrosation in an aqueous solution of an inorganic acid has been used to synthesise dinitroso-compounds based on *N*-alkyl-substituted ethylenediamines [30,68] and nitrosamines containing an olefinic residue at the nitrogen atom [22,82]. In acetic acid a number of labelled [^{14}C]-*N*-nitrosodialkylamines have been synthesised [83].

Taylor and Price [84] attempted to determine the concentration of nitrous acid necessary for successful reaction. They showed for dimethylamine that, when equimolar amounts of the reagents (0.05 *N* amine + 0.05 *N* HNO_2) are mixed, the reaction does not occur. With increase of the concentration of nitrous acid to 0.1 *N*, an adduct with the composition $[(CH_3)_2NH_2]^+.[NO_2]^-.[HNO_2]$ is formed, but the formation of *N*-nitrosodimethylamine was not observed.

The formation of nitrous acid salts in the reaction between secondary α-arylamine hydrochlorides and sodium nitrite in ethanol was observed even earlier by Curtius [17,85,86]. On prolonged refluxing in ethanol, the nitrite salt of the amine is converted into the corresponding nitrosamine:

Ring-substituted *N*-nitrosodibenzylamines have been synthesised in this way. Some investigators employed silver nitrite instead of sodium nitrite [87,88]. The results of the studies quoted [17,84-88] confirm that in the nitrosation of fairly basic amines the reaction must be carried out at comparatively high temperatures.

The dependence of the reaction conditions on the basicity of the amine is also illustrated, for example, by *N*-nitrosodi-(2-bromo-2,2-dinitroethyl)amine, which was obtained by treating di-(2-bromo-2,2-dinitroethyl)amine with sodium nitrite in concentrated sulphuric acid [29]:



In trifluoroacetic acid and trifluoroacetic anhydride, *N*-nitrosodi-(2,2,2-trinitroethyl)amine was obtained from di-(2,2,2-trinitroethyl)amine [89].

In contrast to the work of Curtius and Taylor, in the studies quoted above the nitrosation of weakly basic amines was investigated and the reaction carried out in a strongly acidic medium.

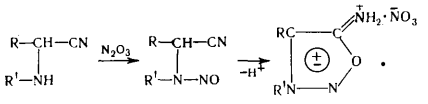
2. Reaction of Nitric Oxide, Nitrogen Trioxide, Nitrogen Tetroxide, and Nitrosyl Chloride with Secondary Amines

The first studies where the application of nitrogen trioxide as the nitrosating agent in the series of aliphatic amines was reported were carried out towards the end of the nineteenth century. Paulman [90], who investigated the properties of sarcosine, found that it reacts readily with "gaseous nitrous acid", forming a nitroso-derivative. Subsequently nitrosiminodiacetic acid [91,92] and di-(2-azapropyl-2-nitroso-3-phenyl)methanol [93] were synthesised in a similar way. The reaction was carried out in an aqueous medium:

$$(HOOCCH_2)_2NH \xrightarrow{N_2O_3;\ H_2O} (HOOCCH_2)_2N{-}NO\ .$$

The dinitrile and the dimethyl esters of nitrosiminodiacetic acid were obtained with nearly quantitative yields in ether [94].

Brookes and Walker [95], who allowed nitrogen trioxide to react with α-aminoacetonitriles, observed that the former is not only a nitrosating agent but also promotes the cyclisation of the intermediate *N*-nitrosoacetonitriles to sydnoneimines:



Despite the fact that the method of introduction of the nitroso-group with the aid of nitrogen trioxide gives as a rule good results, it has not found as wide an application as "acid" nitrosation. This is probably because the process is complicated by the necessity to obtain nitrogen trioxide. The latter is usually obtained from sodium nitrite and sulphuric acid [95] or by the reaction of nitric acid with arsenic oxides [94].

Above its boiling point nitrogen trioxide readily decomposes into NO and NO_2. This property constitutes the basis of the synthesis of nitrosamines. Thus *N*-chlorodialkylamines are readily converted into *N*-nitrosodialkylamines when acted upon by nitric oxide in solutions containing the redox system Fe^{3+}/Fe^{2+} or Cu^{2+}/Cu^{+}. [96] Similarly *N*-nitrosodi(trifluoromethyl)amine was synthesised from *N*-bromodi(trifluoromethyl)amine [97]. A radical mechanism was proposed for the reaction:

$$R_2N{-}Hal \rightarrow R_2N^{\cdot} + Hal^{\cdot},$$
$$Hal^{\cdot} + NO \rightarrow \dot{N}O,$$
$$R_2N^{\cdot} + \dot{N}O \rightarrow R_2N{-}NO\ .$$

The gas-phase or liquid-phase nitrosation of secondary alkylamines probably takes place by a radical mechanism [98,99]. The reaction is performed in an autoclave at a high temperature, after mixing nitrogen oxides and the amine. Judging from patent data, *N*-nitrosodialkylamines are formed when nitric oxide reacts with secondary amines under pressure in the presence of transition metal salts, metallic nickel, palladium, or rhodium [100]. *N*-nitrosodiethylamine is formed when the adduct of diethylamine with nitric oxide is decomposed in the presence of oxygen [101]. The kinetics of the reaction of diethylamine with nitric oxide have been investigated. The reaction is of first order with respect to diethylamine and proceeds via the intermediate adduct $(C_2H_5)_2NH.N_2O_2$, which reacts with a second molecule of nitric oxide and then with diethylamine. The activation energy for the reaction is 12 kcal mole^{-1}. [102]

The use of nitrogen tetroxide and nitrosyl chloride as nitrosating agents has been insufficiently investigated although they have been known for a long time and are used for the nitrosation of amines and amides [16,89,103]:

$$[(NO_2)_3CCH_2]_2NH + N_2O_4 \xrightarrow{CH_3COOH+CH_3COOK} [(NO_2)_3CCH_2]_2N{-}NO + HNO_3\ ,$$
$$Et_2NH_2 \cdot NO_3 + NO \cdot NO_3 \rightarrow Et_2N{-}NO + 2HNO_3\ .$$

The reaction of nitrosyl chloride with secondary amines was investigated by Solonina [104]. When nitrosyl chloride was passed into a solution of the amine in ether, *N*-nitroso derivatives of dipropyl-, di-isobutyl-, and dipentyl-amines were synthesised. Later it was shown that the reaction of nitrosyl chloride with diethylamine hydrochloride results in a quantitative yield of the *N*-nitroso-derivative:

$$Et_2NH_2 \cdot Cl + NOCl \rightarrow Et_2N{-}NO + 2HCl\ .$$

The synthesis of *N*-nitroso-di-t-butylamine in 23% yield from di-t-butylamine and nitrosyl chloride has been described [105].

3. Cleavage of Tertiary Amines Accompanied by Nitrosation. Syntheses of Nitrosamines from Primary Amines

Until recently there has been no unanimous view on the cleavage of tertiary amines with nitrous acid. Not until 1967 was it shown convincingly that tertiary amines can be converted into nitrosamines by nitrous acid [106], although examples of this reaction were known in the past century. Geuther [107] obtained *N*-nitrosodiethylamine from triethylamine, but Heintz [108] was unable to reproduce his results and arrived at the erroneous conclusion that tertiary amines do not react with nitrous acid. This initiated the controversy which continued for more than one hundred years. Subsequently the validity of Geuther's results was confirmed by Solonina [109], who investigated the cleavage of forty nitrite salts of amines and in all cases observed the formation of nitrosamines, and also by other investigators [110-112]. The cleavage of tertiary amines by nitrous acid is discussed in detail in the literature [106,112].

The most probable mechanism of the cleavage includes attack by the nitrosating agent on the free electron pair of the nitrogen atom and the formation of the nitrosimmonium ion. The latter splits off the "nitroxyl" (HNO) and hydrolyses under the reaction conditions to a secondary amine. A ketone or an aldehyde is formed as a side product [106]:

$$R_2N{-}CHR_2' \xrightarrow{HNO_2} R_2\overset{+}{N}\!\!<^{CHR_2'}_{NO} \rightarrow R_2\overset{+}{N}{=}CR_2' + HNO\ ,$$
$$R_2\overset{+}{N}{=}CR_2' \xrightarrow{H_2O} R_2'C{=}O + R_2\overset{+}{N}H_2 \xrightarrow{HNO_2} R_2N{-}NO\ ,$$
$$2HNO \rightarrow H_2N_2O_2 \rightarrow H_2O + N_2O\ .$$

The degree of conversion of the tertiary amine into the nitrosamine reaches 50–70%.

The cleavage of tertiary amines with nitrous acid and nitrosyl chloride has been described [103]. Thus, on refluxing in alcohol with nitrous acid, tribenzylamine is smoothly converted into *N*-nitrosodibenzylamine and benzaldehyde.

The results obtained with nitrosyl chloride are contradictory. In an early study Solonina noted that tri-isobutylamine is cleaved with nitrosyl chloride to *N*-nitrosodi-isobutylamine [104]. According to these data [114], when cyclohexyldimethyl- and dicyclohexylmethyl-amines are acted upon by nitrosyl chloride, *N*-nitrosocyclohexylmethyl- and *N*-nitrosodicyclohexyl-amines are formed respectively. In another publication [115] it was noted that the reaction of trimethylamine with nitrosyl chloride gives only the hydrochlorides of di- and tri-methylamines: the reaction with tribenzylamine results in the formation of the hydrochlorides of tribenzylamine and dibenzylamine and of benzaldehyde [106]. The same products are formed in the reaction of tribenzylamine with nitrosonium tetrafluoroborate [106]. Probably the basicity of the nitrogen atom is important for the cleavage of tertiary amines to the corresponding *N*-nitroso-compounds. For example, triglycineamine, the basicity of the nitrogen atom in which is reduced, is incapable of undergoing cleavage with nitrosation [116]. Diethylaminotrimethylsilane is readily cleaved by nitrosyl chloride [117]:

$$(C_2H_5)_2NSi(CH_3)_3 + NOCl \rightarrow (C_2H_5)_2N{-}NO + (CH_3)_3SiCl .$$

In 1920 a method for the preparation of *N*-nitrosodialkylamines by the cleavage of tertiary amines with tetranitromethane was discovered. The reaction takes place when alcoholic solutions of tertiary amines are heated with tetranitromethane in the presence of pyridine [118]:

$$R_1R_2NCH_2R + C_5H_5N + C(NO_2)_4 \rightarrow R_1R_2N{-}NO + RCHO + C_5H_5N \cdot HC(NO_2)_3 .$$

A large series of *N*-nitrosodiaryl-, *N*-nitrosoarylalkyl-, and *N*-nitrosodialkyl-amines was synthesised by this procedure. Subsequently a similar cleavage was achieved in the absence of pyridine in acetic acid [119]. Nitroform is formed as a side product.

In connection with the nitrosating activity of tetranitromethane, it is interesting to note that this compound exhibits nitrosating and nitrating properties in relation to aromatic compounds [120-122], a nitro-group can be replaced by a halogen [123,124] or an alkyl residue in polar aprotic solvents [125], and is tetranitromethane capable of a number of other extremely interesting reactions [126-128].

Cleavage of tertiary amines accompanied by nitrosation takes place also under the action of bromonitroform in chloroform. This is accompanied by the bromination and nitration of the benzene ring. Thus the reaction of bromotrinitromethane with dimethylaniline leads to the formation of *N*-methyl-*N*-nitroso-*p*-bromoaniline and *NN*-dimethyl-*p*-nitroaniline [129].

In his study of the reaction of silver nitrite with the hydrochlorides of n-propyl- and n-butyl-amines, Meyer observed that, together with other products, low yields of *N*-nitrosodipropyl- and *N*-nitrosodibutyl-amines are formed in this process [130,131]. Deamination of n-propylamine gave a mixture of propanol, 2-propanol, and *N*-nitrosodipropylamine [132].

Under thermolysis conditions, the nitrite salts of methyl- and ethyl-amines tend to undergo similar reactions [18].

When ethyl- and isobutyl-amines were treated with nitrosyl chloride in ether, *N*-nitrosodiethyl- and *N*-nitrosodi-isobutyl-amines were formed together with corresponding alkyl chlorides. It is interesting that the author explained "their formation (nitrosamines) via the preliminary synthesis of secondary amines by the action of the alkyl chlorides on the primary amines". Seconday amines are then converted into nitroso-compounds [133].

Although the method of preparation of the nitrosamines from primary amines has no preparative importance, it is interesting from the theoretical standpoint. Since the mechanism of the denitrosation of amines is presumed to involve the formation of an intermediate carbonium ion [11], the results described above can be accounted for by the alkylation of the primary amine by the carbonium ion:

$$RNH_2 \xrightarrow{HNO_2} R{-}N{=}N{-}OH \xrightarrow{H^+} R^+ ,$$

$$RNH_2 + R^+ \rightarrow \underset{\displaystyle R}{\overset{\displaystyle +}{R}}NH_2 \xrightarrow[-H_2O]{HNO_2} R_2N{-}NO .$$

Cleavage of amines accompanied by nitrosation is of preparative interest as a method for the purification of secondary amines. Thus, when a mixture of primary, secondary, and tertiary amines is treated in succession with a nitrosating agent and potassium permanganate, only the *N*-nitrosodialkyl-amine remains [134]. A method for the synthesis of pure *N*-nitrosodialkylamines by the nitrosation of a mixture of di- and trialkylamines has also been described [104,110].

4. Other Methods

The preparation of *N*-nitrosodipropylamine from the nitrite salt of dipropylamine by fusing the latter or heating it in water has been described [135]. *N*-Nitrosodimethyl- and *N*-nitrosodiethyl-amines are formed when nitrite [18] and nitrate salts of dimethyl- and diethyl-amines are heated [136], via the following mechanism:

$$(CH_3)_2NH \cdot HNO_3 \xrightarrow{\Delta} (CH_3)_2NH \cdot HONO \rightarrow (CH_3)_2N{-}NO + H_2O + O .$$

N-Nitrosodibenzylamine was isolated when tetrabenzylhydrazine [137] and *NN*-dibenzylhydroxylamine were treated with nitric acid [35]:

$$(C_6H_5CH_2)_2N{-}X \xrightarrow{HNO_2} (C_6H_5CH_2)_2N{-}NO;\ X{=}OH;\ N(CH_2C_6H_5)_2 ,$$

It has been reported that *N*-nitrosodibenzylamine is formed when isopentyl nitrite reacts with dibenzylamine [138]. Titov employed benzyl nitrite to nitrosate diethylamine [139]; a continuous method for the synthesis of *N*-nitrosodimethylamine with a yield in excess of 90% by the nitrosation of dimethylamine in alcohol with methyl nitrite has been described [140].

The formation of *N*-nitrosodi-isopropyl-, *N*-nitrosodibutyl-, and *N*-nitrosodi-(β-nitroxyethyl)amines has been observed in the catalytic nitration of the corresponding amines in the presence of zinc chloride [27,141]. In this connection, one may note that the catalytic effect of Cu^{2+} ions in the nitrosation of diethylamine in methanol with nitric oxide under pressure has also been investigated [142,143]. The effects of temperature, pressure, and the concentration of nitrogen oxides on the mode of reaction have been studied. The optimum yield of *N*-nitrosodiethyl-amine (93.8%) is attained in the reaction carried out at 30°C at a pressure of 1 atm. The reduction of temperature to −30°C, an increase of pressure, and an increase of the concentration of nitric oxide leads to a fall of the yield of the nitrosamine to 11–15% owing to the formation of methyl nitrite. The nitrosating species is $CuNO^{2+}$. The kinetics of the reactions were investigated.

According to patent data, when 1,1,1,6-tetranitro-3,6-diazaheptane is nitrated with a mixture of acetic anhydride and nitric acid, 1,1,1,6-tetranitro-3-nitroso-3,6-diazaheptane is formed [144]. We believe that this result is most probably "fortuituous". It is likely that the authors employed nitric acid containing a high content of nitrogen oxides, which were in fact responsible for the nitrosation of the amine.

Nitration of a ternary mixture of ammonium chloride, the ammonium salts of nitroform and di-(2,2,2-trinitroethyl)amine, formed in the condensation of methylenediamine hydrochloride with 2,2,2-trinitroethanol, and nitric acid in acetic anhydride leads to the formation of *N*-nitrosodi-(2,2,2-trinitroethyl)amine with an admixture of the nitramine [89]. The authors attribute the appearance of the *N*-nitroso-derivative to the catalytic effect of the chloride ions. The capacity of a mixture of acetic anhydride and nitric acid to behave as a nitrosating agent was noted by Wright and coworkers [27]. However, the nitrosation of di-(2,2,2-trinitroethyl)amine in this mixture can also take place in the absence of chloride ions under the action of N_2O_4.

The formation of *N*-nitrosodi-(2,2,2-trinitroethyl)amine was observed in the condensation of 2,2,2-trinitroethanol with hydroxylamine and also in the reaction of nitroform with formaldoxime in the presence of sulphuric acid [89]. The mechanism of the reaction was not established:

$$2\,HC(NO_2)_3 + 2\,CH_2{=}NOH \xrightarrow{H_2SO_4} [(NO_2)_3CCH_2]_2N\text{-}NO.$$

IV. PHYSICAL PROPERTIES, STRUCTURE, AND SPECTRA

1. General Characteristics

In the wide class of *N*-nitrosodialkylamines, the properties of the simplest members (*N*-nitrosodimethyl- and *N*-nitrosodiethyl-amines) were most fully investigated. The lower *N*-nitrosodialkylamines are yellow or yellow-green non-hygroscopic liquids, which are partially soluble in water and readily soluble in organic solvents. Their boiling points increase with the increasing size of the alkyl substituents and lie in the range 150–220°C. As a rule, substituted nitrosamines are yellow crystalline compounds. In this connection, it is important to note that *N*-nitrosopolynitroalkylamines are colourless, which is undoubtedly due to the effect of the polynitroalkyl substituents on the $p-\pi$ conjugation in the nitrosamines. Compared with the related nitramines, *N*-nitrosodialkylamines have lower boiling and melting points. The densities of the majority of nitrosamines are relatively low and lie in the range 0.9–1.2 g cm^{-3}, increasing with the molecular weight.

The dipole moments of *N*-nitrosodialkylamines are evidence of a considerable polarity of the molecules. For example, the dipole moment of *N*-nitrosodimethylamine is 3.98 D, [145] while that of *N*-nitrosodibutylamine is 4.32 D. [146] The introduction of electron-accepting substituents into the molecule leads to a decrease of the dipole moment. Thus the dipole moment of *N*-nitroso-*N*-phenylaminoacetic acid is 3.18 D [147] and those of *N*-nitrosomethylaniline and *N*-nitrosodiphenylamine are 3.62 and 3.39 D respectively [148]. The replacement of each methyl group by a phenyl group leads to a decrease of the dipole moment of the nitrosamine by 0.3 D. [148] Therefore we believe that it is of interest to investigate the dipole moments of nitrosamines with other electronegative substituents such as trifluoro-, trichloro-, and trinitromethyl groups, which will make it possible to trace their effect on the conjugation in the nitrosamino-group by the dipole moment method.

The average refraction of the N–N bond in *N*-nitrosodialkyl-amines hardly differs from the value in asymmetric dialkyl-hydrazines and amounts to 1.99. The refraction of the >N–N=O fragment is 7.748 and slightly exceeds the group refraction in dialkylhydrazines [54,149]. The parachors of the N=O and >N–N=O groups in a number of *N*-nitrosodialkylamines have been determined and the average values of these quantities have been found to be 53.4 and 68.0 respectively [54,149].

The literature quotes certain thermochemical parameters for *N*-nitrosodimethylamine: heat of combustion (382 ± 1.5 kcal $mole^{-1}$), heat of formation in the standard state (−10.7 ± 1.5 kcal $mole^{-1}$), heat of evaporation (9.9 ± 0.5 kcal $mole^{-1}$), and heat of formation in the gas phase (−0.8 ± 2 kcal $mole^{-1}$). [150]

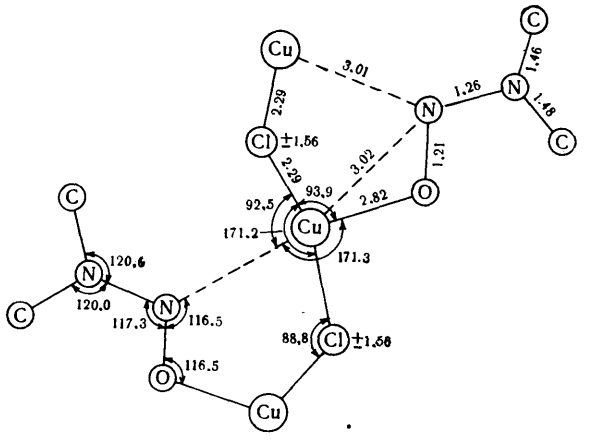
The dissociation energy of the N–N bond in *N*-nitrosodimethylamine, determined by the electron impact method, is 43 kcal $mole^{-1}$, [151] while according to other data it is 32 kcal $mole^{-1}$. [152] This quantity was recently estimated more accurately in a study already quoted [150] and was found to be 55.2 kcal $mole^{-1}$. Thus, contrary to earlier data, the N–N bond in *N*-nitrosodimethylamine proved to be stronger than in *N*-nitro-di-methylamine to the extent of 14.1 ± 5.2 kcal $mole^{-1}$ according to thermochemical data and 11.3 ± 3.0 kcal $mole^{-1}$ according to kinetic data [150]. These data appear to be the most correct, since they are consistent with the hypothesis of $p-\pi$ conjugation in the nitrosamine group, as a result of which the amount of N–N multiple bond character in nitrosamines is enhanced (about 49%) compared with that in nitramines (about 15%). [153–155]

2. Structure and Spectra

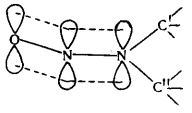
The molecules of aliphatic nitrosamines have coplanar structures in the gaseous and crystalline states. Both nitrogen atoms are in the state of sp^2 hybridisation, which is confirmed by the C′–N–N (120.3°), C″–N–N (116.4°), and N–N–O (113.6°) valence angles in *N*-nitrosodimethylamine. The bond lengths in *N*-nitrosodimethylamine are as follows: 1.235 Å for N–O, 1.344 Å for N–N, 1.461 Å for C–N, and 1.129 Å for C–H. It is interesting that the N–N bond in *N*-nitrosodimethylamine is shorter by 0.04 Å than in *N*-nitrodimethylamine, which has been attributed to the greater electron-accepting activity of the nitroso-group compared with the nitro-group [156]. The N–N bond length in *N*-nitrosodimethylamine agrees well with its enhanced multiplicity and strength compared with those in *N*-nitrodi-methylamine.

The planar disposition of the nitrosoamino-group has been established by an X-ray diffraction study of the adduct of *N*-nitrosodimethylamine with copper chloride. The bond between the copper atom and the nitrosamine is formed via the oxygen atom of the nitroso-group. The nitrogen atom of the nitroso-group is located at equal distances from the neighbouring copper atoms. The considerable difference between the Cu–O and Cu–N distances may be due to the fact that the copper atom is displaced by 0.2 Å from the plane passing through the chlorine atoms [157]. The shortening of the N–N bond in the complex compared with the free nitrosamine can be

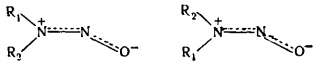
accounted for by the transfer of electron density from the dimethylamino-group to the nitroso-group [156]:



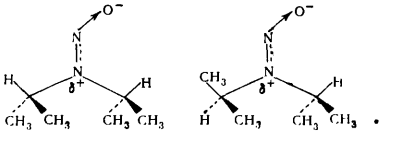
The disposition of the atoms in the nitrosamino-group in one plane naturally facilitates the overlapping of the *p* orbital of the amino-nitrogen atom with the π-electron cloud of the N⋯O bond. The force constant of the N⋯O bond in nitrosamines is 6.8 mdyn Å^{-1}. [158] According to this value, the multiplicity of the N⋯O bond in nitrosamines is between 1 and 1.5:



In a number of studies the internal rotation about the N–N bond with partial double bond character was investigated. The barrier to rotation about this bond is estimated as approximately 24 kcal mole^{-1}. [159–161] This leads to the appearance of *s-cis-trans* isomerism in nitrosamines. The presence of the isomers of a large number of *N*-nitroso-derivatives has been demonstrated by NMR spectroscopy [162,163]:



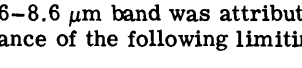
Only the *cis*-methyl isomer has been detected for *N*-nitrosomethylphenylamine. Both isomers have been found for *N*-nitrosoethylphenylamine and *N*-nitrosoisopropylphenylamine. The conformations of the alkyl substituents in *N*-nitrosoisopropylmethyl-, *N*-nitroso-t-butylmethyl-, and *N*-nitrosodi-isopropyl-amines are discussed in the same paper. The following conformations are characteristic of *N*-nitrosodi-isopropylamine:



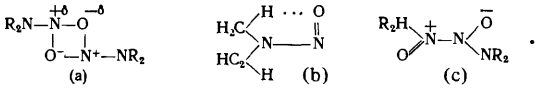
ΔH for the *cis–trans* isomerisation of *N*-nitrosobenzylmethyl-amine is less than 1 kcal mole^{-1}. [158] The *cis-trans* isomers of benzyl-2,6-dimethyl-*N*-nitrosoanilines were separated by thin-layer chromatography. The bulky 2,6-dimethylphenyl group evidently stabilises the isomers. Both substances are stable in the crystalline state [162]. Rotational isomerism has also been observed for *N*-nitrosobenzylisopropylamine [164,165]. The equilibrium mixture of the isomers was separated into its components by crystallisation from carbon disulphide [165]. The ratios of the areas of proton signals for certain *cis*- and *trans*-isomers have been investigated as a function of the bulk of the alkyl substituents. The screening of the protons of the *cis*-isomers is more pronounced than that of the protons of the *trans*-isomers, owing to the diamagnetic anisotropy of the N=O bond [166].

In a study of the optical rotatory dispersion it was observed that an intense cotton effect is characteristic of various nitrosamines in the range 350–400 nm. [167] The $n-\pi^*$ and $\pi-\pi^*$ transitions are active in the nitroso-chromophores [168–171]. For example, in aqueous solution of *N*-nitrosodimethylamine the $\pi-\pi^*$ transition is shown in the region of 228 nm and the $n-\pi^*$ transition in the region of 332 nm. [169] The studies on the optical circular dichroism of nitrosamines have been reviewed in a monograph [172]. The sector rule for nitrosamines and its correlation with the stereochemistry of these compounds have been described [161].

Although a large number of infrared spectra of nitrosamines have been described in the literature, few systematic accounts of the assignments of the absorption frequencies are available [77,159,173–180]. In one of the first detailed studies of the infrared spectroscopy of nitrosamines, Haszeldine and Jander [174] drew attention to the inconsistency between the absorption bands of the N=O bond in nitrosamines and those for nitramines, nitrites, and *C*-nitroso-compounds. They observed in the infrared spectra of nitrosamines three relatively intense bands in the region of 7.1–7.4, 7.6–8.6, and 9.15–9.55 μm. The first two were assigned to the vibrations of the N=O bond and the last to the vibrations of the N–N bond. The appearance of the 7.6–8.6 μm band was attributed by the authors to the resonance of the following limiting structures:



To confirm these conclusions, a study was made of the effect of various solvents and the state of aggregation on the nature of the spectral changes [77,175]. It was found that the spectra of nitrosamines in the liquid state differ from those recorded in solvents (carbon tetrachloride and chloroform), particularly in the range of frequencies characteristic of the N=O bond. The authors attribute these changes to three causes: (a) dipole–dipole interaction between molecules, (b) intramolecular binding of the alkyl hydrogen by the oxygen atom of the nitroso-group, and (c) dimerisation of the molecules:



The predominance of a particular type of interaction depends on the conditions under which the nitrosamine exists. In the gaseous states the molecules are of course not associated and therefore the N=O absorption band is closer to that in the spectra of nitramines. In the liquid state monomer–dimer equilibrium obtains and the N=O absorption band is displaced towards longer wavelengths (6.74 and 6.93 μm respectively for *N*-nitrosodiethylamine).

Polar solvents have a similar effect. The N–N absorption band varies in exactly the same way. For example, in the spectrum of gaseous *N*-nitrosodiethylamine it is in the region of 9.55 μm and in that of the liquid substance it is displaced to 9.35 μm. The idea of a monomer–dimer equilibrium in nitrosamines was supported by Tarte [176] and by Piskorz and Urbański [177].

An interesting observation was made in a study of the infrared spectrum of *N*-nitrosodi-(2,2,2-trifluoroethyl)-amine, one of the few *N*-nitroso-derivatives containing electron-accepting substituents [77]. In this substance the N=O absorption bands are displaced under the influence of the trifluoroalkyl groups towards shorter wavelengths and are located in the region of 6.45 μm for the gaseous nitrosamine and in the region of 6.60 μm for the liquid substance. The displacement of the bands was attributed by the authors to a decrease of the polarity of the *N*-nitrosodi-(2,2,2-trifluoroethyl)amine molecule, which reduces sharply the interaction between the individual molecules. It is interesting that the N–N bond vibration frequencies in *N*-nitrosodi-(2,2,2-trifluoroethyl)amine in solution, or following a change in the state of aggregation, are displaced less than for unsubstituted nitrosamines.

Williams et al. [178], who postulated the occurrence of mesomerism in nitrosamines, suggested that, when the spectra are recorded in polar solvents, the absorption bands associated with the N=O bond vibrations (6.6–6.7 μm) should be displaced towards longer wavelengths. On the other hand, the N–N absorption band should be shown at lower wavelengths. This hypothesis was confirmed experimentally. In the spectra of *N*-nitrosodimethylamine in carbon tetrachloride and methylene bromide $\lambda_{N=O}$ is 6.85 and 6.94 μm, the corresponding values for the N–N absorption band (λ_{N-N}) being 9.66 and 9.52 μm. An analogous situation was found in the spectra of other nitrosamines.

The wavelength corresponding to the N=O bond in the nitrosamines is much higher than for *C*-nitroso-derivatives which can be accounted for by the greater contribution to the structure of nitrosamines of the canonical form (II). [178] The hypothesis of the dimerisation of nitrosamines put forward by Haszeldine and coworkers was rejected by Williams [178] and other investigators [171,179,180].

The Table summarises the principal literature data on the infrared spectra of nitrosamines.

Comparison of the infrared spectra of *N*-nitrosodi-(2,2,2-trifluoroethyl)amine with those of unsubstituted analogues demonstrates that electron-accepting substituents have a significant influence on the structure of the nitrosamino-group, probably by reducing the degree of p-π conjugation. This conclusion has been confirmed experimentally in a study of the chemical properties of *N*-nitrosopolynitroalkylamines. It is significant that in the infrared spectrum of *N*-nitrosodi-(2-bromo-2,2-dinitroethyl)amine and *N*-nitrosodi-(2,2,2-trinitroethyl)amine, bands with ν_{NO} = 1490 and 1520 cm^{-1} and ν_{N-N} = 980 and 1020 cm^{-1} respectively are characteristic of the nitrosamino-group†.

In the ultraviolet spectra of nitrosamines there are two absorption bands in the region of 235 and 365 nm, [174] 230 and 374 nm, [177] 230 and 365 nm, [77] and 228 and 332 nm [169] (in water). The first of these is more distinct than the second. The bands were assigned by comparing the spectra of nitrosamines with those of nitrites and nitramines. In the ultraviolet spectra of nitramines, there is a strong absorption in the region close to 235 nm and in the spectra of nitrites in the region of 375 to 380 nm. [77,175] Therefore the absorption band in the region of 230–235 nm in the spectra of nitrosamines characterises the N–N bond and the absorption in the region of longer wavelengths is due to the N=O bond [175].

The positions of the bands in the ultraviolet as well as infrared spectra, depend greatly on the nature of the solvent. For example, on passing from a non-polar solvent to water, the 365 nm band is displaced to 331 nm. This shows that the N=O bond is sensitive to external effects. A similar observation was made in a study of the ultraviolet spectrum of *N*-nitrosodi-(2,2,2-trinitroethyl)amine [89].

Electron-accepting substituents have an appreciable effect on the absorption by the nitroso-group. Whereas the absorption by the N=O bond in *N*-nitrosodiethylamine occurs in the region of 360 nm, in the *N*-nitroso-derivatives of di-(2,2,2-trinitroethyl)-, di-(2-bromo-2,2-dinitroethyl)-, and di-(2,2,2-trifluoroethyl)amines it is displaced to the region of 380 nm. Information about these effects of the nature of the substituent on the >N–N=O fragment is also provided by mass spectrometric data. For example, *N*-nitrosodimethylamine dissociates with formation of $C_2H_4N^+$ as the major ion (19.2%), while *N*-nitroso-di(trifluoromethyl)amine gives the CF_3^+ major ion (37.8%). [181]

V. CHEMICAL PROPERTIES

Aliphatic nitrosamines are highly reactive. The reason for their reactivity is that the nitrosamino-group has four lone pairs of electrons, which make nitrosamines potential Lewis bases. The occurrence of p-π conjugations with the withdrawal of the electron cloud towards the oxygen atom is responsible for many interesting reactions of nitrosamines. In the first place these are the complex-formation reactions, reaction with inorganic acids, reduction to *NN*-substituted hydrazines, oxidation and nitration, cyclisation to sydnones, and sydnoneimines, and photochemical reactions.

†The absorption frequencies were assigned by the authors of the review on the basis of the spectra quoted by Grimes et al. [89]

2. Reaction with Inorganic Acids, Hydrogen Bonds, and Complex-formation Capacity of Nitrosamines

When inorganic acids act upon nitrosamines, the nitroso-group is split off with formation of amine salts. In one of the first studies [6] it was already noted that, when hydrogen chloride is passed into an emulsion of *N*-nitrosodiethylamine in water, the nitroso-derivative rapidly dissolves. When an ethereal solution of *N*-nitrosodiethylamine is treated with hydrogen chloride, a salt with the composition $(C_2H_5)_2NNO.HCl$ is formed, and then readily decomposes on addition of water or alcohol [52].

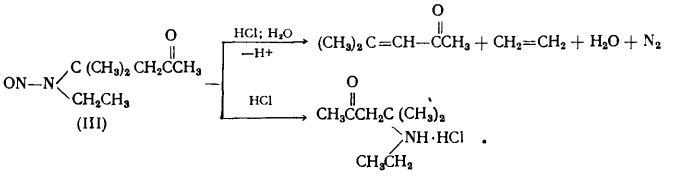
N-Nitrosodimethylamine decomposes on heating with hydrochloric acid into dimethylamine hydrochloride and nitrous acid. Hydrochloric acid acts similarly on *N*-nitrosodibutylamine [31], *N*-nitrosomethylallylamine [82], *N*-nitrosodibenzylamine, and others [43,55,182]:

$$R_1R_2N{-}NO \xrightarrow{HCl;\ H_2O} R_1R_2NH \cdot HCl + HNO_2 .$$

Hydrogen chloride has a more pronounced denitrosating activity [6,42,113,134]. Some investigators have also proposed a method for the preparation of pure secondary amines involving the treatment of nitrosamine solutions in ether or toluene with hydrogen chloride [42,134].

It is interesting that the denitrosation takes place more readily than the hydrolysis of the nitrile group. Thus, in an attempt to hydrolyse the dinitrile of *N*-nitrosiminodiacetic acid, Curtius [94] isolated as the main product the hydrochloride of the dinitrile of iminodiacetic acid.

The carbonyl group has a significant influence on the result of the denitrosation. When the nitroso-derivative (III) is treated with hydrochloric acid, ethylene and mesityl oxide are formed [41]. In contrast to hydrochloric acid, hydrogen chloride has only a denitrosating effect:



It has been noted that, when *N*-nitrosopolynitroalkylamines are denitrosated, it is impossible to isolate the salts of polynitroalkylamines or the free amines. Evidently in this case a more profound degradation of the molecule takes place, owing to the reduced basicity of the amino-nitrogen in polynitroalkylamines [89,183].

Apart from hydrochloric acid and hydrogen chloride, bromine and sulphuric acid have been used as denitrosating agents [113,184]:

$$(C_6H_5CH_2)_2N{-}NO \xrightarrow[-NO]{Br_2} (BrC_6H_4CH_2)_2NH \cdot HBr .$$

The study of the kinetics of the cleavage of aliphatic nitrosamines by acids led to the hypothesis that the splitting off of the nitroso-group is preceded by the occurrence of an equilibrium between the nitrosamine and its protonated form. The protonated nitrosamine then splits off the nitroso-group in the form of the nitrosonium cation and is itself converted into the corresponding amine:

$$R'RN{-}N{=}O + H^+ \leftrightarrows R'R\overset{+}{N}H{-}N{=}O ,$$
$$R'R\overset{+}{N}H{-}N{=}O \rightarrow R'RNH + \overset{+}{N}O \ (\text{slow}) .$$

The hydrolysis is easier the more electrophilic is the R or R′ group. In hydrochloric acid the denitrosation takes place more readily than in sulphuric or perchloric acid. The authors explain this by the nucleophilic reaction

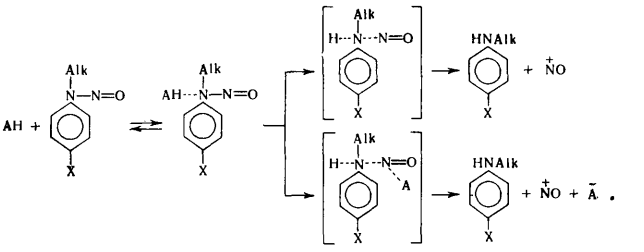
$$\overset{+}{N}H{-}N{=}O \xrightarrow{Cl^-} \overset{+}{N}H{-}N\begin{matrix}Cl\\O^-\end{matrix} \rightarrow NH + NOCl .$$

The rate of hydrolysis obeys the Hammett equation [185,186]:

$$\lg K + H_0 = \text{const.}$$

According to the data of Porai-Koshits and coworkers [187–190], the denitrosation of aliphatic-aromatic nitrosamines takes place by a "push–pull" mechanism. Preliminary protonation of the nitrosamino-group was not observed. The splitting off of the nitroso-group is promoted by the additional polarisation of the N–N bond owing to the formation of a hydrogen bond involving the nitrogen atom of the amino-group. The formation of the new N–H bond takes place simultaneously with the splitting off of the nitroso-group.

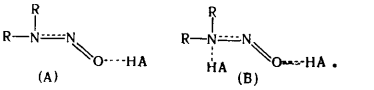
The presence of electron-accepting substituents in the *para*-position of the aromatic ring lowers the basicity of the amino-nitrogen in the nitroso-derivative and in this case the nucleophilic attack by the acid anions plays a decisive role. However, acid anions participate in the splitting off of the nitroso-groups only in the presence of hydrogen ions. On the basis of the results obtained, the following reaction mechanisms have been proposed as a function of the structure of the nitrosamine:



The results of studies on the formation of hydrogen bonds in aliphatic nitrosamines and also their chemical behaviour show that the reaction centre is located at the oxygen atom of the nitroso-group, which is inconsistent with the above hypothesis concerning the denitrosation of nitrosamines.

We believe that a more correct mechanism of the denitrosation of aliphatic nitrosamines involves electrophilic attack on the oxygen atom of the nitroso-group. The latter is readily eliminated as a result of the generation of partial positive charges at the nitrogen atom [157]:

The reaction of nitrosamines with trichloroacetic acid in cyclohexane takes place with formation of one or two hydrogen bonds and may be described by the following structures [168]:



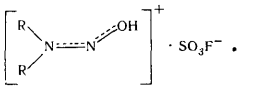
A number of changes takes place in the ultraviolet spectrum of *N*-nitrosodimethylamine in aqueous sulphuric acid solution due to acid–base interaction [169]:

$$R_2NNO \ldots (H_2O)_x \overset{H_2SO_4}{\rightleftharpoons} R_2NNO \ldots (H_2O)_x H_2SO_4 ,$$
$$R_2NNO \ldots (H_2O)_x \leftrightarrows R_2NNO \ldots (H_2O)_x HSO_4^- ,$$
$$R_2NNO \ldots (H_2O)_x HSO_4^- \rightleftarrows R_2NNOH^+ \ldots (H_2O)_x ,$$
$$R_2NNO \ldots (H_2O)_x HSO_4^- \leftrightarrows R_2NNO \ldots (H_2O)_x (H_2SO_4)_2 ,$$
$$R_2NNO \ldots (H_2O)_x HSO_4^- \rightleftarrows R_2NNO \ldots (H_2O)_x (HSO_4)_2 .$$

The attempts to isolate the salts of the nitrosamine and sulphuric acid were unsuccessful, but unstable white 1 : 1 crystalline adducts of 72% perchloric acid with *N*-nitroso-di-n-heptylamine, *N*-nitrosodi-n-octylamine, and *N*-nitrosodi-(2-ethylhexyl)amine were obtained, which indicates the possibility of proton transfer to the oxygen atom of the nitroso-group.

Nitrosamines form hydrogen bonds with formic, acetic, and trifluoroacetic acids and with alcohols, phenols, and amines [171 191-193]. The proton-donating activity of alcohols in the formation of the hydrogen bond increases in the series primary > secondary > tertiary. The equilibrium constants for the hydrogen-bonded complexes of nitrosamines and phenols increase linearly with the pK_a of the phenols [191].

A detailed study of the protonation of *N*-nitrosodimethyl- and *N*-nitrosodiethylamines and also *N*-nitrosopiperidine by NMR spectroscopy was undertaken [194]. The characteristic signal associated with the interaction of the proton with the nitrosamine occurs only in fluorosulphonic acid at 0°C and below. In other acids the spectra also show changes characteristic of structure (A); the dialkylamino-group is not protonated. The spectra shows that the formation of the hydrogen bond or protonation involves the oxygen atom of the nitrosamino-group. A structure with a delocalised positive charge has been proposed for the adducts of nitrosamines with fluorosulphonic acid:



The delocalisation of the positive charge probably prevents further protonation of the molecule.

A study of the competing protonation of *N*-nitrosodimethylamine and dimethylformamide by trifluoroacetic acid in 2-nitropropane showed that the nitrosamine is a weaker base [194].

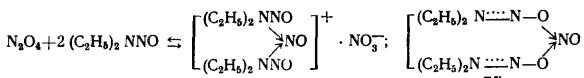
The basic nature of the oxygen atom is shown by the capacity of nitrosamines to give rise to brightly coloured stable complexes with bromoplatinic acid, the composition of which corresponds to the formula $[R_2NNO.H]_2PtBr_6$. [195] Complexes of nitrosamines with boron trifluoride are formed when equimolar amounts of the nitrosamine and boron trifluoride-ether are mixed or when an ethereal solution of the nitrosamine is treated with boron trifluoride [196]:

The stability of the complexes increases with the electron-donating capacity of the substituent linked to the nitrogen atom. The complex with *N*-nitrosodiphenylamine could not be isolated. It is interesting that in the adduct of boron trifluoride and *N*-methyl-*N*-nitrosoaniline the N–N bond is so much weakened that rapid rearrangement to *N*-methyl-*p*-nitrosoaniline takes place:

The results of spectroscopic analysis showed that the oxygen atom of the nitrosamino-group behaves as the electron donor in these complexes, although the possibility of the involvement of the amino-nitrogen in the formation of the donor-acceptor bond has also been suggested [158].

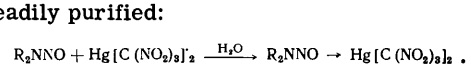
The NMR spectra of the adducts of *N*-nitrosodimethylamine with BF_3, PCl_5, $SbCl_5$, $AlCl_3$, and $ZnBr_2$ showed that the methyl groups are non-equivalent, as in the free nitrosamine. The non-equivalence of the methyl groups is evidence that the amino-nitrogen in the complexes remains in a state of sp^2 hybridisation. Consequently the acceptor is linked to the oxygen atom [197]. This structure is also confirmed by the high dipole moments (7.3 and 7.5 D) of the complexes of *N*-nitrosodiethyl- and *N*-nitrosodipropyl-amines with boron trifluoride.

N-Nitrosodiethylamine forms a 2 : 1 complex with nitrogen tetroxide, which was confirmed by studies of the phase diagram, viscosity, and electrical conductivity of nitrosamine–N_2O_4 mixtures [103,198,199]. On the basis of ultraviolet spectroscopic data, structure (IV) was attributed to the complex [199], but, in the light of the above concepts concerning the structure of nitrosamines, structure (V), where the oxygen atom of the nitrosamino-group functions as the electron donor, is evidently more likely:



(IV) (V)

Recently it was discovered that *N*-nitrosodialkylamines readily form complexes with di(trinitromethyl)mercury in water [200-202]. The compounds are stable on storage and can be readily purified:

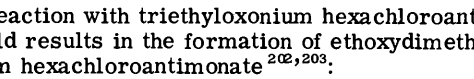


N-Nitrosopolynitroalkylamines, for example *N*-nitroso-di-(2,2,2-trinitroethyl)amine, do not react with di(trinitroethyl)mercury, in contrast to their unsubstituted analogues. This finding can be accounted for by a weakening of the electron-donating activity of the oxygen atom of the nitroso-group owing to a decrease of the degree of p-π conjugation caused by the polynitroalkyl groups.

The reactions of nitrosamines with other electrophilic agents are based on the complex-forming capacity of the former. For example, on heating to 60°C, *N*-nitrosodimethylamine reacts with methyl iodide [203]:

The reaction with triethyloxonium hexachloroantimonate in the cold results in the formation of ethoxydimethyldiazonium hexachloroantimonate [202,203]:

O-Alkylnitrosimmonium salts are formed in high yields when nitrosamines are allowed to react with triethyloxonium fluoroborate or a mixture of alkyl iodide and silver perchlorate [204,205]:



The study of the chemical behaviour of the salts and their infrared spectra showed that they are *O*-derivatives.

Dimethyl sulphate alkylates *N*-nitrosodimethylamine with formation of trimethylnitrosimmonium methyl sulphate. It is interesting that this adduct readily reacts with sodiocyclopentadienyl, forming the monomeric hydrazone of cyclopentadienone [206]:

2. Reduction to *NN*-Substituted Hydrazines

The reduction of the nitroso-group to the amino-group is one of the characteristic reactions in the nitrosamine series. It was discovered by Fischer in the synthesis of dimethylhydrazine [19]. The reaction takes place when an acetic acid solution of *N*-nitrosodimethylamine is treated

with zinc dust. Apart from dimethylhydrazine, ammonia and dimethylamine were isolated. Later diethylhydrazine [207], piperidylhydrazine [208], isobutylmethylhydrazine [209], etc. were synthesised in this way; dimethylhydrazine was obtained in a higher yield [52].

When *N*-nitrosodiethylamine is reduced with the zinc and acetic acid, the formation of tetraethyltetrazene together with diethylhydrazine was observed [210]. A similar reaction was noted in the reduction of nitrosamines with hydrogen in the presence of palladium deposited on calcium carbonate [211]:

$$2\,(C_2H_5)_2N{-}NO + H_2 \rightarrow (C_2H_5)_2N{-}N{=}N{-}N(C_2H_5)_2\,.$$

Several ring-substituted dibenzyl derivatives of hydrazine were described by Curtius [17,212,213] and other investigators [87,88]. Using a modified method of reduction in ethanol and milder reaction conditions, they increased the yields of the desired products to 75%. A number of arylalkyl and dialkyl derivatives of hydrazines were synthesised by the same method [137,214,215].

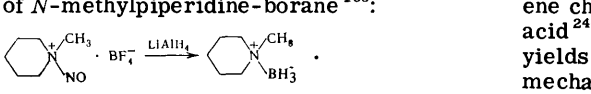
Apart from zinc and acetic acid, sodium amalgam [78,113] and also tin and hydrochloric acid [113] were employed to reduce nitrosamines. In the latter case hydrazine is not formed but the nitrosamine decomposes with elimination of the nitroso-group. The available data on the reduction with sodium amalgam are contradictory. Hydrazinoacetic acid and its dimethyl ester are formed from the corresponding nitrosamines in low yields, while *N*-nitrosodibenzylamine is converted into ammonia and dibenzylamine [113].

The method of reduction of *N*-nitrosodialkylamines with zinc in acetic acid is effective only for methyl-, ethyl-, and propyl-substituted nitrosamines [215]. Starting with the n-butyl derivative, secondary amines appear as the main reaction product. A general method of reduction with lithium aluminium hydride, developed for the synthesis of di-n-propyl-, di-n-butyl-, and di-n-pentylhydrazines as an example [215], has been proposed for the higher *N*-nitrosodialkylamines. Subsequently it was established that the result of the reaction depends on the nitrosamine: lithium aluminium hydride molar ratio. Thus for the reduction of *N*-nitrosodimethylamines the molar ratio of the components must be 1 : 2, [216] and in the case of *N*-nitrosodiphenylamine the ratio must be 1 : 1. [217] The yield of the desired product is affected also by the order of mixing of the components.

It is interesting that in the first stage of the reaction of the nitrosamine with lithium aluminium hydrides coloured complexes are formed, which are converted into dialkylhydrazines only on treatment with water [217,218]:

$$2\,R_2N{-}NO + 2\,LiAlH_4 \rightarrow (R_2N{-}N)_2AlLi + LiAlO_2 + 2\,H_2\,,$$
$$(R_2N{-}N)_2AlLi + 2\,H_2O \rightarrow 2\,R_2N{-}NH_2 + Li\,AlO_2\,.$$

The appearance of side products in the case of aromatic nitrosamines can be explained by the decrease of the polarity of the N–O bond owing to conjugation with the benzene ring. The reduction of *N*-methylpiperidine-nitrosyl fluoroborate with lithium aluminium hydride leads to the formation of *N*-methylpiperidine-borane [106]:



The catalytic hydrogenation of nitrosamines on the palladium catalyst in the presence of iron salts under pressure [219], reduction with zinc and aluminium in the presence of mercury salts or reduction with zinc in hydrochloric acid [220], and other reduction processes [221] have been described. The reaction of *N*-nitrosodialkylamines with zinc dust in formic acid in the presence of mercury(II) chloride results in the formation of an interesting class of compounds–*N*-isocyanodialkylamines [222].

Numerous modifications of the methods of hydrogenation of *N*-nitrosodialkylamines are quoted in the patent literature [223–233]. Compared with catalytic hydrogenation, the reduction of nitrosamines with sodium in liquid ammonia or alcohol [234] gives lower yields of dialkylhydrazines.

Nitrosamines can be reduced electrochemically to the corresponding hydrazines [235–237] or amines with elimination of one nitrogen atom in the form of ammonia. *NN*-Substituted hydrazines are formed via the mechanism

$$R_2NNO + 4\,H^+ + 4e \rightarrow R_2NNH_2\,.$$

The studies on the electrochemistry of nitrosamines have recently been reviewed in a monograph [238] and therefore they will not be discussed here.

When *N*-nitrosodialkylamines are hydrogenated in sulphuric, hydrochloric, nitric, acetic, or oxalic acids in the presence of Group VIII elements on charcoal or silica gel under pressure, hydroxylammonium salts are formed [239].

Nitrosamines undergo far-reaching cleavage on treatment with sodium hydrosulphite in an alkaline medium or when acted upon by lithium in liquid ammonia. This is known as the Overberger–Lombardino reaction and takes place via the intermediate formation of *N*-nitrenes, which readily decompose with evolution of nitrogen:

$$(RCH_2)_2N{-}NO \xrightarrow{Na_2S_2O_4;\,OH^-} (RCH_2)_2N{-}NHOH \xrightarrow[-H_2O]{} (RCH_2)_2N{-}\ddot{N} \xrightarrow[-N_2]{} \rightarrow (CH_2R)_2\,.$$

The Overberger–Lombardino reaction has been discussed in detail in monographs [240,241].

3. Oxidation and Nitration

Nitrosamines are important starting materials for the synthesis of secondary *N*-nitramines. According to the existing hypotheses, this reaction is based on the oxidation of the nitroso-group to the nitro-group.

The use of hydrogen peroxide with nitric acid for the oxidation gives low yields of nitramines and the desired product is contaminated [242]. Best results were obtained when nitric acid mixed with ammonium persulphate was employed [27]. Trifluoroperacetic acid proved to be a very convenient oxidising agent for nitrosamines [243]. The simplicity of the process and the purity and high yields of the final products made the oxidation of nitrosamines with trifluoroperacetic acid a valuable preparative method for the synthesis of secondary nitramines. For example, when *N*-nitrosodiethyl- and *N*-nitrosodibutylamines were acted upon by a mixture of trifluoroacetic acid in 90% hydrogen peroxide, the corresponding *N*-nitramines were obtained in 80% yield. When 30% hydrogen peroxide was employed, the yield of nitramines fell. A mixture of hydrogen peroxide and trifluoroacetic anhydride in methylene chloride may serve as a source of trifluoroperacetic acid [244]. This modification of the oxidation reaction yields pure nitramines in yields of 90% and above. The mechanism of the conversion of nitrosamines into nitramines under the influence of trifluoroperacetic acid has not been investigated:

$$R_2NNO \xrightarrow{CF_3COO{\cdot}OH} R_2NNO_2\,.$$

When *N*-nitrosodiethylamine was oxidised with nitronium pyrosulphate, acetaldehyde and acetic acid were

formed. The oxidation of *N*-nitrosodiethylamine with nitrogen pentoxide is very vigorous. The reaction may be controlled only by diluting the reactants [199]:

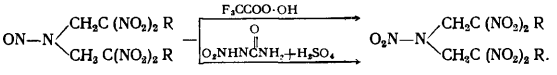
$$2\,(C_2H_5)_2NNO + N_2O_5 \rightarrow 2\,C_2H_5NO_2 + 2\,CH_3COOH + HNO_2 + HNO_3,$$
$$C_2H_5NO_2 + HNO_2 \rightarrow CH_3C(NOH)NO_2 + H_2O.$$

Until recently the reaction of nitrosamines with nitric acid was investigated only for aromatic compounds [245,246]. It has been shown [247] that ethyl *N*-isobutylcarbamate reacts with fuming nitric acid at −80°C to give a mixture consisting of 90% of ethyl *N*-isobutyl-*N*-nitrosocarbamate and 10% of ethyl *N*-isobutyl-*N*-nitrocarbamate. When the *N*-nitroso-derivative is subsequently treated with 100% nitric acid, the *N*-nitrated product is formed. The reaction was not investigated in detail. In other studies [29,144] it was shown that certain *N*-nitrosopolynitroalkylamines are readily converted into the corresponding nitramines under the influence of nitric acid or a mixture of nitric and sulphuric acids:

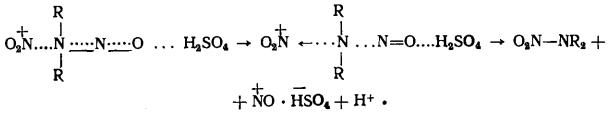
$$[BrC(NO_2)_2CH_2]_2N{-}NO \xrightarrow{HNO_3} [BrC(NO_2)_2CH_2]_2N{-}NO_2.$$

It is important to note that *N*-nitrosopolynitroalkylamines are resistant to oxidation by trifluoroperacetic acid [89,248]. If the oxidation of nitrosamines with trifluoroperacetic acid is assumed to be analogous to the hydroxylation of olefins, the negative results obtained in the oxidation of *N*-nitrosopolynitroalkylamines can probably be accounted for by the deficiency of electrons in the >N⁺⁻N⁺⁻O system owing to the electron-accepting influence of the substituents.

On the other hand, in *N*-nitrosopolynitroalkylamines the N–N bond should be weakened compared with the unsubstituted analogues. This leads to the possibility of an electrophilic substitution of the nitroso-group by a nitro-group in compounds of this kind. We believe that a convincing proof of the substitution of the nitroso-group is provided by the reaction of *N*-nitrosopolynitroalkylamines with nitrourea in sulphuric acid, leading to the formation of *N*-nitro-derivatives [248]. Nitrourea in sulphuric acid is known to be a source of nitronium cations [249]:



The reaction of *N*-nitrosopolynitroalkylamines with nitronium perchlorate in sulphuric acid is also accompanied by the formation of *N*-nitrosopolynitroalkylamines [248]. In an organic solvent (carbon tetrachloride) nitration does not occur. Since the presence of an acid and a nitronium cation is essential for the nitration of nitrosamines, the reaction can probably be described in terms of a "push–pull" mechanism:

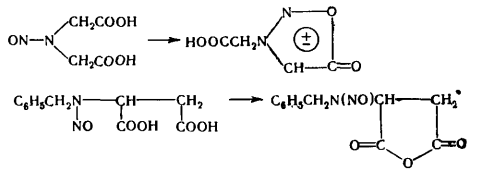


Thus the conversion of nitrosamines into nitramines can be achieved not only by the oxidation of the nitroso-group, but also by its electrophilic substitution by a nitro-group. The latter type of reaction is particularly characteristic of nitroso-derivatives containing electron-accepting substituents, for example polynitroalkyl derivatives.

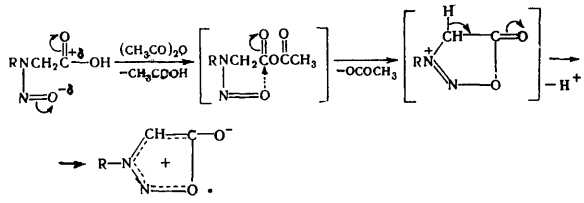
4. Cyclisation of α-Nitrosaminocarboxylic Acids and Their Nitriles into Sydnones and Sydnoneimines

In 1935 Earl and Mackney [250] obtained by treating *N*-nitroso-*N*-phenylglycine with acetic anhydride a cyclic compound, which was called sydnone (in honour of the place where it was first synthesised). Later it proved possible to introduce into the cyclisation reaction the nitriles of α-nitrosaminocarboxylic acids [95], which resulted in the formation of sydnoneimines. The initial discoveries were followed by an intense investigation of the methods of synthesis and properties of this interesting class of compounds. Two reviews dealing with the chemistry of sydnones and sydnoneimines were published [2,3] the second of which appeared comparatively recently and therefore we shall only mention the methods for the mechanism of the cyclisation of nitrosamines into these compounds.

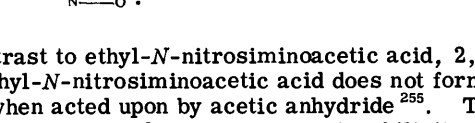
Usually acetic anhydride is employed for the cyclisation. However, trifluoroacetic anhydride, thionyl chloride, and *NN'*-di-isopropylcarbodi-imide can also be used for this purpose [251,252]. *N*-Nitrosodicarboxylic acids, for example nitrosiminodiacetic acid, are cyclised similarly to monocarboxylic acids [253,254], but cases are known where only the carboxy-groups are involved in the reaction [95]:



The formation of sydnones is based on the nucleophilic nature of the oxygen atom of the nitroso-group, and takes place via a mixed anhydride (when anhydrides are employed as the dehydrating agents), which already at room temperature splits off in succession an acetate ion and a proton [2,252]:

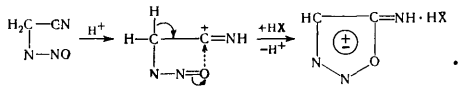


In contrast to ethyl-*N*-nitrosiminoacetic acid, 2,2,2-trinitroethyl-*N*-nitrosiminoacetic acid does not form a sydnone when acted upon by acetic anhydride [255]. This is probably due to the reduction of the nucleophilicity of the oxygen atom in the >N–N=O fragment under the influence of the trinitroethyl group. In the cyclisation of polynitroalkyl-*N*-nitrosaminoacetic acids, it is essential to employ trifluoroacetic anhydride, which increases the electrophilicity of the carbonyl carbon atom in the intermediate mixed anhydride:

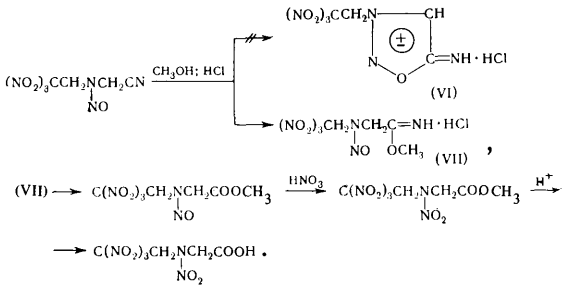


The nature of the cyclisation of the nitrile of α-nitrosaminocarboxylic acids to sydnoneimines is determined by the capacity of the nitrile group to combine with

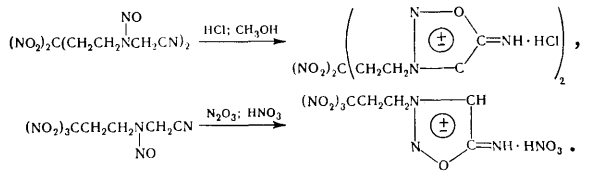
electrophilic agents. The reaction is achieved under the influence of hydrogen chloride [256] or nitrogen oxides [96]:



The powerful influence of the electron-accepting substituents on the conjugation in the >N⋯N⋯O fragment can be demonstrated yet again for the nitriles of polynitroalkyl-*N*-nitrosaminocarboxylic acids as an example. Thus, in attempts to cyclise the nitrile of 2,2,2-trinitroethyl-*N*-nitrosaminoacetic acid in methanol under the influence of hydrogen chloride, the imino-ether (VII) was isolated instead of the expected sydnoneimine (VI), the structure of (VII) being demonstrated unambiguously by its conversion into *N*-nitramino-2,2,2-trinitroethylacetic acid [257]:

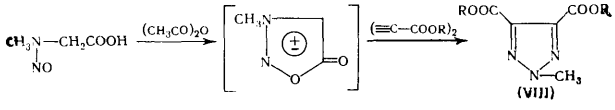


The formation of the imino-ether (VII) is possible only when the nucleophilic properties of the oxygen atom of the nitroso-group are weakened, as a result of which the intermediate carboimmonium ion $(NO_2)_3CCH_2N(NO)CH_2\overset{+}{C}=NH$ undergoes methanolysis, which competes with the ring-closure reaction. The removal of the nitro-groups to the γ-position relative to the nitrosamino-group weakens their influence on the polarisation of the oxygen atom and promotes the formation of the sydnoneimine [257]:

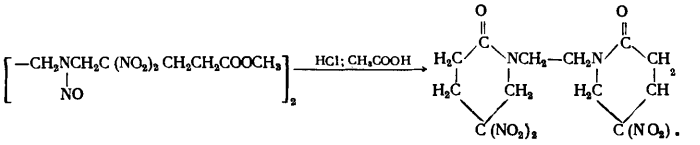


Sydnones and sydnoneimines are reactive mesoionic aromatic compounds. The hydrogen atom in the 4-position in the ring is readily substituted by halogens, nitro-groups, sulpho-groups, etc. Sydnones may be employed to synthesise hydrazines [45]. They undergo the 1,3-dipolar-cycloaddition reaction with unsaturated compounds, forming pyrazoline derivatives [258]. In contrast to sydnones, sydnoneimines undergo ring opening under conditions of alkaline hydrolysis, the amides of α-nitrosaminocarboxylic acids being formed [95]. Sydnoneimines form readily *exo*-*N*-nitroso- and nitro-derivatives.

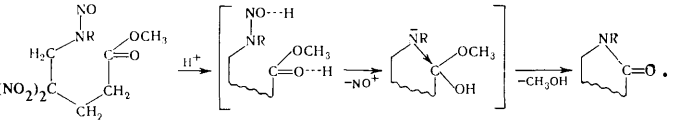
When *N*-nitrososarcosine is heated with acetic anhydride in the presence of acetylenedicarboxylic acid esters, carbon dioxide is evolved and a cycloadduct (VIII) is formed [259]:



Recently it has been established for esters of polynitroalkyl-*N*-nitrosaminocarboxylic acids that yet another type of cyclisation is characteristic of *N*-nitroso-compounds. When *N*-nitrosodi-(4-methoxycarbonyl-2,2-dinitrobutyl)amine and *NN*-dinitrosodi-(4-methoxycarbonyl-2,2-dinitrobutyl)ethylenediamine were treated with a mixture of acetic and hydrochloric acid, *N*-(4-carboxy-2,2-dinitrobutyl)-$\gamma\gamma$-dinitro-δ-valerolactam and ethylenedi($\gamma\gamma$-dinitro-δ-valerolactam) were isolated [260]:

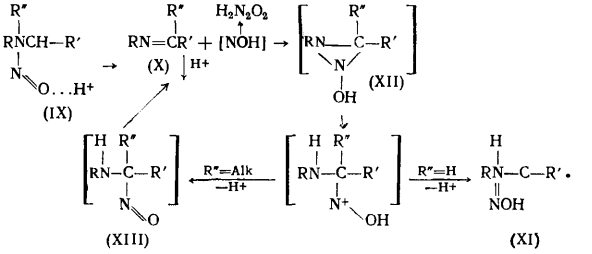


The reaction is accompanied by vigorous evolution of nitrogen oxides. The nature of closure to the lactam ring shows that the nitroso-group is split off as the nitrosonium cation with transfer of the bonding electron pair to the nitrogen atom of the amino-group. The presence of acid promotes the elimination of the nitroso-group and the protonation of the carbonyl carbon atom, while the presence of a five-membered carbon chain at the nitrogen atom creates favourable steric conditions for ring closure. The mechanism of the formation of the lactam ring can be represented as follows:



5. Photochemical Reactions of Nitrosamines

Several years ago reports appeared about a new reaction in the nitrosamine series: photolytic decomposition in the presence of acids [261,262]. On ultraviolet irradiation in methanol or water in the presence of hydrochloric acid, nitrosamines are converted into amidoximes, secondary amines, alkylideneimines, and other compounds. It is suggested that in the first reaction stage a complex (IX) is formed, which decomposes to the imine (X) and a nitroxyl in a solvent cage via an excited triplet radical-ion π-complex. The amidoxime (XI) is formed as a result of the recombination of (X) and NOH. The recombination is possible either via the addition of the monomer of hyponitrous acid and a proton to the C=N double bond of (X) or via the intermediate formation of *N*-hydroxyaziridine (XII) with subsequent rearrangement of the latter to the amidoxime:



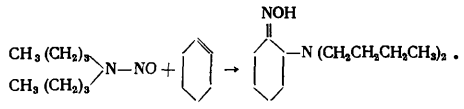
In this case, when the carbon atom of the C=N bond of (X) does not split off a proton (R″ ≠ H), for example in the photolysis of *N*-nitrosodicyclohexylamine, the OH group is lost and a *C*-nitroso-compound (XIII) is formed. Elimination of NOH from (XIII) again leads to the alkylideneimine (X). Therefore the retardation of the nucleophilic attack

on NOH is accompanied by the hydrolysis or polymerisation of the primary photolysis product. It is evident that the steric factor plays an important role in the photoelimination reaction and therefore *trans–anti* elimination of NOH from the photoexcited nitrosamine–proton complex takes place. The intermolecular mechanism of the photoisomerisation of *N*-nitrosodialkylamines has been discussed [263].

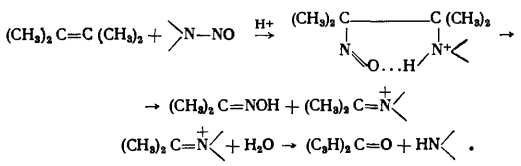
The photolytic decomposition of nitrosamines leads ultimately to the formation of aldehydes and ketones. For example, *N*-nitrosodibutylamine gives a high yield of butyraldehyde after the hydrolysis of the amidoxime (XI), while *N*-nitrosodicyclohexylamine gives rise to cyclohexanone [264].

In the presence of acids the photolytic addition of *N*-nitrosamines to various olefins takes place smoothly [265–267]. Formally the photoaddition reaction takes place via the dissociation of the N–N bond with subsequent addition of the nitroso- and amino-groups to the C=C bond and formation of a *C*-nitroso-compound as the primary reaction product. The latter undergoes secondary reactions, which lead to the final product [265].

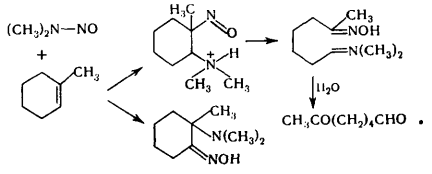
N-Nitrosodibutylamine adds to cyclohexene with formation of the oxime of 2-di-n-butylaminocyclohexanone in 38% yield [267]:



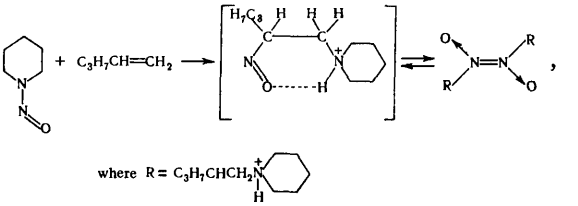
The nitroso-group adds as a rule to the most hydrogenated carbon atom. This observation made it possible to achieve the photolytic addition of nitrosamines to a multiple bond with subsequent dissociation of the C–C bond [266]. Thus irradiation of a mixture of tetramethylethylene and nitrosopiperidine leads to the formation of acetone and acetoxime:



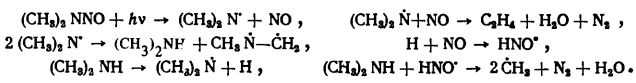
Similarly α-methylstyrene forms acetophenone and di-(1-piperidinyl)methane. When the carbon atom bound to the nitroso-group is combined with a hydrogen atom, the reaction stops at the stage involving the isomerisation of the *C*-nitroso-derivative to the oxime and the C–C bond is not ruptured. Sometimes intramolecular proton transfer can be faster than the isomerisation to the oxime. *N*-Nitrosodimethylamine reacts with 1-methylcyclohexene, forming predominantly 6-oxoheptanal [265]:



The addition of *N*-nitrosopiperidine to pent-1-ene is accompanied by the formation of a dimer of the *C*-nitroso-derivative via the mechanism [265]:



When *N*-nitrosodimethyl- and *N*-nitrosodiethylamines were photolysed in the vapour phase, hydrogen, nitrogen, alkanes, secondary amines, and nitrogen oxides were detected in the reaction products [152]. These results suggest that, in contrast to the low-temperature photolysis, the process has a radical mechanism:



VI. CERTAIN ASPECTS OF PRACTICAL APPLICATION

The lower *N*-nitrosodialkylamines, in particular *N*-nitrosodimethylamine, are largely employed in the synthesis of asymmetric dialkylhydrazines. Dimethylhydrazines are one of the most important components of rocket fuels [268,269]. A mixture of dimethylhydrazine, dimethylamine, and ammonia, obtained by the hydrogenation of *N*-nitrosodimethylamine in the vapour of liquid phase, has been recommended for guided rockets and missiles [228,229].

It has been noted in the patent literature that nitrosamines may be employed as antioxidants in fuels, lubricating oils, and rubbers [98]. There is an interesting prospect of the employment of nitrosamines as special fuels, stabilisers for aromatic halogeno-compounds, fungicides, insecticides, and bactericides and also as intermediates in the manufacture of medicinal preparations [61,98,270].

N-Nitrosodimethylamine is employed in the form of aqueous solutions or powders as a nematocide. In a dose of 112 kg per hectare it protects tomatoes from the nematode *Meloidogyne incognita* and in doses of 56 to 112 kg per hectare it is non-phytotoxic for carrots, tobacco, cabbage, and the cotton plant; however, it inhibits to some extent the growth of [lima] beans and peas [270].

N-Nitrosodimethylamine has been recommended as a solvent in the manufacture of fibre from polyacrylonitrile [271].

However, the high toxicity of nitrosamines should be noted. For example, *N*-nitrosodimethylamine has been included in the group of carcinogenic and irritant substances. It is recommended that the possibility of the contamination of air by this compound be completely prevented [272].

The Mössbauer Effect and the Study of the Chemical Consequences of Nuclear Transformations

S.I.Bondarevskii, A.N.Murin, and P.P.Seregin

The present review deals with one of the most important branches of radiochemistry, of considerable practical and applied importance (the preparation of "labelled" compounds, the enrichment of radioactive isotopes) and scientific and theoretical interest. An understanding of processes involving atoms which have undergone a nuclear transformation in the solid phase will make it possible to solve many problems of the physics and chemistry of the solid state. The bibliography contains 151 references.

CONTENTS

I. Introduction 51

III. The influence of K-capture, isomeric transition, and β-decay on the forms of stabilisation of a Mössbauer atom 53
IV. Processes of energy loss by recoil atoms in solids 56
V. The "solid-solution" problem 59

I. INTRODUCTION

The history of the study of so-called "hot" atoms, or "recoil atoms" dates from the discovery of Szilard and Chalmers[1]. The extensive practical development of reactor and cyclotron irradiation made the preparation of the radioactive isotopes of many elements and the study of the chemical effects accompanying radioactive decay or the course of a nuclear reaction readily attainable. The forms in which the recoil atoms are stabilised are determined by dissolving the irradiated or labelled solid specimen, followed by radiochemical analysis of the solution containing the radioisotope formed. This method of study is general in character and is obligatory; the concentrations of recoil atoms are so small that the observation of their chemical behaviour is possible in principle only if use is made of their radioactivity. So long as we are interested in practical problems (for example the enrichment of isotopes) no particular objections can be made to the use of an appropriate solvent and carriers. This method, however, acts as a brake on the development of theories of the mechanism and the forms in which recoil atoms are stabilised in the solids themselves. In fact, in general it is impossible, having detected particular chemical forms of the element being studied in solution, to reach the unambiguous conclusion that their behaviour in solution is a consequence of only the radioactive decay or a nuclear reaction in the solid phase. They may obviously also be a consequence of the reaction of the primary decay fragments with the solvent or with one another. The introduction of additional methods of investigation (the study of thermal annealing, the influence of the conditions of dissolution, etc.) can also give complete information on the true state of recoil atoms in a crystal lattice. It is obvious only that the interpretation of results from the chemical effects of nuclear transformations, obtained by these methods, requires an exceptionally careful attitude towards the dissolution procedure. There arises the complex problem of the correspondence between the forms of stabilisation in the solid and in the solution. Unfortunately, most radiochemical studies are carried out without even an attempt to take account of, or even to assume, the possible consequences of dissolution.

It is clear that the introduction of any experimental method which does not require the dissolution of a substance and which gives information on the behaviour of recoil atoms directly in the solid phase is extremely desirable. This additional possibility was provided for radiochemistry by Mössbauer's discovery of the phenomenon of nuclear gamma-resonance (NGR). Since the production of "Mössbauer" levels is always a consequence of some preceding radioactive decay (β-decay, α-decay, K-capture, isomeric transition) or nuclear reaction [(n,γ), (a,p), Coulombic excitation], it may be concluded that emission Mössbauer spectroscopy can be used successfully to study the chemical consequences of nuclear transformations in solids.

Several advantages of the NGR method for the solution of chemical problems can be listed.

1. The forms in which the recoil atoms are stabilised are studied directly in the solid phase.
2. The conditions of Mössbauer experiments are standardised and reproducible (unlike radiochemical techniques, with countless variations in the conditions of irradiation, dissolution, etc.).
3. The observations are made in a range of temperatures (from helium temperatures to $\sim 1000^\circ$K) which is difficult to attain in the irradiation of substances for radiochemical purposes in the usual form, particularly with subsequent chemical treatment of the target.
4. The consequences of a nuclear transformation are studied in a time interval of $10^{-7}-10^{-9}$ s. These intervals are fairly long compared with the duration of the electronic and relaxation processes accompanying the nuclear transformation, but they are still shorter by many orders of magnitude than the time intervals attainable in radiochemistry. Thus the systems studied are "protected" from the annealing phenomena which take place intensively in many instances at the ordinary temperatures and duration of treatment of the targets.

Although almost all information on the NGR method has been obtained by specialist physicists and has not dealt explicitly with radiochemical problems, it is possible to summarise the results obtained and to analyse them from the viewpoint of radiochemistry. Our aim is to discuss the possibilities provided by the use of the Mössbauer effect in the solution of radiochemical problems.

The present review consists of two sections, one of which is devoted to an NGR study of the relaxation times and forms of stabilisation of Mössbauer atoms produced by nuclear transformations characterised by low values of the recoil energy (K-capture, isomeric transitions, and β-decay). The other section is devoted to an examination of the processes of energy loss by recoil atoms during nuclear reactions [(n,γ), (d,p), Coulombic excitation] involving the formation of atoms with high energy. A separate paragraph gives some information on the parameters of NGR spectra required for the subsequent discussion (a more detailed examination of the problems of NGR theory can be found in a number of monographs[2-4]).

II. MÖSSBAUER EFFECT

Let us consider the emission of a gamma-quantum by a nucleus which is in an excited state and is rigidly fixed in a crystal. In this instance the recoil momentum is absorbed not by an individual nucleus, but by the whole crystal, so that the expression for the recoil energy E_R is written in the form

$$E_R = \frac{E_0^2}{2Mc^2},$$

where E_0 is the energy of the gamma-quantum, M the mass of the crystal, and c the velocity of light. It follows from this expression that the recoil energy is negligibly small and that the gamma-quantum carries with it all the energy of the isomeric transition.

The probability density $W(E)$ for the emission of a gamma-quantum with energy E is given by the equation

$$W(E) = \frac{1}{2\pi} \cdot \frac{\Gamma^2}{(E-E_0)^2 + \frac{1}{4}\Gamma^2},$$

where $\hbar/\tau = \Gamma$ is the width of the spectral line, and τ is the lifetime of the excited nucleus. The last equation thus describes the form of the nuclear spectral line.

Let us consider the following experiment. Let us assume that we have a source of monochromatic gamma-quanta (for example a ^{57m}Fe nucleus in stainless steel) which can move at a velocity of $\pm v$ relative to an absorber (^{57}Fe atoms in stainless steel). If the source is stationary, some of the gamma-quanta of the source, passing through the absorber, will be absorbed, and in accordance with the expression for $W(E)$, the absorption will be maximal. If however the source is moving relative to the absorber at a velocity $\pm v$, the energy of the gamma-quantum will be equal to

$$E = E_0 \pm E_0 \cdot \frac{v}{c}$$

and the absorption will decrease. The dependence of the count rate behind the resonance absorber on the velocity of the source relative to the absorber is called the Mössbauer spectrum.

Up to the present we have considered a radiating atom rigidly fixed in a crystal—the recoil energy is negligibly small, and all the gamma-quanta are "Mössbauer" quanta.

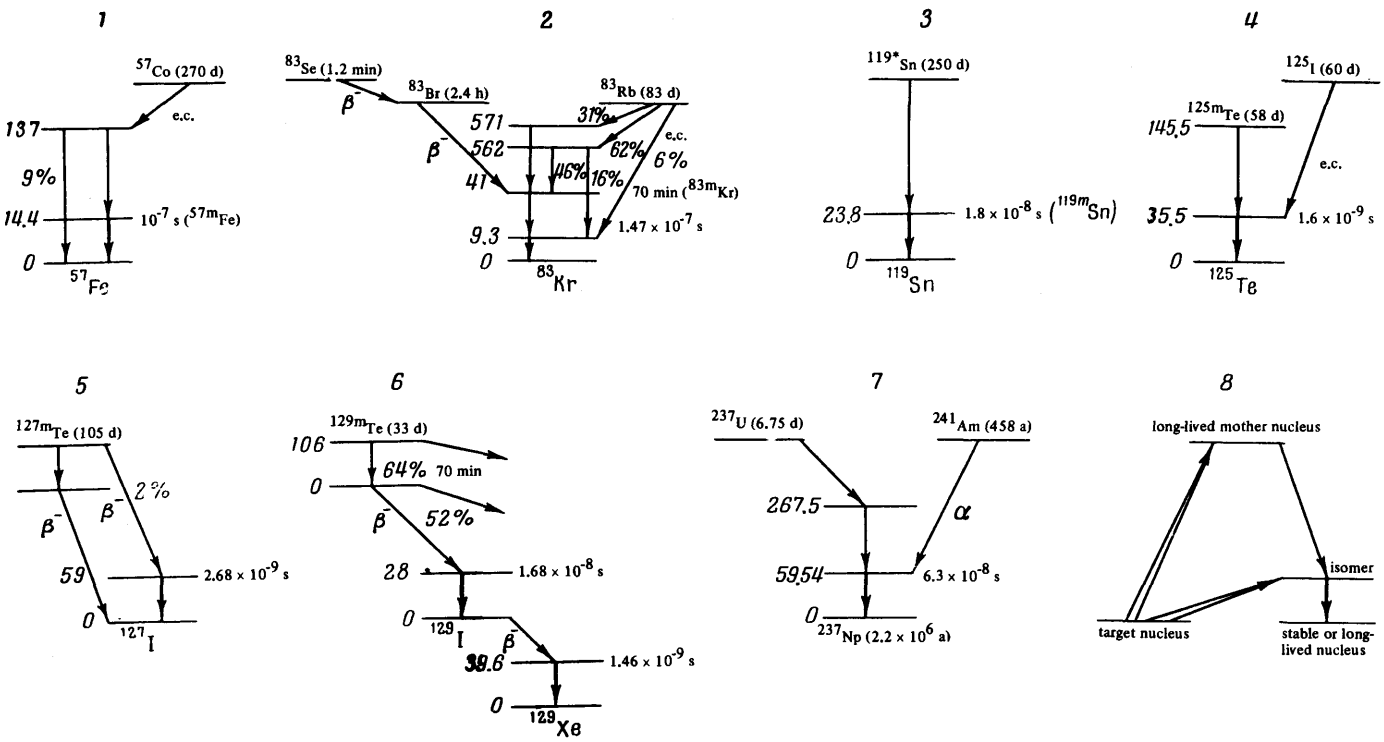

Figure 1. Decay processes leading to the formation of Mössbauer levels: *1*) ^{57}Fe; *2*) ^{83}Kr, *3*) ^{119}Sn, *4*) ^{125}Te, *5*) ^{127}I, *6*) ^{129}I and ^{129}Xe, *7*) ^{237}Np, *8*) general scheme for the formation of a Mössbauer level.

In a real example of gamma-quantum emission, however, the excitation of phonons of the crystal lattice is possible, leading to the partial loss of energy by the gamma-quantum, as a result of which the number of Mössbauer gamma-quanta decreases. The fraction of gamma-quanta emitted by non-phonon transitions is characterised by the quantity f—the Mössbauer coefficient. It is obvious that f characterises the "rigidity" of the lattice, and this coefficient will be small for atoms weakly bound to the matrix (for example, displaced from the normal lattice sites).

The energy of an isomeric transition depends on the electron density at the nucleus, so that for different compounds of the Mössbauer atoms the lines of the NGR spectra relative to a standard absorber (or source) will show a quite definite velocity shift, determined by the valency state (the so-called chemical shift). When the Mössbauer atom is in a distorted environment (different from cubic), the NGR spectrum shows quadrupole splitting, and finally when the M atom is introduced into a magnetic matrix, the phenomenon of Zeeman splitting of the spectrum is possible. Schemes for the formation and decay of various Mössbauer nuclei are given in Fig. 1.

III. THE INFLUENCE OF K-CAPTURE, ISOMERIC TRANSITION, AND β-DECAY ON THE FORMS OF STABILISATION OF A MÖSSBAUER ATOM

As a result of the removal of an electron from the K-shell (or L-, M-, etc. shells) in electron capture or a converted isomeric transition, a singly ionised excited atom is formed; this excitation is removed either by radiative transitions, leading to movement of the vacant position from the K-shell into the L-shell and then to the M-shell, etc., or by the emission of electrons (the Auger effect) leading to the accumulation of a high positive charge in the atom. Since there are a vast number of ways in which cascades of vacancies can develop, the final charge states of the atoms are not the same, that is a spectrum of charges is formed. The actual existence of multiply-charged ions when this process takes place in free atoms has been proved by mass spectrometry[5].

It is assumed that the accumulation of a large positive charge on an individual atom in a molecule produces forces of electrostatic repulsion, as a result of which the molecule dissociates, and the multiply-charged ion is in the "free" state[6]. The subsequent fate of this ion depends on the matrix in which the nuclear process takes place; within a definite time interval it reacts with the surrounding medium and is converted into stable forms (the forms of stabilisation).

There naturally arises the problem of the relaxation times of these highly charged metastable states of the atoms. If these times are much greater than the lifetime of the Mössbauer levels, the NGR emission spectra should contain lines corresponding to these states; if however these times are commensurate with the lifetimes of the Mössbauer levels, the spectra should show broadened lines.

An important feature of radiochemical theory is the assumption that the varied chemical forms obtained in a radiochemical analysis, for example in the study of an isomeric transition, are due to nuclear processes and can be only partly attributed to the influence of the subsequent chemical operations.

The process of β-decay (in the absence of a converted isomeric transition) does not lead to the formation of highly-charged ions, and the chemical changes accompanying β-decay are determined by the essential features of this process (the chemical behaviour of the daughter atom as distinct from the mother atom).

We can consider two basic problems:

1) what are the lifetimes of the metastable highly-charged states?

2) what are the forms in which Mössbauer atoms are stabilised?

1. LIFETIMES OF METASTABLE STATES

In the first moment after the formation of a Mössbauer level as a result of K-capture and an isomeric transition the atom is multiply-charged. It may be assumed that the law for the decay of these states (that is their conversion into the usual valency forms) obeys the exponential relationship[7]

$$I(n) = I_0(n) \exp\left(-\frac{\tau}{\theta(n)}\right),$$

where $I_0(n)$ is the intensity of the n-charged state in the initial moment after the formation of the Mössbauer level, τ the lifetime of the Mössbauer level, and $\theta(n)$ the lifetime of the n-charged state.

It is obvious that the metastable states, the lifetimes $\theta(n)$ of which are comparable with τ, should be revealed in the NGR spectra; the emission lines should be broadened, since[7]

$$\Gamma = \hbar\left[\frac{1}{\tau} + \frac{1}{\theta(n)}\right]$$

Thus the appearance of broadened lines in the emission NGR spectra may indicate that they belong to highly-charged states, the lifetimes of which are comparable with the lifetime of the Mössbauer level.

Electron capture in ^{57}Co has been most extensively studied in this connection. It was noted that if the decay of ^{57}Co takes place in a metal, the NGR spectrum always shows one line, corresponding to an Fe^0 atom (if the matrix is ferro- or antiferromagnetic, the spectrum will of course contain six lines). From this it may be concluded that in metals, in which there is a sufficient number of "free" electrons, the neutralisation of multiply-charged iron ions takes place in a time interval much smaller than 10^{-7} s.[3]

In semiconductors and dielectrics, however, which do not contain sufficient "free" electrons, the neutralisation possibly takes place much more slowly, so that the multiply-charged ions which have not decayed are revealed in the NGR spectrum by the production of a broadened line. This suggestion was put forward by Wertheim[8], when he found that the emission spectrum of cobalt oxide ^{57}CoO (at 295°K) contained two lines, one of which, from the chemical shift, corresponded to bivalent iron, whereas the second (slightly broadened) line corresponded to tervalent iron atoms (Fig. 2). Thus according to Wertheim, the multiply-charged iron ions in cobalt oxide are stabilised as Fe^{2+} (since CoO is isomorphous with FeO), and Fe^{3+} is a metastable form, which is converted into Fe^{2+} in a time interval of $\sim 10^{-7}$ s. More highly-charged states were not detected in the spectrum, and this led Wertheim to the conclusion that their lifetime is much less than 10^{-7} s. The spectra of cobalt oxide were subsequently studied by other workers[7,9-20], some of whom[7] also interpreted their results in terms of metastable states.

A large number of ionic salts of cobalt and iron labelled with ^{57}Co have been studied[13,14,19,21-25]. The studies of the iron salts are of greatest interest, since in this instance it is possible to study both emission and absorption NGR spectra in a single specimen. The two spectra for

$[Fe(NH_4)_2(SO_4)_2.6H_2O]$: ^{57}Co (Fig. 3) show that the absorption spectrum corresponds to only bivalent iron, whereas the emission spectrum shows a characteristic distortion, assigned[23] to the presence of metastable tervalent iron. The emission spectrum of $^{57}CoSO_4.7H_2O$ was interpreted analogously[24]. Finally, the spectrum of $^{57}Co(NH_4)_2(SO_4)_2.6H_2O$, in addition to bivalent and metastable tervalent iron, also showed metastable quadrivalent iron[23].

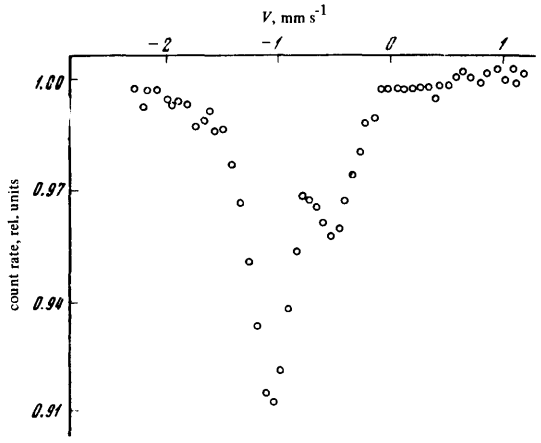

Figure 2. NGR spectrum of ^{57}CoO. Absorber—stainless steel[20].

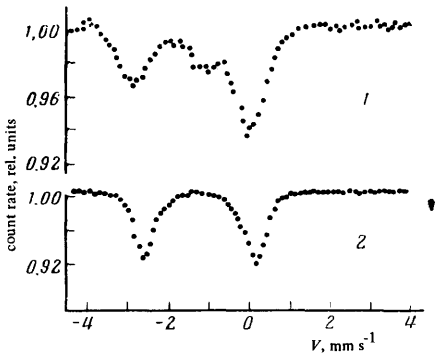

Figure 3. Emission spectrum of $[Fe(NH_4)_2(SO_4)_2.6H_2O]$: ^{57}Co (*1*) and absorption spectrum of $[Fe(NH_4)_2(SO_4)_2.6H_2O]$ (*2*).[14].

While referring the reader to the original papers[7-25] for details, we would point out that the only proof of the production of metastable states after the decay of ^{57}Co is provided by the broadening of the corresponding lines in the NGR spectra. The broadening may, however, be due to some other phenomenon (see below), so that in general, independent experiments which would determine directly the lifetime of these metastable ions are required. Studies of this kind were made by Triftshauser and Craig[12,14,21] for a large number of compounds of cobalt and iron, labelled with ^{57}Co. These involved essentially the application of the method of delayed coincidence; they recorded the gamma-quanta emitted by ^{57m}Fe nuclei in the time intervals (4–43), (43–86), (86–146), and (146–200) ns after the formation of the Mössbauer level (the moment of formation of ^{57m}Fe was recorded by detecting the 122 keV gamma-quantum—see Fig. 1). For the "ordinary" spectrum of ^{57}CoO, recorded without a delay, the authors cited[12,21] obtained $I(+3)/I(+2) \simeq 0.6$ (here $I(+3)$ and $I(+2)$ are the intensities of the Fe^{2+} and Fe^{3+} lines in the spectrum). If it is assumed that tervalent iron is metastable, this ratio should be different for different delay times[26]. It was found[12,21], however, that the ratio $I(+3)/I(+2)$ is independent of the delay time. Analogous results were also obtained for the systems NiO : ^{57}Co, $[Fe(NH_4)_2(SO_4)_2.6H_2O]$: ^{57}Co, $^{57}CoSO_4.7H_2O$, and $^{57}CoCl_2.2H_2O$.[12,14,21]. In other words, the tervalent iron ions formed after the decay of ^{57}Co are also stable, and the time required for the stabilisation of the multiply-charged states of the iron atoms is much less than 10^{-7} s.

Highly charged metastable states similarly were not observed in the formation of other Mössbauer levels (for example for the isomeric transition in ^{119}Sn). It may be concluded with a high degree of reliability that the relaxation times of highly-charged states in solids are much shorter than the lifetimes of the Mössbauer levels (10^{-7}–10^{-9} s).

2. FORMS OF STABILISATION OF MÖSSBAUER ATOMS

a. Electron Capture

It has already been noted that for the decay of ^{57}Co in metals, the NGR spectra in non-magnetic matrices consist of single lines with a chemical shift close to that for Fe^0. This is to be expected, since metals contain sufficient free electrons.

Similarly, in compounds of bivalent iron and cobalt labelled with ^{57}Co we should expect the formation of Fe^{2+}. In fact, in $CoCl_2$, iron is stabilised[13,23,27,28] only in the form of Fe^{2+}, but in $CoCl_2.nH_2O$ (n = 2, 4, or 6) the spectra show characteristic distortion, attributed[23] to the production of tervalent iron ions. Analogous distortions in the NGR spectra of $CoSO_4.7H_2O$, $CoSO_4$, $Co(NH_4)_2(SO_4)_2.6H_2O$, and $[Fe(NH_4)_2(SO_4)_2.6H_2O]$: ^{57}Co were also attributed to the production of tervalent iron[14,23,24], and this may be related to distortion of the structure of the crystal lattice[14] in the environment of the ^{57}Co atom.

An interesting explanation of the distortion of the spectra of $CoCl_2.nH_2O$ was put forward by workers[13] who studied the dependence of the form of these spectra on the quantity of hydrate water in the compound (n = 0, 2, 4, 6) and concluded that the spectrum of $CoCl_2.2H_2O$ consists of the superposition of the spectra of $CoCl_2$ and $CoCl_2.2H_2O$, that is that the distortion of the spectrum is due to the formation of different hydrates of $CoCl_2$.

A large number of studies have been made of the emission spectra of ^{57}Co in various matrices: Co_3O_4, Co_2O_3,[19,20,29,30] NiO,[31-35] MgO,[34-38] MnO,[34,35] CaO,[37,38] CaF_2,[39] $SrTiO_3$,[40] NaF,[22] NaCl,[27,41] AgHal,[42-48] KCl,[49] semiconducting compounds[50-56], and organic compounds of cobalt[57,58]. None of these papers reported the appearance, in the Mössbauer spectra, of lines related to charged states of iron, which would not have been characteristic of the chemistry of iron.

It may be noted that for CoO the production of a tervalent iron line has not yet been fully explained: some

authors [12,14] consider that this is due to the non-stoichiometry of cobalt oxide, whereas others [13,15] suggest that there exist two forms of cobalt oxide—CoO^{I}, in which iron is stabilised in the form of Fe^{2+}, and CoO^{II}, in which Fe^{3+} is stable (for a continuation of the discussion, see Refs. 17, 18, and 59).

K-capture in the case of ^{125}I in copper [60,61] produces in the NGR spectrum only lines corresponding to Te^{0}. For $NaIO_3$, distortion of the spectrum was observed, and this was attributed [60] to the formation of two charged states of tellurium.

Thus the process of K-capture in a solid leads to a limited number of forms of stabilisation of the Mössbauer atom. A characteristic feature of the NGR spectra is their broadening (for example the broadening of the line for tervalent iron in the emission spectrum of cobalt oxide), which apparently indicates a slight difference in the environment of each individual atom.

b. Isomeric Transition

The multiply-charged ions of ^{119m}Sn produced in the conversion of 65.3 keV gamma-quanta in metals and intermetallic compounds are stabilised, as expected, in the form of Sn^{0}. It is obvious that in quadrivalent tin compounds the tin atoms should be stabilised in the form of Sn^{IV}, and this is observed experimentally (for example, tin(IV) oxide, calcium and barium stannates). The situation is more complex for bivalent tin compounds, in which the expected form of stabilisation of the Mössbauer atoms is Sn^{II}. For example, it was found [62] that the emission spectrum of Sn^{II} oxalate shows a bivalent tin doublet, but it was found to be broadened relative to the absorption spectrum of the oxalate, and the magnitude of the effect was smaller; in the opinion of the authors cited, this was due to the existence of some of the ^{119m}Sn atoms in a locally distorted environment. This local distortion may be the result of a strongly converted isomeric transition preceding the Mössbauer transition.

An analogous picture of broadening of the emission spectra of ^{83}Kr has been observed [63-69]. In fact, most mother nuclei of krypton (^{83}Rb, ^{83}Br, and ^{83}Se) decay with the formation of ^{83m}Kr (half-life 70 min). After the converted 31.7 keV gamma-transition, a strongly ionised Mössbauer atom is formed. It is this process which leads to breakdown of the charge symmetry of the ligands and broadening of the ^{83}Kr spectra in dielectrics [66,68]. It was reasonable to assume that processes involving the relaxation of these distortions should take place much more intensively in semiconductors and metals than in dielectrics, and the emission spectra of krypton in this case will have narrow lines. This suggestion has been confirmed [68] (see Table 1).

The isomeric transition in ^{125m}Te in PbTe, metallic tellurium, amorphous tellurium, and tellurium dioxide does not give a set of valency states in the NGR spectra [70,71]. The hydrated compounds H_6TeO_6 and $Na_2H_4TeO_6$, however, show distortions of the spectra†, which were interpreted [71] as due to the production of Te^{IV} atoms together with Te^{VI}. It may be noted that this is not the only possible interpretation, since by analogy with hydrated compounds of cobalt the distortions of the spectra of these compounds may also be due to the formation of a set of Te^{IV} [Te^{VI}? (Ed. of Translation)] with different concentrations of hydrate water.

Thus although the metastable multiply-charged atoms formed after a nuclear transformation are stabilised fairly rapidly (at least in a time interval much shorter than 10^{-7}–10^{-9} s), local distortion of the lattice (as a consequence of the nuclear process) causes each individual atom to have an environment differing slightly from that of the other atoms, and this is responsible for the broadening of the NGR emission spectra and the small magnitude of the effect. It is therefore possible that on dissolution, the atoms which have undergone a nuclear transformation in the solid and have essentially identical chemical character will be distributed in different chemical forms (because of the influence of the nature of the local environment of the recoil atom) in the dissolution process, although the NGR spectrum may correspond to only one state.

Table 1.

c. β-Decay

The influence of β-decay on the charge states of Mössbauer atoms has been studied for the example of ^{129}I ($^{129}I \xrightarrow{\beta^-} {}^{129m}Xe$). [72-75] It was found that the sources KIO_4 and $Na_3H_2IO_6$ give one line, so that the following compounds are apparently formed:

$$IO_4^- \xrightarrow{\beta^-} XeO_4, \quad IO_6^{5-} \xrightarrow{\beta^-} (XeO_6)^{4-}$$

The β-decay of ^{129}I in $NaIO_3$, $KICl_4.H_2O$, and $KICl_2.H_2O$ gives XeO_3, $XeCl_4$, and $XeCl_2$ respectively; the emission spectra of these products coincide with the absorption spectra. No additional lines were detected (it may be noted that the lifetime of ^{129m}Xe is $\sim 1.5 \times 10^{-9}$ s).

The influence of the β-decay of ^{129}Te on the charge states of ^{129}I has been studied [76-80]. ZnTe, [76-79] tellurium, tellurium dioxide, $Te(NO_3)_4$, [78] and magnesium, calcium, strontium, and barium orthotellurates [80] give spectra corresponding to the existence of one charge state of ^{129}I.

Slightly different results were obtained in a study of the β-decay of ^{127}Te. In ZnTe and tellurium, one charge state of the iodine atoms was detected [76,81-83], whereas in H_6TeO_6 one broad line was obtained; this was attributed [83] to the formation of other products in addition to IO_6^{5-}. It may be noted that for the orthotellurates of the alkaline earth metals (^{129}I NGR) it was found [80] that the width of the spectra depends on the history of the specimens and cannot be attributed to the production of a set of chemical forms of iodine. In this instance [83] the broadening of the spectrum of H_6TeO_6 may be similar in character.

† By distortion of the emission NGR spectrum, we mean a difference between its parameters or form and those of the corresponding absorption spectrum.

Thus emission Mössbauer spectroscopy indicates fairly unambiguously that daughter atoms are stabilised in a time interval much smaller than 10^{-9} s, in an extremely limited set of chemical forms and valencies. The chief role in the production of the large number of chemical forms frequently detected in radiochemical analysis is played by the dissolution process.

IV. PROCESSES OF ENERGY LOSS BY RECOIL ATOMS IN SOLIDS

To describe the chemical behaviour of highly energetic recoil atoms in a solid, models incorporating the results of the radiochemical analysis of irradiated systems and the theories of the mechanisms of energy loss by a "hot atom", developed in solid state physics, are being developed. In was noted in the introduction that the study of "hot" atoms or "recoil" atoms was based on the discovery of Szilard and Chalmers. These historically developed names are explained by the fact that the atoms produced in a nuclear reaction, as a consequence of the law of preservation of momentum, have a recoil energy which is much greater than the energy of the chemical bonding of the atom in the original molecule. Rupture of the chemical bond and decomposition of the mother molecule are thus unavoidable. In the study of the chemical effects of nuclear reactions by radiochemical methods, however, it is often necessary to assume high retention values (up to 100%). Thus it is obvious that the problem of the behaviour of so-called "hot" atoms—the loss of their excess of energy and the interaction with the environment—is a central problem in the study of the chemical consequences of nuclear reactions.

We may note several criteria by means of which radiochemists can judge the value of the theories developed in this field: 1) the ability of the model to give information on the nature of the primary products, that is the changes produced by the recoil atom in its original environment (we have in mind changes in the chemical, electronic, and three-dimensional structures); 2) its ability to reflect the influence of the crystal lattice parameters (that is the individuality of the chemical compound) on the nature of the changes produced; and 3) the ability of the model to establish the relationship between the picture of the changes in the solid and the picture of the distribution of the radioisotope among the different chemical forms in solution.

It should immediately be said that no single theory satisfying these criteria to a sufficient degree has yet been developed in radiochemistry and nuclear chemistry.

The phenomena of "retention" (that is the existence of radioactive atoms in the mother form) and "yield" (that is the existence of radioactive atoms in chemical forms differing from the mother form) are explained in radiochemistry by means of models of various kinds, proposing different mechanisms for the interaction of a hot atom with the environment in a crystal lattice. The principal models of the process of energy loss by recoil atoms have been described in detail[1].

In the "billiard ball" model, the hot atom loses the recoil energy as a consequence of several elastic collisions with the atoms of the lattice. This leads to the idea of a molten region (with an original local temperature of $10^{-6}-10^{-7}$°K) occupying a volume of $\sim 3 \times 10^5$ atoms and existing for about 10^{-8} s. We should expect that partial mixing of the substance in the molten zone would take place and that the distant environment would influence the chemical behaviour of the recoil atom.

The "ligand loss" model assumes the production of a series of charged fragments formed by a hot atom which has left its original environment (for example MnO_3^+, MnO_2^{3+}, MnO^{5+}, and Mn^{7+} in the (n,γ) reaction in potassium permanganate). Although the initial valency of the atom remains the same, the yields of the different chemical forms of the hot atom are attributed to the different reactions of the dissolving medium with the fragments produced in the solid.

The "hot zone" model, based on the theories of solid state physics on the movement of charged particles in a crystal lattice, leads, for example, to the following zone parameters for a recoil atom which has been stopped: for the typical example of an (n,γ) reaction, the volume of the region in the lattice heated above the melting point (~ 1000°K) corresponds to ~ 1000 atoms, and the lifetime of this "hot zone" is $\sim 10^{-11}$ s. It is suggested that the fusion region consists of a superheated solid rather than a melt, although genuine fusion is possible at its centre.

Thus these models indicate the existence of significant collective changes in the region of the arrested hot atom (significant changes in the chemical, electronic, and three-dimensional structures of the environment). According to these models, which are used to explain the variety of chemical forms produced by recoil atoms, the chemical bonding in the original molecule is generally broken, the hot atom is in the "free" state, and in the final analysis its environment is different from that in the mother matrix.

The values of the retention obtained by radiochemical analysis can be explained only by introducing different mechanisms for the conversion of the recoil atoms into the form of the original compound. Four forms of retention are usually considered[6]: preservation of the original bonds in the molecule in the nuclear process—a comparatively rare situation (primary retention), and return to the original chemical form as a result of: reactions of the "hot" atoms by a mechanism of elastic collisions and epithermal reactions of the radioactive atoms (secondary retention), reactions of radiation-chemical synthesis (tertiary retention), and finally thermal reactions of the recoil atoms and processes of thermal isotopic exchange (quaternary retention).

It is obvious that emission Mössbauer spectroscopy (when the Mössbauer transition is a direct consequence of a nuclear reaction in the solid phase) can be used to verify some of the assumptions of these models. Thus the existence of a melt in the zone of the recoil atoms (for the "billiard ball" model) with a lifetime of 10^{-8} s should make it impossible to observe the NGR emission spectrum. If the "ligand loss" or "hot zone" models are realised, extremely significant changes in the spectra are unavoidable, due to the fact that only a very small number of recoil atoms are in a truly initial "mother" environment after $10^{-7}-10^{-9}$ s. In this instance the part of the emission spectrum corresponding to the mother chemical form of the Mössbauer atom in the solid (that is the retention) can be produced only by the recoil atoms which have been preserved in this form by a primary retention mechanism ("the rare case of preservation of the original bonds in the molecule") and by the mechanism of epithermal reactions of the radioactive atoms. Tertiary and quaternary retention cannot contribute to the total retention when the Mössbauer experiment is carried out directly "under the beam" (for example, excitation of the ^{57m}Fe level as a result of (d,p) and (n,γ) reactions and Coulombic excitation). Secondary retention by the mechanism of "hot" atom reactions, as shown above, similarly cannot contribute to the total retention because of the existence of a molten region

in the zone of the recoil atom at the moment of emission of the resonance gamma-quantum.

It is clear that the experimental observation of the Mössbauer effect after a nuclear reaction makes it possible to follow the fate of highly energetic recoil atoms. The actual existence of NGR spectra, and also their parameters, obviously make it possible to discuss the substance of various models of the process of energy loss by hot atoms in a crystal lattice.

1. USE OF THE MÖSSBAUER METHOD TO STUDY PROCESSES OF ENERGY LOSS BY HOT ATOMS

a. Metallic Targets

Coulombic excitation of the ^{57m}Fe level by α-particles with energy 3 MeV in a target of magnetic iron [84-87] did not show a decrease in the Mössbauer coefficient f for the target relative to f for ^{57}Co, introduced by diffusion into stainless steel (the difference was not greater than 5%). Similarly, differences were not observed in the chemical shift and fine magnetic structure of the Mössbauer spectra of the two sources.

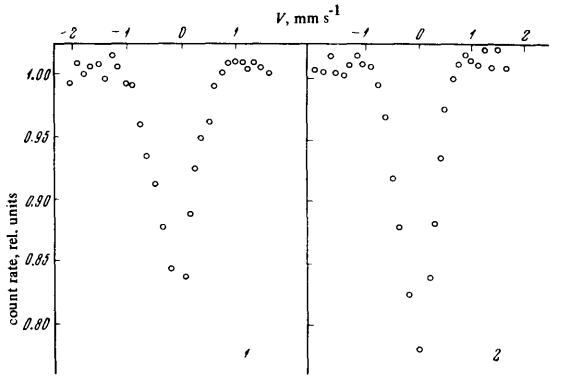

Figure 4. NGR spectrum from a source obtained by the (d,p) reaction in non-magnetic iron (*1*) and from a source obtained by the introduction of ^{57}Co into non-magnetic iron by diffusion (*2*). The background was not taken into account. Absorber—stainless steel [94].

A unique method of Coulombic excitation of the ^{57m}Fe level was used by Sprouse and coworkers [88]: the ^{57m}Fe atoms ejected from a stainless steel target by oxygen ions with energy 36 MeV were passed through a vacuum on to a support of copper, aluminium, gold, or magnetic iron, which thus acted as Mössbauer sources. Comparison of the spectra obtained in this way with the spectra of ^{57}Co introduced into the same matrices showed that the two types of spectra are identical.

It may be concluded that in metals, the atoms which have undergone Coulombic excitation are in the lattice sites for a time interval much smaller than 10^{-7} s, and that their environment does not differ from the environment in the ordinary lattices (otherwise, the magnitude of the effect would decrease, a chemical shift would be observed, and the internal magnetic field acting on the iron nucleus would change). This conclusion is confirmed by analogous results obtained for the Coulombic excitation of the Mössbauer level of ^{61}Ni [89] and the Mössbauer levels of the rare earth elements in metallic targets [90-92]. Thus a metallic ^{184}Yb target has been used as source [91], the metal also acting as absorber. The Mössbauer spectrum consisted of a singlet line, the width of which was greater than that of the natural line by a factor of only 1.3. The magnitude of the effect was $f_{expt} \simeq 0.05 \pm 0.03$, whereas $f_{theor} = 0.08$. All this led to the suggestion [91] that radiation changes do not take place close to the Mössbauer atom. It should be remembered that the recoil energy for Coulombic excitation may reach 100 keV.

The reaction ^{56}Fe$(d,p)^{57m}$Fe in metallic iron has been studied [93-95] (recoil energy ~ 500 keV). The NGR spectra for ^{57m}Fe, obtained by the (d,p) reaction in non-magnetic iron, and for ^{57}Co introduced by diffusion into the same matrix [94] are given in Fig. 4. The results of the treatment of these spectra are given in Table 2.

Table 2.

Parameters of the spectra	Source	
	^{56}Fe$(d,p)^{57m}$Fe	^{57}Co
Chemical shift, mm s^{-1}	0.00	0.00
Amplitude of effect, %	31±4	29±2
Width, mm s^{-1}	0.37±0.04	0.36±0.04

For the ^{57m}Fe source obtained by the (d,p) reaction, a chemical shift relative to the ^{57}Co source in the same matrix is not observed (Table 2). The magnitude of the effect and the width of the line in the spectrum remain unchanged.

For a magnetic iron target, the (d,p) reaction similarly does not lead to a decrease in the effect or to a change in the fine magnetic structure of the NGR spectrum [93-95].

The temperature of the local environment of the ^{57m}Fe recoil atom formed in the (d,p) reaction in magnetic iron was determined [95] from the temperature dependence of the magnitude of the magnetic splitting of the spectrum. In the range of target temperatures between −195° and +40°, the temperature of the environment of the recoil atom was found to be equal to the macro-temperature of the target.

Thus in the (d,p) reaction in a metal lattice, as in the Coulombic excitation examined above, the recoil atoms are produced in a time interval much less than 10^{-7} s, in normal lattice sites, and the temperature of their environment is equal to the macro-temperature. It is obvious that the formation of a molten zone and turbulent mixing of the substance in the recoil zone would have led unavoidably to significant changes in the NGR spectra, but this was not observed experimentally.

The reaction ^{56}Fe$(n,\gamma)^{57m}$Fe in metallic magnetic iron was also studied by the NGR method [96]. The spectrum obtained was the same as the spectrum of ^{57}Co in an analogous matrix, indicating that the ^{57m}Fe atoms after the (n,γ) reaction under the beam (recoil energy $\leq$ 540 eV) are in normal lattice sites. The (n,γ) reaction, carried out under a neutron beam for ^{155}Gd and ^{157}Gd [97] and for ^{39}K [98,99] in metallic targets similarly does not lead to the production of displaced Mössbauer atoms.

b. Non-metallic Targets

Experiments on the study of various nuclear reactions by the NGR method in non-metallic targets are of the greatest interest for the solution of chemical problems of the behaviour of hot atoms in solids.

The Coulombic excitation of the ^{57m}Fe level in Fe_2O_3 showed a decrease in the quantity f for this source relative to f for the source Fe_2O_3 : ^{57}Co. [85-87] The fine structure of the spectrum of the Fe_2O_3 target remains unchanged, as does the chemical shift. The authors cited [85-87] suggest that some of the ^{57m}Fe recoil atoms, after Coulombic excitation, are displaced from the normal lattice sites, leading to a decrease in f. There are no grounds for assuming the possibility of the production of molten zones on energy loss by the hot atom; if this were the case, the NGR spectrum would show a change in fine structure and a chemical shift.

Analogous results were obtained for the Coulombic excitation of the Mössbauer level in ^{73}Ge. [100-102] The decrease in f for the target cannot be attributed to the existence of a hot zone, since the width of the spectrum would have increased [101].

Coulombic excitation of the ^{174}Yb Mössbauer level in Yb_2O_3 [91] gave a spectrum identical to the absorption spectrum of Yb_2O_3. The authors cited [91] concluded that the greater part of the ^{174}Yb atoms after the Coulombic excitation remain in the lattice sites.

The $^{56}Fe(d,p)^{57m}Fe$ reaction in non-metallic targets leads to a decrease in f relative to f for ^{57}Co in the same matrices [95].

The $^{56}Fe(n,\gamma)^{57m}Fe$ reaction in Fe_2O_3 and $FeSO_4.7H_2O$ led to a slight change in the NGR spectra of these targets relative to the spectrum of ^{57}Co in Fe_2O_3 and the absorption spectrum of $FeSO_4.7H_2O$. For Fe_2O_3, a slight decrease in the effective magnetic field acting on the iron nucleus was observed, and for $FeSO_4.7H_2O$ a line characteristic of tervalent iron appeared [96]. This indicated the production of displaced atoms in the targets; for $FeSO_4.7H_2O$, these atoms may also be stabilised in the form of Fe^{3+}.

It should be emphasised that even in such complex compounds as Fe_2O_3 and $FeSO_4.7H_2O$, a considerable proportion of the recoil atoms remain in the normal lattice sites, that is their environment after the (n,γ) reaction is the same as the original environment.

In a study of the (n,γ) reaction under a neutron beam for ^{157}Gd and ^{155}Gd isotopes by the NGR method, it was established that in oxide targets (unlike metallic targets) a slight change in the spectrum is observed; a possible reason for this is that some of the recoil atoms are in displaced positions [97].

It has been shown [98] that, for example, for a source in the form of a KCl target [the reaction $^{39}K(n,\gamma)^{40}K$] the magnitude of the effect is close to the theoretical (f_{expt} = 0.11 ± 0.02, f_{theor} = 0.12 at 80°K), and the width of the spectrum differs little from the theoretical. This may confirm that in the reaction $^{39}K(n,\gamma)^{40}K$ in KCl, the greater part of the potassium atoms at the moment of emission of the Mössbauer gamma-quantum ($\tau \simeq 4 \times 10^{-9}$ s) are in lattice sites. It may be noted that the recoil energy in this case reaches 800 eV.

Various complex compounds of potassium, for example $KAlSi_3O_8$, have been used as targets for irradiation by neutrons [99], but all the spectra consisted of a single line, the width of which exceeded the natural width by a factor of not more than 1.3. This indicates again that there are no significant radiation changes in the environment of an atom which has undergone an (n,γ) reaction.

The $^{118}Sn(n,\gamma)^{119m}Sn$ reaction in tin oxide under conditions of prolonged reactor irradiation has been studied [62,103]. It was found that the spectrum of irradiated ^{118}SnO, in addition to the Sn^{II} doublet, contained a weak Sn^{IV} line. The spectrum of the same specimen, dissolved in hydrochloric acid and frozen, showed a marked increase in the intensity of the Sn^{IV} line (Fig. 5). This is apparently related to the fact that in the (n,γ) reaction under the conditions of prolonged irradiation in a reactor, some of the recoil atoms are displaced, and the intensity of the line from these tin atoms is slight when the spectrum is dissolved. All the radiating atoms are in identical conditions, and this leads to an increase in the intensity of the Sn^{IV} line.

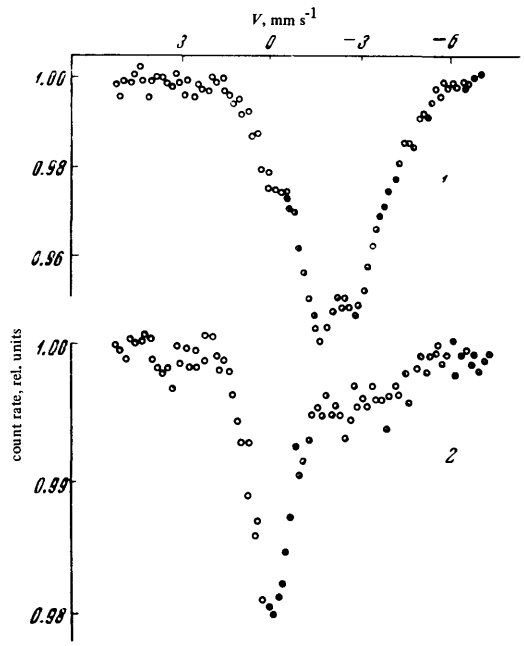

Figure 5. NGR spectra of ^{118}SnO, irradiated in a reactor, at 80° K (*1*) and a hydrochloric acid solution of the same specimen at 80°K (*2*). Absorber—calcium stannate [62].

Slightly different results were obtained for the reactor irradiation of ^{118}SnO and $^{118}SnO_2$, [104] when complex NGR spectra were obtained. The results were interpreted in terms of the "hot" zone model. Later work [62], however, did not confirm these results.

Interesting results were obtained in a study of α-decay in ^{241}Am. [105-111] The spectrum of $^{241}AmO_2$ in NpO_2, and for comparison the spectrum of $^{237}UO_2$ in NpO_2 (the β-decay of ^{237}U gives the same Mössbauer level ^{237}Np), [105] are given in Fig. 6. It can be seen that the effect is much smaller for α-decay than for β-decay. Since the recoil energy after the α-decay of ^{241}Am is ~ 93 keV, displacement of some of the daughter atoms from normal crystal lattice sites is possible, and this decreases the value of f. The theory of the Mössbauer effect after α-decay has been developed [112] and it has been shown that relaxation processes may be responsible for the broadening of the line.

Thus the existence of emission Mössbauer spectra after nuclear reactions characterised by high recoil energies [Coulombic excitation, α-decay, (d,p), and (n,γ)] clearly indicates that a considerable proportion of the recoil atoms, at the moment of emission of the resonance gamma-quanta, are in normal lattice sites. The existence of molten regions, mixing of the substance, and the production of significant radiation damage in the region of the recoil atom are not confirmed. It of course follows from these spectra that some of the recoil atoms after the nuclear reaction are in a local environment which is different from the mother environment, and this is revealed by broadening of the lines and a decrease in the effect.

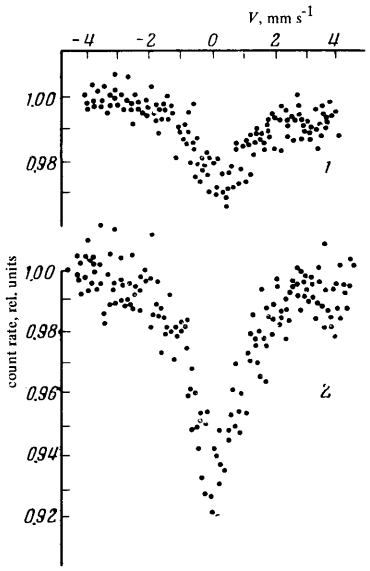

Figure 6. NGR spectra of $^{241}AmO_2$ (*1*) and $^{237}UO_2$ (*2*). Absorber—NpO_2.[105]

The next paragraph describes briefly studies carried out in the last ten years in the field of the physics and chemistry of the solid state, the essential feature of which is the departure from models based on a description of significant changes in the region of the arrested hot atom.

2. PRESENT IDEAS ON PROCESSES OF ENERGY LOSS BY RECOIL ATOMS

We shall try to follow the analogy in the results of the following studies: 1) the solution of the problem from the equilibrium and dynamics of the formation of defects in the crystal lattice; 2) the determination of the parameters of the reaction zone of the recoil atom by radiochemical experiments; and 3) the study of chemical effects in crystals bombarded with accelerated ions.

About ten years ago, theories of so-called crowdions and focusons—new mechanisms of the transfer of atoms and the energy of atoms in crystals—were put forward [113-117]. These theories have been confirmed by calculations on electronic computers [118,119] and by comparison of the results with experiment.

Among the many conclusions following from these calculations, the following is of particular interest: the propagation of the energy of the primary atom in the crystal does not produce phenomena resembling fusion or the turbulent mixing of atoms. Calculations for the recoil energy characteristic of the (n,γ) reaction do not confirm the existence of high temperatures, continuation of the existence of a hot zone, or the collective nature of the changes.

To verify these ideas regarding the dynamics of radiation damage, radiochemical experiments were carried out to determine the parameters of the reaction zone of the recoil atom [the (n,γ) reaction].[120-124] The homogeneous mixed crystals $K_2ReBr_6-K_2SnCl_6$; $K_2ReCl_6-K_2SnBr_6$; $K_2OsBr_6-K_2SnCl_6$; and $K_2ReBr_6-K_2OsCl_6$ were studied. The systems were irradiated with neutrons, and the products of the $^{185}Re(n,\gamma)^{186}Re$ reaction were determined quantitatively (by ionophoresis). For the $K_2ReBr_6-K_2SnCl_6$ system, for example, the K_2ReBr_6 concentration was varied in the range 1–28 mole %. The essential features of the experiments were as follows. The primary retention should be represented by the form of $ReBr_6^{2-}$ retained by the billiard ball mechanism at low concentration of K_2ReBr_6—in the form of $ReCl_6^{2-}$, and for retention by the hot zone mechanism we should expect a set of all forms of hexabromochlororuthenates $ReBr_{6-n}Cl_n^{2-}$ $(6 \geqslant n \geqslant 0)$ with the conditions that the K_2ReBr_6 concentration is not too small.

Analysis of the results led to the following conclusions: 1) the billiard ball mechanism does not apply in any of the systems studied; 2) the concept of fusion in the reaction zone of the recoil atom is refuted, since otherwise the distribution of the yields of all possible bromochlororuthenates should have been close to the random distribution, and this is not observed; and 3) the region of the reaction zone of the recoil atom is smaller and broken down to a smaller extent than is assumed in the hot zone model; fusion processes and significant turbulent mixing of the atoms do not take place in the reaction zone.

Let us now consider experiments on the study of chemical reactions with accelerated ions[125]. These experiments make it possible to compare the results for the chemical distribution of ^{51}Cr atoms in different compounds of chromium subjected to bombardment by accelerated $^{51}Cr^+$ ions or irradiated with thermal neutrons. The results[125] show that the same radioactive products are obtained on dissolution of the crystals after both experiments, and also that a similarity is observed in the kinetics of formation of the $^{51}CrO_4^{2-}$ fragments on thermal annealing (that is complete similarity in the processes of increase in retention on annealing in the two experiments). In the opinion of the authors cited[125], this similarity confirms the hypothesis that the changes in the valency state of radioactive atoms on annealing reflect processes of electronic rearrangement in the crystal in the zone of the ^{51}Cr atom rather than restoration of the altered original molecule. It may be assumed that this conclusion confirms indirectly the theory that the changes produced by a recoil atom in a crystal lattice are small and purely local.

V. THE "SOLID–SOLUTION" PROBLEM

As already noted, one of the fundamental problems in the comparison of information obtained in the study of a solid and its solution is the determination of the influence of the solvent medium on the crystal. It is hoped that the use of the NGR method will provide new and promising possibilities in this connection. The use of other indirect methods to determine the nature of the environment of a recoil atom, not related to the dissolution procedure, is also of interest.

Promising possibilities are provided by the study of the angular correlation of cascade radiation as applied to the chemistry of hot atoms. Thus for $KReO_4$ crystals irradiated with neutrons, considerable breakdown of the angular correlation of the gamma-quanta of ^{188}Re was observed[126]. In the opinion of the authors cited, this indicates that irradiated $KReO_4$ contains forms of ^{188}Re different from the mother form. Nevertheless, chemical analysis of irradiated perrhenates shows 100% retention. This example appears sufficiently clear and demonstrates in this specific instance the "incompatibility" of information obtained before and after dissolution. An interesting feature is that the observed breakdown of the angular correlation to some extent agrees with the information obtained from emission Mössbauer spectroscopy, where the broadening of the lines and the decrease in the magnitude of the effect are attributed to the existence of some of the radiating Mössbauer atoms in an environment different from the mother environment.

In the comparison of the results obtained by the NGR method (and "physical" methods in general) and radiochemical results, allowance must also be made for possible changes in the initial distribution of the chemical forms of the hot atoms in the crystal, depending on the accumulated radiation dose, the extent of the defect character of the original specimens, the irradiation parameters, processes of thermal and radiation annealing, and a number of other factors.

Thus a study of the irradiation of $H_2TeO_4.0.36H_2O$ and H_2TeO_4 in a reactor established[127] that the yield of reduced forms of ^{131}I (the target was dissolved in aqueous KOH solution containing various iodine carriers) increases with increase in the integral neutron flux and the dose of accompanying gamma-radiation.

A study of the neutron irradiation of crystalline tellurium dioxide showed that the increase in the yield of reduced forms of ^{131}I is related to the effect of gamma-irradiation. It was proved[128] that the increase in the yield of reduced forms is due to the reduction of IO_3^- to I^- by reaction with elementary tellurium, formed by the gamma-irradiation of tellurium dioxide.

In the irradiation of $KSb(OH)_6.H_2O$ with thermal neutrons, the retention in the forms Sb^{3+} and Sb^{5+} depends on the quantity of water in the specimens[129].

From these examples it is clear that the borrowing of information from the radiochemistry of a given element for the interpretation of NGR spectra, and naturally the reverse borrowing, are in general inapplicable. Comparison of the results obtained by the two methods is desirable and allowable when the same specimens are studied, with detailed allowance for possible complicating features.

Examination of the information obtained by emission Mössbauer spectroscopy establishes some general features in the consequences of seven forms of nuclear transformation in solids [electron capture, isomeric transition, α-decay, β-decay, Coulombic excitation, and (n,γ) and (d,p) reactions].

1. The metastable highly-charged states of atoms produced as a consequence of nuclear transformations in a solid are discharged in a time interval much smaller than the lifetime of a Mössbauer level ($10^{-7}-10^{-9}$ s) and are converted into stable forms characteristic of the macrochemistry of the given element.

2. The emission Mössbauer spectra generally correspond to an extremely limited set of forms of stabilisation of the recoil atoms (one or two), whereas the use of delicate analytical procedures in radiochemistry often reveals a rich spectrum of chemical forms and valencies. This "discrepancy" is apparently related to the influence of the local environment of the recoil atom (revealed in the emission NGR spectra by broadening of the lines and a decrease in the magnitude of the effect) on the distribution of the radioisotope being studied among different chemical forms during dissolution.

3. The study of the processes of energy loss by hot atoms by Mössbauer spectroscopy does not show the existence of molten zones and mixing of the substance in the reaction region of a highly energetic recoil atom. Even in comparatively complex compounds at high recoil energies, a considerable proportion of the Mössbauer atoms at the moment of emission of the resonance gamma-quantum are in the normal sites of the crystal lattice, and their environment does not differ from the original environment.

---o0o---

In the two years since the review was written, a large number of papers on the use of the Mössbauer effect to study the after-effects of nuclear transformations in solids have been published. Of work by Soviet authors, mention must first be made of the studies by Nesmeyanov and coworkers[130-132], who investigated the influence of the converted isomeric transition in ^{125}Te and electron capture in ^{125}I on the chemical state of the daughter atoms. Anomalous charge states of Te were not detected, and stabilisation takes place in the usual forms of the macro-chemistry of this element.

The emission spectra of tin in alkali metal and silver halides have been studied[133,134]; no influence of the strongly converted isomeric transition in the 250-day isomer ^{119}Sn on the charge state of the daughter atoms was detected. Similarly, proof was not obtained for the existence of after-effects of electron capture in impurity ^{57}Co atoms introduced into the CoS lattice[135] and semiconducting compounds $A^{III}B^{V}$.[136] The problem of the influence of nuclear transformations on the chemical state of impurity tin and iron atoms in ionic crystals has been studied[137]. It is suggested that the absence of after-effects is related to the "rigidity" of the lattice of the matrices studied (a measure of this "rigidity" is provided by the Debye temperature). Murin and coworkers[138] assume as a working hypothesis that on obtaining recoil energy much greater than the energy of the bond formed by the atom in the lattice, a daughter atom may not leave the lattice site, because of breakdown of the correlation between the momentum and the energy of recoil.

Outstanding among work by authors in other countries is a paper[139] describing a detailed study of the influence of electron capture and β-decay on the chemical state of daughter atoms. The authors cited[139] consider that the changes in the local environment of atoms which have undergone a nuclear transformation (and hence the production of a large number of chemical forms of the daughter atoms) may be observed in lattices with low Debye temperatures or in lattices with a high concentration of defects (irrespective of the magnitude of the Debye temperature). It is suggested that stabilisation of the hot atoms leads to electronic structures characteristic of the macro-chemistry of the given element.

The problem of determining the lifetimes of the metastable states of ^{57m}Fe atoms formed after the decay of ^{57}Co in Cu_2O, MgO, and Al_2O_3 lattices has been studied[140]; it was shown that the iron atoms are stabilised in the usual valency states in time intervals much smaller than the lifetime of the Mössbauer level.

The Mössbauer effect has been studied for atoms which have undergone a nuclear reaction accompanied by a high recoil energy: the $^{56}Fe(n,\gamma)^{57}Fe$ reaction in metallic iron and Fe–Al alloys[141,142]; the α-decay of ^{241}Am;[14] and the Coulombic excitation of various nuclei[144-151]. Although the number of papers devoted to nuclear transformations accompanied by vast recoil energies is increasing rapidly, the problem of the behaviour of recoil atoms of this kind still remains a subject for discussion.

Formation of Network Polymers

E.B.Trostyanskaya and P.G.Babaevskii

Methods of analysing the formation of network polymers from polyfunctional compounds and determining their structural parameters are surveyed, and experimental data obtained by these methods on the formation of network polymers from monomers and oligomers are examined. The data permit assessment of the possibilities and the establishment of general laws for the formation of polymer networks in the initial and the final stages of the reactions. The problems of the controlled synthesis of network polymers from polyfunctional compounds are discussed on the basis of the experimental results which have accumulated. The list of references comprises 114 items.

I. INTRODUCTION

Advances in the synthesis of linear polymers and investigations of their structure stimulate the development of methods for the detailed study of network polymers. Establishment of the laws governing the formation and the structure of network polymers and also the discovery of methods for their controlled synthesis would promote a rational approach to the control of technical processes in the manufacture and processing of materials based on them, since network polymers, unlike linear polymers, are usually formed in the course of these processes.

According to the definition given long ago by Staudinger [1] network (spatial or three-dimensional) polymers are those in which the component chains are joined by chemical bonds in three directions. Among all the types of chemical and physical bonds only covalent bonds are able to form a spatially fixed structure, which is irreversible after breakdown. Other bonds, including ionic and coordinate bonds, are labile and delocalised in space, and may form three-dimensional structures, such as e.g. in ionomers, polycoordinate polymers, etc. Therefore the term "network polymers" should be applied only to polymers whose chains form a network of covalent bonds distributed in space, the so called polymer network. All other types of interaction—ionic, coordinate, hydrogen, or intermolecular bonds, physical contact and entanglement—may also appear in the polymer network, and make their contribution, often very considerable and even predominant, to its formation, structure, and properties.

Polymers which contain a large number of strong but labile bonds (ionic, coordinate, hydrogen, etc.) between the linear chains formed by covalent bonds, and which under certain conditions possess properties characteristic of network polymers, must be regarded as quasi-network polymers.

Network polymers can be obtained by cross-linking existing linear macromolecules with covalent bonds and also by introducing polyfunctional monomers, oligomers, or mixtures thereof into the reaction. Macromolecules can be combined by covalent bonds only when the polymer chains are flexible. In practice this method is applied only in the vulcanisation of elastomers. The second method is generally applicable, and enables network polymers to be obtained with almost any properties—from elastomers with an open network to the so-called "hardened" polymers with a dense network. Recently, therefore, work has been developed especially intensively in this direction. Broad investigations are being conducted into the laws of the formation of polymer networks by reactions of polyfunctional compounds, methods are being developed for the direct investigation of the structural characteristics not only of open-network but also of dense-network polymers, and ways are being studied for the directed synthesis of network polymers having a specified structure and properties. The present paper attempts to summarise the principal results obtained in these investigations.

II. METHODS FOR ANALYSING THE FORMATION OF NETWORK POLYMERS AND ESTIMATING THEIR STRUCTURAL PARAMETERS

Flory [2,3] applied a statistical method for analysing the formation of network polymers by the polycondensation of monomers containing more than two functional groups in the molecule. He correlated the degree of conversion P of the functional groups with the probability of branching of the polymer chains during their growth (branching α coefficient). The following relations exist between P and α in the reaction systems which are encountered most frequently.

1. For a polyfunctional monomer RA_f, whose functional groups react with one another,

$$P = \alpha \qquad (1)$$

2. For a mixture of a polyfunctional monomer RA_f with a difunctional monomer $R'B_2$, where the groups A react only with the groups B, we have

$$P_A = \sqrt{\frac{\alpha}{r}} \qquad (2) \quad ; \qquad P_B = \sqrt{\alpha \cdot r} \qquad (3)$$

where P_A and P_B are the degrees of conversion of groups A and B respectively, and

$$r = \frac{n_A f_A}{n_B f_B},$$

is the ratio of the initial components, n_A, n_B, and f_A, f_B being respectively the numbers of moles and the functionalities of the monomers A and B.

An infinite three-dimensional network of the monomer units interconnected by covalent bonds is formed (gel point) at a critical value of the branching coefficient

$$\alpha_{crit} = \frac{1}{f-1} \quad (4)$$

where f is the functionality of the polyfunctional compound. Until the gel point is reached, values of α lie in the range $0 < \alpha < \alpha_{crit}$.

In the polycondensation of the above reaction systems gel formation occurs ideally when conversion of the functional groups corresponds in Eqns. (1)–(3) to the critical value of α. Thus in the polycondensation of a trifunctional monomer gel formation starts when the degree of conversion of the functional groups is one-half, the corresponding conversion for a tetrafunctional monomer being one-third.

In the polycondensation of a polyfunctional monomer with a difunctional monomer a polymer network is formed only if $\frac{1}{2} < r < 2$. When $r = 1$,

$$P_{A,g} = P_{B,g} = \sqrt{\alpha_{crit}}. \quad (5)$$

where $P_{A,g}$ and $P_{B,g}$ are the degrees of conversion of groups A and B respectively at the gel point.

Statistical analysis of polycondensation beyond the gel point enables the proportion by weight of the sol W_S (the quantity of reaction products unattached to the polymer network) to be related to the coefficient of branching α, and hence to the degree of conversion of the functional groups—Eqns. (1)–(3) and (5):

$$W_s = \frac{(1-\alpha)^2\alpha'}{(1-\alpha')^2\alpha} \quad (6)$$

where $\alpha' < \alpha$ for any physically meaningful value of β in the equation $\beta = \alpha(1-\alpha)^{f-2}$, in which β is an arbitrary quantity in the range $0 < \beta < \alpha_{crit}(1-\alpha_{crit})^{f-2}$. The value of α beyond the gel point lies in the range $\alpha_{crit} < \alpha < 1$. Thus in the polycondensation of a trifunctional monomer $\alpha_{crit} = \frac{1}{2}$ and $\beta = \alpha(1-\alpha)$. For any β in the range $0 < \beta < \frac{1}{4}$, we have $\alpha' = 1-\alpha$, and then

$$W_s = \frac{(1-\alpha)^3}{\alpha^3} \quad (7)$$

Reactions of polyfunctional monomers involving step-by-step (migration) polymerisation conform to similar statistical laws [4,5].

Statistical analysis of the polymerisation of polyvinyl monomers with isolated double bonds, which is propagated by a chain mechanism, presents considerably greater difficulties [6–10]. This is due to the complexity of allowing statistically for different mechanisms of termination of growing macroradicals or macroions. In the simplest case of the copolymerisation of monovinyl and divinyl derivatives the degree of conversion of double bonds at the gel point can be calculated from the equation [6,7]

$$\beta_{crit.} = \frac{1}{\lambda(P_W - 1)} \quad (8)$$

where β_{crit} is the proportion of double bonds which have reacted at the gel point, P_W is the weight-average degree of polymerisation at the gel point, and

$$\lambda = \frac{2M_2}{M_1 + 2M_2}$$

is the proportion of the double bonds in the reaction system which is due to the divinyl monomer, M_1 and M_2 being the numbers of moles of mono- and di-vinyl monomers respectively. No statistical analysis has been made of the reactions of polyvinyl monomers outside the limits of gel formation.

The structure of the polymer network following the gel point is characterised by the frequency (density) of branch points in it, which is expressed by the concentration of effective chains, i.e. those joining two branch points, or by the average length of the chain segment between them. The concentration of chains is expressed as the number of chains N_C or the number of moles of chains n_C in unit of volume of the polymer. The length of the effective chains is estimated as the conventional mean molecular weight M_C of the segment of polymer chain between adjacent branch points. These parameters are interrelated as follows:

$$n_c = \frac{N_c}{N_A} = \frac{\rho}{M_c} \quad (9)$$

where N_A is Avogadro's number and ρ the density of the polymer.

Calculation of the structural parameters of the polymer network expected theoretically from the composition of the initial reactants and the extent of reaction after gel formation will depend on how the structure of the network is represented. A polymer network can be regarded as a combination of chain segments attached at both ends (effective chains), and segments attached at only one end (ineffective chains), to branch points in the network. In the polycondensation of a trifunctional monomer RA_3 with a difunctional monomer $R'B_2$, provided that the groups A react only with the groups B, the number of moles of effective chains after gel formation can be related statistically to the degree of conversion by the formula [11].

$$n_c = \frac{3}{2}\left[P^3\left(1-\frac{q^6}{P^6}\right) - 3q^2P\left(1-\frac{q^2}{P^2}\right)\right] \text{ moles of A} \quad (10)$$

where P is the degree of conversion of groups A and $q = 1 - P$ the proportion of groups A which have not reacted.

In the reaction of a difunctional compound with a small amount of a polyfunctional compound the polymer network can be regarded as comprising long chains formed by the difunctional monomer units and joined together by units of the polyfunctional monomer, which in this case can be regarded as points of a tetrahedral network. The number of moles of effective chains in unit volume of the polymer to be expected theoretically from the composition of the reaction system when the reaction has gone to completion can then be estimated by means of the equation [12,13]

$$n_c = Z \cdot \varepsilon \cdot C \quad (11)$$

where $Z = \frac{1}{2}f$ is the mean number of chains per molecule of an f-functional monomer, ϵ the fraction of the f-functional monomer which has reacted with all the functional groups, and C the number of moles of the f-functional monomer per unit volume of the reaction mass.

In the particular case of the copolymerisation of a monovinyl monomer with a small quantity (up to 3 mole %) of a divinyl monomer, with complete conversion of the double bonds, the number of effective chains per unit volume of the polymer is [14]

$$N_c = \frac{2\rho[M_2] \cdot N_A}{(1-[M_2])M_1 + [M_2] \cdot M_2} \quad (12)$$

The mean molecular weight of the effective chains is calculated as [15]

$$M_c = \frac{2M_1}{f_2}\left(\frac{1}{[M_2]} - 1\right), \quad (13)$$

and the number of moles of effective chains per unit volume is [12]

$$n_c = C(2[M_1] + 3[M_2]) \quad (14)$$

where $[M_1]$, $[M_2]$, M_1 and M_2 are respectively the mole fractions and the molecular weights of the mono- and di-vinyl monomers, $f_2 = 4$ is the functionality of the divinyl monomer, and C is the number of moles of the divinyl monomer in unit volume of the reaction system.

With increase in the content of the divinyl monomer in the reaction system above 3 mole % the length of the effective chains becomes comparable with that of the chain of the divinyl monomer. In this case three chains—two formed by monovinyl monomer units and one divinyl monomer chain—must be regarded as meeting at a branch point. The number of effective chains in unit volume of the polymer can then be calculated from the relation [14]

$$N_c = \frac{3\rho[M_2] \cdot N_A}{(1-[M_2])M_1 + [M_2] \cdot M_2} \quad (15)$$

When the initial components have complicated compositions, the mean value M_C can be most easily calculated by choosing the most probable structure for a branch point in the polymer network, i.e. the most probable number of chains converging at one such point, and their molecular weight [16].

Approximate determination of the density of branch points in polymer networks is possible either from an analysis of the products of the controlled degradation of the polymer or from certain properties of the polymer which are related theoretically to the density of branch points. The former method involves chemical breakdown of the polymer network into linear macromolecules, which are analysed by the usual physicochemical methods [17-20]. In connection with the latter method it must be noted that theories relating the structural parameters of polymer networks to the physical properties of the polymers have been worked out only for ideal, tetrahedral networks having a low concentration of branch points.

According to the theory of rubberlike elasticity the concentration of effective chains in unit volume of an ideal network is related to the equilibrium deformation characteristics [21-23]:

$$n_c = \frac{G}{RT} = \frac{E}{3RT} = \frac{\sigma}{RT(\alpha - \alpha^{-2})} \quad (16)$$

where G is the equilibrium shear modulus, E the equilibrium modulus of elasticity under tension (compression), σ the equilibrium tensile (compressive) stress calculated on the initial cross-section of the specimen, R the universal gas constant, T the absolute temperature, and

$$\alpha = \frac{\pm\Delta l}{l_0} + 1 = \frac{l}{l_0},$$

the stretch (shrinkage) factor, in which l is the length of the deformed specimen, $\pm\Delta l$ the elongation (contraction) of the specimen, and l_0 the initial length of the specimen. According to the theory of the swelling of ideal networks in solvents or their vapours n_C is related to the equilibrium swelling by the equation [3]

$$n_c = \frac{\ln a - [\ln(1-v_2) + v_2 + \chi v_2^2]}{V^0\left(v_2^{1/3} - \frac{2}{f}v_2\right)} \quad (17)$$

where a is the activity of the solvent vapour (for the liquid $a = 1$), v the fraction by volume of polymer in the swollen specimen, χ a thermodynamic parameter of polymer–solvent interaction, V^0 the molar volume of the solvent, and f the functionality of the polymer network (the number of effective chains converging at one branch point). For polymer networks with equilibrium swelling the concentration of effective chains and the deformation properties are related by the formula [3]

$$n_c = \frac{\sigma v_2^{1/3}}{RT(\alpha - \alpha^{-2})} \quad (18)$$

A relation has been established also between the osmotic pressure P_{osm} of the equilibrium (swollen) polymer network and the concentration of effective chains therein [24]:

$$n_c = \frac{P_{osm}}{RT} \quad (19)$$

III. LAWS OF THE FORMATION OF NETWORK POLYMERS FROM POLYFUNCTIONAL MONOMERS AND OLIGOMERS

In the vast majority of cases network polymers are synthesised from complicated mixtures of polyfunctional compounds of indeterminate composition, which have been termed resins. They contain not only unchanged initial monomers but also various proportions of oligomers with different numbers of monomer units and different amounts and arrangements of functional groups or other reactive centres responsible for formation of the polymer. Since the exact composition of the resin is unknown, and is easily altered by the slightest change in the conditions of synthesis, it is impossible to predict the structural parameters of the future polymer network. Therefore the numerous studies of the formation of network polymers with resins as examples have shed little light on the laws of the formation and structure of polymer networks. Only the synthesis of polymers from individual polyfunctional compounds (monomers and oligomers) or from specified mixtures will enable sufficient experimental data to be accumulated to elucidate these rules.

1. Reactions of Polyfunctional Monomers and Oligomers in the Initial Stage

The laws governing the reactions of polyfunctional compounds in the initial stage can be assessed from the agreement between experimental results on the degree of conversion of the functional groups at the instant of gel formation and values calculated theoretically (Eqns. 1–5). The degree of conversion is easily determined by the usual methods of quantitative analysis, since the system remains soluble up to the gel point, and the reactivity of the functional groups is easily developed. The accuracy of these investigations is determined largely by the accuracy with which the instant of gel formation can be fixed in the reaction system.

According to theoretical views the point of gel formation involves an instantaneous qualitative change in the properties of the reaction mass, including an infinite increase in viscosity and the appearance of a fraction which is insoluble even in boiling solvents. Most methods of establishing the gel point have been based on fixing these changes. It has also been proposed to determine the start of gel formation from the abrupt change in the electrical [25] and dynamic mechanical [26] properties of the reaction mass. These methods are both inaccurate and

complicated experimentally. They usually require rearrangement of the apparatus to continue monitoring the formation of polymer networks after the gel point has been reached.

One of the most convenient methods for fixing the gel point is to monitor continuously the variation in the modulus of elasticity of the reaction mass by means of a torsion pendulum, in which the inertial mass is suspended by a thread comprising monofils impregnated with the test material [27-31]. This method is simple and quite accurate, and it enables formation of the polymer network to be monitored until the final stage of the reaction.

Investigations of reactions of polyfunctional compounds occurring by a step mechanism (polycondensation and step-by-step polymerisation) show that in many cases the laws of the reactions preceding gel formation are very nearly statistical [2,4,5] (see Table 1). Nevertheless, Andrianov and his coworkers have shown that, for the polycondensation of several oligomeric organic ether-acids, organic alcohols, and organometallic alcohols, variation in the number of monomer units in the oligomers causes the experimental values for the extent of reaction at the gel point to vary from that calculated statistically [32-34] (see Table 1). The start of gel formation has been found to depend on the length of the chain in the polyfunctional compounds also in the reaction of diglycidic esters with amines [35] and of several oligomeric di-isocyanates with polyfunctional alcohols [36].

Table 1. Experimental and theoretical (Eqns. 1–3) degrees of conversion of several reaction systems at the gel point.

Reaction system	r	P_{gel} expt.	P_{gel} theor.	Method of fixing gel point	Ref.
Tricarballylic acid, adipic acid, diethylene glycol	1.00 0.80	0.879 0.991	0.879 0.955	measurement of viscosity by falling sphere method	2,3
Propanediphenylene diglycidate, hydrophthalic anhydride	1.00 0.80 1.43	0.55 0.50 0.68	0.577 0.516 0.690	formation of insoluble fraction	4,5
Dimeric diglycidic ester, hydrophthalic anhydride	1.35	0.597	0.581	ditto	
Pentaerythritol tetra-adipate +					
$HO(CH_2)_2OH$	1.0	0.20	0.575	appearance of fraction insoluble in boiling solvent	32,33
$HO(CH_2)_4OH$	1.0	0.25	0.575		
$HOCH_2CH_2OCH_2CH_2OH$	1.0	0.27	0.575		
$HO(CH_2CH_2O)_2CH_2CH_2OH$	1.0	0.33	0.575		
$HO(CH_2CH_2O)_3CH_2CH_2OH$	1.0	0.35	0.575		
$O[Si(CH_3)_2CH_2OCH_2CH_2OH]_2$	1.0	0.40	0.575		
$C_6H_5Si[OSi(CH_3)_2CH_2OCH_2CH_2OH]_3$	1.0	0.36	0.41		
$Si[OSi(CH_3)_2CH_2OCH_2CH_2OH]_4$	1.0	0.23	0.33		

Discrepancies between experimental and calculated degrees of conversion of double bonds at the gel point are observed especially frequently in the polymerisation of polyvinyl derivatives or their copolymerisation with monovinyl monomers [6,37,38].

The deviations in the formation of a polymer network in the initial stages of the reaction of polyfunctional compounds probably arise from the implausibility of several postulates underlying the statistical analysis. It is difficult to suppose that under actual conditions cyclisation is completely absent, or that reactive groups maintain constant activity. Furthermore, the increase in molecular weight during the reaction is accompanied by a sharp intensification of the role of intermolecular interaction.

These deviations may become predominant with certain reaction systems or conditions, and then the reactions of polyfunctional compounds will not obey statistical laws at all. In some cases, for example, ring closure in a polyfunctional compound is energetically more advantageous than chain growth. This results in the preferential formation of cyclopolymers, with the maintenance of solubility until the limiting stages of the reactions. Such phenomena are observed in the polymerisation of divinyl derivatives in which the double bonds are separated by the number of atoms necessary for the formation of stable rings [39-41]. Similarly the polycondensation of silanetriols may lead to the formation of polycyclic or ladderlike polymers [42-45]. The reaction of anhydrides of tetracarboxylic acids with diamines, and of tetramines with dicarboxylic acids, usually yields polycyclic or ladderlike structures [46], though under certain conditions network polymers can be formed from the same components [47].

The marked departure in the laws of the reactions of polyfunctional compounds from those to be expected statistically in the initial stages may also be a consequence of differences in the activity of the reactive groups of the polyfunctional compound or of a marked change in reactivity of still unreacted groups after addition of a monomer unit to the polymer molecule [48-50]. In the limit three-dimensional structures of restricted size may be formed, dispersed in the reaction mass, the so called microgels or popcorns [48,51,52]. In this case the gel point is the instant of aggregation of the microgels by chemical combination to form a macrogel of statistically non-uniform density.

2. Polymer Networks in the Final Stage of Formation

Analysis of the degree of conversion of functional groups in the reactions of polyfunctional compounds before the start of gel formation and comparison with the theoretical values show that the development of reactions in fairly close conformity with statistical laws (formation of a uniform polymer network at the gel point) can be accompanied by marked deviations towards the preferential formation of cyclic polymers or microgel structures. The polymer structure produced in the initial stage will obviously have a decisive effect on the further course of the reaction. Thus if polymers of polycyclic or ladderlike structure are the main products in the initial stages, the reaction will develop in this direction also in its later stages, although intermolecular reactions may become increasingly probable. If, however, gel formation occurred by aggregation of microgels, further increase in density of the network of microgels with a small number of chemical bonds between them may continue beyond the gel point. In the extreme case the polymer in the final stage of the reaction will comprise densely cross-linked particles (micrograins, popcorns) distributed in an open-network matrix [51-53]. These suggestions, together with qualitative data on the non-uniform swelling of films [52,54] and the non-uniform structure observed with the electron microscope [55-67] in investigations of several network polymers, may lead to the conclusion that formation of a statistically uniform polymer network at a late stage in the conversion of polyfunctional compounds is improbable, being an exception rather than the rule [48]. However, the globular structure of network polymers mostly observed in electron-microscopic investigations is not necessarily a criterion of the microgel structure of

the polymer network. It may, for example, result from the preservation of globular structures characteristic of the chains of the initial polyfunctional oligomers or of their restoration after formation of the polymer network, similarly to what is observed with several network polymers [68,69]. These formations characterise the morphological structure of network polymers and depend, as with polymers having linear macromolecules, on the nature of the chains and the physical state of the polymer.

When investigating the laws of the formation of network polymers from polyfunctional compounds, we must first take into account the topological structure of the polymer network, which is characterised quantitatively by the concentration of effective chains. Comparison of experimental structural parameters of the network with those calculated theoretically from the composition of the reaction system and the conversion of functional groups will make it possible to elucidate details of the formation of a polymer network in the terminal stages of the reaction.

(*a*) Experimental estimation of structural parameters of polymer networks

Quantitative analysis of the conversion of functional groups is considerably more complicated in the later stages of the reaction than before the gel point. Use can be made of infrared spectroscopy [70], analysis of functional groups by conducting reactions in polymers of equilibrium swelling [5,32,70], analysis of secondary products liberated during polycondensation [71], thermal effects of the reaction [72], dilatometric analysis [73], etc. The choice of method depends mainly on the type of reactive groups involved in formation of the network polymer.

It is almost impossible to elucidate the laws of the formation of polymer networks beyond the gel point by comparing the experimental degree of conversion of the functional groups with the value calculated theoretically from the sol fraction (Eqn. 7), since the latter tends to zero long before the degree of conversion reaches 100%. At 75% conversion of the functional groups of a trifunctional monomer the theoretical sol content is already down to at most 3.5% of the weight of the reaction mass. Such a small sol fraction lies within the limits of experimental error for an extraction with boiling solvent.

Theoretical values of the structural parameters of polymer networks are calculated from the degree of conversion of the functional groups by means of Eqns. (10) and (11), or from Eqns. (12)–(15) when conversion is complete.

Experimental methods of determining density parameters of polymer networks involving their chemical degradation can be used effectively only if two types of covalent bonds differing markedly in chemical stability—weak bonds, which can be easily broken, and more stable bonds—are present in the polymer network. Examples are provided by network copolymers of unsaturated polyesters with styrene [17,18] and certain other di- and monovinyl derivatives [19], and also network polyester-urethanes [20]. Degradation methods are suitable for polymers having any concentration of chemical branch points, but they cannot take into account the effectiveness of the network chains, and they cannot be applied to the large number of network polymers having identical and stable bonds.

Methods based on theoretical relations between the structural parameters of the networks and the physical properties of the polymers (Eqns. 16–19) are the most promising and widely developed at the present time. These rules, deduced from statistical theories of rubberlike elastic deformations and the swelling of ideal tetrahedral networks with point connections and perfectly flexible chains, agree well with experimental data when the polymer contains only chemical branch points and M_C for the network considerably exceeds a segment of the polymer, i.e. in the case of open-network elastomers [3,21–23]. In the analysis of network polymers with poor chain flexibility and in the vitreous state, only the individual correlation of the experimental network parameters found under specified conditions with those calculated from the composition of the initial components and the degree of conversion of the reactive groups will enable the applicability of the method to be established and the reliability of the results to be assessed.

The applicability of the statistical theory of rubberlike elasticity to polymer networks for the experimental determination of their parameters over a wide range of concentrations of chemical branch points resulting from the reactions of polyfunctional compounds has been investigated in detail by Tobolsky and his coworkers on copolymers of vinyl monomers with oligomeric ester–maleates having a specified structure between the double bonds [12], copolymers of vinyl monomers with oligomeric ethylene dimethacrylates [12,74–78], and products of the hardening of the propanediphenylene diglycidate with various ethyleneamines [13]. The relative deviation of the structural parameters of networks from the ideal values calculated from the composition of the reaction mixture, allowing for the degree of conversion of the reactive groups and the effective participation of polyfunctional compounds in the reaction, is measured by the coefficient

$$\Phi = \frac{G}{n_0 RT} \qquad (20)$$

where n_C (in moles cm^{-3}) is the calculated density of chemical links in the network, and G the experimental equilibrium shear modulus of the network polymer in the rubberlike elastic state.

These investigations showed satisfactory agreement between theoretical and experimental network parameters for polymers whose $G-T$ curve included a horizontal section (rubberlike elasticity plateau—Fig. 1). When G is determined for temperatures 50–100 deg above the glass point of the polymer, the value of Φ varies over the range 1–3 depending on the type of network polymer (Table 2). The quantity G reaches 10^8 dyn cm^{-2} and varies little with the nature of the polymer chains. This is characteristic of polymer networks containing ten or more σ-bonds between adjacent network points (an aromatic ring is regarded as equivalent to one σ-bond). Equation (16) cannot be applied at the higher density characteristic of most dense-network polymers. The empirical equation [79]

$$\lg G = 7.0 + \frac{293\rho}{M_0} \qquad (21)$$

(where ρ is the density of the polymer at the experimental temperature), relating the density parameters of the network to the equilibrium modulus G, can be used up to the value $G = 2 \times 10^9$ dyn cm^{-2}. Fig. 2 compares the relations between G and M_C given by the theory of the rubberlike elasticity of ideal networks and by the empirical equation [21].

Kuvshinskii and his coworkers have also shown that the theory of rubber elasticity can be used to determine the network parameters of polymers obtained by the copolymerisation of several monovinyl and divinyl monomers [14].

Gul' et al. have established[80] that the theoretical relation between the equilibrium stress and moderate and small deformations (16) can be used to estimate the concentration of effective chains in the network formed by the copolymerisation of styrene with oligomeric ester-maleates. A linear relation with a correlation coefficient of 0.8–0.85 is found between the concentration of branch points determined by degradation of the copolymer with subsequent analysis of the hydrolysis products n_{chem} and the concentration calculated from the equilibrium deformation n_{phys} (with $n_{phys} < n_{chem}$ always).

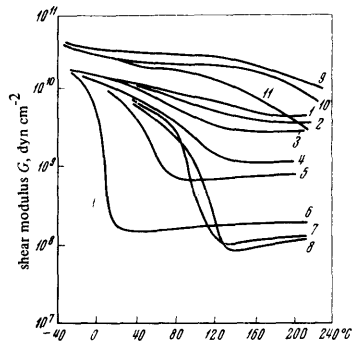

Figure 1. Temperature dependence of equilibrium shear modulus for network polymers from dimethacrylates of: 1) ethylene glycol; 2) triethylene glycol; 3) tetraethylene glycol; for network copolymers of tetraethylene glycol dimethacrylate with ethyl acrylate containing different proportions (mole %) of dimethacrylate: 4) 68; 5) 42; 6) 15.1; for network polymers from propanediphenylene diglycidate and: 7) diethylenetriamine; 8) triethylenetetramine; and for hardened resins of formaldehyde with: 9) melamine; 10) phenol; 11) urea.

Table 2. Divergence between structural parameters of polymer networks found experimentally from the equilibrium modulus of rubberlike elasticity and those calculated theoretically.

Network polymer	Equilibrium modulus G, dyn cm^{-2}	Coefficient Φ	Ref.
Сополимер стирола и тетраэтиленгликольди-			
Copolymer of styrene + 5–15 mole % of tetraethylene glycol dimethacrylate (TEGDMA)	$2.93—8.51 \cdot 10^7$	1.74—1.79	12.76
Copolymer of methyl methacrylate + 10–20 mole % (TEGDMA)	$6.67—17.2 \cdot 10^7$	1.50—1.62	
Copolymer of ethyl acrylate + 5–8 mole % (TEGDMA)	$1.37—8.93 \cdot 10^7$	0.77—1.18	
Copolymer of styrene + oligoether-maleates with mol. wt. of chain between double bonds:			
159 (70 wt.%)	$4.35 \cdot 10^8$	3.13	12
259 (20–70 wt.%)	$3.18—13.5 \cdot 10^7$	1.22—2.06	
362 (60–70 wt.%)	$2.5—2.94 \cdot 10^8$	1.99—2.79	
Polymer from propanediphenylene diglycidate + equimolecular quantity of:			
ethylenediamine	$1.43 \cdot 10^8$	1.36	
diethylenetriamine	$1.91 \cdot 10^8$	1.87	13
triethylenetetramine	$1.78 \cdot 10^8$	1.78	
tetraethylenepentamine	$1.87 \cdot 10^8$	1.88	

A fairly close correspondence between calculated (from the composition of the initial reactants) and experimental values of the modulus of rubberlike elasticity is observed also with network polymers obtained from propanediphenylene diglycidate and anhydrides of dibasic acids containing radicals of various sizes[81] (Table 3).

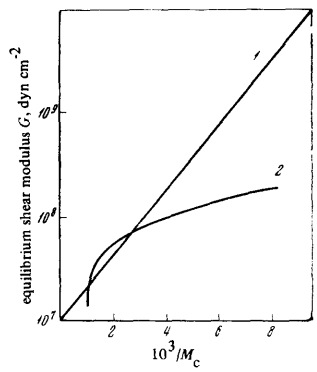

Figure 2. Dependence of equilibrium shear modulus on M_c above the glass point of network polymers from: 1) empirical equation $\lg G = 7.0 + 293\rho/M_c$; 2) kinetic theory of rubberlike elasticity $G = \rho RT/M_c$.

Quite good agreement with experimental parameters, found from the equilibrium modulus of rubberlike elasticity, is obtained for networks formed by the polymerisation of oligomeric ester-dimethacrylates with complete conversion of double bonds[82] (Table 4) if the theoretical value of M_c is taken to be not the molecular weight of the initial oligomer but its molecular weight divided by the functionality (4 in the present case).

Table 3. Calculated and experimental modulus in rubberlike elastic state of copolymers of propanediphenylene diglycidate with various anhydrides (temperature in all cases 100 deg above the glass point of the polymer)[81].

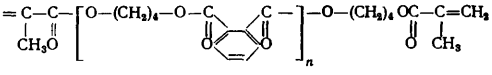
Acid anhydride	Modulus of rubberlike elasticity, dyn cm^{-2}		$\Phi = \frac{E_{exp}}{E_{calc}}$
	E_{exp}	E_{calc}	
Succinic	2.6	2.5	1.04
Methylsuccinic	1.9	2.2	0.87
Dodecylsuccinic ($C_{12}H_{23}$)	0.53	1.2	0.44
Phenylsuccinic	1.4	1.9	0.74
Maleic	3.1	2.7	1.15
Phthalic	1.9	2.2	0.87
Hexahydrophthalic	1.25	2.1	0.60

Hence the network parameters can be estimated quite accurately by determining the elastic characteristics of network polymers above their glass point. Unfortunately, there are many rigid dense-network polymers, of very great practical importance, whose glass points are above or very close to the temperature of degradation. This method cannot be applied to such polymers[12] (Fig. 1, curves *9–11*).

The relation established by Flory between the degree of swelling of polymers and the density of points in ideal

networks [3] (Eqn. 17) is of especial interest for estimating network parameters. Here the greatest experimental difficulty is encountered in determining the thermodynamic polymer–solvent interaction parameter (the Huggins constant χ). This parameter is usually determined by investigating the solubility and the properties of solutions of polymers identical in chemical composition with the network polymers [83–85]. However, especially in network polymers obtained from polyfunctional compounds, the structure of the monomer units is too diverse and is difficult to reproduce in soluble products. Furthermore, variation in the density of points in a polymer network is necessarily accompanied by a change in the chemical composition of its chains [70]. This substantial difficulty was eliminated by using solvent vapours for swelling and by linearising Eqn. (17). [86] By determining the sorption isotherm for the solvent vapour on polymers we can simultaneously determine graphically both the density of network points and the polymer–solvent interaction parameter [16,71,87]. Furthermore, determination of the degree of swelling of a polymer in the solvent vapours simplifies the experiment and improves its accuracy. Without danger of error due to extraction of the sol fraction it is possible to determine the swelling of a network polymer in the vapours of solvents over a wide range of temperatures, since at normal temperature the solvent often does not ensure destruction of physical junction points in the polymer network, and equilibrium swelling is restricted not only by chemical but also by physical junction points.

Table 4. Deviation between experimental and theoretical values of M_C for network polymers obtained from oligoester–dimethacrylates (MBP-n) [82].



Initial oligomer	Mol. wt. of oligomer	$M_{c,\,theor}$	$M_{c,\,exp}$	$\Phi = \frac{M_{c,\,theor}}{M_{c,\,exp}}$
MBP-1	446	111	85	1.30
MBP-2	666	166	160	1.02
MBP-3	886	221	280	0.78

The experimental parameter for the density of network points is, of course, higher than the theoretical value. Thus the density of branch points in a network copolymer of methyl methacrylate and methylene dimethacrylate, determined from the swelling in benzene at room temperature, is roughly ten times the value calculated from the composition of the initial mixture and supported by analysis of the degradation products of the network [88] (Table 5). Similar results have been obtained by Nielsen in an investigation of the swelling of epoxide network polymers [65].

Complete destruction of physical links in a network can be achieved by swelling the polymer in the vapour of a specially selected solvent at a certain temperature. Thus the presence of stable hydrogen bonds in networks obtained from a diglycidic ester and an oligomeric amide demands the application at an elevated temperature (70°C) of a solvent (dioxan) capable of rupturing these bonds (Table 6). Under these conditions experimental results agree with theoretical values. In the absence of stable physical links in the polymer from a diglycidic ester and an aliphatic diamine there is close agreement with theory when experiments are conducted with a non-polar solvent (dichloroethane) at low temperatures.

Table 5. Comparison of experimental estimates of concentration of chains in copolymers of methyl methacrylate with methylene dimethacrylate from degradation n_{deg} and from swelling in benzene n_{sw}. [88]

Dimethacrylate in copolymer, mole %	$10^5 n_{deg}$, moles g^{-1}	$10^5 n_{sw}$, moles g^{-1}	$\Phi = \frac{n_{sw}}{n_{deg}}$
0.201	1.61	16.0	10.0
0.509	3.56	35.7	10.0
1.04	5.61	50.6	9.2

Only acetone vapour at 50°C cleaves the hydrogen bonds in polymethylenephenols from trishydroxymethylphenol and hydroxymethyloligomethylenephenols, and the experimental values of M_C approach those calculated theoretically from the structure of the initial compounds and the degree of conversion of the hydroxymethyl groups [71,87] (Table 7). It has been found also that, on swelling in cyclohexanone vapour, only at elevated temperatures does the experimental concentration of chains approach the statistical value in the network formed by the polycondensation of phenol with formaldehyde [11].

Table 6. Structural parameters, determined under various conditions of swelling in the vapour, for network polymers from propanediphenylene diglycidate and a diamine or oligoamide [16].

Second component						
Compound	% on stoichiometric quantity	$M_{C,\,theor}$	Sorbed solvent	Sorption temp., °C	$M_{c,\,exp}$	$\Phi = \frac{M_{c,\,theor}}{M_{c,\,exp}}$

				75	205	1.18

The structure of the physical links in network polymers facilitates the development of rubberlike elastic deformations and permits the use of Eqn. (18) to determine the density of chemical links alone. Table 8 shows good agreement between the parameters of network polyester–urethanes determined by this method and those calculated from the composition of the reaction mixture [89].

Thus investigation of the equilibrium swelling of polymers in solvents and especially in their vapours, and study of the deformation properties of the swollen polymers, are the most promising methods for estimating the structural parameters of polymer networks. Successive destruction of physical links by choice of solvent and the temperature of its vapour will significantly enrich our views on the role and stability of the physical links in polymer networks.

(*b*) Formation of polymer networks in the later stages of reaction

Experimental analyses of the structural parameters of polymer networks indicate that in most cases the concept of the topological structure of a network polymer as a statistical distribution in space of chains linked at points is sufficiently close to reality. In the microgel (heterophase) structure of networks it is difficult to expect such good agreement between the experimental chain concentrations found by means of physical theories of polymer networks and those calculated theoretically from the structure of the initial reactants and the degree of conversion of reactive groups. The often observed low experimental density parameters of the networks compared with the theoretical values can be explained by the presence of defects in the structure of the network at chemical links, and high values by the presence of stable physical links, which produce an apparent increase in the concentration of effective chains in the network.

Table 7. Structural parameters of network polymethylenephenols determined under various conditions of swelling in vapours [71,87].

Polymethylenephenol from:		M_c, calc	Sorbed solvent	Sorption temp., °C	M_c, exp	$\Phi = \frac{M_c, \text{calc}}{M_c, \text{exp}}$
Trishydroxymethylphenol		41	benzene	25	40	1.01

	$n=3$	200	benzene	25	60	3.35
			acetone	50	220	0.92
	$n=5$	320	benzene	25	60	5.40
			acetone	50	380	0.84

Experimental methods of estimating structural parameters of polymer networks which involve destruction of all physical links reveal the causes of imperfection of networks which occur at chemical branch points during their formation. If the formation of network polymers in the initial stages preceding the gel point is very nearly random, the imperfection of the polymer network with respect to chemical links at a later stage in the reaction may be caused by the appearance of ineffective chains, i.e. chains attached at only one end to network points or forming closed rings (loops).

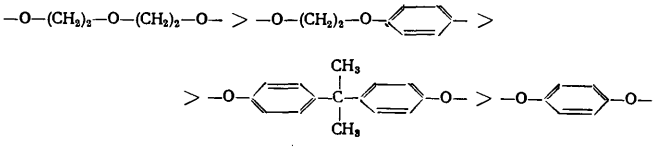
If the reactive groups are present in the central portion of the initial polyfunctional compound (of molecular weight M), even on complete conversion the proportion of the total number of chains which are ineffective is $2M_c/M$. [3,90] Hence there is no point in using polyfunctional oligomers having reactive groups near the centre if the expected value of M_c for the network is less than one-tenth of the molecular weight of the oligomer. An example of such structures is provided by polyester-maleates hardened by copolymerisation with styrene. The concentration of effective chains in them, found by physical methods, is considerably lower than the theoretical value or that found by analysis of the degradation products, if the proportion of ineffective chains in the network is disregarded [12,80].

The imperfection of a network produced by a polyfunctional compound with terminal reactive groups is determined solely by their degree of conversion and by the consumption of functional groups in the formation of rings (loops).

Table 8. Comparison of structural parameters determined from the equilibrium deformation of swollen and unswollen specimens of network polyester–urethanes formed from polyester (PE) from diethylene glycol and adipic acid ($M = 1600$) + tolylene di-isocyanate (TDI) + 1 : 1.5 mixture (A) of bis- and tris-hydroxyethylamines [89].

PE : TDI : A	M_c, calc	M_c, exp when swollen	M_c, exp when unswollen	$\frac{M_c, \text{calc}}{M_c, \text{sw}}$	$\frac{M_c, \text{sw}}{M_c, \text{unsw}}$
1:1.10:0.035	33800	33000	3700	1.02	8.90
1:1.15:0.070	24000	25000	3300	0.96	7.60
1:1.20:0.100	20000	24000	2600	0.92	9.20

In consequence of the tendency of polyfunctional compounds to cyclisation, a polymer network may not be formed at all, as already noted. If, however, a network is formed, its imperfection beyond the gel point, as a result of the consumption of functional groups in the formation of rings, should be especially marked in open networks. In some cases it has been possible to estimate the part played by ineffective groups in network polymers obtained by the copolymerisation of monovinyl derivatives with small quantities of divinyl derivatives, provided that conversion of double bonds is complete. In the copolymerisation of styrene with various divinyl derivatives, for example, the tendency to cyclisation varies with the structure of the chain in the divinyl component as follows [15]:



The extent to which the divinyl derivative was involved in cyclisation was estimated from the difference between the theoretical network density (from Eqn. 12) and the value found experimentally from the swelling of the copolymer in solvents (Eqn. 17). The tendency to cyclisation increases with increase in the functionality of the polyvinyl derivative [15].

Table 9 also illustrates the effect of the length and rigidity of the chain between the double bonds in the divinyl component on its ability to form ineffective loops [91]. The density of network points was calculated theoretically from the composition of the mixture and the degree of conversion of the double bonds, and was determined experimentally from measurements of the rubberlike elastic deformation of specimens in the swollen state (Eqn. 18).

The increase in network imperfection in polyether–urethanes with increase in length of the flexible chains of the oligomers, consisting of ether links [92,93], is probably also determined mainly by the formation of ineffective

loops (Tables 10 and 11). The high experimental parameters in the case of the denser networks [92] are evidently caused by a greater concentration of physical links in the form of hydrogen bonds. With increase in the density of chemical links in the polymer network it obviously becomes increasingly difficult to separate effective chains and ineffective loops, and in the case of dense-network polymers this becomes altogether impossible. The imperfection of a network formed from oligomers having terminal functional groups is then determined solely by the degree of conversion of the functional groups.

In complete conversion of functional groups in the terminal stage of the formation of network polymers may be due to diffusion and steric hindrances [94,95], which depend on the length and flexibility of the chains in the polyfunctional compounds and on the number and arrangement of the functional groups. Steric hindrance increases with increase in the density of network points and with intensification of the physical interaction between the network chains, i.e. with diminished probability of collision between functional groups. If at some stage the temperature of the reaction system falls below the glass point of the resulting polymer, reaction almost ceases [43,96]. In the copolymerisation of monovinyl monomers with divinyl monomers, for example, increase in the concentration of the latter makes the attainment of complete conversion of the double bonds more difficult owing to the rise in the glass point of the network copolymer, which becomes higher than the reaction temperature [43] (Fig. 3). Increase in the length and flexibility of the chain in the divinyl derivative raises the limiting degree of conversion of the double bonds. Similarly, in the formation of a network polymer from propanediphenylene diglycidate and a tetramine raising the reaction temperature above the glass point of the polymer diminishes the imperfection of the polymer network [65] (Table 12). A diminution in the functionality of the components also facilitates conversion of functional groups at the terminal stage of the synthesis of a polymer [97]. In the hardening of a diglycidic ester with acid anhydrides, increase in the bulk of the anhydride molecule, and hence increase in the steric and diffusion hindrance, increase the difference between calculated and experimental network parameters [81] (Table 3).

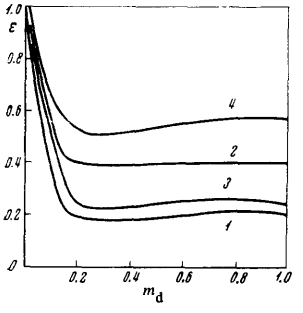

Figure 3. Dependence on their mole fraction m_d of the efficiency ϵ with which various divinyl monomers (dimethacrylates of different diols) are involved in the formation of a network polymer when copolymerised with methyl methacrylate [43]: 1) ethylene glycol; 2) decamethylene glycol; 3) 2,2-dimethylpropanediol; 4) 2-butyl-2-ethylpropanediol.

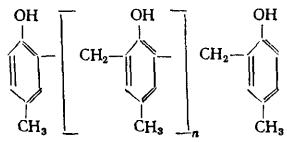
In the homopolymerisation of oligomeric ester-diacrylates it has also been established [72] that formation of the polymer network following the gel point is retarded by diffusion and steric hindrance, and the degree of conversion of the double bonds hardly ever reaches 100%. Increase in the length and flexibility of the oligomer chains facilitates attainment of the limiting degree of conversion of the double bonds.

The role of diffusion restrictions has been variously assessed in the synthesis of certain open-network polymers, especially polyether-urethanes [20,98-101].

There is a conviction that, when rigid polyfunctional molecules are used in the synthesis of network polymers, it is altogether impossible to achieve complete conversion

of functional groups owing to insuperable steric and diffusion hindrance[102]. In certain cases, however, a suitable choice of the structure of the initial reactants and of the reaction conditions may permit almost complete conversion. For example, the polycondensation of trishydroxymethylphenol proceeds until the hydroxymethyl groups have been completely converted[103] (Fig. 4). Trimeric methylenephenol containing hydroxymethyl in the terminal groups undergoes polycondensation with similar almost complete conversion of hydroxymethyl groups[71,87] to form a polymer network approximating to that calculated statistically (Table 7). With increase in the number of monomeric units in the oligomer to five and seven the proportion of hydroxymethyl groups which do not react is 33% and 38% respectively, obviously owing to steric and diffusion restrictions. The reactivity of the active hydrogen atoms in the phenolic rings of the oligomethylenecresols



drops similarly as soon as the number of units in them exceeds four[104,105]. The explanation offered[105] for this phenomenon is that the oligomers coil up owing to the presence of hydrogen bonds between the hydroxy-groups, which hinders access to the reactive groups.

Table 12. Effect of reaction temperature on structural parameters of polymer networks from propanediphenylene diglycidate and triethylenetetramine (proportions 7 : 1)[65].

40	92	0.82
60	93	0.83
120	97	0.87

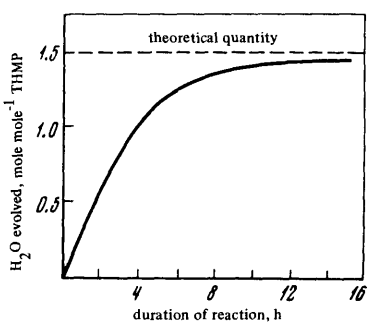

Figure 4. Kinetics of the polycondensation of trishydroxymethylphenol at 130°C.[103]

The presence, during formation of a polymer network, of a solvent or a plasticiser to promote the coiling of molecules into dense tangles increases the probability of intramolecular cyclisation and the formation of a microgel structure[20,48,77]. On the other hand, the presence of a plasticiser diminishes steric and diffusional hindrance, which allows greater conversion of functional groups and diminishes the imperfection of dense networks[78]. Long side radicals in the initial components may act as an intramolecular plasticiser[78].

Table 13. Effect of plasticiser on formation of polymer network from propanediphenylene diglycidate and triethylenetetramine in the proportions 7 : 1.[65]

Diglycidate / Plasticiser	Glass point, °C	Dynamic modulus at T_{gl} + 30 deg $10^{-7}G$, dyn cm^{-2}	M_c calc	M_c expt, from G	$\Phi = \frac{M_{c,\,theor}}{M_{c,\,exp}}$
100/0	92	8.6	305	367	0.83
90/10	84	6.8	425	411	1.04
80/20	65	4.9	544	496	1.10
70/30	60	3.9	664	580	1.14
60/40	50	3.6	783	615	1.28
50/50	26	1.5	903	1950	0.42
30/70	10	0.84	1142	3640	0.31

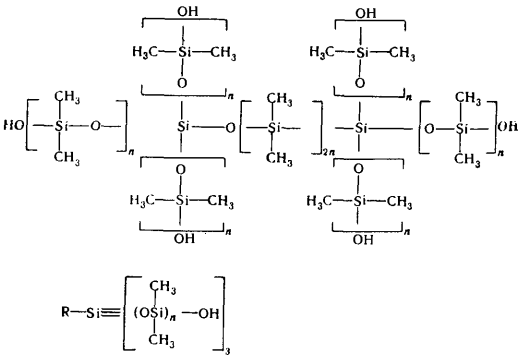
The presence in the propanediphenylene diglycidate–triethylenetetramine system of a small quantity of an active plasticiser, e.g. an oligomeric ester with a terminal carboxy-group, promotes more complete conversion of functional groups, and thus diminishes the imperfection of the network. With a high plasticiser content the tendency to cyclisation is predominant. This leads to formation of a polymer having structural parameters which differ markedly from the theoretical (Table 13).[65] Under such conditions the polymer network may have a microgranular (heterophase) structure, as is confirmed by a study of the dynamic mechanical properties of these polymers[79].

IV. CONTROLLED SYNTHESIS OF NETWORK POLYMERS

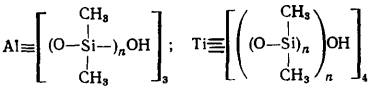
The experimental results which have accumulated on the formation of network polymers from polyfunctional compounds permit us to assess the prospects of developing syntheses of such polymers having a controlled structure. The choice of the initial compounds should obviously ensure the maximum probability of formation of a polymer network having a uniform distribution and a specified concentration of branch points, and also ensure that all monomer units are involved in effective chains. The most promising for the controlled synthesis of network polymers are oligomers containing reactive groups in the terminal units (telofunctional oligomers), since the use of oligomers having functional groups in intermediate units will result in the formation of a polymer network having a large number of ineffective terminal chains even with complete conversion of the functional groups.

The use of individual telofunctional oligomers containing two or more functional groups capable of reacting among themselves, in which the chains between the terminal units differ in nature and length, enables the structural parameters and the properties of the network polymers to be controlled within quite wide limits.

Andrianov and his coworkers have developed methods for synthesising network polymers of controlled structure



by the polycondensation of oligomeric polyfunctional organosiloxanes [106]. By regulating the value of n we can obtain network polymers which are in the vitreous or in the elastic state at room temperature. Similarly, we can obtain various network polyalumino- and polytitano-organosiloxanes



A procedure has been developed for the controlled synthesis of network polymers from oligoester–telo-acrylates

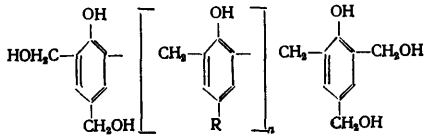
by chain polymerisation at the terminal acrylate groups [72].

Table 14. Some properties of network polyester–acrylates as functions of nature and length of oligomeric block in initial oligomers [72].

Initial oligoester-dimethylacrylate				Shrinkage on polymerisation, vol. %	Mechanical constants			
symbol	R′	R	n		hardness H_B, kgf cm^{-2}	effective modulus, kgf cm^{-2}	specific impact strength, kgf cm cm^{-2}	bending strength σ_b, kgf cm^{-2}
MDP-n	—CH$_2$—CH$_2$—O—CH$_2$—CH$_2$—		1	7.5	12.0	—	5.0	1150
			2	4.8	8.6	—	10.0	1600
			3	4.3	6.9	—	11.4	1550
			4	3.7	1.1	—	16.0	930
			5	—	0.9	—	19.0	740
MBP-n	—(CH$_2$)$_4$—		1	—	12.8	8700	3.5	845
			2	—	8.9	8650	5.7	1120
			3	—	6.4	7170	10.5	900
MBS-n	—(CH$_2$)$_4$—	—(CH$_2$)$_8$—	1	—	0.9	—	9.7	195
			2	—	0.4	—	10.2	65

The network density is regulated by the number of ester units between the acrylate groups, and the rigidity by the structure of the radicals R and R′. The properties of network polymers from oligoester–acrylates differing in nature and size are listed in Table 14.

Network polymethylenephenols (phenol–formaldehyde polymers) of controlled structure can be obtained by the polycondensation of trishydroxymethylphenol and hydroxymethyl derivatives of oligomethylenephenols (hydroxymethyl-oligomers) having the structure [71,87]



The structural characteristics of the resulting polymer networks and several properties of the network polymers are given in Table 15.

Table 15. Properties of network products of the polycondensation of hydroxymethyl-oligomers as a function of the structural characteristics of the network [71,87].

Initial hydroxymethyl oligomer	M_c(expt.) based on		Density at 20°C, g cm^{-3}	Mechanical constants				
	chem. links	chem. and H bonds		bending modulus, kgf cm^{-2}	Rockwell hardness	specific impact strength, kgf cm cm^{-2}	compressive strength, kg cm^{-2}	δ_{bend}, kgf cm^{-2}
 (THMP)	55	40	1.300	43500	35 32—37	3.5 2.8—4.0	1100	600
 (HMP-1-PHM)	95	50	1.280	41500	32 30—33	7.5 6.7—9.2	1250	1200
 (HMP-3-PHM)	220	65	1.230	40000	30 30	9.5 8.4—10.6	1120	1650

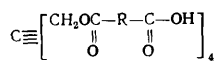
Nevertheless, the use of individual telofunctional oligomers does not always make it possible to control the density of the polymer network by varying the length of the oligomeric block without changing its nature. Variation in the length of an oligomer leads to a sharp change in the conditions for formation of the polymer network. Increase in length usually results in an increased tendency to intramolecular cyclisation of the oligomer and a decreased maximum degree of conversion of functional groups. As a consequence the imperfection of the network with respect to chemical links increases, and is difficult to control. This effect can be diminished by using binary systems for the synthesis of network polymers. They should comprise a telofunctional oligomer of a particular nature, with a definite number of units between the terminal functional groups (depending on the proposed density of network points), together with a polyfunctional compound of considerably lower molecular

weight (a hardener). The low molecular weight of the second component facilitates the achievement of limiting conversion of functional groups for almost any length of oligomer. In order to prevent the competing process of intramolecular cyclisation, it is necessary that functional groups on the same component should not interact. This method is being used increasingly to control the synthesis of open-network polymers (vulcanised rubbers). Thus the polymerisation or copolymerisation of dienes in the presence of telogens of definite structure yields rubbers of low molecular weight (polynomers) with functional groups in the terminal units, which are involved in formation of a polymer network on reaction with a vulcanising agent [90,107].

Esters containing hydroxy-groups in the terminal units, obtained by the polycondensation of dibasic acids with excess of dihydric alcohols, are used as telofunctional oligomers for the controlled synthesis of elastic open-network polyurethanes. Oligomeric ethers obtained by the polymerisation of hydroxylated rings contain similar terminal groups. The vulcanising agent can be a tri- or a tetra-isocyanate [93,108].

Oligomeric ethers and esters containing terminal alcoholic hydroxyls yield with excess of di-isocyanates oligomers, containing terminal isocyanato-groups, termed macrodi-isocyanates (precondensates). The hardeners are polyfunctional alcohols or amines of low molecular weight [89,108].

The use of such hardeners promotes more complete formation of polymer networks from oligomeric acid esters [32-34,109]



In the case of oligomeric diglycidic esters the best conditions for the production of polymer networks are provided by the use of hardeners of low molecular weight—amines or acid anhydrides [35,97].

The use of telofunctional oligomers of a specified structure to synthesise network polymers having a controlled structure permits the establishment of a relation between the network parameters and the properties of the polymers, and hence the production of polymers having specified properties. Besides the data in Tables 14 and 15 and in a review [79] there is some information on the effect of the structural parameters of networks on the properties of epoxide polymers [81,96,110,111], polyurethanes [108], copolymers of divinyl oligomers with monovinyl monomers [112,113], and several other network polymers [114]. However, it is difficult to establish an unambiguous relation between the structure of the initial oligomers and the properties of the network polymers, since the properties especially of dense-network polymers are often determined in decisive measure by other factors besides the network density. Among these are the conditions of formation of the polymers, which determine their morphological structure, shrinkages in volume resulting in the appearance of internal stresses, the test conditions, the presence of fillers, etc. Many properties of network polymers depend more on their physical state than on the density of chemical links in the polymer network. In this connection more experimental data must be accumulated on the formation of network polymers and their properties with careful control of the structure of the initial oligomers and the parameters of the resulting networks.

Plasticisation of Polymers

V.A.Voskresenskii, E.M.Orlova, E.I.Abramova, and N.S.Prokhorova

The Review surveys published information on the development of theories of the plasticisation of amorphous and crystalline polymers by plasticising additives of low and high molecular weight, the phenomenon of antiplasticisation, the action of small additions of plasticisers, and the effect of the chemical structure, size, and shape of plasticiser molecules on the plasticisation of polymers.
The applicability of modern physical and physicochemical methods (thermomechanics, thermography, rheology, nuclear magnetic resonance, infrared spectroscopy, dielectric and mechanical losses) to the investigation of plasticised systems is reviewed.
The list of references contains 213 items.

CONTENTS

4. Modern methods of investigating plasticised systems 83

I. INTRODUCTION

The development of effective methods for the modification of macromolecular compounds[1] is of great value for future progress in this field, and plasticisation plays an important part among these methods[2]. Indeed, polymers rarely find practical use in the individual (pure) form, owing to their brittleness, difficulty of processing into goods, tendency to crack during storage and in use, etc. Plasticisation is able not only to eliminate these defects but also to confer a new combination of valuable technical properties on the modified polymer.

The problem of the plasticisation of polymers has attracted the attention of many investigators, whose results in this field have been partly summarised in earlier reviews[3-5] and a series of papers by Soviet and foreign authors[6-13]. The present Review is devoted mainly to the part played by the chemical structure of the plasticiser in the plasticisation of polymers, blended systems, and modern methods for investigating plasticised polymers.

For a long time the problem of the plasticisation of polymers was solved exclusively by empirical methods. With the development of the science of polymers, and the expansion of knowledge of their structure, views on the nature of plasticisation also changed. The development of ideas on plasticisation can be arbitrarily divided into several stages. The first stage is characterised by a particularly empirical approach to the selection of plasticisers, the role of which was reduced merely to a lubricating effect. Then, beginning with the work of Obrist[14] (during the 1920s and 1930s), colloid-chemical concepts predominated, polymer–plasticier systems being regarded as lyophilic colloids, in which the plasticisers formed solvate sheaths on the surface of unsymmetrical particles of the polymer as the disperse phase.

However, more fundamental investigations of the nature of macromolecular compounds had already begun in the 1930s. The work of Kargin, Papkov, and Rogovin[15] showed that colloid-chemical concepts were not applicable to plasticised systems. The main kinetic laws of the behaviour of polymers during dissolution and swelling were established[16], and the heats of dissolution of vitreous polymers were studied as a function of the density of packing of the structural units.

During this period plasticisation was first interpreted as a factor diminishing the brittleness of polymers, promoting the occurrence of relaxation processes, and preventing the formation and growth of cracks under the influence of specific deforming forces[17,18]. Subsequently a quantitative relation was found between the strength of polymers and the duration of the action of deforming forces on them[19-22].

Considerable successes in studying the structure of polymers and their orientation behaviour were achieved by X-ray and electron diffraction methods[23,24]. Some part was played also by determinations of differential heats of sorption[25]. Ideas developed on the nature of the fluidity and elasticity of polymers[26,27] have remained unchanged until the present time.

It was also established[28-30] that linear polymers can exist in three physical states—vitreous, viscoelastic, and viscofluid—depending on the temperature. Two additional (intermediate) physical states—constrained-elastic and constrained-plastic—have since been established[31]; nuclear magnetic resonance has revealed[32] the existence below the glass point T_{gl} of several transition temperatures, the dependence of which on the chemical structure of the polymers has been studied.

The next stage in the development of ideas on plasticisation covered the 1940s to the early 1960s. During this period a fundamentally new approach to investigation of the plasticisation of polar and non-polar polymers was apparent especially in papers by Zhurkov and his coworkers[33-35]. Their researches enables them to formulate the now widely known rule of plasticisation—"the rule of equal mole fractions"—according to which the plasticising effect of polar plasticisers on polar polymers is the same at equal mole fractions of the former and is independent of the size, chemical nature, or structure of the plasticiser molecules. Roughly similar conclusions were reached by Fuoss[36] from a study of the plasticisation of poly(vinyl chloride), but with copolymers of vinyl chloride the laws of plasticisation were more complicated.

In a comparative study of the effect of the volume and molar concentrations of various plasticisers on the glass point of polymers, Kargin and Malinskii found[37,38] that the fall in the glass point of non-polar and weakly polar polymers conforms fairly closely to the "rule of equal

volumes" which they had deduced, according to which equal volume fractions of plasticisers produce the same plasticising effect. Since this rule and the above "rule of equal mole fractions" are obviously consequences of two different mechanisms of plasticisation, they are each obeyed only by certain systems, in which one of the mechanisms predominates, while many actual systems may exhibit larger or smaller departures from either rule [39].

Kargin and Slonimskii [40] established that small plasticiser molecules, while located between and separating the macromolecular chains, do not necessarily diminish the interaction between them, since the plasticiser itself is able to interact with macromolecular chains. They attribute the change in viscosity resulting from introduction of the plasticiser, i.e. the plasticising effect, mainly to a change in the geometrical arrangement of the molecules [40].

Energetic interaction of plasticiser molecules with certain functional groups in polymer macromolecules and the formation of a kind of molecular sorption compound have been noted qualitatively also in several other papers [41-43]. The action of plasticisers on polymers has been attributed [44] to the presence in polymer and plasticiser of groups capable of interaction, the most advantageous mutual arrangement, the shape of the plasticiser molecules, and purely geometrical factors.

A typical plasticiser is not distributed randomly in a polar polymer, since it interacts predominantly with the polar groups in the latter, blocking their force field [11]. It was established that agglomerating plasticisers significantly depress the glass point of polymers [40].

Kargin and his coworkers [45-47] showed that the rules of "equal mole fractions" and "equal volumes" applied to crystalline polymers, graft copolymers, and block copolymers.

New ideas on the structure of linear polymers, put forward by Kargin, Kitaigorodskii, and Slonimskii [48-50], provided a more accurate explanation of the nature and mechanism of plasticisation. This work opened up a new stage in the development of the theory of plasticisation.

Kargin et al. [51] studied the plasticisation of a rigid-chain polymer (cellulose) showing poor compatibility with plasticisers, and discovered two different mechanisms of plasticisation. They examined the action of plasticisers on cellulose in terms of the bundle theory of the structure of linear polymers. Plasticisation takes place within a bundle if the interaction energy of plasticiser molecules with active groups of the polymer chains is stronger than the intermolecular interaction in the polymer itself. The action of plasticisers which are completely miscible with the polymer leads to breakdown of any secondary structures. If the interaction of plasticiser molecules with the reactive groups in the polymer chains is significantly weaker than the intermolecular forces in the polymer itself, the plasticiser is able to interact only with molecules on the surface of the secondary structures: plasticisation is then accomplished only between bundles (interstructural plasticisation), without any significant change in the elastic properties of the system. Polymer materials obtained by interbundle plasticisation are characterised by great durability, high specific impact strength, and frost resistance [52,53].

Kozlov et al. [54] showed that plasticisation was possible both within and between bundles in the case of polycarbonates, which are characterised by relatively slow relaxation and crystallisation processes, and tend to form clearly developed secondary structures.

Kargin et al. [55] found that plasticisation of crystalline polystyrene produces a significant change in the conditions for formation of secondary structures characteristic of the unplasticised polymer. They note that with crystalline polymers equal fractions by volume of different plasticisers lead to the formation of spherulites of different sizes: the "rule of equal volumes" is not observed.

The new ideas on the mechanism of plasticisation are applicable, of course, also to amorphous linear polymers such as poly(vinyl chloride). [56,57] Thus the introduction of small quantities of a plasticiser into this polymer increases its degree of order [58-62]. In this case the plasticisers do not soften the polymer, but make it more rigid and brittle. The reflections on the X-ray diffraction photographs become sharpest at a plasticiser content of ~ 10 wt.%. [58,61]

With several vulcanised rubbers it has also been noted [63] that their mechanisal properties vary non-monotonically with small additions of plasticisers. This phenomenon has been explained by differences in the mobility of structural units, the stress peak at the apex of a microdefect being smoothed out.

It is possible [57] to explain the hardening of poly(vinyl chloride) by small portions of plasticisers in terms of interstructural and intrastructural plasticisation. Small additions of polar plasticisers cause interstructural plasticisation, the rigidity and strength of the polymer increasing, while the dielectric loss angle diminishes [64]; large portions of the same plasticisers, however, lead to intrastructural plasticicsation, accompanied by the opposite changes in the properties of the given polymer system. It is obvious that systems containing small proportions of plasticisers exhibit two opposite tendencies—to denser packing of chains and bundles, and to disorder under the influence of thermal motion—with the former ultimately predominating [65,66].

The variation in glass point produced by the introduction of small additions of plasticisers into crystalline polymers is oscillatory in character, as a consequence of structural changes in the polymer [67]. In several cases small additions of a plasticiser may cause the structural plasticisation of multicomponent systems, as has been demonstrated [68] for the Viniflex lacquer–tritolyl phosphate system.

Lipatov [69-71] investigated the vitrification of polystyrene and poly(methyl methacrylate), filled with glass powder and containing various quantities of a plasticiser (dimethyl phthalate), and established that the plasticisation of filled polymers is an interstructural effect, depending on the destruction of polymer–filler surface and polymer–polymer bonds.

2. PLASTICISATION AND CHEMICAL STRUCTURE OF PLASTICISERS

The above rules of plasticisation suggested by Soviet scientists played an important part in the development of ideas on the nature and mechanism of the phenomenon. The question naturally arises as to the extent to which the chemical structure of a plasticiser, or at least its homologous series, influences the plasticising effect. (The plasticising effect can be defined as the relative depression of the glass point, as the relative durability and increase in elasticity, or as the relative change in other physical properties of the polymer, under the influence of equimolecular portions of different added plasticisers.)

In the early papers of several foreign and Soviet workers [72-76] no great importance was attached to the chemical structure of plasticisers. Only the compatibility of the components, not the plasticising effect, was actively influenced by the chemical structure of polymer and plasticiser. The relative effect of plasticisers on linear polymers was regarded as depending mainly on their concentration: plasticisers having molecules of about the same size and shape exerted similar plasticising effects.

Baker [77] studied the X-ray photographs of plasticised crystalline polymers, and suggested that the original crystalline structure changes in the presence of an agglomerating plasticiser. With lubricating plasticisers an amorphous halo is merely superimposed on the phase pattern of the polymer. However, in a study of vinyl polymer–tritolyl phosphate systems, Alfrey [78] did not detect any changes in the original crystalline structure of the polymers under the influence of the plasticiser. Nevertheless, the specificity of the action of plasticisers, and the need to take chemical structure into account when selecting them, have been noted in many cases [79].

The influence of the chemical nature, size, and shape of the plasticiser molecules on the plasticisation of linear polymers by equimolecular proportions of trioctyl phosphate, tritolyl phosphate, etc. has been determined [80-82]. Plasticisers differing in the length of the hydrocarbon radicals and in molecular weight also behaved differently in compositions [83]. The effect of the chain length of the non-polar part of the plasticiser molecule on the glass point has been studied with polyvinylbutyral [84] and with other systems [85].

Experiments on synthetic rubbers showed [86,87] that with a divinylstyrene rubber the maximum plasticising effect is given by non-polar plasticisers, low contents of which satisfied the "equal volume rule" quite well. Significant deviations from this rule were observed with higher plasticiser contents, the glass point of the rubber then being lower in the presence of non-polar plasticisers than with polar plasticisers; the effect of the chemical structure of the plasticiser becomes appreciable in this case.

Many foreign scientists found that the plasticising effect depended on structural features of the plasticisers [88-90]. In particular, the mechanical properties of linear polymers were found [91] to vary with the chemical structure of the plasticiser (influence of the length of the hydrocarbon chain and of the relative content of polar groups in methacrylic esters on the plasticising effect). Here difference in chemical structure had a substantial effect on the modulus of elasticity and the strength of specimens having the same content of different plasticisers.

Polar plasticisers are usually more effective than feebly polar plasticisers towards poly(vinyl chloride). [92] The solvent power, compatibility, and effectiveness for poly(vinyl chloride) have been shown [93,99] to diminish appreciably with decrease in the relative content of polar groups in ester plasticisers.

The minimum pour point of plasticised polymers exhibited [94] a specific dependence on the structural characteristics of plasticisers having the same molecular weight: the elasticity of the polymers increased to a certain point with increase in the chain length of lateral hydrocarbon radicals in the plasticisers used—phthalic esters.

The bonds in the polymer–plasticiser system are complicated in nature [95,96], depending on their structural characteristics. It is emphasised that small quantities of different plasticisers are retained to different extents by the polymer. A point is reached at which increase in the plasticiser content does not lead to further bonding to the polymer chains. It is this portion of the plasticiser which is liable to migrate in the first instance.

Study of dielectric losses [97] and vitrification [98] in some linear polymers established that the plasticiser molecules associate with a definite number of active groups in the macromolecules depending on their chemical nature.

The role of plasticisers has been reduced [100] mainly to diminishing the steric hindrance to rotation of functional groups in macromolecular chains. The efficiency of the plasticisers is determined in considerable measure by their structure.

An electron-microscopic study [101] of the cellulose nitrate–dibutyl phthalate and cellulose nitrate–softener systems revealed that the texture of the resulting films varies substantially and depends on the solvent power of the plasticisers, i.e. on features of their structure.

The effect of chemical structure is apparent [102] both in differences in the compatibility of polymers with plasticisers, which depends on interaction energy between polymer and plasticiser molecules and on the entropy of mixing, and in differences in the plasticising effect, which depend on the shape and size of the plasticiser molecules. Poly(vinyl chloride) has been used to study the plasticising effect as a function of the structure, polarity, size, and shape of the plasticiser molecule [103,104]. With 1- and 2-naphthols the position of the functional group OH in the naphthalene molecule has been shown [105] to be important in determining the magnitude of the effect: thus 1-naphthol is a more effective plasticiser and is more compatible with this polymer than is 2-naphthol, although the polarity of the latter is the higher (the dipole moments of 1- and 2-naphthols are respectively 1.0 and 1.3 D).

The structure (degree of branching) of lateral hydrocarbon radicals in the plasticiser molecules has an appreciable influence on the plasticising effect [106]. Thus oxides of tetrahydrophthalates having branched side-chains are less effective towards poly(vinyl chloride) than are plasticisers of the same type containing linear chains. A similar effect has been observed in other systems [99].

Tager and his coworkers [107,108] used a thermomechanical method to investigate the effect of plasticisers of a new type—diphenic and naphthalic diesters and diphenic monoesters—on the glass point of polystyrene and poly(methyl methacrylate) with the same plasticiser content in the polymers. It was found that the lower the critical temperature of mixing the lower was the glass point of the plasticised polymers. As the alkyl radical in the plasticiser molecule became more bulky, the glass point first fell appreciably, and then rose. This diminution in the efficiency of the plasticisers is attributed to an unfavourable geometrical arrangement in the polymer phase of plasticiser molecules having long aliphatic radicals.

Among these compounds diphenic diesters show an outstanding plasticising effect, which is explained by the less rigid character and large set of conformations of their molecules, as a consequence of which they can be distributed among the polymer macromolecules in a large number of ways. This creates favourable conditions for better compatibility of the components and a stronger plasticising action. With naphthalic esters, which contain a rigid, planar fused-ring system, the number of possible conformations is considerably smaller, compatibility with the polymer is less, and the plasticising effect is weaker.

In the papers cited above it is concluded that the equal mole fraction and equal volume rules have limited

applicability, and that peculiarities of chemical structure must be taken into account both in selecting plasticisers and in interpreting individual facts relating to the phenomenon of plasticisation.

Considerable interest attaches to work [109] on the antiplasticisation of polymers, which is analogous to interstructural plasticisation [2]. Certain classes of organic compounds have been shown to antiplasticise polycarbonates based on bisphenols. Additions of up to 30% increase the modulus of elasticity and the strength and decrease the elongation per unit length. The depression of the glass point of the polymers is appreciably smaller than when the usual plasticisers are used.

Antiplasticiser molecules, while being polar compounds, are relatively rigid owing to the presence of cyclic structures [110]. Aromatic compounds usually exert a greater antiplasticising action than do saturated alicyclic compounds, and polycyclic compounds are more effective. Antiplasticiser molecules should also have a definite minimum size (the thickness or cross-section of such molecules should be not less than 5–5.5 Å).

An antiplasticising effect is observed [111] on the introduction into a polycarbonate of up to 15 wt.% of certain aromatic compounds containing sulphur and nitrogen, but ordinary plasticisation is observed with greater additions. Substances having a high glass point exert an appreciable antiplasticising action, but substances of lower glass point are able to plasticise the same polymers [112].

Under otherwise similar conditions the compatibility of polymers with antiplasticisers diminishes with rise in the glass point of the latter. In general antiplasticisation occurs only when polymer and antiplasticiser molecules are rigid and polar. Antiplasticisation usually improves the resistance of polymers to cracking under stress.

Antiplasticisation cannot be explained solely by crystallisation of the polymer. New bonds, detected by differential thermal analysis and by infrared spectroscopy, are formed between polar groups of the polymer and of the plasticiser. Antiplasticisation increases the density (decreases the free volume) of the polymer.

o-Tolidine as a modifying additive to poly(vinyl chloride) possesses the properties of an antiplasticiser, since it improves substantially the breaking stress under tension and diminishes the elongation per unit length [113].

Plasticisers have varied effects on the thermal stability and on the thermo-oxidative degradation of poly(vinyl chloride). [114] Oxides of hexahydrophthalates, while effectively plasticising this polymer, also stabilise it to light and to heat [115].

Maloshuk and Voyutskii [116] have shown that, in the plasticisation of the acrylonitrile copolymer SKN-40, the equal mole fraction rule is adhered to closely only by plasticisers which are of completely the same type chemically. Straight-chain and branched-chain plasticisers, as well as plasticisers of different classes, give different cohesion values.

An interesting phenomenon was discovered by Kozlov and his coworkers [117] when studying the action of mixtures of plasticisers on polystyrene. A mixture of a plasticiser of low molecular weight (phenyltributoxysilane) and an oligomeric plasticiser (polydiphenylsiloxane) gives a substantial synergic effect, and the observed displacement of glass and melting points considerably exceeds the additive values. In the plasticisation of poly(vinyl chloride) with mixtures of dibutyl phthalate (intrastructural plasticiser) and a chloroalkane (interstructural plasticiser) a transition was observed from one type of plasticisation to the other [118].

The work of various investigators, who have attempted to use the principles of the theory of interstructural and intrastructural plasticisation to make a quantitative estimate of the contribution made by the structural characteristics of plasticisers and to determine their role in the various stages of structure formation, opens up new opportunities for greater knowledge of the nature of polymers.

3. PLASTICISATION OF POLYMERS BY COMPOUNDS OF HIGH MOLECULAR WEIGHT

During recent years communications have appeared on the possibility of obtaining technically valuable polymeric compositions, which have been termed blended systems. Thus a non-volatile plasticiser—a butadiene—nitrile rubber—was suggested [119–121] for modifying thermoplastic rigid-chain polymers. A study has been made rather earlier [122] of products of the blending of SKB [a synthetic butadiene rubber] with natural rubber. Slonimskii and Komskaya [123] investigated products of the blending with one another of such rubbers as SKB, SKS-30 [a butadiene–styrene synthetic rubber], SKN-18 [a butadiene–acrylonitrile synthetic rubber], natural rubber, etc.

Study of the physicochemical nature of the phenomenon began during the same period, blending being interpreted [124–127] mainly as the plasticisation of one polymer by the other. Reznikova et al. [128] accomplished the plasticisation of poly(vinyl chloride) by butadiene–acrylonitrile synthetic rubber, studied the effect of the composition of the copolymer on compatibility and plasticising effect, and showed that the nitrile groups ensure compatibility between the copolymer and the poly(vinyl chloride), while the butadiene part exerts the actual plasticising action. Investigation of the mechanism of plasticisation established that the "mole fraction rule" was not applicable to the plasticisation of poly(vinyl chloride) by macromolecular plasticisers such as the above synthetic rubber. The limited mutual compatibility of the polymer components was also noted.

Voyutskii [102] showed that the mutual solubility of polymers is determined mainly by the change in the heat content of the system: in most cases polymers dissolve one in another only if the heat of mixing is positive. Compatibility depends also on the shape and structure of the macromolecules of the blended polymers.

Poly(vinyl chloride) can be blended in all proportions with chlorinated polyethylene [129], to give compositions of great strength, frost resistance, and good dielectric properties. Polyesters of phosphoric and cycloalkylphosphinic acids and their derivatives have also been proposed [130] as plasticisers of high molecular weight. The use of polymeric plasticisers is correctly assessed [131] as one of the most important methods for modifying polymers.

Alekseenko, Mishustin, Voyutskii, and their coworkers [132–135] undertook broad investigations of the blending of polymers. They noted the decisive role played by the polarity of the interacting components: the greater the polarity of the polymers, the greater their compatibility. In an investigation of ternary mixtures of polymers Alekseenko and Mishustin showed [136] that the plasticising action on poly(vinyl chloride) and poly(vinyl acetate) of a series of other polymers depends on the polarity of the latter. Blending requires that the polymers should be of similar polarity, and that denser packing of the macromolecular chains should be possible. However, these

workers note that the polarity of individual macromolecules may not completely balance out on blending, and the resulting system may interact with other polar polymers with the formation of ternary systems. Polar and non-polar rubbers are able to blend together [132,137] only if polar components predominate in the compositions, when the molecules of the non-polar rubber become polarised, and the polarities of the components are equalised. The possibility of blending a butadiene–vinylidene chloride rubber with rigid polymers—poly(vinyl chloride) and poly(vinyl acetate)—was also investigated [138]. The compatibility of these polymers with the rubber was assessed from the tensile strength and the elongation at rupture of films obtained by rolling followed by extrusion. A butadiene–vinylidene chloride rubber was shown to have a plasticising effect on poly(vinyl chloride); the nature of the polar groups was found to have little significance, only the polarity of the interacting substances being important.

Addition to polyethylene of the synthetic rubbers—SKB, SKS-30, DVKhB-70, SKS-30-1, SKN-18, SKN-26, SKN-40—and also polyisobutylene has been recommended to facilitate processing into articles and modification of the properties [139]. Addition of up to 25% of polyisobutylene and of the rubbers DVKhB-70 and SKS-30-1 (a ternary copolymer of butadiene, styrene, and methacrylic acid) improves the physicochemical constants of polyethylene specimens, but addition of the rubbers SKB and SKS-30 impairs its physicomechanical properties. Polyethylene blends with the above rubbers in all proportions, but does not blend with highly polar rubbers of the SKN type.

In a study of the compatibility of cellulose nitrate and poly(vinyl chloride) with several synthetic rubbers (e.g. DVKhB-70, SKN-140, SKS-30, and SKS-30-1) Alekseenko [140] observed the differing behaviour of a mixture of solutions of the polymers in a common solvent. The inadequate stability of certain mixtures with time is explained by incompatibility of the components. Mixtures of the polymer solutions may separate into layers because the energy of interaction between macromolecules of the polymers exceeds that between solvent and polymer molecules. The experiments showed that separation into layers might result also from the formation of aggregates containing the initial components in various proportions.

Polymers can be blended as latices and as aqueous dispersions; blended systems are obtained also by mixing and then extruding the finely powdered polymers; and latices or dispersions can be mixed with solutions of the polymers, and then dried and extruded [141]. Investigation of a system comprising poly(vinyl alcohol) and a carboxylated rubber showed that the latex composition considerably surpasses in mechanical properties a blended system of similar composition obtained by rolling, which is explained by a more uniform distribution of poly(vinyl alcohol) chains between the rubber globules.

In a study of the possibility of blending certain polymers Slonimskii and Struminskii [142,143] found that binary mixtures of equally concentrated solutions of polybutadiene and a butadiene–styrene copolymer, natural rubber and polystyrene, separate into two phases, although the heat of mixing of the polymers is positive. This anomaly was explained by change in the packing density of molecules of the initial polymers on mixing.

Lel'chuk and Sedlis [144] studied the compatibility of macromolecular substances with the aim of determining the possibility of plasticising poly(vinyl chloride) with polymeric plasticisers. Plasticising power was measured by the depression of the glass point of the composition compared with that of the unplasticised polymer. butadiene–nitrile rubber containing 35–40% of acrylonitrile showed the best compatibility and efficiency.

Berlin, Kargin, and their coworkers [145,146] examined the blended systems formed by poly(vinyl chloride) with methylvinylpyridine rubber (SK MVP) and with nitrile rubber SKN, and showed that a certain schedule of treating the mixtures on rolls yields graft copolymers by chemical interaction between functional groups of the poly(vinyl chloride) and those of the rubbers. With SK MVP rubber as modifier cross-links of the pyridinium type are formed, and with SKN *N*-substituted nitrilium salts may be formed. Addition of small quantities (5–10%) of the above modifiers produces a sharp improvement in the stability of poly(vinyl chloride) to impact loads.

Slonimskii et al. [147] investigated the mechanical properties of polymer mixtures, and showed in particular that the X-ray photographs of mixtures of crystalline and amorphous polypropylene and polyisobutylene confirmed the incompatibility of the components: the mixtures are two-phase colloidal systems. Addition of an amorphous component diminishes the strength of polypropylene and prevents development of the high stresses necessary for the production of constrained viscoelastic deformations, so that the elongation of the specimens on rupture is decreased. It was shown also that mixtures of crystalline polymers, e.g. polypropylene and polyethylene, exhibit microheterogeneity. A similar situation can be observed with a mixture of polypropylene and polyisobutylene.

Polytetrafluoroethylene possesses superior physicomechanical and dielectric properties and great chemical stability. However, it cannot be fabricated into articles by injection moulding, extrusion, hot pressing, etc., but requires special, laborious procedures. Numerous attempts to improve the workability of polytetrafluoroethylene by adding small quantities of greases, fillers, polyisobutylene, etc. have not yielded practical results.

The possibility of modifying polytetrafluoroethylene with high-density and low-density polyethylene has been studied [148,149]. After careful grinding and mixing, the polymers were blended in the solid phase by pressing or on rolls at 150–155°C. With increase in the polyethylene content the breaking stress on stretching increased substantially, the optimum content being 30 to 50%. It is interesting that, whatever the proportions of the components, blended systems of this type give X-ray photographs characteristic of the original crystalline polymers. Differential thermal analysis has established [150] that the melting ranges in the blended systems coincide with those of pure polyethylene and pure polytetrafluoroethylene. This indicates that this blended system is formed not by chemical interaction, with the formation of some new chemical compound like a block copolymer, but by secondary intermolecular bonds between the chains of the initial polymers, without change in their original crystalline structure. The above compositions constitute an example of polymer systems in which the introduction of a macromolecular modifier (polyethylene in the present case) results not in a weakening but in a strengthening of intermolecular interaction.

Experiments by several workers [144] on the blending of poly(vinyl chloride) with various brands of nitrile rubbers also confirmed that up to 150–160°C the latter act as plasticising additives in the compositions. Blended systems have been obtained from polyethylene, polystyrene, DVKhB rubber, and other polymers [151].

Dogadkin et al. [152,153] showed that polymer mixtures of optimum composition improve the resistance of vulcanised rubbers to fatigue on repeated deformation, in comparison

with those based on the individual rubbers. In mixed systems the disintegration of specimens subjected to repeated deformations also begins with the growth of microcracks formed at the site of some structural defect. However, a microcrack arising in a medium of lower modulus of elasticity slows down or ceases its further growth on meeting a rubber particle of higher modulus, owing to the possibility of stress relaxation at the apex of the crack. If, on the other hand, the microcrack arises in a medium of higher modulus of elasticity, the overstresses at the apex of the growing crack readily relax on encountering particles of a disperse phase having greater pliability.

In most cases blended systems do not form true solutions [154]: i.e. they are not thermodynamically compatible. Hence they are microheterogeneous (heterophase).

Most blended systems can be regarded as a kind of plasticised system [155] primarily because, as with ordinary plasticisation, the polymeric component of the mixture having the more rigid chains shows some depression of its glass point, increase in deformability, and decrease in the strength of the material, although all these effects are less strongly developed than with agglomerating plasticisers of low molecular weight.

Zelenev and Bartenev [156] studied the relaxation properties of mixtures of polar and non-polar rubberlike polymers over a wide temperature range. They showed that, with non-compatible rubbers (SKS-30 and SKN-26) below the glass point, no significant changes occur in the properties relative to those of the pure rubbers, whereas in the case of a mixture of compatible rubbers (SKS-30 and natural rubber) the low-temperature maximum of mechanical losses diminishes and moves to higher temperatures. Mechanical losses and X-ray diffraction have been used [157] to investigate the relaxation properties of some heterogeneous polymer compositions based on a crystallising isoprene rubber SKI-3 blended with a partly crystalline polymer (isotactic polypropylene), and to establish that polypropylene causes the formation of ordered structures: i.e. it is a structure-forming agent.

It has been shown [158] that butadiene–nitrile rubber (SKN-40) has a considerable plasticising effect on cellulose acetate–butyrate, which conforms to the equal-volume rule and is molecular in character.

The chemical structure of the plasticising components obviously plays a considerable part in the plasticisation of polymers by macromolecular substances. Furthermore, the re-formation of supermolecular secondary structures on contact of a polymer with another, plasticising polymer probably occurs differently from in the presence of a plasticiser of low molecular weight.

It must be remarked that, on the whole, blended systems have not yet been studied at all adequately, and many interesting theoretical and practical papers may be expected to appear in this field in the near future. Thus ternary systems, consisting of two polymers and an antiplasticiser, which increase significantly the strength of blended systems while maintaining all other performance figures, may be of great interest [151].

4. MODERN METHODS OF INVESTIGATING PLASTICISED SYSTEMS

The thermomechanical method proposed by Kargin and Sogolova [159], and subsequently modernised by Teitel'baum [160], has been of great value in studying the mechanism of the plasticisation of polymers at all stages. Thermomechanical curves can be obtained in principle by use not only of compressive forces [161] but also of stretching [162], bending, twisting, etc. forces. The thermomechanical method is interpreted [163] as recording creep (the gradual accumulation of deformation) with a constant load and a gradual rise in temperature at a constant rate. Such regularities in plasticisation as the equal mole fraction and equal volume rules, and to a considerable extent the laws of interstructural and intrastructural plasticisation, were discovered by the successful application of the principles of the thermomechanical method of investigation [164].

The thermomechanical method has been used [165] to study the plasticisation of polymers undergoing crystallisation (cellulose triacetates). Plasticisers (butyl stearate and tritolyl phosphate) depress the glass point, but, because of the crystallisation of the polymer, the plateau of rubberlike elasticity on the thermomechanical curves is located below that for the pure polymer: i.e. the deformability is not increased but is diminished.

Infrared spectroscopy has been widely used to investigate the structure and properties of individual macromolecular compounds [166,167]. It enables us to assess the nature of the forces of intermolecular interaction between certain groups in the polymer chains and the plasticiser, as was first demonstrated by Zhurkov and Levin [168].

An investigation was made by infrared spectroscopy [169] of the interaction between poly(vinyl chloride) and an antiplasticising additive (*o*-tolidine). The appearance in the absorption spectrum of the composition of a band at 3200 cm^{-1} indicates the formation of a hydrogen bond between the amino-group and the polar CHCl group of the polymer. Hydrogen bonding in this case may explain the significant hardening of the polymer on being blended with *o*-tolidine. However, the number of papers on the application of infrared spectroscopy to investigate the plasticisation of polymers is extremely small.

The thermographic method is of great value for investigating plasticised systems, and is quite widely used at the present time to study [170] individual macromolecular compounds. Mikhailov et al. [127] studied the polyethylene–polypropylene system by this method, and showed that blending is observed at quite definite proportions of the components, one of which (polyethylene in the present case) is a plasticiser for the other.

Under the influence of polar agglomerating plasticisers the positions on the differential thermal analysis curves of the effects due to vitrification and breakdown of the crystalline phase are displaced to lower temperatures in the intrastructural plasticisation of poly(vinyl chloride) [171]. At certain temperatures modifying additives (*o*-tolidine, 4,4′-dinitrobiphenyl, etc.) containing active functional groups NH_2 and NO_2 were found to interact chemically with the CHCl groups of the polymer. Thermography also reveals the change in the endothermicity of pyrolysis of the polymer produced by plasticisers, which permits monitoring of the effect of water of crystallisation and other forms of moisture on the course of plasticisation [172].

Thermographic investigation [173,174] of the plasticisation of poly(vinyl chloride) with anthracene, anthraquinone, and *p*-terphenyl showed that anthraquinone displaced the endothermic effects on the differential thermal analysis curves to higher temperatures, whereas the other two compounds produced a shift to lower temperatures. Thus this method of investigation enables us to assess the effectiveness of plasticisers with a given polymer. At the same time cases can be observed of depression of the crystallisation point of plasticisers under the influence

of a polar polymer, and the presence of a small amount of crystalline phase can be recorded in such a polymer as suspended poly(vinyl chloride).

A thermographic study has been made [175] of the effect of plasticisers on transition temperatures in poly(vinyl chloride). This method can also be used [176] to study transformations in blended systems, e.g. a poly(vinyl chloride)—butadiene–acrylonitrile elastomer.

Nuclear magnetic resonance, which enables the mobility of molecules as a whole, of groups, and of atoms to be studied directly, has also acquired great value for investigating individual polymers [177] and plasticised systems [178]. When applied to plasticised polymers this method may yield information on the molecular motion of the plasticiser in the polymer phase, which has been studied [179] for plasticised polystyrene.

The efficiency of plasticisers can be determined by measurement of the spin–spin and spin–lattice relaxation times T_2 and T_1. [180] The influence of the chemical structure of plasticisers on their efficiency can also be followed in these nuclear magnetic resonance experiments. The method enables the type of plasticisation (intrastructural, interstructural, or mixed) to be established [181] for a given polymer, e.g. poly(vinyl chloride), by determining the concentration dependence of the dimensionless quantity T_2/T_1^0, which may serve to characterise the interaction between polymer macromolecules and the plasticiser.

The dielectric loss method [182,183] provides an efficient means for revealing the relation between the properties of polymer systems and their molecular structure. It has been used to study molecular relaxation over wide ranges of temperature and frequency in the rubberlike elastic state of pure and plasticised polymers [184,185], and to calculate relaxation times, the form of their distribution, and correlation factors in the expression for the effective dipole moment [186,187]. These parameters are sensitive to the molecular structure both of the polymers themselves and of plasticising additives present in them. The dielectric loss method can also be used to study [188-191] the influence of the chemical nature and structure of plasticisers on the plasticising effect as shown by the dielectric characteristics of the polymers.

The dielectric loss method has been used to establish [192,193] the dependence of the plasticising effect with poly(vinyl chloride) on the size and shape of the plasticiser molecules, the type, number, and position of functional groups and of benzene rings, and also the displacement of the temperature of maximum tan δ relative to the pure polymer.

Rheological investigations of polymer–plasticiser systems are acquiring great value, providing a basis for processing schedules, and establishing the structure of the melt and certain physical properties of plasticised systems [194-200].

Viscometry has been used [201] to investigate the interaction of poly(vinyl chloride) with plasticisers as a function of the nature of the latter. Viscosity and the points at which swelling, gel formation, and dissolution of the polymer start show an extremal dependence on the type of plasticiser.

The resonance method [202] (determination of the dynamic mechanical characteristics) is of great interest for the investigation of plasticised systems. Zelenev and Bartenev [203] studied the effect of plasticisation (with dibutyl phosphate, dioctyl sebacate, and dibutyl sebacate) on the relaxation properties (mechanical losses) of polar and non-polar rubberlike polymers over a wide temperature range. At high temperatures plasticisers are more effective with non-polar rubbers, and at low temperatures with polar rubbers. The action of plasticisers has different mechanisms in the regions of the main, low-temperature, and high-temperature mechanical-loss maxima. In each case there are differences with polar and with non-polar rubbers. Study of vulcanised filled mixtures of polar and non-polar rubbers has shown [204] that the combination of dynamic mechanical with physicomechanical measurements gives a fairly complete idea of the character and properties of compositions based on mixtures of rubbers, in particular on their degree of microheterogeneity.

The resonance method enables us to trace [205] the dependence of the velocity of sound on the composition of the mixture and the glass and pour points. Its use reveals the ordering and denser packing of poly(vinyl chloride) macromolecules at low concentrations of a plasticiser of high molecular weight, and also the increase in the velocity of sound and in the strength of poly(vinyl chloride) with increase in the SKN-40 content [206].

In several cases plasticisation itself can be used as a method for studying the structure and other properties of polymers [207]. By varying the plasticiser content in poly(vinyl chloride) in suspension and in a latex, for example, a transition in structure can be observed. At plasticiser concentrations below 50% the supermolecular secondary structures of the polymer form a fibrillar network immersed in a continuous liquid phase. At higher concentrations the structure consists of fibrils which have coalesced to enclose droplike inclusions. This leads to an anomalous variation not only in strength but also in electrical conductivity, permeability to gases, and several other properties.

Plasticisation has been used [208] to study the variation in the strength of poly(vinyl chloride) with time. Interstructural (interbundle) plasticisation with small amounts of plasticisers is found to increase the durability of poly(vinyl chloride)–plasticiser systems.

---o0o---

Despite definite advances in the plasticisation of polymers and methods of investigation, several important and complicated problems, in our view, face this branch of science and technology, including

(*a*) development of a unified theory of plasticisation, which will enable the type of plasticiser having a definite plasticising effect to be selected for each type of polymer from the chemical structure of the interacting component;

(*b*) study of the part played by different types of plasticisers at separate stages in the formation of supermolecular secondary structures during polymerisation and processing, which will predetermine a combination of physical properties of the polymers [209];

(*c*) research into the possibility of obtaining synergic effects in the action of mixtures of plasticisers for a wide range of polymers;

(*d*) separation and application of general-purpose plasticisers combining several functions—like e.g. oxides of tetrahydrophthalates [106], which are not only efficient plasticisers but also good stabilisers for poly(vinyl chloride); and

(*e*) further study of the plasticisation of network polymers, the plasticisation of polymers by macromolecular compounds [210,211], and the formation of blended systems by mixing latices and aqueous dispersions of polymers [212,213].

Successful solution of this far from complete list of problems will permit a substantial broadening of our views on the phenomenon of plasticisation and improvement in the technical standard of the production and application of plasticised polymeric materials.

General Theory of Separation and Chromatography

V.P.Chizhkov

The fundamental characteristics of the operation of chromatographic columns have been discussed from the standpoints of the general theory of separation; relations applicable in principle to any method of the chromatographic separation of binary mixtures, regardless of the nature and magnitude of the elementary separation step on which it is based, are presented. The bibliography includes 34 references.

I. INTRODUCTION

In connection with the elaboration[1] and development[2-5] of the circulation chromatographic method whereby it is possible to employ repeatedly the same stationary sorbent bed for the separation of a binary mixture, there arose the necessity to compare it with other processes involving the separation of binary mixtures in columns (distillation, thermal diffusion, centrifuging, etc.). At first sight, the concept of theoretical plates developed in a number of studies[6-8] might serve for this purpose. However, in chromatography the theoretical plate bears no relation[9] to the concept of the theoretical separation stage in the general theory of separation[10].

Comparatively recently the concept of an ideal cascade in chromatography was developed[11]. This involved the introduction of the idea of the height equivalent to the theoretical stage (HETS), which is equivalent to the analogous idea employed earlier for a chromatographic column with complete (special) phase reversal at the ends of the separation zone[12,13]. However, when formulating a specific problem—the comparison of various versions of the continuous circulation-type separation of binary mixtures—the relation between the general theory of separation and chromatography was inadequately elucidated and was limited essentially to the discovery of an analogy between partition in terms of relative concentrations in the chromatographic column and in an ideal fine-separation cascade.

In order to reflect more completely the existing relation, a parallelism is drawn here between chromatographic separation processes and liquid extraction processes, on the basis of which a clearer definition of HETS in chromatography is given together with its relation to the height equivalent to a theoretical plate (HETP) and the optimum conditions for chromatographic separation are discussed. An analogy is also drawn between the operation of a chromatographic column with full phase reversal and a rectangular fine-separation cascade and certain new methods of gas-chromatographic separation are discussed.

II. ANALOGY BETWEEN LIQUID EXTRACTION AND CHROMATOGRAPHY IN THE LIGHT OF THE GENERAL THEORY OF SEPARATION

In the study of chromatographic separation processes an analogy is often drawn between them and liquid extraction processes. This analogy has in fact led to the development of the concept of the theoretical plate in chromatography. The chromatographic column is regarded as consisting of individual elements (plates). Equilibrium must be attained in each such element, i.e. the process takes place as follows: initially the substance enters the first element where equilibrium is established, then the same thing occurs in the second element and in the next, etc., i.e. the real process is imagined to take place on the pattern of the processes occurring in Craig apparatuses[14-16].

In the present section the analogy between liquid extraction and chromatography will also be employed for the further development of the concept of the ideal cascade in chromatography.

1. Ideal Liquid-Extraction Cascade

We shall analyse the operation of a separation apparatus the three stages of which are shown in Fig. 1. The apparatus is a cascade consisting of N series-connected theoretical separation stages. Here the theoretical or ideal stage is understood, as usual[17], as a stage in which the duration of the interaction between the phases is sufficient for the attainment of equilibrium characterised by the elementary separation step. Thus the extract and the material leaving the theoretical stage are solutions in thermodynamic equilibrium with one another.

We shall restrict the treatment to the case of immiscible extractants and to extraction with independent partition of the components (which is frequently observed for dilute solutions, particularly when the partitioned components are undissociated substances or substances which do not react

with any components of the extractant[17]). One of the separation stages in this cascade is shown in Fig. 2 with an indication of the streams and the corresponding concentrations. The separation stage has the following characteristics: a feed flux L at a concentration x enters it with two fluxes emerging at the other end—one partially enriched in the component extracted (L', x') and the other partially depleted in the component (L'', x''). In the case of extraction

$$L' = \varkappa u c_1 + \varkappa u c_2 = \varkappa u c_0 , \quad (1)$$

$$L'' = \varkappa_1 v a_1 + \varkappa_1 v a_2 = \varkappa_1 v a_0 . \quad (2)$$

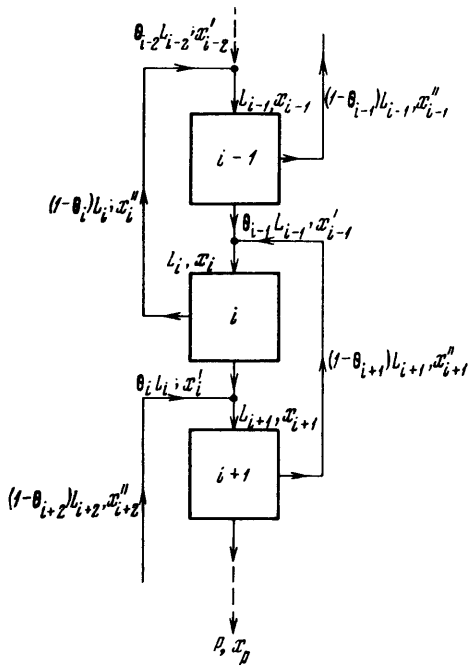

Figure 1. The cascade.

Here u and v are the linear velocities of the extractants, $\varkappa$ and $\varkappa_1$ are the fractions of the cross-section of the stage occupied by the extractants, c_1 and c_2 are the amounts of the first and second components of the mixture to be separated in the first extractant, and a_1 and a_2 are the amounts of the first and second components in the second extractant.

Bearing in mind that

$$L = L' + L'' , \quad (3)$$

we obtain

$$L = \varkappa u (c_0 + \lambda a_0) , \quad (4)$$

where

$$\lambda = \frac{\varkappa_1 v}{\varkappa u} \quad (5)$$

is the ratio of the extractant fluxes.

Then

$$x' = \frac{c_1}{c_1 + c_2} = \frac{c_1}{c_0} , \quad (6)$$

$$x'' = \frac{a_1}{a_1 + a_2} = \frac{a_1}{a_0} . \quad (7)$$

Since

$$Lx = L'x' + L''x'' \quad (8)$$

by substituting Eqns. (1), (2), (4), (6) and (7) in Eqn. (8), we obtain

$$x = \frac{c_1 + \lambda a_1}{c_0 + \lambda a_0} . \quad (9)$$

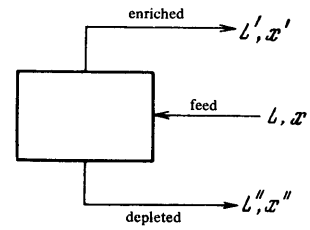

Figure 2. A stage in the cascade.

The relative concentrations[18] will be correspondingly defined by the following equations:

$$\xi' = \frac{x'}{1 - x'} = \frac{c_1}{c_2} , \quad (10)$$

$$\xi'' = \frac{x''}{1 - x''} = \frac{a_1}{a_2} , \quad (11)$$

$$\xi = \frac{x}{1 - x} = \frac{c_1 + \lambda a_1}{c_2 + \lambda a_2} . \quad (12)$$

Introducing the ratio of the enriched fraction to the feed flux (the degree of separation[18]), we obtain

$$\theta = \frac{L'}{L} = \frac{c_0}{c_0 + \lambda a_0} . \quad (13)$$

The degree of separation attained in one stage is called[18] the separation factor α. The latter is defined as the ratio of the relative concentration in the enriched fraction to the relevant concentration in the depleted flux:

$$\alpha = \frac{\xi'}{\xi''} = \frac{a_2}{a_1} \cdot \frac{c_1}{c_2} = \frac{k_2}{k_1} , \quad (14)$$

where k_1 and k_2 are partition coefficients.

Another measure of the degree of separation achieved in the stage is the effective separation factor[18] β:

$$\beta = \frac{\xi'}{\xi} = \frac{1 + \lambda k_2}{1 + \lambda k_1} . \quad (15)$$

Hence

$$\lambda = \frac{\beta - 1}{k_2 - \beta k_1} . \quad (16)$$

It is known[17] that in the separation of components by liquid extraction best results are achieved when the volume ratio of the phases corresponds to symmetrical separation:

$$\lambda_0 = \frac{1}{\sqrt{k_2 k_1}} . \quad (17)$$

We shall attempt to explain this result from the standpoint of the general theory of separation. For this purpose, the principle of the rationality of the cascade formulated previously[19,20] will be employed.

In principle, the role of each stage and of the entire separation cascade consists in the separation of the mixture components. In terms of thermodynamics, this means that under all conditions the operation of the cascade and all its elements consists in a decrease of the entropy (of mixing) of the system. Hence a cascade operating without mixing in any of its units fractions with different concentrations of the component to be extracted must evidently be regarded as thermodynamically the most effective (ideal).

Fig. 1 shows that each stage of the cascade is fed by two fluxes: by the enriched flux from the upper adjacent stage and by the depleted fraction from the lower stage. Only in these units is there a possibility of the mixing of fractions and consequently it is in fact here that particular care should be taken to avoid an increase of entropy.

Thus according to the principle of the ideality of the cascade,

$$\ldots\ ;\ x''_{i+2} = x'_i;\ x''_{i+1} = x'_{i-1};\ x''_i = x'_{i-2};\ \ldots \tag{18}$$

and consequently

$$\ldots\ ;\ x_{i+1} = x'_i;\ x_i = x'_{i-1};\ x_{i-1} = x'_{i-2};\ \ldots \tag{19}$$

Conditions (18) and (19) can also be expressed in terms of relative concentrations:

$$\xi''_{i+1} = \xi'_{i-1} = \xi_i\ . \tag{20}$$

By definition of the effective separation factor,

$$\xi'_i = \beta\xi_i\ . \tag{21}$$

According to Eqn. (20), for an ideal cascade,

$$\xi'_i = \beta\xi''_{i+1} \tag{22}$$

and

$$\xi'_{i+1} = \beta\xi'_i\ . \tag{23}$$

Multiplying together the last two equations, we obtain

$$\xi'_{i+1} = \beta^2\xi''_{i+1}\ , \tag{24}$$

but, by definition of the separation factor,

$$\xi'_{i+1} = \alpha\xi''_{i+1}\ , \tag{25}$$

so that

$$\beta = \sqrt{\alpha}\ . \tag{26}$$

This relation between the effective and thermodynamic separation factors is[10,18-20] the fundamental property of the ideal cascade.

Using Eqns. (14), (15) and (26), it is easy to show that condition (17) is identical with the fundamental property of the ideal cascade and is thus a necessary and sufficient condition for its determination.

For the practically important case of fine separation[10,18-20] where $\alpha - 1 \ll 1$, the geometrical mean may be replaced by the arithmetical mean. Then

$$\lambda_0 \simeq \frac{2}{k_1 + k_2}\ . \tag{27}$$

The resulting equation is identical with the equation derived previously[21] in the calculation of the optimum ratio of the carrier fluxes in a countercurrent chromatographic column and can thus serve as additional confirmation of the validity of the concept of the ideal cascade in chromatography.

It is useful to note that so far in the general theory of separation only one type of ideal cascade has been considered—the continuous-operation ideal cascade characterised by a maximum[10,18,19] on the overall flux distribution curve, the positions of which coincides with the feed point. However, according to the literature data[17], condition (17) is valid not only for a liquid extraction cascade with continuous feed but also for fractional extraction in a Craig apparatus[17], where the distribution of the component fluxes is Gaussian[17,22]. On this basis, one may consider two types of ideal cascade differing in the specific distribution of the component fluxes.

It is possible to show that the overall degree of separation q_0 achieved by the ideal cascade is defined[10] by an equation of the following form:

$$q_0 = \frac{\xi_N}{\xi_0} = \alpha^{N/2}\ . \tag{28}$$

For the case of fine separation we have correspondingly

$$\xi_N = \xi_0\ e^{N/2\cdot(\alpha-1)}\ , \tag{29}$$

where ξ_0 is the relative concentration at the feed point.

On the basis of the above equations, one can imagine how the transition from the second type of ideal cascade to the first may occur. Indeed, we can find the changes which will occur when, during the separation of a binary mixture, the latter is continuously introduced at the feed point. If the condition of extraction with independent partition of components is not thereby violated, the relative concentration partition law should hold, so that continuous introduction of the mixture may be regarded as an infinite number of pulse injections of the mixture at the feed point, which leads to a superposition of a large number of Gaussian distribution curves[11].

2. HETS in Chromatography

HETS in chromatography may be determined from a consideration of the chromatographic zone for a binary mixture. Fig. 3 shows that

$$A'_1 = A_{\max_1}\exp\left[-\frac{(s'_1)^2}{4D^*_1 t}\right]\ , \tag{30}$$

$$A_{0,1} = A_{\max_1}\exp\left[-\frac{(s^0_1)^2}{4D^*_2 t}\right]\ , \tag{31}$$

where

$$s'_1 = \pm\,(l - s^0_1)\ , \tag{32}$$

$$D^*_1 = \frac{D_{\mathrm{eff}_1}\varkappa}{\Gamma_1}\ , \tag{33}$$

$$A_1 = c_1\Gamma_1\ , \tag{34}$$

$$\Gamma_1 = \varkappa\left(1 + \frac{\varkappa_1}{\varkappa}k\right) = \varkappa(1 + k'_1)\ , \tag{35}$$

and D_{eff_1} is the effective diffusion coefficient[22,23].

After dividing Eqn. (30) by Eqn. (31) and using Eqn. (32), we obtain

$$\ln\frac{A'_1}{A_{0,1}} = \frac{l}{4D^*_1 t}[2s^0_1 - l]\ . \tag{36}$$

For the second component

$$A'_2 = A_{\max_2}\exp\left[-\frac{(s'_2)^2}{4D^*_2 t}\right]\ , \tag{37}$$

$$A_{0,2} = A_{\max 2}\exp\left[-\frac{(s_2^0)^2}{4D_2^* t}\right], \quad (38)$$

where

$$s_2^l = s_2^0 + l . \quad (39)$$

Having divided Eqn. (37) by Eqn. (38) and using Eqn. (39), we have

$$\ln\frac{A_2^l}{A_{0,2}} = -\frac{l}{4D_2^* t}[2s_2^0 + l] . \quad (40)$$

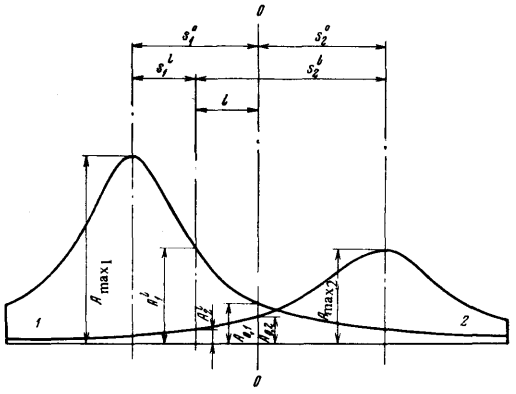

Figure 3. A chromatographic band.

By combining Eqns. (36) and (40) and putting $D_1^* = D_2^*$, we obtain

$$\ln q_0 = \frac{l(s_1^0 + s_2^0)}{2D^* t} . \quad (41)$$

The values of s_1^0 and s_2^0 may be found using the equation derived previously[11,21] for the calculation of the velocities of the chromatographic zones in a system of coordinates linked to the feed cross-section of the chromatographic band:

$$v_{s_1} = \frac{s_1^0}{t} = \frac{u(1-\lambda_0 k_1)}{1+k_1'} , \quad (42)$$

$$v_{s_2} = \frac{s_2^0}{t} = \frac{u(1-\lambda_0 k_2)}{1+k_2'} . \quad (43)$$

From the condition

$$v_{s_2} = -v_{s_1} , \quad (44)$$

we obtain

$$\lambda_0 = \frac{\tilde{\alpha}+1}{k_2 + \tilde{\alpha}k_1} , \quad (45)$$

where

$$\tilde{\alpha} = \frac{\Gamma_2}{\Gamma_1} . \quad (46)$$

On substituting Eqn. (45) in Eqns. (42) and (43), we obtain

$$|s_1^0| = |s_2^0| = \frac{\varkappa u}{\Gamma_1}\frac{\alpha-1}{\alpha+\tilde{\alpha}} \cdot t , \quad (47)$$

whence

$$\ln q_0 = \frac{l}{\frac{D_{\text{eff}_1}}{u}} \cdot \frac{\alpha-1}{\alpha+\tilde{\alpha}} . \quad (48)$$

The application of the concept of HETS to columns is known[10,17] to be useful only in the separation of isotopes where $\alpha - 1 \ll 1$. In the separation of the usual mixtures, the best characteristic is the height per unit transfer[10,17] (HET), since with a correct choice of the determining phase, HET is independent of α, in contrast to HETS.

Taking this into account, we can transform Eqn. (48) for the case of $\alpha - 1 \ll 1$, obtaining

$$\ln q_0 \simeq \frac{l}{\frac{D_{\text{eff}}}{u}} \cdot \frac{\alpha-1}{2} . \quad (49)$$

We may note that under these conditions Eqn. (45) becomes identical with Eqn. (27), which makes it possible to compare Eqn. (49) with Eqn. (29) and thus obtain

$$\text{HETS} = \frac{D_{\text{eff}}}{u} . \quad (50)$$

The resulting value of HETS differs significantly from the concept of HETP widely used at the present time in chromatography[22,23]:

$$\text{HETP} = \frac{2D_{\text{eff}}}{u_0} , \quad (51)$$

where u_0 is the velocity of the developer in a system of coordinates linked to the column. It is evidently of interest to compare these two concepts.

In the separation of a mixture on a stationary sorbent in a system of coordinates linked to the feed cross-section[11,21], there is a countercurrent of the eluent and the sorbent and the following equation applies:

$$u_0 = u + v . \quad (52)$$

Using Eqn. (27), it is possible to show that

$$u = u_0 \cdot \frac{k'}{1+k'} . \quad (53)$$

On substituting the value of u from Eqn. (53) in Eqn. (50), we obtain after some rearrangement the expression

$$\text{HETS} = \text{HETP} \cdot \frac{1+k'}{2k'} , \quad (54)$$

from which it follows that the values of HETS and HETP are identical only when $k' = 1$. When $k' \ll 1$, HETS differs significantly from HETP. We may note that, when $k' = 0$ (no sorption of the components to be separated), the concept of HETS loses significance, since this quantity tends to infinity, which is physically understandable because the absence of sorption of the components separated implies also the absence of chromatographic separation.

Eqns. (28) and (48) are used to determine HET in chromatography. Under conditions where $\tilde{\alpha} = \sqrt{\alpha}$, Eqn. (45) is transformed into Eqn. (17). On this basis (for any value of α), one can write

$$\text{HETS} = \frac{D_{\text{eff}_1}}{u} \cdot \frac{(\alpha+\sqrt{\alpha})\ln\alpha}{2(\alpha-1)} \cdot \frac{\frac{\sqrt{\alpha}-1}{\sqrt{\alpha}}}{\frac{\sqrt{\alpha}-1}{\sqrt{\alpha}}} = \frac{D_{\text{eff}_1}}{u} \cdot \frac{\frac{1}{2}\ln\alpha}{1-\frac{1}{\sqrt{\alpha}}} . \quad (55)$$

According to the literature data[17],

$$\text{HETS} = \text{HET} \cdot \frac{\ln\varepsilon}{1-\frac{1}{\varepsilon}} , \quad (56)$$

where

$$\varepsilon = k_2\lambda_0 = \sqrt{\alpha} . \quad (57)$$

Comparison of Eqns. (55) and (56) shows that

$$\mathrm{HET} = \frac{D_{\mathrm{eff}1}}{u} \quad . \tag{58}$$

3. The Validity of the Assumption that $D_1^* = D_2^*$

Eqn. (49) may be transformed into a formula analogous to the formulae for the calculation of the number of theoretical plates n in the chromatographic column[2,23,24]. Indeed, if it is assumed that $l = s_1^0$, then

$$2\ln q_0 = 2\ln\left[\frac{A_1 \cdot A_{\max 2}}{A_2 \cdot A_{\max 1}}\right] = 2\ln\left[\frac{A_{\max 2}}{A_2}\right] = \sigma^2_{\max} \quad , \tag{59}$$

where $\sigma_{\max_2}$ is the number of standard deviations at a specified peak height. According to Eqns. (49) and (54),

$$\sigma^2_{\max 2} = \frac{s_1^0}{\mathrm{HETP}} \cdot \frac{2k'}{1+k'}(\alpha - 1) \quad . \tag{60}$$

From Eqns. (47) and (53), we have

$$s_1^0 = \frac{u_0}{1+k'} \frac{k'}{1+k'} \cdot \frac{\alpha - 1}{2} \cdot t \quad . \tag{61}$$

On substituting Eqn. (61) in Eqn. (60), we obtain

$$t = \frac{\mathrm{HETP}}{u_0} \cdot \frac{\sigma^2_{\max 2}}{(\alpha-1)^2} \frac{(1+k')^2}{(k')^2} \quad . \tag{62}$$

Since

$$t = \frac{H}{u_0}(1+k') \quad , \tag{63}$$

where H is the height of the chromatographic column, it follows that

$$n = \frac{\sigma^2_{\max}}{(\alpha-1)^2}\left(\frac{1+k'}{k'}\right)^2 \quad . \tag{64}$$

According to Purnell[24],

$$n = \frac{36}{(\alpha-1)^2} \cdot \left(\frac{1+k'}{k'}\right)^2 \quad , \tag{65}$$

while according to Zhukhovitskii[23],

$$n = \frac{32K_1}{(\tilde{\alpha}-1)^2} = \frac{32K_1}{(\alpha-1)^2} \cdot \left(\frac{1+k'}{k'}\right)^2 \quad , \tag{66}$$

where K_1 is the separation criterion.

According to Martin[2],

$$n = \frac{16\sigma}{(\tilde{\alpha}-1)^2} = \frac{16\sigma}{(\alpha-1)^2} \cdot \left(\frac{1+k'}{k'}\right)^2 \quad . \tag{67}$$

Eqn. (64) is identical with Eqns. (65), (66), and (67). The conclusions based on the equations formulated (see, for example, Purnell and Quinn[24]) are satisfactorily confirmed in practical chromatographic analysis despite the assumption of the equality of D_1^* and D_2^*. Therefore Eqn. (49) derived here should also hold in practice both by analogy and as a result of its relation to the equations already available. Indeed, on the basis of Eqn. (49), one can imagine the way in which the transition from the periodic version of development-type circulation chromatography to its continuous separation version with periodic additional feed and take off may be achieved[5,11]. Without resorting to the above assumption, it is difficult to account for the real existence of continuous-operation chromatography such as the method proposed for gas chromatography by Pichler and Schulz[25].

4. Optimum Conditions for Chromatographic Separation

If the role of the chromatographic column consists only in the separation of the binary mixture to the required degree of purity (sufficient, for example, for analysis), then in principle it is possible to ensure conditions of chromatographic separation such that the work of separation is a minimum. The study of the optimum separation conditions in the general theory of separation leads to the conclusion that cascades with reduction of the fluxes from one separation element to another (and in the case of low separation factors cascades with a continuous variation of the fluxes) are most convenient. When certain laws governing the distribution of the fluxes and the relative concentrations (corresponding to the distribution in an ideal cascade) operate, the work of separation in such cascades is a minimum[10]. Bearing in mind the analogy found between a chromatographic column and an ideal cascade, it is therefore of interest to elucidate under what conditions the chromatographic column most closely approaches the ideal cascade.

According to Eqn. (45), when

$$\tilde{\alpha} = \sqrt{\alpha} \tag{68}$$

the volume ratio of the phase fluxes in the chromatographic column becomes equal to the analogous ratio in the ideal cascade [see Eqn. (17)]. Thus condition (68) may be called the optimum condition for chromatographic separation. From it and from the fundamental equation of the ideal cascade, it follows directly that under optimum conditions

$$\tilde{\alpha} = \beta \quad . \tag{69}$$

On substituting the values of $\tilde{\alpha}$ and β from Eqns. (15) and (46) in Eqn. (69) and using Eqn. (35), it is easy to show that condition (69) corresponds to the equality $u = v$. Consequently, judging from Eqns. (5) and (17), the equality

$$\frac{\varkappa_1}{\varkappa}\sqrt{k_2 k_1} = k'_{\mathrm{av}} = 1 \quad , \tag{70}$$

also constitutes a condition identical with the optimum condition.

It is remarkable that the limiting value of k', determined[24] from the condition for the minimum duration of analysis and corresponding to the complete absence of resistance to mass transfer in the stationery phase, is about 0.9, which is close to unity.

III. THE RELATIVE CONCENTRATION PARTITION LAW IN THE CHROMATOGRAPHIC CONCENTRATION OF ISOTOPES

Spedding et al.[1] succeeded for the first time in showing experimentally that, by observing the conditions[26] for the sharpening of the fronts of the chromatographic zone of a binary isotope mixture, it is possible to transfer the zone across a length of the sorbent bed exceeding by a factor of 50–100 the intrinsic length of the zone without the slightest spreading. An analogous result can evidently be arrived at with the aid of the thermal factor in chromatography[3,4]; the chromatographic enrichment method then becomes more economical[4], since the consumption of expensive chemical reagents is replaced by the consumption of low-potential heat.

Fig. 4 shows the stationary chromatographic zone of a binary isotope mixture moving down the bed of a stationary sorbent. In a system of coordinates linked to the zone, there exists[12,13] a countercurrent of the sorbent and the

solution and the flux of the mixture with the sorbent is equal to the flux of the mixture with the solution:

$$L' = \varkappa_1 v a_0 = \varkappa_2 c_0 \tag{71}$$

and

$$\frac{a_1}{a_2} = \text{const} \cdot \frac{c_1}{c_2} \ . \tag{72}$$

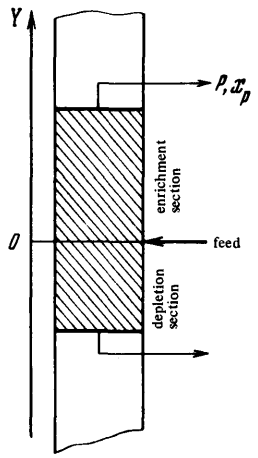

Figure 4. A stationary chromatographic zone.

The latter equation is valid when the sorbent is in thermodynamic equilibrium with the solution. Using Eqn. (71), one can also write[12,13]

$$\text{div}\, I = \frac{\partial x'}{\partial s} - \frac{\partial x''}{\partial s} - \frac{D_{\text{eff}}}{u} \frac{\partial^2 x'}{\partial s^2} \ . \tag{73}$$

At the instant of attainment of equilibrium div $I = 0$ and

$$\Delta x = x' - x'' = \frac{D_{\text{eff}}}{u} \cdot \frac{\partial x'}{\partial s} \ , \tag{74}$$

i.e. a concentration gradient is established in the zone such that the reverse diffusion flux will fully balance the entire flux of the first (extracted) component.

For substances with similar physicochemical characteristics ($\alpha - 1 \ll 1$), Eqn. (14) may be approximated[18] in the following way:

$$\Delta x = (\alpha - 1)\, x' (1 - x') \ . \tag{75}$$

On substituting Eqn. (75) in Eqn. (74), we obtain after integration

$$\xi_l = \xi_0 e^{lu/D_{\text{eff}}(\alpha - 1)} \ . \tag{76}$$

Hence, according to Eqn. (50)

$$N_{\min} = \frac{\ln q_0}{\alpha - 1} \ . \tag{77}$$

The resulting expression is the familiar Fenske equation[10] for the calculation of the number of theoretical separation stages in a rectangular cascade with total phase reversal. We may note that, for the chromatographic column under consideration, this equation could be formulated immediately, since Eqns. (71) and (72) in no way differ from the familiar equations[10] for mass transfer in a column with total phase reversal.

In the presence of take off[13] the expression for the flux of the first component through a cross-section in the enrichment section of the zone must be written in the following way:

$$I = L' \left[(\alpha - 1)\, x' (1 - x') - \frac{D_{\text{eff}}}{u} \frac{dx'}{ds} \right] + Px' \ , \tag{78}$$

where P is the take-off flux. At equilibrium a concentration gradient is established in the zone such that the reverse diffusion flux will balance the entire flux of the first component with the exception of the take-off flux:

$$\begin{gathered} L' \left[(\alpha - 1)\, x' (1 - x') - \frac{D_{\text{eff}}}{u} \cdot \frac{dx'}{ds} \right] + Px' = Px_p \ , \\ \frac{dx'}{ds} = \frac{u}{D_{\text{eff}}} (\alpha - 1)\, x' (1 - x') - \frac{u}{D_{\text{eff}}} \frac{P}{L'} (x_p - x') \ . \end{gathered} \tag{79}$$

Using Eqn. (50), it is easy to find that

$$\frac{dx'}{dN} = (\alpha - 1)\, x' (1 - x') - \frac{P}{L'} (x_p - x') \ , \tag{80}$$

i.e. the familiar mass-exchange equation[10] widely employed in the theory of isotope separation.

From the general theory of separation, it is known that[10] Eqn. (80) describes also the cascade in which the flux L' is a continuous function of the number of the stage with a maximum at the feed point. The overall flux is then

$$\Sigma L' = \int L'\, dN = \int L'\, dx' \frac{dN}{dx'} = \int \frac{dx'}{\frac{1}{L'} \cdot \frac{dx'}{dN}} \ . \tag{81}$$

In the ideal cascade the overall flux is a minimum[10,18,19]. According to Eqn. (81), the overall flux is a minimum when the integrand $x'(dN/dx')$ is a minimum for all x', i.e. when the reciprocal is a maximum:

$$\frac{1}{L'} \frac{dx'}{dN} = \frac{(\alpha - 1)\, x' (1 - x')}{L'} - \frac{P}{L'} \ . \tag{82}$$

From the condition for the maximum, i.e. by differentiating Eqn. (82) with respect to L' and putting $(\partial / \partial L')[(1/L')(\partial x'/\partial N)] = 0$, one can find[10]

$$L'_{\text{id}} = \frac{2P}{\alpha - 1} \cdot \frac{x_p - x'}{x' (1 - x')} \ . \tag{83}$$

On substituting Eqn. (83) in Eqn. (80) and integrating, we obtain Eqn. (29).

The expression for the flux at any stage in the cascade for any value of the separation factor has been obtained by the method of finite differences[27,28].

IV. NEW METHODS OF GAS CHROMATOGRAPHIC SEPARATION

Adsorption may be regarded[29] as a result of the attraction of gas molecules to adsorbent molecules. In consequence of this attraction, a potential force field is established above the adsorbent. If this field is regarded as constant at a certain distance h, then

$$a = ShC_0 e^{-\Delta v / kT} \ , \tag{84}$$

where Δv is the difference between the energy of the molecule near the adsorbent and in the gas phase and S is the surface area of the adsorbent.

We may note that an equation analogous to Eqn. (84) describes[29] also the distribution of molecules in the gravitational force field. In this connection a new method of gas-chromatographic separation of heavy element isotopes in the artificial gravitational field of a gas centrifuge (gas–gas chromatography) has been proposed recently[30]; it differs from the familiar method (in a countercurrent gas centrifuge[10]) to the same extent that gas–liquid chromatography differs from distillation.

The centrifuge[30] is a cylinder *1* rotating at a high angular velocity (Fig. 5). The internal wall of the cylinder is a porous partition *2* firmly bound to the cylinder. The partition has narrow channels, positioned at right angles to the axis of the apparatus, in which the molecules of the components separated can pass freely. Along the axis of the centrifuge, the carrier gas moves in a continuous stream. The channels in the partition are then also filled by the carrier gas and play a role analogous to that of adsorption centres in gas-adsorption chromatography. When the apparatus rotates, a gravitational field identical with the field of sorption forces is established.

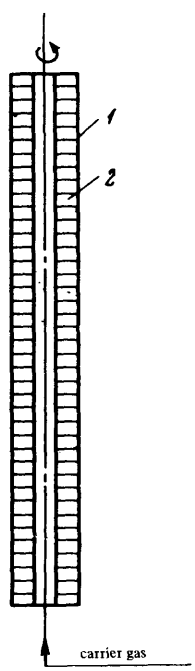

Figure 5. Gas centrifuge: *1*) cylinder; *2*) porous partition.

When a sample of the mixture to be separated is introduced into the stream of the carrier gas, zones corresponding to individual components may be obtained at the outlet from the apparatus by virtue of the repeated partitioning of the molecules of these components between the moving gas phase and the stationary phase and also by virtue of the difference in the partition of the components caused by the difference between their molecular weights Δm. In this case the separation factor is defined by the following equation[10]:

$$\alpha = e^{\Delta m\, \omega^2 \cdot \Delta r / kT}, \qquad (85)$$

where ω is the angular velocity of the gas centrifuge and r is the radius.

Large separation factors can be obtained only at relatively high angular velocities and correspondingly high rates of rotation (above 60 000 rev min^{-1}). Thus in the separation of uranium isotopes[10] in a countercurrent centrifuge with $\Delta r = 6$ cm for $\Delta m = 3$ g $mole^{-1}$, $k = 8.315 \times 10^7$ erg $mole^{-1}$ and $T = 300°K$, we would have $\alpha = 1.085$. Calculation[31] for a mixture of UF_6 containing uranium isotopes, carried out on the assumption that the difference in absorbability is determined by the difference between the zero-point energies, gives $(\Gamma_2 - \Gamma_1)/(\Gamma_2 + \Gamma_1) = 10^{-5}$.

To obtain small amounts of the isotopes of light and intermediate elements, thermal diffusion columns[10]—the simplest laboratory apparatus for isotope separation—are now widely employed. However, separation on thermal diffusion columns (as in the case of fractional distillation) requires comparatively large amounts of the initial mixture. In this connection the chromatographic method in a thermogravitational field is also of interest[21]. The separation factor in the thermal diffusion of a binary mixture is determined[10] by an equation of the following form:

$$\alpha = 1 + \delta \frac{\Delta T}{\bar{T}}, \qquad (86)$$

where

$$\delta = \frac{105}{108} \cdot \frac{\Delta m}{2m} \cdot R_T = \delta_0 R_T \qquad (87)$$

and R_T is a correction coefficient taking into account the nature of the intermolecular forces.

When the gravitational field of the gas centrifuge is brought into coincidence with the thermal field, it is evidently possible to achieve a method of gas-chromatographic separation which in many cases is not inferior to chromatography in a sorption field.

The analogy may be drawn further by considering other known methods of separation in countercurrent columns[10]. As usual, the choice of the method[10] will determine the value of the separation factor, the thermodynamic efficiency (characterising the energy consumption), the nature of the apparatus, and finally the conditions of the analysis or the scale of the process. In this connection it is useful to recall that the concept of the ideal cascade developed here leads to the introduction in chromatography of concepts such as the work of separation, the separating power, and the separating potential[10,18,19,32–34]. By calculating the cost of all things consumed in the operation of the separating column per hour, it is possible to calculate the cost per unit separating power when a particular technological procedure is employed. Clearly the best technological procedure is one which ensures the minimum cost per unit separating power. The calculation of the cost of one kilogram-separating unit per hour[32] is analogous to a comparison of separating apparatus in terms of the efficiency in real technological processes.

Conjugation in the Series of Phosphorus(III) Compounds

E.N.Tsvetkov and M.I.Kabachnik

In its electronic effect phosphorus(III) is usually regarded as an analogue of tervalent nitrogen. However, in recent years it has been shown that substituents with phosphorus(III) do not exhibit a π-donor effect, which is characteristic to a greater or smaller extent of groups containing the elements in Periods II and III with lone pairs of electrons. On the other hand, substituents with phosphorus(III) exhibit a π-acceptor effect, characteristic of *meta*-orienting groups, and probably due to the interaction with the vacant orbitals of phosphorus. Thus, in contrast to elements of Periods II and III with lone electron pairs, phosphorus(III) is incapable of $p-\pi$ conjugation. The absence of the capacity of the lone electron pair of phosphorus to undergo delocalisation (or the presence of only insignificant capacity of this kind) has been explained by an enhanced *s*-character of the lone pair orbital, which is confirmed by data for the valence angles in phosphorus(III) compounds. The physical and chemical properties of phosphorus(III) compounds in which there is a possibility of $p-\pi$ conjugation are discussed in the review from this standpoint. All the properties are consistent with the hypothesis of the predominant *s*-character of the lone electron pair of phosphorus.
The bibliography includes 361 references.

I. INTRODUCTION

The development of the chemistry of organophosphorus compounds is to a considerable degree due to phosphorus(III) compounds, which, by virtue of their high reactivity, occupy an outstanding place among other types of organophosphorus derivatives. The most interesting reactions of phosphorus(III) compounds are accompanied by an increase in valence and the involvement of the lone pair in the formation of a new bond. Thus the properties of phosphorus(III) compounds associated with the participation of the lone pair in intermolecular electronic steps have been widely investigated. Nevertheless little is known about the nature of the lone electron pair of phosphorus and its intramolecular interactions with attached π-electronic systems. Phosphorus in the tervalent state is perhaps the only element in the Second and Third Period forming organic derivatives about the electronic effect of which there has been virtually no information until recently. By analogy with nitrogen and other elements with lone electron pairs and also according to its position in the Periodic System, it was usually postulated[1,2] that it should be an *ortho–para* directing substituent with a highly pronounced π-donor conjugation effect.

According to the classical concepts developed by the English School of Chemistry[3] the capacity of the lone electron pair of any atom for $p-\pi$ conjugation is associated with the position of the element in the Periodic System. Thus, within the limits of a single Period, it decreases from left to right and within the limits of a single Group from above downwards:

$$R_2N > RO > F;\ F > Cl > Br > I;\ RO > RS\ .$$

Later these qualitative relations were confirmed on the quantitative scale of resonance effects proposed by Taft[4,5].

Using these relations, one may expect that the effect of π-donor conjugation of substituents with phosphorus(III) will be greatest among the elements of the Third Period:

$$R_2P > RS > Cl$$

Compared with nitrogen, the effect should be only slightly reduced, to the same extent as on transition from oxygen to sulphur. Apart from π-donor conjugation, a π-acceptor d-orbital interaction effect, which is probably characteristic of all the elements in the Third Period but is shown in a pure form only in the case of silicon, can also be postulated for phosphorus(III). However, on the whole these comparisons might have led to the expectation that substituents with phosphorus(III) would be *ortho–para* directing and would exhibit a positive mesomeric effect.

However, the study of the chemical properties of phosphorus(III) compounds showed that, contrary to the above considerations, phosphorus is greatly inferior in its capacity for $p-\pi$ conjugation not only to nitrogen but even to sulphur and chlorine. Moreover, so far no property has been found involving a distinct effect of the capacity of the lone electron pair of phosphorus for $p-\pi$ conjugation in the ground state of the molecule. Therefore the above series should be reformulated as follows:

$$RS > Cl > R_2P\ .$$

Owing to the absence or insignificance of the π-donor effect, phosphorus(III) exhibits distinct π-acceptor properties, probably via $p_\pi - d_\pi$ conjugation and therefore belongs to *meta*-directing groups. Chemically this was demonstrated for the first time by the authors of the review together with Chang Jung-yu in experiments on the directive influence in the addition of secondary amines to vinyl derivatives of phosphorus(III).[6-8] Subsequently these conclusions were confirmed and developed by the present authors with other collaborators[9-15] and in a number of studies in the Soviet Union[16,17] and abroad[18-40].

In order to account for the unusual properties of phosphorus(III), we put forward a hypothesis together with Bochvar and Lobanov[9,11,12] according to which the reason for the lack of capacity for (or low tendency towards) $p-\pi$ conjugation of the lone electron pair of phosphorus(III) is due to the type of hybridisation of its orbital or more precisely its enhanced s character, which was confirmed by data on the geometry of phosphorus(III) compounds.

In the present review an attempt is made to examine consecutively from the standpoint of this hypothesis the physical and chemical properties of phosphorus(III) compounds in which an effect of $p-\pi$ conjugation is possible. In the first place much attention has been devoted to the structure of the electronic shell of phosphorus(III) and the geometry of its compounds. Next the physical and chemical properties associated with the lone electron pair of phosphorus in both ground and optically excited states are considered on the basis of these data.

We believe that such treatment is particularly necessary, since the view that phosphorus(III) is a complete analogue of nitrogen, which exhibits π-donor properties in aromatic and unsaturated compounds, has become firmly rooted in the literature. This view is sometimes encountered in monographs[1,2] without serious experimental justification. The problem of $p-\pi$ conjugation in phosphorus(III) compounds was partly dealt with in a recent monograph by Hudson[41] which has been translated into Russian. However, these problems are treated from traditional standpoints and the latest data which contradict the view expounded are not discussed.

II. THE STRUCTURE OF THE ELECTRONIC SHELL OF TRICOORDINATE PHOSPHORUS

A. GROUND STATE

The electronic shell of the neutral phosphorus atom contains 15 electrons. Ten of these are in the first and second quantum levels K and L ($1s^2 2s^2 2p^6$) and five occupy the s and p orbitals of the M valence shell ($3s^2 3p^3$). The latter has a further five unfilled d orbitals; the $3s$ and $3p$ orbitals do not differ in symmetry from the $2s$ and $2p$ orbitals but are more diffuse. The p orbitals are symmetrical relative to the three coordinate axes.

The symmetry of the d orbitals is more complex. Their distribution in space is shown in Fig. 1, where each of the five d orbitals is presented separately, and also in Fig. 2, where a steric model of superimposed d orbitals is shown. In the isolated atom all the d orbitals are energetically equivalent (degenerate). Under the influence of the electric fields of adjacent atoms, the energy levels of the d orbitals are split into two groups: d_γ orbitals (d_{z^2} and $d_{x^2-y^2}$) directed along the coordinate axes and having lower energies, and d_ϵ orbitals (d_{xy}, d_{xz}, and d_{yz}), which have maxima at 45° to the coordinate axes. Apart from the s and p orbitals, the d_γ orbitals (sp^3d and sp^3d^2 hybridisations) are usually employed in the formation of σ bonds. The d_ϵ orbitals probably participate in the formation of $p_\pi - d_\pi$ bonds.

The energy difference between the $3s$ and $3p$ orbitals of phosphorus is less than between the $2s$ and $2p$ orbitals of

nitrogen[41] (Fig. 3). The valence shell of the latter also consists of five electrons ($2s^2 2p^3$), but, in contrast to phosphorus, it does not have d orbitals in the same quantum level. Therefore the transition of the valence electrons of nitrogen to the d orbital (for example $2s \rightarrow 3d$) is coupled with a greater energy expenditure (about 530 kcal mole^{-1}) than the analogous transition of phosphorus electrons ($3s \rightarrow 3d$, 380 kcal mole^{-1}). It appears that in many ways this difference is responsible for the specific features of phosphorus chemistry. Possibly other higher phosphorus levels (4s, 4p) also have an effect. The energy levels of the electronic configurations of the unionised phosphorus atom (based on spectroscopic data) are quoted in van Wazer's book[42].

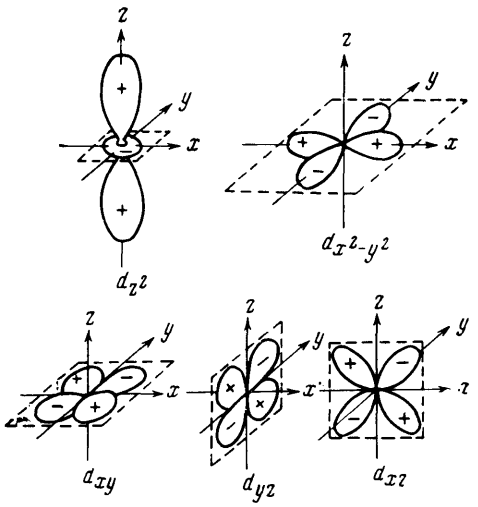

Figure 1. The form and relative orientations in space of d orbitals[359].

B. VALENCE STATE

The valence state of phosphorus(III), i.e. the state of the electrons of its valence shell on formation of three σ bonds, naturally differs from the ground state. According to the quantum-mechanical theory of valence[43,45] in its simplest form, when bonds are formed by any atom, for example phosphorus, nitrogen, oxygen, or sulphur, p orbitals are employed, since they give rise to stronger bonds than s orbitals (the strength is 1 for the 2s orbital and 1.732 for the 2p orbital). Accordingly, the angles in the compounds of the above elements, for example in hydrides, should be 90°. Indeed, in the case of the hydrides of phosphorus, sulphur, and higher analogues the valence angles only slightly exceed 90° (Table 1). However, ammonia and water have almost tetrahedral valence angles. The increase of the valence angle, even if only slight, is evidence of a deviation of the valence state from the ground state.

The orientation of bonds in a particular direction in space is explained in valence theory by the directed orientation of p and d orbitals. Geometry inconsistent with their configurations is regarded as a result of hybridisation with other orbitals, in particular s orbitals. The hybrid $s-p$ orbitals form stronger bonds than the pure p orbital (the strength for the sp^3 orbital is 2) and therefore the tetrahedral configuration is the most favourable from this point of view. However, the tendency for molecules with lone pairs of electrons to form a tetrahedral configuration is counteracted by the opposing tendency to retain the lone s electron pair, since the latter has the lowest energy. As a result, the valence angle assumes an intermediate value between the right angle and the tetrahedral angle. The above considerations do not of course explain the differences in the geometries of the molecules in the Second and Third Periods. The reasons for these differences in valence angles are much more complex.

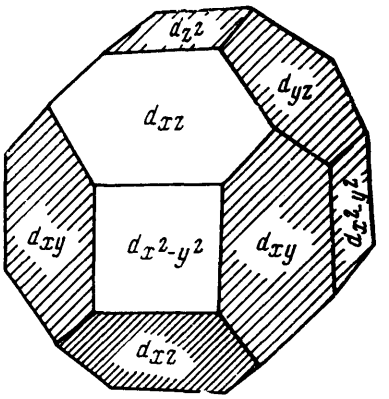

Figure 2. A steric model of superimposed d orbitals[360].

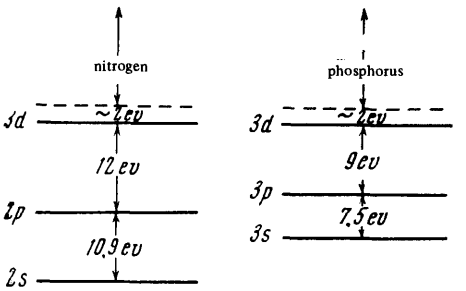

Figure 3. Atomic energy levels of nitrogen and phosphorus[41].

At the present time there exist two approaches to this problem, according to one of which, based on valence theory, the main reason for the increase of valence angles is the Coulombic repulsion of the atoms linked to the central element. This hypothesis was put forward for the first time by Pauling[43,44]. Subsequently the Coulombic and exchange repulsion of bonding electrons was also taken into account.[45] These factors should play a smaller role in the case of central atoms with large radii and therefore the repulsion and correspondingly the valence angles should be greater for compounds of elements of the Second

Period. Mulliken[54] calculated the repulsion energy of hydrogen atoms in the phosphine molecule and showed that, owing to the large radius of the phosphorus atom, it is smaller by a factor of approximately 3 than for ammonia (the N–H and P–H bond lengths are respectively 1.014 and 1.414 Å). Even when the valence angle in PH_3 is altered to 90° and in NH_3 to 120°, the repulsion energy in the first case is smaller by a factor of approximately 2 than in the second. In his examination of these problems from the standpoint of valence theory and the LCAO-MO method, Mulliken concluded that, apart from the repulsion of atoms not linked by valence bonds, account must be taken also of $p-d$ hybridisation, which gives rise to additional stabilisation of the pyramidal phosphine molecule compared with ammonia. Analogous reasoning is applied also to Group VI elements.

Table 1.

Molecule	Valence angle, deg	References	Molecule	Valence angle, deg	References
NH_3	107.3	46	H_2O	104.5	50
PH_3	93.8	47	H_2S	92.1	51
AsH_3	91.8	48	H_2Se	91.0	52
SbH_3	91.3	49	H_2Tl	89.5	53

Recently Hutchinson[55] examined this problem from the standpoint of the strength of hybrid bonds or more precisely the values of the overlap integrals for the s and p orbitals. It was found that the increase of the amount of s character in the hybrid orbitals of elements of the Second Period and the correspondingly greater deviation from a valence angle of 90° leads to an increase of bond strength, since the overlap integral for 2s orbitals is greater than for 2p orbitals. This is not observed in the Third Period and therefore the deviations from an angle of 90° are in this case minimal.

Thus both valence theory and the LCAO-MO method yield merely a qualitative treatment and do not provide an answer to the question why the valence angles in compounds of the elements of the Second Period are close to the tetrahedral value, while in the remaining compounds they are approximately 90°. This was probably the reason for the development of an alternative theory of directed valences—the theory of the repulsion of electron pairs in the valence shell (see for example Refs. 56 and 57 and the literature quoted therein). According to this theory, the formation of directed bonds is due to the repulsion, in consequence of the operation of the Pauli principle, of the electron pairs of the valence shell and the latter can be both unshared and involved in bond formation. In the case of four equivalent pairs, their repulsion leads to the formation of a tetrahedral configuration. The repulsion between lone pairs is more pronounced (the pair occupies a larger proportion of the valence shell) than between bonding pairs, since the latter are located in the field of two nuclei. Accordingly the valence angles of molecules with lone electron pairs are somewhat smaller than the tetrahedral value and this increases on passing from one to two lone pairs (ammonia and water; see Table 1).

In contrast to the elements of the Second Period, the valence shells of which have only four electron pairs, the elements of the Third Period are capable of expanding the valence shell to six electron pairs. Theoretically the number of electron pairs can reach nine but compounds with such coordination have not so far been found. The most likely distribution of these electron pairs is along the angles of a regular octahedron. The bonds formed by these pairs will be at right angles to one another. Probably the 90° angle is limiting and its further decrease involves considerable repulsive forces. The decrease of the limiting valence angle from 109°28′ to 90° on passing from elements in the Second Period to those in higher Periods can be accounted for by the increase of the radius and the decrease of the electronegativity of the central atom, which leads to the removal of the lone pairs to a greater distance from the nucleus and a decrease of the repulsion between them. Thus the repulsion between the lone and shared pairs in elements of the Third and higher Periods leads to a greater mutual approach of the bonds, up to the limiting angle of 90°.

With the aid of this purely qualitative concept and certain auxiliary postulates, it is possible to account for the geometry of a large number of compounds. We may note that recently Bader and Preston[58] criticised these hypotheses.

Whatever the reasons for the differences between the valence angles in elements of the Second Period and higher Periods, the fact of this difference is itself important, since it indicates a difference between the valence states of the elements in these Periods within the limits of a single subgroup, or, in other words, a difference in the nature of the hybridisation of their atomic orbitals.

In order to determine the type of hybridisation, it is possible to employ data for the geometry of molecules and also certain physical methods (nuclear magnetic resonance and nuclear quadrupole resonance).

According to the theory of directed valences, valence angles are determined by the nature of the hybridisation of atomic orbitals. Thus, knowing the valence angles, it is possible to determine the type of hybridisation of the relevant atom in different compounds. However, the use of this principle requires certain assumptions. In the first place it is necessary to assume that the interorbital and internuclear angles are the same, i.e. the bonds are not "bent". For elements the valence shells of which contain only s and p electrons, for example nitrogen, this assumption is quite sufficient to determine the nature of hybridisation, since there is an unambiguous relation between the interorbital angle and the type of $s-p$ hybridisation. The problem of the valence state of elements in higher Periods, in particular phosphorus, is much more complex. The third quantum level contains, apart from the s and p orbitals, also d orbitals, which may be involved in hybridisation. Therefore, in the presence of several types of branching, it is necessary to select orbitals responsible for hybridisation, which always involves certain assumptions. Otherwise several different valence states will correspond to a single valence angle. For example, in phosphorus, which has three types of orbitals, the valence angle of 90° may be due to both the p_3 state and sp^3-d^2 hybridisation.

In determining the type of hybridisation of phosphorus(III) orbitals, one usually starts with the hypothesis that σ bonds are formed by s-p hybrid orbitals. The role of d orbitals in the formation of phosphorus(III) σ bonds is regarded as insignificant and is neglected. However, d orbitals can participate in the formation of π bonds (partial

double bond character). This hybridisation scheme was adopted in a number of studies for the theoretical interpretation of the NMR chemical shifts[59-62], in a discussion of dipole moments and quadrupole interaction constants for halides of Group V elements[63], in quantum-chemical calculations for phosphorus(III) and phosphorus(V) compounds[64-66], and in a number of other investigations[42].

However, we must point out that certain authors considered it necessary to invoke *d* orbitals in order to account for the geometry of the hydrides of Group V elements. Thus in calculations on phosphine Boyd and Lipscomb[67] thought it necessary to take into account the *d* orbitals, since best agreement with experimental data is then obtained. Mulliken used *d* orbitals in a discussion of the valence angles in phosphine[54]. Gordy and coworkers[48-50] considered the valence angles in the hydrides of arsenic, antimony, and sulphur and pointed out the inconsistency between the types of hybridisation determined from the valence angles and from the quadrupole interaction constants; they believe that the reason for this is the absence of an unambiguous correlation between the valence angles and the degree of *sp* hybridisation for elements where *d* orbitals can participate in hybridisation. We may note that the lack of agreement between the results obtained with the aid of the two different approximate methods cannot alone be regarded as proof of the participation of *d* orbitals in hybridisation, but it does demonstrate yet again the approximate nature of the method used to determine the type of hybridisation from the valence angles.

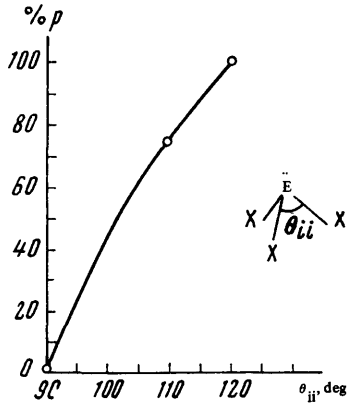

Figure 4. Variation of the percentage *p* character of the orbital of the lone electron pair with the valence angle θ_{ii} for symmetrical EX_3 molecules.

In order to assess the type of hybridisation of the orbitals of the lone electron pair of phosphorus or another element in the molecule of the type EX_3, one may employ a plot relating the amount of *p* character of this orbital to the X–E–X valence angle θ_{ii} (Fig. 4). We constructed such a plot[11] on the basis of three reference points corresponding to the *s*, sp^3, and *p* states of the lone pair. In the *s* state the X–E–X angle formed by the pure *p* orbitals is 90°. When the angle θ_{ii} increases, the amount of *p* character of the lone electron pair will increase and will reach 75% for the tetrahedral configuration (sp^3 hybridisation, 109°28 angle). Therefore an X–E–X angle of 120° (sp^2 hybridisation) will correspond to the full *p* character of the lone electron pair. An analytical expression for this relation was found[12] from the condition for the orthogonality of the hybrid atomic orbitals:

$$\% p = \frac{3\cos\theta_{ii}}{\cos\theta_{ii} - 1} \cdot 100\ \% . \qquad (1)$$

As already stated above, the valence angle in phosphine is approximately 94°C. When methyl groups are combined with the phosphorus atom, the valence angles increase and reach 99° for trimethylphosphine (Table 2).

*The average valence angle is quoted for the crystal.

In general a valence angle of about 100° is characteristic of the majority of phosphorus(III) compounds and the angle does not usually depend significantly on the type of substituents†. Compounds with methyl, aryl, alkoxy-, dialkylamino-,[77] or halogeno-groups have this angle (Table 3). The valence angles of cyclic compounds (cyclopolyphosphines, phosphorous anhydride) are also close to 100° or somewhat lower[86].

Gillespie[56] explained the slight increase of valence angles in phosphorus trihalides on passing from chlorine to iodine (Table 3) by the decrease of electronegativity and the increase of the atomic radius of the halogen. The anomalous (from the standpoint of this relation) angle in phosphorus trifluoride (104°) was regarded as due to a certain amount of double bond character of the P–F bonds, which arises owing to the partial transfer of the lone pair of fluorine to the vacant orbitals of phosphorus or, in

† The 120° valence angle, postulated in trisilylphosphine on the basis of spectroscopic data[74], was not confirmed by an electron diffraction study (Table 3). The valence angle of the phosphorus atom in tri-(*o*-tolyl)-phosphine (117°), calculated by Schindebauer from the dipole moment of this compound[75], is probably incorrect[76].

other words, owing to $p_\pi - d_\pi$ bonding. The increase of electron density in the bonds leads to an increase of the repulsion forces and an increase of the valence angles. Since the mesomeric effect is more pronounced for fluorine than for chlorine, the valence angles in phosphorus trifluoride are greater than in phosphorus trichloride. The hypothesis of $p_\pi - d_\pi$ bonding can probably be used to account for the valence angle of about 100° in the majority of phosphorus(III) compounds, since all the substituents enumerated above, which give rise to this type of angle, are capable of $p_\pi - d_\pi$ interaction (for the methyl group, hyperconjugation is possible). From this point of view, it is interesting that the valence angles in the nitrile group, which is incapable of such conjugation, do not differ from those in phosphine. This applies also to the silyl group, despite its considerable bulk‡.

If this hypothesis is correct, Eqn. (1) will yield a high value for the amount of p character of the lone electron pair, since it was derived on the assumption that the valence angles deviate from 90° only due to s-p hybridisation and no account is taken of the possible additional $p_\pi - d_\pi$ bonding factor and its effect on the geometry of the molecule.

$(C_6H_5)_3P$	—		18.4	55

*J_{P-H} was assumed to be the same as in methylphosphines.

The use of Eqn. (1) leads to the conclusion that, for the majority of phosphorus(III) compounds, the amount of p character of the lone electron pair is 40–50%, which corresponds to an angle of 100° ± 1°. In unsubstituted phosphine, primary phosphines, and trisilyl- and tricyanophosphines, the lone electron pairs have predominantly s character.

For primary and secondary phosphines, the spin–spin splitting constants J_{P-H}, which depend on the amount of s character (s_p, %) of the phosphorus orbital in the P–H bond, can also be used to estimate the nature of the hybridisation of the lone electron pair [88]:

$$J_{P-H} = 29.30\, s_p \qquad (2)$$

This method, based on the same assumptions as the one described above, permits an approximate assessment of the nature of hybridisation in those cases where there are no data for the geometry of the molecule. If it is assumed that the amount of s character of the phosphorus orbital in the P–C bonds of primary and secondary phosphines is the same as in tertiary phosphines (i.e. is clearly too high), then it is possible to calculate by Eqns. (1) and (2) the percentage of s character in the bonding phosphorus orbitals and in the orbital of the lone electron pair. Table 4 lists the values of J_{P-H} for primary and secondary phosphines, the contribution of s_p hybridisation, and the percentage of p character of the lone electron pairs in these compounds; however, these data must of course be regarded as only approximate.

It has been stated that in many cases the ^{31}P NMR chemical shifts for phosphorus(III) compounds can be used for the same purposes [60].

The valence angles in nitrogen(III) compounds are usually larger than in the corresponding phosphines and in ammonia and alkylamines are close to the tetrahedral value (Table 5). The introduction at the nitrogen atom of substituents capable of $p-\pi$ conjugation [phenyl and carbonyl groups and a phosphorus(III) or phosphoryl group [77]] increases the valence angles approximately by 10° to a value approaching 120°. Correspondingly, the lone electron pair of nitrogen is of the p type to the extent of 70% and above. In those cases where the valence angle is close to 120° the lone electron pair is almost entirely of the p type.

Thus the assessment of the type of hybridisation from valence angles or by other methods leads to the conclusion that the lone electron pair of phosphorus(III) differs from that in nitrogen in analogous compounds by having a much smaller amount of p character. An increase of the amount of p character is also observed on passing from phosphorus to sulphur.

In contrast to phosphorus, sulphur has a second lone electron pair. With a valence angle of 90°, σ bonds should be formed by pure p orbitals. Then, if one of the lone pairs is fully of the s type, the other is a purely p electron pair. In the hybridisation of the orbitals of the lone electron pairs the amount of p character will vary from 100 to 50% (sp hybridisation). When the hydrogen atoms in hydrogen sulphide are replaced by alkyl or aryl

‡ We may note that the valence angles of the tricyanomethane anion [87], an electronic analogue of tricyanophosphine, amount to about 119.5° in $NH_4C(CN)_3$.

groups, the valence angles are found to increase (Table 6) with a corresponding increase of the amount of p character of the lone electron pairs, which reaches about 72% in the case of diphenyl sulphide§.

Chlorine has three lone electron pairs of which one may be of the s type and the other two of the p type in the limiting case. For sp^2 hybridisation, the amount of p character of any of the lone electron pairs will be 66.6%.

Thus a distinctive feature of the structure of the valence shell of phosphorus(III) is a reduced amount of p character of the lone electron pair compared with the other elements of Periods II and III. This feature is reflected in the physical and chemical properties and in the capacity of the lone electron pair for $p-\pi$ conjugation.

III. $p-\pi$ CONJUGATION AND THE HYBRIDISATION OF THE LONE PAIR OF ELECTRONS

As already stated in the introduction, the capacity of the lone electron pair of any element for $p-\pi$ conjugation depends on the position of this element in the Periodic System and hence on the quantum level where the lone pair is located and, within the limits of a single Period, on the nuclear charge or the electronegativity of the element.

Yet another factor, which is usually hardly taken into account, namely the nature of the hybridisation of the electron pair¶, should play an important role[12]. Indeed, p or d orbitals are necessary for the formation of π bonds; s orbitals are incapable of interaction with p_Z orbitals, since the overlap integral S_{AB} of the s orbital of the A atom with the p_Z orbital of the B atom is zero[45], as shown in Fig. 5 taken from Coulson's book[45]. It follows from Fig. 5 that, by virtue of the difference in sign between the two parts of the p function, the integrand in $S_{AB} = \int \Psi_A \Psi_B \, d\tau$ is the sum of two terms equal in magnitude but opposite in sign (the elements $d\tau_1$ and $d\tau_2$ located symmetrically relative to AB axis correspond to these terms)[45]. The overlap integral becomes zero by virtue of symmetry properties. Thus p and sp hybrid lone electron pairs are capable of $p-\pi$ conjugation and in the latter case the capacity for conjugation is determined by the amount of p character of the lone pair.

§ The amount of p character of the orbital forming the σ bond was calculated from the formula

$$p = \frac{1}{1-\cos\theta_{ii}} \cdot 100\,\%,$$

where θ_{ii} is the valence angle.

¶ This problem was dealt with very briefly by Higashi et al.[102]

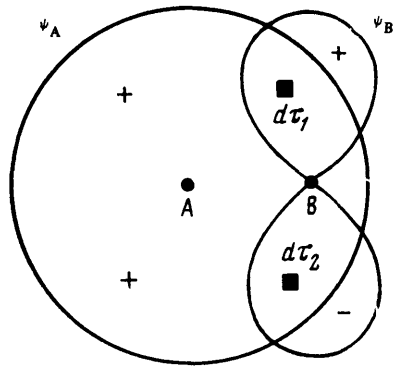

Figure 5. Schematic illustration[45] of the equality to zero of the S_{AB} overlap integral of the s orbital (Ψ_A) with the p_Z orbital (Ψ_B).

As shown above, the lone electron pair of phosphorus has a reduced amount of p character compared with the lone pairs of nitrogen, sulphur, and other elements in Periods II and III. Thus one may expect that in the case of phosphorus(III) $p-\pi$ conjugation in the ground state will be either greatly weakened and masked by other effects or, when the percentage of p character is very small, will be absent altogether. The experimental confirmation of this conclusion will be discussed below.

IV. PROPERTIES OF PHOSPHORUS(III) COMPOUNDS IN THE OPTICALLY UNEXCITED STATE

A. PHYSICAL PROPERTIES

1. Configuration Stability of Phosphorus(III) Compounds

A remarkable property of phosphorus(III) compounds is their configurational stability, which leads to optical activity in asymmetric molecules. This characteristic, which very sharply distinguishes phosphorus(III) compounds from the corresponding nitrogen(III) derivatives, is caused by the high energy barrier to the inversion of the pyramidal configuration of phosphorus associated with the high deformation energy of its valence angles. Theoretical calculations of the energy barrier to inversion yielded different results†. Here we shall note only the most correct calculations by Weston[108], which indicate that optically active phosphines may exist. Weston showed that phosphines have much higher energy barriers to inversion than amines (Table 7) and calculated the rate constants for their racemisation. For trimethylphosphine, the period of 50% racemisation at 20°C proved to be about 1 h. Hence Weston concluded that the optical isomerism of phosphines can be observed only at low temperature. Horner and Winkler[107] showed experimentally that optically active phosphines are more stable (in the sense of the retention of their configuration) than follows from Weston's calculations. They not only retain their optical activity at room temperature but can also be distilled without appreciable racemisation. Measurements of the rate of racemisation

† A good description of the history of this problem is given in McEwen's review[103]; see also other reviews[104,105].

at 130°C gave a high activation energy for the racemisation of dextrorotatory methylphenylpropylphosphine (about 30 kcal mole^{-1}). For the less stable diphosphines[108], where a rapid change in configuration occurs above 125°C, the activation energy for inversion is 26 ± 2 kcal mole^{-1} according to NMR data. It is interesting that changes in configuration are also not observed in many reactions involving the lone electron pair[103]. Configurational stability is characteristic not only of phosphines but also of the esters of phosphorus(III) acids, as shown by the geometrical isomerism of a number of five- and six-membered cyclic phosphites observed by the NMR method[109-119].

Table 7. Barriers to inversion of compounds of Group V elements according to spectroscopic data[106].

Compound	Inversion barrier, kcal mole^{-1}	Compound	Inversion barrier, kcal mole^{-1}	Compound	Inversion barrier, kcal mole^{-1}
NH_3	5.93	$P(CH_3)_3$	22.0	AsH_3	35.0
$N(CH_3)_3$	8.19	PF_3	45.1	$As(CH_3)_3$	29.2
PH_3	31.8	PCl_3	68.1	$Sb(CH_3)_3$	26.7

Thus phosphorus differs from nitrogen not only by the smaller valence angles but also by the stability of the pyramidal configuration, the change in valence angles requiring a significant expenditure of energy. The stability of the configuration has a most direct bearing on the problem of $p-\pi$ conjugation. The point is that, for $p-\pi$ conjugation to be appreciable, a significant increase of the amount of p character of the lone pair and a corresponding increase in valence angles is necessary. Then the energy expenditure on the deformation of valence angles cannot be compensated by the conjugation energy, since even in the most favourable case (conjugation of the amino-group with the benzene ring) the resonance energy does not exceed[117] about 10 kcal mole^{-1} and for the phosphino-group it can be considerably less. Hence it becomes understandable why valence angles at the phosphorus atoms do not increase even in the presence of substituents capable of conjugation with the lone electron pair.

Probably the above relation between the optical activity of phosphines and the low tendency of the lone electron pair of phosphorus towards $p-\pi$ conjugation is more general and is not characteristic solely of phosphorus. One may suppose that the absence of $p-\pi$ conjugation (or only insignificant conjugation) can be expected for those classes of compounds, asymmetric representatives of which can exist in an optically active form despite the presence of lone electron pair at the asymmetric central atom. This criterion may be employed in the discussion of the problems of $p-\pi$ conjugation in those cases where the molecular geometry is unknown.

2. Dipole Moments of Phosphines

In a discussion of the dipole moments of phosphines in connection with the problems of $p-\pi$ conjugation, three problems are of primary interest: the effect on the dipole moments of the nature of hybridisation of the phosphorus orbitals; the direction of the dipole moment in aliphatic and aromatic phosphines; the magnitude and direction of the mesomeric dipole moment.

Table 8 lists the dipole moments of unsubstituted phosphine, primary, secondary, and tertiary phosphines, and also ammonia and the corresponding amines. The lower dipole moment of unsubstituted phosphine compared with ammonia shows in particular that, in contrast to the lone pair of nitrogen, that of phosphorus makes an insignificant contribution to the overall dipole moment of the molecule. This is probably evidence of a greater amount of s character of the lone electron pair of phosphorus compared with nitrogen[125]. When the hydrogen atoms in phosphine are replaced by alkyl groups, a gradual increase of the dipole moment is observed, which is probably due, on the one hand, to the positive inductive effect of the alkyl groups and, on the other hand, to the increase of the moment of the lone pair due to the increase in the amount of its p character. It is interesting to note that the opposite tendency obtains for amines; on passing from ammonia to tertiary amines, the dipole moment falls (Table 8). Possibly this is caused by a lowering of the moment of the lone electron pair[125] as a result of the increase in the amount of its p character. The point is that the purely s and p electron pairs do not have a dipole moment by virtue of the symmetry of their orbitals[102]. Hybridisation leads to the appearance of a dipole moment, which is a maximum in the case of the sp state. An increase in the amount of p character of the lone electron pair from 50 to 100% or its decrease from 50 to 0% will reduce the dipole moment. These opposed tendencies in the variation of the dipole moments of amines and phosphines yet again demonstrate the different natures of their lone electron pairs.

The direction of the dipole moments in aromatic phosphines was determined by Sutton and coworkers[126], Klages and Langpape[127]‡, and also Schindlbauer and Hajek[129]. The direction of the moments in aliphatic amines and phosphines is the same, the negative pole of the dipole being located at the heteroatom. In aromatic amines the sign of the dipole moment changes as a result of $p-\pi$ conjugation and the benzene ring becomes the negative pole. On the other hand, in aromatic phosphines the direction of the dipole moment is maintained: the negative pole is the phosphorus atom as before. This follows from a comparison of the dipole moments of *para*-substituted phosphines: electron-donating substituents in the *para*-position increase and electronegative substituents decrease the moment (Table 9). A similar phenomenon is observed

‡ Klages and Langpape[127] quote unduly high dipole moments of trialkylphosphines, which were not confirmed by subsequent studies[121,128].

also in halogenobenzenes. Here too the direction of the dipole moment also remains unchanged, but its magnitude is reduced, mainly owing to $p-\pi$ conjugation[1]. In this case the mesomeric moment can be readily estimated approximately by Sutton's rule[1,130,131], namely from the difference between the dipole moments of aromatic and aliphatic compounds. This rule is known to apply only to regular groups, the direction of the dipole moments of which coincides with the direction of the benzene ring–substituent bond. In other cases vector subtraction is necessary. The mesomeric moment of dialkylphosphino-groups has not yet been determined. However, simple comparison of the dipole moments of aromatic and aliphatic compounds can lead to certain interesting conclusions. Thus, on passing from trimethylphosphine to dimethylphenylphosphine, a slight increase of the dipole moment is observed (Table 10). When a correction is applied for the effect of the solvent[121], the difference is somewhat reduced.

The decrease of the dipole moment may be due to the inductive effect of the phenyl group and the effect of $p-\pi$ conjugation (when it occurs). The moment may increase owing to $p_\pi-d_\pi$ conjugation or as a result of an increase in the moment of the lone electron pair (an increase in the valence angle). One may assume that the valence angles do not change significantly when the methyl group is replaced by a phenyl group. Since there is no decrease of the dipole moment on passing from trimethylphosphine to dimethylphenylphosphine, one must conclude that $p-\pi$ conjugation does not play an appreciable role and the mesomeric effect is due to $p_\pi-d_\pi$ conjugation. This conclusion is confirmed by a comparison of the moments of other aliphatic and aromatic phosphines (Table 9)§.

The weak π-donor capacity of phosphorus is indicated also by the dipole moments of phosphinoboranes R_2BPR_2 determined by Coates and Livingstone[132]. The lone electron pair of phosphorus interacts to a very slight degree (if at all) with the vacant p orbital of boron. Here phosphorus also constitutes the negative pole of the dipole. As a result of the conjugation of the lone electron pair of nitrogen with the p orbital of boron, in dialkylamino-boranes the negative pole is displaced to boron. Coates and Livingstone find this behaviour of phosphorus surprising and account for it by the different dimensions of the $2p$ orbital of boron and the $3p$ orbital of phosphorus. Without denying the role of this factor, we may, however, point out that the principal cause of this behaviour should probably be sought in the different nature of the hybridisation of the lone electron pairs of phosphorus and nitrogen.

The problem arises whether systems with phosphorus-(III) are possible in which $p-\pi$ conjugation in the ground state plays an appreciable role and whether there are methods whereby it can be observed. A sufficiently clear-cut answer cannot at present be given. If the above method of estimation of the nature of the hybridisation of orbitals from the valence angles yields the correct information about the valence state of phosphorus despite the assumptions made, one may postulate that such cases should occur. According to an estimate, the lone electron pair in tertiary amines has approximately 50% of p character. If such a pair is conjugated with a powerful electron-accepting substituent, the energy of $p-\pi$ interaction can also be appreciable. One cannot exclude the possibility that such conjugation would be reflected in the chemical or physical properties of the compound.

Goetz and coworkers[133,134] measured the dipole moments of substituted arylphosphines of the type p-$XC_6H_4P(C_6H_5)_2$ and p-$XC_6H_4P(C_2H_5)_2$. It was found that the observed dipole moments are usually higher than the values calculated assuming additivity. In the case of electron-donating substituents (methoxy- and dimethylamino-groups) this is evidence of $p_\pi-d_\pi$ conjugation, since $p-\pi$ conjugation may be postulated for halogens. It is remarkable that the differences between the observed and calculated dipole moments of diphenyl-p-methoxyphenyl- and p-dimethylaminophenyl-phosphines proved to be significantly greater than for their oxides and sulphides: the $p_\pi-d_\pi$ conjugation in the oxides and sulphides must be considerably more pronounced than in the phosphines. We may note that the observed and calculated dipole moments of tri-(p-chlorophenyl)-phosphine are identical. According to the data of other workers[136], the dipole moment of cyanodiphenylphosphine also agrees with the value calculated assuming additivity. Possibly the above differences between the observed and calculated dipole moments are not associated with $p-\pi$ conjugation but with other factors, in particular the imperfection of the model chosen for the calculations.

§ Using the high dipole moments of trialkylphosphines quoted by Klages and Langpape[127], Hudson[41] concluded that the lowering of the dipole moment on passing to aromatic phosphines is due to $p-\pi$ conjugation. This conclusion is open to objection, since the data of Klages and Langpape were not confirmed.

Thus one cannot at present give a definite answer to the question of the possible $p-\pi$ conjugation in systems with electron-accepting substituents posed above.

B. CHEMICAL AND PHYSICOCHEMICAL PROPERTIES

The study of the directive influence in electrophilic substitution in the benzene ring constitutes a classical chemical procedure for the investigation of the electronic effect of the substituent. Unfortunately this method cannot be applied to phosphorus(III) compounds because of the high nucleophilicity of phosphorus(III) itself, which leads to preferential attack of the electrophilic agent on the phosphorus atom. Nucleophilic substitution in aromatic phosphorus compounds is so far unknown. The only example of a direct investigation of the directive influence of phosphorus(III) is that of the nucleophilic addition of vinyl derivatives of phosphorus(III) to a double bond. It was in fact first employed for this purpose.

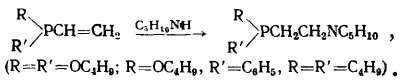
The electronic effect of groups with phosphorus(III) is investigated mainly by physicochemical methods, whereby it is possible to elucidate the nature of the resonance effects by indirect procedures. At the present time there exist two different approaches. The first of these is associated with the study of the effect of phosphorus(III) on the properties of the functional groups in the same benzene ring. The use of correlation analysis methods, in particular the Hammett equation, permits an indirect determination of the nature of the directive effect of the substituent. Valuable information about the nature of the π-electronic effects of phosphorus(III) is provided by protophilic deuterium exchange in aromatic phosphines and a number of other chemical properties. The second approach is based on reactions in which phosphorus is the reaction centre. This involves the study of the effect of substituents at the phosphorus atom on the reactivity of the lone electron pair, which permits an assessment of its capacity for delocalisation (the basicity of phosphines, alkylation reactions, and the addition of sulphur).

1. Electronic Effects of Phosphorus(III) as a Substituent

a. Directive influence in the addition of piperidine to vinyl derivatives of phosphorus(III). According to their directive influence in reactions involving ionic addition to vinyl derivatives of the type $CH_2=CH-X$, the substituents X can be divided into two types: the first includes π-donor groups, which as a rule direct the ionic part of the reactant to the α-position in relation to the substituent and the second group includes electron-accepting groups directing the reactant to the β-position. Substances of the first type, for example alkyl vinyl ethers and vinylamines, show a greater tendency to combine with electrophilic agents; substances of the second type, for example acrylonitrile, combine more readily with nucleophilic agents.

Vinyl derivatives of phosphorus(V) are typical electrophilic systems and readily combine with nucleophilic agents. It has been shown[6-8,137,138] that in all cases of addition the reactant is directed to the β-position regardless of the nature of the group at the phosphorus atom.

It was found unexpectedly[6-8] that the same type of directive influence is characteristic also of the vinyl compounds of phosphorus(III), although their reactivity is much lower than that of the phosphorus(V) compounds. The addition of piperidine was observed only under the conditions of prolonged heating of the reactants at 140–160°C:



$(R=R'=OC_4H_9;\ R=OC_4H_9,\ R'=C_6H_5,\ R=R'=C_4H_9)$.

The most reactive are the esters of vinylphosphonous and phenylvinylphosphinous acids, which combine with piperidine in the absence of catalysts. Piperidine hydrochloride accelerates the reaction but does not alter the site at which the addition takes place. The replacement of both butoxy-groups by phenyl groups leads to a sharp decrease of the reactivity of the double bond: in the absence of a catalyst and even in the presence of an acid catalyst, the addition could not be achieved. In the case of the more electropositive dibutylphosphino-group, the addition under the influence of piperidine hydrochloride still takes place, possibly owing to the formation of dibutylvinylphosphine hydrochloride.

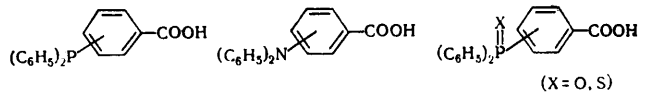
Thus, as regards the directive influence in the addition reaction, phosphorus(III) resembles silicon, which does not have a lone electron pair and for which a β-directing effect is also typical[139,140]. Later a β-directing effect was observed in the reaction of lithium diphenylphosphide with β-diphenylphosphinostyrene[141] and also in the reaction of butyl-lithium with vinylphosphines[142]. We may note that β-addition under the influence of a powerful nucleophilic agent such as butyl-lithium was also observed with phenyl vinyl sulphide[143]. Recently a β-directing effect was observed[144] in the addition of diphenylphosphine and diphenylarsine to vinyl- and ethynyl-phosphines in the presence of basic catalysts. The reaction of vinyl phosphorus(III) compounds with phenyliminobenzonitrile can be regarded as evidence in favour of a β-directing effect of substituents with phosphorus(III).[145,146]

The β-directing effect in the non-catalytic addition of piperidine is evidence either of the absence or of the insignificance of the π-donor effect in phosphorus(III). Its electron-accepting influence on the polarisation of the multiple bond or its stabilising effect on the transition state can be accounted for by $p_\pi-d_\pi$ conjugation and possibly by an inductive effect (since the electronegativities of H and P are the same and the inductive effect of the group will depend on the substituents at the phosphorus atom).

The data for the frequencies of the C=C stretching vibrations in the Raman spectra of vinyl and allyl derivatives of phosphorus(III) also agree with the conclusion that $p-\pi$ conjugation is absent[147]. A characteristic feature of $p-\pi$ conjugation—an increase in the integrated intensity of the double bond line, which is fairly distinct for the vinyl derivatives of nitrogen and sulphur and is not observed in vinylsilanes—is absent from the spectra. Vinyl derivatives of phosphorus(III) differ little from alk-1-enes as regards the spectroscopic effect of the double bond. Thus, according to both chemical and spectroscopic characteristics, vinyl compounds of phosphorus(III) are closer to vinylsilanes than to vinyl sulphides and vinylamines.

b. Effect of substituents with phosphorus(III) on the properties of functional groups in the benzene ring. For the investigation of the directive influence of phosphorus(III), indirect methods, in particular correlation analysis, have also been successfully employed. The authors of the present

review together with Lobanov[9,10,148] determined the ionisation constants of *m*- and *p*-diphenylphosphinobenzoic acids and for comparison the ionisation constants of *m*- and *p*-diphenylaminobenzoic acids and the corresponding benzoic acids containing groups with phosphorus(V):



(X = O, S)

The results are presented in Table 11. It was found that, regardless of the valence of phosphorus, all the phosphorus-containing substituents investigated increase the ionisation constant of benzoic acid and are therefore electron acceptors. Correspondingly Hammett's σ constants for phosphorus-containing substituents are positive.

Table 11. Ionisation constant (pK_a) of phosphorus-substituted benzoic acids XC_6H_4COOH and the σ, σ_I, and σ_R constants of the substituents X [1 : 1 (by volume) aqueous alcohol, 25°C].[9,10,148]

X	pK_a	$\frac{k_{meta}}{k_{para}}$	σ	$\sigma_p-\sigma_m$	σ_I	σ_R
H	5.72	1	0.00	0.00	0.00	0.00
p-$(C_6H_5)_2P$	5.39	0.76	0.19	0.08	0.05	0.14
m-$(C_6H_5)_2P$	5.51		0.11			
p-$(C_6H_5)_2N$	6.10	—	−0.29	—	—	—
m-$(C_6H_5)_2N$	5.77	2.18	−0.07	−0.22	0.11	−0.40
p-$(C_6H_5)_2P(O)$	4.88	—	0.53	—	—	—
m-$(C_6H_5)_2P(O)$	5.11	0.58	0.38	0.15	0.27	0.26
p-$(C_6H_5)_2P(S)$	4.97	—	0.47	—	—	—
m-$(C_6H_5)_2P(S)$	5.24	0.54	0.29	0.18	0.15	0.32

It is significant that *para*-phosphorus-substituted acids are stronger than the *meta*-substituted acids. This is evident from the ratios k_{meta}/k_{para}, which are less than unity, and also from the positive differences $\sigma_p - \sigma_m$, which are characteristic of *meta*-directing groups. Consequently all the phosphorus-containing substituents investigated are *meta*-directing. On the other hand, as was to be expected, the diphenylamino-group lowers the ionisation constant of benzoic acid to a greater extent when present in the *para*-position than when present in the *meta*-position and is thus an ortho-*para*-directing substituent.

The inductive (σ_I) and resonance (σ_R) components of Hammett's constants were calculated[148] from the constants σ_m and σ_p (Table 11). These values particularly clearly illustrate the nature of the electronic effect of substituents with phosphorus(III) and phosphorus(V). The inductive effect of the diphenylphosphino-group proved to be small, in agreement with the electronegativity of phosphorus. The groups with phosphorus(V) are of course characterised by larger inductive constants. The inductive effect of the diphenylamino-group exceeds that of the diphenylphosphino-group, which is consistent with the difference between the electronegativities of nitrogen and phosphorus (3.0 and 2.1 according to Pauling). The resonance effects of phosphorus-containing groups, particularly the diphenylphosphino-group, are interesting. It has been found that, in contrast to the diphenylamino-group, the diphenylphosphino-group is a π-electron acceptor despite the presence of a lone electron pair. The diphenylamino-group is a π-donor substituent, although its mesomeric effect is of course somewhat reduced compared with that of dialkylamino-groups. The resonance effects of substituents with phosphorus(V) are positive and exceed the resonance effect of the diphenylphosphino-group. These results permit an approximate estimation of the $p-\pi$ conjugation effect. The difference in the values of σ_R for the diphenylphosphino- and diphenylphosphinyl groups is caused, on the one hand, by the increase of the extent of $p_\pi - d_\pi$ conjugation owing to the presence of a positive charge at the phosphorus(V) atom and some compression of *d* orbitals and, on the other hand, by the absence of $p-\pi$ conjugation, which may occur in the case of phosphorus(III). We cannot estimate the contribution of each effect but the overall contribution, i.e. the difference between the values of σ_R for these groups, is very insignificant and amounts to only 0.12, which most probably indicates that the effect of $p-\pi$ conjugation is close to zero for the diphenylphosphino-group.

These results were later confirmed by other workers[16-29]. Unfortunately there is no information in the literature for *meta*-substituents with phosphorus(III) exception for the data quoted above. The results of Schiemenz[19,20] for phosphorus-containing groups in the *para*-position virtually agree with those obtained by ourselves. Somewhat different values of σ_p were found by Baldwin et al.[22] from the ionisation constants of phosphorus-substituted benzoic and arylphosphonic acids in aqueous tetrahydrofuran (THF). They are low for all phosphorus-containing groups. This may be associated with the effect of the solvent.

Table 12. Ionisation constants (pK_a) of phosphorus-substituted phenols XC_6H_4OH and the constants σ^-, σ_m, and σ_R^- of the substituents X [1 : 1 (by volume) aqueous alcohol, 25°C].[13,149-151]

Makhamatkhanov and the authors of the review[13,149-151] measured the pK_a of *meta*- and *para*-phosphorus-substituted phenols. Schiemenz measured the pK_a of *para*-phosphorus-substituted dimethylanilines[19,20]. The nucleophilic constants σ^- calculated from these data, which characterise the effect of electron-accepting substituents in the case of an electron-donating reaction centre, and the constants σ_m are listed in Table 12. These results differ somewhat from those of Schiemenz, probably owing to the difference in the reaction series¶. The σ^- constants for phosphorus-containing substituents are positive and exceed

¶ It is known that the constants σ^- are not universal and depend strongly on the nature of the reaction centre and the type of reaction.

the corresponding Hammett constants σ_p, which is evidence of an effect of the direct polar conjugation of the phosphorus-containing groups with the reaction centre. The difference $\sigma^- - \sigma_p$ for the diphenylphosphino-group is 0.07 in phenols and 0.13 in substituted dimethylanilines. Thus the electron-accepting effect of the direct polar conjugation of phosphorus(III) with the electron-donating reaction centre is small but distinct. The constants σ_m for phosphorus-containing groups, determined from the pK_a of the corresponding phenols and benzoic acids, agree satisfactorily among one another.

The constants σ^- and σ_m for the dimethylphosphino-group were found from the ionisation constants of dimethylphosphinophenols[150,151] (Table 12). They proved to differ little from the analogous constants for the diphenylphosphino-group.

Analogous results were obtained also for other reaction series. Thus positive albeit somewhat high values of σ_p for the diphenylphosphino-group (0.3 and 0.5) were derived from data for the reactivity of *p*-diphenylphosphinostyrene in copolymerisation with styrene and methyl methacrylate[152]. The constant σ_p for the diethylphosphino-group (0.03) was determined by Stepanov et al.[17] from the basicity of tetraethyl-*p*-phenylenediphosphine. The significant difference between this value and σ_p for the dimethylamino-group (−0.83) is noteworthy.

c. Electronic effect of substituents with phosphorus(III) according to data obtained by various physical methods. The electronic effect of phosphorus-containing groups was investigated by physical methods (infrared spectroscopy[18,19] and ^{13}C NMR, ^1H NMR, and ^{19}F NMR spectroscopy[23-32,153,154]) and in many cases the corresponding σ constants were determined. On the whole, these data agree with the results derived by chemical methods. The systematic study of the electronic effect of phosphorus-containing groups with the aid of ^{19}F NMR, undertaken by Taft and coworkers[27,38], Johnson and Jones[29], and also Schindlbauer and Prikoszovich[26,153,154], is of greatest interest. The σ constants which they found in many cases agree well with our data but the resolution into inductive and resonance components is somewhat different: according to ^{19}F NMR data, the σ_I constants are somewhat high and the resonance constants σ_R are low compared with the chemical results. It is noteworthy that the data of the above workers do not always agree with one another (Table 13). This is precisely why much importance cannot be attributed to the negative values of $\bar{\sigma}_R$ for the dimethylphosphino- and bis(dimethylamino)phosphino-groups. According to the results of a study of pentafluorophenyl phosphorus(III) compounds, dimethyl- and diphenyl-phosphino-groups are π-acceptor substituents[30-32] (see also other investigations[33-38]). ^1H NMR and ^{13}C NMR data for dialkylethynylphosphines also indicate a π-electron accepting effect of dialkylphosphino-groups[39,40]. Probably the problem of the exact estimation of the resonance and inductive effects of dialkylphosphino- and related groups with phosphorus(III) cannot be regarded as finally solved†, but it is already clear that the resonance effect of dialkylphosphino-groups is close to zero.

† For example, it is not clear why σ_I for the dimethoxyphosphino-group is smaller than for the dimethylphosphino-group (Table 13), since the opposite relations are observed for substituents with phosphorus(V).[143] The reason for the large value of σ_I for the dimethylphosphino-group compared with the bis(dimethylamino)phosphino-group is also obscure.

The ^1H NMR spectrum of triphenylphosphine indicates a small effect of the diphenylphosphino-group on the magnetic screening of the ring protons compared with benzene[155,156]. The type of spectrum changes from a singlet to a doublet depending on the solvent and the concentration of triphenylphosphine, which is evidence of a similarity of the chemical shifts of *o*-, *m*-, and *p*-protons[155]. On passing from deuterochloroform to hexadeuterobenzene, the spectrum is split and the signal of *o*-protons shifts by 0.09 p.p.m. towards weaker fields and those of *m*- and *p*-protons shift by 0.25 p.p.m. towards stronger fields, but the exact values of the chemical shifts have not yet been determined[156].

Table 13. The constant σ_I and $\sigma_{\bar{R}}$ of phosphorus-containing groups X_2P according to ^{19}F NMR data for phosphorus-containing fluorobenzenes.

The ESR spectra of the radical-anions obtained from triphenylphosphine[157] and dimethylphenylphosphine[158] show that the diphenyl- and dimethyl-phosphino-groups are electron-accepting substituents according to their influence on the distribution of spin density‡. The ESR spectra of 2,6-di-t-butylphenoxy-radicals containing substituents with phosphorus(III) and phosphorus(V) in the 4-position lead to a similar conclusion[160].

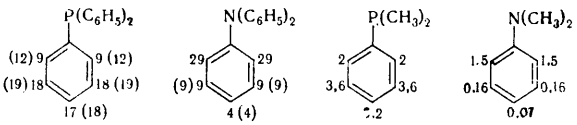
The different capacities of the lone electron pairs of nitrogen and phosphorus for resonance delocalisation are clearly shown in the mass spectra of the compounds of these elements. The principal fragment formed on electron impact from the bis(diphenylamino)methane molecule[161] is the resonance-stabilised cation $(C_6H_5)_2\dot{N}=CH_2$. The analogous diphosphinomethane gives rise to a more complex spectrum of fragments, among which species arising as a result of the migration of the phenyl group predominate: $C_6H_5\dot{P}\equiv CH$ and $(C_6H_5)_3\overset{+\cdot}{P}$. The $(C_6H_5)_2\dot{P}=CH_2$ fragment is formed in a smaller amount[161]. Comparison of the mass spectra of other phosphorus and nitrogen compounds lead to the same conclusions[162].

Thus physical methods confirm more or less convincingly the results of chemical studies.

d. Effect of substituents with phosphorus(III) on the rate of protophilic deuterium exchange in arylphosphines. It appears that at the present time one reaction involving the direct substitution of hydrogen in the benzene ring, under the directive

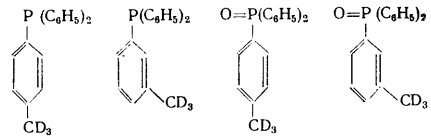
‡ Account must be taken of the fact that the formation of radical-anions from phosphines under the influence of metallic potassium in tetrahydrofuran is complicated by the cleavage of the phosphorus–carbon bond[159].

influence of phosphorus(III), is known, namely the metallation of diphenylphosphine by butyl-lithium, which results in a low yield (5.9%) of the *meta*-lithio-derivative[163]. Metallation of triphenylamine also leads to *meta*-substitution[164,165]. For a more detailed study of the effect of phosphorus-containing substituents on the reactivity of hydrogen atoms and methyl groups in the benzene ring, the authors of the review together with Yakovleva, Shatenshtein, and coworkers[14,167-169] investigated the kinetics of isotope exchange in deuterated triphenylphosphine, triphenylamine, dimethylphenylphosphine, and many other compounds. The partial rate factors for deuterium exchange (f) in liquid ammonia catalysed by potassamide or sodamide (the figures are quoted in brackets) are given below. The analogous data for dimethylaniline are included for comparison[170,171]:



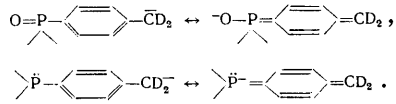
Comparison of the f_n for amines and phosphines indicates significant differences in the electronic effects of nitrogen and phosphorus: in the case of phosphorus the exchange is much faster than in the case of nitrogen. It is interesting that the approximate equality of the exchange rate constants for the *meta*- and *para*-positions of the ring is characteristic not only of phosphines but also of their oxides (1.2×10^{-6} and 0.8×10^{-6} in 1 : 1 t-butyl alcohol–diglyme in the presence of potassium t-butoxide at 120°C), which yet again indicates the similarity of the electronic effects of phosphorus(III) and phosphorus(V).

The electron-accepting properties of the diphenylphosphino-group are shown particularly clearly in the exchange involving the methyl groups of isomeric diphenyltolylphosphines:



(in 1 : 1 t-butyl alcohol–diglyme in the presence of potassium t-butoxide at 120°C).

The exchange rate constants quoted show that the exchange involving the *para*-methyl group is approximately 25 times faster than for the *meta*-methyl group. In the corresponding oxides the difference increases to a factor of 200. These data are evidence of the presence of π-acceptor conjugation in the carbanion or in the transition state arising in the exchange involving diphenyl-*p*-tolylphosphine and its oxide and probably having a structure similar to that of a carbanion:



Thus in the study of hydrogen exchange in aromatic and aliphatic phosphines it proved impossible to detect any signs of $p-\pi$ conjugation.

The electron-accepting properties of phosphorus(III) are observed[14] also when the relative rates of deuterium exchange in methyl groups attached to phosphorus and nitrogen atoms are compared, analogous relations being observed for oxygen and sulphur[172,173] (the exchange was carried out in liquid ammonia in the presence of potassamide, the rate of exchange involving the methyl group of toluene under the same conditions being adopted as a unit):

$C_6H_5N(CH_3)_2$	$(C_6H_5)_2NCH_3$	$C_6H_5OCH_3$
0.0001	0.0002	0.003
$C_6H_5P(CH_3)_2$	$(C_6H_5)_2PCH_3$	$C_6H_5SCH_3$

2. Reactions Involving the Lone Electron Pair of Phosphorus(III)

The effect of substituents on the reactivity of the lone electron pair of phosphorus(III) has been inadequately investigated quantitatively. A more or less systematic study has been made only of the effect of substituents on the basicity of phosphines. The kinetic studies on the alkylation of phosphines and the addition of sulphur and phenyl azide are few and it is not always possible to arrive at any conclusions concerning $p-\pi$ conjugation.

a. Basicity of phosphines. The effect on this property of electronic and steric factors and of the hybridisation and hydration of the phosphonium cation has been discussed in fair detail by Hudson[41] and Arnett[174]. We shall deal only with problems concerning $p-\pi$ conjugation and shall consider certain studies which were not included in the above reviews.

When comparing the structure–basicity correlations for amines and phosphines, one is struck in the first place by the sharp difference in the effect of $p-\pi$ conjugation on the basicities of these two classes of compounds. During the last ten years a number of correlations have been proposed for amines in which account is taken of the effect on the basicity of electronic factors and solvation[175-179], the lowering of basicity owing to the conjugation of the unshared electron pair with the benzene ring being estimated as equivalent to approximately 3pK units (the agreement between the estimates of this quantity by different workers is not altogether satisfactory). A correlation for phosphines proposed by Henderson and Streuli[180] is analogous to Hall's first correlation for amines[175], where account is taken only of the inductive effects of substituents (Taft's σ^* constants). Tertiary, secondary, and primary phosphines give rise to three linear relations with similar slopes. It is interesting that, in contrast to aromatic amines, aromatic phosphines satisfy this relation. The deviations observed for certain arylphosphines (about 0.5pK unit) might be attributed to a slight $p-\pi$ conjugation, but the deviations are not always of the same sign and probably differ little from the average statistical scatter in the correlation. According to the data of Drenth and Hogervorst[181], the relations of Henderson and Streuli hold satisfactorily also for tertiary alkynylphosphines.

It was shown[182] that in the correlation of the pK_a for phosphines with the σ_{ph} constants for substituents at the phosphorus atom, primary, secondary, and tertiary phosphines give rise to a single linear relation, which is also satisfied by aromatic phosphines. If one remembers that, in terms of the system of σ_{ph} constants, the phenyl group is characterised by an electron-donor resonance effect[183] ($\sigma_I^{ph} = 0.27$, $\sigma_R^{ph} = -0.76$), it becomes clear that on protonation phosphorus in aromatic phosphines exhibits only electron-accepting properties and the lone pair probably does not interact with the π-electron systems of the benzene rings.

By potentiometric titration in nitromethane, Stepanov, Bokanov, and Korolev[16,17,184,185] determined the basicities of a number of ring-substituted diethylphenylphosphines [p-$XC_6H_4P(C_2H_5)_2$], including both electron-donating and electron-accepting substituents. The basicity of these compounds varies linearly with Hammett's σ-constants ($r = 0.9986$ and $s = 0.067$) but not with the σ^- constants, the latter relation being characteristic of substituted anilines. Hence it follows that the electronic effects in the protonation of phosphines are analogous to those in benzoate anions and in this sense differ fundamentally from the effects involving amines. These results also indicate the occurrence of $p_\pi - d_\pi$ conjugation in the protonated phosphine molecule and the insignificance (or absence) of the conjugation of the lone electron pair of the phosphorus atom with the aromatic ring in the molecule of the base.

Goetz and coworkers[186,187] investigated the basicity of phosphines of the same type and also substituted triarylphosphines [p-$XC_6H_4P(C_6H_5)_2$] in 80% alcohol. On the basis of analogous Hammett relations§, they concluded that both $p_\pi - d_\pi$ and $p - \pi$ conjugations occur in phosphines in the ground state. Since the substituents X were exclusively *ortho-para*-directing, the validity of the Hammett relation in this case is evidence only of acceptor conjugation but not of the delocalisation of the lone electron pair. However, on the whole the data for the basicities of substituted arylphosphines are not inconsistent with the hypothesis of the existence of a weak $p - \pi$ conjugation.

b. Alkylation of phosphines. Henderson and Buckler[188] investigated the kinetics of the alkylation of phosphines by alkyl halides. They found that the rate of reaction is determined mainly by inductive and steric factors, although in many cases there are exceptions which have not been fully accounted for. Trialkylphosphines with unbranched substituents (with the exception of the methyl group) and also triaryl and mixed alkylarylphosphines give an imperfect $\lg K - \Sigma\sigma^*$ linear relation, which can nevertheless be attributed to the absence or insignificance of the $p - \pi$ conjugation effect in aromatic phosphines.

c. Addition of sulphur and phenyl azide to aromatic phosphines. The addition of sulphur to substituted triphenylphosphines was investigated by Bartlett and Meguerian[189] and also Goetz et al.[190] The first group of investigators found for a small number of examples (with chlorine and methyl groups as substituents in the benzene rings) that the reaction is of second order and the rate constants are consistent with the Hammett equation (we may note that a similar relation obtains also when the σ^0 inductive constants are employed). Goetz and coworkers established that the reaction is not exactly of second order. Thus definite conclusions concerning the presence or absence of $p - \pi$ conjugation cannot be arrived at on the basis of these data. Nor can one reach conclusions about $p - \pi$ conjugation from studies on the kinetics of the addition of azides to substituted triphenylphosphines recently carried out by Leffler and Temple[191,192].

§ In the correlation of the basicities of aryldiethylphosphines Goetz and coworkers[187] employed averaged Jaffé constants and found that the points corresponding to Cl and Br deviated appreciably from the resulting straight line, to which the authors attributed fundamental importance. It is easy to show that, when McDaniel and Brown's σ constants are employed, a linear relation is obtained with a high correlation coefficient and applies to all the substituents.

C. PROPERTIES OF CERTAIN INDIVIDUAL TYPES OF COMPOUNDS

1. Carboxylic Acid Phosphides

The phosphides of carboxylic acids, containing the group $\diagup\!\ddot{P}-\underset{|}{C}=O$, constitute an interesting system. The presence of the polar carbonyl group and the lone electron pair creates more favourable conditions for $p - \pi$ conjugation than in the $\diagup\!\ddot{P}-\underset{|}{C}=C\diagdown$ systems. These compounds are analogues of carboxylic acid amides, in which there is a very pronounced conjugation of the lone electron pair with the carbonyl group. The study of the chemical and physical properties of carboxylic acid phosphides showed in many cases a difference from the properties of amides, which can probably be regarded as evidence of only a weak $p - \pi$ interaction in this system.

Like carboxylic acid amides, the corresponding phosphides exhibit appreciable acylating properties. According to the data of Tyka and Plazek[193,194], triaroyl phosphides on being heated for many hours with alcohols (140–160°C), give the corresponding esters in quantitative yields. The reaction with aqueous ammonia or aniline results in a quantitative formation of the corresponding amides. Monoacyl phosphides have analogous properties[195,196]. It is interesting that the reverse reactions do not take place. Probably the carbonyl group in phosphides is somewhat more reactive than in amides, but, as stated by Issleib and Priebe[195], there are no fundamental differences between phosphides and amides in this respect.

It is significant that, in contrast to amides, the lone electron pair of phosphorus in monoacyl phosphides retains its reactivity. Thus monoacyl phosphides yield methiodides and form complexes with salts of nickel, mercury, cadmium, and other heavy metals[196,197]. The ease of their oxidation (up to self-ignition) and the capacity to add sulphur and bromine are all evidence of the absence or insignificance of the delocalisation of the lone electron pair of phosphorus[196,197].

Interesting results were obtained in a study of the physical properties of carboxylic acid phosphides. According to Issleib and Löw[196], the ν_{CO} frequencies in amides and phosphides differ little from one another and lie in the range 1640–1680 cm^{-1}, i.e. are much lower than in ketones (Table 14). These results have also been confirmed by Kostyanovskii and coworkers[197-204].

Kostyanovskii and coworkers[197,202,204,205] found that, together with the band indicated above, the spectra of phosphides contain, in contrast to amides, a second band located at a frequency higher by approximately 100 cm^{-1}, which they also attributed to the stretching vibrations of the carbonyl group (Table 15). The presence of two bands was explained by the existence of two stable conformers, the low-frequency band being attributed to the *trans*-conformer (the *trans*-positions of the lone pair and the CO group) and the high-frequency band to the *cis*-conformer. The authors state that the relative intensities of these bands change as a function of the solvent and temperature. Since the conjugation of the lone electron pair and the carbonyl group cannot be achieved for geometrical reasons (the π-electron system of the carbonyl group and the orbital of the lone electron pair do not lie in the same plane), the authors explain the lowering of ν_{CO} by the conjugation of the carbonyl group with the phosphorus d orbitals, which leads to a lowering of the multiplicity of the C=O bond

owing to the reverse polarisation of the carbonyl group with the appearance of a positive charge at the oxygen atom.

$$\rangle\ddot{P}-C=O \leftrightarrow \rangle\ddot{P}=\bar{C}-O^{+}\cdot$$
(I) (II)

Table 14. Comparison of the ν_{CO} frequencies for amides and phosphides $RCOER'_2$ according to the data of Issleib and Löw[196].

Element	ν_{CO}, cm^{-1}			
	R = R′ = alkyl	R = alkyl, R′ = aryl	R = aryl, R′ = alkyl	R = R′ = aryl
N	1655	1680	1645	1655
P	1650	1670	1640	1655

This treatment is open to objection. The relative contribution of structure II with the unusual polarisation of the carbonyl group to the resonance system should be very small and the insignificant reverse polarisation of the bond, which on the whole has a certain amount of semipolar character ($\bar{C}-\bar{O}$), should lead to an increase and not to a decrease of the amount of double bond character in the carbonyl group and hence to an increase of ν_{CO}. If it is assumed that the multiplicity of the C=O bond is reduced owing to structure (II), then the factors promoting the reverse polarisation should lead to a further decrease of ν_{CO}. Nevertheless ν_{CO} in phosphorus(V) systems of the type $RCOP(O)R'_2$ and $[RCO\dot{P}R'_2R''X^-]$, where both inductive and mesomeric effects should stabilise resonance structure (II), is higher and not lower.

The decrease of ν_{CO} in amides is due to $p-\pi$ conjugation, which leads to a lowering of the multiplicity of the C=O bond. At first sight it may appear that the lowering of ν_{CO} in phosphides is due to the same phenomenon, but this is contradicted by other chemical and physical data which indicate the absence or insignificance of $p-\pi$ conjugation in systems with phosphorus(III).

For an understanding of the causes of the lowering of ν_{CO} in carboxylic acid phosphides, it is useful to examine the variation of ν_{CO} in carbonyl-containing compounds of the type CH_3COX, where X are atoms or groups containing elements in Pe iods II and III (Fig. 6 and Table 16). One must bear in mind that ν_{CO} does not depend significantly on the mass of the substituents[210] (provided that the mass exceeds 12) and therefore ν_{CO} is determined mainly by electronic factors. For example, it has been shown that ν_{CO} is sensitive to the inductive effects of substituents[211,212].

On passing from carbon to nitrogen, ν_{CO} falls approximately by 60–90 cm^{-1} despite the higher electronegativity of nitrogen, which is due to $p-\pi$ conjugation¶. On further transition to oxygen and fluorine, there is a steady increase of ν_{CO} in conformity with the increase of the inductive and the decrease of the mesomeric effects of these elements. On passing from carbon to silicon, which has a lower electronegativity, ν_{CO} decreases and it was shown that in this case the decrease is caused by a change in the inductive effect of the substituent and not by other factors.

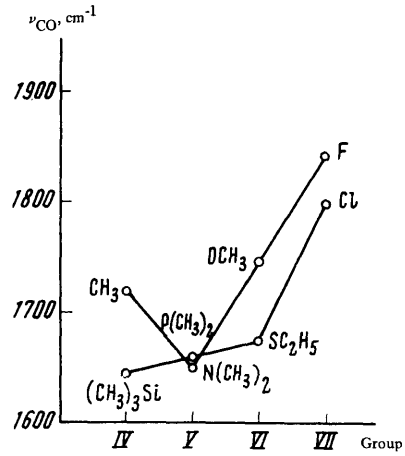

Figure 6. Variation of ν_{CO} in CH_3COX molecules, where X are substituents containing Group IV–VII elements in the Second and Third Periods.

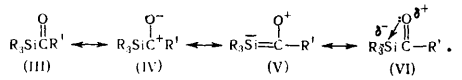
In α-silyl-substituted ketones ν_{CO} is reduced approximately by 70 cm^{-1} compared with ν_{CO} in the corresponding ketones without the α-silyl group[208,214–218]. In disilyl-substituted ketones an even greater shift is observed[219]. The replacement of the α-carbon atom of ketones by silicon has a surprisingly powerful effect also on the energy of the electronic transitions[215,218,219], leading to a red shift of the bands in the ultraviolet spectrum and the appearance of a colour in α-silyl-substituted (yellow) and disilyl-substituted (red-violet) ketones, which is not

¶ In amides, where $p-\pi$ conjugation cannot be achieved for geometrical reasons, ν_{CO} does not fall. Thus ν_{CO} = 1756 cm^{-1} for 2,2,6-trimethyl-7-quinuclidone[213].

observed in the ketones having similar structures without the silyl groups. To account for these observations, it was suggested that the lone electron pair of the oxygen atom in the carbonyl group interacts with the silicon *d* orbitals ($n-d$ interaction[215]) and it was postulated that in the excited state the π^* orbitals of the carbonyl group are conjugated with the silicon *d* orbitals[220]. The possible electronic interactions in silyl-substituted ketones can be represented by a set of resonance structures[221] (III–VI):



(III) (IV) (V) (VI)

Examination of this problem with the aid of the simple and extended Hückel methods led to the conclusion[222] that the main reason for the observed influence of silicon and also germanium on the electronic and vibrational spectra is the change in the σ-donor capacity of the substituting α-atom†. This view was confirmed by spectroscopic measurements of the basicity of the carbonyl group in $R_3XCOC_6H_5$.[221] The basicity decreases in the series Si > Ge > C, which is evidence against structures (V) and (VI) in the ground state. Thus it has been shown that the electronegativity of silicon, i.e. its inductive and not mesomeric effect, plays the main role in the changes of ν_{CO}.

For other elements of Period III, with the exception of phosphorus, a lowering of ν_{CO} in the system CH_3COX, analogous to that with silicon, is observed and one may assume that it is caused by a decrease of the inductive effect of X, since the decrease of the mesomeric effect, which takes place on passing to the elements of the Third Period, should lead to an increase of ν_{CO}. This general tendency does not hold only in the case of phosphorus: ν_{CO} in phosphides is reduced compared with ν_{CO} in ketones but not amides. Compared with silicon, there is some increase of ν_{CO} instead of a decrease, as in the case of carbon and nitrogen. One may suppose that the decrease of ν_{CO} for phosphides compared with ketones is caused, by analogy with silicon, by a decrease of electronegativity on passing from carbon to phosphorus and the approximate equality of the ν_{CO} for phosphides and amides is associated with the absence or insignificance of the $p-\pi$ conjugation effect in carboxylic acid phosphides. Issleib and Löw[196] believe that the reason for the decrease of ν_{CO} in phosphides is the polarisability and reduced electronegativity of phosphorus compared with nitrogen.

Two absorption bands, assigned to $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transition, have been observed in the ultraviolet spectra of phosphides[197,202,204] (Table 17). Compared with amides, which have only one band associated with the $\pi \rightarrow \pi^*$ transition, a bathochromic shift of the absorption maximum should be noted, although it is not as pronounced as in the case of silyl-substituted ketones. A colour is observed only for the phosphides of aromatic and heterocyclic carboxylic acids. The reason for the bathochromic shift is probably the reduced electronegativity of phosphorus.

The introduction of a second acyl group at the phosphorus atom has little effect on the vibrational and electronic spectra (Tables 15 and 17), while in the case of nitrogen a second acyl group increases ν_{CO} and the bathochromic shift in the ultraviolet spectrum[202]. This is associated with a change in the nature of the conjugated system in diacyl derivatives of nitrogen and probably with the absence of $p-\pi$ conjugation in diacyl phosphorus compounds.

Thus the sum total of all the data considered probably indicates the absence from phosphides of $p-\pi$ conjugation analogous to the amide resonance.

2. Phosphorus(III) Cyanides

From the standpoint of the conditions for the occurrence of $p-\pi$ conjugation, the $\diagdown\ddot{P}-C\equiv N$ system is more favourable than the $\diagdown\ddot{P}-C=O$ structure. In this case there is no conformational limitation to conjugation. In the discussion of valence angles it was already noted that the C–P–C valence angle in tricyanophosphine is 93.5°, which corresponds to almost complete *s* character of the lone electron pair of phosphorus and hence the absence of capacity for $p-\pi$ conjugation. Therefore the study of the properties of such compounds is of great interest for the conjugation problem.

The chemical properties of phosphorus(III) cyanides have been hardly investigated. Michaelis[225] pointed out that aryldicyanophosphines add chlorine vigorously. Cyanodiphenylphosphine adds sulphur on interaction with $PSCl_3$. Tricyanophosphine forms complexes[227] with aluminium hydride and also with aluminium chloride and bromide. These reactions indicate the retention of reactivity by the lone electron pair despite the powerful inductive effect of the cyano-groups.

As already mentioned, the dipole moment of cyanodiphenylphosphine does not differ from the value calculated assuming additivity[136], which is evidence of either the absence or low contribution of $p-\pi$ conjugation in the molecule. This is consistent also with the vibrational spectra of tricyanophosphine. A correlation[228] between $\nu_{C\equiv N}$ and the electronegativity of the element has been established for the cyanides of various elements. The cyanides of elements with lone electron pairs (fluorine, chlorine, bromine, iodine, and sulphur) give rise to a single linear relation and elements incapable of $p-\pi$ conjugation (carbon, mercury, silicon, and potassium) form another straight line. It is interesting that phosphorus is included among the second group of elements, while sulphur is included among the first. The authors emphasise this finding, which is surprising in their opinion.

The lowering of $\nu_{C\equiv N}$ in phosphorus(III) cyanides compared with alkyl cyanides is probably not caused by conjugation but by the reduced electronegativity of the phosphorus atom. The changes in $\nu_{C\equiv N}$ in $X-C\equiv N$ systems, where X are elements in the Second and Third Periods, are analogous to those described above for the carbonyl compounds CH_3COX (Fig. 7 and Table 18).

† The interaction of the π bond of the carbonyl group with the silicon *d* orbitals is postulated in the excited state[223].

3. Phospholes

The problem of the aromaticity of five-membered phosphorus-containing heterocycles, the so called phospholes, which are the phosphorus analogues of pyrrole, furan, and thiophen, bears a direct relation to problems of $p-\pi$ conjugation.

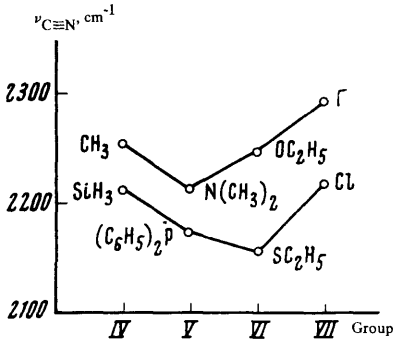

Figure 7. Variation of $\nu_{C\equiv N}$ in X–C≡N molecules, where X are substituents containing Group IV–VII elements in the Second and Third Periods.

A number of polyphenyl derivatives of phospholes were synthesised at the beginning of the 1960's [236-242]. Recently simple representatives of this class of compounds were obtained: 1-phenylphosphole [243] and 1-methylphosphole [244,245]. The study of these compounds [238-241,245-247] showed that, in contrast to aromatic heterocycles, they combine the properties of dienes and saturated compounds of the heteroatom, i.e. phosphines. Phospholes enter into all the reactions characteristic of phosphorus(III) compounds: they are oxidised, add sulphur, and give rise to quaternary phosphonium salts and complexes. On the other hand, pentaphenylphosphole, for example, behaves as a diene forming an adduct with maleic anhydride [238,239].

Table 18. Variation of $\nu_{C\equiv N}$ in XC≡N molecules (in the condensed phase of solution).

X	$\nu_{C\equiv N}$, cm^{-1}	References	X	$\nu_{C\equiv N}$, cm^{-1}	References
CH_3	2254	229	SiH_3	2212 (gas)	233
$N(CH_3)_2$	2212	230	$P(C_6H_5)_2$	2172	136
			$P(CN)_2$	2204	228
OC_2H_5	2245	231	SC_2H_5	2155	234
F	2230 (gas)	232	Cl	2215	235

Tetraphenylthiophen and tetraphenylfuran do not form analogous adducts even under severe conditions. Pentaphenylphosphole forms complexes with iron carbonyls both via the phosphorus atom and via the diene system [238,239]. 1,2,5-Triphenylphosphole forms two types of adduct with acetylenedicarboxylic acid ester—as a diene and as a phosphine with formation of phosphoranes [248].

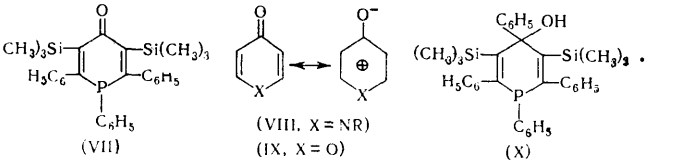
Some evidence for aromaticity was obtained in the study of the simplest phospholes. Thus Märkl and Potthast [243] state that 1-phenylphosphole does not dimerise at 20°C, in contrast to its oxide, and is comparatively difficult to oxidise and combine with sulphur to form a dimeric oxide and sulphide. The NMR spectrum of 1-phenylphosphole resembles that of 1-phenylpyrrole. Quin and coworkers [244,245] enumerate a number of properties, which in their opinion indicate a significant degree of delocalisation of the lone electron pair in 1-methylphosphole: the higher stability of the phosphole compared with that of dienes; the shift of the proton signals in the NMR spectrum towards weaker fields, indicating the existence of a ring current and a similar shift of the signals of the methyl protons; the indication by the ^{31}P NMR spectrum of a reduced electron density at the phosphorus atom compared with alkyldivinylphosphines; the similarity of the ultraviolet spectrum to that of 1-methylpyrrole; the fragmentation on electron impact similar to that of pyrrole and thiophen derivatives; a basicity (0.5) lower by approximately five powers of ten than the expected basicity of methyldivinylphosphine; the absence of reactions with carbon disulphide and nickel chloride. On the other hand, 1-methylphosphole is readily oxidised and forms a phosphonium salt with methyl iodide, which suggests the retention of the reactivity of the lone electron pair of the phosphorus atom. Thus the available data do not allow a final conclusion concerning the presence or absence of aromatic properties in phospholes. However, even if phospholes do exhibit aromatic properties, they are weak and they do not have a significant influence on the overall properties of these heterocycles.

We may note that thermochemical and calculated quantum-chemical data support the existence of aromatic properties in phospholes. According to these results, described in fair detail in Hudson's book [41], phospholes should actually have more pronounced aromatic properties than pyrroles, a result which must naturally be treated with caution‡.

There are no data on the geometry of phospholes. Earlier we pointed out that [12] the valence angles at the heteroatoms in pyrrole, furan, and thiophen are approximately equal to those in the hydrides of the corresponding elements. If this holds also for phosphorus, the valence angles at the phosphorus atom in phospholes should differ only slightly from those in unsubstituted phosphine, i.e. they should not exceed 100° in any case. The predominantly *s* character which the lone electron pair possesses in this case is in good agreement with the absence of pronounced aromatic properties in phospholes.

4. Phosphacyclohexadienones

Märkl and Olbrich [249] recently synthesised 3,5-trimethylsilyl-1,2,6-triphenylphosphacyclohexa-2,5-dien-4-one (VII), the phosphorus analogue of γ-pyridone (VIII) and γ-pyrone (IX), which are known to have aromatic properties owing to the delocalisation of the lone electron pair of the heteroatom X over the ring:



‡ A planar ring structure was postulated in the calculation.

The phosphacyclohexadienone (VII) does not exhibit the ambident reactivity characteristic of pyrones and pyridones. Thus alkylation and protonation take place at the phosphorus atom and not at the oxygen atom. Compound (VII) enters into reactions characteristic of phosphorus(III) and ketones. The carbinol (X) obtained in the reaction with phenyl-lithium does not form with perchloric acid the corresponding pyrylium salt analogue. All these properties indicate the absence of appreciable delocalisation of the lone electron pair of the phosphorus atom in the phosphacyclohexadienone, although the authors in fact believe that the involvement of the dipolar structure probably should not be entirely excluded.

We shall not consider here the problem of phosphabenzenes, since the lone electron pair of phosphorus does not participate in the conjugated ring system.

V. PROPERTIES OF PHOSPHORUS(III) COMPOUNDS IN AN OPTICALLY EXCITED STATE

A. ULTRAVIOLET SPECTRA OF PHOSPHINES

Examination of the ultraviolet spectra of the simplest chromophoric systems with lone electron pairs of the type CH_3X, where X is a substituent containing elements in Groups V–VII and Periods II and III, shows that the position of the long-wavelength absorption band is inversely related to the electronegativity of the central atom of the substituent X: with increase of the electronegativity of the central atom, the long-wavelength absorption band is displaced towards shorter wavelengths (Table 19). There is a corresponding increase in the excitation energy, which is attributed either to $n \rightarrow \sigma^*$ transitions or, as in some cases, to Rydberg transitions of an electron from lone pair[257-259]. Within the limits of the Second Period, there exists an approximate linear relation between the position of the absorption band and the electronegativity of the central atom (see lines I and II in Fig. 8*a*). On passing from the elements of the Second Period to those of the Third in Groups VI and VII, the absorption bands are displaced towards longer wavelengths (see lines I and II in Fig. 8*b*), in conformity with the decrease of the electronegativity of the elements. However, in Group V the opposite phenomenon is observed—phosphines absorb at shorter wavelengths than amines, which leads to a breakdown of linearity. Thus phosphorus is an exception to the general relation. One may suppose that this blue shift, i.e. the increase of the energy of the long-wavelength transition, in phosphines is associated largely with the lower and not the excited energy level of the lone electron pair, i.e. with the enhanced *s* character of its orbital.

If phosphorus satisfied the above relation, then, according to its electronegativity (2.1 on Pauling's scale), the long-wavelength transition of trimethylphosphine should occur in the region of 240–260 nm instead of the observed wavelength of about 200 nm. The energy difference between the 200 and 250 nm transitions[102] is approximately 28 kcal mole^{-1}. Table 19 lists the parameters of the ultraviolet spectra of other phosphines and, for comparison, data for the corresponding amines. In all cases the long-wavelength transitions of phosphines are displaced towards shorter wavelengths compared with amines, which can probably be regarded as confirmation of the conclusion that the lone electron pair of phosphorus has enhanced *s* character.

Analogous, albeit less pronounced, changes in the position of the long-wavelength absorption bands are also observed for monophenyl derivatives[260-262] (Figs. 8*a* and 8*b*). In this case the long-wavelength transition is of a different type, although the attached element with a lone pair has a significant influence on the nature of the spectrum. The maximum of the long-wavelength absorption band is displaced towards shorter wavelengths on passing from nitrogen to oxygen and fluorine, i.e. on increase of the electronegativity and decrease of the π-donor capacity of the element.

Table 19. Long-wavelength absorption bands of chromophoric systems with lone electron pairs.

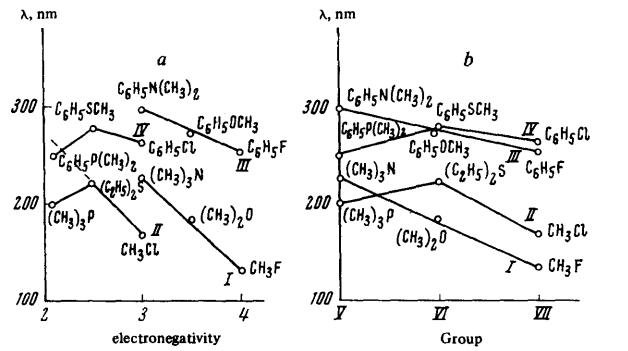

Figure 8. Variation of the positions of the long-wavelength absorption band maxima in the spectra of compounds of the type CH_3X and C_6H_5X (X are substituents with lone electron pairs containing Group V–VII elements in the Second and Third Periods) with Pauling's electronegativity of the central atom of the group X (*a*) and with the positions of the central atom in the Periodic System (*b*).

A small bathochromic shift is observed on passing from fluorine to chlorine and from oxygen to sulphur. Again this behaviour breaks down in the case of phosphorus (see Figs. 8*a* and 8*b* and Table 20). According to the general tendency, phosphorus compounds should be characterised by absorption at the longest wavelengths. In fact, however, dimethylphenylphosphine absorbs at shorter wavelengths than the analogous nitrogen and sulphur compounds and, according to the data of Bowden and Braude[261], even fluorine compounds, despite the lower electronegativity of phosphorus compared with those of the above elements. This anomaly in the spectra indicates a significant difference in the structure of the valence shell of phosphorus in

phosphines and possibly also a different type of electronic transition. One may suppose that it is also caused by enhanced *s* character of the lone electron pair of phosphorus.

It is interesting to note that in those cases where tervalent dicoordinate phosphorus enters into a conjugated system, anomalies of this kind are not observed in the spectra and phosphorus compounds absorb at longer wavelengths than the analogous nitrogen compounds. Thus the phosphamethinecyanines synthesised by Dimroth and Hoffmann[263] have a deeper colour than the corresponding azamethine- and methine-cyanines (Table 21). The analogous arsenic compounds absorb at even longer wavelengths[264]. An approximately linear relation is actually observed between the position of the long-wavelength absorption band maximum and the electronegativity of the central atom (Fig. 9). A bathochromic shift of the long-wavelength absorption maximum relative to the maxima of the corresponding carbon and nitrogen analogues takes place also for other compounds of dicoordinate phosphorus – dibenzophosphorin[265] and 2,4,6-triphenylphosphabenzene[267,269].

Aryl phosphide anions[41], the electronic analogues of aryl sulphides and arenethiols, are also deeply coloured. The appearance at the phosphorus atom of a second lone electron pair with a much more pronounced *p* character than the first leads to a shift of the absorption band towards longer wavelengths in accordance with the electronegativity of phosphorus.

The first data on the ultraviolet spectra of aromatic phosphines were obtained at the beginning of the 1950's. Extensive data have now been accumulated but so far the nature of the observed electronic transitions is not altogether clear.

The introduction of phosphorus(III) into the benzene ring leads to a sharp increase of the absorption intensity in the region of 250–260 nm, which exceeds the usual increase of intensity accompanying the breakdown of the symmetry of the benzene ring, and also to a bathochromic shift of the benzene *K* band. This was first shown by Bowden and Braude[261] for dimethylphenylphosphine and then by other workers[134,135,260,270-276] for other aromatic phosphines. An increase in the number of phenyl groups at the phosphorus atom causes a comparatively small change in the position of the absorption band but leads to an appreciable increase of intensity, which, however, does not rise in proportion to the number of benzene rings[260,271].

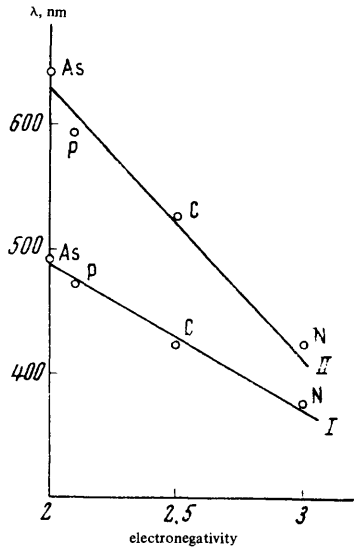

Figure 9. Variation of the positions of the maxima of the long-wavelength absorption bands in the spectra of cyanine dyes of types I and II (Table 21) with Pauling's electronegativity of the central atom.

This effect is shown particularly clearly by aromatic amines. The band intensities are influenced by steric factors. Thus the introduction of a methyl group into the *ortho*-position of 1-phenyl-1-phosphacyclopentane decreases the intensity of the long-wavelength band[270] although not as much as for dimethylaniline[279]. The intense absorption in the region of 250–260 nm is associated with the lone electron pair of phosphorus(III), since this band disappears in the oxidation or formation of phosphonium salts. In phosphorus(V) compounds a low-intensity band with a vibrational fine structure is observed in the same region. We may also note that in phosphorus(V) derivatives there is no progressive increase of intensity on introduction of benzene rings at the phosphorus atom and the rule of additivity holds[271,272].

All these factors are regarded by some workers as evidence for the occurrence of $p-\pi$ conjugation in aromatic phosphines in the ground state. Thus Jaffé[271,272] believed that the ultraviolet spectra of the triphenyl derivatives of Group V elements in the tervalent state indicate

the existence of powerful conjugation between the benzene rings§. This view was supported also by Rao and coworkers[274,275], who assigned the 260 nm band of triphenylphosphine initially to the $n \rightarrow \pi^*$ transition and then to the $\pi \rightarrow \pi^*$ transitions, i.e. to the modified benzene B band, and regarded it as an analogue of the long-wavelength absorption by triphenylamine (297 nm). A similar assignment was made by Schindlbauer and coworkers[276,277], who discussed the spectra of more complex aromatic phosphines. Schiemenz[278] believes that the principal bands in the spectrum of di(cyanoethyl)phenylphosphine and cyanoethyldiphenylphosphine are similar to those associated with the long-wavelength transition of dimethylaniline, although in the case of triphenylphosphine he refrains from a definite assignment of the long-wavelength absorption.

Cullen and coworkers[280,281] stated that triphenylamine is the sole representative of triphenyl derivatives of Group V elements whose benzene rings are conjugated. The spectra of the remaining compounds of the series differ significantly from that of triphenylamine. By mathematical analysis of the spectroscopic data for arylarsines, these workers isolated two long-wavelength maxima, one of which was assigned to the $\pi \rightarrow \pi^*$ electronic transition of the substituted benzene ring on the basis of the influence of solvents and substituents on its position and the other (the principal intense absorption band) was assigned to the $n \rightarrow \pi^*$ transition. This investigation influenced also the interpretation of the ultraviolet spectra of arylphosphines.

Shaw et al.[155] made a similar analysis of the ultraviolet spectra of arylphosphines with different numbers of phenyl groups at the phosphorus atom (Table 22). They assigned the principal intense band with a maximum in the region of 250–260 nm to the $n \rightarrow \pi^*$ transition of an electron from the lone pair to a non-bonding orbital of the benzene ring. The low-intensity bands with maxima in the region of 270–280 nm were assigned to the $\pi \rightarrow \pi^*$ transitions of the electrons in the substituted benzene ring. These bands differ little in their positions and intensities from the long-wavelength bands of monosubstituted benzenes, for example toluene[282]: 269 nm (2.4), 262 nm (2.45), 255 nm (2.3), and 249 nm (2.15). This interpretation is equivalent to the acknowledgement of the absence (or insignificance) of $p-\pi$ conjugation in the ground state and the delocalisation of the lone electron pair in the optically excited state. The problem of the presence or absence of weak $p-\pi$ conjugation in the ground state remains open. Shaw and coworkers believe that such weak conjugation is possible in triphenylphosphine on the basis of the long-wavelength displacement of the band associated with the $\pi \rightarrow \pi^*$ transition. The recently published spectra of mono-, di-, and tri-phenylphosphines in the gas phase[283] are interesting in this respect. The spectral curve for triphenylphosphine has a shoulder in the region of 300–310 nm.

A similar interpretation was made by Stepanov and coworkers[184,185] in an examination of the ultraviolet spectra of substituted aryldiethylphosphines. On the basis of the effect of substituents in the aromatic ring and at the phosphorus atom on the position of the absorption maximum, they concluded that the intense long-wavelength band of phosphines is an *R* band ($n \rightarrow \pi^*$ transition) and the $\pi \rightarrow \pi^*$ transition is in the majority of cases masked by this intense absorption.

The interpretation of the long-wavelength band as due to the $n \rightarrow \pi^*$ transition is consistent with the enhanced *s* character of the lone electron pair of phosphorus, and hence with the absence or insignificance of $p-\pi$ conjugation in the ground state and with the physical and chemical properties of aromatic compounds; it explains the "phosphorus" anomaly in the spectroscopic behaviour described above.

The assignment to the $n \rightarrow \pi^*$ transition was made[284] also for the long-wavelength band in the spectra of vinylphosphines in the region of 230–240 nm and the 260–270 nm band for *trans*-diphosphinoethylenes. The absorption in the region of 180 nm observed previously[147] probably refers to the unperturbed band of the $\pi \rightarrow \pi^*$ transition, which usually undergoes a bathochromic shift in the spectra of vinylamines and vinyl sulphides. However, we may note that the above assignments are so far purely qualitative and have not been confirmed by calculations.

B. MOLECULAR REFRACTIONS OF PHOSPHORUS(III) AROMATIC COMPOUNDS

Without considering the problem of the molecular refractions of organophosphorus compounds as a whole, which was recently examined in detail by Tolkmith[285] and partly by other investigators, we shall deal here only with a specific problem—the exaltation of the molecular refractions (ΔMR_D) of aromatic phosphorus(III) compounds. In recent years Kharrasova and Kamai examined the molecular refractions of aromatic phosphorus(III) compounds[290-294].

The replacement of an alkyl group at the phosphorus atom by a phenyl group is always accompanied by the exaltation of molecular refraction, which is regarded as evidence for the conjugation of the lone electron pair of phosphorus with the π-electron system of the benzene ring. ΔMR_D is not constant and depends on the substituents at the phosphorus atom and in the benzene ring and their positions.

The values of ΔMR_D for the simplest mono- and diphenyl compounds of phosphorus(III) are listed in Table 23. In most cases it was compiled using the results of the present authors. For this reason, the ΔMR_D data presented serve merely as an illustration and are not increments to atomic refractions of phosphorus. The smallest exaltations are observed for primary and secondary phosphines and chlorophosphines. When alkyl, alkoxy-, and dialkylamino-groups are introduced at the phosphorus atom, ΔMR_D gradually increases and in the case of the last two groups these value differ significantly from the ΔMR_D for chlorophosphines¶. The introduction of a

§ Subsequently Jaffé apparently abandoned this treatment[273] and stated that the absorption by triphenylphosphine in the region of 260 nm cannot be definitely attributed either to the *B* or *K* band.

¶ Kharrasova and Kamai state[291] that the replacement of chlorine by an alkoxy-group in aromatic compounds of phosphorus(III) does not alter its atomic refraction.

second phenyl group increases the exaltation by 0.5–0.7 cm^{-3}. For triphenylphosphine[299], ΔMR_D = 2.65 cm^3.

The exaltations of disubstituted aromatic compounds (Table 24) depend on the nature of the substituents and their positions in the benzene ring. For *meta*-isomers, ΔMR_D differs only significantly from the sum of the ΔMR_D for the corresponding mono-substituted compounds, whereas for the *para*-isomers they are significantly higher than this sum. In other words, ΔMR_D increases with increasing length of the conjugation chain. The above dependence of ΔMR_D on structure makes it significantly more difficult to devise an additive scheme for the calculation of the molecular refractions of aromatic phosphorus(III) compounds.

Table 23. Exaltation of the molecular refractions of certain mono- and di-phenyl compounds of phosphorus(III) [$C_6H_5PX_2$ and $(C_6H_5)_2PX$].

Recently Zaitsev[305] proposed correlation equations for the calculation of ΔMR_D for disubstituted benzenes. As experimental data accumulate, this scheme can probably be used also for organophosphorus compounds.

The absolute values of the above exaltations are fairly high and comparable with those for aromatic amines. However, in order to compare the exaltations of phosphorus and nitrogen compounds, it is probably more reasonable to employ, instead of the absolute value of ΔMR_D, its ratio to the corresponding atomic refraction, which makes it possible to take into account the different polarisabilities of the elements. This ratio, which may be called the relative exaltation, is analogous to the specific refraction of Auwers and Eisenlohr[306] but is more convenient for comparing the analogous compounds of various elements.

The relative exaltations for aromatic phosphines are smaller by a factor of approximately 3 than for aromatic amines. Thus, as regards the breakdown of the additivity of molecular refractions, it would appear that phosphorus(III) compounds may be regarded as typical conjugated systems, although inferior in this respect to aromatic amines. The problem arises of the reliability of the exaltation of molecular refraction as a criterion of the occurrence of conjugation.

According to Vol'kenshtein[307], "static exaltation, extrapolated to infinitely long wavelengths, i.e. zero frequencies, is of physical significance". Then the breakdown of the additivity of molecular refractions may be evidence of conjugation in the ground state of the molecule. When the wavelength of the irradiating light is reduced, the exaltation will increase as the irradiation frequency approaches the frequency of the intrinsic absorption by the substance. For example, according to the data of Vasil'ev[308], at infinitely long wavelengths *p*-nitroaniline has an exaltation of 2.7 cm^3, which indicates the occurrence of conjugation in the ground state. The exaltation at 4358 Å reaches 14.85 cm^3. The increase of exaltation is due to the absorption of energy and the transition of some of the molecules to an optically excited state, where the additivity of molecular refractions found from the increments for the ground state should not hold. Certain exaltations are due precisely to this effect and are not associated with conjugation in the ground state. No data are available on the dispersion of the exaltations of molecular refractions for arylphosphines. One cannot exclude the possibility that in this case the exaltations are associated with the intrinsic absorption by the substance and on extrapolation to infinite wavelengths the molecular refractions will be additive. This is confirmed indirectly by the virtual absence of exaltation from vinyl compounds of phosphorus(III),[147] the intrinsic absorption bands of which are displaced towards shorter wavelengths[284].

Recently Zaitsev[309] demonstrated the existence of an approximate correlation between ΔMR_D and the electronic absorption spectra of monosubstituted benzenes.

Thus the exaltation of the molecular refractions of aromatic amines by itself gives no information about the conjugation in the ground state of these molecules. Nor should one forget $p_\pi - d_\pi$ conjugation as a possible cause of exaltation in certain cases.

---o0o---

The properties of phosphorus(III) compounds discussed, both physical and chemical, have been explained on the hypothesis of an enhanced *s* character of the lone electron pair of phosphorus and to some extent constitute its confirmation. We may note that the nature of the hybridisation of the lone electron pair is fairly rarely taken into account in discussions of $p-\pi$ conjugation†, even in certain quantum-chemical studies[283,312]. Usually it is postulated that any lone electron pair is capable of $p-\pi$ conjugation to some extent, which depends on the position of the element in the Periodic System. Much attention has been devoted to the dependence of conjugation on steric factors (various types of non-coplanarity of the *p*-orbital axes), while the effect of changes in valence angles and of the hybridisation of the lone electron pair is rarely taken into account, although it is known that the *s* orbital does not form a bond with the p_Z orbital[45]. We believe that the chemistry of phosphorus(III) has shown that the hybridisation of the lone electron pair is a significant factor influencing the $p-\pi$ conjugation and the properties associated with it. Probably the geometry of the molecule always affects the conjugation not only because of a change in the relative distribution of the overlapping orbitals but also via a change in the very nature of the orbitals and the suggested hypothesis is probably more general and of wider significance than for the chemistry of phosphorus alone.

The problem naturally arises whether it is possible to predict on this basis cases in the chemistry of other elements where the lone electron pair of the atom loses the capacity for $p-\pi$ conjugation by virtue of its enhanced *s* character. The necessary conditions for the observation of this effect are the presence of only one lone electron pair and the closeness of the valence angles at the heteroatom to 90°C. On the basis of data for the valence angles in the hydrides of various elements (see p. 181, Table 1), one may note in what cases the absence of the capacity for $p-\pi$ conjugation in the lone electron pair of the atom is to be expected.

A sharp decrease of valence angles is observed on passing from elements in the Second Period to those in the Third Period within the limits of Groups V and VI. As shown above, in Group V this change in angles is accompanied by a change in directive influence. Since the valence angles in the hydrides of arsenic and antimony steadily decrease, approaching 90°, one may suppose that the lone electron pairs of these elements will also lack the capacity for $p-\pi$ conjugation. In Group VI, transition from the Second to the Third Period is not accompanied by a change in the type of directive influence of the central atom owing to the presence of two lone electron pairs. However, in the case of the tricoordinate state of Group VI elements, for example in 'onium compounds, the pattern of the changes in directive influence should be the same as in Group V elements. An analogous change in directive influence may also be expected for the tricoordinate state of Group IV elements, i.e. in the case of their anions, and the anions of silicon and its analogues should differ sharply in their electronic influence from carbanions.

The experimental data for certain properties (the type of directive influence of the central atom, basicity, and configurational capacity) of π-electron systems containing Group IV–VI elements in the tricoordinate state were recently examined by the present authors[313]. They agree with the hypotheses put forward. Here we shall recall only studies dealing with problems of directive influence and certain others which had not been dealt with previously.

Together with Lobanov, Kamai, and Chadaeva, the authors of the review[314] showed that arsenic, the closest analogue of phosphorus in the Group, resembles the latter in its electronic influence and its lone electron pair also lacks the capacity for $p-\pi$ conjugation. This is also indicated by the data of Kostyanovskii and coworkers[315].

It is interesting that the 100% *para*-directing effect in the nitration of a triphenyloxonium salt, which is unusual for 'onium compounds, observed by Nesmeyanov and coworkers[316] follows logically from the proposed hypothesis. The change in the type of directive influence on passing from oxonium to sulphonium salts is analogous to the inversion of directive influence on passing from nitrogen to phosphorus. Triphenyloxonium salts are electronic analogues of triphenylamine and probably have similar molecular geometry and hence their lone electron pair is almost entirely of *p* type‡. The lone electron pair of triphenylsulphonium salts, the electronic analogues of triphenylphosphine, probably has an appreciable amount of *s* character and hardly participates in $p-\pi$ conjugation. Finally, one must also bear in mind *d* orbitals with likewise promote the *meta*-directing effect. A similar *meta*-directing effect is observed with selenonium salts[317].

Some data whereby the hypotheses put forward may be checked are provided by five-membered diene heterocycles. Anionic cyclic systems containing Group IV elements should not have aromatic properties with the exception of the cyclopentadienide anion, which is derived from an element of the Second Period. The same applies also to Group V elements, nitrogen being an exception in this case. Group VI elements, which have two lone electron pairs, should all form aromatic heterocycles without exception. In the tricoordinate state, the same Group VI elements will not form aromatic heterocycles, with the exception of oxygen.

The facts known at present do not contradict the above hypotheses. We shall not dwell on the widely known examples of aromatic heterocycles—pyrrole, furan, thiophen, selenophen, and the cyclopentadienide anion. According to the hypotheses, the ring compounds with sulphur(III) (thiophen oxide), which is an unstable reactive diene, has no aromatic properties, although it does have a lone electron pair[318]. In this respect, the study of oxonium salts of furan, which should be aromatic, is of very great interest. As already stated, phospholes do not have very marked aromatic properties. However, one may assume that, in the form of phosphide anions, phospholes will behave as aromatic systems analogous to the

† These problems are partly dealt with in monographs[102,310] and certain papers[75,311].

‡ The *meta*-directing effect observed in the nitration of 2-phenylpyrylium salts[3] is not inconsistent with the *para*-nitration of triphenyloxonium salts, since in the first case the lone electron pair is probably located in the plane of the aromatic ring and is not conjugated with the benzene ring.

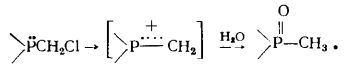
cyclopentadienide anion. The study of the silacyclopentadienide anion, the silicon analogue of the cyclopentadienide anion, has so far not provided a definite answer to the question of its aromaticity[319].

Another range of phenomena is closely associated with the problems discussed. Indirect evidence for the geometry of silicon(III) [Si (IV) tricoordinate Si? (Ed. of Translation)] compounds and hence for the type of directive influence of the negatively charged atom is provided by the inability of silicon to form a double bond[320]. We believe that this demonstrates the closeness of the valence angles in tricoordinate silicon compounds to 90°, the predominantly s character of the free silicon orbital, and hence the absence of $p-\pi$ conjugation in these systems (positively or negatively charged).

The forced decrease of the valence angles of carbon and nitrogen leads to analogous phenomena. This concerns all cases associated with Bredt's rule—the impossibility of the existence of double bonds or resonance interactions at the bridgeheads of bicyclic systems: the absence of amide resonance from quinuclidones[321] and the much lower basicity of dehydroquinuclidine and analogous compounds compared with the corresponding saturated compounds[322,323], the absence of resonance stabilisation from bicyclic carbanions with the charge at the bridgehead[324], etc. The impossibility of π-electron interactions in all such cases is due not only to the unfavourable geometrical disposition of the corresponding orbitals, which is usually emphasised, but also to the enhanced s character of the orbital at the bridgehead. The closeness of the average valence angle at the bridgehead in bicycloheptane systems to 100° has been pointed out by Sim[325].

Returning to phosphorus, we may note that the problem of the possibility of detecting $p-\pi$ conjugation in certain special cases is of great interest. We believe that there are three ways whereby phosphorus(III) systems may be formed in which $p-\pi$ conjugation is possible: (1) optical excitation of molecules; (2) the formation of a cationic centre in the α-position relative to phosphorus(III): (3) a "forced" change in the valence angles of the phosphorus atom by the introduction of bulky substituents or by the formation of cyclic structures.

Analysis of the ultraviolet spectra of aromatic phosphines leads to the extremely reasonable conclusion that in an optically excited state $p-\pi$ conjugation may occur. Its observation requires a study of the properties of optically excited molecules. One cannot exclude the possibility that the presence in the molecule of a powerful electron-accepting centre, for example a carbonium ion, leads to the delocalisation of the lone electron pair of phosphorus(III). Evidence for this is provided by the study of the reaction of tri(chloromethyl)phosphine which we investigated[326]:



Hydrolysis and reaction with alkoxides lead to the reduction of the chloromethyl group and the oxidation of phosphorus(III) and not simple substitution. This reaction, which we called "pseudoallyl rearrangement", probably indicates some delocalisation of the lone electron pair in the transition state.

The third way, involving a change in the valence angles at the phosphorus atom, has at present not been investigated at all, although isolated data show that the desired results may be obtained by this procedure. Mark and van Wazer[327] showed that the lone electron pair of tri-t-butyl phosphite has an enhanced reactivity, which they explained by an increase of the valence angles and of the p character of the lone electron pair. Subsequently this was confirmed[328] by the ^{31}P NMR method. Arbuzov and Zoroastrova[329], who synthesised a number of cyclic phosphites, noted that seven- and eight-membered phosphorochloridites ignite spontaneously in air, in contrast to the remaining members of the series. This finding has received no explanation. If one bears in mind that, according to X-ray diffraction data[330-335], the valence angles in 8–12-membered rings exceed the tetrahedral value (for example, in cyclononylamine hydrobromide[331] the C–C–C angles are in the range 111–124°), this anomaly can be understood. Probably an increase in the valence angles at the phosphorus atom leads to an increase in the amount of p character of the lone electron pair and an increase in its reactivity.

ADDENDA

During the preparation of this manuscript for the press, certain studies were published which the authors feel it necessary to include in the review. Wherever possible the additional data were introduced into the main text. In addition, three new small sections have been written, supplementing the sections on "The Basicity of Phosphines", "Phospholes", and "The Properties of Certain Individual Types of Compounds".

The barrier to the inversion of 1-isopropyl-2-methyl-5-phenylphosphole[336], determined by the NMR method, proved to be very low (ΔG_{25} = 16 kcal mole^{-1}), in contrast to tertiary phosphines for which the inversion barrier is 29–36 kcal mole^{-1}. The authors explain the lowering of the barrier by the energy gain due to the delocalisation of electrons in the transition state of the inversion process.

Proton Affinity of Unsubstituted Phosphine in the Gas Phase

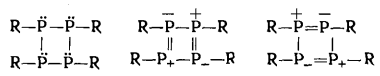
In contrast to ammonia, amines, and substituted phosphines, unsubstituted phosphine is known[41,174] to have an extremely low basicity in water (pK_a = −8 or −14), which Gibbs[337] explained by the almost complete s character of the lone electron pair of phosphorus and hence high rehybridisation energy from the p^3 to the sp^3 state in the phosphonium cation. On the basis of calculations using the Born–Haber cycle, Wendlandt[338] concluded that, despite the low accuracy of the values obtained, in the gas phase ammonia and phosphine differ little in their proton affinity (proton affinity is understood as the enthalpy, with the sign reversed, of the reaction $B + H^+ = BH_4^+$).

This led to another view, according to which the low basicity of unsubstituted phosphine in water is a consequence of the low solvation energy of the phosphonium ion[41,338,339]. Subsequently new estimates of the proton affinity of unsubstituted phosphine were published[340,341] (153 and 194.4 kcal mole^{-1}), which differed from Wendlandt's results (209 kcal mole^{-1}). According to the latest data[342] obtained by ionic cyclotron resonance, the proton affinity of unsubstituted phosphine is 185 ± 4 kcal mole^{-1}, which is smaller by 22 kcal mole^{-1} than the proton affinity of ammonia[343] (207 ± 3 kcal mole^{-1}). This value is comparable with the difference between the basicities of phosphine and ammonia in water (23–32 kcal mole^{-1}). Hence

it follows that solvation probably does not play a major role in the difference between the basicities of unsubstituted phosphine and ammonia in water.

Conjugation in Compounds with a P–P Bond

The problem of the possible aromatic properties of cyclopolyphosphines $(RP)_n$ (n = 4, 5, or 6) owing to the delocalisation of the electrons in the lone pairs of the phosphorus atoms and represented by the resonance structures



has been discussed in the literature[344,345]. This hypothesis was put forward[346,347] to account for the long-wavelength absorption in the ultraviolet spectra of cyclopolyphosphines (275–290 nm for alkyl derivatives), which is absent from the spectra of tertiary phosphines, and also for the low basicity of cyclopolyphosphines[347] ($pK_a < 1$) compared with phosphines ($pK_a = 2-10$). To confirm this treatment of the ultraviolet spectra, a quantum-chemical calculation was carried out[346].

Analogous evidence (ultraviolet spectra[348,349] and dipole moments[350]) was adduced in support of the existence of a partial double bond character in diphosphines in the ground state and certain polyphosphine heterocycles[351]. Some chemical properties of polyphosphines have also been explained[344,345,352] by the conjugation of the lone electron pair of phosphorus with the d orbitals of an adjacent phosphorus atom.

The valence angles at the phosphorus atom have been determined for trifluoromethyl[353,354], phenyl[355,356], and cyclohexyl[357] derivatives of tetra- and penta-phosphines. In most cases they do not exceed 100°. This implies that the lone electron pairs of phosphorus atoms are predominantly of s type and their conjugation with the d orbitals of phosphorus (the formation of a π bond) can hardly influence significantly the properties of cyclopolyphosphines in the ground state. We believe that the observed long-wavelength shift can be due both to $p_\pi - d_\pi$ conjugation in the optically excited state and to differences between the properties of the P–P (polyphosphines) and C–P (tertiary phosphines) σ bonds i.e. the difference between the electronegativities of carbon and phosphorus (see the section "Carboxylic Acid Phosphides"). The operation of the latter factor is supported, in particular, by the bathochromic shift in the ultraviolet spectra of diphosphine disulphides[349] (compared with trialkylphosphine sulphides), which cannot be accounted for by conjugation. The low basicity of cyclopolyphosphines may be associated with the enhanced s character of the lone electron pairs of phosphorus. The approximate equality of the P–P bond lengths, which are independent of the valence state of phosphorus and of the nature of groups attached to it[357], is also evidence against conjugation in the ground state.

Recently, in a discussion of the causes of the weak nucleophilic properties of the lone electron pair of phosphorus in trisilylphosphine, the hypothesis was put forward[358] that the lone s electron pair of phosphorus forms a σ bond with the d orbital of silicon located along the Si–P bond axis (for example the $s-d_{Z^2}$ σ bond). The hypothesis of additional σ bonding, rather than the π bonding, discussed above, may serve as an alternative explanation of the properties of compounds with a P–P bond.

Thus the properties of polyphosphines may be understood in terms of hypotheses other than that of $p_\pi - d_\pi$ conjugation in the ground state, which is difficult to reconcile with the extensive experimental data on the properties of phosphorus(III) compounds§.

§ Added in proof. The weaker nucleophilic properties of the lone electron pair of phosphorus in triethyl phosphorothioite can be understood similarly; the hypothesis of the d hybridisation of the lone electron pair of phosphorus was recently put forward to account for it[361].

Reactions of Organic Derivatives of the Elements with Polyhalogenomethanes

S.F.Zhil'tsov and O.N.Druzhkov

The review discusses the reactivity of organic derivatives of the elements (with one or two "non-organic" atoms) in relation to halogenomethanes. The chemical reactivity of true organic derivatives of elements in Groups I-V in reactions with alkyl halides is determined by the type of the compound and the nature of the element-carbon bond. Particular attention has been devoted to initiated processes.
The bibliography includes 250 references.

I. INTRODUCTION

Extensive empirical data have now accumulated on reactions of organic derivatives of the elements (ODE) with polyhalogeno-derivatives of methane. These reactions are of definite theoretical interest and are employed in organic syntheses.

The reactivity of ODE depends on the type of compound and the nature of the element and the organic group bound to the atom of the element. Some ODE react with polyhalogenomethanes at a low temperature and others only on heating, irradiation with ultraviolet light, or in the presence of initiators. The sharp differences between the reactivities of ODE and the use of different conditions in studies on the reactions are frequently the reasons for the contradictory interpretation of the mechanism of the reaction of ODE with polyhalogenomethane.

The literature dealing with the reactions of true organic compounds of Group I–V elements with polyhalogenomethanes is critically examined in this review in order to be able to discuss the mechanisms of these processes, their general characteristics, and the general relations governing them.

II. REACTIONS OF ORGANOMETALLIC COMPOUNDS OF GROUP I ELEMENTS

The reactions of organometallic metallic compounds (OMC) of Group I elements with polyhalogenomethanes have been investigated in greatest detail for lithium derivatives. Organolithium compounds react vigorously with di-, tri-, and tetra-halogenomethanes in hydrocarbon, ether, or tetrahydrofuran (THF) solutions at a low temperature (between −100° and −60°C). The greatest number of communications deal with reactions of compounds of the type RLi (R = CH_3,[1-6] iso-C_3H_7,[1,7] n-C_4H_9,[8-12] s-C_4H_9, t-C_4H_9, n-C_5H_{11},[2] cyclo-C_6H_{11},[10] C_6H_5,[13,14] and substituted vinyl[15,16]) with methylene dichloride. The main products of the reaction are lithium chloride and saturated and unsaturated cyclopropane hydrocarbons and their chloro-derivatives.

It has been shown[12] that dichloromethyl-lithium is formed as an intermediate:

$$RLi + CH_2Cl_2 \rightarrow RH + CCl_2HLi\ .$$

The presence of a dichloromethyl derivative in the reaction mixture was confirmed by reactions with mercury(II) chloride and zinc chloride, which led to the isolation of bis(dichloromethyl)mercury (m.p. 154–155°C) in almost quantitative yield and bis(dichloromethyl)zinc, which is stable at room temperature.

Dichloromethyl-lithium is an unstable compound, which decomposes above −60°C. There is no unanimous view concerning the mechanism of its decomposition. Arguments are quoted in favour of a bimolecular decomposition[12]:

$$2Cl_2HCLi \rightarrow 2\ LiCl + ClCH{=}CHCl\ .$$

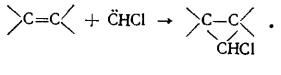
However, the majority of investigators postulate the participation of free chlorocarbene in reactions of organolithium compounds with methylene dichloride:

$$Cl_2CHLi \rightarrow LiCl + \ddot{C}HCl,$$

which makes it possible to account for the presence in the reaction mixture of many of the compounds formed.

Insertion or addition reactions are most characteristic of carbenes and a number of monographs[17,18] and reviews[19-21] have been devoted to them.

The reaction of organolithium compounds with methylene dichloride in the presence of olefins[4-6,9,22] leads to the formation of chlorocyclopropanes in high yields:



This reaction may be employed for preparative purposes. Chlorocarbene reacts with benzene, phenol[23], pyrrole, and indole[24] with ring expansion and adds to triphenylphosphine[25] with formation of ylide.

Chlorocarbene is inserted in the C–Li bond of the initial organometallic derivative with formation of a substituted chloromethyl-lithium derivative[10,14]:

$$R{-}Li + \ddot{C}HCl \rightarrow RCHClLi .$$

The decomposition of the latter gives rise to alkyl- or aryl-carbenes:

$$RCHClLi \rightarrow LiCl + R\ddot{C}H$$

(R = alkyl[8,10] or aryl[13,14]).

Alkylcarbenes tend to undergo intermolecular isomerisation, which leads to the formation of olefins and cyclopropanes. Thus the reaction of pentyl-lithium with methylene dichloride in ethyl ether solution at –30°C or in pentane solution at 30°C results in the formation of hex-1-ene (94–95%)† and n-propylcyclopropane (5–6%) owing to the isomerisation of the pentylcarbene formed initially. The principal products isolated in the analogous reactions of s-butyl-lithium and t-butyl-lithium are 2-methylbut-1-ene, ethylcyclopropane and *trans*-dimethylcyclopropane for the first compound and 2-methylbut-1-ene, 2-methylbut-2-ene, and 1,1-dimethylcyclopropane for the second[10].

In contrast to alkylcarbenes, arylcarbenes[13,14] undergo telomerisation or recombine to form symmetrical diarylethylenes (30–34%).

In the reaction of organolithium compounds with methylene dibromide, a bromine atom and not a hydrogen atom is split off from the latter:

$$RLi + CH_2Br_2 \rightarrow RBr + CH_2BrLi \rightarrow \ddot{C}H_2 + LiBr .$$

The carbene adds to olefins[4,26,27] or is inserted in the carbon–metal bond of the organometallic compound taken in excess[28]. Bromobenzene (25%), benzyl bromide (21%), and dibenzyl (37%) were isolated from the reaction mixture of phenyl-lithium[29] with methylene dibromide. In the reaction of methyl-lithium[30] with methylene dibromide the products are methyl bromide (5%), ethyl bromide (48%), and propyl bromide (13%):

$$RLi + \ddot{C}H_2 \rightarrow RCH_2Li ,$$

$$RCH_2Li + \ddot{C}H_2 \rightarrow RCH_2CH_2Li ,$$

$$RCH_2Li\ (RCH_2CH_2Li) + CH_2Br_2 \rightarrow RCH_2Br\ (RCH_2CH_2Br) + CH_2BrLi ,$$

$$RCH_2Li + RCH_2Br \rightarrow RCH_2CH_2R + LiBr .$$

Butyl-lithium reacts with bromochloromethane[31] at –110°C with formation of chloromethyl-lithium (90%) and bromochloromethyl-lithium (10%). The first compound was identified by carboxylation to chloroacetic acid. Its reaction with cyclohexene gives norcarane[32]. Chloromethyl-lithium is less stable than dichloromethyl-lithium.

Reactions of organolithium compounds with substituted dihalogenomethanes (dibromodiphenylmethane[33], 1,1-dibromoalkanes[30,34,35], and dichlorodiphenylmethane[29]) have been described. The products of the reaction of phenyl-lithium with dichlorodiphenylmethane are tetraphenylethylene and triphenylmethane.

Organolithium compounds react vigorously with tri- and tetra-halogenomethanes. The primary reaction product is a trihalogenomethyl derivative of lithium:

$$RLi + CXCl_3 \rightarrow RX + Cl_3CLi ,$$

$$(R{=}CH_3,\ C_2H_5,\ n\text{-}C_4H_9,\ C_6H_5\ \text{etc.},\ X{=}H,\ Cl,\ Br,\ I) .$$

† Here and henceforth the yield of the reaction product is indicated in brackets.

The formation of trichloromethyl-lithium has been demonstrated in the reaction of butyl-lithium with chloroform in tetrahydrofuran[39] or in a tetrahydrofuran–ethyl ether–petroleum ether mixture[11] at –110°C. The compound was identified by the products of its reaction with mercury(II) chloride, carbon dioxide, and benzophenone. The reaction with mercury(II) chloride led to the isolation of bis(trichloromethyl)mercury (m.p. 146.5–148.5°C with decomposition) in 91% yield. It has been noted[36] that trichloromethyl-lithium is less stable than dichloromethyl-lithium. At –65°C it decomposes in 30 min to the extent of 40–50%:

$$Cl_3CLi \rightarrow LiCl + \ddot{C}Cl_2 .$$

Tribromomethyl-lithium was obtained by the reaction[37] of butyl-lithium or phenyl-lithium with carbon tetrabromide in tetrahydrofuran solution at –110°C and also by the reaction[38] of trichloromethyl-lithium with carbon tetrabromide. It was identified by carboxylation to tribromoacetic acid. Bromoform is formed in its reaction with methanol[37].

Organolithium compounds react with $CXCl_3$ (X = H, Cl, Br, or I) in the presence of cyclohexene[11,25,26,36,39,40] with formation of 7,7-dichloronorcarane, the yield of which is 50–90%. However, the yield of 7,7-dibromonorcarane in the analogous reaction with bromoform[4,27] and carbon tetrabromide[26,37] is low (8–19%).

The formation of dihalogenonorcaranes has been regarded[33,36,41–43] as a result of the predominantly molecular interaction of trihalogenomethyl-lithium with the olefin and not the addition of the free dihalogenocarbene to cyclohexene.

Franzen[44–46] believes that butyl-lithium reacts with dibromodifluoromethane, forming free difluorocarbene. The latter adds to olefins, triphenylphosphine, and butyl-lithium taken in excess. The involvement of difluorocarbene is postulated in the reactions of the lithium compound with trifluoroiodomethane[47], which takes place with formation of tetrafluoroethylene (43%).

The reactions of organolithium compounds with polyhalogenomethanes are frequently employed as a source of carbenes for a wide variety of organic syntheses based on the latter.

Thus alkyl and aryl derivatives of lithium react vigorously with polyhalogenomethanes at a low temperature. In the initial stages of the reaction the corresponding halogenomethyl derivatives of lithium are produced. They decompose with formation of lithium halides and reactive carbenes.

It is to be expected that the organometallic compounds of the remaining alkali metals will react similarly with polyhalogenomethanes.

III. REACTIONS OF ORGANOMETALLIC COMPOUNDS OF GROUP II ELEMENTS

The reactions of organometallic compounds of Group II elements with polyhalogenomethanes have been investigated for magnesium, zinc, cadmium, and mercury compounds. In such reactions the organic derivatives of these elements show markedly different reactivities.

Organomagnesium compounds react vigorously with various halogeno-derivatives at low temperatures and therefore their reactions do not require initiation.

The alkyl compounds of zinc and cadmium react fairly readily with halogenomethanes ($CHBr_3$, $CHCl_3$, CCl_4) but the reactions of aryl derivatives take place only in the presence of an initiator.

The reactions of organomercury compounds with polyhalogenomethanes are observed on heating to the temperature of the onset of decomposition of the former compounds. The reactions occur more readily in the presence of oxygen and peroxides or under the influence of ultraviolet light.

1. Reactions of Organomagnesium, Organozinc, and Organocadmium Compounds

The reactions of organomagnesium compounds with polyhalogenomethanes have been investigated for asymmetric compounds of the type RMgX (R = alkyl, or aryl and X = halogen). The reaction of phenylmagnesium bromide[48] with chloroform leads to the formation of triphenylmethane (80%). Its yield is lower (about 25%) in the corresponding reactions[49] with bromoform and iodoform. Later it was shown[50] that chloroform reacts with phenylmagnesium bromide to form triphenylmethane (76%) and small amounts of biphenyl and bromobenzene. The products of the reaction of bromoform and iodoform with this magnesium derivative are tetraphenylethane (up to 60%) and triphenylmethane[51]. The products of the reaction of phenylmagnesium bromide with carbon tetrachloride are hexaphenylethane (50–80%) and bromobenzene[52]. A complex mixture of products is formed in the reactions of alkyl derivatives of magnesium. Ethylmagnesium bromide reacts with carbon tetrachloride to form methane and ethylene[53]. The products of its reaction with bromoform are ethyl bromide, methylene dibromide, 3-methylpentane, and acetylene[51].

The reactions of organomagnesium compounds have been investigated in greatest detail by Villieras[54–57]. It was established that these reactions, like those of organolithium compounds, lead to the formation of intermediate halogenomethyl derivatives of the metal. In the reaction of isopropylmagnesium chloride with dihalogenomethane[56] at −80°C the exchange of the halogen in CH_2X_2 for the MgCl group is observed, the halogens being arranged in the following sequence in terms of the ease of their exchange:

$$I > Br \gg Cl,$$
$$RMgCl + CH_2X_2 \rightarrow RX + XCH_2MgCl.$$

Grignard reagents react with bromotrichloromethane[56], carbon tetrachloride, and chloroform[57], forming the trichloromethyl derivative CCl_3MgX. The final products of the reaction of RCH_2MgCl with chloroform are RCH_2Cl and a mixture of olefins ($RCH{=}CHCH_2R$ and $RCH{=}CH_2$). In the reaction of organomagnesium compounds[57] with bromoform the products are alkyl bromides and the dibromomethyl compound $CHBr_2MgX$, which decomposes with formation of bromocarbene or reacts with the initial organometallic compound:

$$CHBr_2MgX + RMgX \rightarrow MgXBr + RCHBrMgX \downarrow \; RC\ddot{H} + MgXBr.$$

The alkylcarbene is converted into a mixture of various olefins. It is suggested[57] that the reactions of organomagnesium compounds with polyhalogenomethanes proceed via a four-centre transition state:

$$CHBr_3 + RMgCl \rightleftharpoons \left[\begin{matrix} HBr_2C\cdots MgCl \\ \quad\;\; \cdots \\ Br\cdots R \end{matrix}\right] \rightleftharpoons CHBr_2MgCl + RBr.$$

Organozinc and organocadmium compounds R_2M exhibit the same reactivity in relation to polyhalogenomethanes, which depends on the nature of the group R linked to the metal atom. Alkyl compounds of zinc[58–60] and cadmium[61] react vigorously with bromoform, chloroform, and carbon tetrachloride at room temperature. Diethylzinc also reacts with chloroiodomethane[62] and methylene di-iodide[63,64] with formation of unsaturated hydrocarbons. The reaction of diethylzinc with methylene di-iodide[65,66] and also with ethylidene di-iodide[67,68] in the presence of olefins is accompanied by the formation of cyclopropanes (30–90%):

$$(C_2H_5)_2Zn + CH_2I_2 \rightarrow C_2H_5I + C_2H_5ZnCH_2I \xrightarrow{>C=C<} >C(CH_3)-C< + C_2H_5ZnI.$$

Aryl compounds (diphenylzinc and diphenylcadmium[69]) do not react with chloroform and carbon tetrachloride even when the reaction mixture is heated to 100°C. However, in the presence of oxygen the reactions proceed readily at room temperature.

The principal products of the reaction of diethylcadmium with carbon tetrachloride are ethyl chloride, ethylcadmium chloride, and cadmium chloride, the yield of the latter increasing with the molar ratio[61] $OCl_4 : R_2Cd$. When cyclohexene is introduced into the reaction mixture, the reaction is retarded so much that an increase of temperature to 80°C is required for its occurrence. 7,7-Dichloronorcarane was not detected in the products. The mechanism of the reaction of diethylcadmium with carbon tetrachloride is somewhat obscure.

As mentioned above, aryl compounds of zinc and cadmium are inert with respect to polyhalogenomethanes under the usual conditions. When oxygen is introduced into the reaction mixture[70,71], the reaction between phenyl derivatives [of the two metals] and $CXCl_3$ (X = H or Cl) proceeds readily with formation of benzene (X = H), chlorobenzene (X = Cl), ααα-trichlorotoluene, phenol, biphenyl, and hexachloroethane. The initiating effect of oxygen is associated with the oxidation of the organometallic compound, which is accompanied by the generation of phenyl radicals. The latter react with the polyhalogenomethane or the initial zinc or cadmium compound:

$$C_6H_5^{\cdot} + CXCl_3 \rightarrow C_6H_5X + Cl_2C^{\cdot},$$
$$(X{=}H, D, Cl)$$
$$C_6H_5^{\cdot}\,(Cl_2C^{\cdot}) + (C_6H_5)_2M \rightarrow C_6H_5C_6H_5\,(C_6H_5CCl_3) + C_6H_5M^{\cdot},$$
$$(M{=}Zn, Cd)$$
$$C_6H_5M^{\cdot} + CXCl_3 \rightarrow C_6H_5MCl + \dot{C}XCl_2,$$
$$2\dot{C}XCl_2 \rightarrow CXCl_2{-}CXCl_2.$$

Thus the reaction of diphenylzinc[71] and diphenylcadmium[70] with chloroform and carbon tetrachloride in an oxygen atmosphere involves the participation of free radicals.

2. Reactions of Organomercury Compounds

The greatest number of communications deal with reactions of organomercury compounds with chloroform and carbon tetrachloride. Mercury compounds react with polyhalogenomethanes on heating to the temperatures of the onset of decomposition of the organometallic compound. As early as 1864, Alexeyeff and Beilstein concluded[60] that the reaction of diethylmercury with bromoform is accompanied by the formation of ethyl bromide and propene. In the reaction of diethylmercury with iodoform[72], ethylmercury iodide, ethyl iodide, ethylene, and acetylene are formed. Diphenylmercury does not react at 130°C with bromoform and chloroform but does react with iodoform, forming tri-iodomethylphenylmercury[73] $C_6H_5HgCI_3$ (m.p. 153–155°C). We believe that the asymmetric mercury

compound and the corresponding halogenomethyl derivatives of magnesium discussed above are not formed by the same mechanism. In the present case the reaction probably begins with the decomposition of iodoform:

$$CHI_3 \rightarrow HI + \ddot{C}I_2 ,$$
$$(C_6H_5)_2Hg + HI \rightarrow C_6H_6 + C_6H_5HgI ,$$
$$C_6H_5HgI + \ddot{C}I_2 \rightarrow C_6H_5HgCI_3 ,$$
$$C_6H_5HgCI_3 + \ddot{C}I_2 \rightarrow C_6H_5HgI + C_2I_4 .$$

These processes account for the formation of the reaction products.

Diphenylmercury and dinaphthylmercury[74-76] begin to react with chloroform and carbon tetrachloride above 200°C. The principal products of the reaction of diphenylmercury with the above halogenomethanes are phenylmercury chloride, benzene, $\alpha\alpha\alpha$-trichlorotoluene, and hexachloroethane. The reaction has a free-radical mechanism:

$$R_2Hg \rightarrow RHg^{\cdot} + R^{\cdot} , \quad (1)$$
$$RHg^{\cdot} + CXCl_3 \rightarrow RHgCl + Cl_2XC^{\cdot} , \quad (2)$$
$$(X=H, Cl)$$
$$R^{\cdot} + CXCl_3 \rightarrow RX + Cl_3C^{\cdot} ,$$
$$Cl_3C^{\cdot} + R_2Hg \rightarrow RCCl_3 + RHg^{\cdot} , \quad (3)$$
$$2Cl_3C^{\cdot} \rightarrow C_2Cl_6 .$$

Phenylmercury radicals not only react with the polyhalogenomethane to form phenylmercury chloride but also decompose with the liberation of mercury or recombine:

$$2RHg^{\cdot} \rightarrow RHg{-}HgR \rightarrow R_2Hg + Hg .$$

Alkyl compounds of mercury[77-79] R_2Hg (R = C_2H_5,[79] n-C_3H_7,[78,80] iso-C_3H_7,[77] and n-C_4H_9[79]) react in a more complex manner with chloroform and carbon tetrachloride, forming alkylmercury chloride, mercury, calomel, alkyl chloride, chloroform, saturated hydrocarbons (RH) and olefins (R-H), and hexachloroethane, and in the reaction with chloroform also methylene dichloride. The initial stage of these reactions is the dissociation of the organometallic compound into radicals according to Eqn. (1). Possibly there is a molecular interaction of the organomercury compound with the polyhalogenomethane accompanied by the formation of alkyl mercury chloride and free radicals:

$$R_2Hg + CXCl_3 \rightleftarrows [R_2Hg \cdot Cl_3XC] \rightarrow RHgCl + R^{\cdot} + Cl_2XC^{\cdot} . \quad (4)$$

One can also postulate that in the initial reaction stage a trichloromethyl derivative of mercury is formed and serves as a source of dichlorocarbene, which would initiate the process. However, the introduction into the reaction mixture of trichloromethyl compounds of mercury[79], which decompose under the reaction conditions with generation of $\ddot{C}Cl_2$, did not lead to its acceleration.

The occurrence of free-radical processes has been confirmed using inhibitors[79]. It has been shown[77-79] that initiated decomposition of the initial organometallic compound plays a considerable role in these reactions:

$$R^{\cdot} (Cl_2XC^{\cdot}) + RHgR \rightarrow RH (Cl_2XCH) + \dot{R}_{-H}HgR . \quad (5)$$

This results in the formation of unstable organomercury radicals with an unpaired electron at the carbon atom. The nature of their decomposition depends to a considerable degree on the nature of the alkyl group linked to the metal atom:

$$\dot{R}_{-H}HgR \begin{cases} \rightarrow R_{-H} + RHg^{\cdot} , & (a) \\ \rightarrow R_{-H} + Hg + R^{\cdot} . & (b) \end{cases} \quad (6)$$

The radicals formed from the ethyl derivative decompose both via mechanism (6a) and (6b). With increase of the chain length of the primary alkyl residue (R = n-C_3H_7 and n-C_4H_9), their decomposition takes place predominantly via reaction (6b), while the corresponding derivative containing a secondary alkyl residue (iso-C_3H_7 and s-C_4H_9) is cleaved with formation of alkylmercury radicals via reaction (6a). The latter react with chloroform and carbon tetrachloride forming the alkyl mercury chloride [reaction (2)].

Alkyl radicals participating in the reaction initiate the decomposition of the organometallic compound or react with polyhalogenomethanes. It has been shown for isopropyl radicals[77] that they abstract from chloroform not only hydrogen atoms but also chlorine atoms. The ease of abstraction of hydrogen, deuterium, and chlorine from $CHCl_3$ and $CDCl_3$ decreases in the sequence H > Cl ≃ D.

Among organomercury compounds, alkoxy-derivatives[80,81] of the type RHgOR′ react with chloroform most readily. Their reaction[81] takes place at room temperature with a quantitative yield of the corresponding trichloromethyl compounds:

$$RHgOR' + CHCl_3 \rightarrow RHgCCl_3 + R'OH$$
$$(R=n\text{-}C_3H_7, \text{ cyclo-}C_6H_{11}, C_6H_5CH_2, C_6H_5; R'=(CH_3)_3C) .$$

Thus the thermal reactions of the symmetrical mercury compounds R_2Hg with polyhalogenomethanes have a free-radical mechanism.

Organomercury compounds dissociate into radicals under the influence of ultraviolet light:

$$R_2Hg{-} \begin{cases} \rightarrow 2R^{\cdot} + Hg , \\ \rightarrow RHg^{\cdot} + R^{\cdot} . \end{cases}$$

The photochemical reaction of mercury compounds with polyhalogenomethanes takes place readily at room temperature. These processes were investigated in greatest detail by Razuvaev and coworkers.

The photolysis of R_2Hg has been investigated in solution in bromoform (R = C_6H_5,[82] carboxyphenyl, or methoxycarbonylphenyl[83]), chloroform (R = CH_3,[84] C_2H_5,[85] 2-methoxycarbonylethyl[86], mesityl[87], $C_6H_5CH_2$,[88] $C_6H_5CH_2CH_2$,[89] C_6H_5,[82,90] o-tolyl[91], p-tolyl[92], p-anisyl[93], p-chlorophenyl[91], carboxyphenyl and methoxycarbonylphenyl[83], α-naphthyl[94], and β-naphthyl[95]) and carbon tetrachloride (R = CH_3,[84,96] C_2H_5,[79] n-C_3H_7,[78,79] iso-C_3H_7,[78,79] n-C_4H_9,[79] s-C_4H_9,[79] $C_6H_5CH_2$,[96] C_6H_5,[75,90,96] o-tolyl[91], p-tolyl[92], p-anisyl[93], carboxyphenyl and methoxycarbonylphenyl[83], α-naphthyl[94], and β-naphthyl[95]). In these reactions the RHg radicals abstract a halogen atom from the polyhalogenomethane. Mercury and calomel are formed together with the alkyl- or aryl-mercury chloride. The yields of these substances depend on the nature of the group R linked to the mercury atom. The relative amounts of mercury and alkylmercury chloride vary particularly markedly in the photochemical reactions of alkyl derivatives of mercury with carbon tetrachloride. As in thermal reactions, the yield of mercury increases with the chain length of the primary alkyl residue[79] (more than 90% for di-n-propylmercury). On the other hand, with the secondary isopropyl residue, the corresponding alkylmercury chloride is formed preferentially. In these processes the organomercury compounds undergo initiated decomposition via mechanisms (5) and (6). In contrast to thermal reactions, the olefins formed react with the solvent giving 1,1,1-trichloroalkanes or 1,1,1,3-tetrachloroalkanes:

$$-\overset{|}{C}=\overset{|}{C}- + Cl_3C^{\cdot} \rightarrow -\overset{|}{\dot{C}}-\overset{|}{C}CCl_3 \xrightarrow{CXCl_3} -\overset{|}{C}X-\overset{|}{C}CCl_3 \quad (7)$$
$$(X = H, Cl)$$

The presence of calomel in the reaction mixture is due to the reaction of mercury[97] with carbon tetrachloride or the dealkylation of alkylmercury chloride under the influence of radicals:

$$RHgCl + Cl_3C^{\cdot} \rightarrow CHCl_3 + \dot{R}_{-H}HgCl \rightarrow R_{-H} + {}^1/_2Hg_2Cl_2 . \quad (8)$$

The radical R formed in the reaction interacts with the organometallic compound or the halogeno-derivative, abstracting chlorine from carbon tetrachloride or hydrogen from chloroform and bromoform, with the exception of benzyl radicals[88] which largely recombine. In the photolysis of organomercury compounds in a mixture of a protic solvent (alcohol, ethylcellosolve) and carbon tetrachloride the R radicals react only with the first solvent, abstracting a hydrogen atom[98] and forming RH.

In the photochemical reactions with chloroform and carbon tetrachloride the asymmetric organometallic compounds RHgR′ also undergo dealkylation[88,98,99] with formation of RHgCl. The more firmly bound group remains attached to mercury. In many cases the process is accompanied by symmetrisation[100]:

$$2RHgR' \rightarrow R_2Hg + R'_2Hg .$$

Among the mixed mercury compounds, peroxy-derivatives of the type[101] RHgOOR′, hydroxides[102-106] RHgOH (R = C_6H_5,[102,103,105,106] $C_6H_5CH_2$,[103] mesityl[104], or *p*-dimethylaminophenyl[104]), and benzyl- and phenylmercury derivatives of succinimide[107,108] react most readily with carbon tetrachloride and chloroform. The reactions of these compounds lead to the formation of the corresponding chlorides RHgCl.

In the case of many hydroxides, the initial stage of the process is usually believed to be their dissociation into radicals:

$$RHgOH \rightarrow RHg^{\cdot} + HO^{\cdot} .$$

We believe that the mechanism of the reaction of the hydroxides with polyhalogenomethanes is more complex. It is doubtful if these compounds undergo homolysis at the Hg–O bond, which is stronger than the Hg–C bond. Probably the comparatively ready occurrence of the reaction is due to the participation in it of oxides, which are present in the hydroxides and are formed as a result of the dehydration of the latter[109]:

$$2RHgOH \rightleftarrows (RHg)_2O + H_2O .$$

This conclusion is based on the finding that alkoxy-derivatives of mercury RHgOR′ (in this case R′ = RHg) react with polyhalogenomethanes under fairly mild conditions.

The reactions of organomercury compounds with halogenomethanes do not take place solely under the influence of heat and light. Organic peroxides and oxygen have an initiating effect on them. Razuvaev showed[74] that the temperature in the reaction of diphenylmercury with carbon tetrachloride may be considerably reduced (from 260° to 50°C) when benzoyl peroxide is introduced into the reaction mixture. Acetyl peroxide has a similar effect[110]. The principal reaction products are phenylmercury chloride, ααα-trichlorotoluene, and hexachloroethane. In the reaction with chloroform the products are benzene, phenylmercury chloride, and also small amounts of ααα-trichlorotoluene and hexachloroethane. The initial stage of the process is the decomposition of the acyl peroxide:

$$(R'COO)_2 \rightarrow R'^{\cdot} + R'COO^{\cdot} + CO_2 ,$$
$$(R' = CH_3, C_6H_5)$$

The methyl or phenyl radicals formed in this process interact with carbon tetrachloride generating trichloromethane radicals. ααα-Trichlorotoluene is formed via reaction (3) and phenylmercury chloride via reaction (2). The reaction of asymmetric organometallic compounds RHgR′ with carbon tetrachloride in the presence of peroxides[111,112] is similar to that of diphenylmercury. It has been established that the affinity for the free radical $Cl_3C^{\cdot}$ decreases in the series 2,4,6-$(CH_3)_3C_6H_2$, α-$C_{10}H_7$, *p*-$CH_3C_6H_4$, *o*-$CH_3C_6H_4$, *m*-$CH_3C_6H_4$, C_6H_5, C_2H_5, C_4H_9, $C_6H_5CH_2$, cyclo-C_6H_{11}.

The more reactive group R in RHgR′ recombines with the trichloromethyl radical and the group R′ remains bound to mercury in the resulting compound R′HgCl.

Alkyl derivatives of mercury react somewhat differently with carbon tetrachloride in the presence of a peroxide. The principal products of the reaction of dibutylmercury[113] with carbon tetrachloride (100°C, 7h) initiated by benzoyl peroxide are 1,1,1,3-tetrachloropentane, butyl chloride, chloroform, mercury, and butylmercury chloride. 1,1,1-Trichloropentane was not detected. On the basis of the reaction products, it was concluded that trichloromethyl radicals react with the organometallic compound, forming chloroform:

$$Cl_3C^{\cdot} + R_2Hg \rightarrow R_{-H} + CHCl_3 + RHg^{\cdot} .$$
(olefin)

It is believed[113] that butylmercury radicals decompose with liberation of mercury (up to 63–73%) or react with carbon tetrachloride, forming butylmercury chloride. The formation of tetrachloropentane is due to reaction (7). Under the influence of radicals, dibutylmercury undergoes a decomposition in this reaction analogous to that described above for the thermal and photochemical reactions of alkyl compounds of mercury[79] [reactions (5) and (6)].

Perbenzoic acid[114], the peroxides formed by the oxidation of benzaldehyde or cyclohexene[115], t-butyl peroxide[116], t-butyl hydroperoxide[116], and oxygen[79] have an initiating effect on the reaction of diphenylmercury with carbon tetrachloride or chloroform. It is suggested that perbenzoic acid initially reacts with the organometallic compound to form phenylmercury perbenzoate[114], which decomposes into radicals. t-Butyl hydroperoxide reacts similarly[116]:

$$R_2Hg + (CH_3)_3COOH \rightarrow RH + RHgOOC(CH_3)_3 \begin{cases} \rightarrow RHg^{\cdot} + (CH_3)_3COO^{\cdot}, \\ \rightarrow RHgO^{\cdot} + (CH_3)_3CO^{\cdot} . \end{cases}$$

The initiating effect of t-butyl peroxide[78,116] is due to its reaction with the organometallic compound induced by the nucleophilic attack by active oxygen on the mercury atom with formation of a complex. The decomposition of the latter is accompanied by the generation of free radicals:

$$R_2Hg + (CH_3)_3COOC(CH_3)_3 \rightleftarrows \left[\begin{matrix} R\text{—}Hg\text{—}R \\ \uparrow \\ (CH_3)_3COOC(CH_3)_3 \end{matrix} \right] \rightarrow \begin{matrix} RHgOC(CH_3)_3 \\ + \\ R^{\cdot} + (CH_3)_3CO^{\cdot} \end{matrix}$$

(R = n-C_3H_7,[78] iso-C_3H_7,[78] or C_6H_5[116]).

In these reactions alkyl derivatives of mercury and the alkylmercury chlorides formed mainly decompose under the influence of radicals[78] [see reactions (5), (6), and (8)]. The olefins thus produced react with the solvent, giving a high yield of the corresponding trichloro- or tetrachloroalkanes [reaction (7)].

Organometallic compounds of the type R_2Hg (R = C_2H_5,[79] n-C_3H_7,[78] iso-C_3H_7,[117,118] n-C_4H_9,[79] s-C_4H_9,[79] t-C_4H_9,[118] cyclo-C_6H_{11},[119] or C_6H_5[79]) react comparatively readily with carbon tetrachloride or chloroform in the presence of oxygen. The initial step in the reaction is nucleophilic attack by oxygen on the mercury atom in the

organometallic compound accompanied by the formation of an unstable organomercury peroxide[118,120,121]:

$$R_2Hg + O_2 \rightleftarrows [R_2Hg^{\cdot}O_2] \rightarrow RHgOOR \begin{cases} \longrightarrow RHg^{\cdot} + RO_2^{\cdot}, \\ \longrightarrow RHgO^{\cdot} + RO^{\cdot}. \end{cases}$$

The oxidation products of an organomercury compound[118,120,121] are an alkoxy-compound RHgOR, an alcohol ROH, a ketone or an aldehyde, mercury, and also hydrocarbons. The oxidation is accompanied by the generation of free radicals which react with polyhalogenomethanes. The alkoxy-compound obtained also readily reacts with chloroform and carbon tetrachloride. This results in the formation of a trichloromethyl compound of mercury, which decomposes under the reaction conditions into an alkylmercury chloride and dichlorocarbene:

$$RHgCCl_3 \rightleftarrows RHgCl + \ddot{C}Cl_2 . \qquad (9)$$

In the reactions with added cyclohexene in the reaction mixture, 7,7-dichloronorcarane was detected[79]. Seyferth et al. established[122] that reaction (9) is reversible and the rate of decomposition depends on the nature of the solvent.

The oxidation of organomercury compounds in solution in polyhalogenomethanes is accompanied by initiated decomposition processes via mechanisms (5), (6), and (8), which in this case are less important than in thermal and photochemical reactions in the absence of oxygen[79]. Regardless of the nature of the alkyl group, the main dealkylation product of the organometallic compound is alkylmercury chloride.

Diphenylmercury is known to react[123] with chloroform in the presence of bismuth trichloride, forming phenylmercury chloride, benzene, and biphenyl. Bismuth trichloride probably behaves as a catalyst.

Thus organomercury compounds of the type R_2Hg do not react with polyhalogenomethanes under ordinary conditions. Their reaction is observed only under the influence of heat, ultraviolet light, oxygen, or organic peroxides and proceeds via a free-radical mechanism.

IV. REACTIONS OF ORGANIC COMPOUNDS OF GROUP III ELEMENTS

The reactions of organometallic compounds of group III elements with polyhalogenomethanes have been investigated mainly for alkyl compounds of aluminium and thallium. There is only one report[124] of the reaction of triethylindium-ether with chloroform and bromoform in hexane solution accompanied by the formation of the corresponding diethylindium halide. The reactions of organoboron compounds with polyhalogenomethanes have been described using as examples the reactions of vinylarylboron butoxide with bromotrichloromethane[125] at room temperature under the influence of ultraviolet light:

$$CH_2{=}CH{-}\underset{\displaystyle C_6H_5}{\underset{|}{B}}{-}OC_4H_9 + CBrCl_3 \rightarrow Cl_3CCH_2CHBr{-}\underset{\displaystyle C_6H_5}{\underset{|}{B}}{-}OC_4H_9 .$$

The first report on the reaction of organoaluminium compounds with chloroform and carbon tetrachloride was published by Hilpert and Grüttner[126]. In particular, they concluded that, when triphenylaluminium is dissolved in chloroform, triphenylmethane and a crystalline substance, probably diphenylaluminium chloride, are formed. The views concerning the reactivity of alkyl compounds of aluminium in relation to polyhalogenomethanes and the mechanism of their reaction with the latter are extremely contradictory.

It has been noted[127] that triethylaluminium reacts slowly with methylene dichloride at 55°C. Under these conditions, ethylaluminium sesquichloride and diethylaluminium hydride do not react with this chloro-derivative. However, methylene di-iodide reacts with triethylaluminium[128] (in molar proportions of 1 : 2) in benzene solution at room temperature with formation of ethyl iodide and ethylene. The iodomethyl derivative of diethylaluminium is formed as an intermediate:

$$R_3Al + CH_2I_2 \rightarrow RI + R_2AlCH_2I \rightarrow R_2AlI + {}^1/_2C_2H_4 .$$

When the reaction was carried out with added cyclohexene, norcarane was isolated (20%). The participation of free carbene in the reaction has not been suggested[129,130].

Chloroform reacts with triethylaluminium[127,131] more vigorously than does methylene dichloride. For equimolar proportions of the reactants, the main products are methylene dichloride and ethyl chloride. At 70°C hydrocarbons (butane, butene, hexane, and hexene) are formed in addition to the above compounds. The reaction of diethylaluminium hydride with chloroform (at the boiling point of the latter) is accompanied by the formation of methyl chloride. Under these conditions, ethylaluminium sesquichloride does not react with trichloromethane. The reaction of aluminium compounds with chloroform is regarded as a free-radical process[127]. However, Miller[128] believes that the reactions of organoaluminium compounds with trihalogenomethanes proceed via a stage involving the formation of halogenomethyl derivatives. In particular, he showed that triethylaluminium reacts with bromoform in benzene solution, forming the dibromomethyl derivative $(C_2H_5)_2AlCHBr_2$.

There are contradictory data on the behaviour of organoaluminium compounds in carbon tetrachloride solutions. According to some reports[132,133], a mixture of such compounds explodes. According to others[134,135], aluminium compounds do not react with carbon tetrachloride at room temperature and the latter is recommended as a solvent for them. Vigorous reaction between triethylaluminium and carbon tetrachloride with evolution of gaseous substances is observed in the presence of titanium tetrachloride[135]. It is suggested that diethylaluminium dichloride is formed initially and is then readily dealkylated[136] by carbon tetrachloride. It is believed[135] that the reaction proceeds with participation of a carbonium ion:

$$2CCl_4 + C_2H_5AlCl_2 \rightleftarrows 2Cl_3C^{\cdot} + C_2H_5^{+}AlCl_4^{-},$$

$$C_2H_5^{+}AlCl_4^{-} + CCl_4 \rightarrow C_2H_5Cl + CCl_3^{+}AlCl_4^{-} \rightarrow AlCl_3 + CCl_4 ,$$

$$C_2H_5^{+}AlCl_4^{-} + C_2H_5AlCl_2 \rightarrow C_2H_6 + (AlCl_4^{-} + \overset{+}{C}_2H_4AlCl_2) \downarrow 2\,AlCl_3 + C_2H_4 .$$

In contrast to ethylaluminium dichloride, diethylaluminium chloride does not react with carbon tetrachloride in boiling benzene[137].

Reinheckel[127,138,139] elucidated the reactions of organoaluminium compounds with carbon tetrachloride to the greatest extent. He showed that, depending on the reaction conditions (molar ratio of the starting materials and temperature of the reaction mixture), the type of interaction changes. A 1 : 3 mixture of triethylaminium and carbon tetrachloride is safe at 0°C, but explodes at 20°C. The mixture in molar proportions of 1 : 10 can be controlled not only at room temperature but also at 75–80°C. The main reaction products are chloroform, methylene chloride, and monochloro-substituted methane, ethane, and propane. These compounds are also formed in the reaction of ethylaluminium dichloride[139] with carbon tetrachloride. Diethylaluminium and carbon tetrachloride in

proportions of 1 : 5 react slowly with formation of chloroform and ethyl chloride. A mixture of diethylaluminium hydride and carbon tetrachloride in molar proportions of 1 : 3 explodes at 80°C, but when the reaction ratio is changed to 1 : 5 the reaction takes place smoothly. The sesquichloride reacts with carbon tetrachloride at a moderate rate in proportions of 1 : 10 but an equimolar mixture explodes at room temperature[127]. Reinheckel believes that these reactions have a free-radical mechanism. At the same time it has been shown[140] that tri-isobutylaluminium reacts with carbon tetrachloride, forming a trichloromethyl derivative:

$$R_3Al + CCl_4 \rightarrow RCl + R_2AlCCl_3 \rightarrow R_2AlCl + \ddot{C}Cl_2 .$$

The yield of di-isobutylaluminium chloride is 92% and that of isobutyl chloride 25%. The dichlorocarbene formed reacts with the initial organometallic compound or cyclohexene and gives rise to 7,7-dichloronorcarane in reactions where the olefin has been added.

The literature data discussed above lead to the conclusion that the initial stage in the reaction of organoaluminium compounds with polyhalogenomethanes, as for the lithium and magnesium compounds, is the formation of the corresponding intermediate halogenomethyl derivatives, which decompose with generation of carbenes. By virtue of their exothermic nature, these reactions are probably accompanied by the thermal decomposition of the organoaluminium compounds.

It has been suggested[141] that unstable halogenomethyl derivatives are formed in the reaction of trimethylthallium with polyhalogenomethanes: CHX_3 (X = Cl, Br, or I) and methylene dichloride and dibromide. The reaction products are methane and $(CH_3)_2TlX$. However, trimethylthallium does not react with carbon tetrachloride and methylene dichloride at room temperature. The reaction of dimethylthallium ethoxide with chloroform results in a quantitative yield of dimethylthallium chloride[141].

V. REACTIONS OF ORGANIC COMPOUNDS OF GROUP IV ELEMENTS

The majority of organic derivatives of non-transition elements (silicon, germanium, tin, and lead) react with polyhalogenomethanes in the same way as organomercury compounds, in the presence of initiators or catalysts. The reactivity increases from silicon to lead compounds. Organotitanium compounds, which have covalent Ti–C σ bonds, react with halogenomethanes much more readily.

1. Reactions of Organosilicon and Organogermanium Compounds

Organosilicon and organogermanium derivatives are fairly inert in relation to polyhalogenomethanes. Tetraphenylsilicon[142] does not react with carbon tetrachloride at the boiling point of the reaction mixture. Tributylgermanium hydride[143–145] reacts with carbon tetrachloride only at 200–220°C with formation of tributylgermanium chloride and chloroform.

The unusual behaviour of tetraethylsilicon in carbon tetrachloride solution on irradiation with ultraviolet light is of interest. Under these conditions, tetraethylsilicon is chlorinated without the abstraction of a radical with formation of chloroethyltriethylsilicon[146] (tetraphenylsilicon and methyltriphenylsilicon did not undergo any changes). The reactions of organosilicon compounds of the type R_4Si, R_3SiH, and R_6Si_2 with polyhalogenomethanes under the influence of organic peroxides have been described.

The main products of the reaction of tetraethylsilicon[146] with carbon tetrachloride in the presence of acyl peroxides are, as in the photochemical reaction, chloroethyltriethylsilicon (a mixture of α- and β-isomers) and chloroform. The free radicals formed in the decomposition of the initiator react with tetraethylsilicon:

$$R'^{\cdot} + (C_2H_5)_4Si \rightarrow R'H + (C_2H_5)_3Si\dot{C}_2H_4 , \quad (10)$$

$$(C_2H_5)_3Si\dot{C}_2H_4 + CCl_4 \rightarrow (C_2H_5)_3SiC_2H_4Cl + Cl_3C^{\cdot} , \quad (11)$$

$$Cl_3C^{\cdot} + (C_2H_5)_4Si \rightarrow CHCl_3 + (C_2H_5)_3Si\dot{C}_2H_4 .$$

In the presence of benzoyl peroxide organosilicon compounds containing double bonds[147] combine with $CXCl_3$ (X = H or Cl) via a free-radical mechanism:

$$R_3SiCH{=}CH_2 \xrightarrow{CXCl_3} R_3SiCHX - \dot{C}H_2CCl_3 . \quad (12)$$

A reaction analogous to reaction (12) has also been described for unsaturated organogermanium compounds[148]. Acetylene derivatives of silicon react with bromotrichloromethane and dibromodichloromethane on irradiation of the reaction mixture by ultraviolet light with formation of the corresponding bromochloropropenylsilanes[149,150].

The reaction of substituted silanes with $CXCl_3$ (X = H, Cl, or Br), carbon tetrabromide, and methylene dibromide has been investigated in the presence of benzoyl peroxide[151–157], t-butyl peroxide[154], and also catalysts—palladium[158], iron pentacarbonyl, or chloroplatinic acid[159]. In this process the polyhalogenomethane is reduced: CX_4 to CHX_3, CHX_3 to CH_2X_2, etc. In the presence of peroxycompounds the reactions proceed via a free-radical chain mechanism[151–157]:

$$(C_6H_5COO)_2 \rightarrow 2C_6H_5COO^{\cdot} ,$$

$$C_6H_5COO^{\cdot} + R_3SiH \rightarrow C_6H_5COOH + R_3Si^{\cdot} ,$$

$$R_3Si^{\cdot} + CH_nX_{4-n} \rightarrow R_3SiX + \dot{C}H_nX_{3-n} ,$$

$$(n=1, 2;\ X=Cl, Br)$$

$$\dot{C}H_nX_{3-n} + R_3SiH \rightarrow CH_{n+1}X_{3-n} + R_3Si^{\cdot} .$$

It has been shown by ESR[160] that the photochemical reaction of substituted silanes and also germanes and stamanes with carbon tetrachloride in the presence of t-butyl peroxide is accompanied by the formation of trichloromethyl radicals:

$$(CH_3)_3COOC(CH_3)_3 \xrightarrow{h\nu} 2(CH_3)_3CO^{\cdot} ,$$

$$(CH_3)_3CO^{\cdot} + R_3EH \rightarrow (CH_3)_3COH + R_3E^{\cdot} ,$$

$$(E=Si, Ge, Sn)$$

$$R_3E^{\cdot} + CCl_4 \rightarrow R_3ECl + Cl_3C^{\cdot} .$$

Photolysis of triethylsilicon iodide in methylene dichloride, chloroform, or carbon tetrachloride solution leads to the formation of triethylsilicon chloride[161]. Polyhalogenomethanes can be arranged in the following sequence in terms of the ease of exchange of iodine for chlorine:

$$CCl_4 > CHCl_3 > CH_2Cl_2 .$$

It is suggested that this exchange takes place via a free-radical chain mechanism.

The reaction of diphenylsilane with methylene di-iodide in the presence of olefins[162] at 189°C is accompanied by the formation of cyclopropanes (17–38%).

The reaction of hexamethyldisilane[163] with carbon tetrachloride in the presence of benzoyl peroxide (at 80°C) or t-butyl peroxide (at 129°C) takes place without the dissociation of the Si–Si bond. It is suggested that (pentamethyldisilyl)methyl radicals participate in the reaction:

they recombine or abstract a chlorine atom from carbon tetrachloride. The primary process is the decomposition of the initiator into radicals, which then react with the initial silicon compound:

$$R^{\cdot} + (CH_3)_6Si_2 \rightarrow R'H + (CH_2)_5Si_2\dot{C}H_2,$$
$$2\,(CH_3)_5Si_2\dot{C}H_2 \rightarrow (CH_3)_5Si_2CH_2CH_2Si_2(CH_3)_5,$$
$$(CH_3)_5Si_2\dot{C}H_2 + CCl_4 \rightarrow (CH_3)_5Si_2CH_2Cl + Cl_3C^{\cdot},$$
$$Cl_3C^{\cdot} + (CH_3)_6Si_2 \rightarrow CHCl_3 + (CH_3)_5Si_2\dot{C}H_2.$$

2. Reactions of Organotin and Organolead Compounds

Organotin and organolead compounds have almost the same reactivity with respect to polyhalogenomethanes. The chemical reactivity of these compounds depends on their type. The hydrides R_3MH react most readily, compounds of the type R_6M_2 react with more difficulty, and the reaction involving R_4M (M = Sn or Pb) is more difficult still. The tetra-aryl organometallic compounds[142] do not react with carbon tetrachloride at the boiling point of the reaction mixture. Tetra-alkyl compounds of tin[164] also do not react with carbon tetrachloride at 100°C. In contrast to the alkoxy-compounds of mercury, monoalkoxy-derivatives of tin are inert with respect to chloroform. Trimethyltin t-butoxide did not react with chloroform on heating the reaction mixture at 140°C for 1 h.[81] However, amino-compounds of the type $R_3SnNR'_2$ undergo an exothermic reaction with CHX_3 (X = Cl or Br), forming trihalogenomethyl derivatives of the organometallic compounds[165-167]:

$$R_3SnNR'_2 + CHX_3 \rightarrow R_3SnCX_3 + R'_2NH.$$

When a mixture of tetra-alkyl compounds of tin with trifluoroiodomethane is heated, fluoroform is formed. In the reaction of tetramethyl-lead with the above halogeno-derivative, a methyl group of the organometallic compound is exchanged for a trifluoromethyl group[168,169], which results in the formation of trifluoromethyltrimethyl-lead $(CH_3)_3PbCF_3$. The reaction takes place similarly under the influence of ultraviolet light. It is suggested that the trifluoromethyl derivative of lead is formed by a free-radical mechanism.

The photochemical reactions of organotin compounds of the type R_4Sn (R = CH_3,[170,171] C_2H_5,[171] n-C_3H_7,[170,171] or C_6H_5[172]) with carbon tetrachloride[171,172] and chloroform[170-172] have been investigated in greater detail. The monochloride and dichloride of alkyl- or aryl-tin derivatives, hydrocarbons, and hexachloroethane were isolated as the main products. In the reaction of the alkylated organometallic compounds with carbon tetrachloride, chloroform and 1,1,1,3-tetrachloroalkanes [see reaction (7)] are also formed. The first step in the reaction is photolysis of the organometallic compound to R and R_3Sn radicals or of carbon tetrachloride to Cl and Cl_3C radicals. Trialkyl(aryl)stannyl radicals react with chloroform or carbon tetrachloride. The resulting $CXCl_2$ radicals (X = H or Cl) react with the alkylated organometallic compounds:

$$\dot{C}XCl_2 + R_4Sn \rightarrow CHXCl_2 + R_3Sn\dot{R}_{-H} \rightarrow R_3Sn^{\cdot} + \underset{\text{(olefin)}}{R_{-H}}.$$

In contrast to the corresponding silicon derivatives [reactions (10) and (11)], the organotin radicals with an unpaired electron at the carbon atom decompose and split off an olefin. Under the reaction conditions, the monochloride of trialkyl(aryl)tin also interacts with polyhalogenomethanes forming R_2SnCl_2.

It is interesting to note that the photolysis of asymmetric tin compounds containing alkyl and aryl groups is accompanied by the abstraction of aryl radicals. Following the reaction of diethyldiphenyltin and dibenzyldiphenyltin[173] with carbon tetrachloride and chloroform, the dichloride of the corresponding dialkyltin was isolated from the reaction mixture.

The photochemical reactions of organolead compounds with polyhalogenomethanes have been hardly investigated. It has been noted[172] that tetraphenyl-lead reacts with chloroform and carbon tetrachloride similarly to diphenylmercury. Diphenyl-lead dichloride, lead chloride, benzene or chlorobenzene, hexachloroethane, and, in the case of chloroform, also metallic lead were isolated from the reaction mixture.

The photolysis of triphenyltin and triphenyl-lead azides in methylene dichloride solution[174] is accompanied by the generation of $(C_6H_5)_3M$ radicals, which react with the halogenomethane, forming triphenyltin or triphenyl-lead chlorides (51-75%).

Oxygen and organic peroxides initiate the reactions of organotin and organolead compounds. The alkyl derivatives of tin[164] R_4Sn (R = C_2H_5, n-C_3H_7, or iso-C_3H_7) react in an atmosphere of oxygen with carbon tetrachloride at 100°C, forming trialkyltin, chloroform, and 1,1,1,3-tetrachloroalkanes as the main products. The organotin compound with a secondary alkyl group (tetraisopropyltin) reacts with carbon tetrachloride at a lower temperature (60°C). It has been noted[175] that oxygen greatly accelerates the reaction of tetramethyl-lead with carbon tetrachloride, which is accompanied by the formation of a white precipitate. The initiating effect of oxygen is associated with the formation of free radicals in the oxidation of the initial tin and lead compounds[176].

The reactions of many organotin compounds (tetraethyltin[177], diethyldimethyltin[177], tetraphenyltin[178], and triethyltin chloride[177]) with carbon tetrachloride in the presence of benzoyl peroxide have been investigated. The reaction of tetraethyltin with carbon tetrachloride at 75-90°C yields triethyltin chloride, diethyltin dichloride, chloroform, ethylene, ethane, benzoic acid, carbon dioxide, and many other compounds[177]. Under these conditions, triethyltin chloride reacts with carbon tetrachloride similarly to tetraethyltin, forming the same products. Tetraphenyltin undergoes complete dearylation. Tin(IV) chloride, chlorobenzene, hexachloroethane and benzoic and phthalic acids were isolated from the reaction mixture[178]. Tetraphenyl-lead reacts with carbon tetrachloride in the presence of benzoyl peroxide, forming diphenyl-lead dichloride and dibenzoate[178]. These reactions are initiated by the free radicals formed as a result of the decomposition of benzoyl peroxide. The above processes have free-radical chain mechanisms.

Organotin compounds with an unsaturated alkyl group (triethylvinyltin[179] and triphenylvinyltin[180]) combine with polyhalogenomethanes $CXCl_3$ [X = H, Cl, or Br; see the analogous reaction (12)] in the presence of benzoyl peroxide.

The reactions of tin and lead compounds with carbon tetrachloride in the presence of catalysts have been described. In the presence of bismuth trichloride (0.5-1.0 mole per mole of the organometallic compound) the tetraphenyl compounds react with carbon tetrachloride at the boiling point of the reaction mixture, forming chlorobenzene, triphenyltin chloride or triphenyl-lead chloride, and diphenyl-lead dichloride. Bismuth trichloride was recovered quantitatively from the reaction mixture[142]. Alkyl[181,182] and aryl[183,184] compounds of tin also undergo

dealkylation (dearylation) at a comparatively low temperature in the presence of bismuth and aluminium chlorides in chloroform solution.

In the presence of aluminium chloride or boron trifluoride tetramethyl- and tetraethyl-lead[185] react with methylene dibromide, forming compounds having the composition $R_3PbCH_2PbR_3$.

As the number of alkyl (aryl) groups linked to the metal atom decreases, the reactivity of the organotin and organolead compounds in relation to polyhalogenomethanes rises. In contrast to the tetra-alkyl derivatives, hexacyclohexyldilead reacts with carbon tetrachloride even at room temperature, forming tricyclohexyl-lead chloride and dicyclohexyl-lead dichloride[175]. Possibly a trichloromethyl derivative of lead is formed as an intermediate in this process:

$$(C_6H_{11})_3PbPb(C_6H_{11})_3 + CCl_4 \rightarrow (C_6H_{11})_3PbCl + (C_6H_{11})_3PbCCl_3 .$$

In the presence of oxygen the reaction terminates much faster. Then the main products are the chlorides of tricyclohexyl-lead and dicyclohexyl-lead (in nearly equimolar proportions), cyclohexyl chloride, hexachloroethane, and carbon dioxide. In an atmosphere of oxygen this organometallic compound reacts vigorously with carbon tetrabromide and is quantitatively converted into dicyclohexyllead dibromide. The problem of the involvement of trihalogenomethyl compounds in these reactions remains unresolved. However, the analogous trihalogenomethyl derivative of tin has been isolated from the reaction mixture in the reaction between hexamethylditin and trifluoroiodomethane. The reaction takes place on heating[186] to 80°C or on irradiation with ultraviolet light[187,188]:

$$(CH_3)_3SnSn(CH_3)_3 + CF_3I \rightarrow (CH_3)_3SnI + (CH_3)_3SnCF_3 .$$

It is suggested that trifluoromethyltrimethyltin is formed in these processes by a free-radical mechanism:

$$R_3SnSnR_3 \rightarrow 2R_3Sn^{\cdot} ,$$
$$R_3Sn^{\cdot} + CF_3I \rightarrow R_3SnCF_3 + I^{\cdot} ,$$
$$I^{\cdot} + R_3SnSnR_3 \rightarrow R_3SnI + R_3Sn^{\cdot} .$$

One cannot exclude the possibility of the formation of an intermediate complex of the organometallic compound with trifluoroiodomethane.

The reactions of hexa-alkylditin compounds with carbon tetrachloride are initiated by oxygen and acyl peroxides[177,189]. In an atmosphere of oxygen, hexaethylditin reacts with carbon tetrachloride forming a mixture of triethyltin and diethyltin chloride[177]. The products of the reaction carried out in the presence of benzoyl peroxide are ethane, ethylene, butane, carbon dioxide, chloroform, triethyltin chloride and benzoate, and diethyltin dichloride[177,189]. These processes have a free-radical mechanism. The high yields of chloroform and ethylene indicate the abstraction of hydrogen atoms from the ethyl group of the organometallic compound by trichloromethyl radicals:

$$Cl_3C^{\cdot} + (C_2H_5)_6Sn_2 \rightarrow CHCl_3 + (C_2H_5)_5Sn_2\dot{C}_2H_4$$
$$\downarrow$$
$$(C_2H_5)_3Sn^{\cdot} + C_2H_4 + (C_2H_5)_3Sn ,$$
$$(C_2H_5)_3Sn^{\cdot} + CCl_4 \rightarrow (C_2H_5)_3SnCl + Cl_3C^{\cdot} ,$$
$$(C_2H_5)_2Sn \xrightarrow{CCl_4} (C_2H_5)_2SnCl_2 .$$

In the presence of freshly precipitated copper, hexaalkylditin compounds react with carbon tetrachloride under milder conditions[190]. Hexaethylditin and hexabutylditin react with carbon tetrachloride at room temperature, forming trialkyltin chloride, chloroform, hexachloroethane, copper chlorides, and coloured organotin compounds.

The reactions of organotin hydrides R_3SnH with polyhalogenomethanes proceed in the absence of initiators or catalysts. The reaction of triphenyltin hydride[145,191] with carbon tetrachloride is exothermic. This results in quantitative yields of chloroform and triphenyltin chloride. Triphenyltin hydride reacts less vigorously with chloroform and methylene dichloride[176]. The reaction leads to the reduction of chloroform to methylene dichloride and of the latter to methyl chloride. Polyhalogenomethanes can be arranged in the following sequence in terms of the rates of the above reactions:

$$CCl_4 > CHCl_3 > CH_2Cl_2 .$$

Alkyltin hydrides also reduce polyhalogenomethanes[192-194]. Tributyltin hydride reduces carbon tetrachloride to chloroform (about 85%) and the latter to methylene dichloride[192]. The above organometallic compound reacts with bromoform and tribromofluoromethane[192], forming tributyltin bromide (up to 95%) and methylene dibromide (62%) and dibromofluoromethane (69%) respectively.

The chemical reactivity of the hydrides depends on the nature of the alkyl group. The rate of reaction of tributyltin hydride with carbon tetrachloride and chloroform is appreciably lower than that of trimethyltin hydride[193].

Owing to their low thermal stability, organolead hydrides have been little investigated. They are much more reactive than the corresponding tin hydrides. The reaction of trialkyltin hydrides with carbon tetrachloride involves the reduction of the latter to chloroform[195].

The mechanism of the reaction of organolead and organotin hydrides with polyhalogenomethanes is insufficiently clear. It is believed that these reactions have a free-radical mechanism.

3. Reactions of Organotitanium Compounds

Among the organometallic compounds of Group IV elements, titanium derivatives have been most thoroughly investigated. In the present review we shall discuss the reactions with polyhalogenomethanes of compounds where an organic group is bound covalently to the titanium atom, i.e. compounds with metal–carbon σ bonds.

The reactions of di- and tetra-valent titanium derivatives with chloroform and carbon tetrachloride were investigated in greatest detail by Razuvaev and coworkers. Titanium(II) derivatives (diphenyltitanium and cyclopentadienylphenyltitanium) are thermally stable. Their reactions with chloroform and carbon tetrachloride involve the splitting off of phenyl groups and the oxidation of titanium to the tetravalent state[196,197]. The products of the reaction of diphenyltitanium[196] with chloroform at room temperature are titanium tetrachloride, benzene, and biphenyl. Cyclopentadienyltitanium trichloride ($C_5H_5TiCl_3$) is formed in the reactions of cyclopentadienylphenyltitanium[197]. Probably the primary step in the reaction is the formation of a complex of the organometallic compound and the polyhalogenomethane, the subsequent reaction of which involves the generation of phenyl radicals.

Compounds of tetravalent titanium of the type R_nTiX_{4-n} ($n = 1, 2, 3$, or 4) have been investigated in greatest detail. They are less stable than the organic derivatives of divalent titanium.

The reaction of tetramethyl titanium[198] with gaseous trifluoroiodomethane in 2 : 1 ethyl ether–hexane solution at −78°C results in the formation of trimethyltitanium iodide and methyl iodide. Tetramethyltitanium-ether

reacts with carbon tetrachloride, forming methyl chloride, methane, and titanium tetrachloride[199]. The products of the reaction of tetramethyl titanium with carbon tetrachloride in ethereal solution in the presence of mercury indicate a homolytic mechanism of this reaction[200]:

$$(CH_3)_4Ti + 2CCl_4 + Hg \rightarrow 3CH_4 + CH_3HgCl + TiCl_4 + Cl_3C^{\cdot}.$$

This is confirmed also by the fact that the analogous system tetraphenyl-lithium–carbon tetrachloride initiates the low-temperature free-radical polymerisation of vinyl chloride[201].

Cyclopentadienyltriphenyltitanium reacts with chloroform between −70° and −50°C. This results in an almost quantitative yield of benzene and cyclopentadienyltitanium trichloride[202].

The reactions of dicyclopentadienyldimethyltitanium[203] and dicyclopentadienyldiphenyltitanium[204,205] with carbon tetrachloride at 60–80°C are accompanied by the dissociation of σ bonds and the retention of the sandwich group. The products are dicyclopentadienyltitanium dichloride (about 75%), hexachloroethane, and respectively methyl chloride (95%) and chlorobenzene. In the thermal reaction of chloroform with $(C_5H_5)_2Ti(CH_3)_2$, dicyclopentadienyltitanium dichloride (75%) and methane (80%) are also formed. Dibenzyldicyclopentadienyltitanium reacts with chloroform similarly[203]. The thermal and photochemical reactions of $(C_5H_5)_2Ti(C_6H_5)_2$ with chloroform are accompanied by the formation of $(C_5H_5)_2TiCl_2$ and benzene[204–206]. It is suggested that dicyclopentadienyltitanium is an intermediate in these reactions:

$$(C_5H_5)_2TiR_2 \rightarrow (C_5H_5)_2Ti + 2R^{\cdot},$$
$$R^{\cdot} + CXCl_3 \rightarrow RX + Cl_3C^{\cdot},$$
$$(X = H, Cl)$$
$$(C_5H_5)_2Ti \xrightarrow{CXCl_3} (C_5H_5)_2TiCl_2.$$

The reactions of organotitanium compounds of this type with polyhalogenomethanes are initiated by oxygen[204,205]. The reaction of dicyclopentadienyldiphenyltitanium with carbon tetrachloride takes place in the presence of oxygen at a lower temperature (45–55°C). Then phosgene, biphenyl, and small amounts of phenol are formed together with dicyclopentadienyltitanium dichloride and chlorobenzene.

Reactions of titanium compounds of the type $RTiCl_3$ (R = CH_3 or C_6H_5) with carbon tetrachloride and chloroform have been described. Phenyltitanium trichloride reacts with chloroform, forming benzene and biphenyl. Chlorobenzene was not detected in the reaction with carbon tetrachloride[207]. The reaction of methyltitanium trichloride[208–210] with carbon tetrachloride leads to the formation of methyl chloride. Data indicating a free-radical mechanism of these reactions have been adduced[209].

VI. REACTIONS OF TWO-ELEMENT ORGANIC COMPOUNDS

The chemistry of organic compounds with two and more non-organic elements, i.e. the chemistry of compounds with carbon–element–element bonds, is developing vigorously at the present time. The previous section dealt with reactions of two-element organic compounds of the type R_3E-ER_3 (E = Si, Sn, or Pb) with polyhalogenomethanes. It is useful to discuss also reactions of organic derivatives having bonds between two different elements. It should only be noted that, despite the large variety of compounds of this type which have been obtained, their reactivity in relation to polyhalogenomethanes has been scarcely investigated. There are only a few data on the reactions of the compounds R_3EM (E = Si, Ge, Sn, or Pb and M = Li or Na) with alkyl halides.

The reactions of triphenylsilyl-lithium with polyhalogenomethanes have been investigated in greater detail. The reaction of this compound with methylene dichloride[211–213] results in the formation of hexaphenyldisilane, methyltriphenylsilane, chloromethyltriphenylsilane, and bis(triphenylsilyl)methane in proportions which depend on the reaction conditions. It is suggested[213] that chloromethyl derivatives of lithium, which serve as a source of carbenes, are formed in these reactions. Their mechanism may be represented as follows:

$$R_3SiLi + CH_2Cl_2 \rightarrow R_3SiCl + CH_2ClLi \rightarrow \ddot{C}H_2 + LiCl,$$
$$R_3SiCl + R_3SiLi \rightarrow R_3SiSiR_3 + LiCl,$$
$$R_3SiLi + \ddot{C}H_2 \rightarrow R_3SiCH_2Li,$$
$$R_3SiCH_2Li \xrightarrow{CH_2Cl_2} R_3SiCH_2Cl + CH_2ClLi,$$
$$R_3SiCH_2Li \xrightarrow{R_3SiCl} R_3SiCH_2SiR_3 + LiCl,$$
$$R_3SiCH_2Li \xrightarrow{H_2O} R_3SiCH_3.$$

Methylene di-iodide reacts similarly. The reaction of triphenylsilyl-lithium with methylene dibromide leads to the formation of hexaphenyldisilane (42–60% with respect to Ph_3SiLi), methyltriphenylsilane (up to 40%), and bromomethyltriphenylsilane (about 10%) with respect to methylene dibromide).

The products of the reaction of triphenylsilyl-lithium[212,213] with CHX_3 (X = Cl, Br, and I) are methyltriphenylsilane, hexaphenyldisilane, mono- and di-halogenomethyltriphenylsilanes, bis(triphenylsilyl)methane, and triphenylsilane. Probably the initial stage is the following process:

$$R_3SiLi + CHX_3 \rightarrow R_3SiH + CX_3Li \rightarrow \ddot{C}X_2 + LiX,$$
$$R_3SiLi + CHX_3 \rightarrow R_3SiX + CHX_2Li \rightarrow \ddot{C}HX + LiX.$$

It has been shown that the yield of reaction products depends on the reactant ratio. In the reaction between the organometallic compound and methyl iodide in molar proportions of 3 : 1, hexaphenyldisilane (60.5% with respect to Ph_3SiLi), bis(triphenylsilyl)methane (19.5%), and methyltriphenylsilane (24% with respect to iodoform) are formed. A change in reactant ratio to 2 : 1 leads to the formation of hexaphenyldisilane and almost equimolar amounts of monoiodomethyl- and di-iodomethyl-triphenylsilanes.

Hexaphenyldisilane (56–73%) and dichloromethyltriphenylsilane (11–42%) are formed at −60°C in the reaction of triphenylsilyl-lithium[213] with carbon tetrachloride. The reaction with carbon tetrabromide is much more complex.

The reactions of triphenylgermylsodium[214–216] with methylene dichloride, chloroform, and carbon tetrachloride have been carried out in liquid ammonia and in ether. The main product of the reaction with methylene dichloride is bis(triphenylgermyl)methane. The above organometallic compound reacts with chloroform and carbon tetrachloride in ethereal solution in a more complex manner, forming mainly hexaphenyldigermane[215,216].

It is interesting to note that bis(triethylgermyl)cadmium[217], like the organometallic alkyl derivatives R_2Cd, reacts vigorously with carbon tetrachloride. The reaction mixture explodes at room temperature. Triethylgermanium chloride (41%), dichlorobis(triethylgermyl)methane (55%), and cadmium chloride (91.5%) are formed in the reaction carried out at −75°C. The mechanism of the reaction has not been elucidated. It is suggested that

dichlorocarbene is involved in the reaction. Probably derivatives of the type $R_3GeCdCCl_3$ or R_3GeCCl_3 are produced as intermediates.

The corresponding mercury compound (like R_2Hg) proved to be less reactive with respect to carbon tetrachloride. The photochemical reaction[218] of bis(triethylgermyl)mercury with carbon tetrachloride involves the formation of mercury (60%), triethylgermanium chloride (36%), and hexachloroethane.

Tris(trimethylsilyl)thallium reacts with chloroform, forming bis(trimethylsilyl)thallium chloride, but does not react with methylene dichloride[219].

The reaction of tris(trimethylsilyl)silane with carbon tetrachloride leads to the formation of tris(trimethylsilyl)silicon chloride and chloroform[220]:

$$[(CH_3)_3Si]_3SiH + CCl_4 \xrightarrow{\text{reflux.}} [(CH_3)_3Si]_3SiCl + CHCl_3 .$$

The reactions of trialkyl(aryl)stannylsodium with methylene dichloride[221,222], chloroform[223-225], and carbon tetrachloride[222,223] have been investigated. The reaction with methylene dichloride results in the formation of the corresponding bis[trialkyl(aryl)stannyl]methanes. The reaction with chloroform is more complex. Trimethylstannylsodium and triphenylstannylsodium react with carbon tetrachloride, forming hexamethyl- and hexaphenylditin.

The reaction of triphenylplumbyl-lithium with methylene dichloride, chloroform, and carbon tetrachloride in tetrahydrofuran solution at −60°C leads to the formation of a high yield of the corresponding bis-, tris-, and tetrakis-(triphenylplumbyl)methanes[226]. The reactions with bromochloromethane yield[227,228] a mixture of compounds, the main component of which is a derivative of the type $R_3Pb(CH_2)_nPbR_3$.

Prolonged photolysis (100 h) of the complex compounds lithium or potassium tetraphenylborates in chloroform solution is accompanied by the formation of benzene, biphenyl, triphenylboron and respectively lithium or potassium chlorides[229]. It is suggested[230] that these reactions take place with participation of phenyl radicals.

The above review shows that organic derivatives with two "non-organic" elements react with polyhalogenomethanes in a fairly complex manner. The mechanism of these processes is still not entirely clear.

VII. REACTIONS OF ORGANIC COMPOUNDS OF GROUP V ELEMENTS

The reactions of organic compounds of phosphorus, arsenic, antimony, and bismuth with polyhalogenomethanes have been described for derivatives of the type R_3E and R_5E. The first data on the reactivity of organophosphorus compounds with respect to polychloromethanes[231-233] were obtained in studies on the chemical properties of triethylphosphine. In particular it was stated that this compound forms an adduct with carbon tetrachloride having the composition $3(C_2H_5)_3P.CCl_4$.

Organic derivatives of tervalent elements combine with trichloroiodomethane[234], forming an adduct with the composition $R_3E.CCl_3I$. The reactions were carried out in ether with the reaction mixture cooled to −46°C. The following compounds were obtained in this way (the melting points and decomposition temperatures are indicated in brackets): $(CH_3)_3P.CCl_3I$ (10°C, decomposes), $(C_6H_5)_3P.CCl_3I$ (72°C, 110°C), $(CH_3)_3As.CCl_3I$ (39°C, 95°C), $(C_6H_5)_3As.CCl_3I$ (−30°C, 100°C), and $(CH_3)_3Sb.CCl_3I$ (5°C, 82°C).

Triphenylantimony in ether does not react with trichloroiodomethane at temperatures ranging from −78° to 20°C. Nor does it react with chloroform when the reaction mixture is illuminated. However, photolysis of triphenylbismuth in chloroform solutions is accompanied by the formation of bismuth trichloride, bismuth, and benzene. Bismuth trichloride and biphenyl are formed in the photochemical reaction with carbon tetrachloride[172].

It has been noted[234] that trimethylphosphine does not react with carbon tetrachloride. However, later it was shown[235] that trialkylphosphines react with carbon tetrachloride in ether when the temperature of the reaction mixture is −10°C. The formation of phosphonium compounds is suggested:

$$R_3P + CCl_4 \rightarrow R_3P\langle^{CCl_3}_{Cl} \qquad (R = n\text{-}C_4H_9,\ n\text{-}C_5H_{11} \text{ etc.}) .$$

In the presence of methanol the latter form trialkylphosphine oxides, methyl chloride, and chloroform:

$$R_3P\langle^{CCl_3}_{Cl} + CH_3OH \rightarrow R_3PO + CH_3Cl + CHCl_3 .$$

Similar results were obtained somewhat earlier[236] in the reaction of triphenylphosphine with carbon tetrachloride or bromotrichloromethane in the presence of ethanol. The mechanism of the reactions of triphenylphosphine with carbon tetrachloride and carbon tetrabromide has been discussed[237-239]. It is believed that a phosphonium compound, formed as a result of the nucleophilic attack by phosphorus on the halogen, is an intermediate in the reaction:

$$R_3\ddot{P}\langle^{X}_{CX_3} \rightarrow R_3P^{+}\langle^{X^-}_{CX_3} \rightarrow R_3P\langle^{X}_{CX_3} , \quad (X = Cl^{237,238}, Br^{239}) \qquad (13)$$

$$R_3P\langle^{X}_{CX_3} + R_3P \rightarrow R_3P{=}CX_2 + R_3PX_2 .$$

The presence of dihalogenomethylenetriphenylphosphorane was established on the basis of the products of the reaction with carbonyl compounds, in particular with benzaldehyde[237,239]:

$$R_3P{=}CX_2 + C_6H_5CHO \rightarrow R_3PO + C_6H_5CH{=}CX_2 .$$

Triphenylphosphine[236] does not react with chloroform and bromoform on heating the reaction mixture to 80°C, but does react with bromoform in the presence of benzoyl peroxide[240]. The initiating effect of the latter was not confirmed in a subsequent investigation[236]. Triphenylphosphine reacts with bromoform at 150°C, forming dibromomethyltriphenylphosphonium bromide[236]:

$$R_3P + CHBr_3 \rightarrow [R_3PCHBr_2]^+Br^- .$$

The reactions of alkyl esters of alkyl- or aryl-phosphinous acids with carbon tetrachloride have been investigated[235,241]. The aryl derivatives[241] react according to the mechanism

$$Ar_2POR + CCl_4 \rightarrow Ar_2P(O)CCl_3 + RCl ,$$
$$(R = C_2H_5,\ n\text{-}C_3H_7) .$$

Reactions of compounds of the type $(RO)_3P$ with polyhalogenomethanes are not considered in this review.

The reaction of amino-substituted alkylphosphines with carbon tetrachloride results in the formation of 1,1,1-trichloroalkanes[242]. Trichlorobutane was isolated in 50% yield from the reaction mixture of bis(diethylamino)propylphosphine with carbon tetrachloride.

The reactions of organic derivatives of the elements of the type R_5E with polyhalogenomethanes have been investigated for pentaphenylphosphorane and pentaphenylantimony. Pentaphenylphosphorane reacts with chloroform and carbon tetrachloride at room temperature. Wittig and Geissler[243] reported that the reaction of this compound with chloroform has an ionic mechanism and involves the formation of tetraphenylphosphonium chloride and benzylidene chloride. In a more detailed study of the reaction of pentaphenylphosphorane with chloroform and carbon tetrachloride by Razuvaev and coworkers[244-248], it was established that these processes take place with participation of free radicals. This results in the formation of a quantitative yield of tetraphenylphosphonium chloride and of chlorobenzene (64%) in the reaction with carbon tetrachloride and of benzene (60–65%) in the reaction with chloroform. Benzylidene dichloride was not detected.

Pentaphenylantimony reacts similarly with chloroform and carbon tetrachloride[249]. Tetraphenylantimony chloride, biphenyl, and respectively benzene or chlorobenzene are formed in thermal reactions (100°C, 20–25 h) and in photolysis. The mechanism of these processes may be represented as follows:

$$R_5E \rightarrow R_4E^{\cdot} + R^{\cdot},$$
$$(E=P, Sb)$$
$$R_4E^{\cdot} + CXCl_3 \rightarrow R_4ECl + \dot{C}XCl_2,$$
$$(X=H, Cl)$$
$$R^{\cdot} + CXCl_3 \rightarrow RX + Cl_3C^{\cdot},$$
$$2R'' \rightarrow R'-R'.$$
$$(R'=Cl_3C, CXCl_2, R)$$

The photolysis of t-butylperoxytetraphenylantimony in carbon tetrachloride and chloroform solutions was investigated recently[250]. The reaction with carbon tetrachloride involves predominantly the dissociation of the Sb–O bond and the formation of tetraphenylantimony chloride (up to 83%). In the reaction with chloroform tetraphenylantimony chloride (41%), tetraphenylantimony oxide (40%), t-butyl alcohol (44%), and benzene (17%) were obtained, together with phenol (6%) and acetone (10%) as side products. These compounds are formed owing to the dissociation of the Sb–O and O–O bonds in the initial compound.

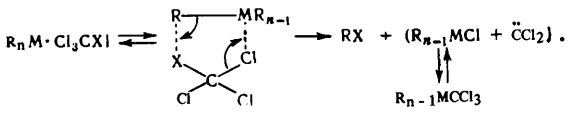
Thus the mechanism of the reaction of organic derivatives of the elements of the type R_3E with polyhalogenomethanes differs radically from the mechanism of the corresponding reactions with compounds of the pentavalent elements R_5E.

---o0o---

Organic derivatives of the elements can be divided into two groups in terms of their reactivity with respect to polyhalogenomethanes. The first includes organic compounds of alkali and evidently alkaline earth metals and Group III metals and also the alkyl compounds of zinc and cadmium, derivatives of divalent tin, and true organometallic derivatives of transition metals (in particular divalent titanium compounds). Their reactions with alkyl halides do not require initiation. Probably the primary step in the reaction of these organometallic compounds with polyhalogenomethanes is nucleophilic attack by the halogen on the metal accompanied by the formation of a complex and then of the corresponding halogenomethyl organometallic derivatives:

$$R_nM + CXCl_3 \rightleftarrows [R_nM \cdot Cl_3CX] \rightarrow R_{n-1}MCCl_3 + RX.$$
$$(X=H, Cl, Br, I)$$

One cannot exclude the possibility that the compound reacts via a five-membered cyclic transition state with formation of the corresponding carbene and its subsequent insertion into the metal–halogen bond formed:



The insertion of carbenes into the metal–halogen bond is used as one of the methods for synthesising halogenomethyl organometallic compounds. Possibly the reaction of the halogenomethyl complex formed with certain organometallic compounds (in all probability with divalent titanium compounds) is associated with the generation of free radicals.

It is striking that the reactions of the majority of organometallic compounds of this group with polyhalogenomethanes are exothermic. Owing to the lack of kinetic data, the mechanism of these reactions still remains insufficiently elucidated.

The addition of polyhalogenomethanes of the type CYX_3 (Y = H, Cl, Br, or I; X = Cl or Br) to compounds of tervalent Group V elements R_3E (E = P, As, or Sb) evidently takes place as a result of nucleophilic attack by the element on the halogen [reaction (13)], which leads to the formation of the corresponding halogenomethyl derivatives.

The second group includes the aryl derivatives of zinc and cadmium, organic compounds of mercury (R_2Hg), titanium, tin, and lead of the type R_4M, compounds of silicon and germanium, and compounds of pentavalent phosphorus, arsenic, antimony, and bismuth. These compounds are less reactive. Their reactions with polyhalogenomethanes takes place on heating, irradiation with light, or in the presence of initiators, and clearly have a distinct free-radical mechanism.

Kinetics and Mechanism of the Reaction of Peroxy-compounds with Phosphites, Sulphides, and Aromatic Amines

D.G.Pobedimskii

The studies dealing with the elucidation of the detailed mechanism and quantitative kinetics of the reactions of peroxy-compounds with phosphites, sulphides, and aromatic amines are reviewed. It is shown how evidence has been obtained by ESR of the existence of the one-electron amine oxidation stage, i.e. the stage involving the formation of radical-cations. The consecutive reactions of the radical-cations formed initially and their relation to the behaviour of the amines as polymerisation initiators are analysed. The characteristics of the detection of free radicals in reactions of phosphites and sulphides with hydroperoxides are examined and certain criteria of the latent radical nature of these reactions are formulated. In the last section correlations of the Hammett equation type for rates of the reactions under consideration and also the correlation between the rate constants on the one hand and the ionisation potentials and electron affinities on the other are discussed within the framework of the one-electron oxidation-reduction mechanism. The bibliography includes 96 references.

I. INTRODUCTION

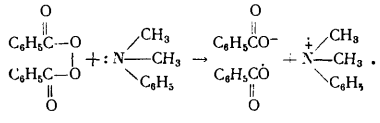
The reduction of peroxy-compounds by phosphites, sulphides, and aromatic amines constitutes a large and important class of organic reactions. On the basis of N. M. Semenov's hypothesis concerning the possibility of the formation of free radicals in the bimolecular interaction between valence-saturated molecules, one may also expect the formation of radicals in the above reactions. This assumption follows from the fact that, since one of the reactants (the peroxide) is a powerful oxidising agent and the other is a powerful reducing agent, the reaction does not require a large activation energy (10–20 kcal mole^{-1}). However, one cannot exclude the possibility that another mechanism, which does not lead to the formation of free radicals, is even more effective. There is no unanimous view in the literature concerning the mechanism of the reactions of peroxy-compounds with amines, phosphites, and sulphides; therefore, it is necessary to make a critical analysis of the results available in this field and their interpretation.

Moreover, there is also a purely practical aspect of the investigation of these reactions associated with the behaviour of aromatic amines as initiators of the radical polymerisation of monomers, phosphites, and sulphides and as synergists in polymer stabilisation processes.

II. KINETICS AND MECHANISM OF REACTIONS OF AROMATIC AMINES

The chemistry of the interaction of aromatic amines with peroxy-compounds, particularly with benzoyl peroxide[1-6], has been investigated in greatest detail. Gambaryan[1] established that primary, secondary, and tertiary aromatic amines rapidly react with benzoyl peroxide (BP) with formation of benzoic acid and *O*-benzoylhydroxylamine or its *N*-alkyl derivatives.

According to Horner's hypthesis[2,3], the first stage for all amines is the formation of a complex of the amine and benzoyl peroxide in which an electron is transferred from the lone pair of the amine to the peroxide molecule, involving the formation of an ion pair and a benzoate radical. For example, for dimethylaniline (DMA) (a tertiary amine), we have



The second stage consists in proton transfer from the methyl group or the benzene ring of the amine radical-cation to the benzoate anion; this is accompanied by the formation of a radical pair, which enters into further reactions leading to the formation of the final products. The appearance of an intense colour when dimethylaniline reacts with benzoyl peroxide in chloroform in the presence of chloride ions is regarded by Horner and Schwenk[2] as evidence of the formation of the dimethylaniline radical-cation.

Dimethylaniline radicals were first obtained by the irradiation of the initial amines with light[7] at a wavelength of 2700 Å or by flash photolysis[8] and were investigated spectophotometrically[7,8]. The absorption spectrum of the radical-cations in aqueous and EPA (ether : isopentane : ethanol = 5 : 5 : 2) solutions is characterised by a broad band with a maximum at 4600 Å.

The appearance of a band with a more diffuse maximum at 4600–4700 Å was observed by Stavrova et al.[9] in the reaction between benzoyl peroxide and dimethylaniline in EPA at 20°C; they attributed this band to the dimethylaniline radical-cation formed as a primary species. Indeed, this result is without any doubt evidence of the formation of amine radical-cations in the benzoyl peroxide–dimethylaniline system. However, the problem arises whether these radical-cations are primary or secondary species. Spectrophotometry cannot provide an unambiguous and reliable answer; electron spin resonance (ESR) is likely to be the most suitable method.

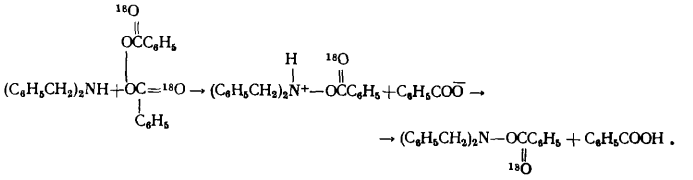
The formation of neutral free radicals in the reaction of benzoyl peroxide with dimethylaniline and other tertiary amines was observed directly in a number of studies. Horner[2] showed that the benzoyl peroxide–dimethylaniline system is capable of initiating the radical polymerisation of various vinyl compounds at 20°C, the initiating agent being the benzoate radical. An analogous initiation effect in the polymerisation of styrene was also observed following the addition of *p*-dimethyltoluidine to benzoyl peroxide[10]. Imoto et al.[11] determined the effectiveness of the initiation at 25°C of the polymerisation of styrene by the benzoyl peroxide–dimethylaniline system. They compared the rate of initiation calculated from the rate of polymerisation and the values of $k_p/k_t^{1/2}$ with the rates of reaction of benzoyl peroxide and dimethylaniline; the effectiveness of the initiation proved to be 0.25. Hrabák[5,12] showed that the rate of reaction of dimethylaniline, methyltolyltoluidine, and tritolylamine with benzoyl peroxide in benzene solution decreased severalfold in the presence of the stable diphenylpicrylhydrazyl (DPPH) radicals or nitric oxide; the replacement of benzene by other solvents also led to retardation of the reaction. The results can be explained by the fact that the radicals arising in the bimolecular reaction of benzoyl peroxide with tertiary amines (HA) initiate the chain reaction according to the mechanism

$$C_6H_5COO\dot{} + HA \rightarrow C_6H_5COOH + \dot{A}\,, \qquad (1)$$

$$\dot{A} + (C_6H_5COO)_2 \rightarrow C_6H_5COO^{\cdot} + C_6H_5COOA\,. \qquad (2)$$

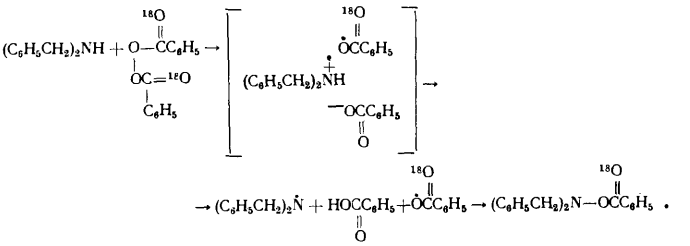
The kinetics of the reaction of benzoyl peroxide with dimethylaniline were studied by many investigators[6,10-15], all of whom established that the rate is proportional to the concentration of amine and peroxide in accordance with a bimolecular mechanism of the initial stage of the process. In one of the papers[6] the activation energy for this reaction is quoted as 14.8 kcal mole^{-1}; according to another[17], it is 12.8 kcal mole^{-1}. As regards the initiation of polymerisation as a method for the quantitative determination of radicals, the studies on different monomers[14-17] yielded for the rate of polymerisation w_n a relation of the type $w_n = k[DMA]^{1/2}[BP]^{1/2}$ corresponding to a bimolecular formation of benzoate radicals. Since the reaction between benzoyl peroxide and dimethylaniline is of the chain type, the experimentally observed second order can be accounted for only by cross termination by benzoate and amine (A) radicals.

Donald and Dorothy Denny[18] investigated the mechanism of the reaction of secondary amines with benzoyl peroxide using isotope tracers. Thus, when benzoyl peroxide, the carbonyl oxygen of which contained 1.32 at.% ^{18}O, was allowed to react with dibenzylamine, *O*-benzoyl-*NN*-dibenzylhydroxylamine was isolated in 57% yield as the product. Chemical determination of ^{18}O showed that the same amount of the isotope is retained in the carbonyl groups of both *O*-benzoyl-*NN*-dibenzylhydroxylamine itself and the product of its solvolysis by sodium ethoxide—(ethyl benzoate). On the basis of these results, a mechanism was proposed, as an alternative to that of Horner, involving a nucleophilic attack by the amine on the peroxy-bond with formation of an ion pair, which is converted into the reaction products via proton transfer:



A similar mechanism is suggested also for the reactions of primary amines[18].

It is noteworthy that the distribution of oxygen-18 in the reaction products may be explained within the framework of the one-electron transfer hypothesis:



Moreover, many facts are contrary to the concept of a nucleophilic mechanism. For example, secondary and primary amines initiate at 25°C the polymerisation of monomers[20,21], although with a low effectiveness; thus the effectiveness for diphenylamine (DPA) [20] is about 10^{-3}. The absorption of nitric oxide by the reacting benzoyl peroxide–diphenylamine system[22] indicates the intermediate formation of free radicals. Bagdasar'yan and Milyutinskaya[20] showed that these radicals are capable of reacting with diphenylpicrylhydrazine (DPPH-H), which is then oxidised to DPPH radicals. Finally, free radicals were detected[23] by ESR following the mixing of benzene solutions of benzoyl peroxide and aniline or its *p*-methyl and *p*-ethyl derivatives (at 20°C); in all cases these proved to be diphenyl(diaryl)nitroxide radicals.

The hyperfine coupling (HFC) constants for the ^{14}N nuclei and the protons of the aromatic ring and the g-factors for these radicals (2.0059) agree well with the above interpretation of the ESR spectra.

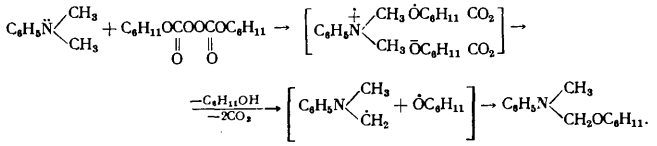
However, direct evidence of the formation of radical-cations derived from the secondary or primary amines (according to Horner's mechanism) is not given in any of the studies quoted above; moreover, all the facts confirming the radical mechanism of the reaction of these amines with benzoyl peroxide are frequently associated with secondary radical products.

The reaction of benzoyl peroxide with aniline, diphenylamine, and secondary aliphatic amines is of the second order (according to the initial rates) and has low activation energies: 16.4 kcal mole^{-1} for diphenylamine[20], 10.7 kcal mole^{-1} for aniline[20], 10.5 kcal mole^{-1} for diethylamine[22], and 14.8 kcal mole^{-1} for di-n-butylamine[22]. Since the reaction of benzoyl peroxide with tertiary amines, for example dimethylaniline, has a chain mechanism, the problem arises whether the mechanism of its reactions with secondary and primary amines is also of the same type. It was shown[20] that the addition of DPPH-H does not affect the rate of reactions of benzoyl peroxide with diphenylamine, although DPPH-H is then converted into DPPH. If this reaction were of the chain type, its rate would decrease in consequence of the formation of the inactive DPPH radicals, incapable of propagating the chain reaction. The absence of an inhibiting effect on addition of isoprene to the benzoyl peroxide–aniline system also indicates that this reaction has a non-chain mechanism. The absence of an isotope effect on replacement in aniline and diphenylamine molecules of a hydrogen atom by deuterium is also contrary to the hypothesis of a chain mechanism for the reaction since in a chain reaction the rate constant ratio k_D/k_H for stage (1) would not be unity. Thus, although the reactions of aniline and diphenylamine with benzoyl peroxide do in fact lead to the formation of free radicals, they are not of chain type.

It is not clear which stage determines the rate of reaction of secondary and primary amines with benzoyl peroxide. The absence of an isotope effect in the reaction of the *N*-deuterated compound[20] is evidence that the transfer of a hydrogen atom or proton from the amine to benzoyl peroxide is not the rate-determining state of the process and it may be that the rate is in fact determined by the transfer of an electron from the amine to the peroxide.

Comparatively little is known about the formation of radicals in the reaction of amines with peroxides of another type—peroxydicarbonates. A striking example illustrating the possibility, in principle, of the formation of radicals in this system is the observation by Vasil'ev and Nalbandyan[24] of chemiluminescence in the visible part of the spectrum arising from interaction between dimethylaniline and dicyclohexyl peroxydicarbonate (CPC) at 20°C in benzene. It was shown that, in the absence of oxygen, the chemiluminescence intensity I is a maximum at the instant of mixing of the reactants and decreases according to the law $I^{-1/2} = I_0^{-1/2} + dt$, which can be readily derived on the hypothesis that the excited product is formed via a bimolecular reaction between dimethylaniline and dicyclohexyl peroxydicarbonate.

Razuvaev et al.[25] analysed the products of this reaction and isolated 1.97 moles of CO_2, 0.88 mole of cyclohexanol, and 0.8 mole of *N*-cyclohexyloxylmethyl-*N*-methylaniline per mole of decomposed dicyclohexyl peroxydicarbonate. On the basis of the composition of the products, a reaction mechanism, analogous to Horner's mechanism for benzoyl peroxide, was proposed:



Since the reaction product is a highly luminescent amine derivative, one may suppose that this compound, formed by radical recombination, in fact serves as the chemiluminescence emitter.

The energy relations of this reaction have not been investigated at all. It is only known that the reaction of di-isopropyl peroxydicarbonate with methyldiphenylamine is described by an Arrhenius temperature equation of the type

$$k = 10^{11} \exp(-19\,400/RT) \text{ litre mole}^{-1}\text{ s}^{-1}.$$ [26]

The oxidation of aromatic amines by organic peracids, which yields amine oxides (in the case of tertiary amines) or phenylhydroxylamines and nitroso-, nitro-, azo-, and azoxy-compounds (in the case of primary and secondary amines), has been for a long time a well known synthetic reaction (its chemistry was described in detail in other reviews[27,28]).

The results of the kinetic analysis of these reactions [second kinetic order, low activation energies (about 13 kcal mole^{-1}) and the absence of an effect of methyl methacrylate (MMA) on the rate] can be accounted for by a nucleophilic mechanism[27,29].

Rassat and coworkers[30] investigated by ESR the intermediate products in the oxidation of a large class of primary, secondary, and tertiary aromatic and heterocyclic amines by *p*-nitro- and *m*-chloro-perbenzoic acids in various solvents: in all cases these proved to be nitroxide radicals. However, the pathways in the formation of these radicals are obscure; it is only clear that they are secondary products derived from the amines. Thus it is at present difficult to arrive at an unambiguous conclusion concerning the applicability of the radical mechanism to the oxidation of amines by peracids solely on the basis of the detection of nitroxide radicals, although this mechanism is not inconsistent with the results of kinetic analysis.

Hydroperoxides also react readily with amines and are at the same time reduced into the corresponding alcohols in fairly high yields (72–100%)[31]. The composition of the amine oxidation products is complex and depends on the nature of the amine[32].

The reactions of cumenyl peroxide with phenothiazine, its 3,3-dimethoxy-derivative, and diphenylamine have been investigated by ESR[33] in deoxygenated (to a residual pressure of 10^{-2} mmHg) benzene solutions between 20° and 160°C. The formation of nitrogen radicals derived from phenothiazine and its derivative was observed even at room temperature. When the thioamine was taken in an excess (100:1 or 10:1) there were no changes in the ESR spectra of these "primary" radicals even on heating to 60–70°C. In the presence of an excess of the hydroperoxide and at 60–70°C the "primary" nitrogen radicals were gradually converted into the "secondary" nitroxide radicals, probably via the mechanism

$$Ar_2\dot{N} + R'OOH \rightarrow Ar_2N{-}OH + R'\dot{O}\,, \qquad (3)$$

$$Ar_2N{-}OH + R'OOH \rightarrow Ar_2N{-}\dot{O} + H_2O + R'\dot{O}\,. \qquad (4)$$

The ESR spectra of the "primary" and "secondary" thioamine radicals differ significantly in the splitting (a_N^{sec} is greater by about 30% than a_N^{prim}), in the nature of the hyperfine structure (HFS), and in the values of the *g*-factors ($g^{prim} = 2.0029$ and $g^{sec} = 2.0038$). With diphenylamine, the nitroxide radicals are detected immediately.

The formation of nitroxide radicals in 100% yield was also observed by Coppinger and Swalen[34] using ESR in the oxidation of a large class of secondary and tertiary aliphatic and secondary aromatic amines by *t*-butyl hydroperoxide (TBHP). These results convincingly demonstrate that nitroxide radicals are formed in all cases according to the mechanism represented by reactions (3) and (4).

The mechanism of the primary elementary steps in the interaction of hydroperoxides with amines remains obscure. It has been suggested that[33] nitrogen radicals are formed from amines by a molecular mechanism:

$$Ar_2NH + R'OOH \rightarrow Ar_2\dot{N} + H_2O + R'\dot{O}\,.$$

A similar mechanism was considered, for substituted hydrazines alone, also by Maruyama et al.[35] When t-butyl hydroperoxide was allowed to react with DPPH-H in benzene at 60°C, they detected and identified by hydrazyls radicals, by comparing the hyperfine structure and the overall width of their ESR spectrum with that of a standard—DPPH radicals. Triphenylhydrazine was oxidised under milder conditions (4°C) and the reaction was accompanied by the successive appearance of three types of ESR spectra, which were attributed respectively to the radicals Ph_2-NPh, PhN-OH, and $Ph_2N\dot{O}$. However, the interpretation of the ESR spectra of the first two radicals gives rise to doubts and consequently the assignment of the spectra to the above products cannot be regarded as unambiguous.

The kinetics of the reactions of hydroperoxides with amines have been investigated in a number of studies. It was shown that the rates of these reactions are

described by second-order kinetic equations; the results of the kinetic analysis are presented in Table 1.

It follows from the analysis of the literature data that the formal kinetics of the reactions of peroxy-compounds with aromatic amines and the composition of the reaction products have been fairly adequately investigated; there is a need for a revision of only the fundamental aspect of the mechanism—the detection and identification of the primary radical-cations derived from the amines and the interpretation of the reactions of the radicals.

Table 1. Pre-exponential factors and the activation energies for the reactions of amines with hydroperoxides.

Amine	Hydroperoxide	Solvent	k_0, litre, mole^{-1} s^{-1}	E_{act}, kcal mole^{-1}	Refs.
Diethylamine	cumenyl hydroperoxide	Water	$8.7 \cdot 10^9$	17.0	36
Triethylamine	cumenyl hydroperoxide	Water	$5.4 \cdot 10^8$	14.7	37
Pyridine	t-butyl hydroperoxide	Chloro-benzene	$1.9 \cdot 10^7$	21.0	38
Triphenylhydrazine	t-butyl hydroperoxide	Benzene	$0.2 \cdot 10^2$	5.6	35*
N-cyclohexyl-*N'*-phenyl-*P*-phenylene-diamine	polypropylene hydroperoxide	Solid phase	$1.3 \cdot 10^5$	13.0	39

* The values of k_0 and E_{act} were determined by the present authors from the data of Maruyama et al.[35]

The results of experiments[40-42] unambiguously confirm the existence of a one-electron amine oxidation stage, i.e. the stage involving the formation of radical-cations; this is clearly confirmed by the observation of the ESR spectra of the radical-cations of dimethylaniline, *NNN'N'*-tetramethyl-*p*-phenylenediamine, 2,2',4,4',6,6'-hexamethoxydiphenylamine, *p*-phenylenediamine, and *N*-isopropyl-*N'*-phenyl-*p*-phenylenediamine formed in the reactions with various peroxy-compounds: benzoyl peroxide, dicyclohexyl peroxydicarbonate, t-butyl hydroperoxide, and olefin ozonides†. The isotropic and anisotropic hyperfine coupling constants for the ^{14}N nuclei and protons of the amino-groups and aromatic rings and also the unpaired electron densities were determined.

For example, the radical-cation derived from dimethylaniline gives rise to an ESR spectrum with a complex hyperfine structure due to the coupling of the unpaired electron with the nitrogen nucleus (a_N = 10.0 Oe), the protons of the methyl groups ($a_{H(NCH_3)}$ = 11.8 Oe), and the *ortho*- (a_H^o = 1.7 Oe), *meta*- (a_H^m = 0.8), and *para*-protons (a_H^p = 5.2 Oe) of the aromatic ring.

It is noteworthy that the observed constant a_N is in good agreement with data[43-45] for the radical-cations derived from *para*-substituted dimethylanilines formed on oxidation of the amines by Ce^{4+} ions in a flow system[43] or electrochemically[44,45]. Table 2 lists the hyperfine coupling constants for the ^{14}N nucleii of the radical-cations of dimethylaniline and its *para*-derivatives (in oersteds); evidently the constants a_N are correlated with Hammett's σ parameters, the relation being linear (Fig. 1).

† The reaction of amines with ozonides had not been reported previously.

Subsequently the electronic structure of the dimethylaniline radical-cation was calculated[45] by the Hückel molecular orbital method. The Coulombic and exchange integrals for the nitrogen atoms were assumed to be given by expressions of the form $\alpha_N = \alpha_C + 0.50\beta_{CC}$ and $\beta_{CN} = \beta_{CC}$. The calculated unpaired electron density at the nitrogen atom ρ_π^N proved to be 0.5181. Using this theoretical value of ρ_π^N, the a_N constant for the dimethylaniline radical-cation can be estimated with the aid of the familiar relation $a_N = Q_N \rho_\pi^N$ (where Q_N = 20.6 Oe).[46] The result is a_N = 10.7 Oe, which is very close to the experimental value in Table 2.

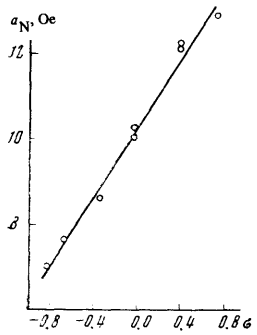


Figure 1. a_N/σ diagram for the hyperfine coupling constant of the radical-cations of dimethylaniline and its *para*-derivatives.

Table 2. The values of a_N (in oersteds) for the radical-cations of dimethylaniline and its *para*-derivatives.

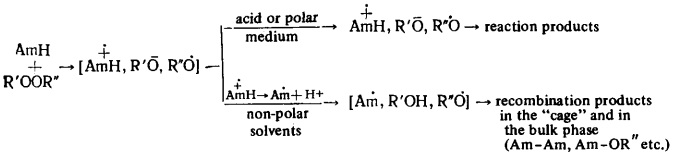
In the ESR spectrum of the radical cation of another amine (2,2',4,4',6,6'-hexamethoxydiphenylamine) there are four lines with intensity ratios close to 1 : 2 : 2 : 1, due to the coupling of the unpaired electron with the ^{14}N nucleus and the NH proton, which are approximately equivalent (a_N = 7.5 Oe and $a_{H(NH)}$ = 8.1 Oe). This radical-cation is very stable: it is clearly detected over a period of several days and in acid media its yield is close to 10%.

The radical-cations derived from amines have been investigated in various solvents. In non-polar solvents the radical-cations are usually unstable and undergo secondary reactions. The sequence of these reactions is well illustrated by the following example.

The radical-cation is deprotonated to give a nitrogen radical. The ESR spectrum of the latter is a 1 : 1 : 1 triplet due to the coupling of the unpaired electron with the nitrogen nucleus (a_N = 8.1 Oe). These nitrogen radicals then recombine to give hydrazine. As a result of a secondary electron transfer from hydrazine to the peroxide or the primary radical-cation, a secondary hydrazine radical-cation is produced. Its ESR spectrum at 20°C and at 77°K consist of five lines due to the coupling of the unpaired electron with the two equivalent nitrogen nuclei. The isotropic hyperfine coupling constant for this radical-cation is 6.6 Oe, the anisotropic coupling constant is 5.2 Oe, and the unpaired electron density at each nitrogen atom is 0.41. [41]

Analysis of the structures of the radical-cations and their reactions enabled the authors [40,41] to propose the following general mechanism for the reaction of peroxy-compounds with aromatic amines:



The mechanism includes electron transfer from the amine to the peroxide and the formation of an ion-radical pair. In acid and polar media the radical-cations are stabilised. In non-polar solvents the radical-cations are deprotonated to give radical products.

The effectiveness of the initiation of polymerisation by the amine–peroxide system may be accounted for by this mechanism: it is determined by the relative probabilities of the release of an individual radical into the bulk phase and of the transfer of a proton from the radical-cation to the anion with subsequent recombination of the radical pair within the cage.

Thus the detection by ESR of the radical-cations of various aromatic amines [40-42] unambiguously proves the validity of the hypothesis that electron transfer is the first stage of the reaction of amines with various peroxy-compounds: diacyl peroxides, peroxydicarbonates, hydroperoxides, and olefin ozonides. This means that the mechanism of the one-electron oxidation of aromatic amines is probably common to all classes of peroxy-compounds; previously direct evidence had not been obtained for this conclusion. One may suppose that this mechanism is probably valid also for aliphatic amines.

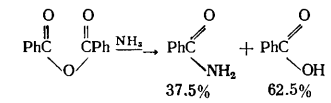
III. KINETICS AND MECHANISM OF REACTIONS OF PHOSPHITES

Whereas the reactions of the majority of peroxy-compounds with amines have been fairly well investigated and there is no doubt that they involve the formation of free radicals, the study of the reactions of peroxy-compounds with phosphites having the general formula $(RO)_3P$ (where R = alkyl or aryl) was until recently restricted solely to stereochemical and isotopic investigations which do not allow unambiguous and reliable conclusions concerning the mechanism of these reactions; moreover, the conclusions concerning the nature of the reactions were frequently made, as will be shown below, on the basis of an analysis of the reactions of phosphite analogues—phosphines R_3P.

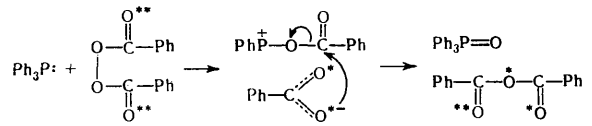
Under mild conditions (at 0°C and below), peroxy-compounds react with phosphines and phosphites to form the corresponding derivatives containing the phosphoryl group P=O (the chemistry of these reactions was described in detail in other reviews [47-51]). The reactions take place with a large heat change (the P=O bond energies are in the range 120–150 kcal mole^{-1} [47,52]). The reactions are also promoted by the easier polarisability of the phosphorus atom compared with the nitrogen atom and possibly $d_\pi - p_\pi$ conjugation, which lowers the energy of the transition state.

Denney and coworkers [53] investigated the mechanism of the reaction of benzoyl peroxide with triphenylphosphine by the isotope tracer method: one of the reactants (benzoyl peroxide) contained ^{18}O in the carbonyl group. It was established that the heavy isotope is fully transferred to only one final product—benzoic anhydride (in the other product, phosphine oxide, there is no ^{18}O). This implies that carbonyl oxygen is not involved in the reaction.

The distribution of ^{18}O in the anhydride was determined by reaction with liquid ammonia. It was found that 37.5% of heavy oxygen is contained in benzamide:



The authors believe that such distribution is possible only when the phosphine attacks the peroxy-oxygen with formation of an ion pair; the latter is converted into the final reaction products by S_N2 nucleophilic substitution:



(* = 1 conventional ^{18}O unit)

An ionic mechanism is also postulated for the reaction of benzoyl peroxide with triallyl phosphite [51] but only on the basis of the usual analysis of the final products (phosphate and anhydride).

However, as in the case of amines, the distribution of ^{18}O in the products of the reaction of benzoyl peroxide with phosphines may be accounted for by the hypothesis of electron transfer as the first stage of the reaction, the isotope tracer method establishing unambiguously only that there is no exchange of carbonyl oxygen atoms without providing more detailed information about the nature of the primary elementary steps of the reactions of peroxides with phosphines and hence also with phosphites.

Among the reactions of phosphites with other peroxy-compounds, those with hydroperoxides are important; the most significant advance achieved is that the mechanism of the elementary stages of these reactions has now been elucidated quantitatively. The first study was published in 1959. Walling and Rabinowitz [54] established that trialkyl phosphites decompose hydroperoxides to a trialkyl phosphate and an alcohol. They suggest that the ion-pair $[(RO_3\overset{+}{P}-OR', {}^-OH]$ is formed as an intermediate. However, Denney et al. [55] believe that the formation of an ion pair of a different structure, $[(RO)_3\overset{+}{P}-OH, {}^-OR']$, converted into the products (phosphate and alcohol) by proton transfer, is more likely. This last hypothesis is based

on the fact that, in the first place, the reduction of hydroperoxides by phosphines in ethanol–$H_2{}^{18}O$ solution yields a phosphine oxide and an alcohol, both without ^{18}O, which can be accounted for by the absence of free OH^- ions and their isotope exchange with the solvent $^{18}OH^-$ ions and, in the second place, by the fact that the optical activity of the initial hydroperoxide is retained in the alcohol formed[56].

However, these arguments put forward by Denney in favour of a nucleophilic mechanism can also be accommodated within the framework of the one-electron mechanism.

Isotope exchange with $^{18}OH^-$ is non-obligatory because the radical–ion pair $[(RO)_3\overset{+}{P}, R'O\bar{O}H]$ can be converted by a monomolecular mechanism into the radical pair $[(RO)_3\dot{P}-OH, R'\dot{O}]$.

Furthermore, the optical activity is retained not only in the $R'O^-$ anions but also in the $R'\dot{O}$ radicals. Thus, in the pyrolysis of the laevorotatory t-butyl α-phenylethyl peroxide in thiophenol, α-phenylethanol is formed[57], i.e. the optical activity does not disappear from the alkoxy-radical‡.

Bearing in mind the unsatisfactory evidence for the mechanism put forward, Denney himself questions it and suggests another mechanism for the initial stage, including the migration of a hydrogen atom in a three-centre activated complex $[R'-\underset{H}{O}\cdots O-P(OR)_3]$. However, this pathway is also unlikely, since it presupposes the dissociation of two bonds simultaneously in a single activated complex. The process most probably consists of a consecutive series of elementary dissociation steps via the intermediate formation of the radicals $R'O$ and $HO\dot{P}(OR)_3$.

On this hypothesis, it was shown[40,59,60] that the introduction of stable iminoxy-radicals, which are powerful free radical acceptors[61], into hydroperoxide–aliphatic phosphite [triethyl phosphite (TEP), tripropyl phosphite (TPP), and iso-octyl diphenyl phosphite] systems leads to their destruction§. This implies that free radicals are formed in the reaction between hydroperoxides and phosphites. The yield of free radicals in the reaction was measured and found to be of the order of 10^{-4}. Direct experiments designed to detect by ESR the free radicals derived from aliphatic phosphites were unsuccessful, probably because of the high rate of destruction of the radicals and their correspondingly low steady-state concentration.

Since the elementary step involving the destruction of radicals is exothermic, the appearance of chemiluminescence in the test system was to be expected; moreover, the energy liberated as a result of these reactions is sufficient for the electronic excitation of their final products [for example, the heat of reaction of triethyl phosphite with t-butyl hydroperoxide, which we estimated as the difference between the heats of formation of the final products (phosphate and alcohol) and the initial reactants, proved to be about 116 kcal mole^{-1}; the values of ΔH_f° for the phosphite and phosphate taken from the literature[62,63] were employed in the calculations].

‡ Recently Bentrude[58] established that the transfer of an oxygen atom from the $R'\dot{O}$ radicals to the optically active phosphines $R_1R_2R_3P$ takes place with retention of the configuration, i.e. the optical activity also does not disappear from the phosphoranyl radical $R_1R_2R_3\dot{P}-OR'$.

§ The experiment designed to investigate the kinetics of the destruction of the acceptor (at 20°C in benzene) was performed on an EPR-2 IKhF spectrometer.

Indeed a luminescence was observed[40,64] in the reaction of t-butyl hydroperoxide with triethyl phosphite and tripropyl phosphite in benzene at 20°C in the absence of oxygen. It was found that the luminescence intensity and the reaction rate constant did not change in the presence of stable iminoxy-radicals; the acceptor was employed at concentrations which were the same as those in the experiments where it was shown by ESR[59] that it captures completely all the radicals released into the bulk phase. This result is important; it implies that the excitation step is not influenced by additional active components of the chemical system, i.e. the emitter (this proved to be the triplet molecule of the reaction product—phosphate[64]) appears in the exothermic step involving the destruction of the free radicals $R'\dot{O}$ and $HO\dot{P}(OR)_3$, which does not take place in the bulk phase but in the "cage" where they are formed.

Thus the chemiluminescence observed in the reaction of t-butyl hydroperoxide with phosphites is a source of information about the processes within the cage.

The question arises of the causes of the low number of radicals released from the cage into the bulk phase (about 10^{-4} of the number of hydroperoxide molecules which have reacted). One of these is probably the small distances between the radicals in the cage.

The cage effect is known[65] to depend strongly on the "diameter" of the cage, i.e. on the distance r_0 between the centres of the radicals of the pair at the instant of its formation. Thus in the thermal decomposition (at 65°C) of diacetyl peroxide, where the CH_3 radicals recombining in the cage are separated by two large CO_2 molecules, the yield of ethane (a measure of the cage effect) is 6% and in the photolysis of azomethane, where the methyl radicals are separated only by an N_2 molecule, the yield of ethane is higher by a factor of 10 (65%). Consequently in the absence of inert molecules the radicals in the $[(RO)_3(OH)\dot{P}\ \dot{O}R']$ pair may be side by side and the probability of the cage effect becomes close to unity.

Another kinetic cause of the low number of radicals liberated from the cage may be the high rate of their disproportionation to the reaction products—phosphate and alcohol; the rate constant for this process may be estimated from the experimental data obtained in the present author's study[40] characterising the dependence of the cage effect in the reactions of t-butyl hydroperoxide with triethyl and tripropyl phosphites on the viscosity of the solvent and temperature.

Since it was established[40] that the radicals are released into the bulk phase only by diffusion (the activation energy for the liberation process $E_f \simeq 2.9$ kcal mole^{-1}, a typical value for the activation energy for the diffusion of species in a liquid[66]), in this case the probability of their release is

$$f = \frac{k_{diss}}{k_{diss} + k_{chem}},$$

and its ratio to the probability of disproportionation in the cage is given by

$$\frac{f}{1-f} = \frac{k_{diss}}{k_{chem}}, \qquad (I)$$

where k_{diss} is the rate constant for the dissociation of the pair (s^{-1}) and k_{chem} the rate constant for the chemical monomolecular conversion of the pair into the reaction products (s^{-1}), i.e. the reciprocal of the lifetime of the

pair. Within the framework of the hydrodynamic Stokes–Einstein model, the viscosity and the rate constant for the dissociation of the pair are related by the expression[67]

$$k_{diss} = \frac{6D}{r_0^2} = \frac{kT}{\pi r_0^3 \eta},$$

where η is the viscosity of the medium and D the diffusion coefficient. Since the probability f of the release of radicals from the cage into the bulk phase is smaller by approximately four powers of ten than the probability of the chemical reaction of the pair, Eqn.(I) simplifies to

$$f \simeq \frac{k_{diss}}{k_{chem}},$$

whence after substituting the expression for k_{diss}, it is possible to obtain a relation between f and the viscosity of the solvent at a constant temperature:

$$f = \frac{kT}{\pi r_0^3 k_{chem}} \cdot \eta^{-1} \qquad (II)$$

and between f and T/η at different temperatures in the same solvent:

$$f = \frac{k}{\pi r_0^3 k_{chem}} \cdot T/\eta \qquad (III)$$

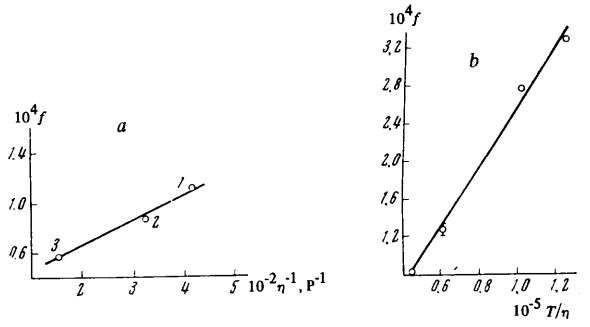


Figure 2. Variation of the number of radicals liberated from the cage into the bulk phase: *a*) with the viscosity of the solvent [according to Eqn. (II)] [1) pentane; 2) hexane; 3) benzene (reaction of t-butyl hydroperoxide with triethyl phosphite at 20°C)]; *b*) with T/η [according to Eqn. (III)] (reaction of t-butyl hydroperoxide with tripropyl phosphite in hexane between −30° and +42°C).

Fig. 2 shows that these formulae hold fairly well under experimental conditions. It follows from both plots that, for an average cage diameter $r_0 = 15$ Å, the rate constant is 1.6×10^{13} s^{-1} (for the reaction with triethyl phosphite) and 4×10^{12} s^{-1} (for the reaction with tripropyl phosphite); these values are close to the frequency of monomolecular decomposition steps; moreover, the linearity of the relation between f and η^{-1} (T = const.) and T/η shows that the rate constant for the disproportionation of radicals within the cage is virtually independent of temperature, as was in fact to be expected.

The kinetic mechanism of the formation of radicals in the reaction of hydroperoxides with aliphatic phosphites can be represented in the following way in a general form:

$$R'OOH + (RO)_3P \xrightarrow{k} \{[R'\dot{O}\overset{+}{O}H \cdots \overset{+}{P}(OR)_3] \rightarrow R'\dot{O}\dot{P}(OH)(OR)_3\} \rightarrow \begin{cases} \xrightarrow{(1-f)k} R'OH + O{=}P(OR)_3 \\ \xrightarrow{fk} R'\dot{O} + \dot{P}(OH)(OR)_3 . \end{cases}$$

In the first stage an electron is transferred from the phosphite to the hydroperoxide with formation of an ion–radical pair; the latter is unstable in neutral solvents and undergoes a monomolecular conversion into a radical pair. The pair disappears mainly by disproportionation within the cage to molecular products—phosphate and alcohol. This mechanism is confirmed by data for radical accepting reactions and chemiluminescence¶; moreover, the idea of electron transfer as the first stage of such reactions is consistent with the capacity of aliphatic phosphites to form paramagnetic charge-transfer complexes (CTC) with typical electron acceptors such as *p*-chloranil[71] trifluoronitrosomethane[72], and others.

Thus the low number of radicals released into the bulk phase (about 10^{-4}) can be explained by such a latent radical mechanism. However, it should be noted that such a low yield may be interpreted also in a different way. It may be assumed that the reaction takes place mainly by non-radical, i.e. ionic or molecular, mechanisms and the contribution of the radical pathway is small (about 10^{-4}). Both alternatives are equivalent in the kinetic sense; therefore, other criteria which would allow a choice will be examined.

One of the characteristics of liquid-phase radical reactions is known to be[73] the cage effect. This effect is associated with the mobility of the species in the liquid phase. Therefore, within the framework of the Stokes–Einstein model, a dependence of the yield of radicals on the viscosity of the solvent is to be expected. Indeed such dependence is found in the reactions of phosphites with hydroperoxides[40,59].

Secondly, the activation energy for the liberation of radicals from the cage into the bulk phase should be close to the activation energy for the diffusion of radicals in the liquid, i.e. 2–4 kcal mole^{-1}.[73] In the reaction of phosphites (tripropyl phosphite in hexane) this energy is 2.9 kcal mole^{-1}.[40]

Thirdly, if the rate constant for the main process is the same in two different solvents with similar viscosities (benzene and styrene) but the yield of radicals in one of them is much higher (more than a factor of ten[59]), one may suppose that the contribution by the radical pathway is much greater. This finding cannot be accounted for without adopting a radical mechanism. It appears that in styrene a new mechanism of the liberation of radicals from the cage, a chemical relay mechanism, obtains; moreover, styrene may affect the lifetime of the radical pair owing to solvation effects.

¶ In principle, the formation of a radical with an unpaired electron at the phosphorus atom as a kinetically independent species is possible also in the reactions of trialkyl phosphites with free radicals, in particular with t-BuO· radicals. Recently this was confirmed experimentally by the observation of the chemically induced polarisation of ^{31}P nuclei in trialkyl phosphates and dialkyl phosphonates[68], by the observation of the ESR spectra of t-butyl radicals[69] as the decomposition products of the primary phosphoranyl radicals $(RO)_3\dot{P}$–O–t-Bu, and also by the analysis of the distribution of the ^{14}C isotope label in tri-t-butyl phosphate[70].

Furthermore, the finding that the chemiluminescence emitter arises in the cage and not in the bulk phase may serve as evidence that mainly radical processes occur in the cage. However, for a clear understanding of the mechanism of the step in which the emitter is formed, analysis of its excited state is necessary. It was found[64] that, in the reaction of t-butyl hydroperoxide with triethyl phosphite, the phosphate molecule in a triplet state is the chemiluminescence emitter. This finding may be regarded as evidence that the chemiluminescence is a result of the reaction of free radicals only. The following considerations lead to this conclusion. We shall assume that the luminescence arises in the ionic reaction $R'O^- + \overset{+}{H}OP(OR)_3 \rightarrow R'OH + O{=}P(OR)_3$ (according to Denney[55]) as a result of proton transfer from the cation to the anion $R'O^-$. The proton in the cation is weakly bound to the oxygen atom via the lone electron pair of the latter; this means that the P=O bond in the cation already exists and is weakly perturbed by the proton. Therefore the anion, on coming into contact with the cation, "abstracts" the proton, so that the energy of the phosphate molecule produced in this process hardly changes. As a result of this, the entire energy liberated in the recombination of $R'O^-$ and the proton is localised at the alcohol molecule and there is a high probability of its degradation via the internal degrees of freedom. Thus, within the framework of Denney's ionic mechanism, it is difficult to explain the excitation of the phosphate molecule. The localisation of the electron excitation energy at the phosphate molecule is to be expected in the disproportionation of the $R'\dot{O}$ and $HO\dot{P}(OR)_3$ radicals, where the abstraction of a hydrogen atom may lead to the triplet excitation of the double bond in the phosphate.

Finally we may recall that low yields of radicals (about 10^{-3}) are observed also in the benzoyl peroxide–diphenylamine system; this finding was also explained[20] by the high rate of recombination of nitrogen and benzoate radicals in the cage. In this case there is no doubt that the reaction proceeds wholely by a radical mechanism. As will be shown below, in this sense the reactions of amines, phosphites, and also sulphides have common properties and common characteristics.

Thus all the above criteria suggest a latent radical mechanism of the reactions of hydroperoxides with aliphatic phosphites.

Within the framework of the concept of the latent radical mechanism, the mutual enhancement of the effectiveness of phenols and phosphites in the inhibition of the oxidation of polymers can be accounted for[60]; it is due to the high effectiveness of the phosphites in the suppression of degenerate branching.

The kinetics of the reactions of hydroperoxides with aliphatic, aromatic, and mixed phosphites have been investigated in a number of studies by measuring the consumption of the hydroperoxide[59,74,75] and stable radicals[59,60] and by following the chemiluminescence, which was first observed[64] in these reactions. It was found that the rates of the reactions are described by a first-order kinetic equation with respect to each component. Thus the rate constant for the reaction of tri-t-butylphenylphenylene phosphite with 1,1-diphenylethyl hydroperoxide in benzene is described by an equation of the form $k = 2.4 \times 10^8 \exp(-14\,000/RT)$ litre mole^{-1} s^{-1}†; the following expression was obtained for the rate constant for the reaction of tripropyl phosphite with *t*-butyl hydroperoxide in hexane[40]: $k = (0.5 \pm 0.1) \times 10^2 \exp(-5200 \pm 1400/RT)$ litre mole^{-1} s^{-1}. Evidently, as in the case of amines, the reactions of phosphites with hydroperoxides have low activation energies.

† We estimated the values of k_0 and E_{act} from Mukmeneva's data[74].

IV. KINETICS AND MECHANISM OF REACTIONS OF SULPHIDES

We shall now consider the reactions involving sulphides which probably constitute yet another example of oxidation–reduction reactions of peroxy-compounds. In the literature there are several examples confirming this hypothesis. Thus in a study of the effectiveness of the initiation of the polymerisation of methyl methacrylate by various hydroperoxides, Minoura et al.[76] observed an acceleration of the process by the addition of dibenzyl sulphide at 50°C. Kinetic analysis showed that the rate of polymerisation is given by

$$w_n = (k_p/k_t^{1/2})[MMA]^{1.3}[R_2S]^{1/4}[R'OOH]^{1/2}.$$

This shows that the free radicals initiating the polymerisation of methyl methacrylate are formed in a bimolecular reaction of the hydroperoxide and the sulphide; however, it should be noted that Minoura et al.[76] did not estimate the effectiveness of such initiation.

The yield of free radicals in the reactions of hydroperoxides with sulphides (dilauryl thiodipropionate and dibenzyl sulphide) was first measured by Pobedimskii and Buchachenko[77] by the method of stable iminoxy-radicals; it proved to be low (about 10^{-4}). Pobedimskii and Buchachenko[77] suggested a kinetic mechanism for the reaction analogous to that used for the reactions of phosphite[59] (see p. 23). As for phosphites, the low yield of radicals in the reactions of sulphides with hydroperoxides can be accounted for by the closeness of the radicals in the pair and the high rate of their disproportionation to the reaction products; even the addition of radicals to the double bond cannot compete, in terms of rate, with the process taking place within the cage. Thus in styrene, where the rate constant is the same as in benzene, the yield of radicals at 20°C was 3.3×10^{-3}. This example and also the data showing the low yield of radicals in the reactions of amines and phosphites[20,59] illustrate the common latent radical nature of the reactions of sulphides, phosphites, and aromatic amines with peroxy-compounds.

Subsequently Schmidt et al.[78] observed by ESR the formation of the radical-cations of derivatives of diphenyl sulphide [di-(4-methylphenyl), di-(4-methoxyphenyl), di-(4-methoxy-3-methyl), di-(2-chloro-4-methoxyphenyl), di-(4-hydroxyphenyl), di-(3,6-dichloro-4-hydroxyphenyl), and di-(6-chloro-4-hydroxyphenyl) sulphides] in their oxidation by persulphate ions in concentrated sulphuric acid solution at 20°C. For example, the ESR spectrum of the radical-cation of di-(4-methoxyphenyl) sulphide (*g*-factor = 2.0079) consists of nine lines with a splitting of 1.25 Oe owing to the coupling of the unpaired electron with the eight equivalent protons of the aromatic rings (probably the unpaired electron density at the *ortho*- and *meta*-protons is the same); the observed ratios of the hyperfine structure intensities (0.6 : 7 : 27 : 54 : 70 : 53 : 23 : 4 : 0.6) proved to be close to the ratios expected for the proton structure (1 : 8 : 28 : 56 : 70 : 56 : 28 : 8 : 1). The isolation of the radical-cations in a pure state in 100%

yield (as the hexachlorostannate) unambiguously demonstrates that the reaction investigated takes place exclusively via one-electron transfer.

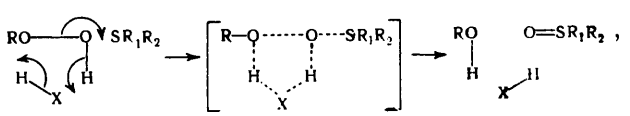
The radical cations $CH_3O-C_6H_4-\overset{+\cdot}{S}-C_6H_4-OCH_3$

were detected[77] also in the reactions of cumenyl peroxide, benzoyl peroxide, and dicyclohexyl peroxydicarbonate with the initial sulphide in trifluoroacetic acid and in its mixtures with polar solvents (i.e. in media where the radical cations are stabilised). The experimental hyperfine coupling constants ($a_H^o = a_H^m = 1.35$ Oe) are close to those measured for the same radical-cations obtained in the oxidation by persulphate ions[78]. This result is important; it can be regarded as confirmation of the suggested mechanism for the formation of free radicals in the reaction of hydroperoxides with aliphatic sulphides[77].

In a number of studies the products and the kinetics of the reactions of peroxy-compounds (diacyl peroxides, peracids, and hydroperoxides) with sulphides were investigated. At moderate temperatures benzoyl peroxide and hydroperoxides usually yield only the sulphoxides $R_2S{=}O$, whereas peracids convert sulphides via sulphoxides into sulphones R_2SO_2.[27,28,79] The rates of these two stages differ significantly; for example, peracetic acid in acetic acid solution oxidises diphenyl sulphide to the sulphoxide about 1000 times faster than the oxidation of the sulphoxide to the sulphone[80]. Horner[81,82] showed that the reactions of sulphides with benzoyl peroxide in chloroform are described by a second-order kinetic equation; aliphatic sulphides reacted at 20°C faster than aromatic sulphides [the rate constant for the reaction of $(C_2H_5)_2S$ is about 3.6×10^{-3} litre mole^{-1} s^{-1} and that for the reaction of $C_2H_5SC_6H_5$ is 4.5×10^{-4} litre mole^{-1} s^{-1}]. Overberger and Cummins[83] found that the reduction of peracids by sulphides also follows second-order kinetics.

The kinetics of the reaction of hydroperoxides with sulphides were investigated in protic and aprotic solvents simultaneously by iodometric titration of the hydroperoxide and chemical determination of the reaction product (the sulphoxide)[27,28,79,84,85]. In alcoholic, aqueous alcoholic, acidic, and basic solutions at temperatures between −65° and +75°C the reaction has the following parameters: (1) 1 : 1 stoichiometry according to the equation $R_2S + R'OOH \rightarrow R_2SO + R'OH$; (2) first order with respect to each component; (3) low activation energies (between 9.5 and 17.5 kcal mole^{-1} depending on the structure of the hydroperoxide[79]; (4) specific Brönsted acid catalysis at pH < 3.[85]

In aprotic solvents unusual kinetic relations were observed. Thus Bateman and Hargrave[84] found that the rate of the reaction of cyclohexyl methyl sulphide with t-butyl hydroperoxide in benzene at 50°C obeys a second-order kinetic equation with respect to the hydroperoxide, while in a benzene–acetic acid (or alcohol) mixture the hydroperoxide is consumed according to first-order kinetics. It was suggested[79,84] that this reaction has a molecular mechanism without the formation of free radicals, via the transfer of a hydrogen atom in a cyclic activated complex:



where X = CH_3COO, ROO, or RO.

However, many facts cannot be explained by the proposed mechanism[79,84] [different kinetic effects of the hydrogen bonds between the hydroperoxide and the molecules of the medium (methanol or acetic acid), unequal effects of the inhibitors and oxygen on the rate of reaction as a function of the solvent, fractional order of the reaction with respect to the sulphide in the absence of oxygen, etc.] and therefore the findings in these investigations cannot be regarded as unambiguous. Moreover, the destruction of stable radicals following their introduction into the hydroperoxide–sulphide system (in the presence of the sulphide alone or the hydroperoxide alone, stable radicals are not consumed)[77] and also the initiation of the radical polymerisation of methyl methacrylate by a hydroperoxide–sulphide system[76] are completely inconsistent with the hypothesis of a molecular mechanism; moreover, the type of relation between w_n and the concentrations of the sulphide and the hydroperoxide corresponds to bimolecular formation of radicals (and not trimolecular as would be expected according to Bateman and Hargrave[84]). A polarographic study of the consumption of t-butyl hydroperoxide in the reaction with dilauryl thiodipropionate at 20°C in benzene also led the authors[77] to the conclusion that the reaction in benzene is of first order with respect to each component.

Thus the detection of radical-cations and free radicals in various sulphide–peroxy-compound systems permits the hypothesis of the existence of a single mechanism for all the reactions of sulphides: it suggests that the reactions following electron transfer have a radical mechanism. Within the framework of these concepts, it is possible to explain also the significance of the specific acid catalysis of the reactions of sulphides with hydroperoxides[85]; it is probably due to the fact that electron transfer from the sulphide molecule to the hydroperoxide takes place with participation of the protonated form of the latter, which is more reactive (a more powerful electron acceptor) than the free hydroperoxide.

V. OXIDATION–REDUCTION NATURE OF THE REACTIONS OF PEROXY-COMPOUNDS WITH PHOSPHITES, SULPHIDES, AND AROMATIC AMINES

An interesting and general result of the reactions of peroxy-compounds with amines, phosphines (and hence also phosphites), and sulphides is, as shown below, the existence of correlations of the Hammett equation type for the rates of these reactions and also correlations between the rate constants and ionisation potentials and electron affinities; the occurrence of identical correlations implies that the mechanisms of all three types of reaction are governed by a common relation. We shall examine these correlations and shall attempt to account for them in terms of an oxidation–reduction mechanism.

From the standpoint of Mulliken's theory[86], electron transfer in a donor–acceptor pair takes place between the higher filled molecular orbital (MO) of the donor and the lower vacant molecular orbital of the acceptor. Calculation of the electronic structures of the various peroxy-compounds by the extended Hückel method[87-89] showed that the lower vacant molecular orbital of these compounds is an antibonding orbital localised in the $2p\sigma$-orbital between two oxygen atoms.

One may suppose that the introduction of electron-accepting substituents into the peroxide and of electron-donating substituents into the donor molecule will lead respectively to a decrease of the energy level of the

antibonding orbital along the O–O bond in the peroxide and to an increase of the level of the donor orbital filled by the lone electron pair.

Bearing in mind that the rates of the reactions of peroxy-compounds with amines, phosphites (phosphines), and sulphides are probably determined by electron transfer from the donor to the peroxide, such mutual approach of the energy levels of the reactants on introduction of polar groups will result in a lowering of the activation energy for the process and hence in an increase of its rate constant.

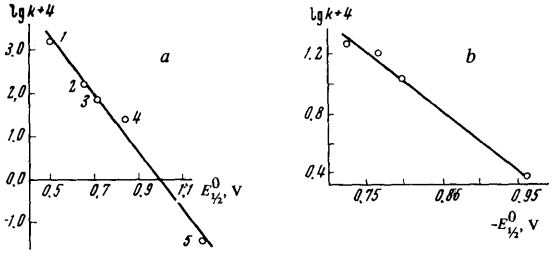


Figure 3. Variation of the logarithm of the rate constant: *a*) with the half-wave oxidation potential for the reaction of benzoyl peroxide with dimethylaniline and its *para*-derivatives [1) CH_3O; 2) CH_3; 3) H; 4) Cl; 5) NO_2]; *b*) with the half-wave reduction potential for the reaction of cyclohexyl methyl sulphide with various hydroperoxides.

Indeed the literature data show that many of the reactions considered here obey the Hammett relation. For example, electron-donating substituents in the benzoyl peroxide molecule decrease the rate of its reaction with dimethylaniline ($\rho = +0.181$).[14] The effect of the substituents in the ring of the dimethylaniline molecule on its reaction with benzoyl peroxide is of the opposite type ($\rho = -4.25$; this value was determined by the present authors from the data of Horner and Scherf[81] for σ° in the range between −0.27 and +1.27‡); then the rates of the reactions of amines with the most electron-accepting and electron-donating substituents differ by a factor not less than 10^3§. Ring substituents have an analogous effect on the rate of reaction of methyl phenyl sulphide with benzoyl peroxide: in the extreme cases the rates of reaction differ by a factor of about 200.[82] However, the slope of the correlation line was smaller ($\rho = -2.2$; this value was determined by the present authors from the data of Horner and Jügens[82] with σ° in the range between −0.27 and +0.78); probably, the effect of substituents on the position of the donor level in the sulphide is somewhat reduced compared with the analogous effect in the amine. Finally, it is known[49] that the reaction of phosphines and benzoyl peroxide is also accelerated by the introduction into the peroxide molecule of electron-accepting substituents.

The rates of the reactions of benzoyl peroxide with dimethylaniline and its *para*-substituted derivatives show an explicit relation also with the polarographic oxidation potentials of the donor molecules. This relation can be understood if one takes into account the fact that the energies of the highest filled orbitals are frequently correlated with the first polarographic oxidation half-wave potential; in this case such a potential corresponds to the first oxidation stage—the abstraction of one electron from the amine molecule with formation of a radical–cation. Table 3 lists the literature values of the rate constants for the reaction of benzoyl peroxide with dimethylaniline and its *para*-substituted derivatives, the first polarographic half-wave oxidation potentials $E^0_{1/2}$ for which are known.

Table 3. Data for the rates of reaction of benzoyl peroxide with dimethylanilines*.

para-Substituent	$E^0_{1/2}$ (in acetonitrile)	$10^4 k_{20°}$, litre mole^{-1} s^{-1}	Solvent in reaction
CH_3O	0.48	1550	Chloroform
CH_3	0.65	166	ditto
H	0.71	76	»
Cl	0.84	26	»
NO_2	1.19	0.04	»

* The values of k were taken from Horner and Scherf[81] and those of $E^0_{1/2}$ from Seo et al.[92]

Fig. 3 shows the variation of the logarithm of the rate constant with the oxidation half-wave potentials of amines which the present authors plotted from the data in Table 3. Evidently the experimental data fit on a straight line described by the empirical equation $\lg k_1 - \lg k_2 = \alpha(E^0_{1/2(1)} - E^0_{1/2(2)})$, where $\alpha = -6.6$. This relation arises in consequence of the general relation between the affinity of the reaction (the free energy change) and its rate, since the affinity of the reaction in the cases under consideration is determined primarily by the difference between the energies of the lowest vacant molecular orbital of the peroxy-compound and the highest filled molecular orbital of the donor.

Another relation is also to be expected: the relation between the rate constants and the second component of the reaction affinity (the energy of the lowest vacant molecular orbital of the acceptor). The polarographic reduction half-wave potential $E^0_{1/2}$ may serve as a measure for the comparison of the electron-accepting properties. It is known[93] that hydroperoxides are reduced at a dropping mercury electrode by a two-electron process:

$$R'OOH \xrightarrow[+2e^-]{+2H^+} R'OH + H_2O$$

and give rise to a single polarographic wave. If it is assumed that the rate-limiting stage in the electrochemical reduction of the hydroperoxide is the transfer of the first electron, then the experimental value of $E^0_{1/2}$ must correspond to the one-electron reduction of the hydroperoxide $R'OOH + e \rightarrow R'O\dot{O}H$ and consequently can serve

‡ The values of σ° recommended by Taft[90] and Jaffe[91] were employed.

§ Attention should be drawn to the fact that the rate constant for the reaction of benzoyl peroxide with dimethylaniline and its derivatives and the hyperfine coupling constants for the ^{14}N nucleii in the radical-cations (see Fig. 1) vary in the opposite sense on introduction of electron-accepting groups into the aromatic ring; this implies that the a_N/σ correlation has a direct bearing on the reactivity of dimethylaniline and its derivatives.

as a measure of its electron affinity. Using this approximation, we shall attempt to find a relation between the rate constants and the potentials $E^0_{1/2}$.

Comparison of the rate constants for the reactions of various hydroperoxides with cyclohexyl methyl sulphide (Table 4) and the data for their polarographic reduction shows that the rate constant increases as the negative value of $E^0_{1/2}$ diminishes.

Table 4. Data for the rates of reaction of cyclohexyl methyl sulphide with various hydroperoxides (at 50°C in methanol)*.

Hydroperoxide	$E^0_{1/2}$ (in methanol–benzene)	$10^4 k$, litre mole^{-1} s^{-1}	E_{act}, kcal mole^{-1}	$10^{-5} k_0$, litre mole^{-1} s^{-1}
$(CH_3)_3COOH$	−0.96	2.2	14.1	7.6
–OOH	−0.80	10.8	—	—
–OOH	−0.77	16.5	12.6	3.1
–OOH	−0.73	18.4	—	—

* The values of k were taken from Bentrude and Wielesek[70] and those of $E^0_{1/2}$ from Willits et al.[94]

Fig. 3*b* shows this relation in a semilogarithmic form, which, like the relation for the amines (Fig. 3*a*), is satisfactorily consistent with the familiar Dimroth equation[95] for oxidation–reduction reactions: $\lg k_2 - \lg k_1 = \beta(E_2 - E_1)$; for the sulphide, the difference between the redox potentials $E_2 - E_1$ is equivalent to the difference between the reduction half-wave potential $E^0_{1/2(2)} - E^0_{1/2(1)}$ and the slope $\beta = +4.2$.

The existence of Hammett type correlations for the rates of the reactions of peroxy-compounds with amines, phosphines (and, by analogy, with phosphites), and sulphides and also the correlations between the rate constants and the ionisation potentials and electron affinities may serve as an indication that in the activated complex an electron is transferred and that this stage is probably rate-limiting.

In conclusion we may note that many reactions are considered to be ionic or molecular only because free radicals are not detected during their occurrence; in fact, however these reactions can frequently be of the latent radical type, i.e. they can proceed via free radicals which are destroyed in the cage immediately after their formation. Clearly new approaches and new ideas are required in order to be able to control processes within the cage by actively interfering with their kinetics. One of such approaches may be the study of dynamic nuclear polarisation in chemical reactions[96].

Reactivity and Thermal Stability of Hexafluorides

N.P.Galkin and Yu.N.Tumanov

The review deals with the possibility of using various physicochemical characteristics of the hexafluorides of *p*, *d*, and *f* elements for a comparative estimation of their thermal stability and reactivity. The force constants of EF_6 molecules, the average bond energy and length, and also the thermodynamic stability constants of the octahedral EF_6 molecules have been used as characteristic properties.
It has been shown that the force constants of the E-F bond are not effective characteristics of the thermal stability and reactivity of all hexafluorides in reactions where more than one E-F bond is dissociated.
Only the thermodynamic stability constants can serve as an objective criterion for the assessment when account is taken of definite dissociation mechanisms of EF_6 molecules (complete or incomplete dissociation).
Within the limits of individual groups of 4*d*, 5*d*, and 5*f* elements and also sulphur, selenium, and tellurium, the variation of the force constants and thermodynamic stability in relation to the incomplete dissociation of the hexafluorides corresponds to the experimental sequences of their thermal stabilities.
The bibliography includes 85 references.

I. INTRODUCTION

Hexafluorides are a class of fluoride compounds formed by certain elements having not less than six *p*, *d*, or *f* valence electrons. Up to the present time, the hexafluorides of 18 elements have been identified: sulphur, chromium, selenium, molybdenum, technetium, ruthenium, rhodium, tellurium, xenon, tungsten, rhenium, osmium, iridium, platinum, polonium, uranium, neptunium, and plutonium. In addition one may expect, by analogy, the formation of the hexafluorides of palladium, iodine, astatine, radon, and americium.

The common properties of hexafluorides are low melting and boiling points and comparatively high volatility under ordinary conditions (Table 1). With the exception of XeF_6, the molecules of hexafluorides EF_6 have the configuration of a regular octahedron belonging to the O_h point group with the element E in the centre. The reactivities of hexafluorides are not the same. Some hexafluorides, for example CrF_6, are so unstable that they can be synthesised and investigated only at very low temperatures, while others (for example sulphur hexafluoride) resemble the noble gases in their chemical inertness.

Hexafluorides have attracted much interest, since those of many elements are obtained and used in individual stages of the technology of the manufacture of nuclear fuel[1-3]. In particular, this accounts for the publication of a large number of studies on the physicochemical properties of both individual hexafluorides and individual groups. Reviews have also appeared on hexafluorides, among which mention should be made in the first place of those by Weinstock[2-4] and O'Donnel and coworkers[5-8].

In Weinstock's work attention was concentrated on the molecular constants of hexafluorides. However, there are certain data on their thermal stabilities[3,4]. O'Donnel and coworkers attempted to make a systematic arrangement of the hexafluorides of certain elements in terms of their reactivities. In particular, they showed that the reactivities of hexafluorides fall on moving down the Groups of the Periodic System, while the thermal stabilities increase on going from elements with 3*d* electrons to elements with 5*d* electrons[5-7].

Table 1. Physicochemical properties of hexafluorides[3,4,8].

Hexafluoride	Type of characteristic electrons of element E	No. of free electrons	Symmetry of ground state of EF_6	M.p., °C	B.p. (sublimation temp.) at p = 1 atm., °C	Critical temp., °C	Vapour pressure at 15°C, mmHg
SF_6	3 *p*	0	A_{1g}	−50.4*	−63.7	45.5	—

* Under the pressure of its own vapour.
** Triple point.

In the solution of certain practical problems associated with the presence in a chemical system of the hexafluorides of several elements or their lower fluorides, it is necessary to employ some qualitative criterion in order to predict the changes in the system which are potentially possible. Thermodynamic analysis is in many cases impossible, since the thermochemical and thermodynamic constants of many fluorides are unknown. On the other hand, an empirical systematic arrangement may prove to be unreliable, since the rate of a chemical reaction depends on the experimental conditions. For example, in the system "uranium hexafluoride–hydrogen" the products may be uranium pentafluoride, tetrafluoride, trifluoride, or the so called "intermediate" fluorides U_2F_9, U_4F_{17}, etc., depending on the temperature, the reactant ratio, and the effect of light. Until recently it was also believed that molybdenum and tungsten hexafluorides are vigorous fluorinating agents[9,10], but later studies[5,11] showed that these two hexafluorides are inert.

In the present review the possibility of using various physicochemical characteristics of hexafluorides for a comparative estimation of their reactivities and thermal stabilities is discussed. Such characteristics may be the force constants of the EF_6 molecules, the E – F bond energies and lengths, and the equilibrium dissociation constants of hexafluorides. An attempt has been made to discover regularities in thermal stability both for the entire class of hexafluorides and for individual series.

II. PRINCIPAL GROUPS OF HEXAFLUORIDES

Depending on the nature of the valence shell of the element forming the hexafluoride or the type of its valence electrons, all hexafluorides can be arranged systematically in groups according to the position of the elements in the Periodic System. The positions of the hexafluorides of various elements in these groups are consistent with the positions of the elements themselves, either in the Periods (horizontal series) or in the Group (vertical series) of the Periodic System. The horizontal series of hexafluorides comprise the groups of hexafluorides of 3*d* (CrF_6), 4*d* (MoF_6, TcF_6, RuF_6, RhF_6), 5*d* (WF_6, ReF_6, OsF_6, IrF_6, PtF_6), and 5*f* elements (UF_6, NpF_6, PuF_6). The vertical series of hexafluorides comprise (1) the hexafluorides of the non-metals in Group VI of the Periodic System (SF_6, SeF_6, TeF_6, PoF_6), (2) the hexafluorides of the transition elements of Group VI (CrF_6, MoF_6, WF_6, UF_6), (3) the hexafluorides of elements with one unshared electron (TcF_6, ReF_6, NpF_6), (4) the hexafluorides of elements with two unshared electrons (RuF_6, OsF_6, PuF_6), (5) the hexafluorides of elements with three unshared electrons (RhF_6, IrF_6), and (6) platinum hexafluoride (PtF_6). The platinum atom in this molecule has four unshared electrons which, judging from the type of the ground state of the PtF_6 molecule (Table 1), are paired. Xenon hexafluoride, the molecule of which does not belong to the symmetry point group O_h, occupies a special place.

The electronic ground states of eleven hexafluorides of sulphur, selenium, tellurium, molybdenum, tungsten, uranium, neptunium, plutonium, rhodium, iridium, and platinum are either non-degenerate or the degeneracy is predominantly of the spin type. The normal vibrational spectra of these molecules correspond to O_h symmetry. The vibrational spectra of the hexafluorides of technetium, ruthenium, rhenium, and osmium have appreciable anomalies (compared with the preceding hexafluorides), which are attributed to the dynamic Jahn–Teller effect[4,12-15]. According to the Jahn–Teller theorem[16], the orbital degeneracy of the electronic ground state of octahedral molecules is reduced by distortion of their configuration, i.e. by a decrease of molecular symmetry. This is the so called static Jahn–Teller effect. However, in the present case the static Jahn–Teller effect is not observed, but there is an anomaly in the infrared absorption spectra owing to a vibronic interaction.

Table 2. Width of the half-absorption bands of certain hexafluorides (cm^{-1}) [4].

Molecule	$\nu_{1/2}$		$\Delta\nu_{1/2}$	Molecule	$\nu_{1/2}$		$\Delta\nu_{1/2}$
	$\nu_1+\nu_3$	$\nu_2+\nu_3$			$\nu_1+\nu_3$	$\nu_2+\nu_3$	
MoF_6	20	31	0	WF_6	17	24	0
TcF_6	23	113	84	ReF_6	36	68	43
RuF_6	21	—	—	OsF_6	23	84	59
RhF_6	19	27	0	IrF_6	18	26	0
				PtF_6	20	26	0
Mean*	21	29		Mean*	20	25	

* The band widths for "anomalous" hexafluorides were disregarded in the averages.

The infrared spectra of the "normal" hexafluorides usually have two characteristic bands corresponding to the compound frequencies $\nu_1 + \nu_3$ and $\nu_2 + \nu_3$ in the region of 1140–1710 cm^{-1} and having almost identical intensities and outlines (Table 2). For each hexafluoride, the long wavelength band corresponds to the compound frequency $\nu_2 + \nu_3$ and the short wavelength band to the frequency $\nu_1 + \nu_3$. However, whereas the outlines of the $\nu_1 + \nu_3$ bands are virtually identical for both "normal" and "anomalous" hexafluorides, those of the $\nu_2 + \nu_3$ bands for different types of hexafluorides are not the same, which is a qualitative criterion of the "anomaly" of the hexafluorides.

The relations between the observed frequencies and the number of unshared valence electrons in the molecules of the "normal" hexafluorides, derived by Weinstock and Goodman[3,4], make it possible to estimate the vibration frequencies ν_2 and ν_5 which the molecules of the hexafluorides of technetium, ruthenium, rhenium, and osmium would have in the absence of the dynamic Jahn–Teller effect. The points corresponding to the ν_2 and ν_5 frequencies of the "anomalous" hexafluorides deviate from the graphical relations. It is interesting to note that the anomalies in the vibrational spectra of the hexafluorides of 4*d* and 5*d* elements are not repeated in the series of the hexafluorides of 5*f* elements.

III. RELATION BETWEEN THE VARIATION OF THE FORCE CONSTANTS OF HEXAFLUORIDES AND THEIR THERMAL STABILITIES AND REACTIVITIES

In certain reviews (for example those of O'Donnel and Stewart[5,6]) attempts are made to relate the regularities in the variation of the reactivities of hexafluorides in the first vertical series (CrF_6, MoF_6, WF_6, UF_6) to the valence force constants (f_d in Wilson's terminology[17]) and average energies of the E – F bonds. Several comments of

a general nature must be made concerning the estimation of the reactivities of hexafluorides with the aid of the force constants. The force constant† $f_d = (\partial^2 V/\partial q^2)_{q \to 0}$, where V is the potential energy of the molecule and q the vibrational coordinate, characterises the resistance of the molecule to the deformation of the equilibrium configuration. However, even for diatomic molecules there is no unambiguous relation between the force constant and the dissociation energy[18]. The quantity $(\partial^2 V/\partial q^2)_{q \to 0}$ characterises merely the curvature of the potential well in the vicinity of the equilibrium position but does not necessarily indicate its depth[19].

The multiplicity of models proposed for the description of the force field of a polyatomic molecule is due to the existence of a set of elastic structural elements the number of which is greater than the number of chemical bonds and independent nuclear coordinates. However, regardless of the choice of model, none of the different types of coefficients can provide a simple individual characteristic of a bond in a polyatomic molecule[20]. The extension of one bond involves a whole group of structural elements, since the valence force constant f_d depends not only on the interaction between two atoms but also on their interaction with other structural elements of the molecule. Only a set of force constants characterises an individual bond in a polyatomic molecule[21].

We shall consider to what extent various force constants of hexafluoride molecules can characterise their thermal stability and reactivity. In the present paper we shall employ the terminology adopted by Claassen[22]:

(1) f_d—valence force constant;
(2) f_α—deformation force constant for the bond angle;

Interaction Constants

(3) f_{dd}—for the interaction of bonds at right angles to one another;
(4) $f_{\alpha\alpha}$—for the interaction of adjacent angles in the same plane;
(5) $f_{d\alpha}$—for the interaction of an angle with the bonds forming its sides;
(6) δ—for the interaction of two opposite bonds;
(7) γ—for the interaction of an angle with a bond perpendicular to its plane;
(8) k—for the interaction between two angles in perpendicular planes having a bond in common;
(9) ϵ—for the interaction between two angles in perpendicular planes without a bond in common.

Seven independent force constants may be isolated for hexafluoride molecules[4]:

(1) $A = f_d$;
(2) $B = \delta$;
(3) $C = 2f_{dd}$;
(4) $D = 2(f_{d\alpha} - \delta)$;
(5) $E = f_\alpha - \gamma$;
(6) $F = 2(f_{\alpha\alpha} - \gamma)$;
(7) $G = 2(k - \epsilon)$.

Many investigators[4,22-36] analysed the normal vibrations of octahedral hexafluoride molecules and calculated the force constants. The force constants depend on the choice of model for the force field. In the present study only the force constants quoted in the review of Weinstock and Goodman[4] are considered. They are listed in Table 3.

† For diatomic molecules.

Figs. 1 and 2 present a graphical interpretation of the relation between the force constants of EF_6 molecules and the charge number of the element E (see p. 157).

Analysis of these relations permits the following conclusions: (1) the valence force constant exceeds approximately by two powers of ten all the remaining force constants; this is a general rule[37]; (2) the independent force constants A, B, E, and partly G of hexafluoride molecules increase on going from 4*d* to 5*d* elements and sharply decrease on going to 5*f* elements; (3) the force constants C and F also increase on going from 4*d* to 5*d* elements; on going to 5*f* elements, the constant C increases and the constant F changes in different ways for each of the vertical series; (4) the constant D decreases on moving downwards along the vertical series; (5) the constants A, B, C, and partly G decrease sharply on moving along the series of 4*d*, 5*d*, and 5*f* elements from left to right, which is consistent with the variation of the thermal stabilities of the hexafluorides; (6) the constants D, E, and F increase along the series of 4*d*, 5*d*, and 5*f* elements (from left to right).

Table 3. Force constants of octahedral hexafluoride molecules[4] [$cm^{-1}/(0.01\ Å)^2$].

Force constant	SF_6	SeF_6	MoF_6	TeF_6	RuF_6	RhF_6	TeF_6	WF_6

C	3.580	1.232	2.597	1.888	1.268	0.986	0.711	0.709
D	5.634	2.160	0.713	0.720	0.767	0.806	0.499	0.488
E	4.346	2.648	0.843	1.083	1.199	1.260	1.090	0.970
F	0.443	0.316	−0.555	−0.183	0.050	0.221	−0.317	−0.455
G	0.848	0.676	−0.415	0.214	0.205	0.234	−0.002	0.454

	ReF_6	OsF_6	IrF_6	PtF_6	UF_6	NpF_6	PuF_6
A	26.353	26.185	25.181	23.033	19.412	19.029	18.451
B	1.802	1.190	0.209	−1.033	0.066	−0.314	−0.425
C	2.293	1.744	1.418	1.322	3.038	2.702	2.314
D	0.480	0.531	0.543	0.526	0.210	0.244	0.255
E	1.243	1.400	1.432	1.446	0.663	0.832	0.899
F	−0.006	0.307	0.476	0.605	0.083	0.229	0.255
G	0.173	0.194	0.213	0.168	0.100	0.050	0.035

One may conclude that the variation of the majority of force constants along the horizontal and vertical series of hexafluorides is of the same type as that of the valence force constant f_d (A). The force constants for sulphur, selenium, and tellurium hexafluorides are quoted only for comparison.

Analysis of the feasible configurations of the xenon hexafluoride molecule[38] showed that it cannot have the structure of a regular octahedron. A model close to the structure of iodine heptafluoride, in which the missing bond is replaced by the electron pair of xenon, is more likely. This is confirmed both by the analysis of the infrared spectrum of xenon hexafluoride[39] and by the study of its structure by electron diffraction[40,41]. Therefore the force constants of XeF_6 cannot be compared with those of other hexafluorides.

On the hypothesis of a relation between the force constants, thermal stabilities, and reactivities of EF_6 molecules, the latter can be arranged in the following series in terms of their thermal stability:

Vertical series:

$$SF_6 > TeF_6 > SeF_6;$$
$$WF_6 > MoF_6 > UF_6;$$
$$ReF_6 > TcF_6 > NpF_6;$$
$$OsF_6 > RuF_6 > PuF_6;$$
$$IrF_6 > RhF_6.$$

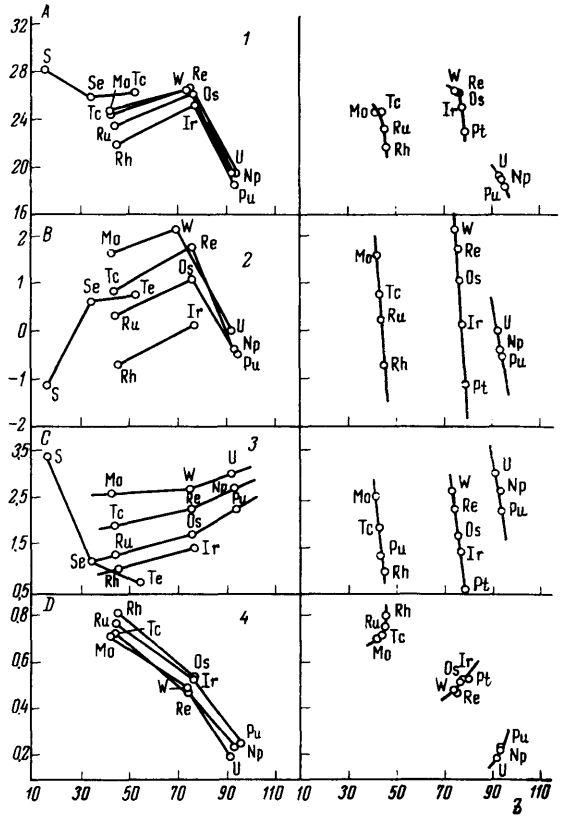

Figure 1. Variation of the force constants A, B, C, and D of EF_6 molecules with the charge number of the central atom of the element E in the vertical and horizontal series of hexafluorides.

Horizontal series:

$$MoF > TcF_6 > RuF_6 > RhF_6;$$
$$WF_6 > ReF_6 > OsF_6 > IrF_6 > PtF_6;$$
$$UF_6 > NpF_6 > PuF_6.$$

When all the elements are arranged in a single series, the following sequence is obtained:

$$SF_6 > WF_6 > ReF_6 > OsF_6 > TeF_6 > SeF_6 > IrF_6 > MoF_6 > TcF_6 > RuF_6 > PtF_6 > RhF_6 > UF_6 > NpF_6 > PuF_6.$$

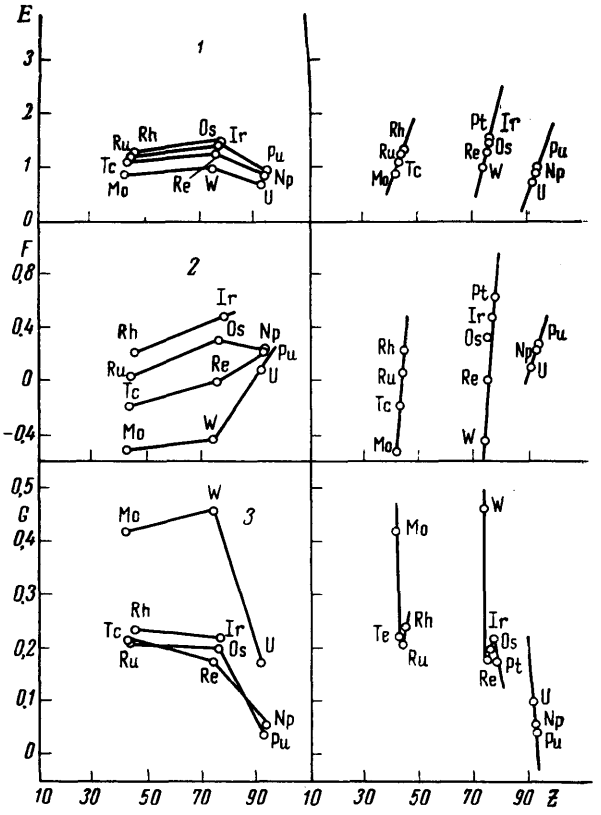

Figure 2. Variation of the force constants E, F, and G of EF_6 molecules with the charge number of the element E in the vertical and horizontal series of hexafluorides.

The last series probably does not fully reflect the actual relation between the thermal stabilities and reactivities of the hexafluorides. Therefore, before dealing with a comparative analysis of the experimental data, it is necessary to analyse the above relations by other methods.

IV. VARIATION OF THE AVERAGE BOND ENERGIES OF HEXAFLUORIDES IN HORIZONTAL AND VERTICAL SERIES

The average bond energy E_0 of the EF_n molecule is defined by the formula

$$E_0 = \frac{D_0^0}{n}, \qquad (1)$$

where D_0^0 is the heat of atomisation of the molecule and n is the number of bonds. The values of D_0^0 are not known for all hexafluorides and the accuracy of the calculation or estimation of some of them is low. For example, one may mention the discrepancy between the data of different workers for the heat of formation of gaseous plutonium hexafluoride: −460 kcal mole^{-1},[42] −473 kcal mole^{-1},[43] −411.2 kcal mole^{-1},[44] and −418 ± 8 kcal mole^{-1} [45]. The last value was recommended by Rand[45] as the most accurate.

The bond energies and heats of atomisation of certain hexafluorides are listed in Table 4. For the majority of the known hexafluorides, the heats of formation are known only under standard conditions, i.e. only the values of $\Delta H^{\circ}_{f,298}$ are available, and in order to find D^0_0 ($-\Delta H^0_0$) a correction must be calculated from the equation

$$\left[\frac{\partial(\Delta H^{\circ}_T)}{\partial T}\right]_p = \Delta C_p, \qquad (2)$$

where ΔC_p is the heat capacity change from 0° to 298°K.

Table 4. Heats of formation, heats of atomisation, and bond lengths and energies in hexafluoride molecules.

NpF_6	−461	42	680	51.52	675.6	55	112.8		1.980	22
PuF_6	−418	45	624	51.52	619.5	55	103.21		1.972	22
XeF_6	−82.9 kcal at 393° K	50					32.3	50	1.90	38

* Estimated from Eqn. (2).

The accuracy of the determination of ΔH°_{298} is usually not sufficiently high to make this correction, but nevertheless in the present study the correction was introduced.

Analysis of the results in Table 4 shows that the bond energies decrease in the horizontal series from left to right like the valence force constants (A) and the constant B, C, and partly G (see curves *1–3* in Fig. 1 and curve *3* in Fig. 2). In the vertical series the bond energy increases in the series of hexafluorides of 4*d*, 5*d*, and 5*f* elements. In the series of hexafluorides of sulphur, selenium, and tellurium, the E – F bond energy is 79.0, 72.5, and 80.6 kcal mole^{-1} respectively. The Xe–F bond has the lowest dissociation energy (only 32.3 kcal mole^{-1}).

Thus if it is supposed that the average bond energy characterises the thermal stability and reactivity of hexafluoride molecules (as was done by O'Donnel and Stewart[5]), then hexafluorides can be arranged in the following series in terms of decreasing thermal stability:

$$UF_6 > WF_6 > NpF_6 > MoF_6 > PuF_6 > ReF_6 > TcF_6 > OsF_6 > TeF_6 > SF_6 > SeF_6 > IrF_6 > XeF_6 .$$

The discrepancy between this series and the experimental stabilities and activities of hexafluorides will be discussed below.

V. INTERATOMIC DISTANCES AND BOND STRENGTH

The use of interatomic E–F distances to characterise the chemical properties of hexafluorides (Table 4) appears to be of doubtful value. In the series of hexafluorides of uranium, neptunium, and plutonium, the interatomic E–F distances decrease but in the series of hexafluorides of 4*d* and 5*d* elements it is difficult to establish a similar sequence. Probably Badger's equation[61], whereby the E–F bond lengths were found (see, for example, Ref. 56 and 60), does not ensure the necessary accuracy owing to the dependence of the calculated force constants on the force field model.

VI. ANALYSIS OF THE THERMODYNAMIC STABILITIES OF HEXAFLUORIDES

A rigorous characteristic of the dissociation of any chemical compound is its thermodynamic stability in this reaction. The thermodynamic stability is characterised by the reciprocal of the equilibrium constants K_e for the corresponding dissociation process:

$$\alpha = \frac{1}{K_e} = \exp\left(\frac{\Delta H^0_0}{RT} - \frac{\Delta \Phi^*_T}{R}\right), \qquad (3)$$

where $\Delta\Phi^*_T$ is the reduced free energy of the dissociation reaction, R the gas constant, and T the absolute temperature. The values of $K_e(\alpha)$ may be related to the corresponding yields of the dissociation products of hexafluorides. For example, for the reaction

$$(EF_6)_{gas} \rightarrow (E)_{gas} + 6(F)_{gas}, \qquad (4)$$

$$\alpha = \frac{(1-x)(1+6x)}{4.6656 \cdot 10^4 x^7 p^6}, \qquad (5)$$

where p is the pressure and x the number of moles of hexafluoride which have reacted.

The values of α depend both on the enthalpy change (ΔH^0_0) and on the change in the reduced free energy ($\Delta\Phi^*_T$), which are calculated from energy and geometrical molecular constants.

The thermodynamic functions for gases consisting of polyatomic molecules (including EF_6 molecules) are calculated in many cases in terms of the rigid rotator—harmonic oscillator approximation. The components of the thermodynamic functions due to translational, rotational, and vibrational motion are calculated. This is because the electronic ground states of polyatomic molecules are as a rule of the singlet type and therefore the partition function with respect to the intramolecular motion of the polyatomic molecule is equal to the sum of the vibrational and rotational partition functions of the electronic ground state[17]. The thermodynamic functions obtained are called virtual, since they do not include the components due to nuclear spins and the mixing of isotopes.

The multiplicity of the electronic ground state is taken into account by introducing into the thermodynamic functions the term $R \ln p_M$, where p_M is the statistical weight of this state.

It is assumed[17] that the electronic ground state of polyatomic molecules with an even number of electrons is of the singlet type (the statistical weight of the state is unity); electronic states with one free electron have a statistical weight of two. Some workers have calculated the thermodynamic properties of many hexafluorides in

terms of the approximation of the rigid rotator–harmonic oscillator model. The entropies, reduced free energies, heat capacities, and enthalpy changes have been calculated in the range 50–1600°K at $p = 1$ atm. for the hexafluorides of uranium[55], plutonium[55,62], molybdenum, tungsten, iridium, and neptunium[55] and in the range 50–2000°K for the hexafluorides of ruthenium, rhodium[60], and technetium[56]. It should be noted that some of the molecular constants employed by Nagarajan to calculate the thermodynamic functions of the above hexafluorides were subsequently revised by Weinstock and Goodman[4] (Table 5).

Table 5. Fundamental vibration frequencies of hexafluoride molecules.

Molecule*	ν_1 (1)	ν_2 (2)	ν_3 (3)	ν_4 (3)	ν_5 (3)	ν_6 (3)

*The degree of degeneracy of the given vibration is indicated in brackets after ν_1, ν_2, etc.

** The estimate was made from the variation of the vibration frequencies with the number of free electrons in the hexafluoride molecules[4]; these are postulated frequencies in the absence of vibronic interaction. The frequencies obtained from the above relation and virtually identical with the experimental values are indicated in round brackets; the frequencies calculated from the Raman frequencies are indicated in square brackets.

The ν_6 frequencies for molybdenum and tungsten hexafluorides, the ν_2 frequency for technetium hexafluoride, etc. have been revised. The Mo–F bond length in the MoF_6 molecule, assumed by Nagarajan to be 1.56 Å,[63] is inconsistent with a later value of 1.83 Å.[59] Moreover, the statistical weight of the electronic ground state in the case of its degeneracy was not taken into account in any of the calculations. This applies to the hexafluorides of technetium, ruthenium, rhodium, rhenium, osmium, iridium, and neptunium.

According to Moffit et al.[64] the lower electronic states of the hexafluorides of rhenium and osmium are orbitally degenerate and the Jahn–Teller theorem predicts instability of the octahedral configuration. As already mentioned above, such instability does not lead to a static distortion of the symmetrical configuration in the gas phase. This is shown by the similarity of the electronic spectra of the hexafluorides of rhenium and osmium on the one hand and those of iridium and platinum on the other. For the last two hexafluorides, the Jahn–Teller theorem does not predict instability of the octahedral configuration. The number of electronic bands in the spectra of all four hexafluorides corresponds to the number predicted by the ligand field theory for the configuration with the O_h symmetry; the absence of the static distortion of the EF_6 molecules was demonstrated by electron diffraction[4] and by the analysis of the infrared spectra of the "anomalous" hexafluorides. In the case of static distortion, one might expect that the force constants for the longer bonds (or larger angles) would differ from the force constants for the shorter bonds (or smaller angles); moreover, one might observe splitting of the infrared absorption bands. The analogies in the vibrational spectra have been interpreted on the basis of a vibronic interaction[12,65]. Quantitatively this interaction was investigated by Weinstock and coworkers[4,14,15,66].

Table 6. Effect of vibronic interaction on the thermodynamic properties of hexafluorides[4].

Hexafluoride	T, °K	$\Delta\Phi^*_T$, cal mole^{-1} deg^{-1}	$\Delta(H^0_T - H^0_0)$, cal mole^{-1}	ΔS^0_T, cal mole^{-1} deg^{-1}
ReF_6	200	0.103	18.5	0.196
	298.15	0.136	20.2	0.203
	900	0.175	12.4	0.189
TcF_6	200	0.087	17.1	0.172
	298.15	0.117	19.1	0.181
	900	0.154	11.1	0.166

The empirical relations between the ground vibration frequencies and the number of unbound electrons[4] enabled Weinstock and Goodman to estimate the frequencies of the hitherto not investigated (CrF_6, PoF_6) and not even synthesised (AmF_6) hexafluorides. The effect of the vibronic interaction on the thermodynamic properties was also estimated by Weinstock and Goodman[4] (Table 6). The corrections obtained ($\Delta\Phi^*_T$ and ΔS^0_T) are virtually negligible for TcF_6 and ReF_6 in the range 200–900°K. Such an error in the calculations of the thermodynamic functions is possible as a result of an error of 1–2 cm^{-1} in the estimation of the vibration frequencies.

For the hexafluorides of osmium and ruthenium, the corrections are of the same order of magnitude as those for ReF_6 and TcF_6, which are listed in Table 6. This implies that the ν_2 and ν_5 frequencies (Table 5) may be employed without additional correction to calculate the thermodynamic properties of rhenium, technetium, ruthenium, and osmium hexafluorides.

Table 7 lists the reduced free energies of certain hexafluorides required for the calculation of their thermodynamic stabilities. They were calculated in terms of the rigid rotator–harmonic oscillator approximation taking into account the corrections for frequencies in the review of Weinstock and Goodman[4] and for the degeneracy of the electronic ground state.

The reduced free energies of the elements forming hexafluorides were taken from Kulikov's monograph[52] and the paper of Gurvitsh and Jungman[67]. The thermodynamic stability constants of the hexafluorides of certain elements were calculated by Eqn. (3) (Table 8).

Fig. 3 presents the logarithms of the thermodynamic stability constants of the hexafluorides in the vertical series at 298°, 1200°, and 2400°K. Analysis of these relations permits the following conclusions:

1. The thermodynamic stabilities of hexafluorides in relation to atomisation reactions decrease along the horizontal series (4*d*, 5*d*, and 5*f* elements).

Table 7. Reduced free energies of certain hexafluorides (cal mole^{-1} deg^{-1}) at p = 1 atm. in the ideal gas state.

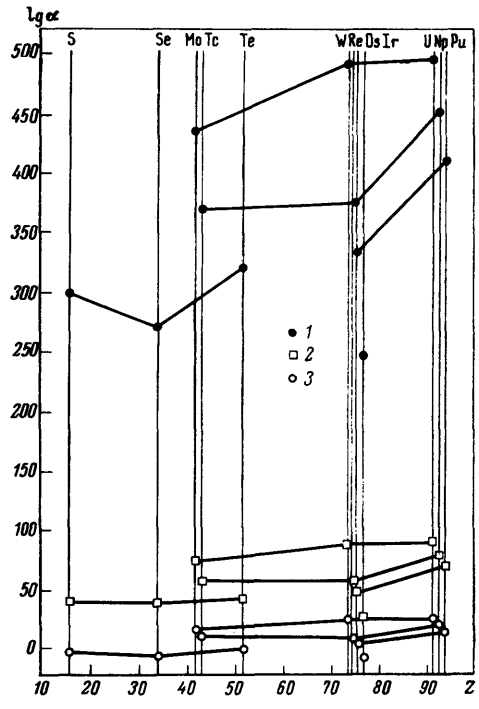

Figure 3. Variation of the logarithms of the thermal stability constants of hexafluorides with the charge number of the central atom; temperature (°K): 1) 298; 2) 1200; 3) 2400.

2. The sequence of hexafluorides in terms of decreasing thermodynamic stability depends little on temperature. In the vertical series the hexafluorides of the actinide elements are the most stable:

$$UF_6 > WF_6 > MoF_6;\ NpF_6 > ReF_6 > TcF_6;\ PuF_6 > OsF_6.$$

However, the difference between the values of $\lg \alpha$ diminishes as the temperature is raised, owing to an increase of the contribution by the entropy factor to the equation $\Delta G = \Delta H - T\Delta S$ compared with the heat of reaction.

3. In the series of non-metal hexafluorides the stability falls from sulphur hexafluoride to selenium hexafluoride, but increases sharply on going to tellurium hexafluoride, so that $TeF_6 > SF_6 > SeF_6$.

4. The sequence of hexafluorides in terms of decreasing thermodynamic stability in relation to the atomisation reaction is as follows:

$$UF_6 > WF_6 > NpF_6 > MoF_6 > PuF_6 > TcF_6 > ReF_6 > OsF_6 > TeF_6 > SF_6 > SeF_6 > IrF_6.$$

The positions of the hexafluorides in this series depend to a considerable degree on the accuracy of the determination of ΔH_0^0 (Table 9). Xenon hexafluoride should occupy the last place in this series.

We shall examine the changes in the thermodynamic stability of hexafluorides in partial dissociation reactions in the first vertical and third horizontal series. The decomposition to the tetrafluoride may be employed as a reaction of this kind:

$$(EF_6)_{gas} \rightarrow (EF_4)_{gas} + 2(F)_{gas}. \qquad (6)$$

The reduced free energies of the tetrafluorides required for the calculation of the stability constants were evaluated

in terms of the rigid rotator–harmonic oscillator model using an empirical method for the estimation of the equivalent geometrical and energy constants[68]. The results of the calculation are presented in Table 10. The calculation was made for only six hexafluorides, since only in these cases was it possible to calculate the heats of reaction at the standard temperature (298.16°K) and the absolute zero (Table 9).

Table 9. Enthalpies of dissociation of hexafluorides by reaction (6) under standard conditions (298.16°K) and at the absolute zero (kcal mole^{-1}).

Hexafluoride	ΔH°_{298}	ΔH°	References to literature employed in calculations	Hexafluoride	ΔH°_{298}	ΔH°	References to literature employed in calculations

PuF_6	102.5	101.3	45	SF_6	—	152,261	17

Table 10. Thermodynamic stability constants of hexafluorides in reaction (6).

T°, K	UF_6	NpF_6	PuF_6	WF_6	MoF_6	SF_6
800	10^{35}	$1.32\cdot10^{21}$	$2.24\cdot10^{13}$	$1.78\cdot10^{48}$	$7.93\cdot10^{27}$	$4.36\cdot10^{28}$
1200	$1.12\cdot10^{17}$	$1.12\cdot10^{9}$	$4.8\cdot10^{3}$	$5.38\cdot10^{23}$	$1.13\cdot10^{20}$	$2.1\cdot10^{14}$
1600	$1.2\cdot10^{9}$	$1.23\cdot10^{3}$	$1.04\cdot10^{-1}$	$1.27\cdot10^{16}$	$1.76\cdot10^{11}$	$1.48\cdot10^{4}$
2000	$2.76\cdot10^{4}$	$1.34\cdot10^{-1}$	$1.78\cdot10^{-4}$	$5.49\cdot10^{9}$	$7.24\cdot10^{5}$	$8.9\cdot10^{-1}$
2400	$1.66\cdot10^{1}$	$1.37\cdot10^{-3}$	$2.29\cdot10^{-6}$	$3.03\cdot10^{5}$	$2.21\cdot10^{2}$	$1.23\cdot10^{-3}$
2800	$8.92\cdot10^{-1}$	$2.81\cdot10^{-5}$	$1.1\cdot10^{-7}$	$2.95\cdot10^{2}$	$6.88\cdot10^{0}$	$2.2\cdot10^{-5}$
3200	$1.74\cdot10^{-3}$	$1.62\cdot10^{-6}$	$1.15\cdot10^{-8}$	$1.61\cdot10^{0}$	9.10^{-3}	$3.81\cdot10^{-7}$

The logarithms of the thermodynamic stability constants of the hexafluorides decrease from left to right along the series of 5*f* elements. When the hexafluorides are arranged in a common series in terms of decreasing thermal stability with respect to reaction (6), the following sequence is observed up to 2300°K: $WF_6 > MoF_6 > UF_6 > SF_6 > NpF_6 > PuF_6$. Above 2300°K, SF_6 and NpF_6 change places.

VII. ANALYSIS OF EXPERIMENTAL DATA FOR THE THERMAL STABILITIES AND REACTIVITIES OF HEXAFLUORIDES

The chemical reactivities‡ of non-metal hexafluorides differ markedly from those of metal hexafluorides. With the exception of polonium hexafluoride, non-metal hexafluorides exhibit unusual chemical inertness. In the reviews by Weinstock already mentioned[2,3], it is reported that the thermal stabilities in this series decrease and the chemical reactivities increase from sulphur hexafluoride to tellurium hexafluoride, the hydrolysis of tellurium hexafluoride, which is the most reactive of the three hexafluorides, requiring not less than 24 h for its completion at room temperature[3]. The information available at present about the thermal stability of sulphur hexafluoride is fairly adequate. The compound is stable in an electric arc[72], which can be accounted for[3] by its high thermal stability. At 2300–2500°K sulphur hexafluoride molecules dissociate into atoms[46]. A wide variety of fragments of SF_6 molecules, obtained in an electric arc, have been isolated[73,74]. The reason for the pronounced insulating properties of sulphur hexafluoride is probably the high electron affinity not only of fluorine atoms and molecules, but also of SF_6 molecules and their fragments[75].

We shall consider the experimental regularities in the variation of the thermal stability and reactivity in the vertical and horizontal series of metal hexafluorides. The first vertical series includes the hexafluorides of chromium (3*d*), molybdenum (4*d*), tungsten (5*d*), and uranium (5*f*). The molecules of all these hexafluorides do not have free electrons. Their chemical reactivity may be characterised by the reactions involving the fluorination of the lower fluorides of various elements (including the lower fluorides of the elements forming the hexafluorides), the sensitivity to hydrolysis, substitution and addition reactions, etc.

The feasibility of reaction (3) is a direct indication that tungsten hexafluoride is chemically less reactive than molybdenum hexafluoride:

$$(WF_4)_{solid} + 2(MoF_6)_{gas} \rightarrow 2(MoF_5)_{solid} + (WF_6)_{gas}. \quad (7)$$

Chromium hexafluoride is thermally unstable at −100°C.[76] Even chromium pentafluoride is more reactive than the hexafluorides of molybdenum, tungsten[11], and uranium[6]. This was demonstrated by studies of the reactions of the above fluorides with the trifluorides of phosphorus, arsenic, bismuth, etc. The reaction with carbon disulphide is particularly instructive:

$$CS_2 + 8CrF_5 \rightarrow 8CrF_3 + CF_4 + 2SF_6, \quad (8)$$

$$2CS_2 + 6MoF_6 \rightarrow (CF_3)_2S_2 + 2S + 6MoF_5. \quad (9)$$

Reaction (8) takes place explosively[11], reaction (9) is also vigorous[11], but tungsten hexafluoride does not react with carbon disulphide[11]. Uranium hexafluoride fluorinates carbon disulphide, various fluorination products being obtained, depending on temperature.[6,77]

On the basis of studies of the behaviour of these four hexafluorides, O'Donnel[6,7,11] believes that the reactivity of the hexafluorides in the first vertical series diminishes in the following sequence: $CrF_6 > UF_6 > MoF_6 > WF_6$. Thus the hexafluoride of uranium (a 5*f* element) is more reactive than the hexafluorides of molybdenum (4*d*) and tungsten (5*d*).

In the series of hexafluorides of 5*f* elements (uranium, neptunium, and plutonium), the reactivity increases from UF_6 to PuF_6.[2–4,6,71]. Uranium hexafluoride may be obtained by the fluorination of the tetrafluoride with plutonium hexafluoride[88]. Neptunium and plutonium hexafluorides are readily decomposed photochemically, so that it is impossible to record their Raman spectra. Americium hexafluoride, the existence of which may be postulated by analogy with platinum hexafluoride, is probably even more unstable[79].

The transition elements of the second intercalary decade (4*d* elements) form four hexafluorides: MoF_6, TcF_6, RuF_6, and RhF_6. Ruthenium and rhodium hexafluorides oxidise xenon even at room temperature, like platinum and plutonium hexafluoride[50], in contrast to UF_6, NpF_6, IrF_6, and OsF_6. Technetium hexafluoride is reduced more readily than rhenium hexafluoride[80]. The hexafluorides of technetium and ruthenium are thermally

‡ As in the work of Canterford and O'Donnel[7], it is assumed that the increase of the thermal stability of the molecule is accompanied by a decrease of its chemical reactivity.

and photochemically unstable, so that it is impossible to obtain their Raman spectra. Molybdenum hexafluoride is the most stable in this series, the other hexafluorides being probably thermally unstable. The experimental evidence for the increase of the reactivity of the hexafluorides from left to right in this series is inadequate, but it is postulated that rhodium hexafluoride is thermally less stable than ruthenium hexafluoride[81].

The series of hexafluorides of 5*d* elements contains WF_6, ReF_6, OsF_6, IrF_6, and PtF_6. Platinum hexafluoride fluorinates the fluorides of neptunium and plutonium to the corresponding hexafluorides[72]. Selenium tetrafluoride reduces platinum hexafluoride to the tetrafluoride, but the hexafluorides of osmium and iridium pass to the pentavalent state under the same conditions[82]. Tungsten hexafluoride does not react with nitric oxide[83], osmium hexafluoride forms $NO^+OsF_6^-$,[83] and iridium and platinum form $(NO)_2IrF_6$ [85] and $(NO)_2PtF_6$ [84] respectively. Canterford and O'Donnel arranged the hexafluorides of 5*d* elements in the following sequence in terms of decreasing thermal stability: $WF_6 > OsF_6 > IrF_6 > PtF_6$. In addition[7], $OsF_6 > RuF_6$, $IrF_6 > RhF_6$.

Among the least thermally stable metal hexafluorides of various series, plutonium hexafluoride has a higher thermal stability than platinum hexafluoride; neptunium and uranium hexafluorides are more stable than ruthenium, rhodium, and platinum hexafluorides. The least stable hexafluoride is probably that of chromium§. There is evidence that the thermal stability of rhodium hexafluoride is lower than that of platinum hexafluoride[85]. From this standpoint, the least stable metal hexafluorides can probably be arranged in the following series in terms of decreasing thermal stability: $PuF_6 > PtF_6 > RhF_6 > CrF_6$.

---o0o---

Analysis of the results presented in this review leads to the conclusion that the thermal stability of a particular hexafluoride, as a characteristic of its reactivity, depends on the type of the dissociation reaction considered. Depending on whether the hexafluoride dissociates completely into atoms or only partially to the penta- or tetrafluoride, a particular sequence of hexafluorides in the vertical and horizontal series in terms of varying thermal stability is obtained.

The experimental thermal stability and reactivity series characterising the incomplete conversion of metal hexafluorides, mainly to the penta- or tetra-fluorides within the limits of individual groups, correspond to changes in the majority of the force constants.

However, if all the hexafluorides are arranged in a single sequence in terms of decreasing valence force constants, the latter is not consistent with the experimental thermal stability series.

The experimental data for non-metal hexafluorides do not agree fully with the variation of the force constants. Probably a higher force constant for the bond is a necessary but not sufficient condition for a higher thermal stability of the hexafluoride. The shifts occurring in the dissociation of the E – F bond are so large, even on partial dissociation, that they no longer depend on the force constants. Moreover, if stepwise dissociation of the E – F bond is postulated, then for reactions (6) one must consider not only the *fd* constant of the EF_6 molecule, but also the *fd* constant of the EF_5 molecule, since on transition from the hexafluoride to the pentafluoride both the geometrical configuration and the average bond energy of the molecule change. For example, the average energy of the U – F bond in the uranium hexafluoride molecule is 122.24 kcal and in the pentafluoride 137 kcal $mole^{-1}$.

The equilibrium constants for the dissociation of hexafluorides to the corresponding tetrafluorides [reaction (6)] probably constitute a more objective criterion of the stability of the hexafluoride in relation to incomplete dissociation (Table 10). In this case the thermal stability of the hexafluoride decreases in the following sequence:

$$WF_6 > MoF_6 > UF_6 > SF_6 > NpF_6 > PuF_6 > PtF_6 > RhF_6 > CrF_6 .$$

From this point of view, the great inertness of sulphur hexafluoride is to be accounted for not by thermodynamics but by kinetic characteristics. The reasons for the position of the hexafluorides SeF_6, TeF_6, TcF_6, OsF_6, IrF_6, and RuF_6 in this series are still not quite clear.

Probably the most objective characteristic of the stability of hexafluorides in relation to total dissociation (atomisation) is provided by the thermodynamic stability constants. The estimates of thermal stability from the average energies of the E – F bonds in hexafluoride molecules agree fully, except for rhenium hexafluoride, with the thermodynamic estimates. The valence force constants are altogether unsuitable to characterise the stability of hexafluorides in relation to the atomisation reaction. The discrepancy between the thermal stability and force constant series constitutes indirect evidence that the decomposition of hexafluorides to atoms takes place via stepwise abstraction of fluorine atoms and, instead of a single force constant of the bond, one must take into account all the force constants of the E – F bonds in the molecules of the hexa-, penta-, tetra-, tri-, di-, and mono-fluorides of the elements.

§ Only the hexafluorides having the octahedral configuration with the O_h symmetry are considered.

Alkali and Alkaline Earth Metal Ozonides

S.A.Tokareva

Data published in the Soviet and foreign literature on alkali and alkaline earth metal ozonides are described systematically and critically discussed. The methods of their preparation, physicochemical properties and reactivities have been examined. Certain concepts concerning the mechanism of the formation of ozonides have been presented.
The bibliography includes 87 references.

I. GENERAL INFORMATION ABOUT ALKALI METAL OZONIDES

As early as the middle of the nineteenth century certain investigators[1,2] noted that alkali metal hydroxides react with ozone to form coloured products, the nature of which was not established. However, the studies in this field up to 1949 were largely qualitative.

Baeyer and Villiger[3] suggested that the coloured products of the reaction of ozone with KOH and RbOH are salts of the hypothetical ozonic acid H_2O_4. Bach[4] believed that the reaction of ozone with potassium hydroxide takes place according to the equation

$$KOH + O_3 \rightarrow KO_4H .$$

The first attempt to investigate the nature of ozonides was made in 1912. Traube[5] showed that the products of the reaction of ozone with potassium hydroxide contain, apart from the two higher potassium oxides K_2O_2 and K_2O_4 and the unreacted potassium hydroxide, a small amount of an orange substance. At room temperature the substance immediately decomposed to K_2O_4. Traube suggested that K_2O_4 is a product of the decomposition of a higher potassium oxide, which he called "ozonate".

In a later study Traube[6] attempted to determine the amount of oxygen evolved on decomposition of potassium "ozonate". He regarded potassium "ozonate" as a compound in which an oxygen molecule is joined by subsidiary valences to one or two KOH molecules, i.e. $KOH.O_2$ or $(KOH)_2.O_2$. According to Traube, these formulae emphasise the capacity of ozonides to evolve molecular oxygen on interaction with water. He represented the conversion of potassium ozonide into the tetroxide as a two-stage process: in the first stage "potassium ozonate" undergoes intramolecular oxidation according to the equation

$$2(KOH)_2 \cdot O_2 = 2K_2O_2 + 2H_2O + O_2 , \quad (1)$$

and in the second stage the potassium peroxide formed reacts with another "ozonate" molecule to produce potassium tetroxide and hydroxide:

$$K_2O_2 + (KOH)_2 \cdot O_2 = K_2O_2 \cdot O_2 + 2KOH . \quad (2)$$

To test the hypothesis that metal ozonides do not contain hydrogen, Strecker and Thienemann[7] investigated the reaction of ozone with pure metals dissolved in liquid ammonia. When ozone was introduced into the blue solution of potassium in liquid ammonia, a white mass was formed initially and then the blue colour disappeared and a dark-brown precipitate and a dark-orange solution were produced. According to the author's hypothesis, the precipitate contained an admixture of a compound of the metal with ozone. Precipitates with admixtures of sodium, rubidium, and caesium ozonides were obtained in this way. The stability of the precipitates decreased from caesium to sodium, as noted previously by Manschot and Kampschulte[8]. Strecker and Thienemann did not succeed in obtaining pure preparations of the "ozone compounds" and in determining accurately their composition because of the marked contamination of the reaction products by ammonium nitrate and nitrite. Therefore it was necessary to investigate the reaction of ozone with ammonia. Strecker and Thienemann[7] showed that nitrates and nitrites are formed in the reaction of ozone with liquid ammonia according to the following equations:

$$2NH_3 + 4O_3 \rightarrow (NH_4)NO_3 + 4O_2 + H_2O , \quad (3)$$

$$2NH_3 + 3O_2 \rightarrow (NH_4)NO_2 + 3O_2 + H_2O . \quad (4)$$

They observed[7] that, when ozone is passed through liquid ammonia, an intense orange colour appears in solution, and rapidly disappears when ammonia is evaporated. The same phenomenon was noted by Manschot and Kampschulte[8]. Strecker and Thienemann suggested that, as with alkalis, an unstable ammonia compound is formed in this system and is readily converted into ammonium nitrate and nitrite.

In 1927 Fichter and Bladergroen[9] published the results of studies in which "potassium ozonide" was obtained on passing fluorine through a concentrated potassium hydroxide solution at −20°C. The resulting preparations were coloured brown. Fichter and Bladergroen suggested that they obtained the same products as Baeyer and Villiger in the reaction of ozone with potassium hydroxide.

Thus in the studies published up to 1949, there was no unanimity concerning the composition of the ozonation products. The reason was that investigators were unable to isolate in a pure form and to elucidate the nature of the coloured substances obtained in the reaction of ozone with alkali metal hydroxides. These substances were called "ozonates" and compositions identical with

those of derivatives of the hypothetical ozonic acid in the form of normal-(K_2O_4) and acid (KHO_4) salts were attributed to them. Later these compounds were regarded as molecular compounds of oxygen with one or two molecules of alkali: $KOH...O_2$ or $(KOH)_2...O_2$.

The present interest in the chemistry of inorganic ozonides was aroused by the work of Kazarnovskii and coworkers[10-14], where the possibility of isolating alkali metal ozonides in a crystalline state was demonstrated for the first time. Crystalline KO_3 (purity about 91%) and very small amounts of NaO_3 (purity up to 90%) and RbO_3 and CsO_3 (purity up to 66%) were obtained.

II. MODERN CONCEPTS CONCERNING ALKALI METAL OZONIDES

A recent study of the physicochemical properties of alkali metal ozonides[10,15] showed that they are higher oxides $M^+O_3^-$ with the molecular ion O_3^-. The presence of the molecular ion O_3^- in ozonides was first established by magnetic[10] and X-ray diffraction[12,16] measurements and was confirmed by spectrophotometry[17,18] and electron spin resonance[17-21].

Two resonating structures with a single free valence were attributed to the O_3^- ion on the basis of magnetic data[10,22]. Measurements of magnetic susceptibility confirm this[10]. $\chi_g = +12.5 \times 10^{-6}$ was found at 20°C, whence $\chi(\text{corr}) = +13.6 \times 10^{-6}$; this gives $\mu = 1.76$ Bohr magnetons, which is close to the theoretical value 1.73 Bohr magnetons for a single unpaired electron.

According to Pauling's data[22], the O–O bond length is 1.35 Å and the <OOO angle between the oxygen atoms is 108°. Starting with the angular form of the O_3 molecule, with an angle of 116° ± 0.5° between the O–O–O bonds and an O–O distance $r = 1.278 \pm 0.002$ Å, Smith[23] found by extrapolation that, like ozone, the O_3^- ion is non linear and has an angle of 110° ± 5° and a distance r = 1.34 ± 0.05 Å, which agrees well with Pauling's data. X-Ray diffraction study[16] showed that the O_3^- ion has an angular configuration with <OOO = 100° and $r = 1.19$ Å, which agrees well with the data of Herman and Giguere[18], who determined the O–O bond length in the O_3^- ion as 1.22 Å on the basis of the infrared spectrum of ammonium ozonide. They also showed[18] that the O_3^- ion does not show a tendency towards dimerisation, in contrast with the isoelectronic NO_2^{2-} ion[24,25], and with the NO_2 molecule.

In an E.S.R. study of potassium ozonide specimens at room temperature and the temperature of liquid nitrogen, Piskunov et al.[19] confirmed the data of Bennet et al.[20] and Marshall and van Osterburg[21]. The closeness of the g-factor to two and also the occurrence of appreciable exchange interaction confirm the above hypothesis that the magnetism of the molecular ion O_3^-, which is responsible for the observed paramagnetic resonance in KO_3, is of the free radical type[19]. The O_3^- ion, which has an odd number of electrons, is the carrier of the enormous chemical reactivity of ozonides, which may be regarded as unusually longlived free radicals. Measurements of the g-factor for perpendicular and parallel orientations of KO_3 gave $g_\perp = 2.012 \pm 0.002$ and $g_\parallel = 2.005 \pm 0.003$.

Nikol'skii et al. estimated the heat of formation of alkali metal ozonides[11] from the known heats of formation of KO_3 (−62.1 kcal mole^{-1}) [14] and an estimate of the lattice energy. Table 1 lists the heats of formation of alkali metal ozonides which they calculated.

The values of r_0 in Table 1 were calculated by the same investigators on the hypothesis that the unit cells of ozonides are constructed in the same way as the corresponding unit cells of azides, which was not confirmed in subsequent studies[16,26]. The author of the review also estimated the heats of formation of alkali metal ozonides from the elements by a comparative calculation[27]. Initially a check was made to find if the variation of the properties of compounds of Group I elements is linear. The following compounds were chosen for the comparison: oxides, peroxides, superoxides, hydroxides, chlorides, perchlorates, nitrates, carbonates, and sulphates. The resulting values are also listed in Table 1.

Table 1. Heats of formation of alkali metal ozonides[11].

Compound	r_0, Å	n	U, kcal	S_M*, kcal	I_M*, kcal	$-\Delta H$, kcal		
						from Ref.11	from calculated data (Ref.15)	from Ref.28

* Data taken by Nikol'skii et al.[11] from a handbook[29].
** Value obtained from experimental data[14].
*** Estimated by Wood and D'Orazio[28].

Wood and D'Orazio[28] estimated by an extrapolation procedure the lattice energy of lithium ozonide as 215 ± 10 kcal mole^{-1} and from this value calculated the heat of formation of the ozonide as −63 ± 15 kcal mole^{-1}. They also estimated the absolute entropy and the free energy of formation of LiO_3, which are 60 e.u. [14] and 45 kcal mole^{-1} respectively.

Using the crystallographic data of Zhdanov and Zvonkova[12], Kazarnovskii and coworkers[14] calculated the lattice energy of KO_3 as 149 kcal mole^{-1}. Knowing the lattice energy and the heat of formation of KO_3, they estimated the electron affinity of the ozone molecule as 66.5 kcal mole^{-1}. This is three times greater than for the oxygen molecule (E_{O_2} = 22 kcal mole^{-1} [30]).

Wood and D'Orazio[28] estimated the electron affinity of the ozone molecule as 44 ± 10 kcal mole^{-1} and that of the oxygen molecule as 14.9 kcal mole^{-1}. These data are much lower than those quoted in other studies[14,30]. In addition, Wood and D'Orazio[28] estimated the heat of formation of the gaseous ozonide ion: $\Delta H[O_3^-\ (\text{gas})] = -11 \pm 10$ kcal mole^{-1}.

Solomon and Kacmarek[31] showed that in the visible region the spectra of solutions of alkali metal ozonides in liquid ammonia are independent of the cation and have a characteristic maximum at 450 nm.

The reactivity of ozonides has been little investigated. The principal studies dealt with the reactivity of potassium ozonide. Alkali metal ozonides react with water according to Eqn. (5), forming oxygen and the hydroxide:

$$2MO_3(\text{solid}) + H_2O(\text{liq}) \rightarrow 2MOH(\text{solid}) + \tfrac{3}{2}O_2 . \qquad (5)$$

Hence it follows that solid ozonides may serve as sources of oxygen.

III. ALKALI METAL OZONIDES

1. Lithium Ozonide

Lithium ozonide has not been obtained in a pure form but its tetrammine $Li(NH_3)_4.O_3$ is known. The tetrammine was synthesised[32] by the reaction of an ozone–oxygen mixture containing 3% of ozone with lithium hydroxide moistened with liquid ammonia ($LiOH : NH_3 = 5 : 0.2$) at −112°. The ozone-treated hydroxide was extracted with liquid ammonia. The tetrammine of lithium ozonide was salted-out from liquid ammonia solution with trifluoromethane. After the evaporation of trifluoromethane and ammonia at −126° and −78°C respectively, the solid red residue consisted of $Li(NH_3)_4.O_3$ with a considerable admixture of LiOH. The standard enthalpy of formation of the tetrammine of lithium ozonide from the elements is -135 ± 5 kcal mole^{-1}.

Several months before the publication of this study[32], the author of the review carried out experiments on the synthesis of lithium ozonide from lithium hydroxide and lithium peroxide[33]. The system was treated with ozone at −110°C, almost at the liquefaction limit of ozone, in a reactor with a screw stirrer for 3 h. The system was extracted with liquid ammonia, after the evaporation of which a thick oily dark-orange liquid remained at the bottom of the vessel. Analysis showed that the lithium : oxygen ratio was 1 : 2.56. The results of the experiments suggest that one can reliably assume that lithium hydroxide and peroxide react with ozone to form compounds of the ozonide type, as shown by the characteristic colour and the analytical lithium : oxygen ratio.

Probably the reason why lithium ozonide is not formed by a method similar to that employed for sodium and potassium ozonides and only a tetrammine is obtained, is the small radius of the lithium ion Li^+ (0.60 Å). The complex ion $Li(NH_3)_4^+$, which is larger than Li^+, can combine with the unstable O_3^- ion.

Wood and D'Orazio[28] estimated the LiO_3 lattice energy as 215 ± 10 kcal mole^{-1}. The heat of formation of LiO_3 calculated from this value is -63 ± 15 kcal mole^{-1}. Wood and D'Orazio[28] estimated the absolute entropy of LiO_3 as 20 e.u. and the entropy and free energy of formation of LiO_3 as 60 e.u. and 45 kcal mole^{-1} respectively and from these results calculated the enthalpies and free energies of the following reactions:

$$2LiO_3 \rightarrow Li_2O + {}^5/_3 O_2 \quad \begin{matrix}\Delta H = -16 \text{ kcal mole}^{-1} \\ \Delta F = -44 \text{ kcal mole}^{-1}\end{matrix}; \qquad (6)$$

$$2LiO_3 \rightarrow Li_2O_2 + 2O_2 \quad \begin{matrix}\Delta H = -26 \text{ kcal mole}^{-1} \\ \Delta F = -46 \text{ kcal mole}^{-1}\end{matrix}; \qquad (7)$$

$$LiO_3 \rightarrow LiO_2 + O_2 \quad \begin{matrix}\Delta H = +2 \text{ kcal mole}^{-1} \\ \Delta F = -19 \text{ kcal mole}^{-1}\end{matrix}. \qquad (8)$$

2. Sodium Ozonide

Sodium ozonide was first isolated by Nikol'skii et al.[11] in 1951, In a study of the reaction of dehydrated powdered sodium hydroxide (98.2%) with an ozone–oxygen mixture (8–9% O_3) at a temperature between −50° and −60°C, they observed that[11] the alkali acquired an intense yellow colour. Extraction with liquid ammonia at the same temperatures yielded a dark-red solution from which, after evaporation of liquid ammonia, a quasicrystalline dark-red product containing up to 90% of sodium ozonide, 2–3% of sodium hydroxide, and 4.6% of water was precipitated; the water was bound to the hydroxide as a hydrate.

The authors noted that sodium ozonide is extremely unstable and decomposes at room temperature with liberation of oxygen and the formation of sodium superoxide according to the equation

$$NaO_3 \rightarrow NaO_2 + {}^1/_2 O_2 . \qquad (9)$$

According to Nikol'skii et al.[11], the process reaches completion after 53 h.

Simultaneously with the work of Nikol'skii et al.[11], Whaley and Kleinberg[15] investigated the nature of the products of the reaction of ozone with alkali metal hydroxides. They confirmed[15] the data of Nikol'skii et al.[11], according to which treatment of sodium hydroxide with ozone at −60°C results in the formation of a yellow substance soluble in liquid ammonia. In addition, Whaley and Kleinberg[15] allowed ozone to react with sodium hydroxide at room temperature and showed that the resulting yellow product is insoluble in liquid ammonia and stable at room temperature. The authors believe they obtained sodium ozonide, although it was not isolated in a pure form. Its presence in the ozone-treatment product was demonstrated by an indirect method—magnetic measurements. McLachlan et al.[17] also noted that treatment of sodium hydroxide with ozone at room temperature results in the formation of a yellow substance. They suggested that the colour is due to the presence of sodium ozonide; the ozonide did not dissolve in liquid ammonia, and the ozone-treated alkali was stable for several hours on storage in closed tubes.

Griffith et al.[34], who investigated the ultraviolet spectra (200–600 n.m.) of sodium hydroxide treated with ozone at room temperature, showed that the spectra are identical with those obtained for a solution of potassium ozonide in liquid ammonia. On the basis of these data, they suggested that sodium ozonide is formed also above 0°C. In addition it was established[15,35] that, when sodium hydroxide is treated with ozone both at room temperature and below 0°C, the superoxide NaO_2 is formed together with the ozonide.

Evidently the data on the synthesis and properties of sodium ozonide are contradictory. Nikol'skii et al.[11] isolated sodium ozonide synthesised at −60°C; it is soluble in liquid ammonia and unstable at room temperature. Whaley and Kleinberg[15] and other investigators[17,34] confirmed these data and showed in addition that the reaction of ozone with sodium hydroxide takes place also at room temperature. Sodium hydroxide treated with ozone at room temperature is stable but sodium ozonide could not be extracted from it with liquid ammonia. Whaley and Kleinberg[15] put forward two explanations. The first is that sodium ozonide may exist in two crystalline forms. This hypothesis was not confirmed by experiment. The second explanation is that, in the reaction between ozone and sodium hydroxide at room temperature, the yield of sodium ozonide is extremely low and its particles are surrounded and protected by sodium hydroxide, which prevents their thermal decomposition and hinders the solubility of the ozonide in liquid ammonia, but this is unlikely.

Subsequently the possibility of the formation of sodium ozonide both above and below 0°C was demonstrated[36]. Moreover it was shown that, in the reaction with ozone, sodium superoxide is formed together with the ozonide. The study of the extraction of sodium ozonide from ozone-treated sodium hydroxide with liquid ammonia showed that the isolation of sodium ozonide synthesised above 0°C involves greater experimental difficulties than the isolation of sodium ozonide synthesised at negative tempera-

tures. The difficulties consist in the fact that sodium ozonide synthesised above 0°C instantly decomposes when the stream of ozone is stopped. The yellow colour of the product remaining after the decomposition of sodium ozonide is due to the presence of sodium superoxide formed in the reaction with ozone. Probably this is in fact the source of the above contradictions concerning the different properties of sodium ozonide synthesised at different temperatures.

The studies[36] on the preparation of sodium ozonide via sodium superoxide showed that, as with potassium and caesium[37], the reaction $MO_2 + O_2 \rightarrow MO_3 + O_2$ is possible also for NaO_2. However, the reaction of ozone with sodium superoxide is only of theoretical value for the explanation of the mechanism of the reaction with ozone owing to the low yield of the ozonide and the difficulty of carrying out the process[36].

Differential thermal analysis of sodium ozonide[38] showed that its decomposition is accompanied by an exothermic effect at $-10° \pm 2°$, due to the vigorous evolution of oxygen; this is consistent with the nature of the thermal decomposition of other alkali metal ozonides. Comparison of the heating curves for alkali metal ozonides reveals a regular increase of thermal stability with increasing atomic number of the element.

Thermogravimetric study of sodium ozonide[38] on a McBain balance made it possible to determine the degree of conversion of sodium ozonide and the rate of its decomposition at −10°, −20°, 0°, and +10°C. It is striking that the highest rate of decomposition of the ozonide is observed at the beginning of the decomposition process. Thermal decomposition of NaO_3 at −20° and −10°C proceeds up to the formation of NaO_2. Above 0°C the thermal decomposition of sodium ozonide is accompanied by the reaction of the NaO_2 formed with the water of crystallisation present in sodium ozonide and proceeds up to the formation of NaOH. At −20° and −10°C water does not enter into the reaction. The density[30] of NaO_3 is in the range 1.56−1.60 g cm^{-3}. The bright brown-red crystals of sodium ozonide exhibit pleochroism in polarised light: the crystals are coloured pale-yellow in the N_p direction and red-brown in the N_g direction. The sodium ozonide crystals are monoaxial and positive. The refractive indices are $N_p = 1.405$ and $N_g = 1.49$.

It should be noted that analysis of sodium ozonide involves considerable experimental difficulties. Direct sampling is impossible because of the extreme instability of sodium ozonide at room temperature. Therefore a special technique was developed for the analysis of sodium ozonide[40], which was subsequently employed for the analysis of other unstable ozonides.

In a preliminary X-ray diffraction study[41] a tetragonal cell with the parameters $a = 10.43$ Å, $c = 6.88$ Å, and $c/a = 0.660$ was provisionally ascribed to sodium ozonide. In a later investigation[52] these values were revised. Indexing of the X-ray diffraction patterns by means of Hall's curves yielded satisfactory agreement between the measured interplanar spacings and the values calculated for a body-centred tetragonal lattice with the ratio $c/a = 0.660$ and the parameters $a = 11.65$ Å and $c = 7.66$ Å. The space group $I4/mmm$ was chosen provisionally.

3. Potassium Ozonide

Potassium ozonide was first isolated in a crystalline state in 1949 by Kazarnovskii et al.[10] in the reaction of an ozone−oxygen mixture with potassium hydroxide below 0°C followed by extraction with liquid ammonia. The preparations obtained contained up to 83−88% KO_3 with KOH as the main impurity. In recent years a number of studies were carried out in order to find new methods for the synthesis of potassium ozonide. It was shown that potassium ozonide can be formed above 0°C at +5°C [43] and +40°C [44]. The highest yield of potassium ozonide was achieved when ozone was allowed to react with powdered potassium hydroxide in a fluidised bed[43,44]. It was shown[44] that the fluidised bed method makes it possible to extend greatly the temperature range in which potassium hydroxide can react with ozone not only in the anhydrous state, but also in the hydrated form.

The synthesis of potassium ozonide at positive temperatures is important for practical purposes. Potassium ozonide is also formed when ozone is allowed to react with potassium alkoxides[45,46]. In the reaction of ozone with potassium t-butoxide and t-perbutoxide, KO_3 is formed in yields of about 10 and 40% respectively. However, the ozonide cannot be isolated with liquid ammonia from the ozone-treated alkoxides, since the alkoxides are also soluble in ammonia[45,46]. In addition, potassium ozonide can be obtained by treating potassium superoxide with ozone[37,45,47,48]. The studies carried out in the Laboratory of Peroxy-Compounds at the Institute of General and Inorganic Chemistry of the USSR Academy of Sciences[37] and based on the estimation of the heat of the reaction

$$KO_2 + O_3 \rightarrow KO_3 + O_2 + 28 \text{ kcal} \qquad (10)$$

showed that, when KO_2 is treated with ozone at 40°C, potassium ozonide is formed in the same yield as in the reaction of ozone with potassium hydroxide and can also be successfully extracted with liquid ammonia.

Other methods for the synthesis of potassium ozonide are known[9,17,49]. Among the available methods, treatment with ozone of a suspension of potassium hydroxide[50] and particularly a suspension of KO_2 in Freons[51] is of considerable interest. The yield of potassium ozonide in the reaction of ozone with potassium hydroxide by the method of Kazarnovskii and coworkers[10] and in the reaction of ozone with potassium superoxide in a fluidised bed set up by a stream of ozonised oxygen[37] does not exceed 5−9%. The yield of the ozonide is largely promoted by two factors—an increase in the area of contact with ozone and an increase in the concentration of ozone.

A method involving the reaction of ozone with potassium superoxide in the liquid phase was developed to intensify the process. Freon-12 [52], which exhibits selective solubility in relation to an ozone-oxygen mixture, dissolving ozone alone, was employed as a solvent for ozone; in addition, it is inert with respect to KO_2 and KO_3. It has been shown[51] that, in the reaction of ozone with potassium superperoxide suspended in Freon-12, an ozonide product containing up to 80% KO_3 is obtained without extraction with liquid ammonia. Potassium ozonide was analysed by the method of Petrocelli and Capotosto[53]. The new method for the synthesis of alkali metal ozonides in Freons leads to the possibility of obtaining concentrated oxonides in a single stage without extraction with liquid ammonia and evaporation in a vacuum.

Potassium ozonide is a red crystalline substance stable only on storage in a hermetically sealed container below 0°C. The study of the kinetics of the spontaneous decomposition of potassium ozonide by chemical methods[13] showed that the reaction proceeds according to the equation $2KO_3 \rightarrow 2KO_2 + O_2$ and has the following thermodynamic parameters: $\Delta H^\circ_{298} = -11.6$ kcal, $\Delta S^\circ_{298} = 33$ e.u., and $\Delta F^\circ_{298} = -21.6$ kcal.

The dissociation of potassium ozonide is an irreversible reaction. The decomposition of KO_3 is autocatalytic with an induction period of 1.67, 20.54, and 205 days at +18.0°, −9°, and −18°C. In the subsequent active period, the rate of decomposition of potassium ozonide increases sharply; the activation energy is 22−23 kcal mole^{-1}. It has been shown by electron spin resonance (ESR) [19] that the decomposition of KO_3 at 22°C over a period between 2 and 7 days takes place approximately according to an exponential law with a time constant of 0.02 h^{-1}. It was established by differential thermal analysis [54] that the limit of the thermal stability of potassium ozonide is at 60° ± 2°C. At this temperature KO_3 is entirely converted into KO_2. To elucidate the mechanism of the decomposition of potassium ozonide, magnetic measurements were made [55] at room temperature and at 0°C. The observed deviations from additivity, which are far outside the limits of the error of the measurements, suggest the intermediate formation of a highly paramagnetic product. It is reasonable to postulate that this product is atomic oxygen, the magnetic susceptibility of which is several times greater than those of KO_3 and KO_2.

At the beginning of the decomposition the oxygen content in the solid phase increases, passes through a maximum when the degree of decomposition of potassium ozonide is about 60%, and then falls to zero for 100% decomposition. The two main elementary steps in the decomposition of potassium ozonide to potassium superoxide and oxygen may be described by the following equations:

$$\begin{gathered} KO_3 \rightarrow KO_2 + O, \\ KO_2 + O \rightarrow KO_2 + O_2, \\ \hline 2KO_3 \rightarrow 2KO_2 + O_2. \end{gathered}$$

The density of potassium ozonide is 1.990 g cm^{-3} [39]. Externally potassium ozonide crystals do not exhibit cleavage planes, the grains are formless, and show pleochroism, noted in an earlier study by Azarov and Korvin [16]. They are coloured pale-yellow in the N_p direction and red-brown in the N_g direction. The crystals are monoaxial, negative, and exhibit appreciable double refraction. The refractive indices are $N_p = 1.391$ and $N_g = 1.670$. The heat of formation of KO_3 was determined by measuring its heat of solution in dilute sulphuric acid [14] and amounts to 62.1 ± 0.9 kcal mole^{-1}.

The solubility of potassium ozonide in liquid ammonia was measured in two ways. In a study of the phase diagram for the NH_3-KO_3 system by an isothermal method, and by visual observations over a range of temperatures [56] (the "visual polythermal" method), it was established that the maximum solubility of 14.82 g/100 g NH_3 is attained at −35°C. Determinations of the vapour pressures of saturated solutions of potassium ozonide in liquid ammonia established [32] that the solubility of KO_3 at −63.5°C is approximately 12 g/100g NH_3.

Potassium ozonide is a powerful oxidant and contains 46 wt.% of active oxygen. It reacts instantly with water both at room temperature and at 0°C, with liberation of oxygen via the intermediate formation of OH radicals. In a study of isotope exchange between free hydroxy-radicals and water in 1957, Kazamovskii et al. [57] proposed the following mechanism for reaction (5):

$$\begin{gathered} KO_3 + H_2O^x = KO^xH + O_2, \\ \cdot OH + H_2O^x = \cdot{}^xOH + H_2O, \\ \cdot O^x H + \cdot O^x H = H_2O^x + {}^3/_2\, O_2^x, \\ \cdot O^x H + \cdot OH = H_2O_2^x. \end{gathered} \qquad (11)$$

Not more than 15% of the hydroxy-radicals are converted into H_2O_2 by reaction (11).

The reaction of hydroxy-radicals generated by potassium ozonide with hydrogen peroxide solution was investigated at 0°C [58]. When KO_3 is introduced into water, instantaneous reaction with liberation of oxygen and the formation of KOH and H_2O_2 is observed. The degree of consumption of OH in the formation of H_2O_2 is 18−24%. In hydrogen peroxide solutions, the formation of H_2O_2 is less pronounced and at $[H_2O_2] = 0.3$ M becomes zero.

A mixture of potassium ozonide powder and ice was investigated by the ESR method with slow increase of temperature from −196° to 0°C [59]. As the mixture is gradually heated to a temperature slightly above 0°C, a sharp decrease of signal intensity and the appearance against its background of a narrow signal with a g- factor of 2.011 are observed. The authors [59] believe that the observed signal is probably due to free hydroxy-radicals formed in the reaction of potassium ozonide with water:

$$KO_3 + H_2O \rightarrow KOH + OH + O_2. \qquad (12)$$

The reactions of formic and acetic acids with hydroxy-radicals and molecular oxygen, generated by potassium ozonide, have been investigated. The experiments at room temperature with aqueous formic acid solutions yielded carbon dioxide, oxygen, and hydrogen peroxide as the products. The reaction with anhydrous formic acid results in the formation of carbon dioxide, oxygen, carbon monoxide, and hydrogen [60]. The reaction with acetic acid vapour is instantaneous, goes virtually to completion, and is accompanied by a blue luminescence. The principal products are carbon dioxide, carbon monoxide, molecular hydrogen, water, and a small amount of methane [61]. Potassium ozonide is inert with respect to F_2O_3 dissolved in Freon-13 in the temperature range between −183° and 103° [62]. The reaction of potassium ozonide with water vapour and carbon dioxide was studied in greater detail. In the temperature range 0−20°C, potassium ozonide reacts vigorously with water vapour, active oxygen being completely liberated with formation of potassium hydroxide dihydrate [63]. At +24°C and 50% humidity potassium ozonide grains fully decompose in 30 h under the action of water vapour. During the first two hours, 87% of oxygen is removed. The average rate of liberation of oxygen during the active period is 10.9 ml g^{-1} h^{-1} but at the same temperature and 100% humidity the average rates of evolution of oxygen is 29.6 ml g^{-1} h^{-1}. [64]

The reaction of potassium ozonide with carbon dioxide takes place only in the presence of water vapour via a stage involving the complete hydrolysis of the ozonide with subsequent formation of potassium carbonate and its hydrates. The rate of evolution of oxygen is determined by the rate of diffusion of water vapour [63,94]:

$$\begin{gathered} 2KO_3 + H_2O \rightarrow 2KOH + {}^5/_2\, O_2, \\ 2KOH + CO_2 \rightarrow K_2CO_3 + H_2O. \end{gathered} \qquad (12a)$$

In the absence of moisture the reaction between KO_3 and CO_2 does not occur. The potassium bicarbonate present in the reaction products is determined by potentiometric titration with acid. The ready formation of potassium carbonate increases the possible usefulness of potassium ozonide as a life-supporting agent [64].

Zhdanov and Zvonkova [12] found from the X-ray diffraction pattern of the powder that potassium ozonide has a lattice close to the tetragonal lattice of potassium azide (KN_3) with the parameters $a = 6.094$ Å and $c = 7.056$ Å. However, the absence from the diffraction pattern of the important reflection with an index of 121, according to their data, does not confirm the hypothesis of a linear configuration of the O_3^- ion. Therefore they believe [12]

that the symmetry of KO_3 is probably lower than that of KN_3. In the light of new data on the structure of the ozone molecule [23], it has been suggested that the KO_3 lattice may be of a different type. As stated above, Smith [23] found that the O_3^- ion is not linear but angular with an angle of 110° ± 5° and $r = 1.34 \pm 0.05$ Å. Since these values are close to the corresponding data for the NO_2^- ion, for which the angle $<O-N-O = 115° \pm 4°$ and $r = 1.34 \pm 0.03$ Å, Smith postulated that the structures of KO_3 and KNO_2 are similar. On the basis of the correspondence of the X-ray diffraction data (l and d) for KO_3 and KNO_2, he believes it to be likely that KO_3 has a monoclinic unit cell of the KNO_2 type and with the same coordination.

Azarov and Korvin [16] showed that potassium ozonide has a body-centred tetragonal unit cell with the parameters $a = 8.597 \pm 0.002$ Å and $c = 7.08 \pm 0.002$ Å; the space group is $I4/mcm$. In view of the similarity of the reflection intensities of KO_3 and KN_3, they believe that these structures are derived from the CsCl structure, where each N_3^- or O_3^- ion occupies a Cl^- site and K^+ occupies a Cs^+ site. They calculated from the coordinates of the atoms that the O_3^- ion is not linear but angular with an angle of 100° and $r = 1.19$ Å.

4. Rubidium Ozonide

Rubidium ozonide was first isolated in 1951 by Nikol'skii et al. [11] The reaction between rubidium hydroxide and ozone was carried out at −30°C with subsequent extraction by liquid ammonia. After the evaporation of liquid ammonia, orange quasi-crystalline rubidium ozonide preparations were isolated with an RbO_3 content between 55 and 66% (the residue was RbOH).

The high percentage of the impurity is due to the considerable solubility of RbOH in liquid ammonia (at −40°C 100 ml of liquid ammonia dissolves 0.9 g of RbOH).

In 1966 96.6% pure rubidium ozonide was obtained [65]. This high rubidium ozonide content was achieved by employing as the starting material rubidium superoxide (93.3%), which in turn was prepared by atomising metallic rubidium in an oxygen and argon atmosphere with the aid of a special sprayer and apparatus described in detail by Vol'nov and Matveev [66]. The reaction of ozone with rubidium superoxide was carried out at 0°C for 50 min in a fluidised bed set up with a stream of ozonised oxygen. Before extraction the ozone-treated rubidium superperoxide contained 70.5% RbO_3.

At room temperature rubidium ozonide decomposes slowly according to the equation

$$RbO_3 \rightarrow RbO_2 + {}^1/_2 O_2 . \qquad (13)$$

The density of rubidium ozonide is 2.75 g cm^{-3} [67]. Polycrystalline RbO_3 specimens exhibit pleochroism; they are coloured pale-yellow in the direction of the smallest refractive index and dark-brown in the direction of the largest refractive index; $N_p = 1.456$, $N_m = 1.576$, and $N_g = 1.750$. The rubidium ozonide crystals are optically biaxial.

The solubility of rubidium ozonide in liquid ammonia in the temperature range between −48° and −84° has been investigated. The RbO_3-NH_3 system is of the type with a simple eutectic at a temperature between −82° and −83°C. The eutectic mixture contains 4.0% RbO_3 (4.3 g of RbO_3 in 100 g of NH_3). [68]

5. Caesium Ozonide

The literature data on the synthesis of caesium ozonide up to 1963 may be regarded as merely exploratory, since pure caesium ozonide had not been obtained up to that time.

In a study of the reaction of ozonised oxygen with CsOH, Manchot and Kampschulte [8] noted that CsOH becomes coloured red, the colour disappearing on subsequent heating to 140−160°C. Traube [6] carried out the reaction of ozone with carefully dehydrated CsOH at temperatures between 20° and 0°C. The coloured product was decomposed by water with evolution of 2% of oxygen and the formation of a very small amount of hydrogen peroxide. When [ozone-treated] caesium hydroxide was stored in the cold, the colour persisted for 14 days. An unstable coloured product with the empirical composition CsOH.O was obtained by Strecker and Thienemann [69] in the reaction of ozone with a solution of metallic caesium in liquid ammonia. Because of the considerable solubility of CsOH in liquid ammonia (1.0 g/100 ml NH_3), the purest preparation obtained by Nikol'skii et al. [11] contained 67.3% $CsOH_3$ and 31.2% CsOH.

In order to prepare pure caesium ozonide, the reaction of caesium superoxide with an ozone−oxygen mixture in a fluidised bed was employed above 0°C [37,48] using the method of Vol'nov and Matveev [66]. Caesium superoxide reacted with ozone in a fluidised bed produced by a stream of an ozone−oxygen mixture containing up to 8% of ozone. After extraction with liquid ammonia, a product containing up to 92.5% of caesium ozonide was obtained [66]. Caesium ozonide is extremely unstable with respect to moisture and carbon dioxide. The caesium ozonide content in the ozone−treated superoxide and in the ozonide itself after extraction with liquid ammonia was found by determining the active oxygen and Cs_2O [48].

In order to determine the limit of the thermal stability of caesium ozonide and to discover the processes occurring during its decomposition, a differential heating curve was recorded on a Kurnakov differential thermal analyser [70]. At the same time measurements were made of the amount of oxygen evolved on heating. The heating curve showed two effects. An exothermic effect, which begins at 70°C and has a maximum at 100°C, corresponds to the decomposition of CsO_3 to CsO_2 and is accompanied by the evolution of oxygen. An endothermic effect at 408°C corresponds to the fusion of CsO_2 with subsequent decomposition to the oxide and liberation of oxygen. The density and the refractive index of caesium ozonide were measured [71]. In transmitted polarised light CsO_3 crystals are coloured dark cherry red and exhibit pleochroism. In the direction of the minimum refractive index, their colour is pale yellow, and in the direction of the maximum refractive index dark cherry red. In thick layers the crystals absorb light almost completely and become opaque. The crystals belong to the middle category and are optically monoaxial and positive. The refractive indices are $N_m = 1.523$ and $N_g = 1.69$. The density measured by hydrostatic weighing is 3.19 g cm^{-3} and the X-ray density is 3.22 g cm^{-3}. Like sodium and potassium ozonides, caesium ozonide has the lowest density compared with the peroxide and the superoxide:

	Cs_2O_2	CsO_2	CsO_3
d_4^{20}	4.47	3.80	3.19

But in the series of ozonides its density is a maximum:

	NaO_3	KO_3	RbO_3	CsO_3
d_4^{20}	1.6	1.99	2.75	3.19

Caesium ozonide crystallises with a body-centred tetragonal lattice, having the parameters $a = 9.75$ Å, $c = 8.75$ Å, and $c/a = 0.9$.[26] The space group is $I4/mcm$.

IV. ALKALINE EARTH METAL OZONIDES

The problem of the formation of alkaline earth metal ozonides remained open until recently. Manchot and Kampschulte[8] noted that, in the reaction of an ozone-oxygen mixture containing 8 wt.% of ozone with magnesium, strontium, and barium oxides at room temperature, ozone was decomposed and at −80°C barium oxide acquired an intense yellow colour, calcium oxide was less strongly coloured, and the colour of magnesium oxide was insignificant. They suggested that these coloured compounds are ozonides. However, this hypothesis was not confirmed either by chemical analysis or other methods. Blumental[72] repeated the experiments of Maschot and Kampschulte and reported the formation of "some kind" of substance which does not decolourise potassium permanganate solution but liberates iodine from acid potassium iodide solutions. Strecker and Thienemann[73] oxidised solutions of metallic barium and calcium in liquid ammonia with an ozone−oxygen mixture. With calcium, they obtained a brown precipitate, which fully decomposed on evaporation of ammonia and was not analysed. These data exhaust the early information about the products of the reaction of alkaline earth metals with ozone.

The first calcium, strontium, and barium ozonides were synthesised in 1966.[74] On the hypothesis that the reaction of ozone with alkaline earth metal hydroxides is described by the equation

$$M(OH)_2 + 2O_3 \rightarrow M(O_3)_2 + H_2O + {}^1/_2O_2 \ , \qquad (14)$$

the thermodynamic functions for this reaction with calcium, strontium, and barium hydroxides were estimated[74]. The results are presented in Table 2.

Table 2. Estimation of the enthalpies of formation of alkaline earth metal ozonides from the elements and the enthalpy and free energy of reaction (14) (±10 kcal).

Compound	ΔH^0_{298} for formation from elements	By reaction (14)	
		ΔH^0_{298}	ΔF^0_{298}
$Ca(O_3)_2$	−169	−69	−83
$Sr(O_3)_2$	−161	−68	−81
$Ba(O_3)_2$	−157	−67	−80

The values of ΔH°_{298} for the formation of the ozonides from the elements were estimated by comparative calculation[27]. It was shown[74] that, in the reaction of ozone with calcium, strontium, and barium hydroxides at −100°C, the latter become coloured yellow, the colour intensity increasing from calcium to barium.

An ESR study of the resulting coloured precipitates at the temperature of liquid nitrogen showed the presence of a typical spectrum of the ozonide ion with $g = 2.01$. The thermal stability of the ozonides increases from calcium to barium. Calcium ozonide decomposes appreciably at −35°C, strontium ozonide a little below 0°C, and barium ozonide at 0°C.

The results of the ESR study suggest that the coloured products are formed in the reaction of the ozone−oxygen mixture with solid alkaline earth metal hydroxides and are ozonides containing the paramagnetic ion O_3^-.

V. AMMONIUM AND TETRAMETHYLAMMONIUM OZONIDES

The capacity for the formation of an ozonide is not characteristic solely of alkali and alkaline earth metals but also of the ammonium ion and its derivatives.

In 1907 Manchot and Kampschulte[8] were the first to predict the possibility of the existence of ammonium ozonide. They found that, when dilute ozone is passed through liquid ammonia, a dark-orange colour is produced, which persists until the liquid is heated. They discovered that the colour is most intense at −70°C and disappears at −60°C. Strecker and Thienemann[7] also observed a short-lived colour when dilute ozone was passed through liquid ammonia, although the product isolated contained mainly ammonium nitrate. Experiments carried out in the Laboratory for Peroxy-Compounds at the Institute of General and Inorganic Chemistry on the reaction of ozone with solutions of metallic calcium in liquid ammonia showed that the solutions assume a bright-orange colour which gradually disappears as ammonia is evaporated[75].

Ammonium ozonide was first isolated in 1962 by Solomon et al.[76] by the reaction of ozone with liquid ammonia at a temperature below −100°C. The absorption spectrum of ammonium ozonide in a mixture with trifluoromethane is analogous to the spectra of other ozonides. The use of a solvent was necessary to keep the system in the liquid state at the low temperature required for the stabilisation of ammonium ozonide. A peak at 450 nm, characteristic of the ozonide ion, was observed in the spectrum of ammonium ozonide. Moreover, the ESR spectra of potassium, tetramethylammonium, and ammonium ozonides were recorded to identify ammonium ozonide. The presence of the ozonide ion was demonstrated in all these compounds. The results are presented in Table 3.

Table 3.

Compound	g-factor
KO_3	2.0124
$(CH_3)_4NO_3$	2.0144
NH_4O_3	2.0119

Ammonium ozonide is stable only below −126°C. It decomposes according to the equation

$$2NH_4O_3 \rightarrow NH_4NO_3 + {}^1/_2O_2 + 2H_2O \ . \qquad (15)$$

Herman and Giguere[18] also showed that ammonium ozonide begins to decompose at temperatures below −126°C and at −90°C the decomposition is complete.

In 1929 Traube and Kyhbier[77] treated tetramethylammonium hydroxide with ozone and obtained a red substance to which they attributed the formula $(CH_3NOH)_2.O_2$. Tetramethylammonium ozonide was first isolated and identified by Solomon et al.[78] It was obtained by the reaction of ozone with tetramethylammonium hydroxide at

25°C. The absorption spectrum of the solution of tetramethylammonium ozonide in liquid ammonia has an absorption maximum at 450 nm, characteristic of all ozonides.

Tetramethylammonium ozonide dissolves in liquid ammonia at −63°C to the extent of 1.3 ± 1 g/100 g NH_3. It is stable up to 25°C and at 25°C decomposes completely over a period of 48 h. The heat of formation of $[N(CH_3)_4]O_3$ from the elements is 49.5 ± 4 kcal mole^{-1}.

VI. SOME HYPOTHESES CONCERNING THE MECHANISM OF THE FORMATION OF OZONIDES

The formation of alkali metal ozonides by the mechanism proposed by Kazarnovskii[11,79] proceeds via an unstable complex of the type $M^+O^-H^+O_3^-$ and a subsequent further reaction with ozone:

$$2\,MOH + 2\,O_3 \rightarrow 2\,MOH \cdot O_3\,, \quad (16)$$
$$2\,MOH \cdot O_3 + 2\,O_3 \rightarrow 2\,MO_3 + 2\,HO_2 + 2\,O_2\,, \quad (17)$$
$$2\,HO_2 \rightarrow H_2O + 1.5\,O_2\,, \quad (18)$$
$$MOH + H_2O \rightarrow MOH \cdot H_2O\,, \quad (19)$$
$$3\,MOH + 4\,O_3 \rightarrow 2\,MO_3 + MOH \cdot H_2O + 3.5\,O_2\,. \quad (20)$$

The overall result is the formation of a mixture of the alkali metal ozonide and the monohydrate of the hydroxide with a simultaneous conversion of a large amount of ozone into oxygen. The activation energy for the reaction of potassium hydroxide with ozone has been estimated as 3.1 kcal.[80]

The following considerations can be put forward concerning the above mechanism for the formation of alkali metal ozonides. The mechanism is based on two hypotheses: the hypothesis of the formation of the unstable complex $MOH.O_3$ of sodium, potassium, rubidium, or caesium (but not lithium) hydroxides with an ozone molecule [reaction (16)] and the hypothesis of the participation of the radical HO_2 [by reaction (17)] in the formation of the ozonides of these elements.

According to Eqn. (20), the ratio of the metal hydroxide monohydrate to the ozonide is 1:2, which means that in the reactions of ozone with sodium and potassium hydroxides the ozonide contents should be 71% and 66.4% respectively. However, it has been shown that not more than 4−5% NaO_3 is detected in the ozone-treated sodium hydroxide[36,81]. This contradiction was eliminated in a mechanism for the formation of ozonides put forward subsequently[82]. Probably the reaction of ozone with alkali metal hydroxides takes place mainly on the surfaces of the solid hydroxides. Isotopic analysis of oxygen in potassium ozonide[75] synthesised from $K^{18}OH$ with the natural composition showed that the oxygen of the hydroxide is involved in the formation of the ozonide.

On the basis of the fact that potassium ozonide is formed also by the reaction $KO_2 + O_3 \rightarrow KO_3 + O_2$ from the superoxide and ozone[11,37,83] and data[80] for the catalytic decomposition of ozone on the KOH surface, it is more probable that atomic oxygen is responsible for the formation of ozonides.

The mechanism proposed for the formation of ozonides[82] presupposes the successive occurrence of the following reactions:

$$3\,O_3 + 2\,MOH \rightarrow 3\,O_2 + 2\,MOH \cdot O + O\,, \quad (21)$$
$$2\,MOH \cdot O + O \rightarrow 2\,MO_2 + H_2O\,, \quad (22)$$
$$2\,O_3 + 2\,MO_2 \rightarrow 2\,MO_2 \cdot O + 2\,O_2\,, \quad (23)$$
$$2\,MO_2 \cdot O \rightarrow 2\,MO_3\,, \quad (24)$$
$$5\,O_3 + 2\,MOH \rightarrow 5\,O_2 + 2\,MO_3 + H_2O\,. \quad (25)$$

Reaction (21) has been confirmed by the data of Schwab and Hartman[80] and the results obtained in a study of the reaction of ozone with sodium hydroxide[36]. The occurrence of reaction (22) has been demonstrated in a study of the reaction of potassium hydroxide with atomic oxygen generated in a glow discharge[84]. Reactions (23) and (24) are components of reaction (10). The overall equation (25) is based on the three experimentally demonstrated intermediate reactions and is consistent with the decomposition of ozone in which n moles of oxygen and n atoms of oxygen should be formed from n moles of ozone.

---o0o---

The data presented in the review show that recently there has been a considerable growth of interest in compounds included in the class of inorganic ozonides. The chemistry of ozonides has been attracting the attention of investigators both in the Soviet Union and abroad.

Evidently the main studies are devoted to problems of the synthesis, structure, and physicochemical properties of ozonides. Very few investigations deal with the reactions of these substances with various classes of compounds: solid, liquid, gaseous, inorganic, and organic. There has been no work at all on the stabilisation of ozonides.

The study of these processes will characterise more fully this new class of compounds and will bring nearer their practical application. The accumulation of experimental data on the synthesis and properties of ozonides and the mechanisms of their formation will help in the elucidation of the mechanism of the formation of important inorganic radicals.

Inorganic ozonides, which are powerful oxidants and sources of oxygen, are very promising substances and further intensification of the study of their synthesis and properties and also ways for their stabilisation will lead to their wider practical application.

Electron Spin Resonance Spectra of Fluorocarbon Radicals

V.I.Muromtsev, R.A.Asaturyan, and I.G.Akhvlediani

A systematic account has been given of the information currently available about the components of the hyperfine coupling tensor of fluorocarbon radicals and also information about the form of the spectra of fluorocarbon radicals containing one and two α-fluorine atoms in polycrystalline specimens. Recent information on the paramagnetic centres in irradiated polytetrafluoroethylene, including fluorocarbon radicals and also radicals formed in their oxidation, is presented. The bibliography includes 24 references.

V. Peroxy-radicals in irradiated polytetrafluoroethylene	181

I. INTRODUCTION

Fluorocarbon compounds are finding increasing application in a wide variety of branches of the national economy. In this connection it is particularly necessary to obtain information about the processes occurring which involve fluorocarbon radicals.

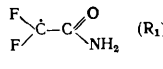
The studies on fluorocarbon radicals by the ESR method have specific features and present certain difficulties. So far the number of unambiguously identified fluorocarbon radicals does not exceed several tens and even as regards the identification of the most thoroughly studied magnetic centres (PC) there exist various mutually exclusive views.

In the present review an attempt is made to give a systematic account of certain radiospectroscopic data on a number of fluorocarbon paramagnetic centres. The first part of the review deals with the available data on the components of the hyperfine coupling tensor of fluorocarbon radicals obtained in the study of irradiated single crystals. The characteristics of the spectra of radicals with one or two α-fluorine atoms in polycrystalline specimens are discussed. The second part of the review considers the results from studies of paramagnetic centres in irradiated polytetrafluoroethylene (PTFE).

II. HYPERFINE COUPLING CONSTANTS OF FLUOROCARBON RADICALS

The broadening of the ESR spectra of fluorocarbon radicals in polycrystalline specimens is caused mainly by hyperfine anisotropic coupling. In order to understand the characteristic features of such spectra, it is extremely important to have information about the constants of the hyperfine coupling tensor for α- and β-fluorine atoms. The values of the constants for α-fluorine atoms in some radicals are presented in the Table

Analysis of the spectra of an irradiated single crystal led Lontz and Gordy[1] to the conclusion that in the radicals



(R₁)

the fragment $\diagdown C-\dot{C}F_2$ is planar and is probably located in the plane of the CON group.

If the magnetic field H_0 is perpendicular to the plane of the crystal, the ESR spectrum consists of three lines with a splitting of 178 Oe between the components. If the field H_0 is in the plane of the radical, a triplet is also observed but the splitting between the components is 24 Oe. In this triplet the splitting is independent of the angle between the direction of the C–C bond in the radical and the direction of the external field.

Constants of the hyperfine coupling tensors

Radical	Constants of HFC tensor for α-F atoms, Oe				Radical	Constants of HFC tensor for α-F atoms, Oe			
	A_1	A_2	A_3	$\bar{A}$		A_1	A_2	A_3	$\bar{A}$
$\dot{C}F_2CONH_2$	178	24	24	75	$CF_3\dot{C}FCONH_2$	201	12	8	74
$\dot{C}HFCONH_2$	189	−4	−16	56	$CO_2^-CF_2\dot{C}FCO_2^-$	150	59	4	71

In the R_1 radical the unpaired electron density is mainly localised at the C–C molecular orbital. At first sight it might appear that, for certain orientations of the magnetic field, the fluorine atoms should be non-equivalent and consequently the spectrum should consist of four lines. However, it is found that, for any orientation, the spectrum consists of three lines the splitting between which depends on the orientation of the radical. The authors believe that the hyperfine coupling constants are due mainly to the unpaired electron density at the fluorine nucleus.

The ESR spectrum of the R_1 radical can be described by the Hamiltonian

$$\mathbf{H} = \beta\,\mathbf{S}\mathbf{g}\mathbf{H}_0 + \sum_{i=1}^{2} \mathbf{S}\mathbf{A}_i\,\mathbf{I}_i - \sum_{i=2}^{2} g_I\beta_I\,\mathbf{I}_i\mathbf{H}_0\,. \qquad (1)$$

The first term of the Hamiltonian represents the coupling between the magnetic moment of the electron and the external field, the second the coupling of the nuclear moments of the fluorine atoms with the magnetic moment of the electron, and the last term is due to the coupling between the nuclear moments of fluorine and the external magnetic field. The tensors g and A characterise the

spin–orbit and hyperfine coupling in the radical. Experiments showed that in the case under discussion the tensors g and A have axial symmetry and their axes of symmetry coincide.

The authors calculated theoretically the energy levels and the ESR spectrum for the paramagnetic centres described by the Hamiltonian (1) in the case where the electron–nucleus interaction is small compared with the interaction with the external magnetic field. The diagram of the resulting energy levels is presented in Fig. 1. The frequencies ν_1, ν_2, and ν_3 correspond to allowed transitions and ν_4, ν_5, ν_6, and ν_7 to forbidden transitions in which the orientations of the electronic and nuclear spins change.

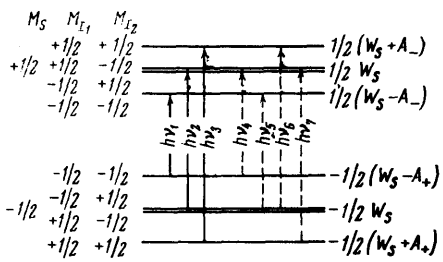


Figure 1. Diagram of energy levels due to the interaction of the unpaired electron with two equivalent fluorine nuclei in the radical $\dot{C}F_2CONH_2$. The continuous and dashed lines indicate the allowed and forbidden transitions respectively.

The splitting between the energy levels of the allowed transitions is given by the expressions

$$h\nu_1 = W_s - \frac{1}{2}(A_+ + A_-)\,,$$
$$h\nu_2 = W_s\,, \qquad (2)$$
$$h\nu_3 = W_s + \frac{1}{2}(A_+ + A_-)\,,$$

where

$$A_+ = [(A_\parallel + W_I)^2\cos^2\theta + (A_\perp + W_I)^2\sin^2\theta]^{1/2},$$
$$A_- = [(A_\parallel - W_I)^2\cos^2\theta + (A_\perp - W_I)^2\sin^2\theta]^{1/2},$$
$$W_s = g_s\beta_s H_0;\quad W_I = 2g_I\beta_I H_0\,.$$

In the case considered the hyperfine coupling tensors for both fluorine nuclei have axial symmetry and, moreover, their principal values coincide. The constant $A_\parallel = A_\perp$ corresponds to the direction of the principal axis of the tensor, which is perpendicular to the plane of the radical; θ is the angle between the direction of the external magnetic field H_0 and the normal to the plane of the radical. The splitting in the ESR spectrum between adjacent components of the triplet is given by the expression

$$t = \frac{1}{2}(A_+ + A_-)\,. \qquad (3)$$

When the magnetic field is perpendicular to the plane of the radical ($\theta = 0$), then $t = A_\parallel$. For $\theta = 90°$, $t = A_\perp = A_2 = A_3$. In the case considered the g-factor is determined by the relation familiar for the case with axial symmetry:

$$g(\theta) = (g_\parallel^2\cos^2\theta + g_\perp^2\sin^2\theta)^{1/2}\,, \qquad (4)$$

where $g_\parallel$ and $g_\perp$ correspond to the parallel and perpendicular orientations of the permanent magnetic field relative to the plane of the radical.

For the R_1 radical, the parameters of the g-tensor are

$$g_\parallel = 2.0025 \pm 0.0010\,,$$
$$g_\perp = 2.0045 \pm 0.0010\,.$$

We may note that in the 3 cm band, for the splitting of the adjacent components of the triplet, W_I may be neglected to a first approximation, particularly for directions of H_0 close to those of the principal axes of the tensor, and Eqn. (3) becomes

$$t = A = [A_\parallel^2\cos^2\theta + A_\perp^2\sin^2\theta]^{1/2}.$$

The average value of the principal components of the hyperfine coupling tensor corresponding to isotropic hyperfine coupling is

$$\bar{A} = \pm\frac{1}{3}(A_\parallel + 2A_\perp)\,.$$

For splittings between adjacent components, one can obtain approximately

$$A = \bar{A} + A_\mu(3\cos^2\theta - 1)\,,$$

where

$$A_\mu = \pm\frac{1}{3}(A_\parallel - A_\perp)\,.$$

The frequencies of the forbidden transitions, indicated in Fig. 1 by dashed lines, are given by the expressions

$$h\nu_4 = W_s - \frac{1}{2}A_+\,,$$
$$h\nu_5 = W_s - \frac{1}{2}A_-\,,$$
$$h\nu_6 = W_s + \frac{1}{2}A_-\,, \qquad (5)$$
$$h\nu_7 = W_s + \frac{1}{2}A_+\,.$$

The ratio of the probability of forbidden transitions to the probability of allowed transitions is

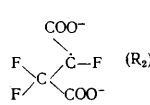
$$r = \frac{C^2(A_+ - A_- + 2W_I)^2}{(A_{ZZ} + A_- - W_I)(A_{ZZ} + A_+ + W_I) + C^2}\,, \qquad (6)$$

where

$$A_{ZZ} = A_\parallel\cos^2\theta + A_\perp\sin^2\theta\,,$$
$$C^2 = (A_\parallel - A_\perp)^2\sin^2\theta\cos^2\theta\,.$$

It is easily seen from Eqn. (6) that the probability of the forbidden transitions depends significantly on the difference $A_\parallel - A_\perp$ and on the value of W_I. For fluorocarbon radicals, the anisotropy characterised by the value of $A_\parallel - A_\perp$ is very high and the forbidden transitions make a significant contribution to the observed spectrum,

In the 8 mm band for certain orientations of the radical, the intensity of the spectra due to the forbidden transitions is comparable to that of the spectra corresponding to the allowed transitions. As an example, Fig. 2 presents the ESR spectra of the radicals



(R_2)

obtained in an irradiated single crystal[2]. For the chosen orientation of the single crystal, two groups of lines consisting of four components are seen on the second derivative absorption spectrum obtained in the 3 cm band (Fig. 2*a*). The splitting between the centres of these groups is due to the interaction with the one α-fluorine atom and the splitting into four components within the

groups is due to interactions with the two non-equivalent β-fluorine atoms.

In the spectrum obtained for the same orientation using the 8 mm band, the components corresponding to the forbidden transitions are very intense (Fig. 2*b*).

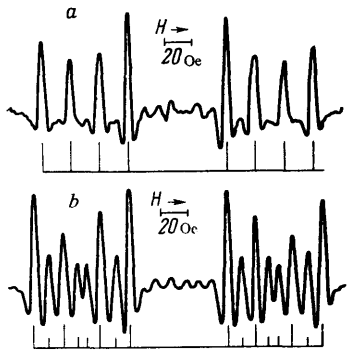


Figure 2. Second derivative absorption spectra for a certain orientation of the radical $CO_2-CF_2\dot{C}FCO_2-$ in a magnetic field H_0 in the 3 cm (curve *a*) and 8 mm (curve *b*) wavelength ranges.

It proved possible to obtain information about the components of the hyperfine coupling tensors for both α- and β-fluorine atoms of the radicals R_2. The anisotropy for the β-fluorine atom is significantly lower than for the α-atoms. The principal values of the hyperfine coupling tensor components for one of the β-fluorine atoms are 63, 23, and 19 Oe and those for the other β-fluorine atom are 71, 27, and 23 Oe.

It is noteworthy that, for reasons which are insufficiently clear, in R_2 the symmetry of the hyperfine coupling tensor for the α-fluorine atom differs from the axial symmetry.

The hyperfine coupling constants of the radicals

(R3)

in irradiated single crystals have been investigated. It was found that the symmetry of the hyperfine coupling tensor for the fluorine atom differs somewhat from axial symmetry. By analysing the spectra in the 3 cm and 8 mm bands, the authors succeeded in demonstrating that the isotropic hyperfine coupling constant is positive and equal to 56 Oe. The principal values of the hyperfine coupling tensor for the fluorine atom proved to be 189, −4, and −16 Oe. The highest value of the component corresponds to the principal axis of the tensor being oriented perpendicular to the plane of the radical. The tensor component equal to −16 Oe corresponds to the direction of the principal axis along the C–F bond of the radical.

The authors estimated the contribution to the tensor components due to the unpaired electron density in the $2p_\pi$ carbon orbitals, the $2p_\delta$ fluorine orbital (the orbital responsible for the C–F δ-bond), and the $2p_\pi$ orbital of the fluorine atom. It was found that, although the unpaired electron density in the $2p_\pi$ carbon orbital is very high, the contribution of this orbital to the largest tensor component is insignificant.

Fluorocarbon radicals containing β-fluorine atoms have also been investigated[4]:

(R4) .

It was found that in the R_4 radical the CF_3 group is rotating at room temperature and each β-fluorine atom has the same values of the principal components of the hyperfine coupling tensor, equal to 36, 17, and 14 Oe. The principal values of the hyperfine coupling tensor components for the α-fluorine atom are 201, 12, and 8 Oe.

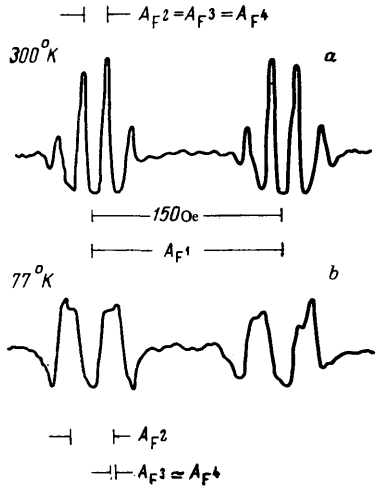

Figure 3. Second derivative absorption spectra for a certain orientation of the radical $CF_3\dot{C}FCONH_2$ in a magnetic field H_0: *a*) 300°K; *b*) 77°K.

Fig. 3 presents the spectra at 300° and 77°K corresponding to a certain orientation of the R_4 radical.

We may note that a decrease of temperature has hardly any effect on the splitting due to the α-fluorine atom. However, the structure due to the interaction with β-fluorine atoms changes significantly.

It follows from the analysis of the spectrum in Fig. 3*b* that at 77°K the rotation of CF_3 is frozen and one of the β-fluorine atoms has higher hyperfine coupling constants than the other two, which may be regarded as equivalent.

III. ESR SPECTRA OF FLUOROCARBON RADICALS IN POLYCRYSTALLINE SPECIMENS

The data for the hyperfine coupling constants of fluorocarbon radicals discussed in the preceding section make it possible to account for the specific features and the form of their ESR spectra in polycrystalline specimens.

The hyperfine coupling constants of fluorocarbon radicals due to α-fluorine atoms are significantly higher than the constants due to β-fluorine atoms. The anisotropic hyperfine interactions of α-fluorine atoms are very large compared with the isotropic interactions. In this connection the broadening of the ESR spectra of fluorocarbon radicals in polycrystalline specimens is due mainly to anisotropic hyperfine interactions.

For hydrocarbon radicals, the overall contour of the spectrum is determined by the broadening of the isotropic hyperfine structure caused both by the anisotropy of the hyperfine coupling and the anisotropy of the g-factor.

The anisotropy of the g-factor for fluorocarbon radicals makes a significantly lower contribution to the overall contour of the spectra in polycrystalline specimens compared with the anisotropy of the hyperfine coupling.

The anisotropy of the hyperfine coupling of β-fluorine atoms is relatively low and therefore hyperfine coupling to them gives rise in the spectra to partially resolved components.

The overall spread of the spectra of fluorocarbon radicals with one α-fluorine atom is approximately equal to the maximum component of the hyperfine coupling tensor for α-fluorine atoms, which usually amounts to about 190 Oe. With two α-fluorine atoms, the spectra extend over about 400 Oe.

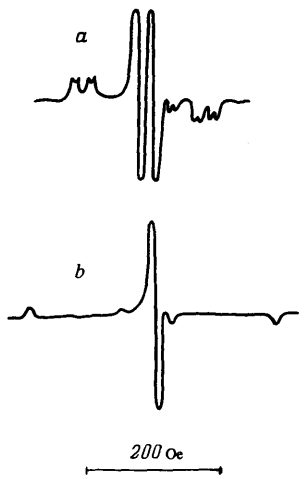

Figure 4. First derivative absorption spectra of the radicals $\dot{C}FHCOONa$ (curve *a*) and $\dot{C}F_2COONa$ (curve *b*).

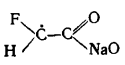
The form of the spectra of fluorocarbon radicals in polycrystalline specimens in the 3 cm band may be calculated without taking into account the forbidden transitions. In the 8 mm band forbidden transitions make an appreciable contribution to the spectrum.

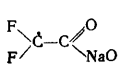
The derivative absorption spectra of radicals containing one or two α-fluorine atoms in polycrystalline specimens are presented in Fig. 4.

For the radicals



(R_5),

the spectrum shows wing components separated from one another by approximately 180 Oe (Fig. 4*a*). For the radicals



(R_6),

containing two α-fluorine atoms, the wing components are separated by a distance of 380 Oe (Fig. 4*b*).

It is noteworthy that the intensity of the wing lines is almost ten times less than the intensity of the central components. The intensity of the wings of the lines is so low that, to a first approximation, one may assume that the spectrum of paramagnetic centres with one or two α-fluorine atoms consists of a relatively narrow singlet.

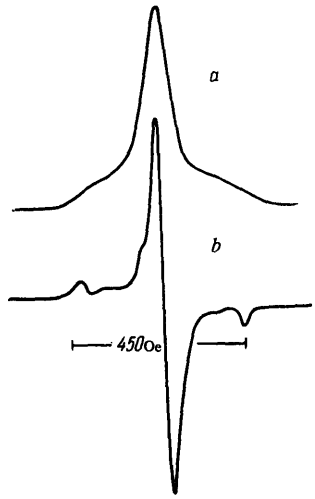


Figure 5. Absorption spectrum and its first derivative for the radicals $-CF_2-CF(\dot{C}F)_2-CF_2-$ at 77°K.

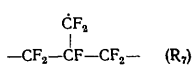
This impression, which arises from an analysis of the derivative of the absorption signals, is due to the characteristic line shape for each fluorocarbon radical. In the spectra of the radicals the overall spread of the absorption is very large but the derivative of the signal decreases fairly rapidly and significantly on passing outside the point corresponding to the maximum slope of the absorption signal. To illustrate these features of the spectra, Fig. 5 presents simultaneously the form of the absorption signal and its derivative for the radicals



(R_7)

in polycrystalline specimens.

IV. PARAMAGNETIC CENTRES IN IRRADIATED POLYTETRAFLUOROETHYLENE

The ESR spectra of irradiated polytetrafluoroethylene (PTFE) have been investigated in a number of studies[5-15]. As a result of radiation-chemical processes, as a rule several types of paramagnetic centres are formed in the irradiated polymers. The fluoroalkyl radicals

$$-CF_2-CF_2-\dot{C}F-CF_2-CF_2- \quad (R_8),$$

are formed in PTFE with a relatively large radiation yield. The ESR spectra of R_8 radicals at two temperatures obtained in two investigations[7,15] are presented in Fig. 6. At 523°K Lebedev et al.[7] observed hyperfine splitting in the spectrum of the R_8 radical due to interaction with four

γ-fluorine atoms (Fig. 6*a*). The γ-splitting is 3.5 Oe. At room temperatures the γ-components are not resolved.

It has been found in studies at room temperature[6] that the isotropic constant for the α-fluorine atom is 92 Oe and that for the β-fluorine atom is 33 Oe. Fig. 6*b* presents the spectrum of the R_8 radical at 77°K.[15] It is noteworthy that at this temperature components due to interaction with the β- and γ-fluorine atoms appear.

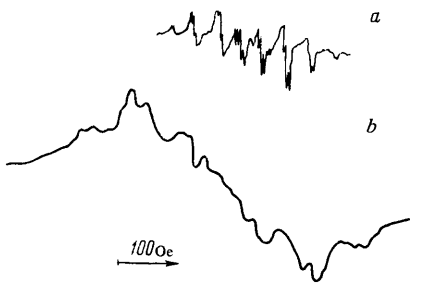


Figure 6. First derivative absorption spectra of the radical $-CF_2-CF_2-\dot{C}F-CF_2-\dot{C}F_2-$ at 523°K (curve *a*) and 77°K (curve *b*).

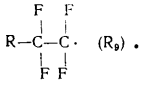
A relatively detailed study of R_8 radicals in PTFE was made for polymers partially oriented by extrusion[11]. It was observed that the width of the individual spectrum components is 9 Oe in cases where the H_0 field is perpendicular to the extrusion axis. When the H_0 field is parallel to the extrusion axis, the width of the component increases by a factor of two. The splitting by the α-fluorine atom is a minimum, amounting to 25 Oe, when the H_0 field is directed along the extrusion axis. It is noteworthy that the form of the spectrum for R_8 radicals at room temperature is determined to a considerable degree by isotropic interactions. The maximum splitting by the α-fluorine atom is only 92 Oe, although for the other fluorocarbon radicals with one or two α-fluorine atoms discussed previously the splitting at the same temperature is greater by a factor of two. This feature of the hyperfine interactions involving the α-fluorine atom at room temperature is somewhat obscure.

Ovenall[11] succeeded for the first time in detecting the terminal radicals



It was found that in the ESR spectra of PTFE specimens with the extrusion axis oriented parallel to the direction of the external field, wing components are observed, the centres of which are separated from each other by 390 Oe, the components having an additional triplet splitting of 25 Oe (Fig. 7). The paramagnetic centres responsible for these lateral components contribute to the central part of the overall spectrum. The observed spectrum may be attributed to the terminal R_9 radicals, since a splitting of 390 Oe can be produced only by two α-fluorine atoms. The triplet splitting of the wing components is due to the two β-fluorine atoms.

The ESR spectrum of the terminal R_9 radicals in polycrystalline specimens was observed for the first time by Bruk et al.[16] It has been shown[17] that the R_9 radicals are formed in irradiated PTFE and the reasons found why they could not be detected for a long time although their concentration is comparable to that of the R_8 fluoroalkyl radicals. The experimental results and spectroscopic considerations on the basis of which the R_9 spectra were identified are considered briefly below.

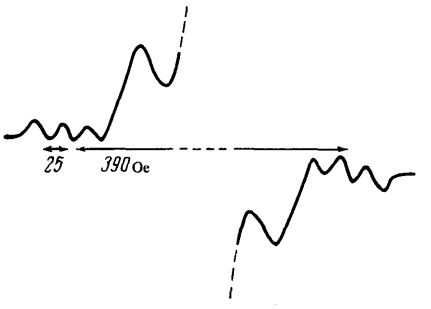


Figure 7. Lateral components of the first derivatives of the absorption signals of the radicals $R-CF_2-\dot{C}F_2$ on irradiation of oriented PTFE (extrusion axis parallel to H_0).

Irradiation of a frozen tetrafluoroethylene (TFE) monomer and secondary processes result in the formation of polymeric PTFE. After an irradiated tetrafluoroethylene specimen is heated to room temperature and the monomer is vaporised, the resulting polymer shows ESR spectra. The intensity of these spectra as well as the yield of the polymer depend on the irradiation temperature. A correlation between the intensity of the spectra and the yield of the polymer is observed also as a function of the radiation dose. As an illustration, Fig. 8 presents the spectra of tetrafluoroethylene specimens irradiated by an identical dose of 125 mrad at 98° and 128°K. It is seen that in the specimen irradiated at 98°K the overall concentration of radicals is higher than in the specimen irradiated at 128°K. After heating, the relative concentrations of paramagnetic centres change. Since the monomer was evaporated at room temperature, evidently the spectra in Figs. 8*b* and 8*d* are due to polymeric radicals.

The form of the spectra of these paramagnetic centres depends relatively little on temperature (Fig. 9). The average *g*-factor is 2.008.

We believe that the validity of the assignment of the spectrum in Fig. 9 to terminal polymeric radicals follows from the analysis of its form. The triplet spectrum may be accounted for by the presence of hyperfine interactions with the two β-fluorine atoms which in fact determine the splitting between the components, equal to 43 ± 1 Oe at room temperature. The splitting is consistent with the data obtained for single crystals in studies on the R_2 radicals; it was found that the isotropic constants for their β-fluorine atoms differ somewhat and are 34.5 and 40 Oe.

The absorption in the central part of the spectrum, where the triplet is in fact observed, is due to the R_9 radicals where the net nuclear spin of the two α-fluorine atoms is zero.

The R_9 spectrum does not show lateral components at a distance of 400 Oe characteristic of radicals with two

α-fluorine atoms. However, the presence in these paramagnetic centres of two α-fluorine atoms follows from the overall width of the spectrum. It is seen in Fig. 9*a* that the width of the absorption signal measured at a level of 0.1 of the maximum value is 300 Oe, while at a level of 0.02 it exceeds 450 Oe. We believe that such a large width of the spectrum can only be caused by the presence of two α-fluorine atoms.

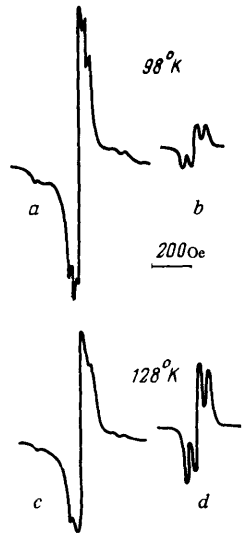

Figure 8. ESR spectra of tetrafluoroethylene irradiated at 98°K (curves *a* and *b*) and at 128°K (curves *c* and *d*). The spectra *a* and *c* were recorded at 77°K; the spectra *b* and *d* were obtained at 300°K after warming the specimens to room temperature.

We may note that recently a spectrum was obtained[19], which was attributed to R_9 radicals stabilised in a hydrocarbon matrix. In its central part it coincides with the spectrum in Fig. 9 and, moreover, it has wing components characteristic of two α-fluorine atoms.

In studies of irradiated copolymers of tetrafluoroethylene and hexafluoropropene (HFP) Iwasaki et al.[20,21], observed that, as a result of irradiation, the radicals

$$-CF_2-\dot{C}(CF_3)-CF_2- \quad (R_{10})$$

$$-CF_2-\dot{C}F-CF_2- \quad (R_{11})$$

are formed in the copolymer together with the R_8 radicals. The form of the spectra of the R_{10} radicals at 77°K and room temperature is presented in Fig. 10. The form of the absorption spectra and of the derivatives of the absorption spectra of the R_{11} radicals at 77°K is shown in Fig. 5.

As in the majority of other cases, the observed spectrum of the irradiated copolymer is due to the superposition of the spectra of paramagnetic centres of several types. Therefore the determination of the true form of the spectra of the R_{10} and R_{11} radicals and their identification presents certain difficulties.

It has been found[20] that the overall spectrum observed for the irradiated copolymer depends on the hexafluoropropene content. With increase of the concentration of hexafluoropropene, the form of the spectrum differs increasingly from the spectrum in TPFE. The authors attributed these spectral changes to the formation in the copolymer of new types of paramagnetic centres containing CF_3 groups.

By studying the dependence of the form of the spectra on the percentage content of hexafluoropropene and also the changes in the form of the overall spectrum as a result of heating the specimens, the authors[20] succeeded in obtaining the spectra of the individual types of paramagnetic centres by the method of graphical subtraction.

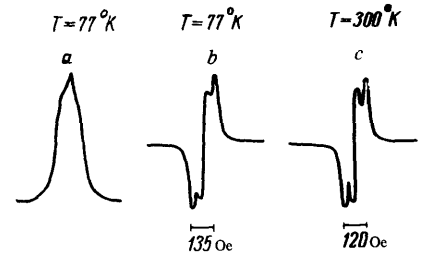

Figure 9. The absorption spectrum (*a*) and its derivatives for the $R-CF_2-CF_2$ radicals at 77° and 300°K (curves *b* and *c* respectively).

Oriented copolymers were prepared to identify the R_{10} radicals. It was found that the form of the spectrum in the copolymer at 77°K is almost independent of the orientation of the specimen in the magnetic field, while at room temperature relatively small spectral changes are observed. At the same time the form of the spectrum in oriented PTFE depends very significantly on orientation. Certain changes in the form of the spectrum as a function of the orientation of the specimen, which may be observed for the irradiated copolymer, can be accounted for by the superposition of the spectra of the R_8 radicals.

The anisotropy of the hyperfine coupling of β-fluorine atoms is known to be significantly less than the anisotropy for α-fluorine atoms[2,4]. The absence of an orientation dependence for the paramagnetic centres which disappear on heating shows that these cannot be α-fluorine atoms.

Using the isotropic hyperfine coupling constants for β-fluorine atoms, Iwasaki et al. constructed model spectra for the R_{10} radicals assuming that the form of the spectrum is due to the superposition of an unresolved isotropic hyperfine structure and obtained satisfactory agreement with the spectra of the paramagnetic centres which disappear on heating the copolymers.

The ESR spectrum of the R_{10} radicals at room temperature consists of weakly resolved components corresponding to the interaction with seven β-fluorine atoms, the splitting between adjacent components being 29 Oe.

At 77°K the R_{10} spectrum consists of a singlet line where the distance between the points of maximum slope is 80 Oe (Fig. 10*b*). It is noteworthy that, since R_{10} contains only β-fluorine atoms, the overall width of the spectrum changes only slightly as temperature is reduced. As a result of the different broadening of the R_8 and R_{10} spectra

over a range of temperatures due to the difference between the anisotropic hyperfine coupling constants, at 77°K the radicals R_{10} make the main contribution to the overall spectrum of the irradiated copolymer, while at room temperature the contribution by R_8 radicals is very significant.

It has been shown[21] that at 77°K and R_{10} radicals are converted into R_{11} radicals under the influence of ultraviolet radiation:

$$-CF_2-\dot{C}(CF_3)-CF_2- \xrightarrow[77^\circ K]{h\nu} -CF_2-CF(\dot{C}F_2)-CF_2- .$$

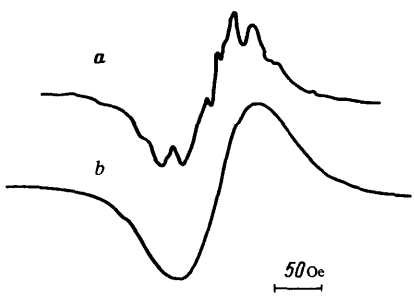

Figure 10. First derivative absorption spectra of the radicals $-CF_2-\dot{C}(CF_3)-CF_2-$ at 300°K (curve *a*) and 77°K (curve *b*).

The R_{11} radicals are stable only at low temperatures. At room temperature R_{11} is reconverted into R_{10}. The changes in the concentrations of R_{10} and R_{11} on ultraviolet irradiation at 77°K and on heating are reversible. The ESR spectrum of the R_{11} radicals has wing components, with a splitting of 450 Oe, characteristic of fluorocarbon radicals with two α-fluorine atoms. The R_{11} spectra were identified both by a comparison with the spectra of known radicals with two α-fluorine atoms, and by chemical considerations following from the reversible changes in the spectra as a result of heating or illumination.

When the copolymer is irradiated at 77°K the spectrum may be represented by the sum of the spectra of the R_8 and R_{11} radicals. On this basis, it was concluded[20] that at 77°K the most probable processes involve the following mechanisms:

a) copolymer $+\gamma \rightarrow \sim CF_2-CF(\dot{C}F_2)-CF_2\sim$;

b) copolymer $+\gamma \rightarrow \sim CF_2-\dot{C}F-CF_2\sim$.

V. PEROXY-RADICALS IN IRRADIATED POLYTETRAFLUOROETHYLENE

The radicals

$$-CF_2-\underset{\diagup\ \ \diagdown}{CF}-CF_2- \quad (R_{12})$$
$$\quad\ O-\dot{O}$$
$$-CF_2-CF_2-O-\dot{O} \quad (R_{13})$$
$$-CF_2-CF_2-\dot{O} \quad (R_{14})$$

have been detected[12] in irradiated PTFE. Until recently only the R_8 fluoroalkyl radicals could be detected in vacuum-irradiated PTFE. For this reason some investigators regarded the presence of R_{13} and R_{14} radicals in PTFE and the interpretation of the corresponding spectra as controversial[22,23].

The ESR spectra of the radicals R_{12}, R_{13}, and R_{14} at room temperature, obtained by Matsugashita and Shinohara[12], are presented in Fig. 11. Subsequent investigations[24] showed that the interpretation of these spectra is correct. However, bearing in mind that even in review articles[22,23] contradictory views are expressed, below we shall consider in detail the results, which confirm the validity of the suggested interpretation.

We believe that there are at least two reasons why the results of Matsugashita and Shinohara[12], which were obtained in 1961, are still controversial. Firstly the R_{12}, R_{13}, and R_{14} spectra of the individual types of paramagnetic centres were obtained by graphical subtraction and their interpretation was in many ways based on chemical considerations associated with the study of the reactions of the paramagnetic centres with various gases. The spectroscopic considerations based on the analysis of the line shape and g-factors were insufficient, although we believe that they were in fact correct.

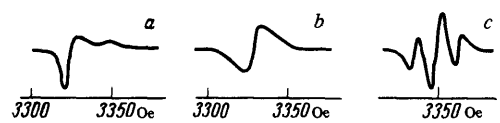

Figure 11. First derivative absorption spectra at 300° of the radicals $-CF_2-\underset{\diagup\ \ \diagdown}{CF}-CF_2$ (*a*), $\quad\ O-\dot{O}$ $-CF_2-CF_2-O-\dot{O}$ (*b*), and $-CF_2-CF_2-\dot{O}$ (*c*).

Secondly Matsugashita and Shinohara[12] failed to resolve the following important problem. According to their data the concentration of R_{13} radicals is comparable to the concentration of R_{12} and therefore it was necessary to postulate the presence of the radical $R-CF_2-\dot{C}F_2$ and the oxidation reaction

$$R-CF_2-\dot{C}F_2+O_2 \rightarrow R-CF_2-CF_2-O-\dot{O} . \quad (7)$$

However, neither Matsugashita and Shinohara nor other investigators were able to detect R_9 radicals in PTFE.

In the R_{12} and R_{13} radicals the unpaired electron is localised mainly in a molecular orbital involving the two oxygen atoms. In this connection it was not clear why at room temperature the R_{12} spectrum is significantly asymmetric, while the R_{13} spectrum is virtually symmetrical. It was also obscure why on irradiation of evacuated specimens containing only small traces of oxygen R_{14} radicals are observed and not R_{12} or R_{13}.

One of the important results associated with the study of the reactions with carbon monoxide was the observation of changes in the spectrum which were attributed[12] to the occurrence of the reaction

$$R-CF_2-O-\dot{O}+CO \rightarrow R-C\dot{F}_2-\dot{O}+CO_2 . \quad (8)$$

However, since there were doubts concerning the validity of the identification of both R_{13} and R_{14} radicals, the interpretation of the changes in the spectra after the introduction of carbon monoxide into the tube remained unconvincing.

According to Matsugashita and Shinohara[12], after oxygen has been admitted at a pressure of 100 mmHg into evacuated tubes containing PTFE irradiated at room temperature, the ESR spectrum of the peroxy-radicals formed is due to the superposition of the spectra of R_{12} and R_{13}.

When the same specimen is heated and re-evacuated at 423°K, it is possible to show by graphical subtraction that the radicals R_{12} disappear from the overall spectrum. On further heating and evacuation at 523°K, the spectrum due to R_{13} vanishes. As a result of heating, the R_{12} and R_{13} radicals disappear and the R_8 fluoroalkyl radicals reappear.

The average value of the g-factor of the R_{13} radicals is $g = 2.016$ and the width of the spectrum measured between the points of maximum slope is about 10 Oe.

Analysis of the width and intensity of the R_8 and R_{14} spectra shows that in evacuated PTFE specimens the concentration of R_{14} is almost one hundred times small than that of R_8. The possibility of detecting R_{14} radicals in a mixture with such values of the relative radical concentrations arises from the fact that the R_{14} radicals have a significantly narrower spectrum.

It is not altogether clear why, despite careful degassing of the polymer, R_{14} radicals are still detected in the specimens.

Iwasaki et al.[20] suggested that the principal chain of the polymer has units containing oxygen bridges:

$$\sim CF_2-CF_2-O-CF_2-CF_2\sim ,$$

the concentration of which is relatively high.

The dissociation of the C–O bond in these units in fact leads to the formation of R_{14}. We believe that this hypothesis is confirmed by the data of Barnaba et al.[24]

The ESR spectrum of R_{14} radicals is a triplet with a splitting of about 14 Oe between the components. The R_{14} radicals were identified on the basis that such triplet splitting is due to fluorine atoms. Since the splitting is small, the implication is that the unpaired electron density at the carbon atom linked to the fluorine atoms is low.

Indirect evidence supporting this interpretation comes from the spectral changes observed with specimen containing peroxy-radicals after the introduction of carbon monoxide. It was noted that the spectrum due to R_{13} disappeared and the intensity of the spectrum of the R_{14} radicals increased; this was explained by the occurrence of reaction (8).

The validity of the interpretation of the R_{13} and R_{14} spectra was confirmed in special experiments carried out by Barnaba et al.[24] in studies on paramagnetic centres in irradiated polytetrafluoroethylene oxide (PTFEO) polymers:

$$\sim O-CF_2-CF_2-O-CF_2-CF_2-O\sim .$$

Barnaba et al.[24] chose experimental conditions where predominantly either R_{13} or R_{14} radicals are detected in irradiated PTFEO. They succeeded in obtaining the spectra of R_{13} and R_{14} radicals using the different stabilities of these paramagnetic centres and in obviating the necessity of using graphical subtraction.

Additional evidence for the validity of the interpretation of the R_{13} and R_{14} spectra was based on the following experimental results. In the overall ESR spectrum recorded at 300°K directly after irradiation in a vacuum (at 273°K) of PTFEO specimens (Fig. 12) it proved possible to isolate the spectra of three types of paramagnetic centres. It was noted that, after treatment at 300°K for 24 h, the wing components of the spectrum of the specimen with a splitting of about 320 Oe disappeared.

Kinetic studies showed that the rate of disappearance of the outer components is the same as the rate of disappearance of one of the components contributing to the central part of the spectrum.

The splitting between the outer components (320 Oe) and the presence of lines associated with these paramagnetic centres in the central part of the spectrum show unambiguously that the mixture of paramagnetic centres includes radicals with two α-fluorine atoms. These centres are either

$$\sim O-\dot{C}F_2 \quad (R_{15})$$

or

$$\sim O-CF-\dot{C}F_2 \quad (R_{16}) .$$

Possibly both R_{15} and R_{16} are present in the specimens.

It is seen in Fig. 12*a* that the concentration of the terminal radicals (i.e. either R_{15} or R_{16}) exceeds the concentration of paramagnetic centres of other types. This follows from the fact that the spectra of the terminal radicals have the largest overall width and their intensities are comparable with those of the spectra of other types of paramagnetic centres.

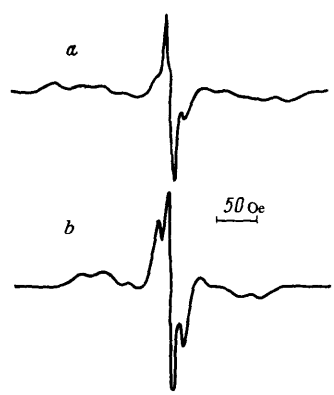

Figure 12. First derivative absorption spectra at 300°K of PTFEO irradiated in a vacuum at 273°K: *a*) immediately after irradiation; *b*) 24 h after irradiation.

After the destruction of the terminal radicals, two further types of paramagnetic centres remain in the specimen. The overall spectrum, corresponding to a particular ratio of the concentrations of these two paramagnetic centres, is presented in Fig. 12*b*.

The triplet spectrum, with a splitting between the components is 12.5 ± 1 Oe and contributing to the central part of the [overall] spectrum, was attributed to the R_{14} radicals.

The fact that the spectrum in Fig. 12*b* is due to the superposition of the spectra of two types of paramagnetic centres was proved by the authors using the different stabilities of these centres. During the storage of irradiated PTFEO in a vacuum at room temperature for several days, the intensity of the outer components (Fig. 12*b*) hardly changed, while the intensity of the central part was appreciably reduced. It was found that

after the admission of ethane to the specimen tube, these paramagnetic centres are destroyed at different rates; according to the authors, this also confirms the presence in the specimen of two types of paramagnetic centre.

In the spectrum in Fig. 12*b* the splitting between the centres of the outer wings is 180 Oe and the splitting within the wing components is 30 Oe. This shows that in the mixture there are paramagnetic centres with one α-fluorine atom and two β-fluorine atoms and therefore the authors reasonably suggested the presence of the radicals

$$\sim O-\dot{C}F-CF_2-O\sim \quad (R_{17}).$$

The relatively high stability of the radicals R_{17} in a vacuum confirms the validity of the suggested identification. The g-factor of the R_{14} radicals is virtually the same as the g-factor of diphenylpicrylhydrazyl (DPPH), which is 2.0036.

Directly after irradiation of PTFEO at 273°K, the concentration of terminal radicals is a maximum. This enabled Barnana et al.[24] to obtain the spectrum of the R_{13} radicals in a virtually pure form, which was found to coincide with the spectrum in Fig. 11 obtained by Matsugashita and Shinohara[12].

Barnaba et al. observed that after the admission of air to the PTFEO specimen irradiated in a vacuum, the reactions

$$R-\dot{C}F_2+O_2 \rightarrow R-CF_2-O-\dot{O}, \qquad (9)$$

$$\sim O-\dot{C}F-CF_2-O\sim + O_2 \rightarrow O-\underset{\displaystyle O-\dot{O}}{\overset{|}{C}}F-CF_2-O\sim \qquad (10)$$

take place. After the admission of air, the PTFEO spectrum is due to the superposition of the R_{12} and R_{13} spectra. When the PTFEO specimen irradiated in a vacuum is allowed to stand so that the concentration of terminal radicals in it is appreciably reduced, the R_{12} radicals make the principal contribution to the overall spectrum after the admission of air. On the other hand, when air is introduced directly after irradiation when the terminal radicals have the maximum concentration, the overall spectrum is due largely to the R_{13} radicals.

The ESR spectra of PTFE specimens irradiated in air are due to the R_{13} radicals. It was found that the R_{13} radicals are less stable at room temperature than R_{12}.

When the specimens are stored, the form of the overall spectrum is seen to change in accordance with the change in the concentration of the radicals R_{12} and R_{13}.

At room temperature the R_{13} concentration diminishes by a factor of two in the course of 100 h, while a similar change in the concentration of R_{12} requires 500 h.

Important evidence confirming the validity of the identification of the R_{13} spectrum is provided by the fact that Barnaba et al. detected the terminal R_9 radicals, showed that their concentration is greatest, and saw directly how the intensity of the ESR signal due to the R_{13} radicals increases by a factor of almost five as a result of reaction (7). The increase of signal intensity as a result of reaction (7) is associated with the fact that the R_{13} radicals have a significantly narrower ESR spectrum compared with that of R_9 and consequently at the same concentrations of paramagnetic centres the amplitude of the R_{13} signal is greater.

We believe that the work of Matsugashita and Shinohara[12] and Barnaba et al.[24] has shown that irradiated PTFE usually contains three types of peroxy-radicals. The present authors' results explained the reasons for the failure to detect the terminal radicals in PTFE.

It was found that the concentration of R_9 is comparable to the concentration of the R_8 fluoroalkyl radicals and that the R_9 radicals in PTFE at room temperature are relatively stable[17]. Therefore there is reason to believe that the R_{12}, R_{13}, and R_{14} spectra have been correctly identified.

Qualitative Analysis in Gas Chromatography

A.N.Korol'

This review presents the most rational and widely employed methods of qualitative gas-chromatographic analysis of complex organic mixtures.
The bibliography includes 147 references.

I. INTRODUCTION

During the eighteen years of its development, gas–liquid chromatography has become one of the most widely used methods for the analysis of substances, in particular organic compounds. The greatest advances have been achieved using this method to separate complex mixtures of substances having low reactivity, the determination of which by other chemical and physicochemical methods involves considerable difficulties. For example, the problem of analysing petroleum fractions was solved by combining various chromatographic procedures. According to the latest data half the analyses of mixtures of organic substances in the U.S.A. are performed by gas chromatography and every seventh analytical chemist regards gas chromatography as his speciality. The comparatively simple equipment (available in many versions), the automatic recording of the results of separation, and the simple analytical procedure have attracted many investigators to gas-chromatographic methods. In the technological control of industrial processes this method is irreplaceable because of the ease with which the determination may be automated.

The advances in gas chromatography, as in all methods of separation, are associated primarily with the exceptionally high separating power of the chromatographic column. The high linear flow rate of the carrier gas and the small spreading of the chromatographic zone make it possible, in principle, to separate any mixture whose components differ, if only slightly, in their sorbability by the packing of the chromatographic column. However, for the analytical chemist it is important not only to separate the mixture into its components but also to evaluate the percentage present and in many cases also to determine their nature, i.e. to carry out qualitative and quantitative analyses. The methods for calculations on chromatograms, the estimation of the maximum accuracy of the chromatographic analysis, and the correlation of the readings of chromatographic detectors with the physicochemical properties of the substances separated are problems which have been successfully solved in many practical applications and here too no fundamental difficulties have been encountered.

The problems of qualitative analysis by gas-chromatographic methods have been investigated much less, although without a preliminary identification of the mixture components a complete quantitative analysis is impossible. It is paradoxical that in gas chromatography a situation has arisen where the final stage of analysis (the quantitative stage) has been developed to a higher degree than the first (the qualitative determination). Until recently hardly any attention was devoted to the problems of systematic identification of the components of the test mixture; the published data deal largely with specific problems.

The first stage of both qualitative and quantitative chromatographic analysis involves an attempt at the most complete separation of all the components of the test mixture. For such separation, use is made of a high-efficiency column preferably combined, with a programmed column temperature control during analysis. If it is known beforehand which components are present in the mixture, then for a qualitative analysis it is sufficient to employ a column which would yield a chromatogram with the number of peaks equal to the number of expected mixture components. In all other cases it is particularly desirable to employ temperature programming to detect the entire range of products. Only after it has been shown that all the components of the test mixture emerge from the column over a fairly short period, is it possible to abandon temperature programming and to employ isothermal analytical conditions. In order to obtain highly effective columns, capillary gas chromatography may be employed, but packed columns with lengths up to 50 m and having efficiencies equivalent to 50 000 theoretical plates have also been described[1]. In preliminary tests it is usually desirable to employ comparatively short packed chromatographic columns, 1–2 m in length, with temperature programming and only then to proceed to highly efficient columns to check the completeness of the separation of the mixture components. Satisfactory results are obtained when 2–3 high-efficiency columns (3–5 000 theoretical plates) with stationary phases of different types are employed. If there are no *a priori* reasons for a particular procedure, one chooses for qualitative analysis the columns which yielded the greatest number of peaks in preliminary tests. Usually columns with stationary phases of moderate or low polarity prove to be the most effective.

After a preliminary separation chromatogram has been obtained, it is necessary to make sure that each peak contains only one substance. For this purpose, the form of each peak in the chromatogram is analysed in the initial stage: a sharp distortion of peak symmetry and anomalous broadening of the bands are frequently indications of incomplete separation of the substances[2]. The most reliable results are obtained when each peak is collected in a trap and the eluate is subsequently separated on a column with a stationary phase of a markedly different type. Sometimes it is useful to treat the eluate chemically in order to obtain derivatives which can then be separated on the chromatographic column. However, in the separation of structural isomers and substances with similar physicochemical properties the above method may prove to be unsuccessful. To separate such isomers, use is made of selective sorbents or high-efficiency columns under isothermal conditions at several different temperatures.

The scheme for successive systematic qualitative analysis is as follows (see Scheme). The test mixture is

Scheme for systematic qualitative analysis by gas chromatography.

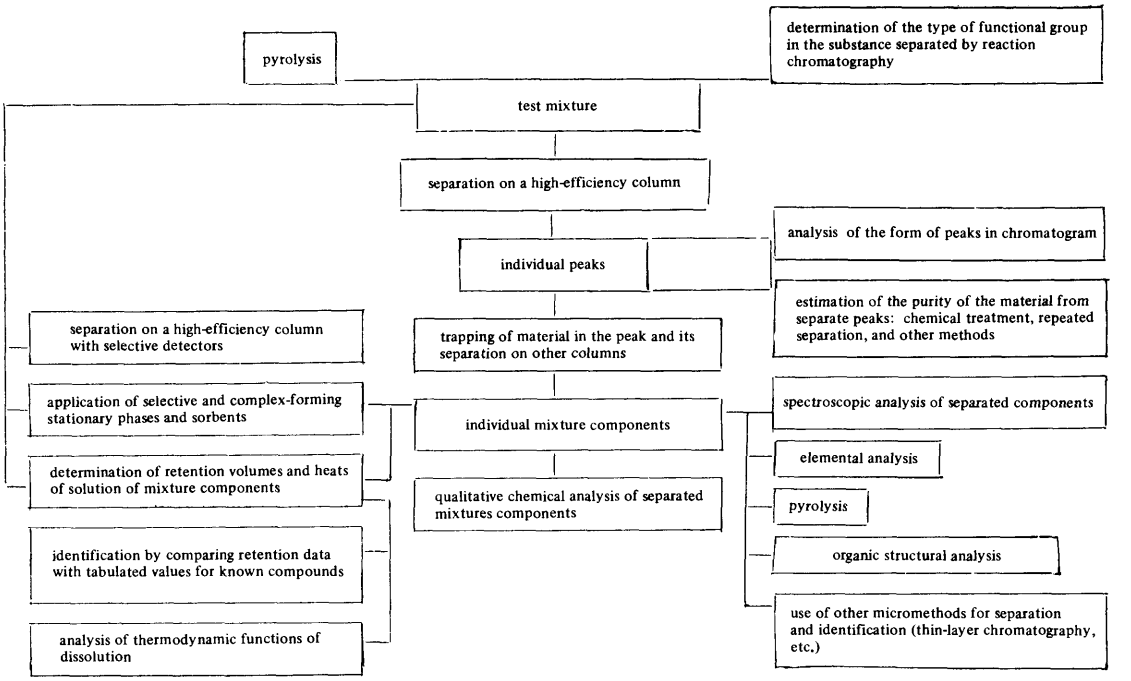

Table of principal methods for identification employed in qualitative gas-chromatographic analysis.

Method	Purpose and range of applicability	Advantages	Disadvantages
Use of stationary phases of different polarity and complex-forming sorbents	detection of individual structural groups and bonds in the molecule and overall estimation of polarity	simplicity of method (moderately laborious)	except when complex-forming sorbents are used, the method yields only approximate information about the polarity of the molecules
Reaction gas chromatography	determination of the functional groups of the compounds in initial mixture	does not require preliminary mixture separation	necessity for modifications of chromatographic apparatus. The functional groups and their position in the molecule are not always determined
Qualititative chemical analysis of separated substances	determination of the functional groups of the compounds after chromatographic separation	possibility of employing a large number of methods in the tests	necessity for complete separation of components investigated; sometimes comparatively large amounts of the substances are required
Organic structural analysis with chromatographic identifiaction of reaction products	determination of the carbon skeleton and the positions of the functional groups in the molecule	high reliability	necessity for the isolation of the pure substances. Laborious procedure
Pyrolysis	analysis of solid substances and high-boiling liquids	high sensitivity to slight changes in molecular structure	special aparatus and pure substances required
Comparison of the retention volumes and heats of solution of the test substances with data for known compounds	applicable to all compounds apart from pairs of isomers difficult or impossible to separate	simplicity of method (moderately laborious)	all the retention data for the substances whose presence is postulated in the mixture must be known or accurate relations for homologous series of these compounds are required
Analysis of thermodynamic functions of dissolution	applicable to all compounds; the molecular size and the number and positions of the functional groups are established	data for the retention of the substances whose presence in the mixture is postulated are not required	the use of semiempirical relations for the given chemical class of compounds; trained investigators needed
Selective detection	in the presence of C, O, Cl, and P atoms and of an aromatic ring in the compounds analysed	preliminary separation not required; high sensitivity	limited number of selectively determined characteristics of the molecules
Spectroscopic analytical methods	determination of the type of functional groups and their distribution and molecular size	extensive information about various molecular properties	need for the pure substances separated, sometimes in large amounts, complexity of the interpretation of the spectra, and the high cost of equipment
Elemental analysis	determination of the relative amounts of the elements in the substance separated	reliable information about elemental composition	need for special equipment and for the purity of the substances separated
Thin-layer and liquid chromatography, determination of physicochemical constants	identification on the basis of tabulated data for known substances	simplicity of method	neeed for the substances separated in pure form, sometimes large amounts; need for data for all the substances which may be present in the mixture

subjected to chemical reactions whereby it is possible to remove or transform chemically certain classes of compounds. Tests of this kind in combination with qualitative tests for functional groups of the separated substances collected in traps make it possible to assign the compounds to particular chemical classes and in many cases to obtain indications of the distribution of the functional groups in the molecule. When literature data are available on the retention of compounds in the same chemical classes as those detected in chemical tests, an attempt is made to compare the relative retention volumes and the heats of solution of the test substances with the tabulated data using 2–3 stationary phases of different types. If the test mixture contains components for which there are no published retention data and the postulated substances are not available in a pure form, then more complex methods of qualitative analysis are employed. The study of the thermodynamic functions of solutions in standard stationary phases makes it possible to elucidate the distribution of the functional groups in the molecule of the test compounds, the size of the molecule, and the structure of its carbon skeleton. The problems can also be solved with the aid of traditional methods of structural organic microanalysis and with the aid of various physicochemical procedures: infrared spectroscopy, mass spectrometry, nuclear magnetic resonance (NMR), determination of the melting and boiling points, and also in combination with other methods of separation, in particular thin-layer chromatography (see Table). Valuable information about the nature of the molecules of the components is provided by selective chromatographic detectors, elemental analysis, and pyrolytic gas chromatography. The main aim of this review is to describe various aspects of the application of these methods in qualitative analysis by gas chromatography.

II. APPLICATION OF QUALITATIVE CHEMICAL REACTIONS FOR THE DETERMINATION OF FUNCTIONAL GROUPS

The purpose of this method of identification in gas chromatography is to determine the type of functional groups in the test substance. Qualitative chemical reactions constitute the simplest and most reliable procedure for solving this problem [3] and such tests are possible both with the entire initial mixture and with the components separated. It is desirable to carry out the reactions with the initial mixture when all or the majority of the components are unknown. On the other hand, when only a few of the components are to be identified, it is more reasonable to establish the chemical nature of their functional groups by qualitative chemical tests on the separated substances.

The initial mixture is treated in reactors incorporated in the gas system of the chromatograph (less often) or functioning separately (more usual procedure). The first method requires a number of precautions in carrying out the reaction: the reaction time and the volume of the reactor must be sufficiently small so as not to affect the retention time or the form of the peaks for the substances separated and the reactor temperature chosen must be close to the temperature of the column or of the metering device. The stream of carrier gas is blown through the reactor during the entire period of the experiment and the chemical nature of the gas should promote the occurrence of the required reactions. In some cases, for example in hydrogenation reactions, the carrier gas must be pure hydrogen or its mixture with an inert gas. The design of the reactors not included in the gas system of the chromatograph can be of any kind. Such a reactor can consist of a tube with an outlet arm, which is closed by a self-sealing rubber system [4]. The outlet arm is connected to the chromatograph via a tap. Volatile reaction products are blown out via the outlet arm of the reactor into the column and the liquid products are collected with a syringe and introduced into the metering device of the chromatograph. The reactor incorporated in the gas circuit of the chromatograph usually consists of a metallic (less often glass) tube filled with a reagent and inserted between the metering device and the beginning of the chromatographic column.

Comparison of the composition of the initial mixture and the reaction products can be made most simply using two identical parallel columns in the same chromatograph with the reactor inserted before one of the columns. After evaporation and metering, the initial mixture is passed through a stream divider, which directs the two parts of the sample into the parallel columns; the ends of these columns are connected to the opposite chambers of the katharometer or differential flame-ionisation detector. In this scheme the pen recorder records only the peaks of the components which have fully or partially reacted, since the detector signals due to the unchanged peaks emerging simultaneously from the two columns cancel out. The reaction products and the composition of the initial mixture can be compared on different apparatus with the same columns. A partial decrease of the peak area of a particular mixture component indicates either that the reaction with the given substance is incomplete or that the peak contains two or more unseparated substances one of which has reacted with the reactor material. The disappearance of the peak is evidence that the substance has reacted with the substance in the reactor.

If the reaction yields volatile products (for example in the esterification of aliphatic acids), the retention data for the reaction products must be determined in order to identify them; an effort is made to select a type of chemical reaction which yields well known and readily available substances—for example hydrocarbons in exhaustive hydrogenation. If the reagent is volatile at the column temperature, then the need for a special reactor may be obviated, the reagent being introduced directly into the chromatographic column via the metering device before or immediately after the introduction of the test mixture. For example, alcohols may be acylated with acetic anhydride in this way.

The reaction with microamounts of substances can be carried out directly in the syringe needle, which is filled with Chromosorb for this purpose and the reaction mixture is then drawn in. After this the needle pierces the selfsealing rubber of the metering device, which is heated to the reaction temperature. The reaction reaches completion in several seconds and by moving the piston of the syringe the volatile products are forced into the chromatographic column where the substances are separated [5].

The methods of reaction gas chromatography enumerated above are based on the fact that they make it possible to compare the compositions of the reaction mixtures and the initial substances on various chromatographic columns. However, it is possible to modify the apparatus in such a way that a comparison may be made using the same chromatographic column with a flow divider [6]. The latter consists of a capillary passing through the reactor; part of the gas stream together with the unchanged components

of the initial mixture flow through this capillary into the chromatographic column. By altering the cross-section of the capillary, it is possible to regulate the amount of unreacted substance. Comparison of the chromatograms for mixture separation using different capillary cross-sections makes it possible to follow clearly the components whose amount decreases as the capillary diameter is reduced (there is a corresponding decrease in the amount of substance by-passing the reactor).

The reaction most widely used for qualitative analysis in gas chromatography is selective or exhaustive hydrogenation of the mixture components. The latter version permits group analysis in terms of the size and structure of the carbon skeleton of the molecule. The oxygen atoms in the test substance are reduced to water and other heteroatoms are either liberated in a free form or are reduced; exhaustive hydrogenation yields the saturated hydrocarbon corresponding to the carbon chain of the initial substance. If the heteroatoms are located between carbon atoms, then, after exhaustive hydrogenation, the corresponding molecular fragments are produced—a set of hydrocarbons the molecular sizes of which are determined by the size of the carbon radicals. In hydrogenation under gas-chromatographic conditions platinum [6,7], nickel [8], and palladium [9,10] catalysts are employed. The platinum catalyst operates at a relatively low temperature but it is also more sensitive to poisoning by sulphide and diene compounds. It is more convenient to carry out hydrogenation on a palladium catalyst in the temperature range between 150° and 260°C. Hydrogenation reactors are employed not only in combination with packed columns but also in combination with capillaries [11].

Reactions which remove particular classes of chemical compounds are most widely employed in the qualitative determination of unsaturated compounds in complex hydrocarbon mixtures. Olefins may be absorbed by a column containing silica gel impregnated with sulphuric acid [12,13] operated at temperatures between 20° and 50°C. In order to absorb ethylene and acetylene, which are not absorbed quantitatively by concentrated sulphuric acid, a solution of silver sulphate in sulphuric acid is employed. Sulphuric acid removes also aromatic compounds [14]. Apart from sulphuric acid, mercury perchlorate [15] and copper(II) chloride [16] are used to eliminate unsaturated compounds. Maleic anhydride absorbs butadiene [17,18].

Straight-chain alkanes are removed from mixtues by molecular sieves [19,20]. Alcohols react with boric or metaboric acids with formation of involatile compounds [3,21]. Aminoacids are converted by oxidation into volatile aldehydes, ninhydrin being employed for this purpose [22]. Reactors with phosphoric acid are used to decarboxylate aliphatic acids [23]. Aldehydes and ketones are removed with sodium bisulphite [24]. The same paper [24] describes a method for the elimination of sulphur-containing components in a reactor containing mercury(I) chloride. Secondary and tertiary alkylbromides are absorbed by silver nitrate [25] and amines by phosphoric acid [26]. Water vapour reacts with calcium carbide [27] and is retained in a reactor containing potassium carbonate [28].

Esterification is widely used in gas chromatography not only for quantitative analysis but also to convert reactive aliphatic acids into readily separated esters. For this purpose, the reaction is carried out between potassium salts of aliphatic acids and sodium ethyl sulphate [29,30] at 300°C or tetramethylammonium salts are pyrolysed [31]. Alcohols form esters with sodium nitrite [32,33] and with acid anhydrides [34]. Esters may be hydrolysed [35] with subsequent chromatographic determination of the products formed. The position of the double bond in the molecule of an unsaturated compound can be established by ozonolysis [36,37].

A very interesting version of qualitative reactions with the initial sample has been described [38]. This type of test is suitable for mixtures of substances the components of which do not boil above 200°C, since the entire mixture must be evaporated at room temperature in a closed vessel before the test. The gas from this vessel is drawn into a syringe on the walls of which the appropriate reactant has been deposited. After the reaction at room temperature the sample is introduced into the chromatograph by moving the piston of the syringe; the chromatogram indicates the composition of the test mixture after the chemical reactions in the syringe.

Much information about the functional groups of the components may be obtained using qualitative chemical reactions on the separated substances beyond the column, transferring them together with the carrier gas into appropriate reagents or collected in traps. The design of the traps depends on the aim of the experiments: universal traps are employed to condense components in amounts ranging from a fraction of a milligramme to 50 mg and special traps are designed where the condensed substance is subsequently subjected to a particular physicochemical determination, for example the recording of the infrared or mass spectrum. Simple glass U-traps attached to the chromatograph via a seal of heat-resistant rubber are normally used in qualitative analysis. To collect or remove very large amounts of the substance (in excess of 50 mg), various traps employed in comparative chromatography are used [39]. Such large amounts of selected separated substances may be needed in structural organic analysis, in the determination of the boiling and melting points, and in certain spectroscopic analyses. To achieve complete condensation of the separated components emerging from the column, it is necessary to create a turbulent gas stream and prevent an unduly high temperature gradient in the trap. The latter condition is particularly important to prevent the creation of a mist and therefore the use of liquid nitrogen and metallic traps is not recommended for the condensation of high-boiling compounds. Traps for semipreparative purposes may be used both at atmospheric and reduced [40] pressures.

The designs of traps for the collection of very small amounts of substance (down to 0.1 mg) has been described [41,42]. The trapping process in such traps takes place in two stages: initially the eluate is collected in a short section of the chromatographic column at a reduced temperature and then, on heating this section a slow stream of gas transfers the fraction collected into the microtrap. Traps for the collection of microamounts of substances which are simple but not really effective consist of the needle of a syringe or short Teflon capillaries [43] cooled with dry ice. For subsequent use, the condensate in such traps in washed off with a solvent or centrifuged.

A number of special traps have been constructed for subsequent employment in the measurement of infrared spectra. Some of them are first filled with a powder transparent to long-wavelength infrared radiation: potassium bromide or lithium fluoride. The products separated in the chromatographic column are condensed on the surface of these powders [44]. Traps where the condensation of the separated substances is achieved on the surface of a cellulose filter [45], which is then placed in an infrared spectrophotometer, have been described. Traps for the collection of very small amounts of separated sub-

stances are also used for the subsequent determination of the infrared spectra of the condensed substances [41,46]. In order to trap the substances for later determination of their mass spectra, traps with an adsorbent filler (molecular sieves, etc.) are used [47]. The substances emerging from the chromatograph are trapped by the sorbent in the cold, then the sorbent is transferred to a tube sealed to the filling system of the mass spectrometer. On heating, part of the substance is desorbed and passes into the mass spectrometer. Traps filled with powders transparent to infrared light have a low trapping efficiency, which may be enhanced by cooling the trap. Devices with adsorbents can be used only to trap relatively low-boiling substances, since desorption of high-boiling substances and substances with highly polar molecules requires high temperatures; there is then a real risk of the degradation or isomerisation of the adsorbed substance.

Qualitative reactions with the separated substances can be performed either directly in the trap or in a vessel after washing the substance out of the trap with a suitable solvent. The principal requirement which must be met in the application of reactions of this kind is high sensitivity (about 10–20 μg). The most suitable are drop reactions and methods specially tested in chromatographic practice [48].

The determination of the carbon skeleton of the separated compound constitutes a very important operation in qualitative chromatographic analysis. For this purpose, use is made of exhaustive hydrogenation on palladium and platinum catalysts [49–51] and attention is concentrated not on the rapidity of hydrogenation but on the completeness of the process and on the prevention of undesirable side reactions such as dehydrogenation and isomerisation. After separation in the chromatographic column, the substance collected in the trap is passed in a stream of hydrogen through the reactor (length about 24 cm), is again collected in a trap, and transferred for analysis on the chromatograph, where the resulting hydrocarbon is identified by its retention time. In those cases where it is very difficult to determine the particular isomer of the alkane formed, a methylene group is introduced [52]. In the analysis of the separated substance there is a possibility of establishing not only the presence of heteroatoms in the molecule but also, in a number of cases, the nature of the chemical bond between the heteroatom and other parts of the molecule, as has been done, for example, with nitrogen [53,54]. In particularly complex cases use may be made of the classical procedures of organic structural microanalysis.

III. THE USE OF RETENTION DATA ON VARIOUS STATIONARY PHASES AND ADSORBENTS

Certain preliminary information about the nature of the substances separated may be obtained by studying the retention of the mixture components on various stationary phases. Best results are obtained by this method in the determination of the retention volumes of substances which were first separated and collected in traps. On the other hand, when the experiments are performed with the entire initial mixture, it is necessary to separate the principal components, otherwise it is impossible to determine to which component particular retention data on various stationary phases refer.

Comparison of the relative retention volumes of the test substances (using a paraffin as a standard) reveals the relative polarities of their molecules [55,56]. If the test compound has polar or readily polarised functional groups (for example, C=O or C–Cl), then on transition from a non-polar to a polar stationary phase the relative retention volume increases. A quantitative estimate of the polarity of the given compound is obtained by measuring such increase. It should be recalled that the polarity of the component characterises only the general properties of the molecule but cannot serve for an unambiguous determination of its structure and the number and nature of the functional groups. Certain relations between molecular structure and the relative retention volumes on various stationary phases have been discussed in a monograph [55].

More definite information about the nature of the test substances is obtained using complex-forming stationary phases and sorbents. For a successful application of such methods, it is necessary that the mixture analysed contains substances which are selectively retained on the complex-forming sorbent. For example, alcohols and phenols are selectively retained on hydroxylated stationary phases. For selective retention of unsaturated compounds, use is made of stationary phases consisting of solutions of silver nitrate in polar liquids (ethylene glycol, benzyl cyanide, *p*-xylyl cyanide, etc.). These stationary phases are used to isolate ammonia [57], olefins [57–60], and other unsaturated hydrocarbons.

The high selectivity of certain adsorbents permits their use in determining the nature of the substances. For example, on silica gel and alumina unsaturated hydrocarbons are selectively separated from saturated hydrocarbons. Bentonites (complex-forming organic clays) with various additives have found the widest application. Isomers of xylene [61], dichlorobenzene [62], dimethoxybenzene, chloroacetophenone, and dimethylnaphthalene [63] are readily separated on these substances. Certain quaternary ammonium bases form complexes with π-donor molecules [64].

1. Identification by Comparing the Retention Data

After the establishment of the presence of particular functional groups in test substances, the compounds can be identified in terms of purely chromatographic quantities—the retention parameters. The retention characteristics are constant only for gas–liquid chromatography and therefore this type of identification is inapplicable to gas adsorption chromatography: in this case the retention volume depends not only on the nature of the compound separated but also on its amount (non-linearity of the adsorption isotherm). Retention parameters such as the relative retention volumes and heats of solution are most widely employed for identification. With the exception of the separation of polar substances on non-polar stationary phases, these quantities are virtually independent of concentration and the amount of the substance separated. If the result of the qualitative chemical reaction depends only on the nature of the functional group of the test compound, then solubility is a function of both the number of chemical groups in the molecule and of the size of the molecule and the structure of its carbon skeleton. Therefore agreement between the retention times of the test and standard compounds on the stationary phase does not constitute an unambiguous proof of their identity: usually in chromatographic practice one compares, for the purpose of identification, the retention volumes on three stationary phases of different types and, when the retention volumes and the relative heats of solution are determined, the

measurements are made on two stationary phases[55]. As a rule at least two liquids (a non-polar and a polar stationary phase) are employed.

For identification, it is most rational to employ relative retention data, since this entails a sharp improvement in the accuracy of the determination and of the agreement between the tabulated data of different authors. The limiting accuracy of the measurements of the relative retention volume is 0.2% and that of the relative molar heat of solution is 0.05 kcal; however, the scatter of the retention data of various authors may reach 5%. The choice of a suitable standard compound plays a major role, since the time required for its emergence must be reliably measured. For a better standardisation of data, it is recommended that the following standard substances be chosen for the measurement of the relative retention parameters: straight-chain alkanes (for non-polar stationary phases), benzene, and carbon tetrachloride; naphthane is suitable at high temperatures. The calculation of the relative retention volume with corrections for the experimental conditions and the determinations of the heats of solution from the temperature variation of the logarithm of the retention volume have been described in a monograph[55]. Identification by comparing the retention parameters can be achieved when pure samples of the substances postulated in the mixture are available (the best procedure) or on the basis of tabulated data[65-68].

If the test mixture is separated at an elevated column temperature, the retention characteristics of the components may be determined in a series of experiments under isothermal conditions with increasing column temperature: at each temperature the retention times are found for those components which are separated within a reasonable time. Then the logarithm of the retention volume is plotted against the reciprocal of the column temperature, the line is extrapolated to the chosen temperature, and the relative retention volumes of all the mixture components at a single temperature are determined from the table of antilogarithms. The determination of the retention volumes and heats of solution of the test substances in mixtures can be recommended only for simple samples containing several peaks of different size. In the general case more reliable results are obtained by collecting the separated substances in traps with subsequent determination of their retention parameters in columns with standard stationary phases.

In a number of studies compounds are identified by a comparison method using the retention indices, but these quantities have no advantages over the relative retention volumes and their use frequently leads to appreciable errors.

If there are no suitable tabulated data for the retention of the compounds thought to be present in the test mixture, it is possible to employ gas-chromatographic correlation methods. Such correlations hold best for the linear relation between the logarithms of the retention volumes of members of a homologous series and the number of carbon atoms in the molecule. The retention volumes for different stationary phases may be calculated by the method of linear correlations[69,70]. The slopes of the lines obtained by plotting the relative volumes for the test and standard substances along the ordinate axes are employed to determine the group to which the component belongs. Although the relation between the retention volumes of the substances separated in non-polar and weakly polar stationary phases and the boiling points has been investigated in a number of studies[70-74], a sufficiently reliable and universal correlation between these quantities has not been established. Such correlations hold only for a narrow range of substances of similar nature but even in optimum cases—solutions of hydrocarbons in hydrocarbon stationary phases—the error exceeds one degree. The boiling point and the logarithm of the retention volume can be unambiguously related only when the components separated and the stationary phase are of a similar type. The plotting of any kind of correlations for aromatic and other highly structured stationary phases, where the entropy factor and the steric hindrance to intermolecular interaction have a significant influence on the retention volume, should be avoided.

The procedure involving the use of various solvents to alter the solubility of the test substance, i.e. the method of determination of the quantity p is extremely promising[75]. The quantity p is the ratio of the solubilities of the test substance in a non-polar and a polar solvent, two immiscible solvents in the same vessel being employed. The values of p are measured for the test substances and then for the compounds whose presence in the mixture is suspected. Since all the measurements are made at room temperature and the choice of solvent is not governed by temperature limitations, it is possible to choose extremely selective solvents whereby the test compounds can be characterised fairly completely. The low temperature in the measurement of solubility favours the occurrence of specific and orientation interactions which make it possible to discover the fine structure of the test compound molecule. Since the amount of solute in each phase is determined chromatographically, the measurement of p is not very laborious. This method has been successfully used to identify isomeric compounds boiling at high temperatures[76-79]. The methods for the comparison of retention data require the availability of all the presumed components or their retention parameters. Certain linear correlations in homologous series may be employed for identification by a comparison method but for this one must be certain that the given test substance belongs to a particular homologous series. At the same time comparison methods have attracted investigators by their extreme simplicity and high reliability of the results. Therefore, when the experimenter has at his disposal the retention data for all the substances postulated in the mixture on 2–3 stationary phases, it is reasonable to employ the comparison method in combination with qualitative chemical analysis.

2. Analysis of the Thermodynamic Functions of Dissolution

If the use of qualitative reactions combined with a comparison of tabulated retention data cannot ensure a convincing identification, it is recommended that the method involving the analysis of the thermodynamic functions for the solution of the substances in standard stationary phases be employed[55]. This procedure has been used with particular success in those cases where there is no information about the substances postulated in the mixture and their physicochemical properties. This method of identification is perhaps simplest for the qualitative analysis of mixtures of polyfunctional compounds and high-boiling isomers, in particular hydrocarbons. An advantage of this procedure is less stringent requirements for the degree of separation of mixture components, since retention data can be determined also for incomplete separation of the components. The main principle of the thermodynamic method of identification consists in the calculation of the thermodynamic functions for the solution of the

postulated substances on the basis of the following characteristics of the molecules: molar refraction, van der Waals radii of the atoms and atomic groups, and the number of internal and external rotational degrees of freedom. The agreement between the calculated and experimental thermodynamic functions of the dissolution of substances in various stationary phases indicates a particular structure of the test substance molecule.

The semiempirical calculation of the heats of solution of various compounds in a non-polar stationary phase is simplest [80]. It is then possible to establish the size of the molecule and the structure of its carbon skeleton; the use of polar stationary phases provides evidence about the number and positions of polar functional groups in the molecule. Analysis of the entropy of solution permits conclusions concerning the rigidity of the molecular structure, the branching of the carbon skeleton, and the number of degrees of freedom associated with rotation—properties which characterise the molecule as a whole. The combination of qualitative chemical tests with the thermodynamic method of identification has been used to determine the products of various chemical reactions—oxidation of olefinic hydrocarbons [81,82], photochemical chlorination of olefins [83], and chlorination of acetone [84] and also for the determination of the composition of industrial mixtures [85].

Identification by the analysis of thermodynamic functions is the only method for the determination of the composition and structure of unknown compounds, particularly those for which no published data are available. However, such identification requires the availability of relations between the thermodynamic functions of solutions and molecular structure. Such relations hold for a fairly wide class of substances, but their use requires prior training of the investigator and a thorough knowledge of the nature of intermolecular forces. The application of this method for identification is possible only in combination with qualitative chemical tests for functional groups.

IV. APPLICATION OF SELECTIVE DETECTORS FOR IDENTIFICATION IN GAS CHROMATOGRAPHY

In a number of studies the high separating power of the gas-chromatographic column has been combined with the analysis of the fractions obtained on separation by infrared spectroscopic and mass-spectrometric measurements. The former provides information about the presence and location of the functional groups in the molecule and the latter about the size of the molecule. The combination of three types of apparatus—a chromatograph, an infrared spectrophotometer, and a mass spectrometer—permits the identification of up to 95% of all volatile organic compounds [1]. The optimum version of this device includes a high-efficiency chromatographic column [of the order of 50 000 theoretical plates] and a complex attachment for the interruption of the separation process during the determination of the spectra of the substances separated. The use of spectrometers as a means of identification imposes certain requirements on such devices: the capacity to record over a short period (3–10 min) the entire spectrum of the test substance and a very high sensitivity permitting the determination of the spectra of small amounts of the substances separated in the chromatographic column. The disadvantages of this combined apparatus include the necessity to interrupt the separation process during the recording of the spectrum and also the high cost of the spectroscopic devices.

One of the versions of apparatus of this kind involves the combination of a chromatograph with a cheap mass-spectrometer having a low resolving power which provides a continuous record for two mass numbers. An apparatus of this type has been called the "Khrommass". [86–88] The use of continuous recording of chromatograms in terms of the coordinates for various mass numbers permits the identification of the substance from the relative peak heights for various characteristic mass numbers [89], but this method becomes complicated with compounds containing more than five carbon atoms in the molecule. The combination of mass spectrometers with chromatographs allows the identification of a large number of compounds [90–92]. An undoubted advantage of the mass-spectrometric detector is its exceptionally high sensitivity, which permits its use in combination with capillary columns. A number of difficulties associated with the inertia of the mass spectrometer then arise; to eliminate this, short heated capillary junctions are employed between the chromatograph and the mass spectrometer [91,93–95] or the carrier gas is removed from the eluate [95,97]. However, the complexity of the design of the mass spectrometer and the need for highly trained operators for such apparatus limits its applicability in chromatographic practice. Reports have been published on attempts to employ radiofrequency mass spectrometers—the so called *QQ*-detectors [98]—but detectors of this kind have a low sensitivity and can be used to determine substances only up to a mass number of 250.

The application of ultraviolet spectrophotometry as a means of identification in gas chromatography is very limited, since its selectivity with respect to molecules having more than six carbon atoms is low, while such molecules in fact constitute the main bulk of the compounds separated by gas chromatography. The use of this method of identification for the analysis of xylene isomers has been described [99] and cases of the application of far ultraviolet absorption spectra in qualitative analysis have been noted [100,101].

The most sensitive selective spectroscopic detector is the flame photometric detector [102]. Its sensitivity exceeds by 1–2 powers of ten that of the flame-ionisation detector.

Two types of detectors, namely the electron capture and thermionic detectors, may be noted among the commonest detectors for qualitative analysis described recently. The operation of the first detector depends on the absorption of the slow electrons emitted by the radioactive source by the molecules of substances having positive electron affinities [103]. The detector signal depends on the capacity of the substance separated to capture electrons, which may be used as a valuable source of information about the properties of the test compound molecule, derived by comparing the chromatograms obtained using selective and non-selective detectors. All organic compounds may be divided into two classes in terms of their capacity to capture electrons: substances with simple capture and substances with capture by conjugated bonds. The first class includes halogeno-derivatives and the second conjugated aromatic systems. The presence of two and more electron-accepting atoms in the compound to be determined increases by 2–3 powers of ten the signal at the electron capture detector (ECD). This type of detector has been successfully used for the selective determination of halogeno-derivatives [104], polynuclear aromatic hydrocarbons [105], and steroids [103]. Since the sensitivity of the electron-capture detector towards substances having electronophilic groups is higher by several powers of ten than for other compounds, comparison of the chromato-

grams obtained using a universal detector and an electron capture detector determines unambiguously the properties of the test substance.

The thermoionic detector is extremely sensitive to chlorine- and phosphorus-containing compounds [106,107]. It is a modification of the flame-ionisation detector, into the flame of which a pellet compounded with an alkali metal salt is inserted. The conductivity of the hydrogen flame increases sharply only when chlorine- and phosphorus-containing compounds emerge from the column. The sensitivity of the thermionic detector is comparable to that of the flame-ionisation detector.

Halogen-containing substances are also determined by the Beilstein test performed visually [108,109] or automatically [101,110]. However, this test does not yield an unambiguous proof of the presence of a chlorine atom in the molecule, since many other compounds also give the same colour in the flame.

Detectors operating in conjugation with chemical reactions, for example automatic titrators, show the greatest selectivity with respect to a narrow range of compounds. The titrators determine selectivity free aliphatic acids [111] and sulphur-containing substances, which are converted into sulphur dioxide in the reactor beyond the chromatographic column [112]. Microcoulometric detectors for the selective detection of organosulphur compounds in complex mixtures have found wide application in the analysis of petroleums [113,114]. They have a very high sensitivity—down to 10^{-6} g of the substance.

A selective detector with a krypton-85 quinol lathrate evolves radioactive krypton on coming into contact with certain substances: chlorine, bromine, nitrogen dioxide, nitrogen oxychloride, and others [115]. This detector may be used for qualitative detection of halogens in the test compound after its combustion.

A detector operating on the principal of piezoelectric absorption can also be included among specific devices [116]. A vibrating quartz crystal is coated by a layer of liquid which absorbs selectively certain components of the mixture to be separated. The detector signal is proportional to the amount of substance absorbed by the liquid layer. The application of this detector is analogous to the use of two and more selective stationary phases for identification.

Detectors involving combustion on a platinum spiral have some selectivity [117,118]; their signal is proportional to the amount of heat evolved on combustion of the separated substance on the platinum spiral; by varying the temperature to which the platinum wire is heated, it is possible to alter the sensitivity of the detector with respect to various substances.

The molecular weight of the unknown substance may be determined by means of a detector the operation of which is based on the density of the gas (gas-density balance) [119-122]; it is applicable to substances with a not unduly high molecular weight—of the order of 100. The measurements are made with two different carrier gases; the main errors arise due to the inaccuracy of the measurements of the peak areas and the inconstancy of the composition of the standard mixture, amounting to about 5% in the most favourable cases. A more laborious method for the determination of molecular weight with the aid of a gas-density balance has been described [122]; in this case the error did not exceed 0.5%. The methods for the determination of molecular weight with a gas-density balance in gas chromatography have not found wide application, since they are suitable only at low column temperatures (the sensitivity of the detector falls rapidly as the temperature increases); on the other hand, the identification of low-boiling substances is not a difficult analytical problem.

Information about the number of carbon atoms in the test substance may be obtained with the aid of detectors involving the combustion of the separated substances to carbon dioxide [123,124]. The peak area is proportional to the number of carbon atoms in the molecule. When the peaks of the same substance in the mixture are compared first using a katharometer and then a device for its combustion, it is possible to estimate the number of carbon atoms in the molecule. Conversion of the separated products into methane, which is then detected by the katharometer, is employed to determine the number of carbon atoms in the molecule. The use of a detector which determines the amount of oxygen consumed in the combustion of the separated substances is very promising [125]. The amount of oxygen consumed is measured by the current necessary to produce this gas by the electrolysis of water. Analysis of the chromatograms obtained with such a detector permits the determination of the number of carbon atoms in the molecule which are not linked to oxygen atoms.

The use of selective detectors makes it possible to elucidate a number of specific properties of the substances separated—the presence of heteroatoms and certain functional groups and the number of carbon, hydrogen, and oxygen atoms in the molecule. Although spectroscopic detectors yield much information about the properties of the molecule, simple selective detectors have found wide application by virtue of their cheapness, simplicity of operation, and high sensitivity in the continuous recording of the results of separation. A disadvantage of selective detectors is high sensitivity for limited classes of compounds only. If the qualitative analysis is carried out in the laboratory fairly frequently, it is desirable to employ spectroscopic devices for identification. In the qualitative analysis of very small amounts of substances, only selective detectors and a mass spectrometer may be employed.

V. THE USE OF OTHER PHYSICOCHEMICAL METHODS FOR THE INVESTIGATION OF SEPARATED SUBSTANCES

In many cases qualitative analysis in gas chromatography is carried out with the aid of other physicochemical methods, for example thin-layer chromatography. Preliminary separation of very complex mixtures is frequently performed in the analysis of petroleum fractions, which involves liquid-adsorption chromatography. The fractions obtained are analysed by gas-chromatography. The converse procedure is also employed: the substances separated on a gas-chromatographic column are deposited on the starting line of the thin-layer chromatographic plate which moves at a constant rate relative to the output from the detector [126-128]. The separated substances are adsorbed on silica gel along the starting line, their positions on the line corresponding to the positions of the peaks on the chromatogram recorded by the katharometer. The chromatograms on the plate are then developed and the R_f values of the spots are determined. The identification is based on the R_f values for silica gel. The principal advantage of this method is its combination of the separation of the substances in terms of the form and size of the molecules by a non-polar stationary phase and in terms of the characteristics of the molecular structure

and the presence of functional groups by silica gel. The system obtained has an exceptionally high separating capacity. A certain disadvantage of the method consists in the fact that thin-layer chromatography requires a relatively large sample, which necessitates the operation of the gas-chromatographic column under conditions of overloading.

The substances separated chromatographically may be investigated by any micromethod. It is possible to determine their boiling and melting points by a micromethod [129] and to record and analyse the NMR spectrum [130]. These methods require a comparatively large amount of the substance (up to 100 mg), which presents certain difficulties, particularly in those cases where the relevant substance is present in the mixture in small amounts. It is somewhat more convenient to investigate the form and colour of the crystals under the microscope—the crystal may be the separated pure substances or the products of their chemical reactions [131]. The microscopic method for the investigation of crystal form makes it possible to distinguish the components of non-separated mixtures provided that they form crystals of different shapes.

Auxiliary physicochemical methods are comparatively rarely required for qualitative analysis in gas chromatography, since they are not very sensitive and universal.

VI. ELEMENTAL ANALYSIS

An additional source of information about the test substance is elemental analysis—this procedure is carried out by classical micromethods with the pure separated compounds collected in traps. The use of gas chromatography in elemental analysis makes it possible to reduce greatly the amount of labour required and to improve the accuracy of the experiments. The high separating capacity of chromatographic columns permits the determination of several elements in one operation. The first stage of elemental analysis in organic chemistry has remained unchanged and is based on the principle of the oxidation or pyrolysis reactions, but gas chromatography allows the use of extremely small amounts of the substances. Two versions of elemental analysis by chromatographic methods are possible: these involve a combination of the apparatus for the decomposition of the substance with a gas chromatograph or the separate operation of these devices with transfer of the reaction products to the chromatograph.

The combined device for the simultaneous determination of carbon, nitrogen, and sulphur consists of a reactor where the specimen is oxidised over copper(II) oxide in a stream of helium at 850°C and a chromatograph [132]. The reaction products (nitrogen, carbon dioxide, and sulphur dioxide) are separated at room temperature on a 1 m chromatographic column filled with Chromosorb P impregnated by 33% DS-550 silicone oil. The time required for the complete separation of the mixture is 4 min and the error of the analysis is 0.3%. If there is no need to determine sulphur, the substances are combusted on a mixture of copper(II) oxide and manganese dioxide at 600°C and the duration of separation is reduced to 1.5 min. Similar devices are used for the simultaneous determination of carbon, nitrogen, and hydrogen [133]; the water formed on combustion reacts with calcium carbide and is determined from the size of the acetylene peak. A mixture of nitrogen, acetylene, and carbon dioxide has been separated on a column containing 5 Å molecular sieves with a programmed temperature change from room temperature to 400°C at a rate of 6 deg min^{-1}. The duration of the complete analysis is 50 min.

Nitrogen and oxygen are determined simultaneously in the pyrolysis of the test substance over "nickel-plated" carbon black at 900°C. [132] The pyrolysis is carried out in the flame of a gas burner over a period of 5 min, the reaction products being separated at room temperature in a 60 cm column with a 5 Å molecular sieve. The analytical error is not greater than 0.8% and the total time required for the determination is 15 min. In all these methods the substance is decomposed in a stream of carrier gas and the outlet from the reactor is connected throughout to the initial section of the chromatographic column. The reaction products are immediately transferred by the stream of carrier gas to the column. The disadvantages of this method include the impossibility of employing oxygen for combustion and the spreading of the chromatographic zone during the finite period of the decomposition of the substance.

The subdivision of chromatographic elemental analysis into two stages makes it possible, at the expense of a slight increase in the analysis time, to separate the chromatograph from the reactor and to employ any conditions for the decomposition of the test substances. The reaction products are collected in a trap whence they are transferred to the chromatograph for analysis. This method for the determination of carbon and hydrogen in organic compounds has been described by Duswalt and Brandt [134]. The test substance is combusted in a stream of oxygen at a reactor temperature of 750°C over silvered copper needles, copper(II) oxide, and platinum, moisture being converted into acetylene by reaction with calcium carbide; carbon dioxide and acetylene condense in a trap and are then separated in a 90 cm silica gel column. The overall duration of analysis is 20 min and the absolute error is 0.5% with respect to carbon and 0.1% with respect to hydrogen. Similar results were obtained also in other investigations [135,136] with a slight modification of the conditions. By combining a gas-density balance as a detector with combustion of the products it is possible to determine the ratio of hydrogen and carbon atoms in the molecule [137]. However, the complexity of the apparatus in this method is not justified by the amount of information obtained with its aid.

By depositing alkali on an inert carrier, one can determine the number of Si–H groups in the molecule from the amount of hydrogen evolved on hydrolysis [138].

Catalytic hydrogenation of the separated substance at 1000°C leads to its complete conversion into methane [139]. The size of the methane peak after such hydrogenation indicates the number of carbon atoms in the molecule of the test substance. Catalytic hydrogenation of nitrogen-containing substances over nickel or magnesium oxide catalysts yields ammonia, the amount of which can be measured chemically or chromatographically [140].

Elemental chromatographic analysis is one of the auxiliary procedures for identification but it yields only the proportions of the elements in the test substance. The structure of the molecule and the location of functional groups in it are determined by other methods, described above.

VII. PYROLYSIS

One of the new trends in the gas-chromatographic identification of compounds is the use of pyrolytic gas chromatography. The pyrolysis is carried out in special cells

(with the amount of test substance between 0.1 and 1 mg) on a platinum wire or a ferromagnetic material, which may be convered by glass. The pyrolysis temperatures lie between 400° and 1200°C. The pyrolysis is usually performed to identify a single substance and more rarely a binary mixture. Pyrolytic chromatography can be most usefully employed for the identification of high-boiling compounds. Solid substances, in particular polymeric compounds, may be identified by this procedure. The pyrolysis products are carried by the carrier gas directly from the pyrolyser to the chromatographic column, where they are separated. The pyrolysis temperature is chosen in such a way that a number of peaks characteristic of the given compound are obtained on the chromatogram. Then the pyrolysis chromatograms of the unknown and known compounds are compared. The identity of the pyrolysis chromatograms is evidence of the identity of the substances compared. The method is the only one available for the identification of high-boiling compounds having isomers with similar properties. Such isomers are extremely difficult to separate on a chromatographic column at a high temperature, since the selectivity of stationary phases falls as the temperature increases. With a correct choice of reaction conditions, pyrolysis chromatograms are characteristic of a given compound [141-143]. The maintenance of rigorous constancy and reproducibility of the pyrolysis temperature is exceptionally important for identification, since the composition of the pyrolysis products varies as a function of reactor temperature. The study of the pyrolysis products at different process temperatures also helps characterise a pure substance. The pyrolytic method has proved extremely effective for the determination of impurities in solids, for example in the analysis of many substances in the living cell [144-147].

In conclusion we must consider the most rational methods for the identification of substances present in the mixture in different proportions. For substances whose concentration in the mixture is from 1% upwards, all the methods described above are applicable in principle, up to structural analysis by methods of organic chemistry. On the other hand, if it is necessary to identify impurity components, two procedures are suitable. The first consists in the concentration of the impurities by chemical or physicochemical methods. The concentrate is then analysed by the usual procedures. On the other hand, if such concentration is impossible, the following methods are employed for identification: selective removal or conversion of the mixture components in reactors, comparison of retention data, and thermodynamic analysis of the properties of the solution. Definite information is provided by mass spectrometers and selective detectors.

Non-empirical Calculations of the Force Constants for Small Molecules

V.P.Morozov and V.V.Rossikhin

The review gives a consistent description and analysis of the ideas underlying the determination of potential constants (coefficients of the potential function formulated as a power series in terms of generalised coordinates) for diatomic and simple monatomic molecules using quantum-chemical methods. Calculations for specific molecules of greatest interest both theoretically and practically are briefly considered; the results of these calculations are presented in the form of tables.
The bibliography includes 80 references.

III. Analytical methods for the calculation of force constants 200

I. INTRODUCTION

The review deals with the present state of the solution of the problem of evaluation of a potential function of the type

$$V = \frac{1}{2!}\sum_{\alpha,\beta} K_{\alpha\beta} q_\alpha q_\beta + \frac{1}{3!}\sum_{\alpha,\beta,\gamma} K_{\alpha\beta\gamma} q_\alpha q_\beta q_\gamma + \frac{1}{4!}\sum_{\alpha,\beta,\gamma,\delta} K_{\alpha\beta\gamma\delta} q_\alpha q_\beta q_\gamma q_\delta + \cdots \quad (1)$$

where $K_{\alpha\beta}$ are harmonic (quadratic) molecular force constants, $K_{\alpha\beta\gamma}$ and $K_{\alpha\beta\gamma\delta}$ are anharmonic (cubic and quadratic respectively) force constants, and q_α are generalised coordinates.

The determination of force constants by the solution of the vibrational–rotational problem involves a fundamental difficulty—the number of unknowns is greater in the majority of cases than the number of equations which may be formulated from the available experimental data.

Therefore the approach based on solving the electronic problem in the adiabatic approximation [1], according to which

$$K_{\alpha\beta} = \left(\frac{\partial^2 E}{\partial q_\alpha \partial q_\beta}\right)_e,\quad K_{\alpha\beta\gamma} = \left(\frac{\partial^3 E}{\partial q_\alpha \partial q_\beta \partial q_\gamma}\right)_e,\quad K_{\alpha\beta\gamma\delta} = \left(\frac{\partial^4 E}{\partial q_\alpha \partial q_\beta \partial q_\gamma \partial q_\delta}\right)_e, \quad (2)$$

is of undoubted interest in connection with the possibility, in principle, of eliminating the above difficulty and also the possibility of achieving a deeper understanding of the nature of dynamic interactions in molecules.

At the present time the principal aim is of course to develop methods for the calculation of force constants and to test their effectiveness on comparatively simple systems, not merely to secure new data for the force constants of specific molecules.

Thus in Eqn. (2) E is the total energy of a molecular system containing N nuclei with charges $Z_1, \ldots, Z_N$ and n electrons†:

$$E = E_e + E_N, \quad (3)$$

where

$$E_e = \langle \Psi_1 H_e \Psi \rangle \quad (4)$$

is the energy of the electronic shells in the field of nuclei with the given configuration and

$$E_N = \sum_{\alpha>\beta} \frac{Z_\alpha Z_\beta}{R_{\alpha\beta}} \quad (5)$$

is the energy of the electrostatic interaction of the nuclei, excluding the kinetic energy of the motion of the latter.

In Eqns. (4) and (5), $\Psi(\mathbf{r}_1, \ldots, \mathbf{r}_n; \mathbf{R}_1, \ldots, \mathbf{R}_N)$ is the electronic wave function and H_e is the electronic Hamiltonian:

$$H_e = \sum_{i=1}^{n}\left(-\frac{1}{2}\Delta_i - \sum_\alpha \frac{Z_\alpha}{r_{i\alpha}}\right) + \frac{1}{2}\sum_{i\neq j}\frac{1}{r_{ij}}\ ; \quad (6)$$

$R_{\alpha\beta} = |\mathbf{R}_\alpha - \mathbf{R}_\beta|$ is the distance between the nuclei α and β, $r_{\alpha i} = |\mathbf{R}_\alpha - \mathbf{r}_i|$ the distance between the ith electron and the α nucleus, and $r_{ij} = |\mathbf{r}_i - \mathbf{r}_j|$ the distance between the ith and jth electrons, the nuclear configuration being described by the vectors $\mathbf{R}_1, \ldots, \mathbf{R}_N$ and the electron configuration by $\mathbf{r}_1, \ldots, \mathbf{r}_n$.

In the adiabatic approximation function (3) plays the role of a potential energy V of the relative atomic vibrations employed in the theory of molecular vibrations [3]. Thus at equilibrium the total energy may be represented by the series (1) and the problem of determining the force constants of the molecule in the given electronic state now reduces to the calculation of the derivatives of the total energy of the system with respect to generalised coordinates.

II. NUMERICAL METHODS FOR THE CALCULATION OF FORCE CONSTANTS

We shall consider initially the possibilities which arise in the solution of the problem of the Hartree–Fock–Roothaan self-consistent field (SCF) method [4,5]. The applications and discussion of various aspects of the self-consistent field method in the calculation of other properties of atoms and molecules may be found in Sokolov's review [6].

Using the Hartree–Fock method, a number of investigators have calculated the electronic energy for various nuclear configurations (in the vicinity of the equilibrium configuration) for diatomic and small polyatomic molecules. Such calculations make it possible to plot potential curves and surfaces and to determine the potential constants by numerical differentiation. It must be emphasised that more calculations of this kind, particularly recently, became possible with increased availability of computers.

A typical example of such an approach, usually referred to in the literature as "traditional", is the calculation of

†The formulae and the numerical results in the review are quoted in atomic units (a.u.), unless otherwise stated [2].

the force constants of diatomic molecules in the ground and excited states by Fraga and Ransil [7] carried out on the basis of the self-consistent field functions in both the one-determinant approximation and taking into account the interaction between the configurations (CI).

In their studies the potential curve is approximated by a third degree polynomial in R of the form

$$E = a + bR + cR^2 + dR^3, \quad (7)$$

the coefficients of which are determined by the least square solution of a set of equations of the type of Eqn. (7) for various values of R and the corresponding E. Since the expressions for the vibrational–rotational constants (ω_e, $\omega_e x_e$, B_e, α_e, and $K_{\alpha\beta}$) can be obtained by solving the corresponding Schrödinger equation with a potential function of the type [8]

$$E = a - fR^2 - gR^3, \quad (8)$$

Fraga and Ransil converted the coefficients of Eqn. (7) into those of Eqn. (8) by the formulae $g = -d$ and $f = (c^2 - 3bd)^{1/2}$. This numerical analysis of the potential curves does not differ in principle from that employed in the majority of investigations. The only difference lies either in the choice of the approximating function or in the method of estimation of the similarity of the functions over a certain interval, etc.

The agreement between the $K_{\alpha\beta}$ calculated in the one-determinant approximation and the experimental values [8] is satisfactory despite the fact that the molecular orbitals (MO) include only the internal and Slater valence atomic orbitals (AO) and the polynomial (7) is restricted to the third power of R (Table 1); the deviations from the experimental values lie in the range 8–20% for the molecules H_2, LiH, and Li_2.

An interesting result was obtained by Nesbet in Hartree–Fock calculations for a number of diatomic molecules [9,10]; an appreciable improvement in the calculation of the force constants in the one-configurational approximation arises when polarisation and deformation of atomic orbitals as a consequence of their intramolecular environment are postulated, in contrast to the hypothesis that the molecular orbitals may be constructed as linear combinations (LC) of undeformed atomic orbitals. This effect may be described by including a greater number of basis functions than in the minimum set, with higher angular quantum numbers than for separated atoms.

To illustrate this, we shall quote the results of this type of calculation for the $^1\Sigma^+$ states of the isoelectronic molecules N_2, CO, and BF carried out by Nesbet [11]; in this case the potential curve is approximated by a series in terms of Chebyshev functions.

Then the analytical expression obtained for the potential curve can be put in the form

$$E = b_0\xi^2 \sum_k b_k \xi^k, \quad (9)$$

where $\xi = (R - R_e)/R_e$. Dunham [12] solved the vibrational–rotational Schrödinger equation with a potential defined by an expression of type (9). This makes it possible to find, using the formulae obtained, all the fundamental spectroscopic constants for a given bound state. Such numerical analysis of the potential curve is usually referred to as the Dunham analysis.

Table 1 shows that there is significant agreement with the experimental force constants. For N_2 as an example, it is seen that the constant $K_{\alpha\beta}$ is somewhat improved compared with the values calculated with the aid of the minimal basal set.

Satisfactory agreement with experiment was obtained also for the F_2 molecule by Wahl [13], who likewise employed the Hartree–Fock–Roothaan procedure in the derivation of the potential curve with subsequent Dunham analysis leading to the force constants. It should be noted that this study is the first in a series designed by the author and his coworkers to obtain Hartree–Fock analytical wave functions for the ground and certain excited states of diatomic molecules. They believe that the calculations should provide a foundation for a critical analysis of the theory of electronic structures of small molecules. Thus the third paper [14] of this series presents the calculations of the wave functions of N_2^+ and N_2 in the ground and excited states with various forms of basis sets. All the calculations were made for a large number of internuclear distances, which makes it possible to calculate the force constants (Table 1). To eliminate computational errors, several polynomial approximations were made varying the number (from 4 to 10) and type of points [15] taken for the Hartree potential curve. The discrepancies between the calculated spectroscopic constants and experiment range from several per cent to several tens per cent and those for the force constant are in the range 34–64%.

Comparison of the potential curves with experiment, carried out in the above investigations and in the work of Leies [16] for the H_2 molecule (the calculation was based on the Hartree–Fock function obtained by Kolos and Roothaan [17]), suggests [18] that the curves are relatively congruent in the vicinity of equilibrium (and when $R < R_e$); the difference in their behaviour increases at larger internuclear distances. In turn, the results of the calculations for the force constants and certain other vibrational–rotational constants are fully consistent with the form of the potential curves. Thus the Hartree–Fock potential increases more rapidly from the point of equilibrium ($K_{\alpha\beta}$ >) but shows a smaller anharmonicity ($\omega_e x_e$ <) than the experimental potential. Such behaviour of the Hartree–Fock potential curves is evidently due to the following factors: the Hartree–Fock molecular orbitals lead to an incorrect dissociation limit for the majority of molecules, i.e. the molecules dissociate to give a series of neutral and ionic atomic states; moreover, the Hartree–Fock potential does not include the correlation energy, which is partly the reason for the effect described above.

Yoshimine [20] shows that, from the standpoint of these factors, the introduction of a scale factor into the wave function and its variation as a function of R to improve the force constants [19] is not particularly useful [although the appropriate variation of the scale factors does in fact alter these constants in the required direction, the change is only slight (Table 1)]. Huo's use of even more extended sets [21] (CO and BF molecules), compared with the basis sets [11], and the optimisation of the scale factors does not lead to a significant improvement of the force constants.

Before proceeding to studies in which attempts were made to improve the E_{H-F}, mention should be made of a very interesting study by Goodisman [22], who showed that the force curve (obtained directly from the expectation value of the one-electron operator $\partial H/\partial R$) leads to better results for $K_{\alpha\beta}$ than the energy curve calculated on the basis of Hartree–Fock functions with limited-basis of functions of the James and Coolidge type, namely the approximation of the energy curve by a parabola in the vicinity of R_e yields the force constant $K_{\alpha\beta} = 0.3795$ a.u. and the calculated values $R_e = 1.385$ a.u. and $\omega_e = 4458\ cm^{-1}$; numerical analysis of the force curve gives $K_{\alpha\beta} = 0.3727$ a.u., $R_e = 1.394$ a.u., and $\omega_e = 4417\ cm^{-1}$

[d]Optimised valence configuration (OVC). [e]Configuration interaction taken into account to a limited extent. [f]Extended basis set compared with c^7. [g]Basis set extended still further (compared with c^{11}). [h]One-determinant non-scaled wave function. [i]One-determinant scaled function. [j]One-determinant one-centre function. [k]One-centre function including configuration interaction. [l]Calculated from Eqn. (12). [m]Simple wave function of the molecular orbital type. [n]Wave function ($1S_a + 1S_b$) calculated on the basis of the virial theorem (I) and the Hellmann–Feynman theorem (II). [o]Wang function. [p]Coulson function. [q]Weinbaum function. [r]Non-scaled Heitler–London wave function. [s]Ditto for the molecular orbital wave function. [t]Scaled Wang wave function; [u]Coulson function; [v]Weinbaum function; [w]On the basis of a variational-perturbation scheme; [z]the anharmonic force constants for certain molecules were calculated by the authors of the review (they are not quoted in the relevant papers) in those cases where the original authors give an insufficiently complete set of spectroscopic constants.

*The experimental values were taken from the references given in column 9.

(experiment gives $K\alpha\beta = 0.3680$ a.u., $R_e = 1.401$ a.u., and $\omega_e = 4440\,cm^{-1}$). The results of this investigation and also the present authors' calculations[23] confirm the conclusion that, when the approximate Hartree–Fock function is close to the true Hartree–Fock function, one may expect a second-order perturbation error in the expectation value of the one-electron operator[24,25].

When account is taken of configuration interaction within the framework of the self-consistent field method, which leads to a correct dissociation limit, the force constants are improved provided that molecular orbitals with higher angular quantum numbers compared with the ground molecular orbital are included in the additional configurations.

Limited allowance for configuration interaction does in fact lead to a correct dissociation limit, but the force constants are not always improved. For example the inclusion by Fraga and Ransil[7] of additional configurations with the ground configuration resulted in a considerable improvement of the quadratic force constants of molecules such as HF and F_2, for which π configurations were included in the calculation (the error in the case of the one-determinant approximation is 49% for HF and 205% for F_2); however, poorer values of $K\alpha\beta$ were obtained for H_2, LiH, and Li_2, since molecular orbitals with higher angular quantum numbers than the ground molecular orbital were not included in the additional configurations of the molecules. This was also shown by Moser, Nesbet, and others[26-28] in Hartree–Fock calculations of the spectroscopic constants of the molecules H_2, CO, LiF, Li_2, and F_2, among which the last merits a more detailed consideration. In their study the wave function with configuration interaction, which is of the form

$$\Psi = \sum_k d_k \Phi_k ,$$

contains several optimised configurations obtained by replacing one of the σ orbitals of the ground configuration by orbitals of a different type. The method is based on a model according to which, when a molecule is formed from Hartree–Fock atoms or ions initially at infinite separation, changes occur mainly in the valence orbitals. This factor is taken into account by the introduction of optimised valence configurations (OVC), which are constructed by the promotion of the valence electron pair from the ground state to an allowed "excited" orbital. By minimising the total energy and the energy of the optimised valence configurations, equations defining the best values of d_k and the orbital coefficients were obtained. The calculations were made for the molecules H_2, Li_2, and F_2, only two configurations being optimised in the last case. We may note that in all cases the molecules dissociate into two Hartree–Fock atoms (Figs. 1 and 2). Dunham analysis gives, particularly for the optimised valence configurations in the case of the H_2 and Li_2 molecules, fairly satisfactory values of $K\alpha\beta$ (Table 1). Evidently this method is very promising for the calculation of spectroscopic constants by the numerical analysis of the potential curve, since it is based on a thoroughly developed expansion technique whilst retaining the simplicity and clarity of the shell model [moreover, the restriction to valence-excited configurations makes it possible to extend the method to systems with a larger number of atoms and to obtain a potential curve approximately congruent with the experimental curve for $R > R_e$ (Figs. 1 and 2), which shows that the correlation effects are partially taken into account]. Somewhat poorer results were obtained for F_2, compared with the other molecules, because the orbitals of the skeleton include orbitals such as $1\pi_u$ and $1\pi_g$, which are known to be of the valence type.

Among the earlier studies dealing with the LCAO-SCF method, with a limited allowance for configuration interaction, mention should be made of the work of Karo and Olson[29] (LiH) and Higuchi[30] (CH), the results of which also confirm the conclusion that molecular orbitals with higher quantum numbers than the ground orbital must be included in the additional configurations, and also the work of Boys et al.[31], where the force constants of the molecules BH and H_2O and the transition complex H_3 (the force constants of H_3 are not observed physically but are necessary for the prediction of reaction rates) were determined by the LCAO-SCF method with allowance for configuration interaction.

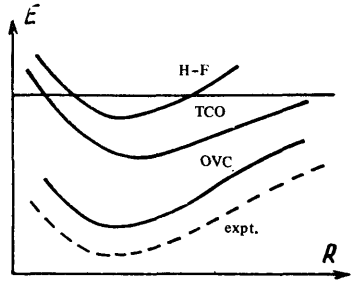

Figure 1.

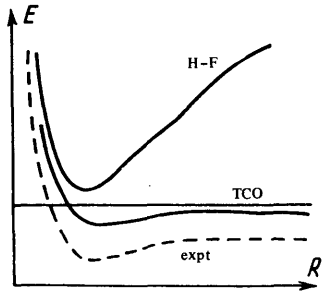

Figure 2.

Table 1 lists the force constant of the BH molecule obtained on the basis of a wave function, representing a linear combination of 23 Slater determinants and calculated for three internuclear distances, and the harmonic force constants of the H_2O molecule (in terms of the valence force system of coordinates[3]), the wave function of which was represented by a linear combination of 96 Slater determinants and calculated for seven nuclear configurations. The results are fully satisfactory for the diagonal force constants. The inconsistency of the results for the non-diagonal constants of H_2O both in magnitude and in sign can be accounted for largely by the errors in the derivation of the interpolation polynomial for the points at which the energy of the corresponding nuclear configuration was calculated.

The improvement of the Hartree–Fock calculations of the force constants by the introduction of configuration interaction has also been demonstrated in a recent investigation by Nesbet[32] of the electronic structure of C_2, which is the first of a series dealing with the study of the potential curves for the ground and certain excited states of the isoelectronic molecules C_2, BN, BeO, LiF, HeNe, and HNa. Here configuration interaction is introduced in two different ways: (1) two possible states which may be formed from four valence orbitals are considered and (2) two different orbital basis sets with six valence molecular orbitals are employed. Analysis of the potential curves shows a quantitative agreement between the experimental and calculated force constants. It is interesting that the statistical relations discovered by comparing the values obtained with experiment permit the prediction of the force constants of hitherto unobserved bound states, which are of interest, for example, for elucidating how molecules in an excited electronic state interact.

In concluding this review of numerical methods for the calculation of force constants, mention should be made of a number of studies[33–39] in which an interpolation procedure was also used to calculate the $K_{\alpha\beta}$, mainly for polyatomic molecules, but where the energies of various nuclear configurations were calculated using the one-centre approximation[36], which constitutes a variety of LCAO. A characteristic feature of the method is the employment of a basis set of functions centred on the same point, which makes it possible to avoid the calculation of many-centre integrals.

It should be noted that for hydrides of the type AH and AH_n the one-centre model both in the one-determinant approximation and with allowance for configuration interaction is very useful for the calculation of the quadratic force constants (Table 1). The one-centre approximation will be considered in greater detail below (p. 200 and p. 201) for reasons which will become clear later.

Summarising, it must be emphasised that the semiempirical methods developed at present for the numerical calculations of molecular force constants are extremely laborious and are applied mainly to diatomic molecules; moreover, the spectroscopic constants obtained by such calculations are still much inferior in their accuracy to the experimental constants, but the trend towards a reduction of errors in the calculations is quite definite.

III. ANALYTICAL METHODS FOR THE CALCULATION OF FORCE CONSTANTS

The analytical methods for the determination of force constants include the following: (1) analytical differentiation of the expression for the energy of the system obtained by a quantum-mechanical method; (2) the use of the differential Hellmann–Feynman theorem; (3) the use of the quantum-mechanical virial theorem; (4) the application of perturbation theory and various semiempirical variation-perturbation schemes.

Calculations of the harmonic force constants for a number of diatomic and polyatomic molecules based on the first procedure were made largely by Bratož and coworkers and also by Bishop and coworkers using both one-centre functions and Hartree–Fock–Roothaan functions in the self-consistent field approximation.

Thus the force constants of the molecules H_2 and LiH were calculated[40,50] from theoretical expressions obtained by Bratož[51] for the first and second derivatives of the total energy with respect to a parameter in terms of the LCAO-MO-SCF approximation and taking into account the configuration interaction[29]. It has been found that, when the method under consideration is employed, the molecular force constants agree better with experiment in the Fock–Roothaan one-determinant approximation than when limited allowance is made for configuration interaction, although the latter does in fact lead to a correct dissociation limit but not always to the best values of the force constants (Fig. 3). In other words, we encounter here an example illustrating the known fact that[25] an approximate wave function giving the best value of the operator for one physical quantity is not necessarily satisfactory for the calculation of the expected value of the operator for another physical quantity. In our case this means that the usual quantum-chemical variational solutions are more sensitive to the position of the limit (the value of the energy) than to the form of the potential surface (the force constants).

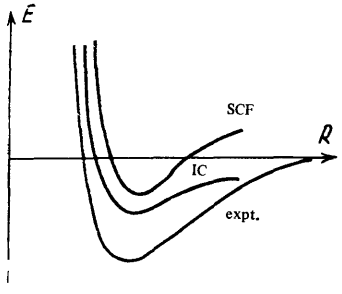

Figure 3.

Later it was shown[40] that, when the energy of the molecule is subdivided into the component E_n due to the interaction between the nuclei and the electrons of the skeleton and E_V due to the contributions of the electrons in the valence orbitals (such subdivision is always possible both in the self-consistent field method and in the method allowing for configuration interaction when in the latter case no account is taken of the excitation of the electrons of the skeleton), i.e.

$$E = E_n + E_v , \tag{10}$$

double differentiation yields

$$K_{\alpha\beta} = K_n + K_v . \tag{11}$$

It is found that $K_n \gg K_V$ for the force constants in the majority of diatomic molecules with a single bond (Table 1) and also for the diagonal force constants of molecules such as H_2O (Tables 2 and 3) and CH_4; this condition makes it possible to write

$$K_{\alpha\beta} \simeq K_n \simeq \frac{2}{R^3} . \tag{12}$$

Thus the main contribution to the force constants of the molecules considered is due to the interaction between the nuclei and the electrons of the skeleton. If the bond is not of a two-electron type, the results are less simple and Eqn. (12) no longer holds.

Bratož and coworkers arrived at a similar conclusion in their investigation [52,53] based on the one-centre model both in the one-determinant approximation and with allowance for configuration interaction, which is fairly acceptable, particularly within the framework of the analytical method for the differentiation of the energy of the system. Functions of this type describe satisfactorily the structure of hydrides the electrons of which are concentrated largely on one of the atoms and permit analytical differentiation of the matrix elements without additional limitations. It should be noted that, in contrast to such functions, the LCAO-MO-SCF functions require in their analytical evaluation on the basis of force constants the calculation of derivatives of many-centre integrals and also derivatives of orbital coefficients with respect to parameters. In view of the considerable difficulities in the solution of these problems, such calculations of the force constants are made largely on the basis of the simple wave functions of the molecular orbital and valence bond types (see below) and also the one-centre functions indicated above.

Table 2. The force constants of the water molecule (10^5 dyn cm^{-1}).

Force constant	K_n	K_v	$K_{\alpha\beta}$	Boys' data	Expt. (Ref.38)
$K_{\varphi\varphi}$	0.88	−0.01	0.87	0.86	0.77
$K_{R\varphi}$	0.31	0.05	0.36	−0.36	0.25
$K_{RR'}$	1.04	−1.11	−0.07	−0.62	−0.11

Thus, in terms of the one-centre approximation, it is easy to obtain [51,52] general formulae for the first, second, etc. derivatives of the energy of the ith state with respect to the nuclear coordinates, for example:

$$E_i^{x} = \sum_{s,t} d_{is}\, d_{it}\, H_{st}^{x} - \sum_{\alpha>\beta} Z_\alpha Z_\beta \frac{R_{\alpha\beta}^{x}}{R_{\alpha\beta}^{2}}, \qquad (13)$$

$$E_i^{xy} = \sum_{s,t} d_{is}\, d_{it}\, H_{st}^{xy} + \sum_{k}{}' [2/(E_i - E_k)] \times$$

$$\times \left(\sum_{s,t} d_{is}\, d_{kt}\, H_{st}^{x}\right)\left(\sum_{s,t} d_{is}\, d_{kt}\, H_{st}^{y}\right) + \sum_{\alpha>\beta} Z_\alpha Z_\beta (2R_{\alpha\beta}^{x} R_{\alpha\beta}^{y} - R_{\alpha\beta} R_{\alpha\beta}^{xy})/R_{\alpha\beta}^{3}, \qquad (14)$$

where d_{is} are the coefficients of the expansion in the wave function with configuration interaction in terms of the wave functions Φ_s of the united atom; H_{st}^{x}, H_{st}^{y}, and H_{st}^{xy} are the first and second derivatives with respect to the nuclear coordinates of the matrix element $H_{st} = \langle \Phi_s, H\Phi_t \rangle$. We may note that in the derivation of Eqns. (13) and (14) no approximation was made, since they are the true derivatives of the total energy for the given wave function with configuration interaction. The formulae will be particularly simple if it is postulated that the non-diagonal matrix elements are of the order of λ relative to the diagonal terms.

The calculation of the harmonic force constants with the aid of the one-determinant wave functions of the ground state, which is centrally-symmetrical, neglecting the second-order term [the first term is retained in Eqn. (14)], corresponds to Platt's electrostatic approximation‡, [54] i.e. to the hypothesis of a rigid electronic skeleton.

The application of the second order theory, i.e. the theory taking into account the second term in Eqn. (14), to calculations on polyatomic hydrides permits a detailed analysis of the various factors influencing the harmonic force constants of the molecules. This was done in the work of Bratož, Daudel, and others [52,53] for the H_2O and NH_3 molecules, the results of the calculations being compared, for water molecules, with the results of Boys [31], and also with experiment (Table 2).

Table 3. Force constants of the ammonia molecule (10^5 dyn cm^{-1}).

Force constant	1	2	3	$K_{\alpha\beta}$	Expt. (Ref.56)
K_{RR}	0.49	1.33	−1.79	9.03	1.17
$K_{RR'}$	0.88	0	−1.09	−0.21	0.08
$K_{\varphi\varphi}$	0.72	0.58	−0.44	0.86	0.91
$K_{R\varphi}$	0.26	0.36	−0.17	0.45	0.44
$K_{R\varphi}$	0	−0.36	0.26	−0.10	0.29
$K_{\varphi\varphi}$	0	−0.20	0.17	−0.03	−0.09

The fact that nuclear terms again make the main contribution to K_{RR} and $K_{\varphi\varphi}$ (as shown in Table 2) was demonstrated also in earlier studies by Longuet-Higgins and Brown [55] where the Platt model was applied to the polyatomic hydrides MH_n for the calculation of the stretching vibration frequencies on the basis of the electrostatic theorem.

Table 3, which gives the results of the calculation of various types of contributions to the harmonic force constants of the ammonia molecule, is also of interest. The first column corresponds to Platt's electrostatic approximation, which also makes the main contribution to the force constants K_{RR} and $K_{\varphi\varphi}$. When the wave function with configuration interaction, is employed, the contribution due to the introduction of additional configurations, neglecting the second term in Eqn. (14), is given in the second column; the electronic skeleton remains rigid as before ($d_{is}^{x} = 0$)—this is the so called "deformation" contribution. Finally, the third column lists the contributions due to the change in the wave function during vibrations, which is taken into account by the second term in Eqn. (14)—the "relaxation" contribution. The relaxation-deformation contributions play an appreciable role in non-diagonal force constants, particularly in $K_{R\varphi'}$ and $K_{\varphi\varphi'}$.

Thus the theory developed by Bratož and coworkers does not postulate that the wave function is spherical and that the electronic distribution is rigid [a rigid distribution is partly attained by taking into account the variation of the

‡We may note that Platt's model, which is based on two hypotheses (that the interatomic distance is close to $R_{1.0}$, the radius of the united atom in which the effective charge is unity, and that the force constant is approximately $4\pi\rho_{1.0}$, where $\rho_{1.0}$ is the electron density for the united atom at radius $R_{1.0}$), gives a satisfactory representation and prediction of the harmonic force constants for hydrides of the type AH.

linear coefficients d_{is} in the wave functions with the nuclear coordinates, which is in fact the reason for the appearance of the second term in Eqn. (14)].

It should be noted that Bishop and coworkers [33-35,37,39,57] carried out one-centre calculations of the force constants of a number of di- and poly-atomic hydrides (LiH, BeH, CH, BH, NH, OH, NH_3, H_2O, CH_4, and others), in different versions, corresponding to the removal of one or other limitation.

In a recent study by Bishop and Randic [38] the variation of non-linear parameters (orbital exponents) with the nuclear coordinates was included analytically in the expressions for the (harmonic) force constants of the H_2O molecule within the framework of the one-centre one-determinant wave function quoted by Allavena and Bratož. [33] The values of the force constants obtained here agree better with experiment than those calculated with the same accuracy but without taking into account the above relation (the agreement is better not only in magnitude but also in sign). In the same study the possibility of applying the authors' approach to one-centre functions, including configuration interaction, is also discussed.

Summarising, we may note that there is no doubt about the usefulness of further study of the functions under discussion, particularly for the calculation of anharmonic molecular force constants.

We shall consider further the possibilities of the differential Hellmann–Feynman theorem [58-60] and the quantum-mechanical virial theorem [61,62], which has recently found some application in the consideration of molecular forces [63-65] and force constants, mainly for diatomic molecules. The respective expressions for the theorems can be written as follows:

$$\frac{\partial E}{\partial x_\alpha} = \langle \Psi, \partial H/\partial x_\alpha \Psi \rangle, \tag{15}$$

$$\langle \Psi, T\Psi \rangle + E + \sum_{\alpha=1}^{N} X_\alpha \frac{\partial E}{\partial X_\alpha} = 0, \tag{16}$$

where, as usual, Ψ is the wave function for the system of $X_\alpha - 3N$ Cartesian coordinates (x_α, y_α, z_α) of N nuclei. It is seen from Eqns. (15) and (16) that the theorems yield the first derivative of the energy as the usual, expectation value of the corresponding operator, which permits $n - 1$ differentiations in order to obtain the nth derivative of the energy. As shown for the first time by Brown [66], the expressions for the harmonic force constants obtained by the differentiation of the Hellmann–Feynman theorem contain the integral of the derivative of the square of the modulus of the electronic wave function of the ground state with respect to a parameter (the internuclear distance in diatomic molecules).

Differentiation of the virial theorem for a diatomic molecule gives

$$K_{\alpha\beta} = \frac{1}{R_e}\left(\frac{\partial}{\partial R}\langle \Psi, V\Psi \rangle\right)_e, \tag{17}$$

or

$$K_{\alpha\beta} = -\frac{1}{R_e}\left(\frac{\partial}{\partial R}\langle \Psi, T\Psi \rangle\right)_e \tag{18}$$

Clinton [67] also concluded that the change in electron density cannot be ignored, since it is responsible for a non-vanishing contribution to the force constant. From this standpoint, he considered Platt's model, which remains attractive from the computational point of view, at least for diatomic hydrides, but is nevertheless purely formal.

Differentiation of the Hellmann–Feynman theorem makes it possible to express the force constant in the form [41]

$$K_{\alpha\beta} = Z_\alpha\left[Q_\alpha + \tfrac{4}{3}\pi\rho(\alpha) - \int \frac{\partial\rho}{\partial x_\alpha}\frac{\cos\theta_\alpha}{r_\alpha^2}d\tau\right]_e, \tag{19}$$

where Q_α is the electron density gradient at the nucleus α due to all the charges outside the limit of the nuclear radius (this term enters into the nuclear quadrupole coupling constant and may be obtained experimentally from the hyperfine structure of the rotational spectra [68] and $\rho(\alpha)$ is the charge density at the nucleus α. With regard to the last term in Eqn. (19), it can be shown, using either Eqn. (20), [96]

$$\frac{\partial\Psi}{\partial x_\alpha} = -\sum_n{}' \frac{(\partial H/\partial x_\alpha)_{0n}}{E_n - E_0}\cdot\Psi_n, \tag{20}$$

or the quantum-mechanical sum rule [42], that

$$-Z_\alpha\int\frac{\partial\rho}{\partial x_\alpha}\cdot\frac{\cos\theta_\alpha}{r_\alpha^2}d\tau = -2\sum_n{}'\frac{|(\partial V/\partial x_\alpha)|_{0n}^2}{E_n - E_0}, \tag{21}$$

the physical significance of which will be elucidated below. We may note that Eqn. (19) makes it possible to establish a relation between the force constant and the nuclear quadrupole coupling constant in a diatomic molecule, which is of considerable interest for theoretical chemistry.

Using the Hellmann–Feynman theorem, Salem [42] obtained second- and third-order force constants for the molecules H_2, Li_2, Na_2, and F_2 and also the force constants and the quadrupole coupling constants for diatomic hydrides from simple wave functions of the molecular orbital and valence bond type; on the basis of the properties of the electron density of the hydrides, it was shown that, for ionic hydrides of the type M^+H^-, Eqn. (19) becomes particularly simple and the force constants of these molecules can be expressed directly in terms of the quadrupole coupling constant:

$$K_{\alpha\beta} \simeq Q_H \simeq \frac{2}{R^3}.$$

Further mathematical forms which the force constants for di- and poly-atomic molecules can assume were investigated by Phillipson [43,69], who showed that the form of the equations depends on whether the virial or the Hellmann–Feynman theorem is employed and also on the coordinate system used to describe the wave functions.

Phillipson also studied the problem of the so called "stable" [70] functions, i.e. the approximate wave functions satisfying theorem (15). In the expressions which he obtained for the force constant account is taken of the dependence on internuclear distance of the parameters entering into the wave function:

$$K_{\alpha\beta} = \frac{1}{R_e}\left[\sum_i\left(\frac{\partial\bar{V}}{\partial\lambda_i}\right)\frac{d\lambda_i}{dR} - \frac{\bar{V}}{R^2}\right]_e, \tag{22}$$

$$\bar{V} = \langle \Psi(\lambda), V\Psi(\lambda)\rangle.$$

$$K_{\alpha\beta} = \left[-\sum_i(\partial\bar{F}/\partial\lambda_i)\frac{d\lambda_i}{dR}\right]_e,$$

$$\bar{F} = -\left\langle \Psi(\lambda), \frac{\partial V}{\partial R}\Psi(\lambda)\right\rangle, \tag{23}$$

where the summation is carried out with respect to all the variational parameters λ_i entering into the function Ψ. We may note that Eqn. (22) was obtained by differentiating Eqn. (16) on the assumption that the variational principle is satisfied, i.e. $dE/d\lambda_i = 0$, and Eqn. (23) was derived from Eqn. (15) on the assumption that the variational principle, the virial theorem, and the Hellmann–Feynman theorem are satisfied for all R.

Using simple wave functions of the molecular orbital and valence bond type, the force constants for H_2^+ and H_2 molecules were subsequently calculated [44] on the basis of Eqns. (23). Best agreement with experiment is achieved when Eqn. (22) is used, since none of the functions investigated satisfy theorem (15). The calculation suggests that, in order to obtain force constants comparable with the experimental values, it is necessary to have functions which describe accurately the curvature of the potential curve near R_e and satisfy the condition of zero force at the equilibrium point.

In a study by the present authors [47] which preceded those of Phillipson [43,44,59], the quadratic and cubic force constants of the H_2 and Li_2 molecules were calculated using relations of type (23) together with an investigation of the possibility of using the atomic wave functions with an angular variation of the effective charge to construct molecular wave functions satisfying the Hellmann–Feynman theorem. It was also shown that, when the condition $F_{R_e} = 0$ is satisfied and a reasonable relation between the parameters (for example the orbital exponents in atomic orbitals) and the internuclear distance is introduced leading to the accurate curvature of the potential curve, satisfactory agreement with experiment is obtained for both the force constants and the binding energy (Table 1), although the latter, as already pointed out, is not necessarily a criterion of the derivation of satisfactory force constants.

Benston and Kirtman [45] continued the studies of the various forms which the second- and third-order force constants of diatomic molecules can assume depending on which coordinates are chosen for the description of electronic motion; they calculated the force constants of H_2 molecules on the basis of functions of the same type (molecular orbital and valence bond). One can say (Table 1) that the force constants may be calculated with adequate accuracy with the aid of both theorems provided that scaled functions, i.e. functions for which the orbital exponents in the atomic orbitals are optimised for all R, are employed.

In a study by the present authors [23,48,49], a new method was developed for the calculation of force constants. It was shown that in the Hartree–Fock–Roothaan self-consistent field approximation it is possible to take into account the variation of the Fock–Dirac density matrix with parameters which depend on the coordinates of the nuclei. However, numerical evaluation of the latter expressions for the nth order derivatives with respect to parameters is associated with a fairly large volume of calculations, mainly the need to calculate the derivatives of two-electron many-centred integrals. The use of the virial theorems (15) and (16) made it possible to represent the force constants in terms of derivatives of the matrix elements of one-electron operators and thus avoid the above difficulty. We shall now quote formulae for the second- and third-order derivatives obtained by direct differentiation of the virial theorem formulated in terms of the LCAO-SCF procedure for diatomic molecules (in terms of a system of electronic coordinates linked with the centre of gravity of the molecule):[23]

$$K_{\alpha\beta} = -\frac{2}{R_e} Sp\left[\rho\frac{\partial T}{\partial R} - \rho(aT + \tilde{Ta})\right]_e,$$

$$K_{\alpha\beta\gamma} = -\frac{3}{R_e}K_{\alpha\beta} - \frac{2}{R_e} Sp\left[\rho\frac{\partial P}{\partial R} - \rho(aP + \tilde{Pa})\right]_e,$$

where $P = \partial T/\partial R - (aT + \tilde{Ta})$, $\rho = C\tilde{C}$, $a = \mu S^{-1}$ and μ is a matrix with the elements $\mu pq = <\partial\chi p/\partial R, \chi q>$.

Specific calculations of the force constants (up to the fourth order inclusive) performed on the basis of one-determinant Hartree–Fock–Roothaan functions for a number of diatomic hydrides and the water molecule [23,71] suggest that the method developed is applicable to the calculation of the potential functions for small molecules.

It is necessary to emphasise the importance of the condition that the approximate wave function employed should satisfy the virial and Hellmann–Feynman theorems if acceptable force constants are to be obtained (Table 1). Moreover, if one ensures that the Hartree–Fock function with a limiting-basis set is close to the true Hartree–Fock function, one may expect a second-order perturbation error in the calculation of the expected value of the one-electron operator [72].

The possibility of deriving theoretical expressions for derivatives higher than second order for the energy of diatomic molecules on the basis of theorems (15) and (16) has been demonstrated recently by Schwendeman [73]. The expressions obtained make it possible to establish rigorous relations between the experimental spectroscopic constants and derivatives of the kinetic and potential energies and hence permit assessment of the suitability of the quantum-mechanical calculations of the latter based on a particular approximate function. The same investigator [53] has carried out such an analysis for carbon monoxide; it consists in the following steps: the values of the total kinetic and potential energies found by Hartree–Fock calculations [11] were used to obtain by a numerical method the derivatives of these quantities with respect to R. These values are compared with those calculated with the aid of the relations indicated above. Thus it is possible to investigate the suitability of particular approximate Hartree–Fock functions for the calculation of force constants on the basis of the virial theorem. In this work on the carbon monoxide molecule, the satisfactory agreement of the calculated derivatives of T, V, and E suggests that there is no doubt that Hartree–Fock functions can be used in thise case. We may also note that, when scaled wave functions are employed, it is possible to achieve a more flexible R-behaviour of the potential curve [45,74].

We shall consider further a method based on the expansion of the electronic Hamiltonian in terms of powers of the displacement of the nuclei from the equilibrium positions with subsequent application of perturbation theory. The method was proposed by Brown [66], and has been developed and employed in a number of studies by Salem, Murrell, Bader, and others [41,42,75,76].

With the aid of second-order perturbation theory, the following expression was obtained for the harmonic force constant in the ground state:

$$K_{\alpha\beta} = \left[\left(\frac{\partial^2 H}{\partial R^2}\right)_{00} - 2\sum_n{}' \frac{|(\partial H/\partial R)_{0n}|^2}{E_n - E_0}\right]_e, \qquad (24)$$

which allows a physical interpretation of the following type: the first term is the average value of the operator d^2H/dR^2 at equilibrium and the second negative term reflects the variation of the force constant with the change in charge distribution caused by a change in the configuration of the molecule.

We must emphasise that the principal disadvantage of this approach and, incidentally, of any other where it is necessary to employ expansion (20) is the need to take into account the wave functions and energies of excited states, which are generally speaking unknown and, moreover, it is necessary to estimate the contributions from continuous energy states.

To eliminate this disadvantage, Benston and Kirtman [46] proposed another procedure [20] for finding the derivatives of the approximate wave functions. According to perturbation theory, the second- and third-order force constants for a diatomic molecule are expressed in terms of Ψ_0 and Ψ_1 respectively and the unperturbed and first-order wave functions. In turn $d\Psi/dR$ corresponds to the function Ψ_1, i.e. the problem reduces to finding Ψ_1. This is done by the variational method (the first attempt was made by Mills [77] for the CH_4 molecule). The formulae expressing $K_{\alpha\beta}$ and $K_{\alpha\beta\gamma}$ in terms of Ψ_0 and Ψ_1, found from the variational principle, are of the form

$$K_{\alpha\beta} \simeq \langle \Psi_0, H_2\Psi_0\rangle + 2\langle \Psi_1^{opt}, (H_0 - E_0)\Psi_0\rangle,$$
$$K_{\alpha\beta\gamma} \simeq \langle \Psi_0, H_3\Psi_0\rangle + 6\langle \Psi_1^{opt}, (H_2 - E_2)\Psi_0\rangle + 6\langle \Psi_1^{opt}, (H_1 - E_1)\Psi_1^{opt}\rangle, \quad (25)$$

where

$$H_n = \left(\frac{\partial^n H}{\partial R^n}\right)_e;$$

the expressions for E_n and Ψ_n are analogous.

For the H_2 molecule discussed by Benston and Kirtman [46], Ψ_1 was approximated by a linear combination of derivatives of the covalent and ionic functions from which Ψ_0 was derived.

The coefficients in the expression for Ψ_1 are then determined from the condition for an energy minimum in the second approximation. The results of the calculations agree well with experiment; for example, the Weinbaum function gives $K_{\alpha\beta} = 0.362$ a.u. and $K_{\alpha\beta\gamma} = -1.43$ a.u., while the experimental values are $K_{\alpha\beta} = 0.368$ a.u. and $K_{\alpha\beta\gamma} = -1.30$ a.u.

In general the different forms of Eqn. (24) obtained depending on the coordinate system chosen for the wave function are not readily susceptible to a quantitative analysis but they may be useful (as well as the expressions obtained from the analytical methods discussed above) for the understanding of the nature of the intramolecular forces. For example, Bader [76] employed such expressions for a qualitative physical interpretation of non-diagonal bond-interaction force constants in the potential function for polyatomic molecules (linear and non-linear triatomic and also pyramidal and planar tetra-atomic molecules), in particular in order to predict their magnitude and sign. It was found that both the magnitude and the sign of such constants are determined largely by the second term in Eqn. (24). It has been shown [75] for diatomic molecules that the first term of Eqn. (24) is largely responsible for the variation of $K_{\alpha\beta}$ in a series of isoelectronic molecules and the second changes steadily from one group of elements with identical nuclei to another, which permits the prediction of the direction of change in the force constant and is fully consistent with the above physical interpretation of the terms of Eqn. (24). Attention should be drawn to the fact that unfortunately very few studies dealing with the solution of this problem have been published in the Soviet literature.

One of the first studies on the application of analytical methods is that of Kovner and Tsimring [78] dealing with the determination of the harmonic force constants of the methane molecule. The idea of the one-centre approximation found an interesting development in investigations carried out in Veselov's laboratory. Thus, using the LCAO-MO method on the basis of a two-centre basis set, Bulychev [79] obtained the force constant for the stretching of the C ≡ C bond in acetylene, in good agreement with experiment; we believe that the force constant for the stretching of the C–H bond calculated by Bulychev is in good qualitative agreement with experiment and evidently the agreement can be improved by extending the basis set.

Adamov and Bulychev [80] carried out an improved calculation of the total energy of the H_2 molecule on the basis of the Weinbaum function corresponding to the superposition of covalent and ionic states; their analysis [80] of the potential curve made it possible to obtain spectroscopic constants in satisfactory agreement with the available data.

In conclusion we wish to express the hope that in the near future the above gap will be filled and that the numerical and analytical methods described here will permit the determination of the relative and absolute values of the potential constants, which will undoubtedly prove useful for the understanding of the nature of the forces between atoms in the molecule and also for the solution of spectrochemical problems.

The Structure of Aqueous Non-electrolyte Solutions (Comparative Analysis of the Thermodynamic Properties of Aqueous and Non-aqueous Binary Systems)

Yu.I.Naberukhin and V.A.Rogov

A comparison of the thermodynamic properties of a large number of aqueous and alcoholic binary systems has established that the following properties are characteristic only of aqueous solutions: (1) negative enthalpies and entropies of mixing at low non-electrolyte concentrations; (2) negative partial molar entropies and enthalpies of water at moderate concentrations. The first property is evidence of the stabilisation of the water structure when the vacancies are filled. The second implies that the solution has a microheterogeneous structure owing to the presence in it of ordered regions (globules). The problem of the nature of the globules and their cooperative properties is discussed.
The bibliography includes 49 references.

3 Moderate concentrations 211

1. INTRODUCTION

Concepts have recently developed as to the nature of the changes in the structure of water under the influence of a non-electrolyte dissolved in it. They reduce to the assertion that, when the vacancies in the water skeleton are filled by a non-electrolyte, the water structure is stabilised. This view explains various effects arising when small amounts of non-electrolytes are dissolved in water: the decrease of the self-diffusion coefficient, compressibility, and ion hydration and the increase of viscosity[1-5]. The filling of the vacancies in the water structure also accounts for the minima in the partial molar volumes of the non-electrolytes[6] and the anomalous variation of the solubility of gases[7,8] and certain other sparingly soluble substances[9].

Despite the abundance of studies and available data, we believe it useful to attempt to approach the problem of stabilisation from a purely thermodynamic standpoint without invoking beforehand any specific models of the water structure. Although the thermodynamic properties of aqueous non-electrolyte solutions have been discussed by Morachevskii[10,11] and Franks[12,13], we believe that one can proceed somewhat further by comparative analysis of the properties of aqueous and alcoholic binary systems. Only such analysis will make it possible to isolate the properties characteristic of aqueous solutions and justify the necessity for hypotheses concerning the collective interactions in aqueous systems. Using the method of comparative analysis, we shall also discuss, apart from stabilisation, the characteristics of the behaviour of aqueous solutions in the microheterogeneous region

(moderate concentrations of the non-electrolyte). In view of the inadequate treatment of this problem in the literature, here we will go beyond the framework of the thermodynamic description and will put forward a molecular mechanism for the phenomenon.

Sufficient experimental data have now been published to make such comparative analysis possible. However, it should be noted that, in the interpretation of the results obtained, most workers employ excess thermodynamic functions (with the usual notation H^E, S^E, and G^E) and not the functions of mixing (H^M, S^M, and G^M). We believe that such an approach is useful only when the system deviates little from ideal behaviour. For the alcoholic and aqueous solutions discussed below, this is known not to be the case. Here it is simpler to interpret directly the functions of mixing. Moreover, these functions can be used to assess the tendency of the solutions to form separate phases. In the present study we will therefore employ exclusively the thermodynamic functions of mixing.

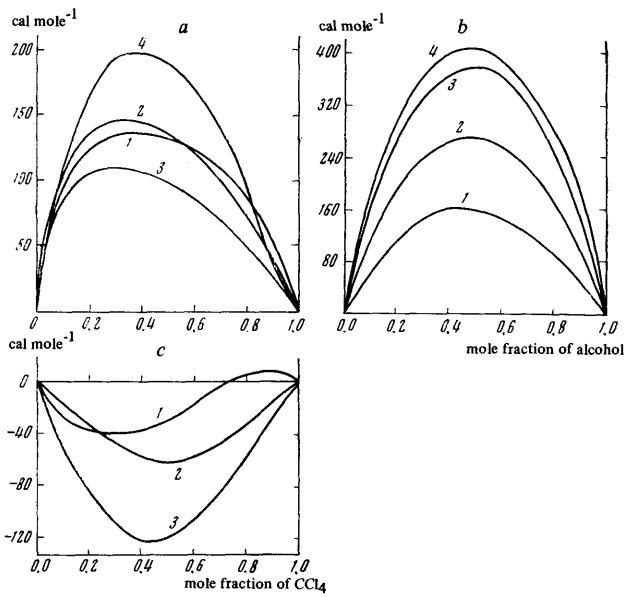

Figure 1. Enthalpy of mixing at 25°C for various systems: *a*) 1) ethyl alcohol–n-hexane; 2) n-propyl alcohol–n-hexane; 3) n-octyl alcohol–n-hexane; 4) isopropyl alcohol–n-hexane[14,15]; *b*): 1) methyl alcohol–acetone; 2) ethyl alcohol–acetone; 3) isopropyl alcohol–acetone; 4) s-butyl alcohol–ethyl methyl ketone[14,16]; *c*): 1) pyridine–carbon tetrachloride; 2) dioxan–carbon tetrachloride; 3) 3,5-dimethylpyridine–carbon tetrachloride[17,18].

2. LOW NON-ELECTROLYTE CONCENTRATIONS

The nature of the phenomena occurring in aqueous solutions at low (up to a mole fraction of 0.1) and moderate non-electrolyte concentrations is significantly different. Therefore in a comparative analysis of aqueous and alcoholic systems it is desirable to consider these two concentration ranges separately.

a. Enthalpy and Entropy of Mixing in Alcoholic Systems

At first sight it appears that the addition of any non-polar liquid to lower alcohols should lead to positive enthalpies of mixing H^M, since dilution of an associated liquid leads to the dissociation of some of the hydrogen bonds. This view is justified for systems of the alcohol–hydrocarbon type (Figs. 1*a* and 2) and also for systems of the alcohol–ketone type (Fig. 1*b*), although one cannot exclude *a priori* the possibility that hydrogen bonds are formed between alcohols and ketones. For this reason, the finding that the mixing of lower alcohols with carbon tetrachloride, a classical inert solvent, at fairly low temperatures leads to negative values of H^M, indicating a powerful interaction between the alcohol and carbon tetrachloride (Fig. 3), is all the more surprising. This increase of H^M cannot be accounted for by the interaction of carbon tetrachloride with the hydrocarbon "tail" of the alcohol, since, first, on passing to higher alcohols, H^M increases and becomes positive (Figs. 3*a* and 3*b*) and, secondly, H^M for the mixing of hydrocarbons with carbon tetrachloride is positive[23]. The increase due to the van der Waals interaction between carbon tetrachloride and the proton of the OH group is evidently also impossible, since the replacement of a strong hydrogen bond by a van der Waals interaction cannot lead to an energy gain.

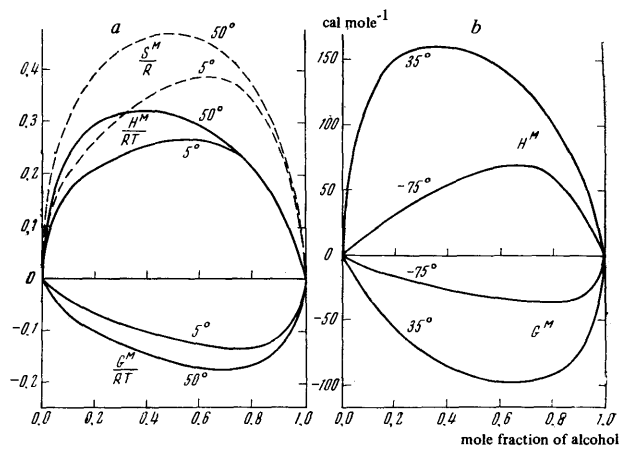

Figure 2. Thermodynamic functions of mixing for various systems:
a) ethyl alcohol–cyclohexane[19]; *b*) ethyl alcohol–methylcyclohexane[20].

Thus only one explanation remains: the increase of H^M at low carbon tetrachloride concentrations in alcohol is due to powerful van der Waals interactions between carbon tetrachloride molecules and the *p*-orbitals of the alcohol oxygen atoms not involved in hydrogen bonding. Each alcohol molecule has two possibilities of forming a hydrogen bond via oxygen and only one via hydrogen. Thus even in a completely self-associated alcohol each of its molecules retains on average one possibility of forming an additional hydrogen bond. Since hydrogen bonds in alcohols do not form a three-dimensional network but lead to

chain or ring structures[24-27], the carbon tetrachloride molecule can come into contact with the oxygen atom of the alcohol without affecting the hydrogen bond. The validity of this explanation is confirmed by the negative value of H^M in dioxan–carbon tetrachloride and pyridine–carbon tetrachloride systems (Fig. 1*c*). On the other hand, the large increase of H^M in the methanol–chloroform system (Fig. 4*a*), due to the formation of a hydrogen bond between chloroform and the alcohol, is evidence of the absence of steric hindrance to van der Waals interaction between carbon tetrachloride and the oxygen atom of the alcohol. Another system where an increase of H^M is observed below −50°C is ethanol–toluene (Fig. 5*a*). Probably this effect can also be accounted for by ready van der Waals interaction between the benzene ring and the oxygen atom.

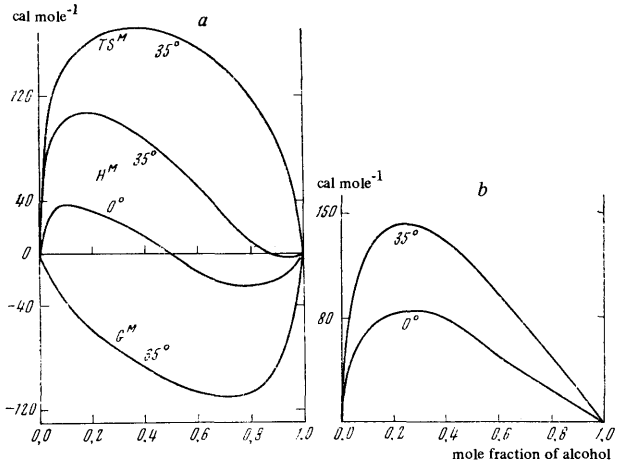

Figure 3. *a*) Thermodynamic functions of mixing for the methyl alcohol–carbon tetrachloride system[21,22]; *b*) enthalpy of mixing in the n-octyl alcohol–carbon tetrachloride system[22].

The above data allow the following conclusions to be drawn: the sign and magnitude of H^M in alcoholic systems can be various and are determined by the characteristics of the interaction of the alcohol with the second component in each specific case. In contrast to the enthalpy, the entropy of mixing in all the systems considered shows the same behaviour and is positive †.

b. Entropy and Enthalpy of Mixing in Aqueous Solutions

Fig. 5*b* and Figs. 6–11 present the heats of mixing for various binary aqueous systems. A characteristic feature of all these curves is the negative sign of H^M at low concentrations of the second component (and at sufficiently low temperatures). Moreover, the enthalpy of mixing is negative also for the dissolution in water of aliphatic and aromatic hydrocarbons and even the inert gases[35,36]. Thus one may assert that the dissolution in water of the majority of non-electrolytes takes place with evolution of heat. This behaviour is an important property of aqueous systems and sharply distinguishes them from the alcoholic solutions discussed above.

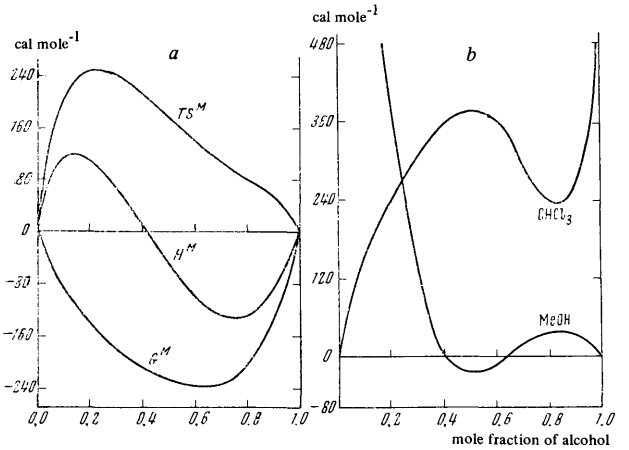

Figure 4. The methyl alcohol–chloroform system at 35°C: *a*) thermodynamic functions of mixing[21]; *b*) partial entropies $T\bar{S}_i^M$ of the components.

We shall now attempt to discover the reasons for such behaviour of H^M in the specific example of the water–acetone system. If the energy gain on mixing the two liquids is regarded as the result of only the pair interactions between their molecules, the negative value of H^M can be accounted for in two ways: (1) the formation of a hydrogen bond between acetone and water; (2) powerful van der Waals interaction between acetone and water.

However, the first hypothesis must be immediately rejected. Indeed, the formation of a hydrogen bond between acetone and water is possible only at the expense of the dissociation of the stronger water–water hydrogen bond; moreover, H^M for the mixing of acetone with alcohols is positive (Fig. 1*b*) and it would be difficult to understand why acetone associates with water but not with alcohols. This explanation is also unsatisfactory because it is not universal and is not applicable, for example, to the dissolution of hydrocarbons and noble gases in water.

The second explanation, based on a powerful van der Waals interaction, requires a more detailed examination. In the first place it is necessary to resolve the difficulty mentioned above: the different signs of H^M in the dissolution of acetone in alcohols and water. The overall heat of solution of acetone consists of the energy loss resulting from the interactions between the molecules of the solvent and the energy gain from the interactions between the solvent and acetone. However, the energy differences between the water–water and alcohol–alcohol interactions are not very great; the same may be said of the alcohol–acetone and water–acetone interactions. Therefore, in order to account for the negative sign of H^M in water, it is necessary to postulate that there is no large positive

† There is no need to quote S^M curves for all the systems in support of this assertion, since the entropy of mixing cannot be negative if $H^M > 0$ (by virtue of the relation $TS^M = H^M - G^M$ and $G^M < 0$). The positive sign of S^M for systems with $H^M < 0$ is illustrated in Figs. 3*a* and 4*a*.

contribution to H^M due to water–water dissociations. We arrive at a similar conclusion by considering other aqueous solutions. Consequently this phenomenon is not caused by the properties of the non-electrolyte but the characteristics of the water structure, i.e. it is necessary to assume that water contains fairly large cavities (vacancies) which accommodate non-electrolyte molecules on dissolution.

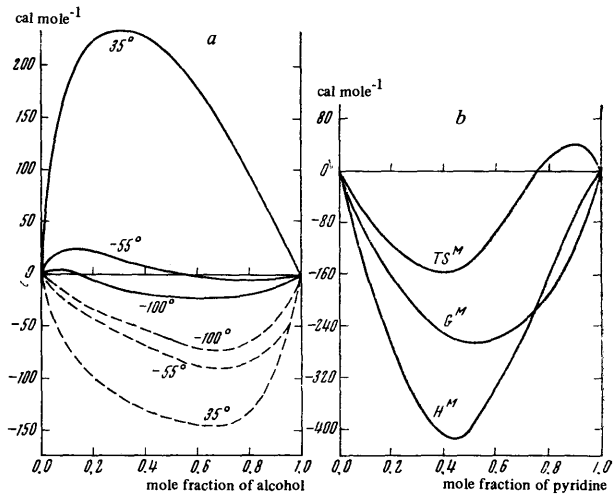

Figure 5. Thermodynamic functions of mixing for various systems:
a) ethyl alcohol–toluene[20] (continuous line—H^M; dashed line—G^M); *b*) water–pyridine at 20°C[28].

The existence of cavities, which is a distinctive feature of the structure of water, may be confirmed by considering the partial molar enthalpies of non-electrolytes on infinite dilution $\bar{H}^M_{H,O}$. In the majority of the systems examined (Figs. 5*b*, 6–9, and 11) $\bar{H}^M_{H,O}$ amounts to 1–3 kcal mole^{-1} in absolute magnitude. This exceeds by several hundred cal mole^{-1} not only the values of $\bar{H}^M_{i,O}$ observed in systems with powerful van der Waals interaction between the components [for example, carbon tetrachloride–dioxan, carbon tetrachloride–pyridine, and carbon tetrachloride–methanol (Figs. 1*c* and 3*a*)], but even the $H^M_{i,O}$ in certain systems with hydrogen bonds [for example, chloroform–dioxan[37], chloroform–acetone[38], and chloroform–methanol (Fig. 4*a*)]. Clearly such a large negative heat change could be accounted for by van der Waals interactions only if it is assumed that water–water bonds are not dissociated on mixing.

However, it is doubtful if these large heat changes are completely determined by van der Waals pair interactions. Indeed, comparison of the values of $\bar{H}^M_{H,O}$ on dissolution in water of alcohols, ketones, hydrocarbons, and the inert gases shows that the heat change is virtually independent of the polarity of the second component although a dependence would be expected for van der Waals interactions.

The inadequacy of the hypothesis of van der Waals interactions alone becomes evident when the entropy of mixing is considered. Comparison of Figs. 5*b* and 6–11 shows that S^M is as a rule negative for all aqueous systems at low concentrations of the second component and at low temperatures, while for all other liquids (see, for example, Fig. 1–4 and 5*a*) S^M is positive even if the mixing is exothermic. The negative sign of S^M is an important characteristic of aqueous solutions, which distinguishes them from other binary systems.

Nevertheless, when water and a non-electrolyte are mixed, a positive contribution to the entropy of the system appears, as for any other two liquids, owing to the interchange of molecules of water and of the second component. The van der Waals interaction between the components leads to a decrease of S^M compared with S^M_{id} but its sign still remains positive. These considerations are fully confirmed by experimental data: we are not aware of a single system without hydrogen bonds where a negative entropy of mixing is observed.

A negative contribution to entropy in the pair interaction between species can arise only if they form a complex, say via hydrogen bonding. However, we have already rejected this possibility for water–non-electrolyte systems. Therefore one must assume that the negative entropy of mixing in these systems is not caused by pair interaction between water and non-electrolyte molecules, but by collective changes in the water structure towards greater order. In such a process the enthalpy of the system should also fall ($\Delta H = \Delta G + T\Delta S < 0$) which makes a contribution to the heat change, additional to the van der Waals interactions. All these collective phenomena have come to be referred to as the stabilisation of the water structure. The energy gain on stabilisation implies that the dissolution in water of small amounts of non-electrolytes does not lead to the dissociation of some of the hydrogen bonds, as in all other highly self-associated liquids, but in fact results in the formation of a certain number of water–water hydrogen bonds or in their strengthening ‡.

Although the conclusion that the concept of stabilisation must be introduced is not based on any particular model of the water structure, it is useful to illustrate the significance of this term with reference to a specific model, for example that of Samoilov[39,40], according to which water consists of molecules forming an ice-like framework blurred by thermal motion and of molecules partially filling the vacancies in the framework. When a non-electrolyte is added to water, it enters the cavities within the framework (without dissociating the hydrogen bonds or disrupting the van der Waals water–water interactions) and displaces some of the "cavity" water molecules to the framework, since by filling part of the cavities it displaces the dynamic equilibrium between the "cavity" and "framework" water molecules[41]. Since this involves the formation of new water–water hydrogen bonds, the enthalpy of mixing should be negative. On the other hand, the transfer of some water molecules to the more ordered phase (the framework) leads to a negative entropy of mixing.

The water–pyridine system requires special consideration. Although here too negative values of S^M are observed (Fig. 5*b*), they cover an unduly wide concentration range. One cannot postulate that the effect associated

‡ The effects associated with stabilisation should evidently decrease with temperature owing to the breakdown of the water structure. This is in fact observed (Figs. 7 and 9).

with stabilisation can be observed up to a pyridine concentration of 50 mole %, where the water structure is certainly disrupted. Probably the explanation of the negative values of S^M for this system consists in the fact that pyridine forms very strong hydrogen bonds with water. Indeed, H^M for this system is high and negative over the entire pyridine concentration range. This explanation is also confirmed by vibrational spectra [42,43]. Probably the behaviour of thermodynamic functions in the water–dimethyl sulphoxide [44,45] and water–diethylformamide systems [46] should be explained similarly.

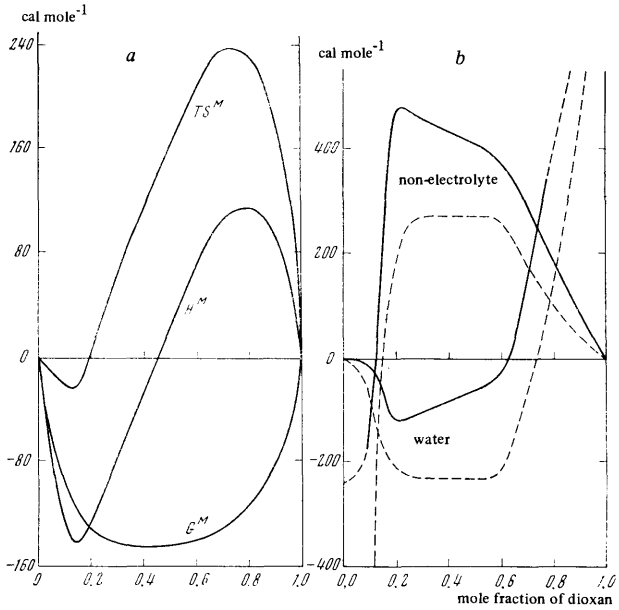

Figure 6. The water–dioxan system at 25°C; *a*) thermodynamic functions of mixing [29]; *b*) partial entropies $T\overline{S}_i^M$ (continuous line) and enthalpies $\overline{H}_i^M$ (dashed line) of the components.

The stabilising effect of the non-electrolyte entering the cavities in the water structure should be reduced with increase of the non-electrolyte concentration. This accounts for the characteristic S shape of the plots of S^M and H^M in aqueous systems against concentration: the negative contributions to S^M and H^M owing to stabilisation are replaced at high non-electrolyte concentrations by positive contributions from the dissociation of water–water hydrogen bonds. It would be extremely interesting to establish the concentration corresponding to maximum stabilisation or, what amounts to the same thing, to the optimum filling of the cavities. The minima in H^M, S^M, or the excess partial volume $\overline{V}_H^E$ are usually compared with this concentration. However, there is a difficulty here. If the stabilising effect of the non-electrolyte and the disruption of the structure are described by fairly smooth concentration functions, the extrema in H^M, S^M, and $\overline{V}_H^E$ need not coincide, since they are a consequence of the superposition of different functions varying in the opposite sense. Then the significance of the term "maximum stabilisation" becomes extremely indefinite. This situation in fact obtains. For example in the water–dioxan system at 25°C a minimum in the excess partial volume of dioxan is observed at a non-electrolyte mole fraction of 0.04, [47] while the minima in H^M and S^M occur at mole fractions of 0.13 and 0.12 respectively (Fig. 6*a*). The extrema in all the functions should coincide only when the stabilisation varies sharply with concentration, for example, when one can speak of the exact instant when the cavities are filled. However, in such a case it would be necessary to seek additional explanations of the observed differences in the positions of the extrema. This dilemma cannot be resolved solely on the basis of thermodynamic data. The first view appears more prudent. Having adopted it, one can assume that the stabilising effect of the non-electrolyte hardly extends beyond concentrations where its mole fraction is 0.10–0.15.

Summarising the above discussion, one may assert that (1) at low non-electrolyte concentrations aqueous solutions exhibit unique properties, which consist in the fact that, regardless of the nature of the second component, the entropy and enthalpy of mixing are negative and (2) these facts provide evidence of a collective stabilisation of the hydrogen bond lattice on addition of a non-electrolyte to water due to an increase in the energy of the hydrogen bonds or in their number.

3. MODERATE CONCENTRATIONS

We shall now consider the behaviour of the thermodynamic functions of mixing for non-electrolyte concentrations corresponding to a mole fraction of 0.2 and above, i.e. in the region where the water structure is disrupted. In the first place we must note that the G^M–concentration curve has sections with low curvature, which are particularly distinct in the water–dioxan system for dioxan mole fractions in the range 0.25–0.6 (Fig. 6*a*). These indicate that the system tends to form two layers, i.e. microheterogeneity of the structure of the solution. Such behaviour of G^M is not in itself an exclusive characteristic of aqueous mixtures, since sections with low curvature on G^M–x curves are encountered fairly frequently in binary systems with positive deviations from ideality (see, for example, Figs. 2, 3*a*, 4*a*, and 5*a*). The particular properties of aqueous solutions are shown in the unusual behaviour of the partial enthalpies and entropies of mixing in the region of microheterogeneity, namely (1) in all systems (with the exception of water–methanol mixtures) $\overline{H}^M_{water}$ and $\overline{S}^M_{water}$ are negative over a considerable concentration range at not unduly high temperatures (see Fig. 6*b*; similar behaviour follows from Figs. 5*b* and 6–11) and (2) in a series of aqueous systems there is a rigorously linear relation between H^M and concentration with corresponding horizontal sections in H_i^M–x curves (Figs. 6, 7*a*, and 9*b*)§.

The first characteristic is indeed an exclusive property of aqueous solutions. In all the non-aqueous systems examined, the partial molar entropies of mixing of both components always proved to be positive. We succeeded in finding only one system which is an exception to this rule, namely methanol–chloroform (Fig. 4*b*).

§ The linearity of the H^M–x relation has been established very reliably. Thus in the water–dioxan system 7 experimental points lie on a straight line [29] and in the system water–t-butyl alcohol 5 points [32].

Here, the negative values of $\bar{H}^{M}_{meth}$ and $\bar{S}^{M}_{meth}$ can evidently be explained by the formation of hydrogen bonds between methanol and chloroform, which can occur without the dissociation of alcohol–alcohol hydrogen bonds, i.e. the reason for the anomalous behaviour of the thermodynamic functions for this system consists in the unusual nature of the proton donor–acceptor properties of the alcohol, to which attention has already been drawn in the first section of the review. Thus the negative partial entropy of mixing is typical only for aqueous systems and therefore must be associated with the characteristics of the water structure.

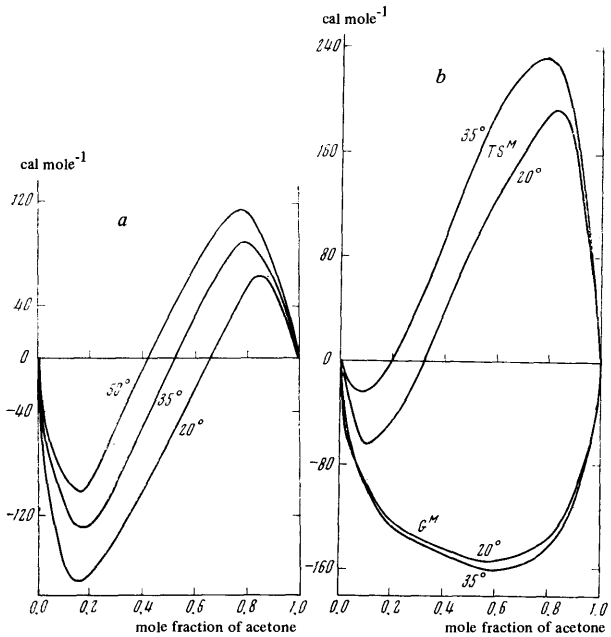

Figure 7. The water–acetone system: *a*) enthalpies of mixing[30]; *b*) entropies and free energies of mixing[31].

The retention of the negative sign of H^{M}_{water} and S^{M}_{water} over a wide range of concentrations, up to a non-electrolyte mole fraction of 0.7, is evidence of the existence in solution at these concentrations of regions where water molecules exhibit a fairly high degree of order. Indeed, by definition, the partial molar entropy of water is the entropy of mixing of a large volume of solution at a given concentration with one mole of water. If the solution is a homogeneous mixture of association complexes of water and the non-electrolyte, the degree of order in water should decrease when it is added to the solution, since water–non-electrolyte complexes are weaker than water–water complexes. Contrary to experiment, this leads to positive values of $\bar{H}^{M}_{water}$ and $\bar{S}^{M}_{water}$. Consequently we are obliged to attribute to this solution a microheterogeneous structure which contains regions (globules) where water exists in an even more ordered state than in pure water. When the added water enters these regions, negative values of $\bar{S}^{M}_{water}$ and $\bar{H}^{M}_{water}$ are in fact obtained. However, in a heterogeneous system of this kind there is another possible mechanism leading to the negative signs of $\bar{S}^{M}_{water}$ and $\bar{H}^{M}_{water}$: the added water can displace the equilibrium between the globules and the disordered phase towards the former. Therefore the assertion that globules are more ordered than pure water is not justified.

We must emphasise that the conclusion that ordered regions (globules) exist in aqueous solution is a fact. It follows logically from two factors: (1) the negative sign of $\bar{S}^{M}_{water}$ and $\bar{H}^{M}_{water}$ and (2) the assertion that water–non-electrolyte association complexes are less stable than the water–water complexes. The first is an experimental fact in the systems investigated; the validity of the second follows from the endothermic heat of solution of water in pure electrolytes (n-propyl alcohol, t-butyl alcohol, acetone, and dioxan) and has also been demonstrated spectroscopically for the case where the non-electrolyte is acetone or dioxan[42,43]. According to this reasoning, we are not justified in assuming that the globules are present in the water–pyridine system, where the second factor does not apply[42,43], and in alcohol–non-electrolyte systems, where the first factor does not hold.

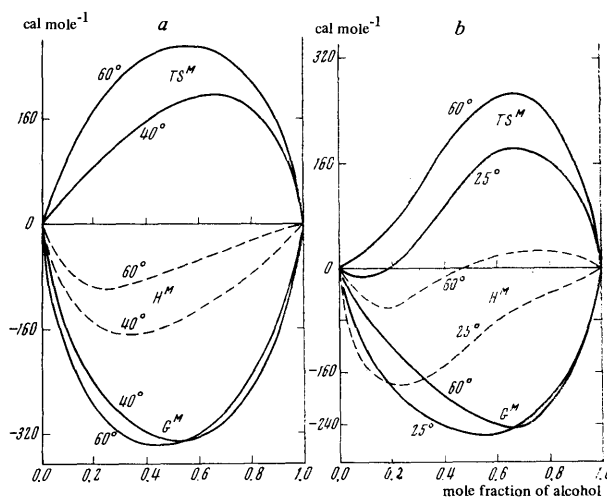

Figure 8. Thermodynamic functions of mixing for t-butyl alcohol systems[32].

We shall now examine the nature of the ordered globules in aqueous solutions. Here we cannot afford to remain at the factual level and must proceed to hypothetical considerations. The following situation is extremely probable. We have seen that a small amount of non-electrolyte leads to definite changes in the water structure, which entails a gain in stabilisation energy as a result of the collective interactions of water molecules. When the electrolyte begins to disrupt water–water hydrogen bonds after filling the cavities, a continuous disintegration of their three-dimensional lattice proves to be more difficult than the fragmentation of the water structure into fairly large structured regions in which collective stabilisation is still possible. In other words, at moderate concentrations the electrolyte can be more readily accommodated in the

interstices between the globules. Then a kind of separation into different phases takes place in the solution: into the "phase" of structured water which contains also a small amount of non-electrolyte (for example in the cavities within the structure) and a disordered "phase" consisting of non-electrolyte molecules and individual water molecules associated with them. We shall refer to such separation into microphases as microlayer formation.

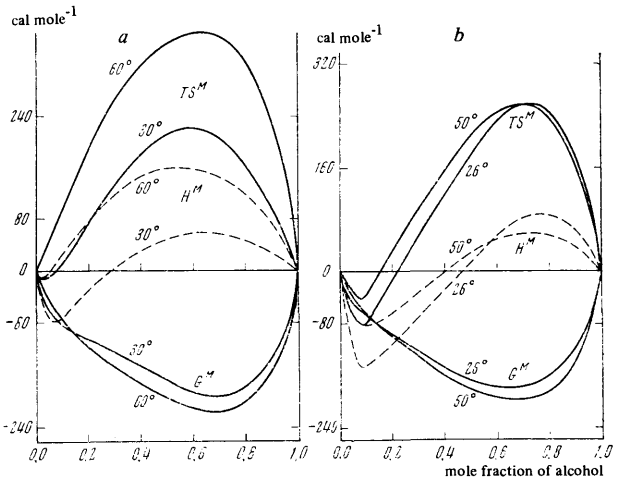

Figure 9. Thermodynamic functions of mixing for various systems:
a) n-propyl alcohol–water [10]; *b*) t-butyl alcohol–water [32].

It is important to emphasise yet again that the reason for the formation of globules is the energy gain due to the collective interactions of water molecules and made possible by the particular structure of the globules¶. The presence of stabilisation energy implies that the globules are thermodynamically stable species and cannot be regarded as fluctuations. Therefore the microlayer formation described here is a very special case of the tendency of solutions to form separate phases, which is usually understood as resulting from the development of concentrations fluctuations.

We shall now attempt to explain the significance of the second characteristic of the behaviour of the thermodynamic functions of mixing of aqueous systems in the region of microlayer formation. The constancy of the partial enthalpies can be most simply accounted for if it is assumed that the non-electrolyte (or water) added to the system always enters an identical molecular environment, which happens, for example, in true phase separation. In the case of microlayer formation, this condition will be fulfilled if the composition of the microphases (globules and disordered regions of the solution) remains constant in the concentration range considered. The composition of the microphases should then correspond to the boundary points of the linear section in the H^M plot. For example, in the water–dioxan system the microphases have the composition (in mole fractions) 0.25 dioxan + 0.75 water and 0.6 dioxan + 0.4 water.

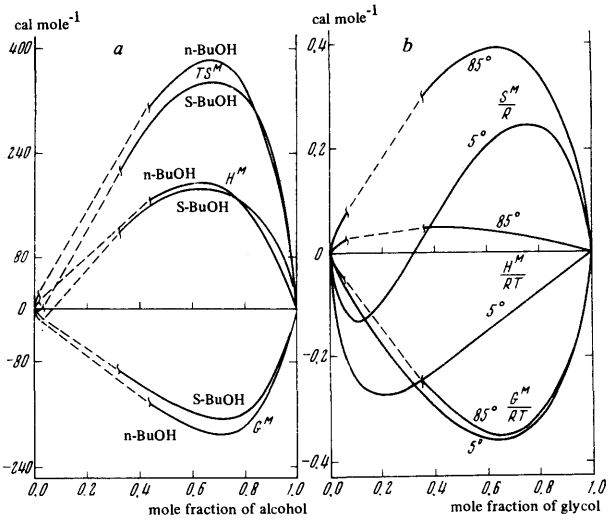

Figure 10. Thermodynamic functions of mixing for various systems:
a) n-butyl alcohol–water and s-butyl alcohol–water at 60°C [10] (dashed line—layer formation region); *b*) water–butane glycol [33].

However, the constancy of the composition of the microphases in microlayer formation is not yet sufficient to ensure the linearity of the variation of H^M. In addition, one must assume that, when the concentration of the solution changes, the dimensions of the globules remain constant and only their number changes. Indeed the enthalpy of the system considered consists of three terms: (1) the enthalpy of the molecules in the disordered phase; (2) the enthalpy of the molecules in the globules; (3) the enthalpy of the interaction of these two "phases". If it is assumed that the dimensions of the globules change, the last two terms will not vary linearly with concentration and special hypotheses are necessary to ensure the linearity of their sum. At the same time the constancy of the dimensions of the globules automatically entails the linearity of the $H^M - x$ relation. Such constancy does not appear strange if account is taken of the above hypothesis that the microphases have constant composition. It therefore follows that, when the concentration of the solution is altered, the molecular environment of the globule remains unchanged. Only the distances between the globules alter, and this should not affect their dimensions.

It is also possible to account for the constancy of the composition of the microphases. The constancy of the composition of the globule is associated with the limited number of the cavities in it. On the other hand, the constancy of the composition of the second "phase" is ensured by the fact that, when the concentration of water in it exceeds a certain critical value, a new globule separates.

¶ We shall not specify the mechanism of the collective interaction. Frank [48,49], who was the first to introduce the hypothesis of the globules (in pure water), believed that this involved the mutual polarisation of water molecules, leading to a strengthening of the hydrogen bonds.

This becomes understandable if we recall that the dimensions of the globules remain constant in the region of microlayer formation, i.e. the globule decomposition processes and hence the globule formation processes are cooperative.

The suggested hypothetical mechanism explains in a natural manner why microlayer formation is revealed more clearly by H^M than by G^M: the curvature in the plot of G^M arises from the entropy of mixing, which contains a non-linear contribution from the exchange of the microphases. This factor makes it possible to estimate roughly the number of molecules in the globule. It it is assumed that the dimensions of both microphases are equal, the maximum energy of their exchange is S_{id}/ν, where S_{id} is the maximum entropy of mixing of the ideal solution and ν is the number of molecules in the globule. This quantity must be set equal to the maximum deviation of the S^M-x relation (or, what amounts to the same thing, the $G^M/T-x$ relation) from linearity in the region of microlayer formation. For the three systems water–dioxan, water–acetone, and water–t-butyl alcohol, ν is approximately 40–80 molecules.

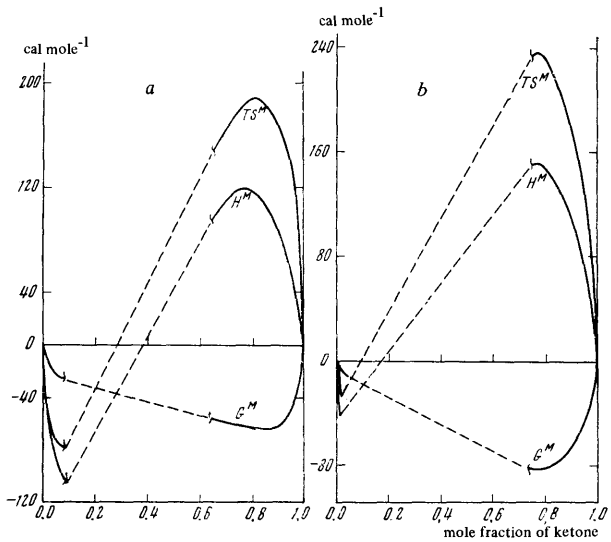

Figure 11. Thermodynamic functions of mixing for various systems:
a) water–ethyl methyl ketone at 20°C [34]; *b*) water–cyclohexanone at 20°C [34] (dashed line–layer formation region).

The experimental finding that the excess volume of the solution V^E is not a linear function of concentration in the region of microlayer formation [47] (in contrast to true phase separation) is also consistent with our microlayer formation model. The point is that the free volume in the packing of particles of different kinds makes a significant contribution to V^E. It is reasonable to suppose that the free volume in the packing of two different microphases in aqueous solution differs from the free volume in the packing of water and non-electrolyte molecules. This in fact leads to the non-linearity of the V^E-x relation.

Thus, at moderate concentrations aqueous solutions also show unusual properties, which must be attributed to the presence in the solution of regions with a high degree of order (globules). Globules probably arise from the mutual stabilisation of water molecules and probably possess (over a concentration range) cooperative properties.

Correlation Equations in Free-radical Reactions

I.B.Afanas'ev

This review deals with the methods of correlation analysis which have been applied to studies of the kinetics of free-radical reactions. It discusses the use of the Hammett and the Taft equation, of the Alfrey-Price scheme, of the Bamford equation, and also the correlations with quantum-mechanical parameters and various additive empirical methods. Polar and resonance effects in free-radical reactions are quantitatively separated by a two-parameter scheme based on the Taft equation. The relationship between the structure of the transition state and the reactivity of the free radicals is considered. 265 references.

I. INTRODUCTION

The basic factors which determine the reactivity of free radicals towards compounds able to react with them (substrates) have already been identified. They include the polar, the resonance, and the steric effect, the dissociation energy of the bond, the type of hybridisation of the atom to which the unpaired electron is attached, etc. In general, these parameters are not mutually independent, and therefore the problems consist not so much in allowing for all the factors which may affect the reactivity of the free radical as in choosing the smallest number of such parameters which are mutually independent or approximately so.

Unfortunately, there is as yet no way of expressing the reactivity of a free radical in terms of even the three basic reaction effects (polar, resonance, and steric). Existing correlation equations apply to specific cases in which one or two of the basic effects are predominant. In the following Sections we shall discuss the correlation equations proposed by various authors for a quantitative description of the reactivity of radicals and substrates, and we shall attempt to apply the two-parameter correlation scheme to free-radical reactions.

II. CORRELATION WITH KINETIC AND THERMODYNAMIC PARAMETERS

1. The Hammett Equation

The Hammett equation - the most widely used correlation equation - was originally applied only to heterolytic reactions. This empirical relationship gives the ratio of the rate (or equilibrium) constants for the reactions of unsubstituted or substituted benzene derivatives in terms of constants[1] of the *para*- and *meta*-substituents (σ):

$$\lg \frac{k_{sub}}{k_0} = \rho\sigma \qquad (1)$$

where ρ is a proportionality constant. The values of σ were obtained by Hammett by comparing the dissociation constants of substituted benzoic acids. The σ constants are usually believed to characterise the polar effect of the substituent, transmitted through the σ-bond system (inductive component) and through the π-bond system (resonance component). Taft has shown[2] that when resonance involving the benzene ring can occur between the substituent and the reactive centre the Hammett σ_p and σ_m values must be corrected, or alternatively an equation of the type

$$\lg \frac{k_{sub}}{k_0} = \rho + \psi$$

must be used, where Ψ is a parameter which characterises the resonance effect, even though the use of Hammett's σ parameter as a purely polar parameter is no longer justified.

Unfortunately, in radical reactions such as the abstraction of hydrogen from ring-substituted toluenes we can expect the substituents to show an additional resonance effect, due to delocalisation of the unpaired electron in the resulting free radical:

(3)

Brown and Okamoto[3] have proposed a different set of constants for the substituents, based on their study of the rates of hydrolysis of substituted cumyl chlorides (denoted σ^+). Since tertiary carbonium ions are formed as intermediates in these reactions, the contribution of the resonance effect to σ^+ is much larger than with the normal (σ) Hammett constants. Therefore the σ^+ scale may prove very useful in studies of free-radical reactions.

a. *Application to free-radical substitution reactions*

During the 1950's it was shown that the Hammett equation is applicable (in principle) to free-radical reactions such as the abstraction of hydrogen from toluenes by bromine[4] and chlorine[5,6] atoms, the reactions of peroxide

radicals with cumene derivatives[7], radical copolymerisation reactions[8], etc. (However, most of this work is now only of historical interest, because our understanding of reaction mechanisms has become much more precise since the advent of such analytical techniques as gas–liquid chromatography and NMR spectroscopy.) Shortly after the publication of Brown and Okamoto's paper[3], Russell[9] proposed a comparison of the correlations σ and σ^+ in the study of the transition-state structure in free-radical substitution reactions of the type

$$R^{\cdot} + R'X \rightarrow RX + R''. \qquad (4)$$

According to Russell, the transition state of these reactions can be treated as the sum of two basic structures:

$$\underset{(I)}{[R^{\cdot}X:R']} \rightleftarrows \underset{(II)}{[R^{\delta-}:X^{\delta+}R']}.$$

If the radical R$^{\cdot}$ has a high reactivity, the structure of the transition state should be (by Hammond's postulate[10]) similar to that of the reactants, i.e. the contribution of structure (I) should predominate. Conversely, in the reactions of low-activity free radicals the transition state should be similar to structure (II), since the passage of these systems over the energy barrier corresponds essentially to a weakening of the R′–X bond and therefore the structure of the transition state is similar to that of the products. Hence the rate constants of active radicals should show a better correlation with the σ parameters (since the resonance effect of R′ in structure (I) is negligible), and the rate constants of relatively inactive radicals should correlate better with σ^+ (since R′ in structure (II) has an unpaired electron, and the resonance in it should be approximately the same as in the free radical).

Hammett's equation has been used mostly in studies of free-radical substitution reactions (Table 1). As the Table shows, most of the publications deal with reactions in which hydrogen is abstracted from toluene derivatives, but Hammett's equation has been used also in studies of hydrogen abstraction from derivatives of ethylbenzene, cumene, allylbenzene, benzyl ethers, benzaldehyde, t-butylbenzene, phenols, neopentylbenzene, anisole, diphenylmethane, thiophenol and aniline, and also reactions in which iodine and chlorine are abstracted from derivatives of iodobenzene and benzenesulphonyl chloride.

Russell's hypothesis has been tested on many reactions. In 1963 Howard and Ingold[55] concluded, from a critical analysis of existing data, that for the vast majority of reactions (including those involving active radicals such as Cl$^{\cdot}$ and $(CH_3)_3CO^{\cdot}$) a more precise correlation is obtained with the σ^+ constants. However, subsequent work has produced many examples of reactions in which correlation with the σ constants is better than with σ^+ (see Table 1).

The numerical value of the proportionality constant ρ in Hammett's equation depends mainly on the structure of the transition state and on the polarity of the free radical. The effect of substituents in the substrate molecule can be expected to be smaller with structure (I) than with structure (II): in other words, ρ should decrease on going from (II) to (I) if all other factors are the same. On the other hand, any increase in the electronegativity of the free radical should increase the rate of reaction with compounds possessing electron-donating substituents. As Table 1 shows, $\rho \leqslant 0$ for all hydrogen abstraction reactions. Since in Hammett's scale the constants for electron-donor substituents are negative and those for electron-acceptor substituents are positive[1,2], it follows that all the radicals examined either show electrophilic properties in these reactions or (as in the case of $CH_3^{\cdot}$) they do not show a polar effect. However, CuCl and $C_6H_5^{\cdot}$ behave as nucleophiles ($\rho > 0$) in halogen abstraction reactions[61,62]. In keeping with this point of view, a qualitative dependence of ρ on the electronegativity of the free radicals is often observed. For example, the absolute value of ρ increases in the series $CH_3^{\cdot} < C_6H_5^{\cdot} < HOOCCH_2^{\cdot} < CCl_3^{\cdot}, Br^{\cdot}$, i.e. in the same sense as the electronegativity of these radicals. However, the dependence is not universal, since the value of ρ is determined by two factors (see above). Thus, $|\rho_{Cl}| < |\rho_{Br}|$, in spite of the fact that chlorine is more electronegative than bromine.

Table 1. Application of Hammett's equation to free-radical substitution reactions.

a) Correlation with σ. b) Correlation with σ^+. c) Correlation coefficient. d) Correlation with σ^0 [16]; p-NO_2 and p-CN showed large discrepancies and were not used in the calculation. e) Correlation with σ worse than with σ^+. f) p-$(CH_3)_3CO$ and p-C_6H_5O not included in the correlation. In the determination of the rate constants for hydrogen abstraction these constants had been assumed independent of the structure of X in $X-C_6H_4C(CH_3)_2OO^\cdot$, but this assumption is incorrect[37]. g) p-CH_3O not included in the correlation. h) m-NO_2 not included in the correlation. i) These values are approximate, due to the side reaction $XC_6H_4O^\cdot + HOC_6H_4Y \rightarrow XC_6H_4OH + {}^\cdot OC_6H_4Y$. j) Correlation satisfactory only for *meta*-substituents. k) Recalculated by Harvey et al.[49] 1) Oxidation of decalin. m) Oxidation of styrene. Earlier results, which were later disproved or to which substantial corrections had to be applied, are not considered in Table 1.

An accurate determination of the value of ρ can help to establish the reaction mechanism. In 1953 Kooyman and coworkers[4] suggested that succinimidyl is formed in the reactions between bromosuccinimide and hydrocarbons, and acts as a chain carrier. They based their suggestion on the fact that the value of ρ in the Hammett equation for the bromination of substituted toluenes by bromosuccinimide was found to be −1.55, i.e. significantly different from the value −0.97 which applies to bromination by molecular bromine. On the other hand, later work showed[22-24] that the parameter ρ does not depend on the structure of the organic part of the *N*-bromoimide, and furthermore that the same value of ρ is obtained for bromination with an excess of molecular bromine. This observation suggests that the chain-propagating radical in bromination reactions with *N*-bromoimides is a bromine atom:

$$Br^\cdot + RH \rightarrow HBr + R^\cdot, \quad (5)$$

$$R^\cdot + Br_2 \rightarrow RBr + Br^\cdot, \quad (6)$$

$$HBr + \text{ } \rightarrow \text{  } + Br_2. \quad (7)$$

The lower value of ρ found by Kooyman and coworkers for reactions with molecular bromine is ascribed to the

fact that reaction (5) is reversible in the absence of excess bromine.

In 1967, the mechanism of the reaction between t-butyl hypochlorite and aromatic hydrocarbons was re-examined[29] in a similar way, because the value of ρ in reactions between substituted toluenes and $(CH_3)_3CO^{\cdot}$ radicals formed by the decomposition of di(t-butyl)peroxyoxalate was much lower than in reactions with t-butyl hypochlorite[25-28] (see Table 1). It follows that the chains are propagated mainly by chlorine atoms in the reactions with t-butyl hypochlorite. This conclusion was subsequently confirmed by Walling and McGuiness[30].

On going to more reactive substrates the absolute value of ρ decreases, as is to be expected from an increased contribution of structure (I) (see p. 218) to the transition state of the reaction†. Therefore, the reactions of $Br^{\cdot}$ and $CCl_3^{\cdot}$ with derivatives of cumene, diphenylmethane, and benzaldehyde show a better correlation with ρ than with ρ^+ [40,41,46-48].

Recently, Japanese workers have used a two-parameter Hammett equation containing the resonance constant E_R in their studies of various chain carriers—substituted cumenes in the polymerisation of styrene, *p*-chlorostyrene, *p*-methoxystyrene, methyl methacrylate[63-65,70] and substituted toluenes, benzaldehydes, and aliphatic–aromatic ketones in the polymerisation of styrene and methyl methacrylate[66-69]:

$$\lg \frac{k_{sub}}{k_0} = \rho\sigma + \gamma E_R \,. \qquad (8)$$

However, Taft himself had shown[2] that the insertion of Hammett's σ into Eqn.(8) cannot give a correct value of the resonance constant, because σ characterises the resonance as well as the polar effect of the substituent. Hence, it is better to use Taft's constants σ^0 [16] as the polar parameters in Eqn.(8), since these constants relate only to the inductive effect of the substituent.

Also, it was recently shown[28] that the methoxy group reacts with free radicals at about the same rate as the methyl group. Therefore, the rate constants of the reactions of *m*- and *p*-methoxytoluene cannot be included when correlation equations are set up for substituted toluenes. It should be noted that the point for *p*-methoxytoluene shows the greatest deviation from the line in plots[63-70] of Hammett's Eqn. (1). Lastly, deviations from Hammett's Eqn. (1) may arise from solvent effects[20] in concentrated solutions. Thus, further work is needed before the resonance constants of Eqn. (8) can be evaluated with confidence.

b. *Application to free-radical addition reactions*

During the addition of free radicals to benzene derivatives the conjugated aromatic system is converted into a cyclohexadienyl double-bond system. Therefore, Hammett's σ values (which apply to systems in which the aromatic character is not disturbed) cannot be used in this case. Furthermore, any study of reactions of this type must include, in addition to the usual assessment of the reactivity of the substrate, the partial rate constants for addition at the *para*-, *meta*-, and *ortho*- positions of each benzene derivative, because the isomeric composition of the products depends on the nature of the substituent. A full kinetic analysis of this type has been attempted only for relatively few reactions[71-75].

It has been shown that the Hammett equation is obeyed by the rate constants for the addition of the radicals $C_6H_5^{\cdot}$, $p\text{-}CH_3C_6H_4^{\cdot}$, $p\text{-}CH_3OC_6H_4^{\cdot}$, $p\text{-}ClC_6H_4^{\cdot}$, and $p\text{-}O_2NC_6H_4^{\cdot}$ to the *meta*-position, the sign changing from positive to negative on going from radicals with electron-donating to radicals with electron-accepting substituents (see Table 2). The Hammett equation can be applied also to reactions in which the radicals cyclo-$C_6H_{11}^{\cdot}$, $C_6H_5COO^{\cdot}$, $p\text{-}CH_3C_6H_4COO^{\cdot}$, $p\text{-}O_2NC_6H_4COO^{\cdot}$, $(CH_3)_2COCOO^{\cdot}$, and $C_6H_5C{\equiv}C^{\cdot}$ are added at the *para*- and *meta*-positions. However, the rate constants for the addition of aryl radicals at the *para*-position do not appear[71] to follow Hammett's equation. Ito and coworkers[71] believe that the deviations from Hammett's equation can be attributed to the resonance effect. They calculate the resonance parameters by using the fact that $\rho_{para} = \rho_{meta}$. The resonance parameters for attack in the *ortho*-position were determined in a similar way. The objections to the use of the ordinary σ constants for the substituents when the Hammett equation has a resonance term are discussed above‡.

Martin and Gleicher[76] showed that the Hammett equation is applicable to the rate constants for the addition of $CCl_3^{\cdot}$ to substituted allyl- and 3-butenylbenzenes, the proportionality constants ρ taking the values −0.29 and −0.20 respectively (Table 2). They consider these values to be too high, and they point out that the trichloromethyl radical can form complexes with aromatic substrates. Cadogan and Sadler[77] found a correlation between the rate constants for the addition of $CCl_3^{\cdot}$ and $HOOCCH_2S^{\cdot}$ radicals to substituted stilbenes and the σ^+ constants of the substituents, but this correlation was limited to a small number of olefins.

In 1948 Walling and coworkers had pointed out[8] that the rate constants for the addition of a polystyrenyl radical to ring-substituted styrenes obey the Hammett equation. Their calculations were based on the copolymerisation constants. More recently, the Hammett equation was shown to be applicable to the rate constants for the polymerisation of substituted styrenes[78]. An attempt to correlate the reactivities of ethyl-(α-substituted benzyl)-acrylates towards copolymerisation with styrene and methyl methacrylate gave a curved Hammett plot[82]. This was ascribed[82] to the resonance effect of the substituents.

In all the examples of free-radical substitution and addition reactions considered so far, the substituents are in the substrate molecules. Reactions between substituted aryl radicals and unsubstituted substrates are difficult to study. The first demonstration of the possible use of Hammett's equation for systems of this type was based[17]

† Exceptionally, the value of ρ for the reaction of $CCl_3^{\cdot}$ with derivatives of toluene[34] (−0.53) is smaller than the values for the reactions of the same radical with derivatives of cumene[36] (−0.67) and neopentylbenzene[38] (−0.94). According to Totherow and Gleicher[38], this is because the reaction of $CCl_3^{\cdot}$ is made more selective by steric hindrance in the latter two cases.

‡ Recent work has raised additional doubts about the correctness of this approach[71]. Thus, the rate constants for the addition of phenyl radicals in both the *para*- and the *meta*-position ($\rho = 0.0$) were found[73] to satisfy the Hammett equation. However, Japanese workers[80,81] find that the value of ρ in the Hammett equation for the addition of $C_6H_5^{\cdot}$ in the *para*-position depends on the method of generating the phenyl radicals. They ascribe this effect to the influence on the measured addition rate constants of the rate of the reaction

$$C_6H_5C_6H_5Y^{\cdot} + X^{\cdot} \rightarrow C_6H_4C_6H_4Y + HX$$

where the structure of X depends on the method of generating the phenyl radicals.

on the substitution reactions of *p*-methyl-, *p*-bromo, and *p*-nitrophenyl radicals with *p*-methoxytoluene ($\rho = +1$) and *p*-nitrotoluene ($\rho = +0.4$). Dickerman and coworkers[79] have shown that Hammett's equation is obeyed in reactions involving the addition of substituted phenyl radicals to styrene, methyl methacrylate, methyl acrylate, and acrylonitrile. Similarly, Yamamoto and Otsu[70] have applied the Hammett equation to the rate constants for the abstraction of hydrogen from cumene-substituted polystyrenyl radicals with different *para*-substituents, and Prokof'ev and coworkers[83] have applied it to the rate constants for the reactions of 2,6-di-t-butyl-4(4-X-phenyl)phenoxyls with t-butyl peroxide.

2. The Taft Equation

The Taft equation, which has been used to study addition reactions of aliphatic compounds, is formally similar to the Hammett equation:

$$\lg \frac{k_{sub}}{k_0} = \rho^* \sigma^* \cdot \quad (9)$$

However, the essential difference between Eqn. (9) and the Hammett equation is that the σ^* constants are related exclusively to the polar effect of the substituents[2].

Until quite recently, the Taft equation had been used very seldom in studies of free-radical reactions. Taft himself quotes[84] only one example of the application of his equation to a free-radical reaction (the reaction between sodium atoms and alkyl chlorides[85]). In 1962 it was shown in the writer's laboratory[86] that the chain transfer constants in the telomerisation of ethylene with chloro- and bromochloromethane are very accurately described by Eqn. (9). (These constants, when the chain length is $n \geq 3$, are essentially the relative rate constants for the abstraction of hydrogen and bromine atoms by n-alkyl radicals, and for the removal of bromine from bromochloromethane by methyl radicals[87]). It is worth pointing out that the rate constants covered a range of 10^6, and the proportionality constant ρ^* lay within the range 2.33 ± 0.04 irrespective of the nature of the functional group.

We then measured the chain transfer constants for a number of other chloro- and bromochloromethanes, and refined the values previously obtained[88-90]. All the results agreed satisfactorily with Eqn. (9). We also showed that the experimental chain transfer constants for the telomerisation of ethylene with chloroform (involving breaking a C−Cl bond) and with chlorobromo- and dibromomethane (involving breaking a C−H bond) are in good agreement with the values predicted by the Taft equation.

In 1962 Patmore and Gritter[97] applied Eqn. (9) to the rate constants for the abstraction of hydrogen from derivatives of cyclohexane by the $(CH_3)_3CO^{\cdot}$ radical, but they amounted some grave difficulties. In recent years the equation has been applied to many other free-radical substitution and addition reactions (Table 3).

Gleicher and coworkers report[99,100] that in reactions with substituted adamantanes the inductive effect of the substituent is apparently transmitted to the reaction centre through space rather than through the carbon−carbon bond system. They calculated the relative rate constants for the reactions with $CCl_3^{\cdot}$ and $Br^{\cdot}$, using the Kirkwood–Westheimer model[102] of the electrostatic effect, and assuming that the positive charge in the transition state is unity. The calculated values turned out to be much larger than the observed rate constants, but their internal consistency was very good if the charge of the transition state was assumed to be fractional and equal to 0.12 ± 0.03 for the reactions with $CCl_3^{\cdot}$ and 0.17 ± 0.03 for the reactions with $Br^{\cdot}$. More recent work from the same laboratory[49] has confirmed that free-space transmission of the inductive effect plays an important part in the free-radical chlorination of substituted t-butylbenzenes.

In general, the rate constants of free-radical reactions should obey an extended form of the Taft equation[2]:

$$\lg \frac{k_{sub}}{k_0} = \rho^* \sigma^* + r^* \sigma^r + \delta E_s \cdot \quad (10)$$

In this equation σ^r and E_S are constants for the substituents, characterising their resonance and steric effects, and r^*

a) Calculated from the results of Evans and Szwarc[87]. b) Hydrated electron. c) Published plot shows unacceptable scatter of experimental points.

and δ are the appropriate proportionality constants. Two partial expressions of Eqn. (10) are of practical importance:

$$\lg\frac{k_{sub}}{k_0} = \rho^*\sigma^* + r^*\sigma^r, \qquad (11)$$

$$\lg\frac{k_{sub}}{k_0} = \rho^*\sigma^* + \delta E_s. \qquad (12)$$

The first application of Eqn. (11) to the study of free-radical reactions was reported in an investigation[107] of the distribution of isomers in the products of the liquid-phase chlorination of aliphatic acids, esters, and nitriles. The constant ρ^* was found to be −0.212, and the hyperconjugation parameter h was also evaluated (h = 0.114, where $h = \frac{r^* \cdot \sigma^r_{CH_3}}{3}$). However, although the correlation was fairly precise, the method of calculation is open to criticism, since the authors allowed for the hyperconjugation with the methyl substituents but ignored the resonance effect of the COOH, $COOCH_3$, and CN groups. In 1965 the writer applied Eqn. (11) to the rate constants for the abstraction of iodine from alkyl iodides by alkyl radicals[108,109]. The use of the two-parameter Eqn. (11) in studies of free-radical reactions is discussed below in greater detail.

Martin and Gleicher showed[101] that the rate constants for the addition of the trichloromethyl radical to substituted olefins obey Taft's equation in its simplest form (Eqn. (9)). Similar conclusions were made for the rate constants of the addition of the polystyrenyl radical to acrylates[103], methacrylates[104], and thioacrylates[105], and also the addition of the poly(methyl methacrylate) radical to methacrylates[106], the substituents being in the alcoholic part of the monomer molecule. However, Eqn. (9) could not be applied to the rate constants of the reactions between free radicals and silicon-containing olefins of general formula $CH_2=CHSiX_1X_2X_3$[110,111], because these reactions involve large steric and resonance effects. Similarly, the rate of addition of the polystyrenyl radical to α-substituted methyl acrylates is determined mainly by the steric effect of the substituents[112].

3. The Alfrey–Price and the Bamford Equations

The Alfrey–Price[113] and the Bamford[114-116] equations were put forward to describe reactivity in radical polymerisation and copolymerisation reactions. A detailed description of these specialised branches of free-radical chemistry lies beyond the scope of the present review, and can be found in recent monographs[117-119]. We shall therefore confine ourselves to the use of the Alfrey–Price and the Bamford equation in quantitative descriptions of the reactivity of small radicals, with special reference to the recent work of Freidlina and Englin[120-123].

According to Alfrey and Price[113], the ratio of the rate constants for the polymeric radical $M_1^{\cdot}$ in copolymerisation reactions with the monomers M_1 and M_2 can be written in the form

$$r = \frac{k_{11}}{k_{12}} = \frac{Q_1}{Q_2}e^{-e_1(e_1-e_2)} \qquad (13)$$

where Q_1 and Q_2 are parameters which characterise the reactivity of M_1 and M_2, and e_1 and e_2 characterise the polar properties of these monomers.

Englin and Freidlina[120] proposed the use of a form of Eqn. (13), modified for chain transfer constants[124], to study the reactivity of telomeric radicals formed in the telomerisation of ethylene with carbon tetrachloride and chloroform. The Alfrey–Price scheme gives

$$C_\infty = \frac{Q_T}{Q_M}e^{-e_M(e_T-e_M)};\quad C_n = \frac{Q_T}{Q_M}e^{-e_n(e_T-e_M)} \qquad (14)$$

where C_n and C_∞ are the partial and the total chain transfer constant of the telogen; Q_M and Q_T are characteristic parameters for the reactivity of the monomer and the telogen; e_T, e_M, and e_n are the polar factors for the telogen, the monomer, and the telomeric radical of chain length n. Using Eqn. (14), Englin and Freidlina evaluated the e_n parameters for the radicals $CCl_3(CH_2CH_2)_n^{\cdot}$, where $n = 1-4$. They found that whilst the radical $CCl_3CH_2CH_2^{\cdot}$ is electrophilic ($e > 0$), the radicals with higher molecular weight acquire nucleophilic properties.

The same authors[121-123] later suggested the use of Bamford's equation[114-116]

$$\lg k_s = \lg k_{3T} + \alpha\sigma + \beta \qquad (15)$$

to study the reactivity of telomeric radicals and telogens, where k_S is the rate constant for the reaction between the radical and any substrate, k_{3T} is the rate constant for the reaction of the same radical with toluene, σ is a constant (analogous to Hammett's σ) which characterises the polar properties of the radical, and lastly α and β are constants characteristic of the substrate molecule.

For the case of chain transfer constants Eqn. (15) can be rewritten

$$\lg C_n = \sigma_n(\alpha_T - \alpha_M) + \beta_T - \beta_M. \qquad (16)$$

These equations were used to calculate σ_n for telomeric radicals in the telomerisation of ethylene, propylene, and vinyl chloride with carbon tetrachloride and chloroform. The σ_n values obtained varied in the right sense, reflecting the decrease in electrophilic character of the radicals both with increase of n and on going from vinyl chloride to ethylene and propylene.

III. CORRELATION WITH THE PARAMETERS OF QUANTUM CHEMISTRY

This review is not concerned with attempts to calculate the rate constants of free-radical reactions of the parameters of their Arrhenius equations by quantum-chemical methods. However, in addition to attempts at direct calculation of the kinetic parameters, considerable effort has been devoted to the comparison of the rate constants and activation energies of free-radical reactions with quantum-mechanical characteristics of the reactivity of the molecules and radicals. These correlations are similar in principle to those based on the use of empirical parameters (such as the constants for the substituents in the Hammett and Taft equations), but the use of quantum-mechanical parameters offers some additional advantages by giving a physical interpretation of the reactivity.

The most widely used among the quantum-mechanical correlation equations is that of Polanyi, which relates the activation energy to the enthalpy of free-radical reactions[125]:

$$\Delta E_{ac} = -\alpha\,\Delta\Delta H. \qquad (17)$$

In this equation ΔE_{ac} is the difference between the activation energies, and $\Delta\Delta H$ is the difference between the enthalpies of reactions of a given type; α is a proportionality constant. Semenov has stated[126] that this expression can be applied, to a first approximation, to the substitution reactions of most free radicals, and can be written in the form

$$E_{ac} = A - \alpha\,\Delta H \qquad (18)$$

As will be shown below (p. 228), the correctness of Eqn. (18) depends on the fact that the transition states of many free-radical reactions of the same type have very similar structures. However, in general, the proportionality constant α is a function of the reactivity of the free radical. The phenomenon has been discussed quantum-mechanically by Bagdasar'yan[119], who showed that α varies from 0 to 1 as the structure of the transition state varies from that of the reactants to that of the products.

Eqn. (17) and (18) have been applied to the abstraction of hydrogen by $CH_3^{\cdot}$ radicals ($\alpha = 0.49$ [127,128]), by Br ($\alpha = 0.86$ [129]), NF_2 ($\alpha \simeq 1$ [128]), and O ($\alpha = 0.36$ [130]). In Bagdasar'yan's calculations[119] for the reactions of $CH_3^{\cdot}$, $CF_3^{\cdot}$, and $D^{\cdot}$, α is found to be 0.38. All these examples apply to the reactions of radicals with aliphatic hydrocarbons only, because the Polanyi–Semenov equation is inappropriate[119] when the reactants contain any substituents other than alkyl groups. However, Eqns. (17) and (18) can be used in the study of reactions of a different type: for example, the abstraction of halogen atoms from alkyl halides by the $^{\cdot}SiCl_3$ radical[131], or the reactions of trifluoromethyl with halogens[132].

Zavitsas and Ehrenson[133] measured the ratio of the rate constants and the difference in the activation energies of the reactions of alkyl and cycloalkyl radicals with bromotrichloromethane and hypochlorites ($R(CH_2)_2COCl$), and evaluated the parameter α from Polanyi's equation. They found that for these radicals α is related to the stabilisation energy E_S by the expression

$$\alpha = 1.9 \cdot 10^{-3} \exp 0.28E_s. \qquad (19)$$

However, the experimental method used by these workers[133] is of doubtful validity, because recent work has shown[29,30] that appreciable amounts of chlorine are formed in reactions involving hypochlorites. Furthermore, we would have expected a linear relationship between α and E: the physical significance of the exponential relationship is not clear.

Eqns. (17) and (18) can be applied also to free-radical addition reactions[134]. Walling used[135] Eqn. (17) to determine the stabilisation energy of radicals formed during the addition of methyl radicals to vinyl acetate, vinyl ethyl ether, and methyl methacrylate.

The many "reactivity indices" which have been proposed for free-radical reactions can be divided into two groups: the parameters which define the polar (or inductive) effect, and those which define the resonance effect in reactions. In 1951 Eyring and coworkers[136] put forward a "semi-classical" approach to the evaluation of the inductive effect, based on a calculation by the MO method of the total charge on covalently bonded atoms[137]. It was shown that the free energy of the reaction between a sodium atom and chloromethanes increases in the same sense as the total charge on the chlorine atom[138]. This effect can be explained by assuming electron transfer from the sodium to the chlorine in the transition state of the reaction: increasing the number of chlorine atoms in the molecule leads to a decrease in the negative charge on the chlorine atom involved in the reaction, and hence to an increased rate of reaction. Thus, the chlorine atoms contribute a purely inductive effect. It is interesting to note that the same correlation equation applies to all the methyl halides investigated (CH_3Cl, CH_2Cl_2, $CHCl_3$, CCl_4, CH_3Br, CH_3I) if a correction for the different polarisabilities of the C–X bonds is applied.

Electron transfer in the transition state of the reaction between sodium and organic halides is confirmed by Wilson and Herschbach's observation of a correlation between the

electron capture coefficients and the rate constants of these reactions[139]. According to Polanyi[140], it is more correct to seek a correlation between the activation energy and the electron affinity for reactions of this type. However, both relationships point to the same mechanism.

The work of Szwarc and coworkers[141,142] bears a close similarity to the above investigations. These workers found an inverse relationship between the logarithm of the rate constants for the addition of the trifluoromethyl radical to methyl-substituted olefins and the ionisation potentials of the olefins[142]. This type of dependence is ascribed to the electron-donating properties of the methyl substituents. According to Stefani and coworkers[143] the logarithm of the rate constant for the addition of the cyclopropyl radical to olefins varies linearly with the ionisation potential of the olefins, which suggests that the cyclopropyl radical behaves nucleophilically.

In 1955 Coulson reported[144] a linear relationship between the logarithm of the rate constants for the addition of the methyl radical to aromatic compounds and the free valency index or the localisation energy of these compounds. This relationship has been widely discussed in the literature. The quantum-mechanical significance of these correlations has been considered in detail in monographs[119,145], and the work of Szwarc and coworkers up to 1958 is fully reviewed by the authors themselves[146]. The localisation energy of one of the π-electrons on the reactive centre decreases if the second electron can conjugate with the substituents of an unsaturated compound. Therefore, the correlation of the rate constants or activation energies with the localisation energies is evidence for the presence of a large resonance effect in these reactions.

Later work has revealed correlations between the localisation energies and the rate constants (and activation energies) for the reactions of the trifluoromethyl and the trichloromethyl radical with aromatic compounds[147,148], of hydrogen atoms with olefins[149] and hydrocarbons[150], and of the ethyl radical with olefins[151]. Chlenov and Basilevskii[152] studied the relationship between the rate constants for the reactions of the methyl, trifluoromethyl, and trichloromethyl radicals with aromatic compounds and the stabilisation energy, defined as the difference between the π-energies of the delocalised transition state and of the reactants. According to these workers, correlation with the stabilisation energy is more satisfactory than with the localisation energy when a large polar effect is present. Unruh and Gleicher[153] obtained a good correlation (correlation coefficient 0.977) between the rate constants for the abstraction of hydrogen from methyl-substituted aromatic compounds by the trichloromethyl radical and the difference between the π-bond energies of the resulting radical and of the reactant, calculated by the SCF LCAO MO method.

IV. ADDITIVE EMPIRICAL METHODS OF CALCULATING THE ACTIVATION ENERGIES AND THE RATE CONSTANTS OF FREE-RADICAL REACTIONS

Additive schemes for calculating by empirical methods the rate constants (and particularly the activation energies) of free-radical reactions have recently been developed to a remarkable degree. The activation energies of the logarithms of the rate constants are treated as empirical functions of a number of parameters which characterise the substrates and the radicals. Though similar to the correlation equations of the Hammett–Taft type, these methods differ essentially from those equations because the parameters on which they rely are not determined by reaction effects (polar, resonance, or steric), but by some specifically chosen components of the energy of the activated complex. The activation energies of radical reactions are treated as functions of the dissociation energies of the "activated" forms of the broken bond and the newly formed bond (i.e. the bonds in the activated complex[154]), expressed as sums of energy terms for the pair interactions of atoms in the activated complex[157], and also as functions of the dissociation energies of the real broken bond and of the newly formed bond[156]. §

These methods have been discussed in detail in a number of review articles, [154–156] and therefore we shall not dwell on them, except for the following observation. There can be no doubt of the reality of the various empirical relationships which have been reported. However, it is exceedingly difficult to define the region over which such relationships apply. Thus, Moin assumes[154] that in any free-radical substitution reaction

$$R^{\cdot} + R'X \rightarrow [R \ldots X \ldots R'] \rightarrow RX + R'^{\cdot} \qquad (20)$$

the dissociation energy of X... R′ in the activated complex is independent of the structure of the attacking radical R·. But this assumption is inconsistent with Hammond's postulate[10] that the structure of the activated complex (i.e. the transition state), and therefore also the dissociation energy of the X... R′ bond, varies from a structure close to that of the reactants (for very reactive R radicals) to a structure close to that of the reaction products (for relatively inactive R radicals).

Moin[154] correctly states that his relationships between activation energies and the dissociation energies of the bonds in the activated complex are similar to the Polanyi–Semenov equation. Hence, the regions of applicability of the two equations should be the same. However, the Polanyi–Semenov equation is applicable only to the reactions of radicals with aliphatic hydrocarbons, in which structurally uniform activated complexes[119] are formed.

V. SEPARATION OF POLAR AND RESONANCE EFFECTS IN FREE-RADICAL REACTIONS

In this Section we shall discuss the application of the two-parameter Taft equation

$$\lg \frac{k_{sub}}{k_0} = \rho^{\cdot}\sigma^{\cdot} + r^{\cdot}\sigma^{r} \qquad (11)$$

to the study of the reactions of free radicals with compounds whose substituents show both polar and resonance effects. Clearly, Eqn. (11) is applicable only if the steric effect of the substituents is negligible.

In contrast to ordinary substitution reactions, whose transition state contains a formally quinquevalent carbon atom (as in the S_N2 reactions, for example), free-radical substitution reactions proceed through a transition state with little steric hindrance:

$$Y^- + CR_1R_2R_3X \rightarrow \left[\begin{array}{c} R_1 \quad R_2 \\ Y \ldots C \ldots X \\ \quad | \\ \quad R_3 \end{array}\right]^- \rightarrow YCR_1R_2R_3 + X^- \quad S_N2 \text{ mechanism}, \qquad (21)$$

$$Y^{\cdot} + CR_1R_2R_3X \rightarrow [Y \ldots X \ldots CR_1R_2R_3] \rightarrow YX + {}^{\cdot}CR_1R_2R_3 \quad \text{Free-radical substitution mechanism}. \qquad (22)$$

§ A new method of calculating the activation energy of free-radical reactions, based on a presentation of the potential energy of the reacting system in terms of Morse curves, has recently been suggested[157,158].

Therefore, the steric effect can often quite correctly be ignored. However, in the presence of several substituents we must consider a special form of the steric effect, in which resonance in the transition state is geometrically precluded. In the following calculations we shall confine ourselves, as a rule, to the rate constants of monosubstituted compounds, with the exception of methyl and halogen substituents.

Only the polar constants (σ^*) of Taft's equation[2] were available in the literature. Therefore, one particular series of free-radical substitution reactions (the reactions of primary alkyl radicals in the liquid phase) was used to calculate the resonance constants σ^r of the substituents by Eqn. (11). As stated above (p. 220), the chain transfer constants $C_{\geqslant 3}$ in the telomerisation of ethylene with halogenomethanes obey the Taft equation in its simplest form (Eqn. (9)), the proportionality constant ρ^* having the value 2.33 to a first approximation irrespectively of the nature of the atom abstracted (H, Cl, or Br). Hence, σ^r was determined from the chain transfer constants $C_{\geqslant 3}$ of monosubstituted derivatives of methane with substituents showing both polar and resonance effects. It was assumed that for this reaction $\rho^* = r^* = 2.33$. This assumption is undoubtedly arbitrary, but it seemed a reasonable one because it yields a single scale for the quantities σ^* and σ^r. However, it must be borne in mind that whereas a change in r^* will produce a change in the absolute value of σ^r, their relative values will remain unchanged. Thus,

$$\sigma^r = \frac{1}{2.33} \lg \frac{C_{sub}}{C_0} - \sigma^*. \qquad (23)$$

The measured chain transfer constants $C_{\geqslant 3}$ for the telomerisation of ethylene with methyl, ethyl, and isopropyl iodide[108,109], 1,1-dichloroethane[89], bromoacetic acid[159], toluene, acetone, acetic acid, and acetonitrile[160] (at 100°) were inserted into Eqn. (23), and also the chain transfer constants for the polymerisation of ethylene with methanol and propylene (at 130° and 1350 atm), obtained by Mortimer[161]. (Although these latter data were obtained at a higher temperature, the effects of temperature and pressure increase can be expected to be mutually compensating to a large extent.)

The results of our calculations are shown in Table 4. The value of $\sigma^r_{CH_2COOH}$ adopted is the average of the values calculated from the chain transfer constants for acetic and bromoacetic acid. The resonance constants of the alkyl substituents were calculated from the chain transfer constants of alkyl iodides. $\sigma^r_{CH_2CH_3}$, found from the chain transfer constant of 1,1-dichloroethane ($C_3 = 0.178$), is practically the same as the value obtained from $C_3^{C_2H_5-I}$.

The resonance effects of the substituents in the substrate molecule which reacts with a free radical are probably determined mainly by the delocalisation of the unpaired electron onto these substituents in the transition state of the reaction. There is nothing new, essentially, in this point of view. The interaction of the unpaired electron with substituents in free radicals has been demonstrated many times. Thus, it has been shown that the stabilisation energy of benzyl radicals is increased by the presence of alkyl substituents[162]. Gilbert and Kreilick[163] have calculated the distribution of the unpaired electron density in substituted phenoxy radicals. They found that the delocalisation of the unpaired electron increases when the substituents $CH_2COOC_2H_5$, $C(CH_3)_3$, and CH_3CO are introduced in the *para*-position.

Furthermore, the distribution of unpaired electron density has a significant effect on the reactivity of the free radical. Thus, the rate of reaction of the methyl radical at the *ortho*-position, the *para*-position, and the oxygen atom of the phenoxy radical depends on the distribution of spin density in the latter radical[164]. Similarly, a relationship has been found between the unpaired electron density distribution in phenoxy and aryloxy radicals and the activation energy of their reactions with t-butyl peroxide[165,166].

Table 4. Resonance constants of the substituents (σ^r) and spin densities in the resulting free radicals (p_R).

R–X	$C_{\geqslant 3}$ (100°)	σ^{*a}	σ^r	p_R
CH_3–I	4.5 [109]	0	0	1.000
CH_3CH_2–I	14.8 [109]	−0.10	0.32	0.919 [167]
$(CH_3)_2CH$–I	48.3 [109]	−0.20	0.64	0.844 [167]
CH_3–H	$1.5 \cdot 10^{-6}$ [a] [86]	0	0	1.000
$HOOCCH_2$–H	0.0037 [160]	1.05	0.40	0.923 [168]
CH_3–Br	0.0025 [a] [159]	0	0	1.000
$HOOCCH_2$–Br	3.7 [159]	1.05	0.31	0.923 [168]
$NCCH_2$–H	0.0283 [160]	1.3	0.54	0.852 [169]
$C_6H_5CH_2$–H	0.0254 [160]	0.215	1.605	0.621[c]
CH_3COCH_2–H	0.0290 [160]	1.12[c]	0.72[c]	0.830 [170, 171]
CH_2=$CHCH_2$–H	0.015[b] [161]	0.1	1.62	0.604 [172]
$HOCH_2$–H	0.0021[b] [161]	0.555	0.795	0.840 [169]
CH_3OCH_2–H		0.520	0.97[c]	0.770 [173]
$C_6H_5OCH_2$–H		0.85	0.66[d]	0.848[c]
CH_3CO–H		1.65	1.15[d]	0.728[c]

a) Calculated value. b) Chain transfer constants in the polymerisation of ethylene at 130° and 1350 atm. c) Obtained by Eqn. (25). d) Obtained from the rate constants for the methyl radical reactions (Table 5) by Eqn. (11).

The delocalisation of the unpaired electron on the substituents of the substrate molecule in the transition state of a free-radical reaction can be compared with the spin-density distribution in the resulting free radical. These ideas were developed by Dixon[174]. However, he points out that direct comparison of spin-density distribution in the radicals with the reactivity of the reacting molecules is impossible, because radicals (unlike molecules) have a planar structure. Therefore, Dixon prefers to use the spin–spin interaction constants of vicinal protons to characterise the delocalisation of electron spin in the transition state. Nevertheless, the transition state for radical substitution reactions involving monosubstituted compounds hardly ever presents geometrical restrictions to the delocalisation of the unpaired electron on the substituent. Hence, we believe that the resonance effect of substituents can be directly related to the spin density in the radicals (calculated from ESR spectra).

We have used spin-density values obtained from the most accurate form of the McConnell equation for the hyperfine structure (HFS) constants of the protons in the methyl groups of the $CH_3\dot{C}HX$ radicals[167,169]:

$$\rho_R = \frac{a^{CH_3}}{29.3\,(1 - 0.081)}. \qquad (24)$$

In this equation, ρ_R is the spin density at the α-carbon atom of the $XCH_2^{\cdot}$ radical, a^{CH_3} is the HFS constant of the freely rotating methyl group of the $CH_3\dot{C}HX$ radical, the factor $(1 - 0.081)$ allows for the delocalisation of the unpaired electron on the CH_3 group[167]. (The traditional

symbol ρ for the spin density has been replaced by p_R to avoid confusion with the proportionality constants ρ and ρ^* of the Hammett–Taft equations.) Values of p_R are listed in Table 4.

We have tried to establish a relationship between the resonance constants σ^r of the substituents, calculated by Taft's Eqn. (11), and the spin density on the substituents in the resulting free radicals, in the form of the equation[175-177]:

$$\sigma^r = b(1 - p_R). \quad (25)$$

Eqn. (25) was solved for the σ^r and p_R values of the radicals $CH_3^\cdot$, $CH_3CH_2^\cdot$, $(CH_3)_2CH^\cdot$, $HOOCCH_2^\cdot$, $NCCH_2^\cdot$, $CH_2{=}CHCH_2^\cdot$, and $HOCH_2^\cdot$. The result, obtained by least squares, was

$$\sigma^r = (4{,}23 \pm 0{,}48)(1 - p_R), \quad \text{correlation coefficient } 0.988. \quad (26)$$

This expression can be used to calculate new values of σ^r and p_R, and other derived quantities. Thus, we obtained $\sigma^r_{CH_2COCH_3} = 0.72$, $\sigma^r_{CH_2OCH_3} = 0.97$, and $\sigma^r_{CH_2C_6H_5} = 0.621$. Since the chain transfer constant for the telomerisation of ethylene with acetone is known ($C^{CH_3COCH_3}_{\geqslant 3} = 0.0290$, Table 4), it follows that $\sigma^r_{CH_2COCH_3}$ can be found in the same way as the other resonance constants: from Eqn. (11) and the known polar constant $\sigma^*_{CH_2COCH_3} = 0.60$.[2] However, this method of calculation gives the anomalously high value $\sigma^r_{CH_2COCH_3} = 1.24$. Therefore, we prefer to use a different value of $\sigma^*_{CH_2COCH_3}$ for free-radical processes. Inserting $\sigma^r_{CH_2COCH_3} = 0.72$ into Eqn. (11) we obtain $\sigma^*_{CH_2COCH_3} = 1.12$. As we shall show below, the new value of $\sigma^*_{CH_2COCH_3}$ can be used with advantage in the study of other free-radical reactions.

The spin-density distribution in the benzyl radical has been determined theoretically by several workers, but the value of $p_{CH_2C_6H_5}$ depends very appreciably on the method of calculation (see, for example, Ref. 178). Inserting into McConnell's Eqn. (24) the value $p_{CH_2C_6H_5} = 0.621$ found by Eqn. (26), we can find a^{CH_3} for the ESR spectrum of the $C_6H_5\dot{C}HCH_3$ radical: $a^{CH_3} = 29.3\ (1 - 0.081)p_{CH_2C_6H_5} = 16.8$ G. It is interesting to note that in a recent paper[179] the HFS constants $a^H = a^{CH_3} = 16.5$ G are proposed for the $C_6H_5\dot{C}HCH_3$ radical.

The Taft equation with polar and resonance terms (Eqn. (11)) can be applied to the reactivity of monosubstituted methane derivatives towards free radicals. All the data available at the time of writing are collected in Tables 5 and 6. We have included only those radicals for which more than four rate constants were known. This gave at least four equations to be solved for evaluating the results by least squares. Since the chain transfer constants of polymeric radicals are the least accurately known, only the constants obtained in the polymerisation of vinyl acetate were considered, because this reaction has been fully characterised. As the Table shows, three correlations were obtained for five reaction rate constants involving the radicals $CH_3(CH_2)_2\dot{C}H(CH_2)_2CH_3$, $HO^\cdot$, $Na^\cdot$: one for six values ($I^\cdot$), one for eight values ($CH_3^\cdot$), one for nine values (polyvinyl acetate radical), and two for ten values ($CF_3^\cdot$ and $C_6H_5^\cdot$).

Table 5. Application of Taft's Eqn. (11) to the rate constants of reactions between free radicals and R–H compounds.

R–H	Rate constants in the gas phase (g.p.) and liquid phase (l.p.)							
	$X(CH_2CH_2)_n^\cdot$ $C^a_{\geqslant 3}$ l.p. 100°	$CH_3^\cdot$ $k\cdot10^{-6}$, g.p. 100° $cm^3\ mole^{-1}\ s^{-1}$	$CH_3(CH_2)_2\dot{C}H(CH_2)_2CH_3$ $C^3_{\geqslant 3}$ l.p. 100°	$CF_3^\cdot$ $k\cdot10^{-6}$, g.p. 100° $cm^3\ mole^{-1}\ s^{-1}$	$\frac{k}{k_{CCl_4}}$ $C_6H_5^\cdot$ l.p. 60°	$HO^\cdot$ [b] $k\cdot10^{-11}$ l.p. $cm^3\ mole^{-1}\ s^{-1}$ 20°	$I^\cdot$ $k\cdot10^{-4}$ g.p. $cm^3\ mole^{-1}\ s^{-1}$	$X(CH_2\dot{C}H)_n$ | $OCOCH_3$ $C^a\cdot10^4$ l.p. 60°

a) Chain transfer constants. b) Rate constants for the reactions of $HO^\cdot$ at pH 7 were chosen for the calculation, because hydroxyl radicals are converted into $O^\cdot$ in alkaline media[231]. c) These values of chain transfer constant were used to calculate σ^r (see Table 4). d) Mean value. e) Reaction with CH_3COOCD_3. f) All these rate constants were recalculated using a corrected value[186] for the rate constant of the recombination of methyl radicals (2.3×10^{13} $cm^3\ mole^{-1}\ s^{-1}$). g) The rate constants for the reactions of methyl radicals were used to calculate the corresponding σ^r. h) Calculated from Taft's Eqn. (11). i) Chloroform taken as standard compound. j) Obtained from $k_{CH_3CHO}/k_{CH_3OH} = 2.25$[216] and $k_{CH_3OH} = 5.36\times10^{11}$ $cm^3\ mole^{-1}\ s^{-1}$. k) Toluene taken as standard compound in Eqn. (11).

All the available data (except a few doubtful ones) were used to analyse the rate constants of the gas-phase reactions of the methyl radical. For example, the results of Raal and Steacie for the reactions of $CH_3^{\cdot}$ with halogenomethanes were not included, because hydrogen halides are formed in these reactions[227-229]. As Table 5 shows, the rate constants for the reactions of methyl radicals are fitted by Eqn. (11) for the special case of $\rho^* = r^* = 1.51 \pm 0.14$. This is not unexpected, since the constant r^* had been taken to be equal to ρ^* for the reactions of alkyl radicals in the liquid phase. Calculations by Eqn. (11) with $\rho^* \neq r^*$ confirmed that these quantities cannot differ by more than 0.17 of a unit of ρ^* for the reactions of methyl radicals. From this correlation expression, and the known rate constants for the reactions of the methyl radical with anisole[191] and acetaldehyde[190], we obtain $\sigma^r_{CH_2OC_6H_5} = 0.66$ and $\sigma^r_{COCH_3} = 1.15$, and also $p_{CH_2OC_6H_5} = 0.848$¶ and $p_{COCH_3} = 0.728$. These resonance constants have been used to set up correlation expressions for other free radicals.

Table 6. Application of Taft's Eqn. (11) to the rate constants of the reactions of sodium atoms with R–Cl compounds.

Rate constant	$(CH_3)_3CCl$	$(CH_3)_2CCl_2$	CH_3CCl_3	CCl_4	$CH_2=CHCH_2Cl$	ρ^*	r^*	r
$k \cdot 10^{-11}$ (Ref. 232) cm^3 mole^{-1} s^{-1} at 247°, g.p.	2.76	42.3	393	2260	27.3	1.234 ±0.007	0.760 ±0.016	0.9996

The correlation expressions for the reactions of other free radicals were obtained in a similar way. The rate constant for the reaction of the phenyl radical with acetonitrile[14] was not included in the calculation because it showed a serious discrepancy, probably associated with the experimental errors inherent in the chosen method[17] of measurement of k. In the study of the reactions of the hydroxyl radical in aqueous solutions the rate constants of the reactions with methane and acetonitrile[214] were excluded from the calculation because the measurements had been made at pH 9, i.e. under conditions where the radical anion $O^{\cdot-}$ is also present[231].

It is evident from Tables 5 and 6 that our correlation expressions have an accuracy of 10–25% for ρ^* and 10–15% for r^*. The only exception is the value of ρ^* for the reactions of the trifluoromethyl radical, which lies within the range from –0.20 to +0.20. These errors are fairly large, but all the correlation coefficients (except for one value of 0.936 for the reactions of the phenyl radical) are greater than 0.950, and two of them are greater than 0.990. Thus, we may conclude that the correlation is entirely satisfactory†.

We must stress that these calculations were made with data from different sources and having different precision. Furthermore, the rate constants of free-radical reactions can seldom be measured to an accuracy of better than 50%. Also, the number of available data was so small that it was not always possible to exclude values of doubtful reliability from the calculation. Hence, the correlation errors are relatively large at this stage, but we think it likely that the correlation will improve when a larger fund of accurate experimental data becomes available.

A qualitative dependence of ρ^* on the electronegativity of the free radicals can be observed for reactions of a given type (ignoring temperature differences and different reaction media). It is found that ρ^* decreases in the sequence

$$X(CH_2CH_2)_n^{\cdot},\ CH_3(CH_2)_2\dot{C}H(CH_2)_3CH_3 > CH_3^{\cdot},\ I^{\cdot} > C_6H_5^{\cdot} > CF_3^{\cdot} > HO^{\cdot}.$$

In this series the electronegativity of the radicals increases from left to right. The value of r^* should be independent of the polar properties of the radicals, and should be determined only by the structure of the transition state of the reaction. The dependence of r^* on the structure of the transition state is discussed again below.

The effect of the statistical factor has been ignored in all the above calculations. "Intuitively", the statistical factor should be equal to the number of equally probable centres of attack of the reagent (for example, the free radical) on the substrate molecule. Benson[234] has tried to develop the concept of a statistical factor from the theory of absolute reaction rates. He has shown that it is not obvious, in general, that the "intuitive" statistical factor can be identified with a factor giving the symmetry numbers in the theoretical rate constant equation. Studies of reactions involving the hydrogen atom[235,236] have shown that the real statistical factor, calculated from the ratio of the pre-exponential terms in the rate constants for the reactions, is not the same as the factor given by "intuitive" considerations. It should be noted that a one-sided calculation of the statistical factor is objectionable also from general considerations, since other, "non-chemical" contributions to the rate constant must be taken into account (for example, the effect of moments of inertia[236]).

¶ Hudson and Root[230] have recently obtained the value $p_{CH_2OCH_3} = 0.831$ by using Eqn. (24) in conjunction with ESR data.

† Migita and coworkers[233] conclude, by comparing the rate constants for the chlorination of chloroalkanes and chlorosilanes, that the resonance effect of chlorine atoms in the α-position to the reaction centre is greater than the hyperconjugation effect of the C–H and C–C bonds. We observe that these workers' rate constants for the chlorination of chloroalkanes and nitriles[92-94,233], obey Taft's Eqn. (11) with $\rho^* = -3.54 \pm 0.28$ and $r^* = 1.27 \pm 0.40$ (at 40°) except for compounds with chlorine atoms in the α-position to the reaction centre. If the rate constants for the chlorination of chloroalkanes with chlorine atoms in the α-position are inserted into this equation, the accelerating effect of chlorine as an α-substituent is found to correspond to $\sigma^r_{CH_2Cl} = 1.5$ and $\sigma^r_{CH_2Cl} = 3.2$. (We note that σ^r for a classical resonance-inducing substituent such as $-CH_2CH{=}CH_2$ is 1.62 (Table 4)). Therefore, we suggest that the effect of chlorine atoms as α-substituents on the rate of chlorination of chloroalkanes should be ascribed not to the resonance effect of chlorine, but to some other effect (for example, the change in hybridisation of the carbon atom).

Nevertheless, all the correlation expressions obtained (as well as some published data[98]) were recalculated to allow for the statistical factor: the effect on the results was negligible within the quoted error limits. In four cases the correlation was more satisfactory without the statistical factor, in four cases the correlation was improved by the statistical factor, and in one case the statistical factor had no effect. None of the effects was large.

Steric preclusion of resonance

As already pointed out (p. 224), the presence in the substrate molecule of several substituents exhibiting a resonance effect can lead to a spatial disturbance of the conjugation of the unpaired electron with the substituents in the transition state of the reaction. Steric preclusion of the resonance was observed in a number of systems, for example in studies of the addition of a methyl radical to unsaturated and to aromatic compounds.[146]

In our calculations of the resonance constants of the ethyl and the isopropyl radical from the chain transfer constants of these radicals in the telomerisation of ethylene with alkyl iodides we found (Table 4) that the resonance effect of two methyl groups is equal to twice the effect of a single methyl group ($\sigma^r_{CH(CH_3)_2} = 0.64$, $\sigma^r_{CH_2CH_3} = 0.32$). This was confirmed by measuring the chain transfer constants in the telomerisation of ethylene with ethyl bromide and isopropyl, and also by inserting the σ^r values obtained into the correlation equations. Hence, no steric preclusion of resonance occurs in radical substitution reactions when a second methyl group is introduced into the substrate molecule.

However, a study by the competitive method of the reactivity of the compounds $CH_3COOH - ClCH_2COOH - CH(COOH)_2$ and $BrCH_2COOH - BrClCHCOOC_2H_5 - BrCH(COOC_2H_5)_2$ has shown that the introduction of chlorine or a second carboxyl into a molecule of acetic or bromoacetic acid increases the chain transfer constant by a factor of 35–25 and 14–4 respectively[159,177]. Using Taft's equation it is readily shown that the reactivity of these compounds can be expressed as the overall effect of the CHClCOOR group (with R = H or C_2H_5), $\Sigma\sigma^* = 1.86-2.10$, and of the group $CH(COOR)_2$, $\Sigma\sigma^* = 1.64-2.06$. (By analogy with other reactions of n-alkyl radicals the proportionality constant is taken to be $\rho^* = 2.33$). Although the polar constants σ^* of these groups are unknown, we can establish that the observed overall effects of the CHClCOOR and $CH(COOR)_2$ groups are almost fully accounted for by the polar effect, noting that $\sigma^*_{CH_2COOH} = 1.05$ [2] and allowing for the "saturation effect" in the summation of the inductive constants (for example, $\sigma^*_{CH_2Cl} = 1.05$, $\sigma^*_{CHCl_2} = 1.94$, $\sigma^*_{CCl_3} = 2.65$). Thus, in these cases the preclusion of resonance is almost total.

VI. RELATIONSHIP BETWEEN THE TRANSITION-STATE STRUCTURE AND THE REACTIVITY OF FREE RADICALS

In the applications of Taft's two-parameter Eqn. (11) to studies of the reactions of alkyl radicals with alkyl bromides and iodides[109,159], and also of the reactions of sodium atoms with alkyl chlorides (Table 6), methyl groups were examined among other substituents. It was found that the effect of methyl groups, like that of the other substituents, can be resolved into a polar and a resonance component. However, in the more general case the influence of alkyl groups in free-radical reactions cannot be described in terms of these two effects alone.

Deviations from Eqn. (11) in the case of methyl substituents are observed in the reactions of free radicals with aliphatic hydrocarbons. The effect of methyl groups on the rate of hydrogen abstraction by radicals from methane, ethane, and propane could have been expected to be additive, as is found for example in the reactions of radicals with methyl-, ethyl-, and isopropyl halides with C–X bond breaking[109,159]. However, as Table 7 shows, the increase in reaction rate for all radicals is much greater on going from methane to ethane than from ethane to propane. Thus, the Taft equation (Eqn. (11)) cannot be applied to these reactions, since the quantities ρ^* and r^* are a function of R′ in the reactions

$$R^{\cdot} + H{-}R' \rightarrow RH + R'^{\cdot} \quad [R' = CH_3, CH_2CH_3, CH(CH_3)_2]. \qquad (27)$$

The writer has shown[237] that a direct proportionality exists between $\lg(k_{C_2H_6}/k_{CH_4})$ (see Table 7) and the dissociation energy of the R–H bond formed in reactions (27). By least squares, the following relationship was obtained

$$\lg\frac{k_{C_2H_6}}{k_{CH_4}} = -(0.048\pm0.005)D(R{-}H) + (6.62\pm0.50), \quad r = 0.913. \qquad (28)$$

As stated above (p. 222), the proportionality coefficient α of Polanyi's Eqn. (17) depends on the structure of the transition state for the reaction. If the ratio of the pre-exponential factors for the reactions with ethane and methane is independent (to a first approximation) of the nature of the attacking free radical, the dependence of α on $D(R-H)$ can easily be obtained from Eqn. (17). Thus, for the reactions with methane and ethane, we have

$$\alpha = \frac{E_{ac}^{CH_4} - E_{ac}^{C_2H_6}}{D(CH_3-H) - D(C_2H_5-H)}, \qquad (29)$$

$$\alpha = \frac{2.3RT}{6000}\lg\frac{k_{C_2H_6}}{k_{CH_4}} - \frac{2.3RT}{6000}\lg\frac{A_{C_2H_6}}{A_{CH_4}}, \qquad (30)$$

where $D(CH_3-H) = 104$ kcal mole^{-1}, $D(C_2H_5-H) = 98$ kcal mole^{-1}.[210] For $\lg(A_{C_2H_6}/A_{CH_4}) = \text{const} \simeq 0$, and $T = 373°K$, we have from Eqns. (28) and (30)

$$\alpha = \frac{2.3RT}{6000}[-(0.048\pm0.005)D(R{-}H) + (6.62\pm0.50)] =$$
$$= -(0.014\pm0.001)D(R{-}H) + (1.89\pm0.14) \qquad (31)$$

These ideas were tested by calculating α directly from formula (29), using published activation energies for the reactions of the radicals F$^{\cdot}$, Cl$^{\cdot}$, Br$^{\cdot}$, I$^{\cdot}$, ROO$^{\cdot}$, $CD_3^{\cdot}$, $CF_3^{\cdot}$, O$^{\cdot}$, H$^{\cdot}$, HO$^{\cdot}$. (The activation energies, as a rule, are known less accurately than the rate constants for the reactions. Hence, the values for the radicals $C_2F_5^{\cdot}$, n-$C_3F_7^{\cdot}$, and CN$^{\cdot}$, which were found to give an unsatisfactory correlation, were ignored). The result was

$$\alpha = -0.015D(R{-}H) + 2.03.$$

It is clear that the agreement with Eqn. (31) is excellent. The values $\alpha_{CH_3} = 0.44$ and $\alpha_{Br} = 0.66$ may be compared with those reported by Trotman-Dickenson (0.49 [127] and 0.86 [129] respectively).

Eqn. (31) is a quantitative statement of Hammond's postulate[10], since α varies from 0 to 1 on going from the initial to the final state[119]. Thus, in accordance with the postulate, the transition state for the most active radical (F$^{\cdot}$) is indistinguishable from the initial state, i.e. $\alpha = 0$,

Table 7. Kinetic parameters of the reactions of free radicals (R·) with methane, ethane, and propane, and dissociation energies of the bonds (D(R–H)).

Radical R·	k_{CH_4}	$k_{C_2H_6}$	$k_{C_3H_8}$	$\lg \frac{k_{C_2H_6}}{k_{CH_4}}$	$E_{CH_4} - E_{C_2H_6}$, kcal mole^{-1} [a]	α	D(R–H) kcal mole^{-1}

CN	1	7.1 [d 263]	7.0 [d 263]	0.85	3.7?	0.34	111 [249]

a) Difference in activation energies; literature references are given in the previous columns. b) Mean value. c) Value of $k_{C_2H_6}$ calculated by using a corrected value of the rate constant for the reaction of the methyl radical with deuteroacetone [240]. d) Rate constants relative to the value for methane, taken as unity.

whereas for I· we have $\alpha = 0.89$, i.e. the transition state adopts the structure of the products almost completely. It follows that Eqns. (28) and (31) are correct only for the chosen range of D(R–H) values, since this range corresponds to a change of the transition state structure from the structure of the reactants to that of the products. In particular, when D(R–H) = 0, $\lg(k_{C_2H_6}/k_{CH_4}) \neq 6.62$ (the value required by Eqn. (28)).

In the reactions of $CH_3^{\cdot}$, $CF_3^{\cdot}$, Cl·, $C_2F_5^{\cdot}$, n-$C_3F_7^{\cdot}$, H·, and O· the transition state is "symmetrical" as expected, i.e. it is mid-way between the initial and the final configuration, since the dissociation energies of the bonds broken and formed in the reactions with methane are approximately equal for these radicals. Published data on the structure of the transition state for the reactions between methyl radicals and hydrocarbons support this conclusion (~50% of initial state character [185]), but earlier work [264] on the transition state of reactions with chlorine had detected only 10% of final state character in the transition state instead of 50% as found in our work. These results were obtained by comparing the differences in activation energy for the removal of primary and tertiary hydrogen atoms in triptane by chlorine atoms with the dissociation energies of these bonds.

However, the absolute rate constants for the reactions of chlorine with ethane, propane, and isobutane are approximately equal: $(2-3) \times 10^{13}$ cm^3 mole^{-1} s^{-1} at 100°. [255,256] Hence, the small difference in activation energy of these reactions is explained by the fact that practically every collision between the reactants leads to reaction—the upper limit of the rate constant for bimolecular reactions is given as 10^{14} cm^3 mole^{-1} s^{-1} by the collision theory—and changes in the structure of the alkane molecule have practically no effect on the reaction rate. However, on going from methane to ethane the rate of reaction of chlorine atoms increases approximately 60-fold (at 100°), and the activation energy changes by 2.9 kcal mole^{-1}, i.e. the reaction rate is very sensitive to the structure of the alkane. Hence, it is more correct to use these data to calculate the structure of the transition state.

It is interesting to note that the transition state has the same structure (~50% of initial state character) for a large number of radicals. This explains why the Polanyi–Semenov equation is so generally applicable.

From the above we may conclude that the increase in the rate constants of free-radical reactions on going from methane to ethane is due first of all to the decrease (by 6 kcal mole^{-1}) in the dissociation energy of the bond to be broken. Bond dissociation energies are also the rate determining factor in the reactions of other alkanes with free radicals. For each radical, the transition-state structure is the same in all the reactions, since Eqn. (17) applies. In the radical reactions of compounds whose substituents have strong polar and resonance effects (chloroform, toluene, etc.) the transition-state structure may differ from that of the same reactions with alkanes. Thus, the points for the reactions of the methyl radical with toluene and propylene [119] fall well away from the plot of Eqn. (17).

Eqns. (28) and (30) can be used either to calculate the kinetic parameters of free-radical reactions or to predict bond energy values (D(R–H)) and the parameter α. Thus, Pritchard and Perona [265] recently measured the rate constants of reactions (27) with the radical $CHF_2^{\cdot}$. They found $\lg(k_{C_2H_6}/k_{CH_4}) = 2.02$ at 100°. From Eqns. (28) and (31) we obtain $D(CHF_2\text{–H}) = 95.9$ kcal mole^{-1}, $\alpha = 0.55$. The experimental value of $D(CHF_2\text{–H})$ is 97.4 kcal mole^{-1}.

As was stated above (p. 226), the proportionality constant r^* of Eqn. (11) should depend on the structure of the transition state and therefore also on the parameter α. Unfortunately, the r^* values given in Table 5 refer to different temperatures, which makes it hard to compare them. However, there can be little doubt that r^* increases with α. (For example, $r^*_{I^{\cdot}} > r^*_{X(CH_2CH_2)^{\cdot}_n} > r^*_{CH_3^{\cdot}} = r^*_{CF_3^{\cdot}}$; the corresponding values of α from Eqn. (31) are 0.86, 0.52, 0.44, 0.40).

Progress in the Chemistry of Nitroxyl Radicals

E.G.Rozantsev and V.D.Sholle

Methods of obtaining nitroxyl radicals by the dehydrogenation of hydroxylamines, oxidation of amines, reduction of nitro- and nitroso-compounds and radical addition to nitrones are considered. Problems of the stability of nitroxyl radicals and their reactivity are discussed—redox reactions, radical reactions, complex formation, and reaction without use of the unpaired electron. There is a bibliography of 283 references.

CONTENTS

I. Introduction 233
II. Methods of obtaining nitroxyl radicals 233
III. Chemical properties of nitroxyl radicals 236

I. INTRODUCTION

Nitroxyl radicals are compounds which contain the >N–O group with one unpaired electron. The structure of this fragment can be represented as the superposition of two valence structures:

$$>\dot{N}^{+}\!-\!O^{-} \longleftrightarrow >\ddot{N}\!-\!\dot{O}\cdot\cdot$$

Depending on the effects of conjugation and the polarity of the medium the contribution of the first or second boundary structure to the principal state of the radical can be different.

There have been many studies, theoretical and experimental, to find the electronic structure of the nitroxyl radical. Unfortunately, the various results do not agree satisfactorily. Thus, some investigators[1-3] give values of ~ 0.8–0.9 for the spin density on the nitrogen atom ρ_{π}^{N} for non-aromatic radicals (0.6 for aromatic), whereas others[4-6] give $\rho_{\pi}^{N} = 0.3–0.4$.

Wieland referred to aromatic nitroxyl radicals as nitroxide or azoxyl radicals. In several studies this terminology was later extended to hetero-chain and heterocylic radicals which were non-aromatic in behaviour. Generally speaking, the term "nitroxide", and also "aminoxide" is unfortunate since it does not reflect the radical nature of these species and contradicts the rules of official nomenclature of organic compounds. In the Soviet literature the term "iminoksily" (iminoxyls) is used for non-aromatic nitroxyl radicals.

II. METHODS OF OBTAINING NITROXYL RADICALS

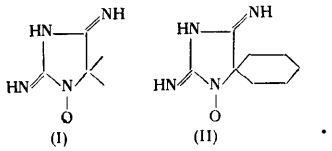
1. Dehydrogenation of Hydroxylamines

The O–H bond of hydroxylamines undergoes homolysis under the action of various reagents and nitroxyl radicals are formed.

In 1901 Piloty and Schwerin[7] obtained the first organic nitroxyl†, porphyrexide (I), by the action of potassium hexacyanoferrate(III) on 1-hydroxy-2,4-di-imino-5,5-dimethylhydantoin; the structure and free radical nature of (I) was established later[9].

† Fremy had obtained the first inorganic nitroxyl ion in 1845 by the oxidation of potassium hydroxylammonium disulphonate with lead(IV) oxide[8].

A spirocyclohexyl analogue of porphyrexide (II) was obtained by the same method in 1944[10]:



(I) (II)

In 1914–1922 Wieland developed a general method for making aromatic nitroxyls which is still widely used. The first stage was the preparation of diarylhydroxylamines:

$$ArNO + XMgAr' \rightarrow Ar\!-\!\underset{\underset{OMgX}{|}}{N}\!-\!Ar' \rightarrow Ar\!-\!\underset{\underset{OH}{|}}{N}\!-\!Ar'$$

The second stage was the single-electron oxidation of the hydroxylamine to a nitroxyl:

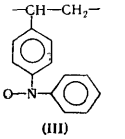
$$Ar\!-\!\underset{\underset{OH}{|}}{N}\!-\!Ar' \xrightarrow{-H'} Ar\!-\!\underset{\underset{O}{|}}{N}\!-\!Ar'$$

Wieland used Ag_2O as the oxidant in the second stage. Diphenyl-, phenyl-*p*-tolyl-, and di-*p*-tolyl-nitroxyls were obtained by this method[11-13]. The first stage of the method can be regarded as a general procedure for obtaining diaryl-, arylalkyl-, and dialkyl-hydroxylamines. In studying the mechanism of this reaction, Murayama showed that the best yields of hydroxylamines are obtained when a large excess of a Grignard reagent is used[14].

Using the Wieland method, Hückel and Liegel[15] obtained phenyl-9-*trans*-decalylnitroxyl in good yield by the action of phenylmagnesium bromide on 9-nitrosodecalin with subsequent oxidation of the hydroxylamine by air.

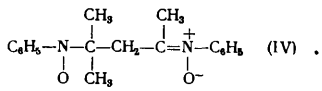
Deguchi and coworkers[16] obtained a series of methyl derivatives of diphenylnitroxyl by the same method.

The macromolecular polyradical (III) was obtained by the reaction of *p*-nitrosopolystyrene with phenylmagnesium bromide followed by oxidation of the hydroxylamine with silver oxide[17]:



(III)

The so-called Kenyon–Benfield radical (IV) is formed in good yield when the condensation product of acetone and phenylhydroxylamine is oxidised[18]‡:

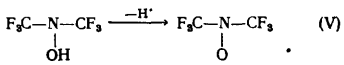


(IV)

Subsequently a series of derivatives of this radical were obtained[19].

Forrester[20] obtained a series of aryl-t-butylnitroxyls by the reaction of ArMgX with t-nitrosobutane and investigated their decomposition products. t-Butylferrocenylnitroxyl was obtained[21] by the action of t-nitrosobutane on ferrocenylmagnesium bromide followed by autoxidation of the hydroxylamine which is formed.

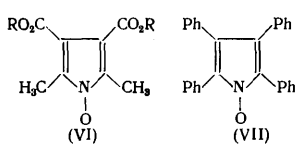
In 1965 Soviet[22,23] and American[24] investigators described the preparation of bis(trifluoromethyl)nitroxyl (V) by the oxidation of the corresponding hydroxylamine:



(V)

The oxidants used were $KMnO_4$, Ag_2O, F_2, and HgO.

In 1963 Rozantsev and coworkers[25] showed that oxidation of certain heterocyclic hydroxylamines of the pyrrol series leads to the formation in the solution of the corresponding nitroxyls (VI):



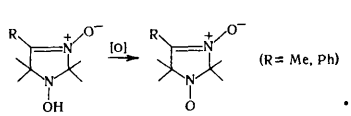
(VI) (VII)

A nitroxyl of similar structure (VII) was isolated by Rio and coworkers[26] in 1968 from the products of the oxidation of 1-hydroxytetraphenylpyrrol by PbO_2.

The same oxidant was used for obtaining acylalkyl-, acylaryl-[27], and arylaminocarbonylarylnitroxyls which are stable in solution[28]. In 1965 Aurich[29] obtained acylphenylnitroxyls by oxidation of the corresponding *N*-hydroxyamides with nickel peroxide[29].

Short-lived aliphatic nitroxyls can be obtained both by the oxidation of hydroxylamines[30,31] and also by photolysis of the latter[31,32].

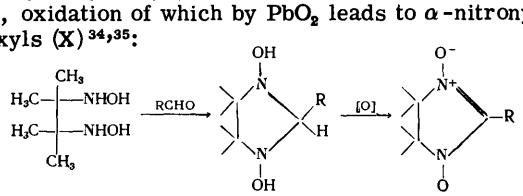
In 1968 Volodarskii and coworkers[33] obtained nitroxyls of structure (VIII) by the oxidation of 1-hydroxy-2,2,5,5-tetramethyl-4-R-3-hydroxyimidazoline by Tollen's reagent or hydrogen peroxide:



(R = Me, Ph)

(VIII)

In the same year Ullman condensed 2,3-bis(hydroxylamino)-2,3-dimethylbutane with aldehydes and obtained 1,3-dihydroxy-4,4,5,5-tetramethyl-2-R-tetrahydroimidazole, oxidation of which by PbO_2 leads to α-nitronylnitroxyls (X)[34,35]:



(IX) (X)

‡ Note added in proof. A cyclic structure has been suggested[283] for (IV).

where R = H, CH_3, C_2H_5, $[CH_2]_{12}CH_3$, CH_2OH, $CH(CH_3)_2$, $CH(OC_2H_5)_2$, C_6H_5, *p*-HOC_6H_4, or *p*-$NO_2C_6H_4$.

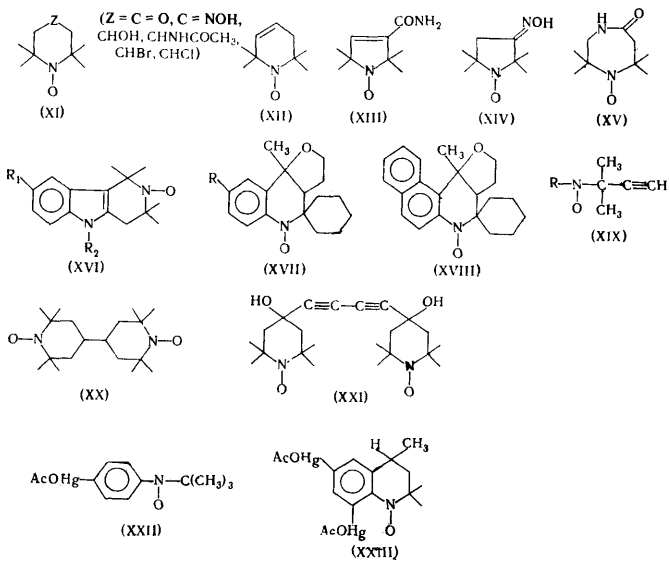
When R = alkyl, the corresponding imidazole can be smoothly oxidised by potassium periodate.

2. Oxidation of Amines

Despite the fact that the preparation of nitroxyls by the oxidation of amines was developed later than the method of dehydrogenation of hydroxyamines, it is now the most important method of making nitroxyls (especially cyclic dialkylnitroxyls).

In 1956 Hoskins[36] recorded the EPR signal of diphenylnitroxyl on passing oxygen into a solution of diphenylamine. Subsequently a large number of nitroxyls was obtained in solution by the oxidation of the corresponding aromatic, aliphatic–aromatic, aliphatic, and acyclic amines. The oxidants used were: hydroperoxides[37–39], hydrogen peroxide with cerium salts[40], RO_2 radicals[41–43], Ag_2O,[44] an alkaline solution of hydrogen peroxide[45], PbO_2,[46] various per-acids[47], the pertungstate ion[48], and benzoyl peroxide[49]. These oxidants can be useful in studying reaction mechanisms and in finding the structure of the nitroxyls.

Oxidation of secondary amines with hydrogen peroxide in the presence of salts of tungstic acid is a convenient method for the preparation of nitroxyls. By this method, developed in our laboratories, stable nitroxyls of the piperidine series (XI) and (XII)[50–53], of hydrogenated pyrrole (XIII) and (XIV)[54,55], of homopiperidine (XV)[56], of carboline (XVI)[57,58], of hydrogenated quinoline (XVII)[59,60], of hydrogenated benzoquinoline (XVIII)[61], aliphatic nitroxyls (XIX)[62], the first non-conjugated biradical (XX)[63], the biradical (XXI)[64], and radicals stable in solution of the benzoxazine, indoline, and carbazole series[65], and organomercury nitroxyls (XXII) and (XXIII)[66] were obtained.



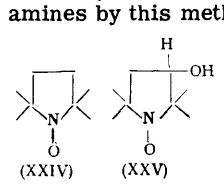
(XI) (XII) (XIII) (XIV) (XV)

(XVI) (XVII) (XVIII) (XIX)

(XX) (XXI)

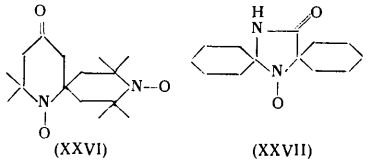
(XXII) (XXIII)

Rassat and coworkers obtained t-butylphenylnitroxyl[67] and certain nitroxyls of the pyrrolidine series (XXIV) and (XXV)[68] on oxidising amines by this method:



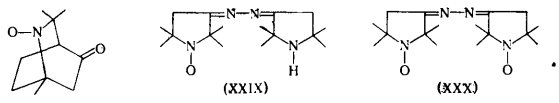
(XXIV) (XXV)

Murayama[69] used the same method to obtain the biradical (XXVI). Then by oxidising 3-oxo-2,5-bicyclohexylimidazoline with hydrogen peroxide in the presence of sodium tungstate in acetic acid medium he obtained the nitroxyl (XXVII)[70].



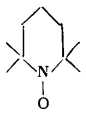
(XXVI) (XXVII)

Oxidation of amines with hydrogen peroxide is readily effected when tungstophosphoric acid and ammonium molybdate are used as catalyst[71]. The monoradicals (XXVIII)[72] and (XXIX)[73] and the biradical (XXX)[73] were obtained by this means. Despite the fact that the use of tungstophosphoric acid accelerates the oxidation the yields of nitroxyls are reduced:



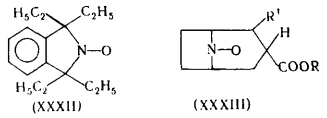
(XXVIII) (XXIX) (XXX)

The mechanism of oxidation of the secondary amines was studied by Lebedev and Kazarnovskii[74], who showed that the oxidant in this instance is the pertungstate ion. They obtained the stable heterocyclic nitroxyl (XXXI):



(XXXI)

Subsequently the method of oxidising amines with hydrogen peroxide in the presence of Na_2WO_4 was extended to tertiary amines. In this way nitroxyls of the isoindoline series (XXXII)[75] were isolated and radicals of the alkaloids of the tropane series (XXXIII) were studied in solution[76]:



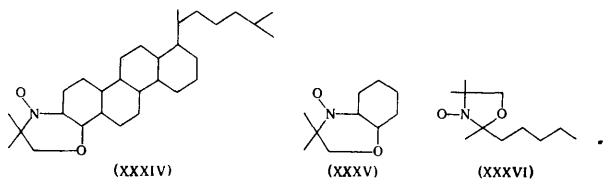
(XXXII) (XXXIII)

In 1964 Tokumaru and coworkers[77] obtained diphenyl, di(methoxyphenyl)-, and di(chlorophenyl)nitroxyls by the action of perbenzoic acid on diarylamines. Di(nitrophenyl)- and dimethoxycarbonyl diphenylnitroxyls are obtained in this instance in very low yields.

Maender and Janzen[78] obtained a large number of triphenylmethyl(alkyl)nitroxyls by oxidation of the corresponding secondary amines with *p*-nitroperbenzoic acid.

Ozone[79], benzoyl peroxide[80], and t-butyl hydroperoxide[81] were used as oxidants in the preparation of nitroxyls from secondary amines.

A specific method for the conversion of ketones into stable nitroxyls has been suggested[82]. On reaction with 2-methyl-2-aminopropanol in the presence of *p*-toluenesulphonic acid, ketones give oxazolidines, which are oxidised by *p*-chloroperbenzoic acid to form the corresponding nitroxyls. The nitroxyls (XXXIV)–(XXXVI) were obtained by this method:

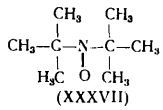


(XXXIV) (XXXV) (XXXVI)

This method was convenient for obtaining certain "spin-labelled" analogues of lipids[83] and steroids[84].

3. Reduction of Nitro-compounds

On reducing $(CH_3)_3CNO_2$ with metallic sodium or polarographically, Hoffmann[85,86] obtained in 1961 di-t-butylnitroxyl (XXXVII):

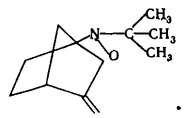


(XXXVII)

In several later studies[87] he made a detailed investigation of the mechanism of this reaction and showed that the primary act of the reduction is the formation of the anion-radical $(CH_3)_3CNO_2^{\cdot-}$ which is then decomposed into NO_2^- and $t\text{-}C_4H_9^{\cdot}$. Recombination of the anion-radical with $t\text{-}C_4H_9^{\cdot}$ leads to the formation of the anion of *NN*-di-t-butylhydroxylamine oxide. The hydrolysis of this salt gives (XXXVII). An analogous mechanism was also proposed for the reactions of tertiary nitroso-compounds with organosodium and organolithium compounds. Several asymmetric nitroxyls were obtained in this way. However, it is noteworthy that the yields of nitroxyls, with the exception of (XXXVII), are extremely low.

The mechanism of reduction of nitro-compounds was also considered by Rassat[88], who used a Grignard reagent[89,90] and $LiAlH_4$ [91,92] as reductants. In studying the reactions of various *para*-substituted nitrobenzenes with t-butylmagnesium chloride[93] the EPR spectra of 22 nitroxyls were recorded, but their structure was judged solely on the basis of the EPR results, which are inadequate.

Rassat and coworkers obtained a stable, optically active nitroxyl (XXXVIII) by the action of t-butylmagnesium chloride on 1-nitrocamphene[94]:

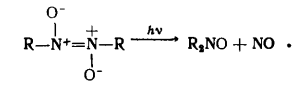


(XXXVIII)

Results have now been obtained[95] which show that not only tertiary but also secondary nitro-compounds can be reduced by this method.

4. Reduction of Nitroso-compounds

In 1964 a group of Japanese investigators described the preparation of nitroxyls in the photolysis of substituted derivatives of nitrosobenzene[96]. Strom and coworkers[97] greatly increased the number of aromatic nitroxyls obtained by this method and found a correlation between the hyperfine splitting constants of the nitrogen atom a_N and the Hammett constant (reviewed by Janzen[98]). Strom and Bluhm[99] assume that the dimer of the nitroso-compound is responsible for the formation of nitroxyls, and that it disproportionates when irradiated:



Despite this assertion a group of Dutch scientists give a strong proof of the formation of nitroxyls directly from the monomeric form[100,101] by the scheme:

$$RNO \xrightarrow{h\nu} R^{\cdot} + NO$$
$$R^{\cdot} + RNO \rightarrow R_2NO^{\cdot}$$

Aliphatic nitroso-compounds form nitroxyls even when irradiated with red light. The formation of nitroxyls also takes place during the thermal decomposition of nitroso-compounds. Tertiary nitroso-compounds thereby yield nitroxyls very readily, but secondary and primary nitroso-compounds require an elevated temperature, which is evidently necessary for the conversion of the dimer into the monomeric form. Ultraviolet irradiation of nitrosoadamantane produced diadamantylnitroxyl[102]. Evidently bistrichloromethylnitroxyl is formed similarly from CCl_3NO.[103]

Photochemical and thermal decomposition of alkyl nitrites evidently also leads to the production of nitroxyls, via the intermediate formation of nitroso-compounds[104-106].

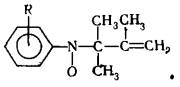
Wajer and coworkers[107] showed that nitroxyls are formed in both the thermal reduction of nitroso-compounds by hydroxylamines[107]:

$$RNO + R'NHOH \rightarrow \underset{\underset{O}{|}}{R-NH} + \underset{\underset{O}{|}}{R'NH}$$

and also in the photochemical reduction of thiophenol[108]:

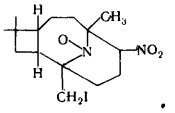
$$2RNO + 2PhSH \rightarrow \underset{\underset{O}{|}}{2R-NH} + PhSSPh$$

In 1966 Sullivan[109] described the production of alkenylarylnitroxyls (XXXIX) by the reaction of nitrosoaryls with 2,3-dimethylbut-2-ene. Here a hydroxylamine is formed as an intermediate, which is oxidised by the nitrosoaryl or by oxygen into the corresponding nitroxyl:



(XXXIX)

Possibly the formation of caryophyllene "iodo-nitrosite" (XL) takes place similarly[110]:



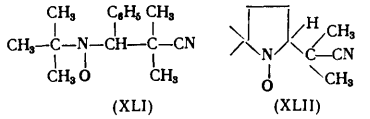
(XL)

As already noted, nitroso-compounds are capable of reacting with active radicals, to form relatively stable nitroxyls. Their ability to do this is now widely used for the collection and establishment of the structure of various radicals formed in polymerisation[111,112], radiolysis[113], photolysis[114,115], and other chemical reactions[101,116-119]. t-Nitrosobutane and nitrosobenzene are most frequently employed as "traps" for radicals.

Nitroxyls are also formed in the reaction of nitrobenzene with stable radicals—triphenylmethyl and 2,4,6-tri-t-butylphenoxyl[120]. A series of aryl-(2-cyanoisopropyl)nitroxyls was obtained by the reaction of nitrosoaryls with the 2-cyanoisopropyl radical[6].

5. Free-radical Addition to Nitrones

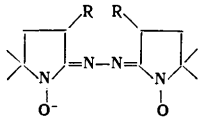
As Brown noted[121], nitrones can give nitroxyl radicals on adding radicals at the double bond. This was confirmed by the experiments of Iwamura and Inamato[122], who obtained the stable nitroxyl (XLI) in 3.2% yield by the reaction of azobutyronitrile with *N*-t-butyl-α-phenylnitrone. The cyclic nitroxyl (XLII) obtained by this method was unstable and rapidly disproportionated in solution:



(XLI) (XLII)

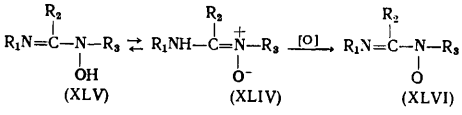
It has been shown[123] that certain nitrones are capable of removing a hydrogen atom from a solvent with the formation of nitroxyl radicals. The ability of nitrones to react with radicals allows them to be used together with nitroso-compounds as "traps" for active radicals[124-126].

Forrester and coworkers[127] described the addition of short-lived radicals to nitrones. They reduced the corresponding azo-1-pyrroline-1-oxide with sodium to give the anion-radical (XLIII)[127]:



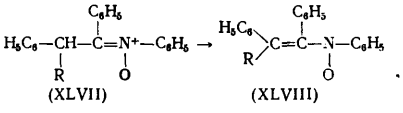
(XLIII)

The oxidation of *C*-aminonitrones (XLIV), which are in tautomeric equilibrium with the corresponding hydroxylamines (XLV), leads to nitroxyls which are stable in solution (XLVI)[128-130].



(XLV) (XLIV) (XLVI)

At the moment the nitrone (XLVII) is produced it is dehydrated with the formation of a derivative of the phenyl(vinyl)nitroxyl (XLVIII)[131]:



(XLVII) (XLVIII)

A survey of the methods of obtaining nitroxyl radicals cannot be concluded without mentioning the old but preparatively convenient method of Meyer[132,133]. In this method oxidation of phenol esters with nitric acid followed by treatment with perchloric acid leads to oxides of diarylammonium salts, reduction of which gives the nitroxides.

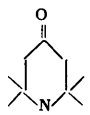
Selective specific reactions of radicals which do not involve the free valency are widely used for obtaining various functional derivatives of nitroxyls[134]. This method of preparation will be discussed in Section III.

III. CHEMICAL PROPERTIES OF NITROXYL RADICALS

1. Decomposition and Stability of Nitroxyls

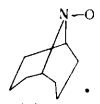
Thermochemical data[135,136] show that the gain in energy of the delocalisation of an electron for the N–O fragment is ~ 30.4 kcal mole^{-1} for heterocyclic nitroxyls.

It is remarkable that 2,2,6,6-tetramethyl-4-oxo-1-piperidyl radical (XLIX)[137] is unstable owing to the impossibility of delocalisation of the unpaired electron.



(XLIX)

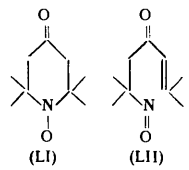
Many heterocyclic amines form nitrones on oxidation[138-141]. Oxidation of heterochain amines leads, through the intermediate formation of nitroxyls, to nitrones[30]. In 1956 Rogers and coworkers[142] proposed that nitroxyl radicals would be stable if their nitrogen atom was framed by tertiary α-carbon atoms, since then the formation of a nitrone would be excluded. Subsequent work showed that actually the absence of α-hydrogen atoms ensures the stability of the nitroxyls. The bicyclic nitroxyls (L)[143], (XXVIII)[72], and (XXXIII)[76], which have α-hydrogen atoms, cannot form nitrones without destruction of a ring owing to Bredt exclusion[144] and therefore should be stable:



(L)

The stability of the nitroxyl (XLI) is explained by the impossibility of its disproportionating to form a nitrone owing to steric hindrance in the region of the reaction centre[122]; the analogous cyclic radical (XLII) is unstable.

According to Murayama[145], the relative instability of (LI) is the result of the carbonyl group activating the hydrogen atoms in position 3 and 5 of the piperidine ring and the radical disproportionating with formation of nitrogen(II) oxide, phorone—of which the nitroso-compound (LII) is a precursor—and 2,2,6,6-tetramethyl-1-hydroxy-4-oxopiperidine:



(LI) (LII)

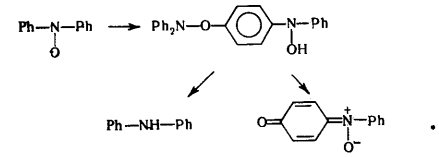
When irradiated for 15 h the nitroxyl (XIII) decomposes according to the first-order law with formation of the diene (LIII) and probably nitrogen(II) oxide[146]. Photolysis of other nitroxyls proceeds only when the radiation is more prolonged:

(LIII)

Photolysis of biradicals also leads to their destruction[147], the EPR spectrum of the biradical being transformed initially into the spectrum of a monoradical and only then does the EPR signal of the monoradical start to disappear.

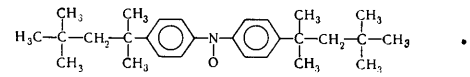
Thermogravimetric investigation of silicon-containing bi- and mono-radicals shows[147] that all these compounds, irrespective of molecular weight and structure, decompose at 195°C with evolution of heat and a decrease in the weight of the specimen.

The decomposition of aromatic radicals was first studied by Wieland and Roth[12], who showed that diphenylnitroxyl disproportionates into diphenylamine and quinone imine oxide:



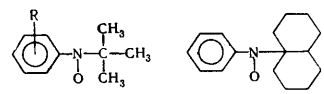
Subsequently an analogous disproportionation was observed with 4,4'-dichlorodiphenylnitroxyl[77]. Aryl alkyl nitroxyls[20,148] and the nitroxyls of the tetrahydroquinoline series[65] decompose similarly, and in the decomposition of certain 4-alkylphenyl-t-butylnitroxyls dimers and trimers were isolated[20].

The most stable series of diarylnitroxyls are 4,4'-dianisylnitroxyl[12,132], 4,4'-dinitrodiphenylnitroxyl[12], 2,2'-dimethyl-4,4',6,6'-tetramethoxydiphenylnitroxyl[132], and the nitroxyl (LIV)[149]; the most unstable are 4,4'-ditolylnitroxyl[11,12]; 2,2',4,4'-tetramethoxydiphenylnitroxyl[132,133], and diphenylnitroxyl[12]. The stability of (LIV) can probably be explained by steric hindrances to dimerisation according to Wieland's scheme:



(LIV)

In studying aryl-t-butylnitroxyls (LV) Calder and Forrester[150] concluded that their somewhat greater stability in comparison with phenyl-t-butylnitroxyl is due to steric factors.



(LV) (LVI)

A noteworthy fact is that unlike phenyl-t-butylnitroxyl (LV; R = H) the structurally similar phenyl-*trans*-decalylnitroxyl (LVI)[15] and the Kenyon–Benfield radical (IV)[18] are stable.

It has been shown[151] that an increase in the stability of the nitroxyls of the hydrogenated quinoline series can be achieved by the introduction into position 2 of the heterocycle of two methyl groups of the geminal type. The introduction of a spiran cyclohexyl screen in this position of the heterocycle sharply increases the stability of the nitroxyls of the hydrogenated quinoline and benzoxazine series[59-61].

The decomposition products and stability of the α-nitronylnitroxyls (XVIII) was not investigated, but it is noteworthy that radicals with alkyl substituents are less stable than those with aromatic[34,35].

2. Redox Reactions of Nitroxyls

Usually the presence not only of an electron donor but also a proton donor is necessary for the reduction of nitroxyls. This evidently explains the stability of nitroxyls in relation to the alkali metals[87].

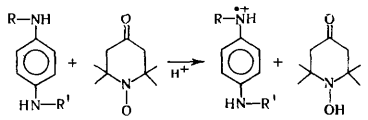
The nature of the products of the reduction of nitroxyl radicals depends on the reductant used or, in hydrogenation with hydrogen, on the catalyst. In the presence of platinum catalyst Adams hydrogenation leads exclusively to the formation of the corresponding hydroxylamines both

for monoradicals [57,84,152,153] and for polyradicals [63]. The use of Raney nickel catalyst leads to the formation of amines [62,154]. Here the reaction proceeds through the stage of formation of hydroxylamine. Reduction with tin(II) chloride in hydrochloric acid [12], zinc in acetic acid [13], and hydrogen iodide also lead to amines [11]. The last reaction enables nitroxyls to be titrated iodometrically [155]. Bistrifluoromethylnitroxyl reacts with gaseous HCl and HBr with the formation of hydroxylamine [23,156]. Phenylhydrazine [12], hydrazine [157], lithium tetrahydroaluminate [158], and formic acid [159] reduce nitroxyls to hydroxylamines. (Lithium tetrahydroaluminate does not reduce the nitroxyl group of the radicals of the hydrogenated pyrrol series [160].) Hydrazobenzene is also a strong reductant of nitroxyl radicals [161]. Kinetic investigation allows the following scheme of reduction to be proposed:

$$>N\dot{-}O + Ph{-}NH{-}NH{-}Ph \rightarrow Ph{-}\dot{N}{-}NH{-}Ph + >N{-}OH$$
$$>N\dot{-}O + Ph{-}\dot{N}{-}NH{-}Ph \rightarrow Ph{-}N{=}N{-}Ph + >N{-}OH\,.$$

In the polarographic reduction of nitroxyls at the dropping mercury electrode [162] hydroxylamines are formed, transfer of an electron preceding the protonisation of the radical.

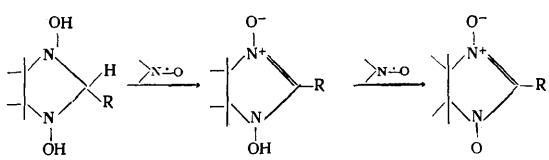
Nitroxyl radicals are widely used in chemistry as mild one-electron oxidants. Thus in acid medium the reaction of nitroxyls with substituted *p*-phenylenediamines leads to the formation of stable cation-radicals [163,164]:



Phenols are oxidised by nitroxyls to quinones [165]; sterically hindered phenols form stable phenoxyl radicals [166].

Nitroxyls of the piperidine series oxidise Fe^{2+} to Fe^{3+}, thereby being converted into hydroxylamines [167]. Interestingly, nitroxyls of the isoindoline and pyrrolidine series do not react with Fe^{2+}. Nitroxyls are also reduced to hydroxylamines by dihydropyridines [168,169] and plastoquinones [170].

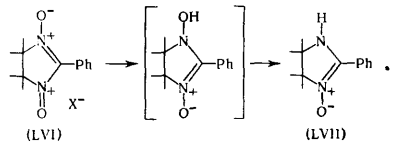
α-Nitronylhydroxylamines are oxidised by nitroxyl radicals to the corresponding α-nitronylnitroxyls [34]:



Nitroxyls are capable not only of accepting electrons but also of donating them, forming highly reactive salts of an immonium oxide $>\overset{+}{N}{=}O,\ X^-$. [34,132,158] To avoid further conversions of the salts of the immonium oxide the oxidation is carried out in an inert medium, using chlorine or bromine as oxidant. Unlike chlorine [171], the use of bromine usually leads to perbromides [172]. Biradicals form salts of an immonium oxide just like monoradicals [158,171,172]. The salts of immonium oxides oxidise primary alcohols to aldehydes and secondary alcohols to ketones, thereby being converted into hydroxylamines. This process can proceed both by a radical and by an intramolecular cyclic mechanism [158]. Nitroxyl halides react violently with tertiary amines with the formation of the amine hydrohalide and a nitroxyl radical. A cation-radical of the amine is formed as an intermediate [158]. Iodometric titration of immonium oxide salts leads to hydroxylamines [158]:

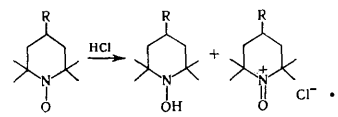
$$>\overset{+}{N}{=}O \xrightarrow{\bar{e}} >N\dot{-}O \xrightarrow[H^+]{\bar{e}} >N{-}OH\,.$$

Immonium oxide salts oxidise aqueous alkali to hydrogen peroxide [35] and are reduced by water to the initial nitroxyl [158]. Boiling (LVI) in alcoholic solution leads to the amine (LVII) through the intermediate formation of a hydroxylamine [35]:



(LVI) (LVII)

Under the action of dry hydrogen chloride, nitroxyls disproportionate according to the scheme [158]:



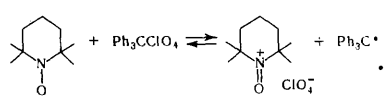
The Kenyon–Benfield radical also reacts [18]. Under the action of dry hydrogen chloride di-t-butylnitroxyl (XXXVII) forms hydroxylammonium chloride [86].

Under the action of acids, nitroxyls rapidly disproportionate [35,158]; the first stage of this process is the reversible protonisation of the nitroxyl group [173,174]:

$$>N\dot{-}O \underset{-H^+}{\overset{+H^+}{\rightleftharpoons}} >\overset{+}{N}\dot{-}OH\,.$$

Aprotic acids act specifically on the ketone-radical (LI). The radical disproportionates into hydroxylamine and immonium oxide salt, which decomposes with the formation of the nitroso-compound (LII) [175]. [As already noted [145], the thermal decomposition of the ketone radical also leads to (LII)]. To explain this process it is not necessary to assume the existence of an ion–radical equilibrium in the solution of the nitroxyl.

Reaction of nitroxyls with Ph_3CClO_4 in the presence of oxygen leads to a salt of the immonium oxide [176]:



This process is complicated by the decomposition of Ph_3CClO_4 with the formation of $HClO_4$ under the action of which the nitroxyl disproportionates as usual.

Nitroxyls of the piperidine series are oxidised by Cu^{2+} ions in methanol solution [159]. This reaction does not take place in water. Interestingly, a reduction product of the radical is formed finally—hydroxylamine, probably as a result of the transfer of a hydride ion from methanol to the oxidised form of the radical:

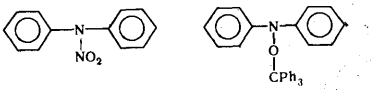
$$>N\dot{-}O + Cu^{2+} \rightarrow >\overset{+}{N}{=}O + Cu^+$$
$$>\overset{+}{N}{=}O + CH_3OH \rightarrow >N{-}OH + \overset{+}{C}H_2OH$$
$$\overset{+}{C}H_2OH \rightarrow CH_2O + H^+\,.$$

A similar process is observed in the reaction of 2,2,6,6-tetramethyl-1-hydroxypiperidine with $Cu(ClO_4)_2$ in triethyl orthoformate solution [177]. In this instance a reduction product of the nitroxyl is also formed—2,2,6,6-tetramethylpiperidine.

Di-t-butylnitroxyl (XXXVII) is capable of promoting the catalytic oxidation of methanol into formaldehyde[178] and is involved in the redox cycle.

3. Radical Reactions of Nitroxyls

Nitroxyls, like all radicals, undergo recombination. (Nitroxyls do not recombine amongst themselves, except for bistrifluoromethylnitroxyl[22]). Diphenylnitroxyl recombines with nitrogen(II) oxide and with triphenylmethyl to form the corresponding derivatives (LVIII) and (LIX)[18].



(LVIII) (LIX)

4,4'-Dinitrophenylnitroxyl is formed with nitrogen(IV) oxide. As Wieland and Roth showed[12], this reaction takes place with saturation of the free valence and with subsequent oxidation of the hydroxylamine formed.

The recombination of diphenylnitroxyl with 2,4,6-tri-t-butylphenoxyl has also been described[179].

Owing to the presence of bulky substituents near the reaction centre, non-aromatic nitroxyls do not react with triphenylmethyl[176] or 1,1-diphenyl-2-picrylhydrazyl[159].

The reaction of nitroxyls with 2-cyanoisopropyl radical, obtained in the decomposition of azoisobutyronitrile, leads to the *O*-2-cyanoisopropylesters of hydroxylamines[159,180].

The presence of phenyl radicals in the system also leads to the corresponding esters, as is observed as side reactions in the reduction of nitroxyls with phenylhydrazine[153].

Nitroxyls are capable of reacting with thiyl radicals formed from benzenethiols[181], thiamine disulphide[182], and tetramethylthiuram disulphide[183].

Aromatic nitroxyls react with both alkyl and peroxide radicals, whereas non-aromatic ones react only with alkyl radicals[184,185], which allows them to be used as acceptors of alkyl radicals[186].

The ability of nitroxyls, in reacting with active radicals, to break radical chains allows them to be used as inhibitors of the radical polymerisation of tetrafluoroethylene[187], chloroprene[188], styrene[189], and 2-vinylpyridine[190]. Nitroxyls can be used as inhibitors for the thermal oxidative destruction of polyamines[191,192], polypropylene[193,194], and polyformaldehyde[194,195], as inhibitors of the photo- and thermodegradation of polyethylene[196] and of poly(vinyl chloride)[197]. Nitroxyls inhibit the autoxidation and polymerisation of styrene[198]. In studying the inhibition of the polymerisation of α-methylstyrene it was shown[199] that the reactivity of the biradicals differs significantly from that of monoradicals.

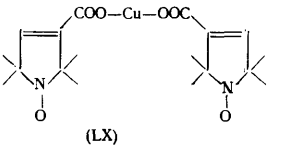
At elevated temperature nitroxyls are capable of removing hydrogen from hydrocarbons[200]. The reactivity of biradicals and polyradicals in reactions involving the removal of hydrogen depends significantly on the spin–spin exchange between the paramagnetic fragments[201].

Kreilick and Weissman[202] observed by the NMR method that in a solution containing a nitroxyl radical and the corresponding hydroxylamines, hydrogen rapidly migrates from the hydroxylamine to the radical. This process resembles the Wieland exchange reaction[13], where the reaction of diphenyl nitroxyl and tetra(methoxyphenyl)-hydrazine leads to di(methoxyphenyl)nitroxyl and tetraphenylhydrazine.

Specific addition reactions of bis(trifluoromethyl)nitroxyl[23,24,156,203–206] will not be discussed in the present review.

4. Complex Formation

The copper salt of 3-carboxy-2,2,5,5-tetramethyl pyrroline-1-oxyl[207] (LX):



(LX)

is diamagnetic, unlike the true biradicals and copper(II) salts, which shows the formation of a complex with participation [in spin pairing (Ed. of Translation)] of the unpaired electrons of both nitroxyl groups and copper ion. Similar complexes with metals of variable valence are formed by paramagnetic Schiff bases[208,209] and xanthogenates[210].

On reacting with palladium salts, di-t-butylnitroxyl (XXXVII) forms the diamagnetic complexes $XPd[ONC(CH_3)_3]_2$.[211] With cobalt halides, (XXXVII) forms paramagnetic complexes which dissociate on dissolution[212].

2,2,6,6-Tetramethylpiperidine-1-oxide forms complexes[177] on reacting with the perchlorates of Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Zn^{2+}, and Cu^{2+}. Nitroxyls form stable complexes with Lewis acids[213,214] and the EPR spectrum shows splitting from the magnetic nuclei of aluminium (for AlX_3) and gallium (for GaX_3).

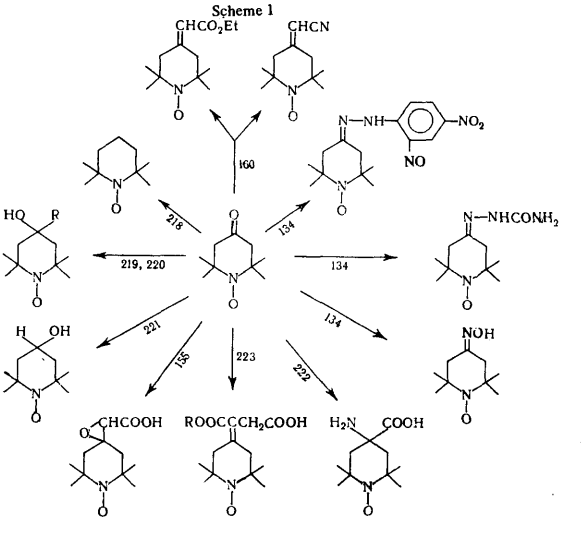
5. Reactions without Use of the Free Valence

The presence in many nitroxyls of the hydrogenated pyridine and hydrogenated pyrrole series of a second functional group separated from the radical centre by a chain of σ-bonds, and the reliable steric screening of the nitroxyl group allowed a class of reactions new in principle to be effected—reactions of radicals without use of the free valence[53,134,215].

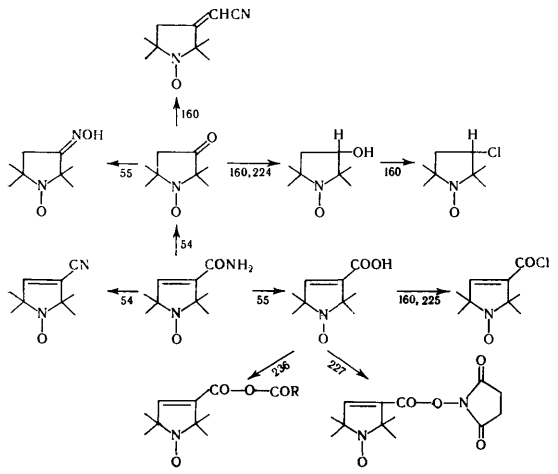
As already noted[216], it is possible that certain reactions of porphyrexide (I) proceed without participation of the unpaired electron, but experimental proof of this has not yet been obtained.

The scheme advanced by Forrester[217] for the reaction of chlorine with (I) is subject to doubt since it was not confirmed experimentally.

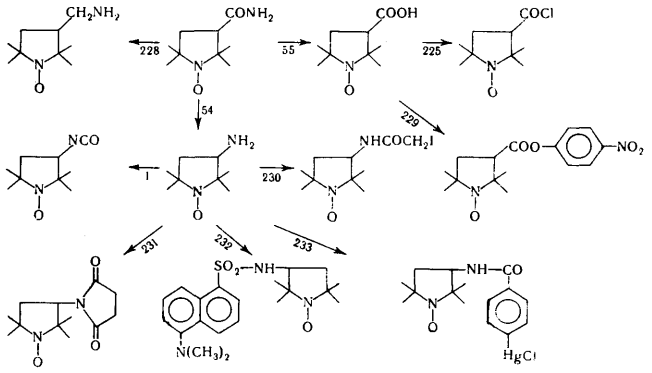
Scheme 1



Scheme 2



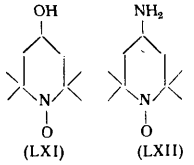
Scheme 3



Schemes 1–3 give an idea of the synthetic possibilities of reactions of radicals not involving the unpaired electron. It is noteworthy that the insignificant yield of paramagnetic products in the reduction of the ketone-radical (LI) with hydrazine and in its reaction with ethylmagnesium bromide undoubtedly show the dominating role in this instance of trivial reactions involving the unpaired electron.

The application to five- and six-membered ketone-radicals of the modified Wittig reaction[234] allowed the corresponding acid- and aldehyde-radicals to be synthesised[160]. However, not all the stages of this preparation are reactions without participation of the unpaired electron.

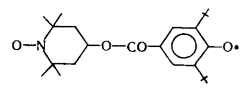
This type of reaction, first effected with ketone-radical (LI), was subsequently extended to other bifunctional nitroxyls. Six- and five-membered hydroxy- and amino-radicals were especially promising in this respect:



(LXI) (LXII)

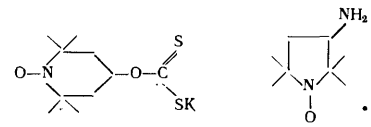
The method of preparation of paramagnetic esters most usually employed is the condensation of an alcohol radical (LXI) with acid chlorides[53,235-237]. In the reaction of alcohols with acid chlorides, hydrogen chloride is released, under the action of which the nitroxyls disproportionate. To avoid this the reaction is carried out in the presence of tertiary amines. As well as acid chlorides, anhydrides[157] and carboxylic acids can be used for the synthesis of paramagnetic esters; in the latter instance dicyclohexylcarbodi-imide was used as condensing agent[228,238]. Reaction of the alcohol-radical (LXI) with the chlorides of dicarboxylic acids leads smoothly to biradicals[239-242]. This method is general for the preparation of polyradicals[242-244]. A series of individual polyradicals was prepared under the action on pyridine solutions of pyrocatechol, hydroquinone, and phloroglucinol of 2,2,5,5-tetramethyl-1-hydroxypyrroline-3-carbonyl chloride[225].

By the action on the alcohol-radical (LXI) of 3,5-di-t-butyl-4-hydroxybenzoyl chloride with subsequent dehydrogenation of the phenol, mixed nitroxyl–phenoxyl biradical (LXIII) was obtained:



(LXIII)

In addition to organic acid chlorides, phosphorus, sulphur and silicon chlorides can be used for obtaining polyradicals[243-247]. Nitroxyl analogues of esters of phosphorus acids were synthesised in this way[248-250]. The alcohol radical (LXI) reacts smoothly with isocyanates. Both monoradicals[53] and polyradicals[239] can be obtained in this way[239]. The reaction of an alcohol-radical with carbon disulphide in alkali leads to the xanthogenate (LXIV), which forms the corresponding biradical under the action of iodine[210]:



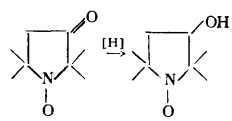
(LXIV) (LXV)

The reaction of the amine-radicals (LXII) and (LXV) with acid chlorides enables a large number of a variety of paramagnetic amides to be obtained[235,236]. The reaction of the amine-radical (LXII) with aromatic aldehydes leads to paramagnetic Schiff bases[208]. The action of di-isocyanates on (LXII) gave the corresponding biradicals[251].

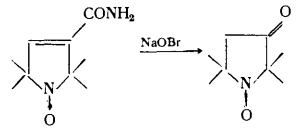
Reactions which do not involve a free valence allowed paramagnetic polymers to be prepared. Thus, the reaction of the alcohol-radical (LXI) with the acid chloride of poly(acrylic acid) leads to the formation of a paramagnetic polymer with a lattice structure[252]. Another approach has also been employed[253]. A paramagnetic polymer is obtained by the polymerisation of the 2,2,6,6-tetramethyl-1-hydroxy-4-piperidine ester of methylacrylic acid.

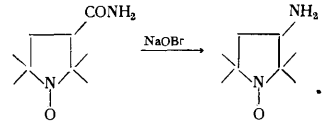
A paramagnetic polymer is also formed in the reaction of sulphur dichloride with diallyl-(2,2,6,6-tetramethyl-1-hydroxy-4-piperydyloxy)silane[254].

Reactions of radicals not involving the use of the free valence can assist in the preparation of nitroxyls which are almost impossible to obtain by other methods. For example, 2,2,5,5-tetramethyl-3-hydroxypyrrolidine 1-oxide cannot be obtained by direct oxidation of an amine, but it is readily obtained by the reduction of 2,2,5,5-tetramethyl-3-oxopyrrolidine 1-oxide with aluminium isopropoxide[255].

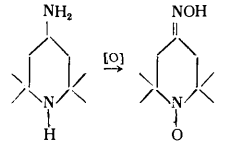


It is also impossible to obtain 2,2,5,5-tetramethyl-3-oxopyrrolidine 1-oxide and 2,2,5,5-tetramethyl-3-aminopyrrolidine 1-oxide by direct catalytic oxidation but they were obtained by the following scheme[54]:



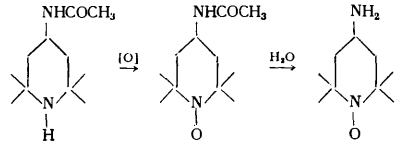


Catalytic oxidation of 2,2,6,6-tetramethyl-4-aminopiperidine with hydrogen peroxide leads to the oxime-radical (LXVI):



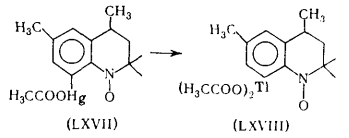
(LXVI)

The amine-radical (LXII) can be obtained by the following scheme[52]:



(LXII)

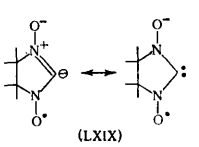
In studying the reaction of the organomercury nitroxyl (LXVII) with thallium(III) isobutyrate replacement of mercury by thallium was observed, with the formation of the organothallium nitroxyl (LXVIII)[256]:



(LXVII) (LXVIII)

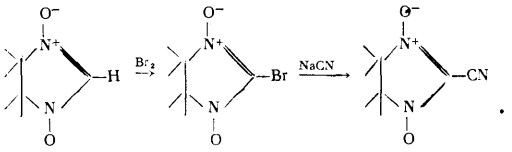
This reaction is evidently an example of a reaction without participation of free valence radicals with a strongly delocalised unpaired electron.

Reactions which do not involve a free valence are also observed in the α-nitronylnitroxyl series (X). Thus (X; R = H) in D_2O rapidly exchanges hydrogen for deuterium[35]. In alkaline media this process takes place with the formation of the anion-radical (LXIX), the existence of which in a solution of potassium dimethylsulphoxide-t-butyoxide was confirmed by the EPR method:

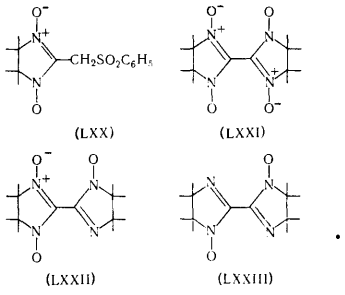


(LXIX)

Replacement of hydrogen by halogen, and then of halogen atoms by hydroxy- and cyano-groups was effected in the α-nitronylnitroxyl series[257]:



Sulphones (LXX)[258] and the conjugated biradicals (LXXI), (LXXII), and (LXXIII)[259] were obtained by such reactions which do not involve the free valence:



(LXX) (LXXI)

(LXXII) (LXXIII)

The change in the form of the EPR spectra of the biradicals on varying the distance between the paramagnetic fragments in conjugation with reactions not involving the free valence can be used for finding the spatial configuration of organic molecules[260].

For example, in the reaction of 2,2,6,6-tetramethyl-4-hydroxypiperidine 1-oxide with the acid chlorides of *cis*- and *trans*-cyclopropanedicarboxylic acids, the corresponding *cis*- and *trans*-esters of these acids were obtained. The *cis*-biradical exhibited a five-component EPR spectrum, which showed the proximity of the two paramagnetic centres. The three-line spectrum of a *trans*-biradical shows the lack of interaction through space of the unpaired electrons, as a result of which electronic exchange is absent.

The discovery and development of the reactions of radicals without involvement of the free valence allowed a new method of investigation to be created, widely used in biochemistry, biophysics, and molecular biology, the so-called "spin-label" method, (see reviews elsewhere[261,262]).

The development of this method, stimulated by the brilliant studies of McConnell, has proceeded in two directions. The first is connected with spin-labelled biomolecules, for example, albumens[263-267], nucleic acids[227,268,269], lipids[270-273], etc. The second direction is the synthesis of paramagnetic analogues and models of physiologically active compounds[78,228,249,250,274,275].

The ability of nitroxyls to migrate in polymers[276] allowed a new method of investigation of molecular motions in polymers[277-279], liquids[280], and biopolymers[281,282] to be investigated—the so-called "spin-probe" method.

Electrophilic Substitution in Cyclopentadienide Anions

M.I.Rybinskaya and L.M.Korneva

The considerable new synthetic possibilities, which have arisen as a result of studies on electrophilic substitution reactions in the cyclopentadienide series, are considered in the review. The possible mechanism of these processes is analogous to the mechanism of substitution in the benzene series. Much attention has been devoted to the problem of the direction of electrophilic attack in cyclopentadienide ions containing both electron-donating and electron-accepting substituents. The bibliography includes 63 references.

CONTENTS

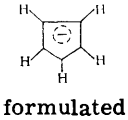
I. Introduction 247
II. Aromatic properties of cyclopentadienide ions 247
III. Reactions with electrophilic agents 248

I. INTRODUCTION

The problem of electrophilic substitution has been most widely studied in the benzene series. However, recently the attention of investigators has been increasingly drawn to problems associated with the study of electrophilic substitution in other aromatic systems, in particular such as the cyclopentadienide ion (CPD ion). The interest in this problem arises mainly from the synthetic requirements which must be met in various substituted cyclopentadienides necessary for the preparation of fulvenes, ylides, sandwich π complexes with transition metals, and many other derivatives. The elucidation of the question of the direction of the electrophilic attack is of particular interest in this problem, since, in contrast to benzene, the cyclopentadienide ion is a non-alternant system.

II. AROMATIC PROPERTIES OF CYCLOPENTADIENIDE IONS

As early as 1901, it was known as a result of Thiele's work [1] that cyclopentadiene exhibits acidic properties†. Thiele found that the potassium salt of cyclopentadiene is fairly stable although very reactive. The high stability of the $C_5H_5^-$ ion was repeatedly confirmed subsequently. In 1928 Goss and Ingold [3] explained the reason for the stability of salts with cyclopentadiene ions by the fact that the six π electrons distributed over the five-membered ring form in this ion an aromatic system resembling that of benzene. On the basis of LCAO-MO calculations, Hückel [4,5] suggested that the cyclopentadienide anion is a stable system, since all four π electrons of the two double bonds and the lone electron pair of the carbon atom remaining after the abstraction of a proton are involved in cyclic conjugation. The negative charge of the cyclopentadienide ion is not localised at an individual carbon atom but is distributed throughout the ion. All the π electrons are located in bonding orbitals, forming a "closed" electron cloud.

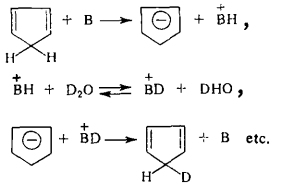


At the same time Hückel formulated the rule of aromaticity.

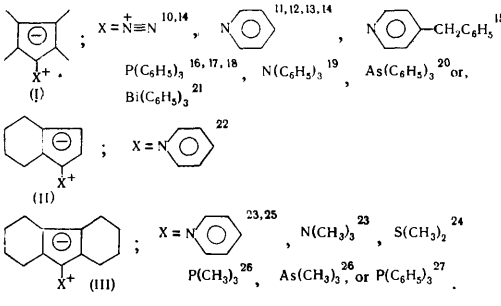
†According to the latest data, $pK = 15$ for cyclopentadiene [2].

Tkachuk and Lee [6] showed experimentally by a tracer atom method (^{14}C) that all five carbon positions in the cyclopentadienide anion are equivalent. Moreover, the equivalence of all five C–C and C–H bonds in the cyclopentadienide ring was demonstrated by X-ray diffraction, electron diffraction, and also spectroscopic methods [7]. The resonance energy for this ion proved to be 48 kcal mole^{-1}. [8]

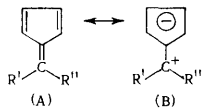
In a study of deuterium exchange in cyclopentadiene, Kursanov and Parnes showed that, in the presence of a base, all six hydrogen atoms are very readily exchanged for deuterium [9]. They also explained this finding by the aromatic properties of the cyclopentadienide ion:



Not only salts with alkali metals and magnesium but also saltlike dipolar compounds containing an organic cation linked by covalent bonds to the cyclopentadienide ion, the so called ylides, are known for cyclopentadienide ions. Usually ylides are unstable compounds but the introduction of the stable aromatic cyclopentadienide ion allows their isolation in a pure form. A wide variety of ylides incorporating cyclopentadienide (type I), indenide (type II), and fluorenide (III) anions linked to the cationic component containing exo- or endo-cyclic atoms of the 'onium-forming elements in Group V (nitrogen, phosphorus, arsenic, antimony and bismuth) and partly Group VI (sulphur) are now known [10–27]:



The study of the dipole moments of certain ylides confirmed their high polarity[28,29]. Fulvenes can be regarded as to some extent of the same type. Their dipole moment is about 1.5 D [30] and the resonance energy is 12 kcal mole^{-1} [31] (i.e. one-third of the resonance energy of benzene). The π-electronic structure of fulvenes can be described by the resonance hybrid of the covalent structure (A) and the polar structure (B):



(A) (B)

where R′ = R″ = H, alkyl, or aryl.

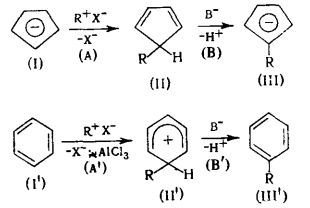
As the electron-donating properties of the substituent at the C_6 carbon atom become more pronounced, the contribution of the polar structure to the resonance hybrid increases. The appreciable contribution of the polar structure is explained, in accordance with Hückel's rule [4,5], by the stability of the cyclic system containing six π electrons.

In contrast to the salts of the cyclopentadienide anion with alkali metals, magnesium, and ammonium cations, the derivatives with transition metal cations lose their ionic properties in most cases. The exceptions will be discussed below. An unusual type of bond, which has been called the π-complex bond, arises under these conditions. The compounds formed, among which ferrocene, nickelocene, and cobaltocene have been most thoroughly investigated, are fairly stable, particularly ferrocene. Dative bonds formed with the *d* electrons of the transition metal make a significant contribution to bond stabilisation in these compounds, in addition to the donor–acceptor bonds.

III. REACTIONS WITH ELECTROPHILIC AGENTS

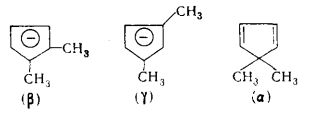
The availability of various cyclopentadienide ions is to some extent limited by the availability of the corresponding cyclopentadienes. The latter may be obtained mainly by two methods: by synthesising the five-membered ring via a cyclisation reaction and by electrophilic substitution in the already existing cyclopentadienide ion. The first method has no direct bearing on the problem under consideration; it is discussed in a useful review by Moritani and Fujiwara [32]. Another method of synthesis, based on the reaction with electrophilic reagents‡, has begun to be developed comparatively recently. It has a number of advantages over the first procedure, since it makes it possible to obtain very complicated derivatives of the cyclopentadienide ion in one or two stages, but, on the other hand, the method is complicated by the formation of side products and involves the necessity to elucidate the direction of electrophilic attack.

The mechanism of electrophilic substitution in the cyclopentadienide ion (stages A and B) is formally similar to the mechanism of electrophilic substitution in the benzene series (stages A′ and B′).[33,34] It is postulated that undissociated cyclopentadienes (II) correspond to the σ complex (II′) in the benzene series:



When various electrophilic agents are employed, the final result in the cyclopentadienide series depends as a rule on whether the substituent introduced is electron-donating or electron-accepting. Since electron-donating substituents increase the electron density of the ring, their introduction results in an increase of the nucleophilicity of the cyclopentadienide ion and, in the presence of sufficient electrophilic agent, it is possible to achieve complete substitution of hydrogen atoms in the initial cyclopentadiene. It is noteworthy that polysubstituted products are obtained even when the initial reactants are employed in 1 : 1 proportions, since some of the cyclopentadienide ions are consumed as a base, as a result of which a certain amount of unsubstituted cyclopentadiene is isolated from the reaction mixture. On the other hand, the introduction of very powerful electron-accepting substituents lowers the nucleophilicity of the cyclopentadienide ion and therefore, under the usual conditions, it is possible as a rule to substitute only two or three hydrogen atoms. Special conditions must be employed to achieve complete substitution.

The cyclopentadienide ion can enter into electrophilic substitution reactions even with weak electrophilic agents such as methyl iodide. Thus in 1965 McLean and Haynes [33,34] showed that, depending on the reaction conditions, different mixtures of products are formed. In liquid ammonia in the presence of a deficiency of a base ($NaNH_2$) the reaction can stop at the monomethylation stage. With increase of the methyl iodide: sodium cyclopentadienide ratio, the yield of polymethylated cyclopentadienes rises. A methyl substituent in the ring has a significant influence on the direction of attack. Two isomers (β and γ) are possible for dimethylcyclopentadienide ions. It has been found that the ratio of the disubstituted β- and γ-derivatives is 3.5 : 1:

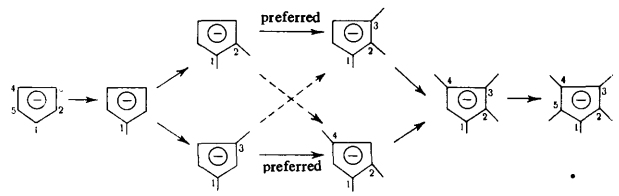


(β) (γ) (α)

It is noteworthy that the ratio of the β- and γ-isomers was determined by analysing a mixture of the corresponding dimethylcyclopentadienes by gas–liquid chromatography. The analysis revealed the presence in the mixture also of a small amount (about 1%) of a product with the second methyl group in the α-position. Thus the selectivity series for attack in the methyl cyclopentadienide ion is $\beta > \gamma > \alpha$. It was discovered that the α-position is approximately 5 times less sensitive to attack by the electrophilic agent than even the γ-position. Since the resulting selectivity series for electrophilic attack corresponds to the distribution of electron density in the methyl cyclopentadienide anion [calculated by Hückel's method (Fig. 1)], the authors suggested that the site of electrophilic substitution in the cyclopentadienide ion may be determined by the distribution of electron density in the ring [33].

‡In the present review we are not considering the reactions of the cyclopentadienide ion with electrophilic agents such as the halides of a number of elements (silicon, tin, mercury, etc.), since the description of such data, closely related to the field of metallotropic reactions, would unduly divert the reader's attention from the main topic.

For the same reason, on further methylation the derivatives obtained from 1,2-dimethyl- and 1,2,3-trimethyl-cyclopentadienide ions predominate over the product which might have been expected from 1,3-dimethyl- and 1,2,4-trimethyl-substituted ions:



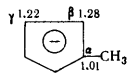


Figure 1. Distribution of electron density in the methylcyclopentadienide ion[33].

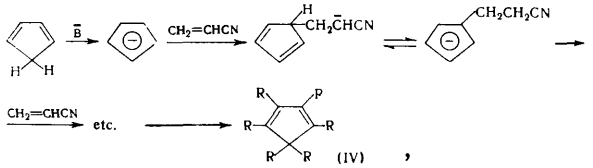
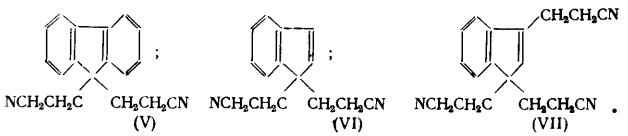
However, Akhrem, Mironov et al.[35], who also made a study of the methylation of sodium cyclopentadienide, note that, when tetramethylcyclopentadienides are employed in this reaction, the *gem*-disubstituted diene is formed in considerable amounts. They believe that in polymethylated cyclopentadienides the site of further alkylation is determined by the operation of factors other than those in the lower homologues.

Another interesting reaction which leads to a substitution product is the cyanoethylation of cyclopentadiene in the presence of a base (benzyltrimethylammonium hydroxide). Unfortunately the details of this reaction have been little investigated, but it is known that, even for equimolar proportions of cyclopentadiene and acrylonitrile, the hexacyanoethylated product (IV) is formed in considerable amounts[36]. The catalytic properties of the base, which are required only to initiate the reaction, are employed:

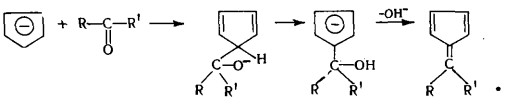


where R = CH_2CH_2CN.

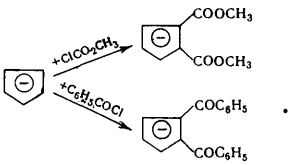
Under the same conditions, fluorene gives the dicyanoethylated product (V) and the reaction of indene with acrylonitrile leads to the dicyanoethylated product (VI) and crystalline tris-(β-cyanoethyl)indene (VII):



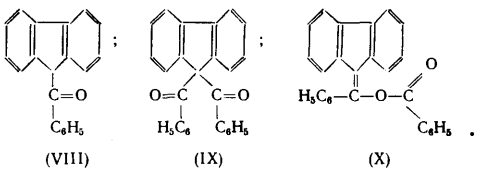
The reaction of aldehydes and ketones with cyclopentadienide ions constitutes the basis of a well known method for the synthesis of fulvenes[37]. The secondary process involving the elimination of the OH ion with formation of the fulvene system completes this reaction:



On the other hand, when electrophilic agents such as methyl chlorocarbonate[38] and benzoyl chloride[39] are employed, the substitution stops at the stage of disubstituted products and in this case, as in the reaction with methyl iodide, the second substituent enters at the β-position relative to the first and the initial cyclopentadienide ion plays the role of a base:

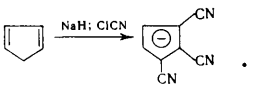


It is noteworthy that lithium fluorenide is also readily benzoylated to a mixture of monobenzoylfluorene (VIII), 9,9-dibenzoylfluorene (IX), and 9,1'-benzoyloxybenzylidenefluorene (X). The relative amounts of the products depend on the nature of the metal and the solvent[40]:

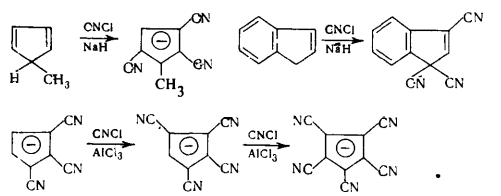


The reaction with cyanogen chloride has been most thoroughly investigated; by this process in the presence of NaH, Webster[41] achieved the substitution of cyano-groups in cyclopentadienides[41].

In contrast to alkyl substituents, the introduction of groups such as CN into the cyclopentadienide ion reduces its nucleophilic activity and therefore the reaction may be stopped at each stage in the presence of a limited amount of cyanogen chloride:



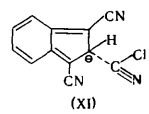
The reaction with cyclopentadiene, methylcyclopentadiene, and indene stops at the stage of the tricyano-product, while tetra- and penta-cyano-derivatives can be obtained from the tricyano-ion only when a Friedel–Crafts catalyst is employed:



The cyano-group is substituted in the tricyanomethylpentadienide anion in the presence of aluminium chloride with formation of tetracyanomethylcyclopentadienide.

In indene the third cyano-group attacks the carbon atom linked to a cyano-group and not a vacant position.

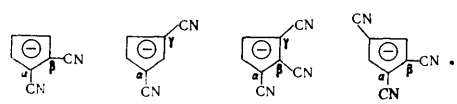
The explanation is that the energy of the transition state (XI) (of the *o*-quinodimethane type) formed on introduction of a cyano-group in a vacant position should be higher:



(XI)

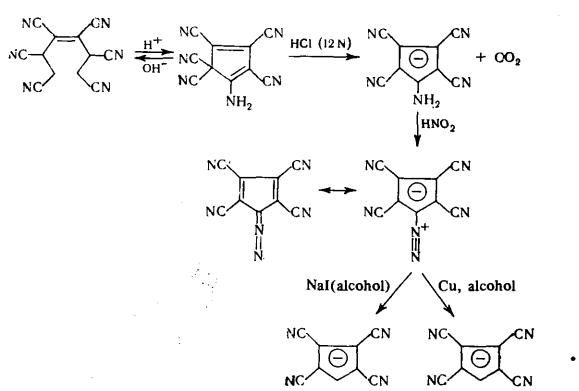
Each cyanocyclopentadienide was isolated and characterised in the form of a potassium or tetraalkylammonium salt. Webster obtained in this way the complete series of cyanocyclopentadienides [41].

The ratio of the $\alpha\beta$-isomer to the $\alpha\gamma$-isomer in dicyano-products is approximately 6 : 1 and in tricyano-products the ratio of the $\alpha\beta\gamma$-isomer to the $\alpha\beta\delta$-isomer is 2 : 1, i.e. the selectivity of the position subjected to electrophilic attack in the substitution of cyano-groups in the cyclopentadienide anion corresponds to the selectivity in its methylation:



It is noteworthy that this method of synthesis of polycyanocyclopentadienides is much simpler than the method based on the cyclisation reaction. As an example, Scheme 1 presents a fairly complex method for the synthesis of the tetracyanocyclopentadienide ion [42,43]:

Scheme 1



The stability of the resulting cyano-derivatives of the cyclopentadienide ion increases with the number of cyano-groups, as can be seen from the pK_a values for the corresponding conjugate acids (Table 1).

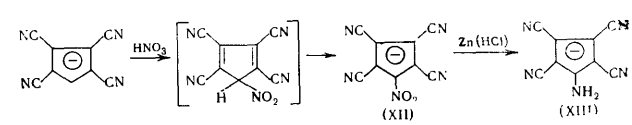
Table 1 shows that tricyanocyclopentadiene is a stronger acid than perchloric acid. The pentacyanocyclopentadienide ion is even more stable. For example, its potassium salt may be heated in air to 400°C without decomposition. The conjugate acid of this anion is very strong: pK_a(in CH_3CN) < -2, for comparison, we have for sulphuric acid pK_a(in CH_3CN) = 7.25. This anion is not protonated even by an acid as strong as perchloric in acetonitrile (spectrophotometric measurements). Probably the pentacyanocyclopentadienide ion has a very strong conjugate acid not only because of the pronounced electron-accepting properties of the five CN groups but also because it has pentagonal symmetry with a uniform delocalisation of the charge in each C–CN group.

It is noteworthy that the pentacyanocyclopentadienide ion and the very stable penta(methoxycarbonyl)cyclopentadienide [44], dicyanodi(ethoxycarbonyl)cyclopentadienide, and tetracyanocyclopentadienide ions [30] do not form ferrocenes on treatment with $FeCl_2$ in consequence of the delocalisation of the negative charge over the electron-accepting substituents. The derivatives obtained proved to be iron(II) salts. The iron(II) tetracyanocyclopentadienide salts are involatile and extremely sensitive to the action of air. These properties indicate an ionic and not a π-complex state of divalent iron.

Table 1. pK_a values for cyanocyclopentadienes in water and acetonitrile [41].

№	Conjugate base	pK_a (in water)	pK_a (in CH_3CN)	pK_a (calc.)
1		15 [2]	—	—
2		9.78	—	—
3		2.52	—	—
4		1.11	10.17 10.17	1.1
5		—	3.40	−5.7
6		—	3.0	−6.1
7		—	1.44 1.99	−7.8 −7.2
8		—	0.0 0.2	−9.1 −8.9
9		—	<−2	<−11
10		—	1.83	−7.3 −6.7

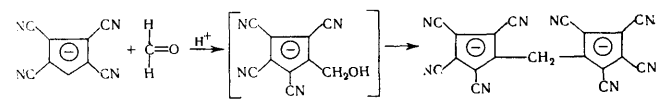
Acid electrophilic agents cannot be employed with unstable cyclopentadienide ions. However, in those cases where the basicity of the cyclopentadienide ion is greatly reduced by the introduction of electron-accepting groups, it is possible to employ also electrophilic agents which are strong acids. Thus concentrated nitric acid nitrates the tetracyanocyclopentadienide ion in 15 min (yield 67%) with formation of the tetracyanonitrocyclopentadienide ion (XII),



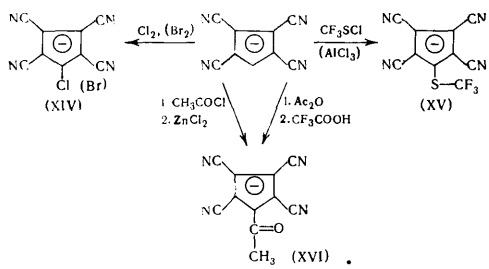
(XII) (XIII)

which could be reduced with zinc dust in hydrochloric acid to the already known [42] aminotetracyanocyclopentadienide

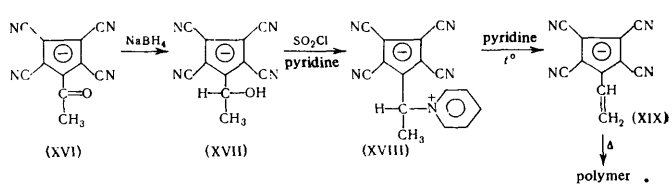
ion (XIII). The reactions of tetracyanocyclopentadienide with formaldehyde and acetaldehyde also take place in an acid medium [45]:



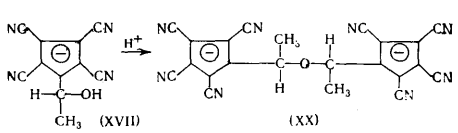
Friedrich [46] and Webster [45], who investigated electrophilic substitution in the tetracyanocyclopentadienide ion, believe that the reactivity of the latter resembles very closely that of anisole. Indeed, like anisole, the tetracyanocyclopentadienide ion reacts readily with halides, but for the reaction with trifluoromethanesulphenyl chloride, acetyl chloride, and acetic anhydride, catalysts of the Friedel-Crafts type or strong acids are required:



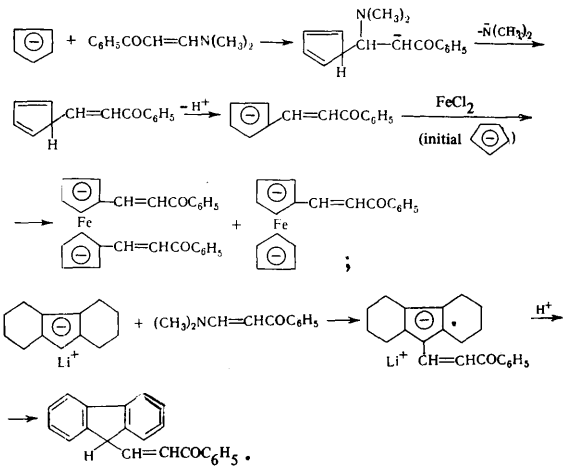
It is noteworthy that the high stability of polycyanocyclopentadienides made it possible to obtain a wide variety of their derivatives. Thus acetyltetracyanocyclopentadienide (XVI) was obtained for the synthesis of tetracyanovinylcyclopentadienide (XIX) according to the following mechanism:



Tetracyanovinylcyclopentadienide (XIX), which was isolated as the tetraethylammonium salt, readily polymerises at 135°C, giving a polymer soluble in acetonitrile. A suspension of the polymer in water may be used as an ion-exchange resin. It is interesting to note that the alcohol (XVII) formed as an intermediate in this synthesis reacts rapidly even with dilute acids to form the dianion of the ether (XX), probably via tetracyanomethylfulvene:



In contrast to polycyano-derivatives, monocyanocyclopentadienide ions, for example 9-cyanofluorene, readily react also with weak electrophilic agents such as alkyl halides [47-49]. By varying the activity of various electrophilic ketovinylating agents, Nesmeyanov and coworkers [50,51] achieved the mono- and poly-ketovinylation of cyclopentadienide ions. The reaction of sodium cyclopentadienide with β-dimethylaminovinyl phenyl ketone gave a monoketovinylated cyclopentadienide, which was identified in the form of ferrocene derivatives:



In this reaction lithium fluorenide gives, after treatment with acid, a high yield of monoketovinylated fluorene.

When a more active electrophilic agent (a β-chlorovinyl ketone) is employed, the reaction does not stop at the monoketovinylation stage but gives rise to coloured polyketovinylated ions, which according to spectroscopic data are most likely to have structure (XXI):

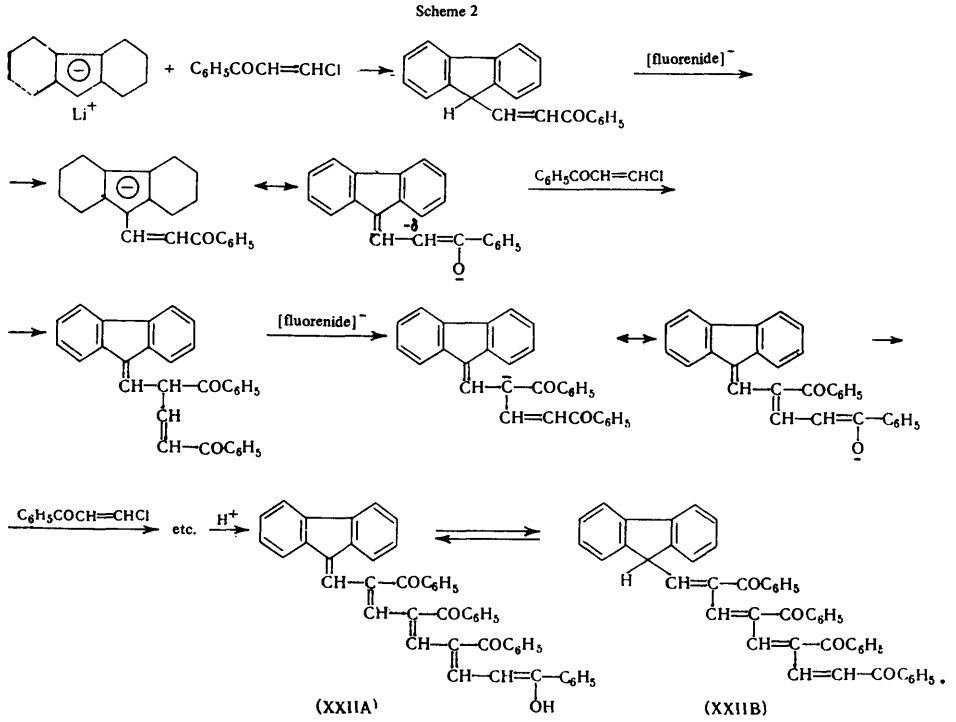
The introduction of five ketovinyl groups into the cyclopentadienide ion can be explained if one remembers that these groups have comparatively weak electron-accepting properties§ and are associated with a considerable steric effect, which lowers the delocalisation of the negative charge owing to the mutual displacement of these groups from the ring conjugation plane. The corresponding conjugate acids of these ions are comparable in strength to carbonic acid (for R = CH_3, pK_a = 7.2 in 50% aqueous alcohol and pK_a = 6.2 in water, while for R = C_6H_5, pK_a = 7.7 in 80% alcohol). However, such delocalisation of the negative charge and possibly also the appreciable steric hindrance proved to be the reason for the inability of the pentaketovinylated ions to form the corresponding ferrocenes on treatment of their sodium salts with iron(II) chloride.

The highly specific behaviour of these ketovinylating agents (RCOCH = CHCl) was noted in relation to lithium fluorenide, which has only one unsubstituted position in the five-membered ring. Whereas with a β-aminovinyl ketone (see above) a monoketovinylated ion was obtained, the reaction with β-chlorovinyl phenyl ketone yielded, after hydrolysis, an orange-red cryptocrystalline tetraketovinylated product, the structure of which has one of two tautomeric forms (XXII, A) or (XXII, B) (Scheme 2) according to molecular weight determinations (mass-spectrometric analysis), spectroscopic characteristics, and chemical reaction data:

---

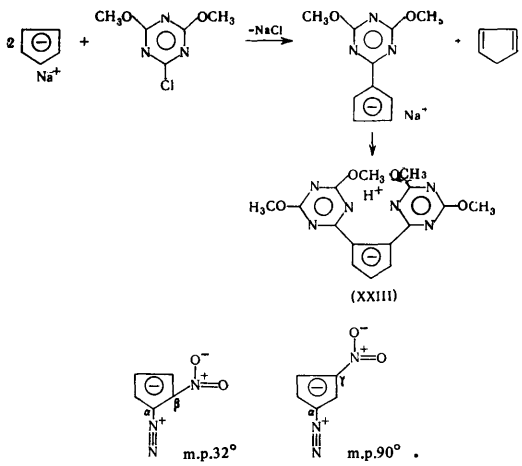
§If one remembers that the transmission coefficient of the *trans*-vinylene group [52] is about 0.5, the electron-accepting properties of the ketovinyl group are seen to be approximately twice as weak as those of the corresponding acyl groups.

Scheme 2

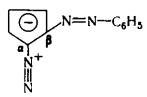


The reaction with 2-chloro-4,6-dimethoxy-*s*-trazine, which leads to the disubstituted product (XXIII),[53] should also be included among the electrophilic substitution reactions of cyclopentadienide ions.

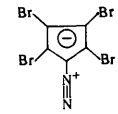
Ylides too are capable of electrophilic substitution reactions. Thus diazocyclopentadiene undergoes electrophilic substitution without the disruption of the ylide π-electron system, attack at the β-position predominating over attack at the γ-position[54]. In the nitration of diazocyclopentadiene the β-substituted product predominates over the γ-substituted product by a factor of 2:



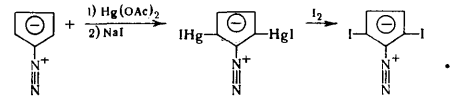
The reaction of phenyldiazonium tetrafluoroborate with diazocyclopentadiene also gives a product substituted in the β-position:



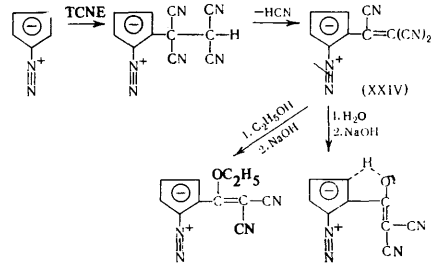
whereas bromination gives tetrabromodiazocyclopentadiene:



On mercuration, diazocyclopentadiene is converted into a very unstable 2,5-bis(iodomercuri)-derivative, which is readily converted into 2,5-di-iododiazocyclopentadiene:

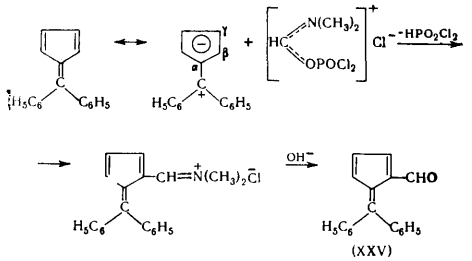


On reaction with tetracyanoethylene, diazocyclopentadiene forms an unstable acid, which easily loses HCN with formation of compound (XXIV), but the Diels–Alder reaction does not occur. Compound (XXIV) undergoes hydrolysis and ethanolysis typical for tricyanoethylenes[55,56]:



Electrophilic substitution in fulvenes has been little investigated. However, fulvenes are capable of electrophilic substitution like other non-benzenoid aromatic systems. Thus 6,6-diphenylfulvene (XXV) is readily formylated with a high yield on treatment with the

Vilsmeier complex[57]. In all the cases investigated, it was found that electrophilic attack on compound (XXVI) takes place at the β-carbon atom[58]:

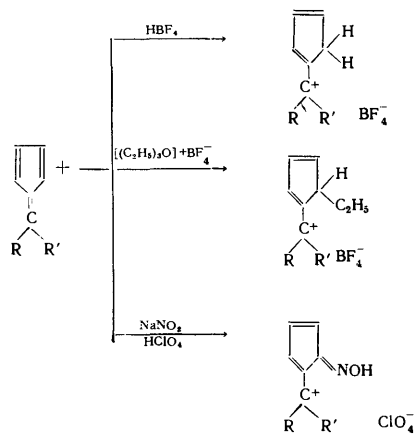


(XXV)

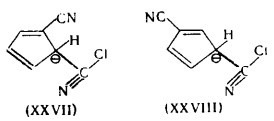
6,6-Diphenyl and 6,6-dimethyl-fulvenes are protonated, alkylated, and nitrosated at −80°C giving the corresponding cyclopentadienes, which are stable only at −80°C[59] (see below).

---oOo---

Thus electrophilic attack on all the cyclopentadienide ions investigated, containing both electron-accepting and electron-donating groups, is directed to the β-position. However, whereas in the presence of electron-donating groups substitution in the β-position could be explained on the basis of the distribution of electron density in the ring, with electron-accepting substituents an enhanced reactivity in the γ-position might have been expected.

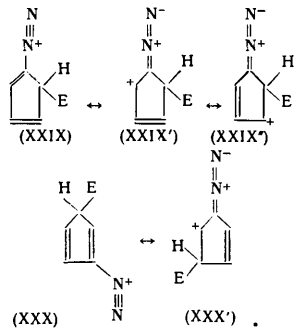


Therefore Webster[41] explains the higher content of the isomer with the CN group in the β-position in the reaction mixture obtained on substituting cyano-groups in the cyclopentadiene ion by the formation of a more stable transition state (XXVII), in consequence of the conjugation of the CN group with a diene system, compared with the transition state (XXVIII) in γ-substitution (a cross-conjugated system):



(XXVII) (XXVIII)

Cram and Partos[54], who studied electrophilic substitution in diazocyclopentadiene, explain their results similarly. They believe that the transition state in β-substitution is more stable, since the cation (XXIX) formed can be represented by three main contributions to the resonance hybrid [(XXIX) ⟷ (XXIX′)↕(XXIX″)], whereas the cross-conjugated cation (XXX) corresponding to γ-substitution has only two contributions [(XXX) and (XXX′)]:



(XXIX) (XXIX′) (XXIX″)

(XXX) (XXX′)

Table 2. Localisation energies (−β).

Model	2-Position	3-Position
	1.149	1.356
	1.685	1.734

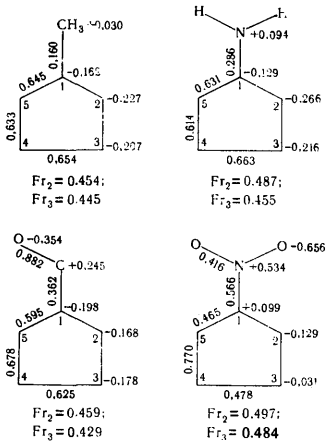


Figure 2. Molecular diagrams for cyclopentadienide ions containing electron-donating and electron-accepting substituents. The numerals against the carbon atoms denote the π-electronic charge and the numerals above the bonds denote the bond order. Fr = free valence index.

A general explanation covering cyclopentadienide ions with electron-donating and electron-accepting substituents is provided by the molecular orbital method. Indeed these results agree with the calculated (by the molecular orbital method) localisation energies (they usually vary in parallel with the free valence index) for monosubstituted cyclopentadienide radicals (Table 2).[60]

The authors note that the results of the calculation should be essentially proved also for the cyclopentadienide ions.

Calculations of the molecular diagrams presented below (Fig. 2) show that the higher reactivity of the β-position in relation to electrophilic substitution in derivatives with electron-donating substituents (CH_3 and NH_2 groups) is indicated both by the π-electronic charge and the free valence index. In the case of electron-accepting substituents, the free valence index again shows the β-position to be more reactive. Calculation of the π-electron density in terms of the Hückel approximation gives a less clear picture. In the presence of an electron acceptor as powerful as the NO_2 group, the β-position is found to have the highest π-electron density. The apparently unusual distribution of electron density under the influence of an electron-accepting substituent is associated with the non-alternant structure of the cyclopentadienyl ring. In the case of the carbonyl group the β-position has a somewhat lower electron density but only slightly so. Evidently calculation taking into account interelectronic interactions would suggest the opposite behaviour also in the presence of the carbonyl group (see the analogous case discussed by Bochvar et al. [61]). Thus the higher reactivity of the β-position regardless of the type of substituent is fully consistent with the π-electron reactivity indices of the substituted non-alternant cyclopentadienyl ring.

It is noteworthy that the electrophilic attack on the β-position observed in the case of fulvenes is also consistent with the calculated distribution of electron density and localisation energy [62,63].

Conversions of Chlorine-containing Aliphatic Compounds in the Presence of Coordination-unsaturated Metals

A.E.Kulikova and E.N.Zil'berman

Conversions of aliphatic chlorine-containing compounds (chloroalkenes, chloroalkanes, and derivatives of chloro-substituted carboxylic acids) occur under the action of aprotic acids. Chloroethylenes are polymerised by a cationic mechanism with the formation of oligomeric and polymeric products. The principal reaction of chloroalkanes and chlorocycloalkanes in the presence of salts of coordination-unsaturated metals is dehydrochlorination, which proceeds either intramolecularly or intermolecularly with the formation of polymers with conjugated double bonds. For polychloro-containing compounds, in addition to the dehydrochlorinations, elimination of chlorine occurs. Perchloroalkanes (from C_3 and higher) in the presence of aprotic acids also undergo degradation with breaking of the carbon-carbon bond. There is a bibliography of 353 references.

I. INTRODUCTION

Chlorine-containing organic compounds are readily available and extremely reactive. They are starting materials for making various organic compounds of practical importance. Many reactions with chlorine-containing products take place in the presence of Friedel–Crafts catalysts. They include the alkylation and acylation of aromatic compounds, addition to alkenes, and replacement of chlorine atoms by other halogens and functional groups and have been discussed in monographs[1-3] and reviews[4-7].

It was noted long ago that reactions involving chlorine-containing compounds in which Lewis acids are used as catalysts are accompanied by conversions of the chlorine-containing reagent itself, which reduces the yield of the main product and contaminates it with various impurities. A characteristic example of such changes is the decarbonylation, in the presence of aluminium chloride, of acyl chlorides with a branch in the α position. Addition of alkyl halides, acyl chlorides, and other compounds to chloroalkenes is accompanied by conversions of each of the reagents separately. In addition to the formation of polyconjugated polymers ("tar"), degradation is observed[4].

Some chloroalkanes and chloroalkenes are widely employed as extractants in heavy organic synthesis (for example, trichloroethylene in the production of ϵ-caprolactam) and in the metallurgical industry for degreasing metal surfaces. Sometimes contact between the solvents used and salts of coordination-unsaturated metals is possible, which brings about the undesirable conversions of the chloroalkanes and chloroalkenes, leading to contamination of the product being extracted and of the solvent.

The reactions of chlorinated hydrocarbons in the presence of Friedel–Crafts catalyst are of independent importance. Thus the dehydrochlorination of chloroalkanes is used for obtaining industrial monomers (vinyl chloride and vinylidene chloride) and trichloroethylene.

The use of chlorine-containing compounds as solvents in the cationic polymerisation of alkenes is well known[8,9]. The part played by the solvent in this is enormous, since the degree of polymerisation of the monomer, the molecular weight, and sometimes also the stereoregularity of the polymer obtained depend partly on it. The effect of the solvent on the course of the polymerisation and the properties of the polymer have recently been linked with the fact that the solvent reacts with the catalyst to form reactive species which participate directly in the polymerisation of the monomer.

Some chlorine-containing compounds can be regarded as models of individual units of such chlorine-containing polymers as poly(vinyl chloride), poly(vinylidene dichloride), chlorinated poly(vinyl chloride), chlorinated polyethylene, etc. Therefore information about the conversions of these compounds in the presence of aprotic acids can be used in studying the mechanism of degradation and analogous conversions of chlorine-containing polymers.

Unlike reactions of organochlorine compounds with other reagents, the conversions of certain solely aliphatic chlorine-containing compounds in the presence of aprotic acids have not been reviewed. The present review is an attempt to survey the available published information on the conversions of chloroalkanes and chloroalkenes in the presence of Lewis acids. This review does not consider the conversions of chlorine-containing aromatic compounds, since the work on this subject has been covered adequately in a monograph[2].

II. CHLOROMETHANES AND THEIR DERIVATIVES

1. CHLOROMETHANES

Chloromethanes are extremely stable compounds and in the absence of atmospheric oxygen they can be stored and distilled without decomposition. The ability of chloromethanes to withstand high temperatures depends on the number of chlorine atoms in them and drops from methyl chloride to chloroform, owing to the decrease in the energy for breaking the C–Cl bond (Table 1). In addition, to high dielectric constants, especially for methyl chloride and methylene dichloride, show that under certain conditions these compounds can be extremely reactive. With such electrophilic compounds as the halides of coordination-unsaturated metals, the chloromethanes form, even at low temperatures (−80, −20°C), stable complexes of the type

$CH_3Cl.AlBr_3$ or $CH_3Cl.Al_2Br_6$, [13,14] in which there is an exchange of halogen atoms between chloromethane and the complex-forming substance [15-17]. With the aid of this reaction, which is effected through a transitional six-membered transition complex [17], carbon tetrabromide can be obtained in high yield from carbon tetrachloride and $AlBr_3$. [18]

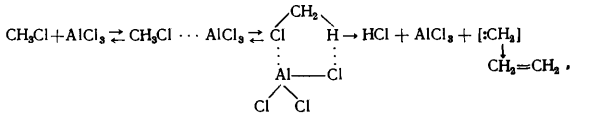
At elevated temperatures more extensive conversions of chloromethanes take place.

Table 1. Characteristics of chloromethanes [10-12].

Chloromethane	Decomposition temp., °C	Energy for breaking the C-Cl bond at 400-500°C, kcal mole^{-1}	Energy for breaking the C-H bond at 400-500°C, kcal mole^{-1}	Dielectric constant at 20°C	Distance between chlorine atoms, Å
CH_3Cl	1400	80.5	98.0	12.61	—
CH_2Cl_2	720	73.4	95.0	8.40	3.16
$CHCl_3$	290	66.5	90.2	4.84	3.04
CCl_4	400	76.0	--	2.24	2.58

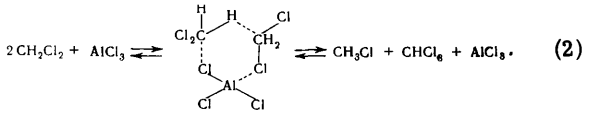
Methyl chloride. Under the action of $AlCl_3$ at 20°C methyl chloride is converted into hydrogen chloride and ethylene [19]. It could be expected that an intermediate product in the conversion of methyl chloride into ethylene would be ethyl chloride, formed as a result of the condensation of two molecules of methyl chloride. However, the main products of the reaction of ethyl chloride with $AlCl_3$ are polymers [20] (see p. 262) and among the products of the reaction of methyl chloride with $AlCl_3$ neither ethyl chloride nor a polymer were observed. It is also improbable that the conversion of methyl chloride into ethylene proceeds by an ionic mechanism [21,22].

It is assumed [23] that this process is carbenoid in nature and proceeds by intermediate formation of a five-membered transition complex (scheme 1):



(1)

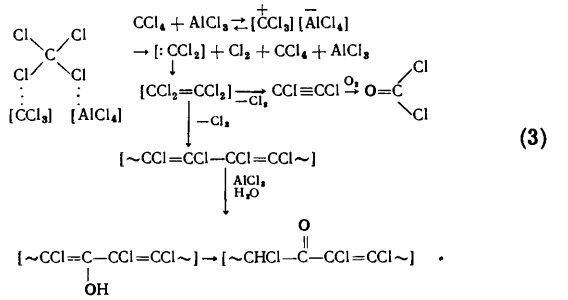
When a mixture of methylene chloride and $AlCl_3$ is heated to 40°C, a disproportionation (little known for chloroalkanes) takes place, as a result of which methyl chloride and chloroform are formed [19] (scheme 2):



(2)

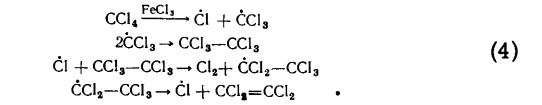
Furthermore, hydrogen chloride, *trans*-1,2-dichloroethylene, and a polymer of composition $(C_2H_5Cl)_n$ were identified in the reaction products. The formation of 1,2-dichloroethylene from methylene dichloride probably takes place just like the formation of ethylene from methyl chloride, by α-elimination of hydrogen chloride. The polymer $(C_5H_5Cl)_n$ had the same composition and properties as the polymer formed on heating chloroform with the same catalyst to 60°C. Evidently when methylene dichloride is heated with $AlCl_3$, the chloroform which is formed in the disproportionation of methylene dichloride undergoes polycondensation. The polycondensation of chloroform [19] in this instance can be based solely on intermolecular dechlorination. This is shown by the carbon : hydrogen ratio in the polymer, which remains equal to 1 : 1, that is, the same as in the initial chloroform.

In contrast with the other chloromethanes carbon tetrachloride in the presence of $AlCl_3$ undergoes conversions only on heating under severe conditions, for example, at 200°C. [19] Here the main process is the ionisation of the carbon tetrachloride with the formation of the rather stable carbonium ion $\dot{C}Cl_3$. [21,22] The appearance of the carbonium ion is shown by the reaction mass being pink, by absorption in the 530 mμm region, and by the quantitative formation of chloroform in the reaction of carbon tetrachloride with n-hexane in the presence of $AlCl_3$. In addition to ionisation, slight conversion of carbon tetrachloride into dichloroacetylene, carbonyl chloride, and a polymeric product of composition $(C_6H_3Cl_2O_3)_n$ is observed [19]. Dichlorocarbene is evidently an intermediate product of this reaction (scheme 3). The possible formation of dichlorocarbene under similar conditions has already been reported [24]. Support for scheme 3 is provided by the fact that when heated with $AlCl_3$ tetrachloroethylene actually undergoes intramolecular and intermolecular dechlorination with the formation of dichloroacetylene and a polymer (cf. p. 261). The presence of hydrogen and oxygen in this polymer is explained by its interaction with water in the presence of $AlCl_3$: [19]



(3)

The conversions of chloromethanes in the presence of aprotic acids in the gas phase have been little studied. The results published on this subject relate mainly to CCl_4. On passing CCl_4 vapour over iron, zinc, copper, and other metal chlorides at 200–300°C, chlorine, hexachloroethane, and tetrachloroethylene are formed [25-27], that is, the same products as are formed from CCl_4 in high-temperature (700–800°C) pyrolysis [28-32] in the absence of catalysts. According to some results [25-27] the catalytic decomposition of CCl_4 into chlorine, hexachloroethane, and tetrachloroethylene proceeds by a radical mechanism (scheme 4):



(4)

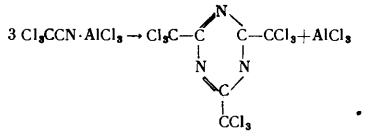
2. SUBSTITUTED CHLOROMETHANES

The replacement of chlorine atoms in chloromethanes by other groups alters the reactivity of the chlorine atoms in chloromethanes. The substituents at which the electronic density is greatest react with aprotonic acids.

Chlorofluoromethanes greatly surpass chloromethanes as regards reactivity in the presence of Lewis acids [33-45]. Under the action of $AlCl_3$ or $AlBr_3$ fluorine-containing chloromethanes readily disproportionate [36-43].

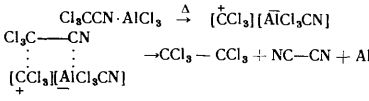
Thus fluoroform is obtained in quantitative yield from dichloro(fluoro)methane at 50°C, [36] whereas under these conditions the disproportionation of chloromethanes is very slow[19].

The introduction of a nitrile group into chloromethanes increases their reactivity even more. The reaction of chloroacetonitriles with aprotic acids begins with complex formation by the nitrile group[2,46,47]. A series of stable complexes of the type $CCl_3CN.MX$, $2CCl_3CN.MX$, and $CCl_2CN.2MX$ is formed. When the complexes are heated to 100°C, trimerisation of the trichloroacetonitrile takes place with the formation of 2,4,6-tris(trichloromethyl)-1,3,5-triazine[46] (scheme 5):



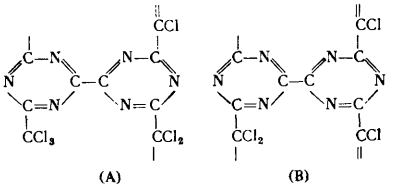
(5)

The same triazine is also obtained by saturation of trichloroacetonitrile with hydrogen chloride in the presence of catalytic amounts of $AlCl_3$ or $AlBr_3$.[48-51] When the complexes of trichloroacetonitrile with $AlCl_3$ are heated to 140–150°C, heterolytic breaking of the carbon–carbon bond of the nitrile occurs, which leads to the formation of hexachloroethane and dicyanogen. The suggested scheme of reaction (6) is confirmed by the formation of chlorotriphenylmethane when the complex $2Cl_3CCN.AlCl_3$ is boiled with benzene. If there were homolytic breaking of the C–C bond the trichloromethyl radical, which is inert in relation to benzene, would be formed[52]:



(6)

In addition to hexachloroethane and dicyanogen, when complexes of trichloroacetonitrile with $AlCl_3$ are heated, polymeric products of composition $(C_9Cl_6N_6)_n$ and $(C_9Cl_4N_6)_n$ are formed, which contain units of composition (A) and (B), were obtained:

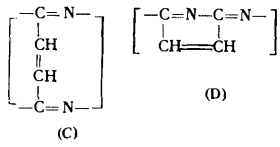


(A) (B)

It has been shown[46] that the formation of these polymers takes place not by the polymerisation of triazine with ring opening[53-55], but by the polymerisation of trichloroacetonitrile and of dicyanogen at the nitrile groups with subsequent dechlorination of the CCl_3 side-groups.

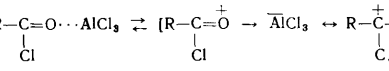
A similar picture is observed in the reaction of dichloroacetonitrile[56] with $AlCl_3$. By heating the complex $2CHCl_2CN.AlCl_3$ to 70°C, 2,4,6-tris(dichloromethyl)triazine can be obtained, which is also formed on prolonged saturation of the nitrile with hydrogen chloride[57]. At temperatures above 80°C the $CHCl_2$ side-groups of the triazine undergo dechlorination under the action of aluminium chloride, with the formation of a polymeric product with conjugated double bonds of composition $(C_6H_3Cl_3N_3)_n$, consisting of triazine rings connected by  bridges[56].

Unlike tri- and di-chloroacetonitriles, monochloroacetonitrile does not trimerise to a triazine in the presence of small quantities of aprotic acids[58]. When the complex $2CH_3ClCN.AlCl_3$ is heated above 200°C, as for other unsaturated nitriles[59-64] polymerisation of the nitrile at the nitrile groups takes place with formation of a chain of conjugated –C=N– bonds. Simultaneously with the polymerisation, dehydrochlorination of the chloromethyl side-groups takes place, as a result of which units of types (C) and (D) arise in the polymer.



(C) (D)

Chloroacetyl chlorides can be regarded as chloromethanes in which the central carbon atom is connected, not solely with chlorine and hydrogen atoms, but also with the  group. As for other acyl chlorides[65,66], the reaction of these compounds with salts probably begins with the formation of complexes of type .$AlCl_3$ or .Al_2Cl_6, in which exchange of halogen atoms between the acyl chloride and the salt can take place[67]. There are differences of opinion concerning the reaction centre in acid chlorides in the formation of complexes. Some consider[6,68-70] that the active centre in organic acyl chlorides is the oxygen of the carbonyl group and with aprotic acids complexes of the following type are formed:



However, it has been shown[71] by infrared spectroscopy that the chlorine in the acyl chloride is subjected to electrophilic attack by the aluminium chloride, which leads to the formation of an ion-pair $[R\overset{+}{C}{=}O][\overline{Al}Cl_4]$. Such a viewpoint is maintained by Palmer and McVie[72]. It has recently been shown[73] spectroscopically that both types of complex formation occur and the predominance of one over the other depends primarily on the structure of the initial acyl chloride. Electron-donating substituents in the acid residue of the acyl chloride increase the electron density in the –COCl group, which facilitates reaction with aprotic acids at the oxygen atom. Electron-withdrawing substituents depress the nucleophilic properties of the oxygen atom and therefore the complex with the catalyst is formed preferentially at the chlorine atom. This evidently relates to a compound such as trichloroacetyl chloride.

When the complexes of acyl chlorides and aprotic acids are heated, they decompose with the liberation of carbon monoxide and the formation, usually, of the corresponding alkyl chlorides[74-81]. Electron-donating substituents in the acid residue accelerate the elimination of carbon monoxide, and electron-withdrawing substituents retard it[82-84]. In this connection the decarbonylation of the acid chlorides in the last instance is carried out at high temperatures and in the presence of large amounts of catalyst. According to these results, when trichloroacetyl chloride is heated to 100°C in the presence of aluminium chloride decomposition of the acid chloride by scheme (7) to carbon

monoxide and carbon tetrachloride takes place[85,86]. In addition to the compounds mentioned, conversion products of CCl_4 (see scheme 3) are also formed—dichloroacetylene and a polymer[86]:

$$CCl_3C(=O)\cdots AlCl_3 \xrightarrow{\Delta} [CCl_3\overset{+}{C}{=}O][\overline{A}lCl_4] \rightarrow CO + [\overset{+}{C}Cl_3][\overline{A}lCl_4] \quad (7)$$

$$[\overset{+}{C}Cl_3][AlCl_4] \rightarrow CCl_4 + AlCl_3 \quad .$$

When dichloroacetyl chloride is heated with aluminium chloride in chloroform solution it also decomposes with release of carbon monoxide[87]. When a mixture of chloroacetyl chloride and aluminium chloride is heated there is an intensive evolution of carbon monoxide and also of hydrogen chloride and chloroacetylene and the formation of a polymeric product with conjugated double bonds and a carbon : hydrogen : chlorine ratio of 4 : 4 : 1.[86] The decomposition of chloroacetyl chloride probably takes place just like the decomposition of trichloroacetyl chloride (scheme 7), that is, through the intermediate production of an acylcation, reaction of which is effected by loss of carbon monoxide[88]. Here the formation of hydrogen chloride and chloroacetylene is due to secondary conversions of methylene dichloride.

Carbonyl chloride with aprotic acids gives stable complexes[69,89] in which exchange of halogen atoms takes place[67]. In the gas phase at 300–400°C[90,91] under the action of aprotic acids decomposition of carbonyl chloride takes place with the formation of carbon monoxide and carbon tetrachloride.

In esters of chloroacetic acids, as in the acyl chlorides of these acids, reaction with Friedel–Crafts catalyst occurs first at the ester group. At low (−20°; +30°C) temperatures, esters of trichloroacetic acid and $TiCl_4$ form unstable complexes of composition $2TiCl_4.CCl_3COOR$, $TiCl_4.CCl_3COOR$, and $TiCl_4.2CCl_3.COOR$.[92,93] The lower stability of these complexes in comparison with esters of unsubstituted aliphatic acids[94–100] is due to the increased electron-withdrawing properties of the CCl_3 group. Spectroscopic investigations in recent years have shown convincingly that complex formation by esters with the salts of coordination-unsaturated metals is effected at the carbonyl oxygen of the ester group[101–106].

Careful heating of the complexes of esters with aprotic acids caused them to melt and dissociate into the initial components. Above the melting points of the complexes and also in the presence of large quantities of aprotic acids some esters decompose readily with formation of alkyl halides and salts of organic acids[107–110]. An analogous picture is also observed on heating a mixture of methyl trichloroacetate and aluminium chloride, taken in a ratio between 1 : 1 and 3 : 1. Methyl chloride and bis(trichloroacetate)–aluminium chloride were thus obtained[111]. When the reaction was carried out under more severe conditions (higher temperature, increase in the excess of $AlCl_3$) tetrachloroethylene appeared in the reaction products in addition to the compounds listed above[111]. The formation of these compounds can be explained with the aid of schemes (8) and (9), according to which complexes (A) and (B) arise as intermediate products of the reaction; in the latter there is exchange of a chlorine atom of aluminium chloride for the acid residue of the ester:

$$CCl_3{-}C(=O\cdots AlCl_3){-}OCH_3 \rightleftarrows CCl_3{-}C(=O){-}OCH_3\ (AlCl_3) \quad (8)$$

(A) (B)

$$CCl_3C(=O)\cdots O(AlCl_2)\cdots Cl{-}CH_3 \xrightarrow{\Delta} CCl_3C(=O)OAlCl_2 + CH_3Cl$$

$$[CCl_3^-] \xrightarrow{-Cl^-} [:CCl_2] \rightarrow CCl_2{=}CCl_2 \quad . \quad (9)$$

The aluminium salt of trichloroacetic acid, like the other salts of this acid[112,113], is further decarboxylated with the formation of the carbanion CCl_3^-, which is converted into dichlorocarbene and then into tetrachloroethylene. The intermediate formation of the $\overline{C}Cl_3$ anion is shown by the fact that when the reaction mass is treated with water chloroform is observed in the products[111].

In the presence of salts of coordination-unsaturated metals alkyl chloroformates readily decompose with liberation of carbon dioxide and an alkyl halide[114,115].

The formation of aluminium salts and chloroalkanes in the reaction of esters with $AlCl_3$ enables the effect of the structure of the esters on their ability to acylate and alkylate aromatic compounds after Friedel–Crafts to be explained. Esters of aliphatic alcohols and organic acids which contain electron-withdrawing substituents (chloroacetic, trichloroacetic, $\alpha\beta$-dichloropropionic, benzoic, oxalic, etc.) only alkylate benzene, since the aluminium salts of these acids exhibit weak acylating properties[111]. Conversely, esters of aliphatic alcohols and unsubstituted aliphatic acids give with benzene both alkylation products and acylation products, since the aluminium salts then formed exhibit high acylating properties[108,110,111,116,117]. And, finally, esters containing electron-withdrawing substituents simultaneously in both the acid and the alcohol radicals do not enter into any reaction with benzene in the presence of Friedel–Crafts catalysts. In this instance the ester probably does not decompose into salt and alkyl halide.

Phenyl-substituted chloromethanes are distinguished by high reactivity. The presence of phenyl groups creates increased electron density at the chlorine atom, as a result of which its mobility increases sharply. The polycondensation of benzyl chloride in the presence of aprotic acids is undoubtedly of interest[118–132]. This reaction was described in detail in a recently published review[133] and allows thermally stable polymers to be obtained from saturated chlorine-containing compounds.

The chlorine in chlorotriphenylmethane is even more labile than that in benzyl chloride. Under the action of Friedel–Crafts catalysts chlorotriphenylmethane dissociates readily with the formation of a stable carbonium ion[134–136]. Here the degree of ionisation of chlorotriphenylmethane depends considerably on the nature of the catalyst and the solvent. In their ability to eliminate a chlorine ion from chlorotriphenylmethane the catalysts are arranged in the following series: $SbCl_5 \simeq FeCl_3 > GaCl_3 > SnCl_4 > BCl_3 > ZnCl_2 > TiCl_4 > SbCl_3 > AlCl_3 > PCl_5$.

III. CHLOROALKENES

1. CHLOROETHYLENES

Chloroethylenes which contain one or two chlorine atoms (vinyl chloride, vinylidene dichloride, and 1,2-dichloroethylene) are stable at high temperatures in the absence of atmospheric oxygen[137–141]. Vinyl chloride does not lose hydrogen chloride even when treated with bases[139].

The extremely high stability of these chloroethylenes, owing to the low mobility of their chlorine atoms, is used for the preparation of vinyl chloride, vinylidene chloride, and 1,2-dichloroethylene by pyrolysis of the corresponding chloroethanes[137,140]. The low lability of the chlorine atoms in these chloroethylenes is explained by the presence of conjugation between the unshared electron pairs of the chlorine atoms and the double bond:

$$CH_2{=}CCl_2 \leftarrow \overset{+}{C}H_2{-}CCl{=}\overset{+}{C}l.$$

Owing to this, the distance between the carbon and chlorine is shortened and becomes less (Table 2) than in saturated chlorinated hydrocarbons (for example, it is 1.77 Å in ethyl chloride).

Trichloroethylene and tetrachloroethylene, unlike the mono- and di-chloroethylenes, are unstable during storage and when heated. To suppress dehydrochlorination and other side-reactions, tri- and per-chloroethylenes were distilled in the presence of stabilisers[142-146]—hydrazones[144,145], epoxy-compounds[146], etc. The diminished thermal stability of trichloroethylene and tetrachloroethylene is due to the greater lability of the chlorine atoms in them. This is shown by the lower ionisation potentials and the increase in the C–Cl bond length in these compounds (Table 2).

Table 2. Characteristics of chloroethylenes[10,147,148].

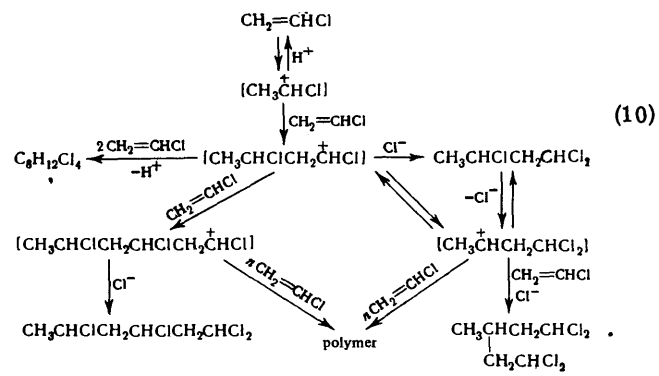
Chloroethylene	Ionisation potential, eV	C–Cl distance, Å	Dipole moment in benzene, D
$CH_2{=}CHCl$	9.99	1.69	1.44
$CH_2{=}CCl_2$	9.79	1.69	1.40
cis-CHCl-CHCl	9.66	1.67	1.85
trans-CHCl=CHCl	9.96	1.69	0.0
$CHCl{=}CCl_2$	8.80	1.82	0.94
$CCl_2{=}CCl_2$	9.50	1.82	0.0

The behaviour of chloroethylenes in the presence of aprotic acids is also different.

From the nature of the changes which chloroethylenes undergo in the presence of Lewis acids they can be divided into two groups. The first group of chloroethylenes (vinyl chloride, vinylidene chloride, and both isomers of 1,2-dichloroethylene) has a tendency to polymerise by a cationic mechanism in the presence of aprotic acids[138,139,149-156]. Trichloroethylene and tetrachloroethylene constitute a second group and are distinguished from the representatives of the first group by their undergoing autocondensation under the action of cationic catalysts.

a. Polymerisation of Chloroethylenes

Vinyl chloride is readily protonated in the presence of cationic catalysts ($AlCl_3$ or $TiCl_4$) owing to the moistness of the catalyst, with the formation of the reactive carbonium ion $CH_3\overset{+}{C}HCl$. This positively charged species, like other carbonium ions[159,160] initiates further polymerisation of vinyl chloride at –10°C[154-156] with the formation of oligomeric and polymeric products (scheme 10). The reaction of the $CH_3\overset{+}{C}HCl$ cation with a molecule of vinyl chloride leads to the formation of a new carbocation $CH_3CHClCH_2\overset{+}{C}HCl$, which is partly neutralised by the chlorine anion with the formation of trichlorobutane[154-158]. Furthermore, by successive addition of one or two molecules of vinyl chloride the dimeric cation is converted further into 1,1,3,5-tetrachlorohexane and tetrachloro-octene. Simultaneously, the cation $CH_3CHClCH_2\overset{+}{C}HCl$ isomerises into the cation $CH_3\overset{+}{C}HCH_2CHCl_2$. The latter reacts with vinyl chloride and is converted into 1,1,5,5-tetrachloro-3-methylpentane. As a result of further chain growth and secondary conversions of the oligomeric compounds with the vinyl chloride a low-molecular-weight polymer with a degree of polymerisation of ~ 30 is obtained, which consists of (–CH=CH–) and ($-\underset{\displaystyle CH_2CHCl_2}{\underset{|}{CH}}-CH_2-$) units in the ratio 1 : 1[154-156].



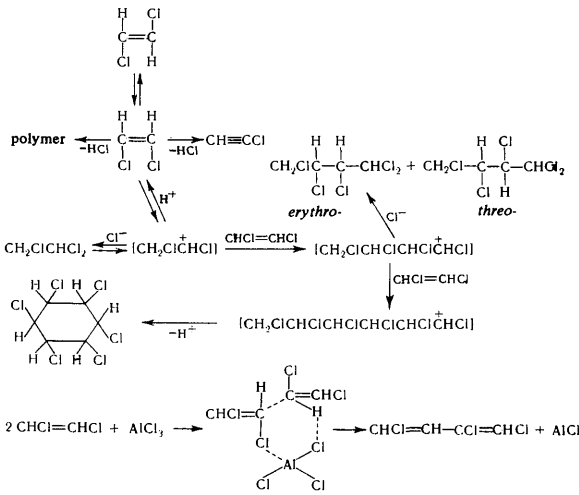
Raising the polymerisation temperature of vinyl chloride to 0°C or over accelerates the reaction, but simultaneously increases the rate of dehydrochlorination of the polymeric product formed. Therefore the polymer contains up to 80% vinylene units[154-156].

Owing to its asymmetric structure and comparatively large dipole moment (Table 2), *cis*-1,2-dichloroethylene is more reactive than the *trans*-isomer[147,161,162]. This is also true of reactions in the presence of aprotic acids. At room temperature under the influence of $AlCl_3$ both isomers of 1,2-dichloroethylene undergo only mutual interconversions into one another (scheme 11)[152]. The isomerisation of *trans*-1,2-dichloroethylene is effected at a greater rate than that of the *cis*-isomer[163,164].

The cationic polymerisation of 1,2-dichloroethylene is effected only at 50–70°C and is broken at the stage of formation of a dimeric compound (mixture of *erythro*- and *threo*-isomers of 1,1,2,3,4-pentachlorobutane)[152,155,156,165] and the trimer α-1,2,3,4,5,6-hexachlorocyclohexane[152,156]. Further polymerisation of 1,2-dichloroethylene does not take place, since the dimers give stable and unreactive complexes with the catalyst ($AlCl_3$) and the trimeric cation is cyclised (scheme 11). Furthermore, under these conditions under the influence of aluminium chloride pseudo-ionic processes of intramolecular and intermolecular dehydrochlorination of 1,2-dichloroethylene and its polymerisation products occur, as a result of which chloroacetylene and a polymeric product consisting of (–CH=CCl–) and ($\rangle C{=}CHCl$) units are formed[152].

Intermolecular dehydrochlorination of 1,2-dichloroethylene can be effected in the transition complex by

simultaneous electron transfer (scheme 12). The hydrogen chloride thereby liberated reacts with 1,2-dichloroethylene, which leads to the formation of 1,1,2-trichloroethane [152,166].

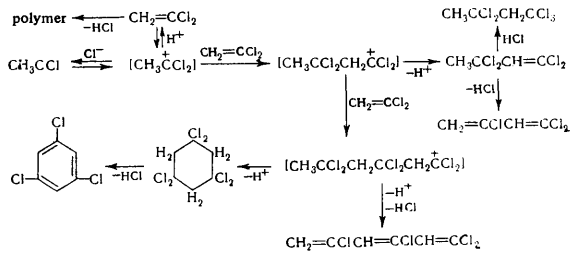


(11)

(12)

Vinylidene chloride at −50°C in the presence of $AlCl_3$ gives low-molecular-weight products of the polymerisation: the dimer [167] 1,1,3,3-tetrachlorobutene [150] and a cyclic trimer, 1,1,3,3,5,5-hexachlorocyclohexane [150]. On raising the temperature the polymerisation is accompanied by disproportionation of the 1,1,3,3-tetrachlorobutene to 1,1,1,3,3-tetrachlorobutene to 1,1,1,3,3-pentachlorobutane and 1,1,3-trichlorobutadiene (scheme 13), and also by dehydrochlorinations, as a result of which unsaturated compounds are formed: 1,1,3,5-tetrachlorohexatriene, 1,3,5-trichlorobenzene and a polymer with conjugated double bonds and with a composition close to $(CH_2Cl)_n$.

In the presence of $ZnCl_2$, which is a weaker complex-forming substance and cyclising agent than $AlCl_3$, vinylidene chloride is smoothly polymerised at 30°C with the production of poly(vinylidene chloride) [153]. This polymer is distinguished from the poly(vinylidene chloride obtained by radical polymerisation [168] by higher crystallinity [153].



(13)

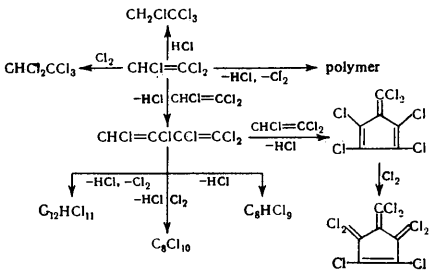
Hence the structure of chloroethylenes and the stability of the carbonium ions formed from them are the deciding factors in cationic polymerisation of these monomers. The chloroethylenes can be arranged according to their ability to polymerise in the following order [156]:

$$CH_2{=}CCl_2 > CH_2{=}CHCl > CHCl{=}CHCl\ [156].$$

It is noteworthy that in the case of vinyl chloride polymerisation in the presence of $AlCl_3$ leads to polymeric products, whereas with vinylidene chloride and 1,2-dichloroethylene the polymerisation is broken at the stage of cyclic trimer formation. Cyclisation of the trimeric cations is explained by the curvature of these cations in space and the possibility of a release of energy in the formation from them of uncharged six-membered rings [169].

b. Autocondensation of Chloroethylenes

For trichloroethylene the tendency to autocondensation is even greater than for 1,2-dichloroethylene (p. 260). In the presence of $AlCl_3$ trichloroethylene loses HCl even at −10°C. [170] As for 1,2-dichloroethylene, the autocondensation of trichloroethylene is probably effected by a pseudo-ionic mechanism and leads to the formation of oligomeric and polymeric products (scheme 14) [170,171]. Here the dimeric product [166,170–176] is a mixture of the *cis*- and *trans*-isomers of 1,1,2,3,4-pentachlorobutadiene [170,171].



(14)

The polycondensation of trichloroethylene and of the products of the oligomerisation to a polymeric product containing units of the −CCl=CCl− type and five-membered rings, proceeds both by dehydrochlorination and by dechlorination. The hydrogen chloride and chlorine thus liberated are partly consumed in the reaction with unsaturated compounds, which leads to the appearance among the reaction products of non-symmetric tetrachloroethane [170] and pentachloroethane [171].

On heating a mixture of tetrachloroethylene and aluminium chloride to 100–110°C, intermolecular and intramolecular dechlorination of tetrachloroethylene occur, with the formation of dichloroacetylene, hexachloroethane, and a polymeric product with conjugated double bonds [19], analogous in composition and properties to the polymer obtained from CCl_4 (cf. scheme 3).

Hence, autocondensation of chloroethylenes under the action of $AlCl_3$ takes place readily in those instances when the chlorine atoms in chloroethylenes (trichloroethylene and tetrachloroethylene) exhibit sufficient lability (cf. Table 2).

2. OTHER CHLOROALKENES

Chloroalkenes without chlorine atoms or with one or two chlorine atoms polymerise according to a cationic mechanism with the formation of oligomeric [177–180] and polymeric [181–183] products. Thus in the presence of $AlCl_3$ at 50°C allyl chloride gives di-, tri-, tetra-, and pentamers [180] which have the structure

$$CH_3CH(CH_2Cl)-[CH_2CH(CH_2Cl)-]_nCH{=}CHCH_2Cl.$$

On raising the temperature to 100–200°C the depth of the polymerisation of the allyl chloride is greatly increased [182,183]. However, simultaneously with this, dehydrochlorination of the polymerisation products takes

place, which leads to the production of a polymer containing unsaturated links of the type $-CH_2-\overset{}{\underset{}{C}}-$ type in $\overset{}{\underset{CH_2}{\|}}$ addition to allyl chloride units[183].

The polymerisation[181] of methyl-substituted allyl chloride—3-chloro-3-methylbut-1-ene—in the presence of $AlCl_3$ is accompanied by exchange of the chlorine atom and methyl group, which leads to the production of a polymer containing different units[181,184-186].

Polychlorine-containing alkenes with aprotic acids form stable, often coloured, complexes[4,187] in which exchange of halogen atoms between the chloroalkene and catalyst takes place[188-191]. The exchange by the halogens is used for obtaining chlorofluoroalkenes; exchange proceeds readily on heating chloroalkenes with fluorides of coordination-unsaturated metals[188-190] (for example, scheme 15).

$$CCl_2{=}CClCHCl_2 \xrightarrow{SbF_5} CCl_2{=}CClCHF_2 \qquad (15)$$

The process of halogen exchange is usually accompanied by rearrangements[190] and disproportionation[192]. Here there is a tendency to accumulate fluorine atoms at one carbon atom of the chloroalkene.

At high temperatures (100–200°C) complexes of polychloroalkenes with aprotic acids undergo deeper changes; in addition to the halogen exchange dehalogenation and heterolytic breaking of the carbon–carbon bond take place[40,193]. Thus on heating a mixture of hexachloropropene with $AlCl_3$ to 160°C, CCl_4, hexachlorobutadiene, tetrachloroethylene and conversion products of tetrachloroethylene (dichloroacetylene, hexachloroethane, and a polymeric product with conjugated double bonds) are formed[193] (scheme 16).

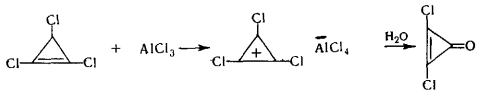
$$CCl_2{=}CClCCl_3\cdot AlCl_3 \rightleftarrows [CCl_2{=}CClCCl_3][\overline{A}lCl_4] \rightleftarrows [CCl_2{=}\overset{+}{C}Cl]\,[\overline{A}lCl_3CCl_3]$$
$$[\overline{A}lCl_3CCl_3] \rightarrow [:CCl_2] + AlCl_4^- \rightarrow CCl_2{=}CCl_2 + AlCl_4^-$$
$$CCl_4 + AlCl_3 \qquad (16)$$
$$\uparrow$$
$$[CCl_2{=}CCl]^+ + [AlCl_4] \xrightarrow{CCl_2=CClCCl_3} CCl_2{=}CClCCl{=}CCl_2 + [\overset{+}{C}Cl_3][\overline{A}lCl_4]$$

In addition to the breaking of the carbon–carbon bond, autocondensation of polychloroalkenes takes place with release of hydrogen chloride and chlorine[187,194] and the production of dimeric compounds. Perchloroalkenes which contain five or more carbon atoms in a chain are readily cyclised under the action of $AlCl_3$ into five- and six-membered rings[4,30], for example, by scheme (17). Here the cyclisation of the perchloroalkenes sometimes takes place with isomerisation of the carbon skeleton[194] and breaking of the carbon–carbon bond.

$$CCl_2{=}CClCCl{=}CClCCl_3 \xrightarrow{-Cl_2} \text{(1,2,3,4-tetrachlorocyclopentadiene)} \qquad (17)$$

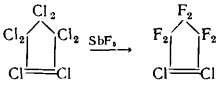
Thus, heating decachloromethylpentadiene in the presence of $AlCl_3$ leads to the production of CCl_4 and hexachlorocyclopentadiene[195].

The conversions of perchlorinated cycloalkenes, which form extremely stable complexes with aprotic acids, are interesting. The complex of tetrachlorocyclopropene with $AlCl_3$ has the properties of an organic salt, since the trichlorocyclopropylium cation which is formed is very stable[196-201]. On treatment with water, this salt is hydrolysed with release of dichloropropenone according to scheme (18).



(18)

Heating the complexes of perchlorinated cycloalkenes with aprotic acids leads to vigorous exchange of halogens between the cycloalkene and catalyst[199-200] (scheme 19). The allyl chlorine atoms are exchanged first[189]:



(19)

Heating such complexes sometimes leads to the isomerisation of a cycloalkene[203] and to the formation of dimeric products[202]. Dimerisation proceeds with opening of the double bonds[195].

IV. CHLOROALKANES

1. CHLOROETHANES

Chloroethanes are comparatively unstable compounds. Some of them decompose with release of HCl even during storage and distillation. The hydrogen chloride of nonsymmetric chloroethanes is lost most easily[204-206]. To increase the thermal stability of chloroethanes stabilisers are added to them[204-207], for example, aliphatic hydroxyacids[207] and epoxy-compounds[205].

Aprotic acids accelerate the dehydrochlorination of chloroethanes, which, like halogen exchange[212-214], is effected through the intermediate formation of complexes of the $CH_3CH_2Cl.Al_2Cl_6$ type[208-211]. Loss of HCl takes place at temperatures considerably lower than the boiling points of the chloroethanes[215,216]. For chloroethanes with a $CHCl_2$ group the thermal stability in the presence of aluminium chloride increases with the degree of chlorination of the neighbouring methyl group, that is,

$$CH_3CHCl_2 < CH_2ClCHCl_2 < CHCl_2CHCl_2,$$

but drops again on going to pentachloroethane[216]. The rate of dehydrochlorination of chloroethanes with a CH_3 group under the action of the same reagent increases with the content of chlorine atoms in the neighbouring methyl group[216]:

$$CH_3CH_2Cl < CH_3CHCl_2 < CH_3CCl_3 .$$

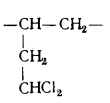
The structure of the initial chloroethanes shows the effect not only on the rate of dehydrochlorination in the presence of aprotic acids but also on the composition of the conversion products of the chloroethanes.

In the presence of $AlCl_3$ at 35–40°C ethyl chloride undergoes a mainly intermolecular dehydrochlorination with the formation of polymeric products with a molecular weight of up to 700 and containing ethylidene units $-\overset{}{\underset{CH_3}{CH}}-$ and carbonyl groups in a ratio of between 10:1 and 30:1.[20] The appearance of carbonyl groups in the polymer is explained[217] by its oxidation at the double bonds. In the reaction of ethyl chloride with $AlCl_3$, in addition to the polymer a little ethylene is also formed, owing to intramolecular $\alpha\beta$-*cis*-elimination of hydrogen chloride from the ethyl chloride. The predominance of intermolecular dehydrochlorination over intramolecular is because there is a high probability of collision of the $CH_3CH_2Cl.AlCl_3$ complexes with one another in the liquid phase. Because the hydrogen in the CH_2Cl group of ethyl chloride is more labile than that in the $-CH_3$ group, intermolecular dehydrochlorination proceeds mainly with involvement of the chloromethyl group. In the dehydrochlorination of ethyl

chloride on metal chlorides ($NiCl_2$, $FeCl_3$, $AlCl_3$) in the vapour phase (300°C) the probability of collision of two molecules of ethyl chloride on the surface of the catalyst is low. Therefore under these conditions there is mainly intramolecular loss of hydrogen chloride with the formation of ethylene[4] and a polymeric product is only produced in small quantities.

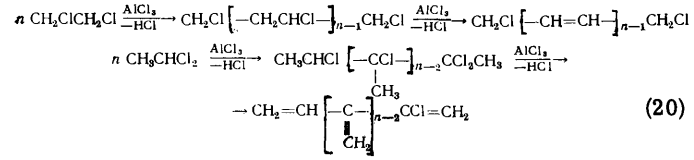
Dichloroethanes. At room temperature and in the presence of small quantities of aluminium chloride there is slight isomerisation of 1,2-dichloroethane into 1,1-dichloroethane[218,219]. This compound is considerably more reactive than its symmetric isomer. Under the action of $AlCl_3$ 1,1-dichloroethane undergoes intramolecular loss of hydrogen chloride with the formation of small quantities of vinyl chloride even at 0°C.[215,219] Furthermore, at 30°C it partly rearranges into the symmetric isomer[219]. At 50–60°C both isomers of dichloroethane undergo intermolecular dehydrochlorination with the quantitative formation of polymeric products with conjugated double bonds[220,221]. The polymeric products of composition $(C_2H_2)_n$ contain predominantly vinylene –CH=CH– (I) and vinylidene $\diagdown C{=}CH_2$ (II) units[221]; they are not polyphenylethylenes, as was suggested earlier[222].

Polymeric products with I and II links cannot be obtained in the dehydrochlorination of poly(vinyl chloride), which is in turn formed by polymerisation of vinyl chloride as already proposed[353]. The present authors heated a mixture of vinyl chloride and $AlCl_3$ under conditions for the polycondensation of dichloroethanes and obtained the same products as were described above (cf. scheme 10). The polymer thus obtained contained mainly the link



and did not contain I units.

Since the reactivities of both the CH_2Cl groups in 1,2-dichloroethane are the same, and in 1,1-dichloroethane the more reactive group is $CHCl_2$,[221] the vinylidene units are formed from 1,1-dichloroethane (scheme 20):



(20)

Mouneyrat[223] obtained tetrabromoethane by heating 1,2-dibromoethane in the presence of bromine and aluminium bromide. From this he concluded that dihalogenoethanes undergo intramolecular dehydrohalogenation on Friedel–Crafts catalysts to acetylene, which then adds bromine and is converted into tetrabromoethane. Evidently, Mouneyrat was wrong, since under the conditions of his experiments the usual bromination, catalysed by aprotic acid[1], should take place. We heated 1,2-dibromoethane in the presence of aluminium bromide or chloride and obtained a polymeric product which is analogous in composition and properties to the polymer obtained from 1,2-dichloroethane.

It is noteworthy that the polymers based on dichloroethanes are, like other poly-conjugated systems[224], thermostabilisers of chlorine-containing compounds[216].

The vapour-phase intramolecular dehydrochlorination of the two dichloroethanes is of interest as an industrial method of obtaining vinyl chloride[225]. The reaction is effected at 300–400°C on acid catalysts (chlorides of zinc, magnesium, iron, aluminosilicate, etc.)[225–228]. Here small quantities of resinous substances are formed as well as vinyl chloride. Furthermore, under these conditions there is also isomerisation of the symmetric isomer of dichloroethane into the non-symmetric[218]. The almost selective dehydrochlorination of dichloroethanes in the vapour phase to vinyl chloride is because here there is little probability of collision of even two molecules of dichloroethane on the catalyst surface. The use of inert gases as diluents has been proposed[229] to even further reduce the probability of such collisions and decrease the formation of resinous substances[229].

1,1,2-Trichloroethane undergoes intramolecular and intermolecular dehydrochlorination in the liquid phase in the presence of $AlCl_3$.[152] Intramolecular elimination of hydrogen chloride to give 1,2-dichloroethylene (mainly the *trans*-isomer)[215] is effected through the intermediate formation of the carbonium ion $CH_2Cl–\overset{+}{C}HCl$. The 1,2-dichloroethylene which is formed reacts further by a cationic mechanism according to scheme (11). The chief reaction which takes place in the reaction of 1,1,2-trichloroethane with $AlCl_3$ is polycondensation with the formation of a polymeric product with conjugated double bonds, including the units –CH=CCl– and $-C(=CHCl)-$ in the ratio 1:1.[152]

In the vapour phase on acid catalysts 1,1,2-trichloroethane undergoes $\alpha\beta$-elimination of hydrogen chloride with predominant formation of *cis*-1,2-dichloroethylene[228,230,231]. Vinylidene dichloride is obtained in addition to 1,2-dichloroethylene[228,230].

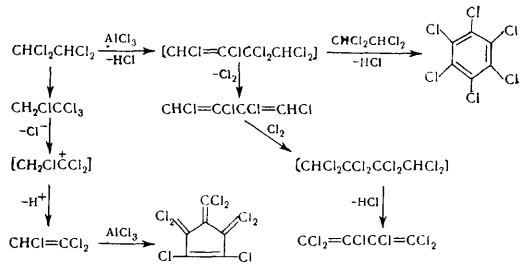
1,1,1-Trichloroethane can be quantitatively converted into vinylidene chloride in the liquid phase under the action of $FeCl_3$.[184,231] In the presence of $AlCl_3$, 1,1,1-trichloroethane also loses hydrogen chloride intramolecularly[150]. However, the vinylidene chloride thus formed is converted further into 1,1,3,3-tetrachlorobutene and 1,1,3,3,5,5-hexachlorocyclohexane under the influence of $AlCl_3$ (cf. scheme 13). The preferential intramolecular dehydrochlorination of 1,1,1-trichloroethane is explained by the fact that this compound, unlike 1,1,2-trichloroethane, gives the relatively stable carbonium ion $CH_3\overset{+}{C}Cl_2$ on reaction with $AlCl_3$. The ionic mechanism of dehydrochlorination of 1,1,1-trichloroethane on acid catalysts[228] is also retained on carrying out the reaction in the vapour phase.

Non-symmetric tetrachloroethane behaves similarly to 1,1,1-trichloroethane in the presence of aprotic acids; in the liquid phase it is smoothly dehydrochlorinated to trichloroethylene[184,215,219,231,232]. Here in addition to trichloroethylene the products are 1,2,3,4,4-pentachlorobutadiene, perchlorofulvene, and 1,2,3,3,5,5-hexachloro-4-(dichloromethylene)cyclopentene[219], which are conversion products of trichloroethylene (see scheme 14).

Non-symmetric tetrachloroethane is smoothly converted into trichloroethylene in the vapour phase on metal chlorides[233,234].

When 1,1,2,2-tetrachloroethane is heated with $AlCl_3$ in the liquid phase, intermolecular dehydrochlorination occurs with the formation of dimeric compounds—1,2,3,4-tetrachlorobutadiene and hexachlorobutadiene—the trimer hexachlorobenzene, and the polymer of composition $(C_6HCl_4)_n$ (scheme 22)[235]. Here the intermolecular elimination of HCl from tetrachloroethane is accompanied by

dechlorination and chlorination, owing to the presence of tetrachlorobutadiene and hexachlorobutadiene among the reaction products. A polymeric product is also the result not only of dehydrochlorination but also the loss of chlorine, and contains five- and six-membered rings.

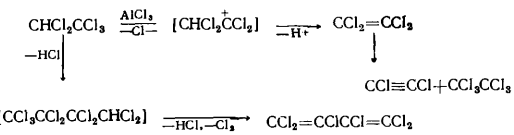


(22)

When 1,1,2,2-tetrachloroethane is heated with $AlCl_3$ in addition to polycondensation it undergoes isomerisation into the non-symmetric isomer[235,236], which under the conditions of the reaction loses HCl intramolecularly with the formation of trichloroethylene.

Dehydrochlorination of symmetric tetrachloroethane on acid catalysts in the vapour phase leads to a mixture of products in which trichloroethylene predominates[228]. In addition to trichloroethylene, tetrachloroethylene, pentachloroethane, and hexachloroethane are also observed[237]. Probably, dehydrochlorination of tetrachloroethane in the vapour phase takes place by a radical mechanism.

Pentachloroethane, like other chloroethanes with the CCl_3 group, forms the stable carbonium ion $CHCl_2-\overset{+}{C}Cl_2$ in the presence of aprotic acids, and this ion is further converted into tetrachloroethylene[215,219,238,239]. In the presence of large quantities of $AlCl_3$ (pentachloroethane : $AlCl_3$ ratio 5 : 1) in the liquid phase (120–150°C) dichloroacetylene, hexachloroethane, and hexachlorobutadiene are formed in addition to tetrachloroethylene[219]. The conversion of pentachloroethane under these conditions take place by scheme (23).



(23)

Tetrachloroethylene is the only product of the pyrolysis of pentachloroethane in the vapour phase (200–350°C) in the presence of aprotic acids[30,240].

Hexachloroethane is very stable on heating, as [might be expected of] a symmetrically constructed compound[30]. In the presence of aprotic acids at 200–250°C (in an ampoule) it does not undergo any changes in the liquid phase[19]. In the vapour phase at 300–400°C on Lewis acids, hexachloroethane is destroyed by a radical mechanism with the formation of tetrachloroethylene and chlorine[25–27].

2. SUBSTITUTED CHLOROETHANES

Replacement of the chlorine atoms in chloroethanes by more electronegative groups (*p*-chlorophenyl[241], fluorine[242]) retards the dehydrochlorination of chloroethanes. In addition there is an increase in the tendency of chlorofluoroethanes to undergo rearrangements[42,242–245]. Isomerisation of chlorofluoroethanes in the presence of aprotic acids proceeds in such a manner that the fluorine atoms are grouped on one carbon atom with the formation of the CF_3 group[245]. In addition to isomerisation there is an exchange of halogen atoms between catalyst and chlorofluoroethane. The introduction into chloroethane of the trichlorosilyl group considerably accelerates the dehydrochlorination of chloroethanes under the action of $AlCl_3$.[246–249] The main direction of this reaction is intramolecular dehydrochlorination with the formation of silicon-containing alkenes[247]. For 2-chloroethylsilane, in addition to dehydrochlorination under the action of $AlCl_3$ there is appreciable elimination of $SiCl_4$.[250–252] This process can proceed with quantitative formation of $SiCl_4$[250] (scheme 24).

$$CH_2ClCH_2SiCl_3 \xrightarrow{AlCl_3} CH_2{=}CH_2 + SiCl_4$$
$$CH_3CHClSiCl_3 \xrightarrow{AlCl_3} CH_2{=}CHSiCl_3 + HCl\,. \qquad (24)$$

3. HIGHER CHLOROALKANES AND CHLOROCYCLOALKANES

Higher chloroalkanes, like chloroethanes, form complexes with halides of coordination-unsaturated metals[253–255] in which there is exchange of halogens between the chloroalkane and the salt[253,256–262]. It has been noted[253–255] that halogen exchange is greatly accelerated when hydrogen chloride is introduced into the reaction mixture.

Aprotic acids bring about various rearrangements of chloroalkanes[157,263,264]. The most frequently encountered rearrangement is the transfer of chlorine atoms from one carbon atom to another[254,255,265–270]. Here the chlorine is usually transferred to the carbon with the greatest number of substituents, that is, from a primary to a secondary to a tertiary. Thus, under the action of $AlCl_3$ propyl chloride is completely isomerised into isopropyl chloride[265]. It is assumed that such isomerisation proceeds by a pseudo-ionic mechanism in an intermediate five-membered complex[255].

Under the influence of aprotic acids, when heated in the liquid phase chloroalkanes readily lose hydrogen chloride[6,266,267,271–275]. Here the chloroalkanes with CCl_3 groups and also alkyl chlorides containing chlorine atoms at secondary and tertiary carbon atoms are usually dehydrochlorinated to alkenes[184,276–286]. Under the action of aprotic acids primary alkyl chlorides are either isomerised[254,255,265–274] into secondary and tertiary alkyl chlorides, which then lose hydrogen chloride intramolecularly, or react by intermolecular dehydrochlorination, which leads to the formation of higher-molecular-weight products[6,270–272]. Thus Friedel and Crafts obtained a dimeric compound (chlorodecane) from pentyl chloride[271,272]. On reaction with aprotic acids compounds with the CCl_3 group are ionised with the formation of carbonium ions[287–289], which are converted by different paths. When a proton is present at a neighbouring carbon atom it is removed and an alkene is formed[4,193,280,281,290]. In the absence of such a hydrogen atom the carbocation can react by the breaking of carbon–carbon bonds[193,290–292] (scheme 25):

$$CHCl_2CCl_2CCl_3 + AlCl_3 \rightleftarrows [CHCl_2CCl_2\overset{+}{C}Cl_2][\overline{AlCl_4}] \rightarrow CCl_2{=}CCl_2 + [\overset{+}{C}HCl_2][\overline{AlCl_4}]$$
$$[\overset{+}{C}HCl_2][AlCl_4] \rightarrow CHCl_3 + AlCl_3 \qquad (25)$$

Perchlorinated alkanes with a long carbon chain (not less than C_5) are cyclised under the action of aprotic acids[30,293].

The main reaction of chloroalkanes in the presence of salts of coordination-unsaturated metals in the vapour

phase at 300–600°C is dehydrochlorination. In this the regularities which are observed in the liquid phase are retained. The dehydrochlorination of the long-chain chloroalkanes is accompanied by the isomerisation of the carbon skeleton[294], the transfer of the double bond along the carbon chain[295,296], and the breakage of a carbon–carbon bond, which leads to the formation of a mixture of alkenes. Completely chlorinated hydrocarbons are decomposed in the vapour phase under the action of Lewis acids with breakage of a C–C bond to give tetrachloroethylene and CCl_4.[297,298]

Chlorocycloalkanes. The conversions of 1,2,3,4,5,6-hexachlorocyclohexane and other chlorinated cyclohexanes have been studied in greatest detail. At moderate temperatures (20–120°C) the reaction of the chlorocyclohexanes with $AlCl_3$ is brought about by exchange of chlorine atoms between catalyst and chlorocyclohexane[299], by the migration of chlorine atoms in the cyclohexane ring[300] and by spatial isomerisation[299–301]. For example, under the action of $AlCl_3$ at 20°C *trans*-1,2-dichlorocyclohexane is partly converted into *cis*-1,2-dichlorocyclohexane and is isomerised to *cis*- and *trans*-1,4-dichlorocyclohexane. On heating γ-1,2,3,4,5,6-hexachlorocyclohexane to 112°C with $AlCl_3$ labelled with the isotope ^{36}Cl there is a vigorous exchange of chlorine isotopes between the catalyst and the hexachlorocyclohexane[299]. Furthermore, isomerisation of the γ-isomer into the α-isomer takes place[299–301]. It is noteworthy that when heated with aprotic acids all the isomers of hexachlorocyclohexane are converted into the α-isomer, the configuration of which is most favourable energetically[301]. At high temperatures (250–400°C) chlorinated cyclohexanes lose hydrogen chloride readily under the influence of aprotic acids[301–305]. Thus hexachlorocyclohexane is dehydrochlorinated in the presence of $FeCl_3$ with the formation of 1,2,4-trichlorobenzene and of its isomerisation product 1,2,3-trichlorobenzene[301]. Here the α-isomer is dehydrochlorinated with greater difficulty than the other hexachlorocyclohexane isomers.

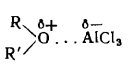
Cyclobutyl chloride and cyclopropylmethyl chloride undergo initial conversions under the action of $AlCl_3$.[306] Cyclopropylmethyl chloride readily rearranges at −40°C into cyclobutyl chloride and 1-chlorobut-3-ene (scheme 26):

(26)

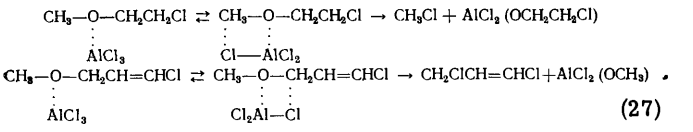
The rearrangement of cyclobutyl chloride into cyclopropylmethyl chloride and 1-chlorobut-3-ene takes place at a higher temperature (+15°C). Kinetic investigations[306] of these conversions show that the rearrangements have an ionic mechanism.

4. SUBSTITUTED CHLOROALKANES

Chloroalkanes which incorporate other halogens (fluorine or bromine) readily disproportionate in the presence of aprotic acids[266,307]. The introduction of alkoxy-groups into chloroalkanes accelerates their dehydrochlorination[308]. The reaction centre of alkoxychloroalkanes in their reaction with aprotic acids could be the ether group. Complexes of the type



are formed, which decompose when heated, with the formation of aluminium alkoxides and chloroalkanes[309]. The ether decomposes in such a way that the radical split off in the form of a halogenoalkane is that which has most tendency to acquire part of the positive charge from the oxygen atom. For example, when 2-chloroethyl methyl ether reacts with $AlCl_3$ it decomposes with liberation of methyl chloride[309], whereas 1,3-dichloro-prop-2-ene is formed from 3-chloroprop-2-enyl methyl ether[310] (scheme 27):



(27)

When the alkoxy-group in the chloroalkanes is in proximity to reactive CCl_3 or CHCl groups, which exhibit labile chlorine atoms, then the conversion of such compounds in the presence of aprotic acids leads to the formation of epoxy-compounds which are subsequently rearranged into ketones and acyl chlorides[311].

When γ- and δ-chlorine-containing ethers are heated with $FeCl_3$ or $SbCl_5$ they are cyclised with the formation of oxacycloalkanes[312–315]. For example, tetrahydrofuran and the metal chloride are formed in high yield from 4-chlorobutyl methyl ether in the presence of $FeCl_3$.[315]

Chloroalkanes which include phenyl groups readily undergo autocondensation under the conditions of the Friedel–Crafts reaction with release of hydrogen chloride and formation of cyclic and linear compounds[316–318]. Thus on heating a mixture of 1-chloro-1-phenylethane and $AlCl_3$ two molecules of the former are condensed and 9,10-dihydro-9,10-dimethylanthracene is obtained[312]. When in a chloroalkane there are 3–5 carbon atoms between the chlorine atom and the phenyl group, such compounds undergo cycloalkylation[319].

5. CHLORO-CONTAINING POLYMERS

The reactions of salts of coordination-unsaturated metals with polymers which are widely used in industry have been most studied. They include homopolymers and copolymers of vinyl chloride and vinylidene chloride and also chlorinated poly(vinyl chloride), which consist of the units $-CH_2-CHCl-$, $-CHCl-CHCl-$, and $-CH_2-CCl_2-$. When these polymers are heated they decompose with liberation of hydrogen chloride[320–323]. Many investigations devoted to the dehydrochlorination of poly(vinyl chloride) (PVC) showed that loss of hydrogen chloride takes place by ionic[322,324], pseudo-ionic[322,325], and radical[321–323] mechanisms. In the presence of salts of coordination-unsaturated metals the dehydrochlorination of PVC is accelerated[320–322,326–331] and proceeds by a pseudoionic mechanism[325,327,328]. Here the rate of dehydrochlorination is even greater when the salts of coordination-unsaturated metals and the hydrogen chloride liberated form rather stable complexes of the type MX.HCl,[322,332–334] which catalyse the decomposition of the polymer, owing to their acidic nature. The dehydrochlorination of PVC under the action of aprotic acids is effected both intramolecularly (which leads to a system of conjugated double bonds[335–338]) and also intermolecularly, as a result of which a structured, insoluble polymer is formed[339]. Furthermore, destruction of the PVC with breaking of the carbon–carbon bond is observed[340]. Organic solvents, such as dimethylformamide and aromatic amines, which form stable complexes with aprotic acids, decrease the catalytic action of these salts, as a result of which the rate of dehydrochlorination of PVC decreases considerably[341–343].

To suppress the dehydrochlorination of chlorine-containing polymers in their manufacture into various articles, stabilisers are usually employed. Salts of coordination-unsaturated metals are used as stabilisers for PVC [320,321,344,345]. They include aluminium, zinc, cadmium, and lead salts of stearic, lauric, caprylic, and other organic acids, and also the dicarboxylates of dialkoxides [320,321]. In addition, basic lead salts of organic and inorganic acids find wide application. The stabilising action of these salts is based on both the bonding of the hydrogen chloride released in the destruction of the polymers and on their reaction with the labile chlorine atoms of the polymer [346-349]. In the latter instance there is exchange of the chlorine atoms in the tertiary alkyl chloride and allyl chloride groupings which are present in commercial PVC [350], by the acyl residues of the salts [333,334,346-349,351] with the formation of ester groups (scheme 28):

$$-\overset{|}{\underset{Cl}{C}}- + Pb(OCOR)_2 \rightarrow -\overset{|}{\underset{OCOR}{C}}- + PbCl(OCOR) . \qquad (28)$$

Since the sub-units which contain the ester groups are more stable thermally than the sub-units with labile chlorine atoms [352] the resistance of the polymer to dehydrochlorination is enhanced as a result of this reaction [333,334,351]. The stabilising action of certain salts of coordination-unsaturated metals is also based on the fact that they form complexes with reactive groups of the polymer (conjugated double bonds, oxygen-containing groups) which give it a colour [332-334]. As a result of complex formation by chromophoric groups with a stabiliser the colour of the polymer is reduced.

---o0o---

Hence the principal reaction of hydrogen-containing organochlorine compounds under the action of aprotic acids is dehydrochlorination, which is intramolecular or intermolecular, depending on the structure of the initial organochlorine compound. Intramolecular elimination of hydrogen chloride takes place through the intermediate formation of relatively stable carbonium ions and leads to the formation of alkenes. Intermolecular dehydrochlorination is effected by simultaneous electron transfer to the transition complex, as a result of which a higher-molecular-weight compound is obtained. In the presence of $AlCl_3$ certain chloroethanes (dichloroethanes, 1,1,2-trichloroethane, 1,1,2,2-tetrachloroethane) can give high yields of polymers with conjugated double bonds which exhibit semiconducting properties. Dehydrochlorination is usually accompanied by parallel processes, such as cationic polymerisation of chloroalkenes, isomerisation, rearrangements, disproportionation, halogen exchange between chlorine-containing compounds and the catalyst, cyclisation, complex formation, breaking of –C–C–, –C–O– and other bonds, dehalogenation, which mainly proceed by ionic or pseudoionic mechanisms. The conditions for the reaction of organochlorine aliphatic compounds with the salts of coordination-unsaturated metals have a marked effect on the direction of these reactions. As a result suitable choice of the reaction conditions enables certain of the above processes to occur preferentially and desirable products to be obtained in high yields.

Addition Reactions with Intramolecular Cyclisation

V.I.Staninets and E.A.Shilov (deceased)

Heterolytic addition reactions in which the effect of the electrophilic agent on a double or triple bond leads to intramolecular cyclisation via an electron-donating group ("the AC reaction") are discussed. These reactions almost always give rise to five- and six-membered rings. Weak electrophilic agents form only cyclic adducts under the conditions of AC reactions, while strong electrophilic agents form, together with cyclic compounds, simple and mixed acyclic addition products. The formation of cyclic adducts is also promoted by the rigid structure of the unsaturated molecule and the nucleophilic properties of the electron-donating group.
The AC reactions obey the kinetic equations for second-order processes. They are distinguished from the analogous trimolecular acceptor-donor addition reactions by the synchronous occurrence of the electrophilic and nucleophilic stages in the elementary step, which is related to the steric conditions of ring formation.
The bibliography includes 124 references.

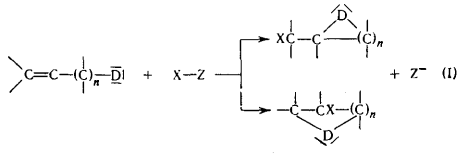
I. INTRODUCTION. THE CONCEPT OF ADDITION REACTIONS WITH CYCLISATION

Reactions where the addition of an electrophilic agent X–Z to an unsaturated molecule containing an electron-donating group D is accompanied by the formation of a heterocycle via the mechanism (two possible modes of these reactions are shown)



(I)

are of particular interest. Unsaturated molecules in which the double bond is incorporated into a cyclic system and also compounds with a triple bond or with heteroatoms in the carbon chain react via mechanism (I). Addition reactions with cyclisation of this type will be referred to as AC reactions.

On the one hand AC reactions have found practical application in the synthesis of a wide variety of heterocyclic compounds. On the other hand, they are of considerable theoretical interest because their study can yield certain new information about heterolytic addition reactions.

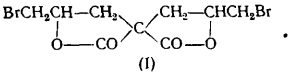
In the literature there are no reviews of reactions of this type—only individual cases and special relations in such reactions are noted in reviews on other topics, in particular those where the problem of "the effect of neighbouring groups" is discussed[1-5].

This review deals with the effect of the structure of the reactants on the nature of AC reactions, the relevant kinetic data are presented, and a general theoretical interpretation of these reactions is given.

The formation of lactones and other cyclisation reactions under the influence of acids are not discussed because they have been partly reviewed elsewhere[3,4] and because the extensive literature data on these reactions merit a discussion in a separate article.

II. STRUCTURAL FACTORS IN ADDITION REACTIONS WITH CYCLISATION

The intramolecular formation of cyclic species in addition reactions was first observed by Fittig and Hjelt[6] in the bromination of diallylacetic and diallylmalonic acids. Structural formulae with a five-membered ring were ascribed to the resulting bromolactones, for example structure (I) for the bromination product of diallylmalonic acid:

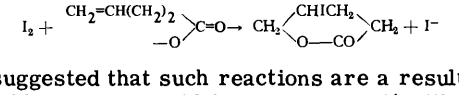


(I)

In order to account for the formation of bromolactones, Fittig and Hjelt assumed the intermediate formation of unstable dibromides, which cyclise with elimination of hydrogen bromide. We may note that similar hypotheses were also put forward subsequently in the discussion of the mechanism of AC reactions.

The intramolecular formation of cyclic species was observed also in the study of the reactions of allylureas and allylthioureas. When these compounds were brominated or iodinated, bromomethyl- or iodomethyl-oxazolidines and thiazolidines were obtained[7,11].

Bougault[12-14] made a detailed and systematic study of the formation of iodine-substituted lactones in the iodination of unsaturated carboxylic acids in aqueous potassium iodide and sodium bicarbonate solutions, i.e. under conditions where the acids are present in the form of anions, for example:



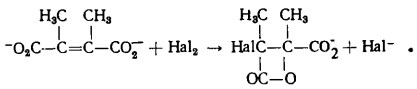
He also suggested that such reactions are a result of the addition of hypoiodous acid *in statu nascendi* with subsequent lactonisation of the resulting iodoxy-acid. He showed that only those unsaturated compounds whose structure allows the formation of a five- or six-membered

ring are capable of iodolactonisation reactions. Subsequently numerous examples showed that this rule is extremely general for AC reactions.

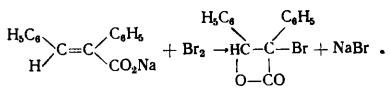
If the structure of the unsaturated molecule does not allow the formation of a five- or six-membered ring, then iodination under the conditions of the Bougault reaction does not occur at all or leads to unstable non-cyclic adducts—di-iodides and iodohydrins.

In particular, acrylate and crotonate anions and their substituted derivatives, the structure of which allows the formation of only four-membered rings, do not react with iodine. Octenic acids, and probably other unsaturated acids in which the electron-donating group is separated from the double bond by more than six atoms, do not form iodolactones[13,15].

However, it is noteworthy that the bromination or chlorination of unsaturated dimethylmaleate and dimethylfumarate anions leads to the rare case of the formation of a four-membered lactone[16]:

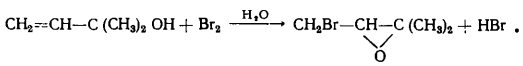


A similar four-membered lactone was obtained recently[7] by the bromination of the sodium and silver salts of *cis*- and *trans*-stilbene-2-carboxylic acids in carbon tetrachloride:



The reaction is accompanied by the formation of polymers and side products. The configuration of the resulting lactone was not indicated.

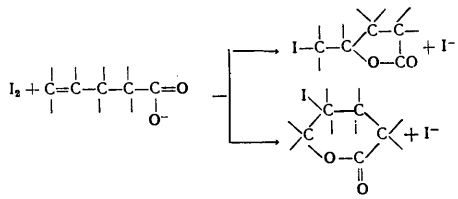
The formation of a three-membered ring was observed in the bromination of dimethylvinylmethanol[18]:



The exclusive formation of five- and six-membered rings in AC reactions has been used for the iodometric determination of $\beta\gamma$- and $\gamma\delta$-unsaturated acids in mixtures with acids having other structures[19]. The composition of mixtures of compounds containing *endo*- and *exo*-bridges (in the form of CH_2 and CH_2CH_2 groups) has been determined similarly[20-22]. Under certain conditions of analysis, only the *endo*-compounds are iodinated.

Bougault established that the derivatives of but-3-enoic acid (4-ethyl, 4-phenyl, 4-benzyl, 4-anisyl, 2,2-dimethyl, 2,4-diphenyl-, 2,2,4-trimethyl-, and other derivatives) form only five-membered iodolactones, in accordance with their structures[13]. Subsequently analogous iodolactones were obtained from 4-methyl-, 4-vinyl-, and 4-ethyl-pent-3-enoic acids[15,23,24]. However, unsubstituted but-3-enoic (vinylacetic) acid reacts with difficulty and, as shown recently[24], forms iodine-free furanones (4-hydroxy-2-oxotetrahydrofuran, its vinylacetic ester, and 2-oxo-3,4-dihydrofuran). These compounds are probably formed as a result of the hydrolysis and elimination of hydrogen iodide from the intermediate iodo-adducts.

Compounds with the structure of pent-4-enoic (allylacetic) acid can form both five- and six-membered rings:



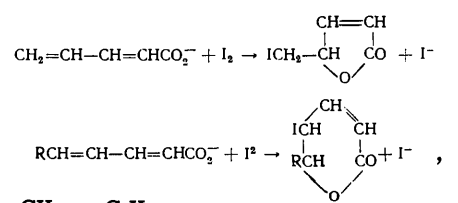
Few reliable data have been published on the mode of cyclisation in those reactions where there is a possibility of the formation of both five- and six-membered rings. In many cases the structures of the resulting cyclic adducts were not established or are only tentatively indicated. This is because the chemical methods for distinguishing five- and six-membered rings are fairly laborious. At the present time spectroscopic methods (infrared and NMR spectroscopy) are being used with great success[25-27].

It has been shown[23] that on iodination unsubstituted pent-4-enoic acid forms only a five-membered iodolactone†. Five-membered iodolactones are also formed from 1- and 3-cyclohexenylacetic acids[23]. However, hex-4-enoic acid gives rise to a six-membered iodolactone[24]. Iodination of *cis*-cinnamylacetic acid results in the formation of a five-membered lactone, while its *trans*-isomer gives a mixture of compounds with five- and six-membered rings[28].

The addition of electrophilic agents in AC reactions involving the competing formation of five- or six-membered rings in general takes place in accordance with the Markovnikov rule. However, the mode of reaction depends not only on the electronic nature of the substituents at the C=C bond but also on the steric effects of these substituent on the stabilisation of the cyclic transition state and on the nucleophilic properties of the electron-donating end of the unsaturated molecule. Therefore an exact prediction of the structure of the AC reaction product is not always possible.

Especially little is known about the effect of electron-accepting groups at the C=C bond on the mode of cyclisation. This is because electron-accepting substituents greatly hinder or even prevent the addition of weak electrophilic agents via the AC reaction mechanism.

If the unsaturated chain of the compound iodinated contains two conjugated double bonds, the rule of the formation of a five- or six-membered ring holds, but the iodocyclisation reaction is retarded[24]. The vinylacrylate anion gives the iodolactone with the dihydrofuran structure and hexa-2,4-dienate (sorbate) and 5-phenylpenta-2,4-dienate anions form six-membered rings on iodination[24]:



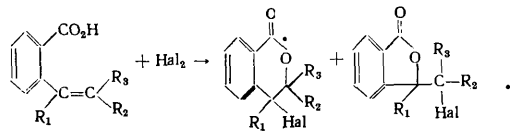
where R = CH_3 or C_6H_5.

Evidently in the reaction with iodine the terminal carbon atom is more active in the CH_2=CH group, while in the RCH=CH group the electrophilic agent acts upon the

† Bougault suggested that the iodolactone from allylacetic acid has a pyran structure[13]. This error was amended by van Tamelen and Shamma[23].

neighbouring carbon atom and ring closure occurs at the atom linked to the R group. Thus the rule established for allyl derivatives holds for compounds with conjugated double bonds.

If the hydrogen atoms in *o*-vinylbenzoic acid are substituted by alkyl groups, iodination results in the formation of both five- and six-membered iodolactones or their mixture:



Berti and coworkers[29-35] investigated the chlorination of 2-vinylbenzoic acids in carbon tetrachloride and in water and their bromination in chloroform and acetic acid. Their results are presented in Table 1, which shows that the accumulation of substituents at the terminal atom of the vinyl group leads to the formation of a six-membered ring, while substitution at the neighbouring atom promotes the formation of the furan ring.

Table 1. Mode of halogenocyclisation of 2-vinylbenzoic acids[35]

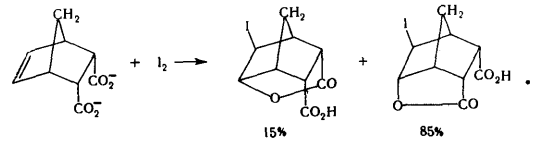
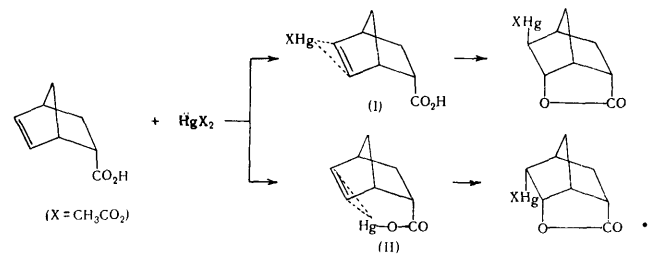
The effect of geometrical isomerism on the formation of five- and six-membered iodolactones was investigated in the iodocyclisation of cinnamylacetic acid and its $\beta\beta'$-disubstituted derivative[28]. *cis*-Cinnamyl acetic acid forms only a five-membered adduct, while the *trans*-isomer gives a mixture of five- and six-membered iodolactones; *cis*-$\beta\beta'$-dimethylcinnamylacetic acids gives rise to a mixture of both products and the *trans*-isomer only the six-membered iodolactone.

AC-reactions have the same fundamental mechanism (I) also in those cases where the double bond is in a ring, provided that the formation of a five- or six-membered ring is possible. Examples of such reactions are known for tetrahydrobenzoic[19,21-23,36] and tetrahydrophthalic acids; their bridged derivatives[37-51], and dihydronaphthoic[52] and cyclohexenylacetic acids[13,23,53]. Iodination and mercuration of these compounds in an aqueous medium usually results in the formation of five-membered rings even in those cases where the structure of the compounds allows the formation of a six-membered ring[24]. A mixture of five- and six-membered iodolactones is obtained in the iodination of *cis*-3,6-*endo*-methylene-Δ^4-tetrahydrophthalate salts[49]:

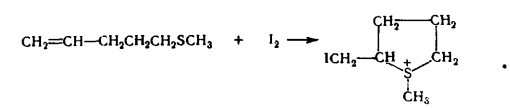


The formation of a mixture of stereoisomeric five-membered lactones in the mercuration of 2,5-*endo*-methylene-Δ^3-tetrahydrobenzoic acid with mercury acetate was noted[54]. The authors explained the formation of the five-membered *cis*-mercurilactone by the intermediate formation of the complex (II):



In contrast to the *endo*-series, unsaturated acids of the *exo*-series do not form lactones on iodination or mercuration, probably because the carboxylate ion is sterically hindered by the methylene group[21,22,43,49,54].

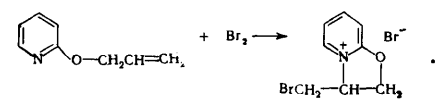
The general rules for AC reactions operate also in those cases where the ring closure does not take place via the carboxylate group but via another electron-donating group. $\gamma\delta$-Unsaturated alcohols, sulphides, and amines give rise on iodination or bromination to five-membered tetrahydrofuran, tetrahydrothiophen, and tetrahydropyrrole derivatives[15,55,56], for example:



o-Allylphenol and 2-allyl-4,6-dichlorophenol form iodomethylbenzotetrahydrofurans. α-(ω-Butenyl)pyridine is converted into 2-iodomethyl-1,5-pyridopyrrolidinium iodide[56].

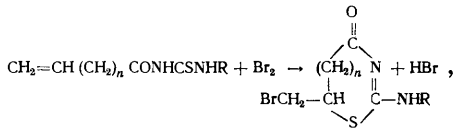
When the chain of the unsaturated molecule contains a heteroatom or a group Δ = O, S, or NH, the iodocyclisation reactions become relatively hindered and in many cases acyclic addition or substitution takes place[57-60]. The compounds $CH_2{=}CHCH_2{-}\Delta{-}CH_2CO_2^-$ and $CH_2{=}CHCH_2{-}\Delta{-}CH_2CH_2N(CH_3)_2$ give rise only to six-membered adducts[57]. It is interesting that a seven-membered ring is not formed on iodination even in those cases where the structure of the initial compound promotes its formation. Thus iodination of the allyloxy-β-propionate ion does not give a cyclic adduct, which could have been only seven-membered in this case[57]. Allyloxymethylamines are iodinated with formation of five-membered rings[61].

When α-allyloxy- and α-allyl-aminopyridines are brominated[56], the closure of the five-membered ring takes place at the nitrogen atom:



There exist examples of ring closure in addition reactions at chains containing several heteroatoms. Thioureas

acylated by residues of $\alpha\beta$-, $\beta\gamma$-, and $\gamma\delta$-unsaturated carboxylic acids react with bromine in carbon tetrachloride and chloroform via the mechanism[62,63]

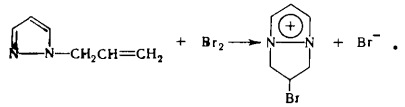


where R=H, alkyl, or aryl and n = 0, 1, or 2.

An interesting case of the formation of a seven-membered ring[63,64] (4-thiazepinone) with n = 2 has been described.

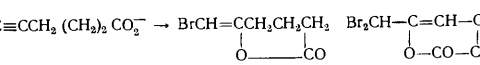
These bromocyclisation reactions are accompanied by the addition of bromine at the double bond, but in the formation of a five-membered thiazoline ring (n = 0) there are no dibromides in the reaction products or their amount is very small, while in the case of larger rings the yield of dibromide is appreciable.

The bromination of 1-allylpyrazole results in a derivative of 3a,6a-diazapentalene[65,66]:

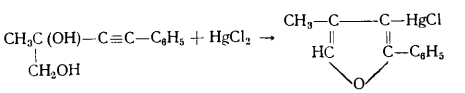


Not many AC reactions for compounds with a triple bond are known. The replacement of a double bond by a triple bond leads to the retardation of the reaction, but in all probability the general rules of AC reactions remain in force. As a result of addition, a compound with an electron-donating group at the double bond is formed in the first stage. This frequently leads to further reactions.

The iodination of propargylacetic and propargylmalonic acids stops at the stage involving the formation of an unsaturated, probably five-membered, lactone[15,67]. In the bromination of hex-5-ynoic acid[68] the reaction proceeds further and yields an unsaturated dibromide:



Primary-tertiary and secondary-tertiary butynediols are converted by mercury(II) chloride into chloromercurifurans[69-72]:



Amines and oxamines containing the propargyl group, $HC\equiv C-CH_2OCH_2NHR$, $HC\equiv C-CH_2OCH_2NR_2$, and $HC\equiv C-CH_2(CH_2)_2NR_2$, also cyclise to five-membered ring compounds on bromination and iodination[61].

III. EFFECT OF THE NATURE OF ELECTRON-DONATING GROUPS AND X–Z ELECTROPHILIC AGENTS IN ADDITION REACTIONS WITH CYCLISATION

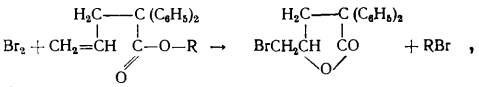
1. Electron-donating Groups

Ring closure in addition reactions takes place with participation of various electron-donating groups: OH, RO^-, NH_2, NHR, NR_2, –SR, CO_2^-, CO_2H, COOR, $\rangle C{=}O$, $CONR_2$, $CSNR_2$, etc. The capacity of these groups for ring closure depends on their nucleophilic properties. Weakly nucleophilic electron-donating groups, for example RSO_3^-, are incapable of ring closure on iodination[15,73]. However, under the influence of powerful electrophilic agents (bromine and chlorine), the same unsaturated sulphonate salts form sultones[74].

Unsaturated amines cyclise only in the form of the free bases with formation of ammonium salts[15,75].

Phenoxides react much more readily than the free phenols[15,76,77], but in the case of unsaturated alkoxides ring closure was not observed, probably owing to the low concentration of the alkoxides in aqueous solutions at low pH.[76,78,79] The free carboxy-group can participate in ring closure, but the conjugate carboxylate anions react much more readily. Therefore it sometimes happens that in aqueous solutions of unsaturated acids the anion and not the undissociated acid itself reacts with the electrophilic agent.

It is remarkable that, under the influence of powerful electrophilic agents, even the ester group can form a lactone with elimination of an alkyl halide[80-83]:



The iodination of the amides of unsaturated carboxylic acids in acidic and neutral aqueous solutions results in the formation of lactims, while in alkaline solutions the products are lactams[15,84-87]. When 2,2-disubstituted allylacetonitriles are brominated in chloroform, lactims are formed together with dibromides[85]. On bromination, allylacetamidomalonic ester yields 6-bromomethyl-4,4-diethoxycarbonyl-2-methyl-5,6-dihydro-1,3-oxazine dibromide[86].

The bromination of allylureas gives 5-bromomethyl-Δ^2-oxazolines together with dibromides[9,88-91]. In contrast, allylthioureas form on bromination and iodination only 5-bromomethyl-Δ^2-thiazolines[7,8,10,11,92-94].

Probably many other electron-donating groups can also participate in AC reactions (for example the epoxy-, N-oxide, oxime, etc. groups, which have not yet been investigated).

Williams et al.[95] recently published a paper in which the results of a study of the bromination and iodination of the alcohols $CH_2{=}CH(CH_2)_nOH$, where n = 1, 2, 3, or 4, are presented. They show a close analogy between the reactions of these alcohols and the halogenation of the acids $CH_2{=}CH(CH_2)_{n-1}CO_2H$. In particular, the maximum rate occurs with n = 3, which corresponds to the formation of a five-membered ring. Bromination results in a mixture of cyclic and non-cyclic addition products (50–60% of cyclic products with n = 3, 5–10% with n = 4, and 0% with n = 1 or 2). Iodination of the alcohols with n = 3 and 4 gives only the cyclic adducts. The quantitative characteristics of the involvement of electron-donating groups in ring closure will be presented in the discussion of the kinetic relations in AC reactions.

2. Electrophilic Agents

Among the known electrophilic agents, iodine, bromine, chlorine, iodine chloride, cyanogen iodide, hypochlorous acid, mercury salts, peracids, 2,4-dinitrosulphenyl chloride, and tellurium and selenium compounds have been investigated in AC reactions. Strong acids can also behave as electrophilic agents in AC reactions but, as already stated, such reactions are not discussed in this review.

Certain electrophilic agents, for example $SnCl_4$, ArN_2^+, etc., have not been tested in AC reactions.

The mode of addition depends on the differences between the electrophilicities of the reactants. Weak electrophilic agents (I_2, $HgCl_2$) often react wholly via the AC reaction mechanism. This applies particularly to those cases where the electrophilic agent (for example I_2 in aqueous KI solutions) is altogether incapable of adding to unsaturated molecules via the usual mechanism. Strong electrophilic agents show a greater tendency to form non-cyclic adducts, particularly in non-aqueous solvents.

According to the literature, in the bromination of many unsaturated acids in non-ionising solvents only the dibromides were isolated even in those cases where bromolactones could have been formed. Incidentally, it is possible that in some cases small amounts of cyclic adducts escaped the notice of investigators.

According to Berti's data, the bromination of *cis*- and *trans*-stilbene-2-carboxylic acids gives a mixture of dibromides and bromolactones. The mixture compositions are different for the two stereoisomers and depend on the nature of the solvent. In particular, the reaction of the *cis*-acid with bromine in carbon tetrachloride results in the almost exclusive formation of the dibromide, while in chloroform the product is mainly the bromolactone.

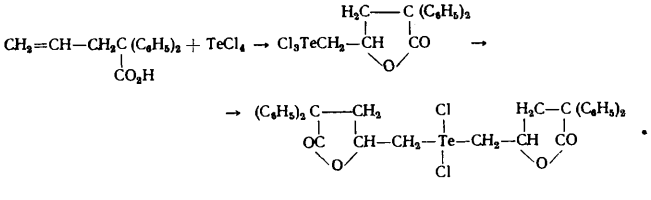
It is interesting that the chlorination of these acids in acetic acid as well as in chloroform and carbon tetrachloride leads to quantitative formation of the chlorolactones.

Data are available on the relative amounts of the cyclic and non-cyclic adducts in the chlorination and bromination products of certain unsaturated compounds in an aqueous medium[96]. Table 2 shows that, when salts of unsaturated acids are brominated and chlorinated, the yield of the halogenolactones is much lower than in iodination, since their iodination takes place with quantitative formation of iodolactones alone. In the reactions with chlorine the amount of lactones formed is much less than in the reactions with bromine (in contrast to Berti's observations in non-aqueous solvents).

Table 2 also shows that compounds with rigidly fixed reaction centres such as the anions of 3,6-*endo*-methylene-Δ^4-cyclohexene-1,2-dicarboxylic acids give higher yields of halogenolactones on chlorination and bromination than the anions of Δ^4-cyclohexene-1,2-dicarboxylic acids, the structure of which permits the inversion of the cyclohexene ring.

Electrophilic agents can participate in AC reactions in different forms. Thus it has been shown that mercury(II) chloride reacts both as $HgCl_2$ and $HgCl^+$, the chloromercury cation being 120 000 times more active than the neutral molecule[97,98]. Moreover, iodine never participates in AC reactions as the iodine cation (more precisely its complex with the substrate molecule), although this form of iodine is the most important active agent in aromatic substitution reactions[99].

Among complex electrophilic agents, 2,4-dinitrobenzenesulphenyl chloride, which readily adds to unsaturated molecules via the usual mechanism but can participate also in AC reactions, is of interest. Tellurium tetrachloride forms 1 : 2 cyclic adducts with $\alpha\alpha'$-diphenylallylacetic acid:



Unsaturated carboxylic acids also cyclise when acted upon by ring-substituted phenylselenium bromides and β-naphthyltellurium iodides[100,101].

In the reaction with peracids as electrophilic agents *cis*- and *trans*-stilbene-2-carboxylic acids are converted into mixtures of epimeric five- and six-membered hydroxylactones[32], for example:

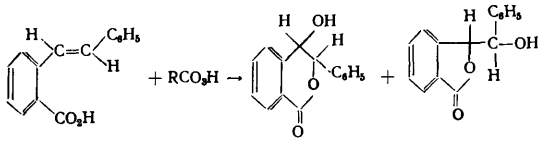


Table 2. Composition of the halogenation products of the sodium salts of unsaturated carboxylic acids in aqueous solutions at 25 °C (according to the data of Staninets et al.[96]).

Halogenating agent and unsaturated acid salt	Yield, %		
	halogeno-lactone	dihalide	halogeno-hydrin
Br, Br_2			
CH_2=CHCH$_2$CH$_2$CO$_2$Na	38	4	58
CH_2=CHCH$_2$CH$_2$CH$_2$CO$_2$Na	19	5	76
CH_2=CHCH$_2$OCH$_2$CO$_2$Na	7	8	85
trans-C_6H_5CH=CHCH=CHCO$_2$Na	0	8	92
trans- 	23	3	74
cis- 	64	3	33
cis-  (*endo*-)	86	7	7
Cl, Cl_2			
trans- 	5	4	91
cis- 	45	—	55
cis-  (*endo*-)	83	8	9

Under the influence of peracids, unsaturated polycyclic carboxylic acids and *o*-allylphenol also participate in AC reactions[102-106].

IV. KINETICS OF ADDITION REACTIONS WITH CYCLISATION

Among AC reactions, the kinetics of iodocyclisation have been investigated in greatest detail. This reaction is very convenient for kinetic studies because it occurs at a measurable and readily controlled rate, is not accompanied by side reactions, and its rate can be readily followed by measuring the decrease in the iodine titre.

The rate of AC reactions with bromine and chlorine are usually too high for measurements by the usual kinetic methods and, moreover, they are accompanied by addition and substitution side processes.

The qualitative kinetic characteristics of iodocyclisation were obtained comparatively long ago. In 1960 de Moura Campos published a series of studies on the rates of iodination of alkyl- and allyl-substituted allylacetic acids [83,107]. However, these were preliminary investigations.

The kinetics of the iodocyclisation of unsaturated compounds of different structures and containing electron-donating groups have been investigated very thoroughly by Shilov and coworkers [15,49,58-61,62,75-77,108-112]. These kinetic measurements were made largely in aqueous solutions.

It was established that all the iodocyclisation reactions investigated obey the simple equation for second-order processes:

$$-\frac{d[I]}{dt} = k[M][I_2] \ ,$$

where [M] is the concentration of the unsaturated compound in its active form, (I) is the analytical concentration of iodine, and $[I_2]$ is the concentration of molecular iodine not bound in the complex I_3^-.

Table 3. The rate constants $k_{20°}$, activation energies $\Delta E^{\neq}$, and the logarithms of the pre-exponential factor $\lg A$ for the iodolactonisation of acid anions with a single multiple bond [15].

Substrate	$k_{20°}$, litre mole^{-1} s^{-1}	$\Delta E^{\neq}$, kcal mole^{-1}	$\lg A$
(I) $CH_2{=}CHCO_2^-$	0	—	—
(II) $CH_3CH{=}CHCO_2^-$	0	—	—
(III) $CH_3{=}CHCH_2CO_2^-$	(0.01)	21	14
(IV) $CH_2{=}CH(CH_2)_2CO_2^-$	84	13.5	11.8
(V) $CH_2{=}CH(CH_2)_3CO_2^-$	10.9	13.2	10.9
(VI) $CH_2{=}CH(CH_2)_4CO_2^-$	0.17	13.2	9.1
(VII) $CH_2{=}CH(CH_2)_5CO_2^-$	0	—	—
(VIII) $CH_3CH{=}CHCH_2CH_2CO_2^-$	142	12.3	12.3
(IX) $C_6H_5CH{=}CHCH_2CH_2CO_2^-$	61	14.8	12.8
(X) o-$CH_2{=}CHC_6H_4CO_2^-$	3.1	16.4	13
(XI) o-$CH_3CH{=}CHC_6H_4CO_2^-$	5.3	16.3	13
(XII) $CH_2{=}CHCH_2CH(CO_2)_2^-$	169	13.5	12
(XIII) $CH{\equiv}C(CH_2)_2CO_2^-$	1.2	14.1	11
(XIV) $CH{\equiv}CCH_2CH(CO_2)_2^-$	3.6	13.9	10
(XV) $CHCl{=}CH(CH_2)_3CO_2^-$	0.025	17.2	11

The constant k depends on the structure, configuration, and conformation of the molecule cyclised, on the reactivity of the multiple bond in relation to electrophilic agents, and on the nucleophilic properties of the electron-donating group D.

Table 3 demonstrates the effect of structural factors in the iodocyclisation of unsaturated carboxylic acid anions‡ in aqueous potassium iodide solutions. It shows that the tendency towards iodocyclisation is shown almost exclusively by compounds with a structure which can give rise to five- and six-membered rings. The formation of the seven-membered iodolactone (VI) is already 70 times slower than that of the six-membered lactone (V) and the rate of formation of rings with more than seven members or less than five members is virtually zero.

The replacement of a hydrogen atom at the extreme carbon atom in the $CH_2{=}CH$-group by an alkyl group appreciably accelerates the iodination [compounds(IV)–(VIII)], while substitution in C_6H_5 has only a slight effect [compound (IX)]. When the benzene ring is incorporated in the chain undergoing closure, the reaction is greatly retarded [compounds (X) and (XI)]. A chlorine located at the double bond also greatly retards the reaction [compound (XV)].

Table 4. The rate constants $k_{20°}$, activation energies $\Delta E^{\neq}$, and the logarithms of the pre-exponential factor $\lg A$ for the iodolactonisation of the anions of alkenoic and alkadienoic acids [112].

Iodinated anion	$k_{20°}$, litre mole^{-1} s^{-1}	$\Delta E^{\neq}$, kcal mole^{-1}	$\lg A$
$CH_2{=}CHCH{=}CHCO_2^-$	0.034	18.5	15.3
$CH_2{=}CHCH_2CH_2CO_2^-$	84	13.5	12.0
$CH_3CH{=}CHCH{=}CHCO_2^-$ (*trans, trans*)	0.062	17.2	14.6
$CH_3CH{=}CHCH{=}CHCO_2^-$ (*trans, cis*)	6.6	14.0	11.1
$CH_3CH{=}CHCH_2CH_2CO_2^-$	142	12.3	12.3
$C_6H_5CH{=}CHCH{=}CHCO_2^-$	0.027	20	15.4
$C_6H_5CH{=}CHCH_2CH_2CO_2^-$	61	14.8	12.8
$CH_2{=}CHCH{=}CHCH_2CO_2^-$	0.95	16.2	12.1
$CH_2{=}CHCH_2CH_2CH_2CO_2^-$	12	13.6	11.1

The experimental data in Table 4 make it possible to estimate the effects of conjugated double bonds on reactivity. Comparison of the rate constants k for the iodocyclisation of acids with a single double bond in Table 3 with the rate constants for the reactions of compounds with analogous structures listed in Table 4 shows that the compounds containing conjugated double bonds are less active by approximately three powers of 10 than their non-conjugated analogues. This retardation is associated with the increase of activation energy. The compensation by the entropy factor is insufficient.

In a series of studies [19,109-111] the changes in reactivity with increase of the rigidity of the molecular structure were investigated. The mono- and di-anions of Δ^4-tetrahydrophthalic acids (I) and (V) and their bridged derivatives (II)–(VII) were iodinated under identical conditions (Table 5).

In almost all cases the reaction leads to the formation of a five-membered iodolactone. The dianion of unsubstituted tetrahydrophthalic acid is iodinated 50 times faster than the monoanion but more slowly than the allylacetate anion (Table 2). When the molecule contains an *endo*-ethylene group [compounds (II) and (VI)], the rate of iodination of the monoanion is 85 times higher than that of its analogue without an inner bond. If the molecule contains a methylene bridge [compounds (III) and (IV)], the rate of iodination increases very greatly: by 4 powers of 10 for the *trans*-isomer and even more for the *cis*-derivative.

We may note that the activation energies in iodolactonisation reactions of monoanions for compounds with a

‡ With the exception of α-alkyl-substituted allylacetate ions discussed in a separate section below.

methylene bridge are lower by 3 kcal mole^{-1} than for the monoanions of compounds without a bridge or with an *endo*-ethylene bridge. The activation energy falls to the same extent on passing from monoanions to dianions [compounds (I)–(V) and (II)–(VI) in Table 5].

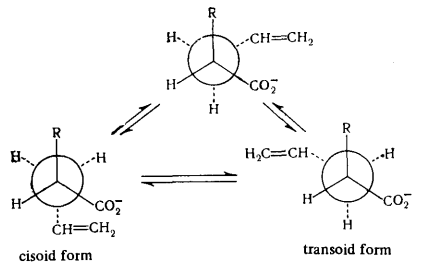
The increase of the rate of iodocyclisation is caused both by the decrease of $\Delta E^{\neq}$ and the increase of the entropy of activation. Consequently there is no "compensation effect" in these systems.

Table 5. Kinetic data for the iodolactonisation of Δ^4-tetrahydrophthalate anions and their bridged derivatives [110].

Compound iodinated	Reaction rate constant $k_{20°}$, litre mole^{-1} s^{-1}	Activation energy $\Delta E^{\neq}$, kcal mole^{-1}	Activation entropy $\Delta S^{\neq}$, e.u.
Acid monoanions			
(I) *cis*-Δ^4-Tetrahydrophthalate	0.4	13.8	24.5
(II) *cis*-3,6-*endo*-Ethylene-Δ^4-tetrahydrophthalate	34	13.7	15.8
(III) *trans*-3,6-*endo*-Methylene-Δ^4-tetrahydrophthalate	4340	10.6	7.6
(IV) *cis*-3,6-*endo*-Methylene-Δ^4-tetrahydrophthalate	15 200	10.9	4.2
Acid dianions			
(V) *cis*-Δ^4-Tetrahydrophthalate	21	10.6	18.4
(VI) *cis*-3,6-*endo*-Ethylene-Δ^4-tetrahydrophthalate	350	10.8	11.8
(VII) 3,6-*exo*-Methylene-Δ^4-tetrahydrophthalate	0	-	-

The *exo*-isomer (VII) is not iodinated at all, which can be readily accounted for by the steric hindrance at the carboxylate ion due to the bridge.

A relation between the rate of iodolactonisation and the proportions of the conformers of the compounds has been established for the anions of α-alkyl-ω-pentenoic acids. These acids exist in cisoid and transoid forms, between which an equilibrium is established, whose position depends on the structure of the compound:



cisoid form transoid form

The constants for the equilibrium between the conformers were calculated using an additive method [112]. The rates of iodolactonisation were measured in the usual way for a number of acids [111]. The results of the kinetic measurements and calculations are presented in Table 6.

Evidently the introduction of an alkyl group in the α-position of allylacetic acid increases the rate of iodination and to a greater extent the more branched is the group. This acceleration corresponds to the content of the *cisoid* conformer in the equilibrium mixture. If the iodination rate constant is referred to the content of the *cisoid* conformer, the calculated values of k_{cis} are found to be constant for all the acids investigated.

Evidently the anions of unsaturated carboxylic acids are iodolactonised only in the cisoid form.

The study of the kinetics of the iodocyclisation of compounds with a heteroatom Δ = O, S, or NH in the unsaturated chain showed that the replacement of a CH_2 group by O, S, or NH retards the reaction (Table 7). [57,59]

Table 6. Dependence of the rate constant for the iodolactonisation of α-R-allylacetate anions on the concentration of their cisoid conformers.

R	$k_{20°}$, litre mole^{-1} s^{-1}	Cisoid conformer, %	$10^{-3}k_{cis}$, litre mole^{-1} s^{-1}

i-C_3H_7	940	75	1.25
sec.-C_4H_9	980	80	1.28
tert.-C_4H_9	1340	88	1.37
		Mean	1.2

Shilov and Tsegel'nyuk [59] explained these changes in reactivity by the lowering of the mobility of the chain undergoing ring closure in the series O < S < NH < CH_2. The absolute values of k and $\Delta E^{\neq}$ naturally depend also on the electronic effects of the heteroatom.

Table 7. Rate constants and activation energies for the iodocyclisation of compounds with the structure [59]

$$CH_2{=}CHCH_2{-}\Delta{-}CH_2CO_2^-.$$

Δ	$k_{30°}$, litre mole^{-1} s^{-1}	$\Delta E^{\neq}$, kcal mole^{-1}	lg$A$	$\Delta S^{\neq}$
O	0.14	14.5	8.63	−3.28
S	0.45	15.8	11.1	−9.79
NH	6.98	17.1	14.3	+4.58
CH_2	22.4	13.1	10.0	−10.9

The most important characteristic of the electron-donating group in the kinetics of AC reactions is its nucleophilicity. This relation can be followed in a series of kinetic experiments on the iodination of unsaturated compounds the chain structure of which remains unchanged and only the component D is varied [15,61,75,77].

Table 8 presents the results of the measurements of the rate constants for iodocyclisation in a group of unsaturated compounds, which leads to the formation of five-membered heterocycles.

Table 9 presents data on the kinetics of the iodination of substituted 2-allylphenols via the mechanism

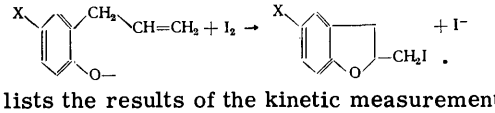

Table 10 lists the results of the kinetic measurements for the iodocyclisation of unsaturated compounds in which the electron-donating groups differ markedly not only in basicity but also in chemical structure. Tables 8–10 list

the pK_a values for the compounds undergoing iodocyclisation as the characteristics of their nucleophilic properties. Evidently the reactivity of the molecules increases with the pK_a.

While the weakly basic SO_3^- group in butene-ω-sulphonate does not participate in the iodocyclisation reaction, the rate constants for the iodination of the strongly basic ω-pentenylamines reach values of 10^5 litre $mole^{-1}$ s^{-1}. For substituted allylphenols, where the variation of basicity is not so great (Table 9), the correlation between the iodocyclisation rate constants and the pK_a is described by the Hammett equation.

Table 8. Rate constants for the iodination of the ω-butenyl derivative[15]

$CH_2=CHCH_2CH_2-R.$

R	$k_{20°}$, litre $mole^{-1}$ s^{-1}	$\Delta E^{\neq}$, kcal $mole^{-1}$	lgA	pK_a
SO_3^-	0	—	—	—
CH_2SCH_3	0.003	17.3	8.0	—
$CONH_2$	0.67	12.2	8.9	−0.4
CH_2OH	1.47	8.9	7.8	—
CH_2NH_2	$1.4\cdot10^5$	2.8	7.2	10.5
CH_2NHCH_3	$2.3\cdot10^5$	1.6	6.7	10.1
$CH_2N(CH_3)_2$	$1.8\cdot10^5$	1.9	7.2	10.3

At the same time comparison of the above tables shows that some of the compounds iodinated have the same or similar pK_a's but the rates of their cyclisation differ markedly. This is not surprising, since the rate of AC reactions does not depend on the basicity of the D component alone.

Other factors which determine the reactivity of the electron-donating component of unsaturated compounds in AC reactions are polarisation, steric, etc. factors which characterise its intrinsic nucleophilicity.

Table 9. Rate constants for the iodination of the ions of X-2-allylphenols[77].

X	$k_{20°}$, litre $mole^{-1}$ s^{-1}	$\Delta E^{\neq}$, kcal $mole^{-1}$	lgA	pK_a
4-Nitro	46	5.2	5.5	7.1
4-Phenylazo	80	5.0	5.5	7.4
4,6-Dichloro	170	3.2	4.6	8.5
4-Chloro	176	3.8	5.3	9.3
4-Bromo	180	4.0	5.5	9.4
4-Methyl	360	3.4	5.2	10.1
4-Methoxy	420	3.2	5.1	10.3

Tables 8 and 9 show that, for the same or similar reaction series, the observed variation of the iodocyclisation rate constant depend mainly on the activation energy, since the activation entropy and the corresponding frequency factors are fairly constant, particularly for allylphenols. For a given reaction series, the relation between the cyclisation rate constant and the nucleophilicity of the electron-donating component is expressed in the fact that the more nucleophilic is the electron-donating component of the unsaturated molecule, the higher is the rate constant and the lower the activation energy.

In the cyclisation of unsaturated compounds the electron-donating components of which differ greatly in chemical structure (Table 10), this relation is less distinct.

Analogous kinetic relations are observed also in the chloromercuration of 2-allylphenols and unsaturated alcohols[97,98]. Phenoxide anions are more reactive in these processes by three powers of 10 than the free phenols.

Table 10. Activation parameters and rate constants for AC reactions.

Compound iodinated	$k_{20°}$, litre $mole^{-1}$ s^{-1}	$\Delta E^{\neq}$, kcal $mole^{-1}$	$\Delta S^{\neq}$, e.u.	lgA	pK_a	Refs.
$CH_2=CH(CH_2)_2CO_2^-$	84	13.5	−5.58	11.2	4.68	15
	173	7.2	−23.7	7.8	8.03	75
	7770	1.7	−35.8	5.1	10.1	77

Interesting experimental data have been obtained, which make it possible to compare the rates of chloromercuration in AC reaction and non-cyclic addition reactions. It has been established that the rate constant k for chloromercuration at 25°C by $HgCl_2$ is 450 times higher for pent-1-en-5-ol than for its methyl ether[98].

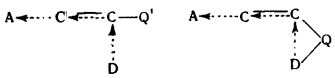
V. THEORETICAL DISCUSSION OF ADDITION REACTIONS WITH CYCLISATION

AC reactions are a variety of addition reactions of a general type involving, apart from the unsaturated molecule, electron-accepting and electron-donating agents, the transition state of which may be described by the scheme D → M → A.[113-115] A characteristic feature of AC reactions is that the nucleophilic component D is linked by a valence bond to the M molecule and therefore the reaction is bimolecular in relation to the addition of the electrophilic agent and intramolecular in relation to the nucleophilic agent§.

§ Previously it was postulated (see, for example, Refs. 6 and 13) that the formation of a ring in addition reactions takes place in two consecutive stages: the product of direct addition of the electrophilic agent to the multiple bond is formed initially and then ring closure takes place as a result of an exchange reaction between the added atom and the electron-donating end of the molecule.

Linstead and May[19] were the first to point out that the mechanism involving simultaneous addition and ring closure is more likely. It is not difficult to demonstrate that the hypothesis of a general two-stage exchange cyclisation mechanism is erroneous. In fact in many cases analogous intermolecular reactions involving addition to multiple bonds do not occur at all and, when direct addition products can be observed (for example, vicinal dibromo-substituted acids), they prove to be stable and their cyclisation is much slower than the corresponding AC reaction. In particular, certain characteristics of chloromercury-cyclisation suggest this hypothesis[69,97,98]. Such reactions evidently cannot be included in the category of AC reactions.

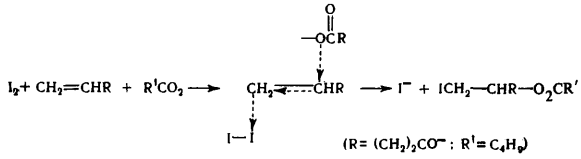
This difference between the transition states can be represented by the scheme



intermolecular reaction AC reaction

As a result of the intramolecular addition mechanism, AC reactions (in which five- or six-membered rings may be formed) sometimes take place much faster than the analogous trimolecular reactions[114-116]¶.

The addition reactions occurring under the influence of weak electrophilic agents, in particular iodine, are especially instructive in this respect. In many such cases trimolecular addition reactions do not occur at all. For example, as already noted, the allylacetate ion readily forms 5-iodo-4-valerolactone under the influence of iodine in aqueous potassium iodide solution. This reaction would correspond to a trimolecular mixed compound involving the anion of allylacetic or other carboxylic acid formed via the mechanism



$(R = (CH_2)_2CO^-;\ R' = C_4H_9)$

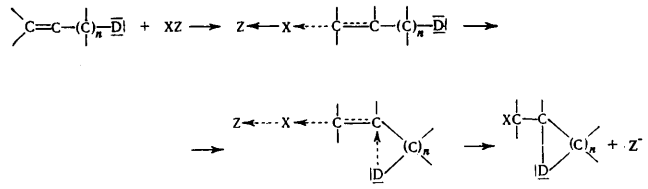
However, even at high concentration of the added anions, for example butyrate anions, this type of reaction does not occur and the rate of iodocyclisation does not change[67].

Competition between cyclic and non-cyclic addition takes place when the reactivity of the ring-closure group is reduced[57] or when more vigorous electrophilic agents are employed, as shown above for bromination and chlorination.

Another characteristic feature of AC reactions is that they are much more sensitive to the nucleophilic properties of the electron-donating component than non-cyclic addition reactions[114,115]. We have seen that the rate constant for iodocyclisation can change by many powers of 10 as the nucleophilic properties of the D component are altered. In reactions involving mixed trimolecular additions, this type of relation is much weaker or is altogether absent. For example, there are data for the rates of chlorination of olefins in the presence of various electron-donating agents in acetic acid[119,120]. The increase of the rate of these reactions is proportional to the concentration of donors in the mixture but a definite relation between the rate constant and the nucleophilicity of the anion is not found.

When allyl alcohol is iodinated, the effect of the nucleophilic properties of the electron-donating agent is appreciable but is nevertheless inferior to that observed in iodocyclisation reactions[121,122].

The above characteristics of AC reactions indicate the particular importance of nucleophilic attack in such processes, in contrast to noncyclic addition reactions. In AC reactions the electron-donating group evidently reacts with the primary weakly polarised complex formed by the electrophilic agent molecule with the multiple bond. The reaction occurs as a synchronous process in which the complex bond is converted into a valence bond and ring closure takes place:



The synchronous effect of the electron-accepting and electron-donating groups on the multiple bond in the molecules in AC reactions can appreciably lower their activation energy. AC reactions proceed with negative activation entropies, the absolute values of which fall from several tens to several entropy units for unsaturated compounds with rigidly fixed reaction centres[49].

The presence in one molecule of two reaction centres (the C=C bond and the electron-donating group) capable of interacting synchronously with the electrophilic agent is also favourable from the standpoint of the entropy change, since such reaction requires a relatively lower structural rearrangement in the reaction system than, for example, in intermolecular acyclic addition.

Acyclic trimolecular addition of iodine occurs only in the presence of powerful nucleophilic agents in view of the weak polarisation by iodine of the multiple bond in the π complex. Weak nucleophilic agents cannot interact effectively with the multiple bond of the weakly polarised π complex of iodine.

If, however, a powerful electrophilic agent, for example bromine, is involved in the intermolecular reaction, a highly polarised complex (probably an ion pair or a σ complex) is formed and is so active that the nucleophilic cooperation of the electron-donating component loses its importance to a considerable degree[96]. AC reactions can also proceed via a σ-complex but only in competition with non-cyclic addition. Although non-cyclic bromination reactions are somewhat accelerated by nucleophilic agents, the nucleophilic properties of strong acid anions are sufficient to complete the addition.

The role of nucleophilic cooperation in AC reactions increases when there is a possibility of the formation of five- and six-membered rings. In the case of small rings (three- and four-membered) there is no nucleophilic cooperation or it is hindered by virtue of certain steric effects. For larger rings, there is a decrease of the probability of a favourable disposition of the multiple bond and the electron-donating end of the molecule as a result of the increase of the number of conformations which the reacting molecule may assume.

These factors operate also in many other chemical reactions, promoting the formation of five- and six-membered rings. In this respect AC reactions constitute a special case obeying the general principle.

As a favourable disposition of the reaction centres—the double bond and the electron-donating group D—is more firmly fixed in the unsaturated molecule M, the AC reaction is facilitated to a greater extent. Therefore in very rigid systems, for example the anions of *endo*-methylenetetrahydrophthalic acids, high rates of ring closure are observed. Conversely, the more mobile is the chain of the reacting molecule, the slower is the AC reaction[49,57,110]. These relations are reflected to some degree in the parameters of the Arrhenius equation when similar series of compounds are considered.

¶ This ease of formation of five- and six-membered rings serves as a confirmation of the old idea that cyclic transition complexes play a major role in heterolytic reactions[117,118].

Thus we find that the differences between the rates of iodination in the series of acid anions with the structure $CH_2=CH(CH_2)_nCO_2^-$ are related to the changes in activation entropy, while the values of $E^{\neq}$ are fairly close (Table 3). Conversely the dependence of the rate of reaction on the nucleophilic properties of D is related to the activation energy and only to a lesser extent to the activation entropy. The acceleration of AC reactions for rigid *endo*-methylene and *endo*-ethylene systems depends both on the lowering of $E^{\neq}$ and the increase of entropy (Table 5). Examination of a large number of the thermodynamic parameters of activation of AC reactions reveals a superposition of various electronic and steric effects, which hinder the isolation of a particular factor in a pure form.

In particular, one can show that the presence of a methylene bridge, which makes the molecule very rigid, is associated with a considerable strain of the double bond, which is estimated as 6 kcal mole^{-1} relative to the unstrained double bond in the cyclohexene ring or the double bond in the same ring with an internal *endo*-ethylene bridge[123]. Thus in AC reactions of molecules with methylene bridges there is, in addition to the steric effect, also the electronic effect associated with the double bond strain. We may note that the products of AC reactions are thermally and chemically more stable than the analogous non-cyclic adducts.

The importance of the formation of five-, six-, and seven-membered active complexes in organic reactions was discussed by Syrkin 10 years ago[124]. He put forward the idea that the electronic perturbations in these processes entail a lowering of the activation energy owing to the formation of more stable quasi-aromatic systems. The idea of the aromaticity of the cyclic complex apparently was not developed further and its applications have been by no means always correct. However, the general assertion of "a kind of parallelism between thermodynamics and kinetics" in chemical reactions is probably valid.

It appears that in AC reactions we have a kind of combination of steric and energetic conditions whereby the electron-donating group is maintained in contact with the polarised atom of the multiple bond. The active electron-donating atom remains at the multiple bond for a longer period than in trimolecular reactions and this corresponds to a lowering of the chemical potential necessary for the formation of stable reaction products.

Thermostable Polymers from Dianhydrides of Aromatic Tetracarboxylic Acids and Tetra-amines

A.A.Berlin, B.I.Liogon'kii, and G.M.Shamraev

The preparation, properties, and structure of polymers based on dianhydrides of aromatic tetracarboxylic acids and tetra-amines are surveyed. Compounds of this type possess excellent thermal stability, resistance to radiation and chemicals, catalytic activity, and semiconductor properties. The fields of practical application of the polymers are examined. A list of 77 references is included.

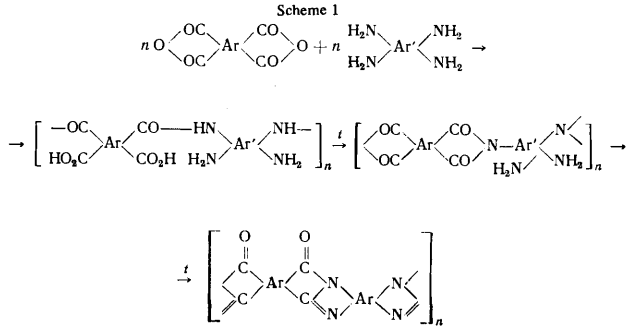
I. INTRODUCTION

At the present time much attention is paid to the synthesis and investigation of thermostable polymers [1]. This has arisen from the demands made by rapid developments in technology—especially such advanced fields as aircraft and spacecraft construction, nuclear power, and electrical technology—for materials capable of operating under severe conditions of high-temperature gas flows and radiation. During recent years progress has been made in producing a series of polymers having a conjugated system comprising various carbocyclic and heterocyclic rings in a macromolecular chain of ladder and block–ladder structure.

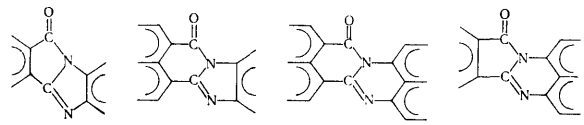
Considerable interest attaches in this series to macromolecular products of the reaction of dianhydrides of aromatic tetracarboxylic acids and tetra-amines (Scheme 1):

Scheme 1



They are polymeric analogues of the highly stable aroylenebenzimidazole dyes [2].

The repeating unit in the macromolecular chains includes a system of fused aromatic carbocyclic and heterocyclic rings



Depending on the type of heterocycles formed in the process the polymers have been termed polyimidazopyrrolones (pyrrones), polyaroylenebisbenzimidazoles or polyaroylenebenzimidazoles, polyperimidinetetrayls, polybisbenzimidazophenanthrolines, etc. In principle none of these names completely represents the structure of the polymers, especially when intermediate groups and complicated fused carbocyclic and heterocyclic rings are present. The Reviewers therefore consider it advisable to use the trivial, but already quite widely employed name "pyrrones" with an indication of the initial components, and only in isolated cases to retain the names of the polymers given in the original papers. The first work on the synthesis of polymers of this class was published in 1965–1966. [3-8] At the present time the preparation and properties of pyrrones are being actively investigated, and these compounds may be expected to find wide application in the immediate future.

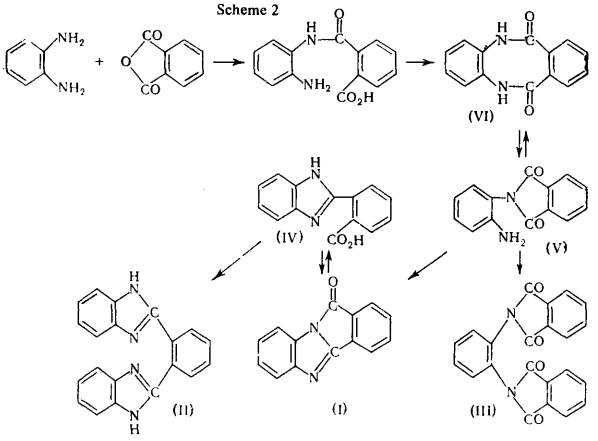
II. REACTION BETWEEN AROMATIC ANHYDRIDES AND *o*-DIAMINES

In the reaction between aromatic dianhydrides and tetra-amines, the formation of the final polymers is preceded by that of several intermediate structures. In

order to elucidate the mechanism of polycondensation, therefore, it is advisable to examine papers on the interaction between aromatic *ortho*- or *peri*-diamines and anhydrides.

Possible reactions in the condensation of phthalic anhydride with *o*-phenylenediamine can be represented by Scheme 2:

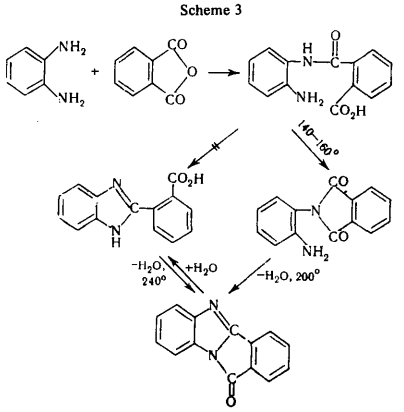
Scheme 2



The reaction products have been described in several papers[2,3,8-10]: depending on the conditions 1,2-benzoylenebenzimidazole (I), *o*-phenylenedibenzimidazole (II), *NN'*-diphthaloyl-*o*-phenylenediamine (III), *o*-benzimidazol-2'-ylbenzoic acid (IV), and *N*-*o*'-aminophenylphthalimide (V) have been isolated. Stetter[11] obtained a substance containing an eight-membered ring (VI) by reaction between phthaloyl chloride and *o*-phenylenediamine. Porai-Koshits and Antoshul'skaya[12] obtained the compounds (II)–(V) by fusing the components in various proportions, and established that compound (III) is formed with the greatest difficulty, whereas (II) and (IV), which contain imidazole rings, are formed more readily. Arient and Marhan found[13] that small quantities of (V) and (VII) are formed initially in methanol at moderate temperatures. At the boiling point only (V) is present in the mixture initially, and the imidazole derivative (IV) is formed. On further heating the composition of the mixture remains almost unchanged: the product contains the two compounds in the approximate proportions 1 : 1.

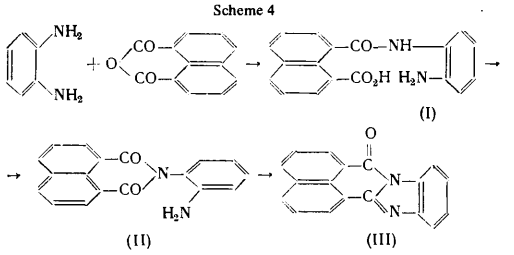
Dawans and Marvel[4] used nuclear magnetic resonance to investigate the products obtained by conducting the reaction in dimethyl sulphoxide: the n.m.r. spectra indicated the presence of a mixture of the final products. It was assumed[4] that competitive formation of the acid (IV) and the amine (V) takes place, one or other product predominating according to the reaction conditions. Colson et al. established[8] that only the amino-imide (V) is formed when *o*-phenylenediamine is heated with phthalic anhydride at 140–160°C for 30 min. Heating this product to 100°C converted it into benzoylbenzimidazole. The latter cannot be formed from the acid (IV) below 240 to 250°C, which is additional evidence for the scheme of cyclisation given by Colson and his coworkers (Scheme 3).

Scheme 3



These results are consistent with those given by Arient[2] showing that *o*-benzimidazolylbenzoic acid is formed only by hydrolysis of 1,2-benzoylenebenzimidazole. If the process takes place in anhydrous medium (in acetic anhydride or in the melt), the reaction halts at the first stage.

Scheme 4



Naphthalic acid reacts with *o*-phenylenediamine in various solvents at temperatures up to 60°C with gradual formation of the amide (I) and from it *N*-*o*-aminophenylnaphthalimide (II). In all cases the final reaction products are the imide (II) and a small quantity of 1,2-naphthoylenebenzimidazole (III).[14] The compound (III) was obtained at higher temperatures. The reaction goes very easily and in quantitative yield[15-17]. 1,2-Naphthoylenebenzimidazole is more stable than 1,2-benzoylenebenzimidazole on prolonged boiling in acid and in alkaline medium. As a consequence, reaction between *o*-phenylenediamine and naphthalic acid ceases at the stage of formation of 1,2-naphthoylenebenzimidazole. On the basis of the above results Scheme 4 has been suggested as the mechanism of the reaction.

Thus it follows from the above results that condensation of aromatic dianhydrides with tetra-amines in anhydrous medium takes place in three successive stages—formation of an amide–amino-acid, cyclisation of the latter to an amino-imide†, and finally conversion of this product into an aroylenebenzimidazole.

†It has been shown recently[18] that the amino-amide is not formed in the reaction of 1,8-naphthylenediamine with phthalic anhydride.

III. SYNTHESIS OF THE POLYMERS

Pyrrones were synthesised by Bell and Pezdirtz [3], Dawans and Marvel [4], the present Reviewers [5], and several other investigators [6-8] almost simultaneously and independently of each other. They used dianhydrides of various *ortho*- and *peri*-tetracarboxylic acids and various tetra-amines (Table 1). In isolated cases the dianhydrides were replaced by the more reactive symmetrical dimethyl dichlorocarbonyl-dicarboxylates, and the stable tetrahydrochlorides have been used instead of readily oxidised tetra-amines.

Table 1. Initial tetra-amines and dianhydrides for the synthesis of pyrrones.

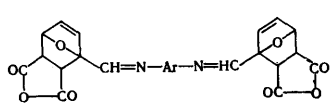
Polymers have been synthesised from dianhydrides of alicyclic tetracarboxylic acids—those of bicyclo[4,2,2]-decane-2,3,7,9-tetracarboxylic acid and its 9-methyl derivative, butane-1,2,3,4-tetracarboxylic acid, and cyclopentane-1,2,3,4-tetracarboxylic acid [33]—and also from hitherto unreported dianhydrides having the structure [26,37,46]



and several others [34].

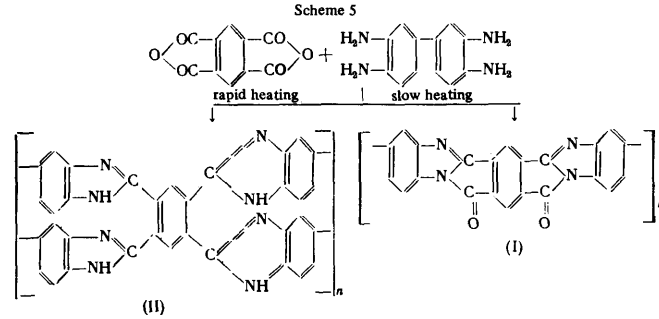
Tetra-amines with spiran structures have also been used for the synthesis [42,43].

Pyrrones have been obtained by conducting the polycondensation in the melt, in the solid phase, and in solution. Two-stage and one-stage methods of synthesis in solution have become most widely used.

1. Polycondensation in the Melt and in the Solid Phase

Polymers have been synthesised from molten pyromellitic dianhydride and various tetra-amines [4]. The mixture of dianhydride and tetra-amine was heated in nitrogen, the temperature being raised gradually to 220°C, and then in a high vacuum at 300–330°C for a few hours. The resulting polymers had predominantly the linear structure (I) (Scheme 5). They were soluble in formic and concentrated sulphuric acids, but in most cases they were insoluble in organic solvents. Their intrinsic viscosity was 0.2–0.5 dl g^{-1}. A rapid rise in temperature during synthesis yields predominantly polymers with network structure (II).

Scheme 5



(II) (I)

Polymers of high molecular weight are formed when the initial reactants are present in equimolecular proportions. Excess of the anhydride increases the yield of polymer (I), but its molecular weight is lower. In most cases the elementary composition of the polymers was consistent with the suggested structure. In order to promote intramolecular cyclisation Dawans and Marvel [4] attempted to dehydrate non-cyclised polymers at low temperatures in the presence of sulphuric acid or acetic anhydride. However, heating with sulphuric acid produced partial sulphonation of the polymer; and in the presence of acetic anhydride (pure or diluted in pyridine) these workers observed acetylation instead of dehydration.

Polymers have been obtained by polycondensation in the solid phase of naphthalene-1,4,5,8-tetracarboxylic dianhydride and biphenyl-3,3′,4,4′-tetra-amine. A mixture of the starting materials was heated under slight applied pressure of nitrogen at 285–295°C for 4 h. The reaction products were cooled in an atmosphere of nitrogen, and dissolved in concentrated sulphuric acid. After supercooling, the logarithmic viscosity of the resulting polymer was 0.22 dl g^{-1}.

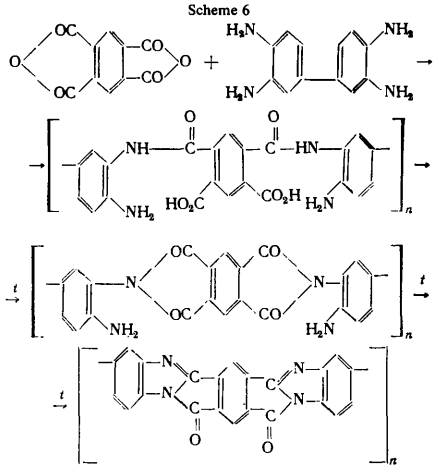
Morgan and Scott [47] have recently proposed a method for preparing polymers of the present type directly at the stage of fabrication into articles. An equimolecular mixture of the dianhydride (of pyromellitic or naphthalene-1,4,5,8-tetracarboxylic acid) and the tetra-amine (biphenyl-3,3′,4,4′-tetra-amine) under high pressure (280 atm) was heated slowly to 450°C in a porous reaction chamber (porous graphite lining). Gaseous and liquid products were driven off under pressure and at a high temperature. The resulting polymers possessed superior mechanical properties and high thermal stability.

2. Polycondensation in Solution

Polycondensation can be conducted in solution in one or two stages. A soluble macromolecular polyamide-amino-acid (PAAA) is obtained in the first stage of the two-stage synthesis. The solvents which have been used are pyridine, dimethyl sulphoxide (DMSO), *NN*-dimethylacetamide (DMAA), *NN*-dimethylformamide (DMFA), 1-methyl-2-oxopyrrolidine [MOP], tetramethylurea, and hexamethylphosphoramide [3-5,31,36,37]. In the second stage the polyamide–amino-acid undergoes polycyclodehydration on heating, with formation of a pyrrone. In the single-stage method the initial reactants are heated to

180–230°C in such solvents as polyphosphoric acid (PPA) or 2,5,8-trioxanonane (diglyme) to yield directly the final polymers.

Scheme 6



From an investigation of the interaction of model compounds Colson et al.[8] suggested the above sequence of reactions (Scheme 6) in the polycondensation of pyromellitic dianhydride with a tetra-amine.

(*a*) Low-temperature polycondensation—synthesis and properties of polyamide–amino-acids

The first stage in the synthesis of pyrrones—the formation of polyamide–amino-acids—and to a less extent the stage in which polyamino-imides are formed are reversible, so that the molecular weight of the polymers depends on many factors. Low-temperature polycondensation is usually conducted in an aprotic solvent. The optimum reaction temperature depends on the reactivity of the dianhydride used. Acid dianhydrides lie in the sequence—pyromellitic > naphthalene-1,4,5,8-tetracarboxylic > perylene-3,4,9,10-tetracarboxylic— according to their activity in forming polyamide–amino-acids[25,31,36,37]. Such passivation of the dianhydrides in this sequence is due to increasing compensation of the positive charges on the carbon atoms of the anhydride ring by the increasing electron-donating power of the aromatic portion. Polyamide–amino-acids with the highest molecular weights have been obtained from pyromellitic dianhydride at temperatures between −30° and +20°C [27–29,39] and from the naphthalenetetracarboxylic dianhydride at 65–80°C.[24,31,35–37]. The perylenetetracarboxylic dianhydride did not give appreciable yields even when the reactants were heated to 150–160°C. Only on prolonged heating at 170–200°C were partly cyclised polymers obtained[25,31], having composition similar to polyamino-imides (Table 2).

The Reviewers have recently been able to lower considerably the temperature of the first stage by using lithium salts. On investigating the synthesis of polyamide–amino-acids from naphthalenetetracarboxylic dianhydride and the tetra-amine of diphenyl ether they

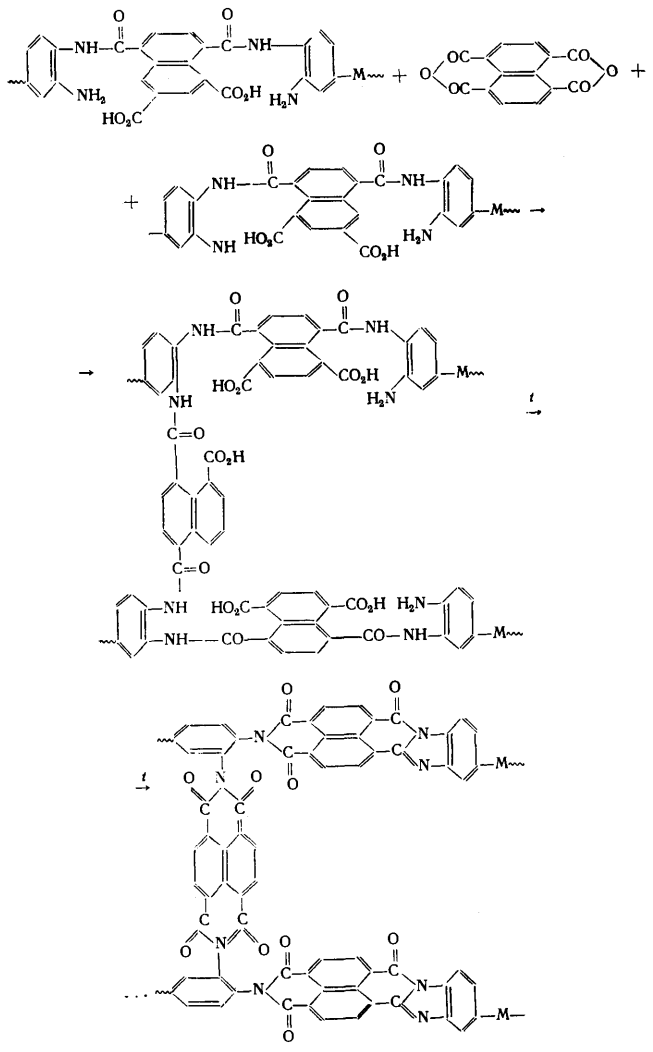
[a] Intrinsic viscosity at 25°C in solvent used for synthesis. [b] Specific viscosity of 0.5% solution in formic acid at 20°C. [c] Intrinsic viscosity in DMSO at 30°C. [d] Specific viscosity of 1% solution in DMFA at 25°C.

established[31,36,37] that up to 50°C the viscosity of the reaction solution increases very slowly and does not exceed 0.2 dl g^{-1}, over the range 65–80°C the increase accelerates considerably, and when the temperature is raised to 100°C individual amino-imide fragments are formed as a result of cyclisation in the chain of the polyamide–amino-acids. This sequence and the rate of addition of the reactants have a substantial effect on the rate of increase in the molecular weight of the polyamide–amino-acids.

Scheme 7



The same factors govern the possibility and time of gel formation. With slow addition of a dianhydride to a solution of a tetra-amine the rate of increase in the molecular weight of the polyamide–amino-acids is small, since transamination plays an important role in this case. Gel formation is observed in the later stages of polycondensation[36]. The time to gel formation decreases with increase in the temperature, the rate of increase in molecular weight of the polyamide–amino-acids, and also the local concentration of dianhydride in the solution. Gels are partly soluble in aprotic solvents and to a considerable extent in concentrated sulphuric acid. On prolonged standing they pass into a product which swells but is insoluble in sulphuric acid. The gels differ little in composition from soluble polyamide–amino-acids, and like the latter have an amorphous structure.

High-temperature cyclisation of a gel, in contrast to the soluble polyamide–amino-acids, yields polymers which are insoluble in sulphuric acid[36]. The main reaction in which polyamide–amino-acids are formed can evidently be accompanied by a secondary reaction between the dianhydride and amino-groups in the chain of the resulting polyamide–amino-acid. Although the basicity and hence the reactivity of these groups is low, the probability of their interaction with the dianhydride increases in the later stages of polycondensation, when little free tetra-amine and few reactive terminal amino-groups are present (Scheme 7).

The intensity of transamination and the probability of secondary reactions leading to gel formation depend significantly on the basicity of the tetra-amine and the reactivity of the dianhydride. Thus addition of pyromellitic dianhydride to a solution of a tetra-amine leads in all cases to the formation of a large quantity of gel. When the solutions are mixed in the opposite sequence, the whole of the polymer is instantly precipitated as a gel. When naphthalene-1,4,5,8-tetracarboxylic dianhydride and various tetra-amines are added together, gel formation is observed only after 2–6 h.[31,36]

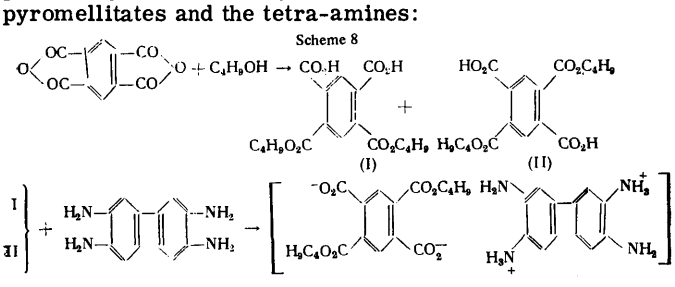
Tetra-amines of low basicity, e.g. bis-3,4-diaminophenyl sulphone, play an active part in transamination. However, their use diminishes the difference in basicity between terminal amino-groups and those in the chain of the polyamide–amino-acids, which favours intermolecular cross-linking of the chains. By using inorganic salts the Reviewers have been able also to vary the optimum conditions for the synthesis of polyamide–amino-acids of high molecular weight and eliminate the possibility of gel formation.

Korshak and his coworkers[39] also observed fairly rapid gel formation at room temperature in the polycondensation of pyromellitic dianhydride with diphenylmethanetetra-amine. A linear product could be obtained by lowering the temperature of the synthesis to between −20° and −30°C. Polycondensation at a high temperature leads to partial imidisation. The temperature at which this latter process begins in an aprotic solvent is determined by the nature of the dianhydride and of the tetra-amine.

Imidisation is accompanied by the separation of a certain amount of water, in whose presence of dianhydride is converted into the less reactive tetracarboxylic acid. A slight (1–2%) excess of the dianhydride is necessary to restore equivalence. Further increase in the excess (above 2%) of pyromellitic dianhydride in the reaction with tetra-amines leads to increased viscosity of the polyamide–amino-acids and rapid gel formation[19]. The synthesis of polyamide–amino-acids from naphthalene-1,4,5,8-tetracarboxylic dianhydride and tetra-amines is characterised by a diminution in viscosity when the excess of dianhydride exceeds 2%.[36] A fall in viscosity is observed also when excess of the tetra-amine is used (Scheme 8).

Bell[48] achieved strict equimolecularity of the components by first obtaining the salts from *m*- or *p*-dialkyl pyromellitates and the tetra-amines:

Scheme 8



Heating these salts in dimethylacetamide gave polymers having predominantly the structure of polyamide–amino-acids. Heating the dry salt in a vacuum or in an inert atmosphere yielded polybenzimidazopyrrolones.

The best solvents for the reaction are dimethylacetamide, dimethyl sulphoxide, and 1-methyl-2-oxopyrrolidine [31,36,37]. The reduced viscosity of polyamide–amino-acids depends on the concentration of the reactants. The presence of moisture in the solvent lowers the viscosity of the resulting precondensates.

Easily oxidisable tetra-amines, e.g. benzene-1,2,4,5-tetra-amine, have been replaced by their stable tetrahydrochlorides for polycondensation with dianhydrides [3,19]. A solution of pyromellitic dianhydride was added over 2–20 h to a suspension of the tetrahydrochloride in the presence of an acceptor for hydrogen chloride. The resulting polymers were identical in structure and properties with those obtained by other methods. Bell and Jewell [19] replaced the dianhydride, which reacts very slowly with tetra-amine tetrahydrochlorides, by dimethyl 4,6-dichlorocarbonylisophthalate. In this case tertiary amines are ineffective as acceptors of hydrogen chloride, while use of the free amine leads to precipitation of the polymer.

Polyamide–amino-acids are coloured (pale yellow to brown) powders soluble in aprotic solvents. Keeping dilute (1–2%) polymer solutions at 20°C decreases the viscosity of the polyamide–amino-acids. A more substantial fall in viscosity occurs in a moist solvent. Gel formation was observed on the prolonged storage of 10% solutions of polyamide–amino-acids (from naphthalene-1,4,5,8-tetracarboxylic dianhydride and 4,4′-oxydiphenylene-1,1′,2,2′-tetra-amine). [36]

Available data on the molecular-weight characteristics of polyamide–amino-acids usually consist merely of an indication of the intrinsic or the reduced viscosity. Osmometric measurements on polymers obtained from pyromellitic dianhydride and certain tetra-amines gave molecular weights of 7000–20 000, while the intrinsic viscosity was 0.4–1.5 dl g^{-1} (in dimethylformamide at 25°C) [19,30].

Most polyamide–amino-acids form strong transparent films when their solutions are evaporated. Polymers having intrinsic viscosity $\geqslant 0.4$ dl g^{-1} are suitable for the preparation of films. The strength of films dried at 125°C (obtained from pyromellitic dianhydride and tetra-amines) is 700–1050 kgf cm^{-2}, their relative elongation 25–35%, and the modulus of elasticity 14 000–28 000 kg cm^{-2}. [29,30] The tensile strength of the polyamide–amino-acid films based on naphthalene-1,4,5,8-tetracarboxylic dianhydride and tetra-amines was 850–950 kgf cm^{-2}. [31,36] These films usually contained 9–12% of solvent.

(*b*) Transformation of polyamide–amino-acids

The conversion of polyamide–amino-acids into pyrrones represents the second stage of polycondensation, and consists in intramolecular polydehydration accompanied by formation of a polyaminoimide and then the final polymer. Polycyclisation is accomplished by heat-treating the polyamide–amino-acid films or powders in a vacuum or in an inert atmosphere, and also by heating their solutions in polyphosphoric acid. Heating involved raising the temperature either smoothly or in steps to 200–400°C and maintaining the polymers at these temperatures.

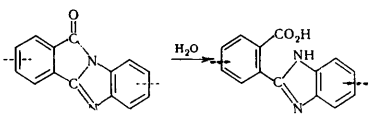
Thermogravimetric analysis proved to be unsuitable for the kinetic study of the polydehydration of films [3,35], since the solvent forms with the polyamide–amino-acid a complex which decomposes at temperatures corresponding to the start of cyclisation of the acid. The thermogravimetric method has been used to investigate the kinetics of the cyclodehydration of various polyamide–amino-acid powders (formed by biphenyl-3,3′,4,4′-tetracarboxylic dianhydride with biphenyl-3,3′,4,4′-tetra-amine, 4,4′-oxydiphenylene-1,1′,2,2′-tetra-amine, and diphenylmethane-3,3′,4,4′-tetra-amine respectively; and by biphenyl-3,3′,4,4′-tetra-amine with the dianhydrides of pyromellitic and naphthalene-1,4,5,8-tetracarboxylic acids). [32,33] Cyclodehydration is found to be of first order [32] and to occur in two stages [33].

Cyclisation has been studied by infrared spectroscopy [3,8,24,31,41,44,50,51]. Polyamide–amino-acids obtained from pyromellitic dianhydride and tetra-amines show characteristic absorption bands due to secondary amides in the region of 1660, 1650, 1540, 1505, 1305, and 1280 cm^{-1}, bands in the region of 1720 and 1605 cm^{-1} due to the presence of carboxy-groups, and bands in the range 3200–3400 cm^{-1} due to amino- and imino-groups. On cyclisation of these acids absorption appears at 1710 and 1720 cm^{-1}, which is characteristic of imide rings, absorption at 1310 cm^{-1} due to the presence of a tertiary nitrogen atom, and a band at 1470 cm^{-1} characteristic of C=N stretching vibrations.

Similar changes in the infrared spectra on passing from polyamide–amino-acids to the final polymers were on the whole observed with naphthalenetetracarboxylic and several other dianhydrides [24,31,50,51]. The most characteristic aspect of the transition to the final polymers is the preservation of only one intense band, usually in the range 1695–1720 cm^{-1}, and the absence of the other bands between 1680 and 1800 cm^{-1} which are characteristic of the unfinished polymers. This is consistent with the infrared spectra of corresponding model compounds.

The retention of other bands (at 1775, 1760 cm^{-1}, etc.) on the cyclisation of polyamide–amino-acids based on *oo′*-tetracarboxylic dianhydrides and *oo′*-tetra-amines [41] probably indicates that they are difficult to cyclise in comparison with those based on the corresponding *peri*-compounds.

Pravednikov et al. showed [44] that heating at 150–160°C polyamide–amino-acid films obtained from pyromellitic dianhydride and tetra-amines yields mainly polymers of amino-imide structure. At these temperatures, however, the rate of formation of imide rings is low, and the degree of conversion rapidly reaches a limiting value. Raising the temperature to 200°C did not effect complete cyclisation of the polyamide–amino-acids. This is due to entropy factors (increasing rigidity of the polymer chains) [8,35,52] and also to the possibility that carboxybenzimidazole repeating units may be formed from units in the final structure as a result of hydrolysis by water liberated during cyclisation [8]:

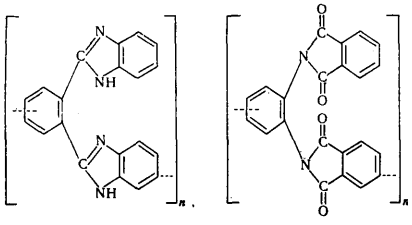


A high degree of conversion of polyamide–amino-acids into the final polymers was achieved at 250–400°C. The

infrared spectra and the elementary composition of polyamide–amino-acid films and powders obtained from naphthalenetetracarboxylic dianhydride and tetra-amines showed, after vacuum heat-treatment, that cyclisation was almost complete at 300–350°C.[31,36,40]

Cross-linking may occur in this temperature range, with the formation of a certain amount of insoluble polymers[31,36]. The intensity of intermolecular cross-linking depends on the mobility of the molecular chains, and is minimal with polymers containing no $-CH_2-$ or $-O-$ hinge groups. A certain quantity (< 5%)of units probably remain uncyclised at these temperatures, and they do not appear in the infrared spectra.

Korshak et al.[34,53] obtained polyimides containing pendant arimide groups attached to the main chain by the interaction of polyamide–amino-acids in solution with anhydrides of aromatic dicarboxylic acids and subsequent heat-treatment. Reaction of polyamide–amino-acids with *o*-phenylenediamine in polyphosphoric acid gave polybenzimidazoles containing benzimide pendants on the main chain of the polymer



(*c*) High-temperature polycondensation in solution

High-temperature polycondensation differs from the low-temperature process in occurring at 115–240°C and yielding polymers predominantly of amino-imide or aroylenebenzimidazole structure. The solvents used were molten phenol, pyridine, dimethylacetamide, dimethyl sulphoxide, 1-methyl-2-oxopyrrolidine, 2,5,8-trioxanonane, and polyphosphoric acid.

Dawans and Marvel[4] heated pyromellitic dianhydride and biphenyl-3,3′,4,4′-tetra-amine in boiling pyridine for 70 h to obtain a 90% yield of a polymer (with $[\eta]_{H_2SO_4}$ = 0.65 dl g^{-1}) corresponding in structure to a polyaminopyromellitimide. Heating the product in a vacuum to 300°C gave a pyrrone. A partly cyclised polymer of higher molecular weight ($[\eta]$ = 0.94 dl g^{-1}) was obtained by heating the reactants in dimethylacetamide at 160°C. Heating the starting materials in a mixture of 2,5,8-trioxanonane and pyridine to 240°C yielded a polymer having a high degree of cyclisation.

Polymeric products, which according to their infrared spectra and elementary composition were similar in structure to a polyaminoimide, were obtained by the reaction of perylenetetracarboxylic dianhydride with biphenyltetra-amine, and also with oxydiphenylenetetra-amine or with diphenylmethanetetra-amine in 1-methyl-2-oxopyrrolidine or dimethyl sulphoxide at 160–200°C, and also in boiling dimethylacetamide[5,7,25,31,37]. They were not soluble in organic solvents, but dissolved in concentrated sulphuric acid and in polyphosphoric acid. The polymers were cyclodehydrated by heating in a vacuum at 350°C.[25,31]

Conducting the single-stage synthesis of pyrrones in polyphosphoric-acid solution enables aromatic tetra-amines that are relatively unstable in air to be replaced by their stable salts, and hence the required proportions of the components to be maintained extremely accurately. Pyrrones with a high degree of cyclisation and the highest molecular weights are obtained in polyphosphoric acid[5,21,24]. Departure from equimolecular proportions of the initial components results in a decrease in the molecular weight of the resulting pyrrones[4,31,36], in contrast to what happens in aprotic solvents.

The temperature of polycondensation in polyphosphoric-acid solution was usually 180–220°C (Table 3). Dawans and Marvel[4] obtained polybenzimidazopyrrolones in this solvent by heating tetra-amine tetrahydrochlorides with pyromellitic dianhydride at 200°C for 2–40 h. The concentration of the reactants was 0.6–3.0 wt.% based on the solvent. The resulting polymers were infusible powders, insoluble in organic solvents but soluble in concentrated sulphuric acid and in polyphosphoric acid. Berlin and his coworkers[5,24,25,31,35–37], as well as Van Deusen et al.[20–21,40], prepared polynaphthoylenebisbenzimidazoles from naphthalenetetracarboxylic dianhydride and tetra-amines. The viscosity (Table 4) and the solubility of the polymers obtained are affected not only by the final temperature of the synthesis but also by the rate of rise in temperature. The optimum temperature is 200–210°C.[31,37] The most rapid rise in viscosity occurs during the first 2 h, after which the rate of rise in viscosity is very small; the reaction can be regarded as almost complete after 6–8 h.

The polymers are soluble in concentrated sulphuric, 85% phosphoric, polyphosphoric, benzenesulphonic, and methanesulphonic acids. They do not decompose on being heated to 320–425°C (the temperature limits of the apparatus)[20,24]. Polymers based on naphthalenetetracarboxylic dianhydride and biphenyltetra-amine dissolve relatively slowly. Solutions of 5–10% concentration have been obtained at ~ 100°C. With polymers based on the same dianhydride and oxydiphenylenetetra-amine or diphenylmethanetetra-amine 5–6% solutions in sulphuric acid can be obtained at room temperature[20]. A method has been worked out for improving the solubility of the polymers by freeze-drying the moist products. This has enabled a porous polymer to be obtained, which is consequently more readily soluble.

Heating pyrrones in a vacuum above the temperature of their synthesis in polyphosphoric acid increases their molecular weight[20,31,37], probably owing to solid-phase polycondensation at the terminal groups. Thus when polynaphthoylenebisbenzimidazole ($[\eta]$ = 0.9 dl g^{-1}) was heated in a vacuum at 215°, 250°, 275°, 300°, and 325°C for 4 h, the intrinsic viscosity of the polymer increased to 1.3 dl g^{-1}; no products insoluble in concentrated sulphuric acid were formed[31,37].

Pyrrones obtained from naphthalenetetracarboxylic dianhydride and a series of tetra-amines possess fibre-forming properties[21,54,55]. X-Ray examination of the polymers shows them to be either amorphous or polycrystalline materials.

Berry and Fox[51] succeeded in reducing a polynaphthoylenebisbenzimidazole (from naphthalenetetracarboxylic dianhydride and biphenyltetra-amine) with dithionite in aqueous pyridine solution. The soluble polymer obtained oxidised readily in the air. The scattering of a laser beam was used to measure the molecular weights of various fractions of the polymer (M = 81 000–167 000 for $[\eta]$ = 2.02–5.48 dl g^{-1}).

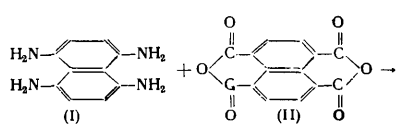
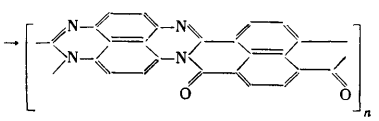
[a]Logarithmic viscosity of 0.25% solution in concentrated sulphuric acid. [b]Intrinsic viscosity measured in DMSO. [c]Logarithmic viscosity in 97% H_2SO_4 at 30°C (0.3 g/100 ml).

The polycondensation of naphthalene-1,4,5,8-tetraamine (I) with naphthalene-1,4,5,8-tetracarboxylic dianhydride (II) and the homopolycondensation of dimethyl 4,5-diaminonaphthalene-1,8-dicarboxylate (III) or the anhydride of the acid (IV) gave polymers (polyperimidinetetrayls) of completely ladder structure[38]:

Scheme 9



(I) (II)



Since (I) could not be isolated in the free state, it was prepared by catalytic reduction in 2,5,8-trioxanonane, and the dianhydride was added to the resulting solution. The polycondensation was conducted in an atmosphere of nitrogen at 180°C for 12 h; after the trioxanonane had been removed, the polymer was heated in a vacuum at 350°C for 2 h (Table 5). Elementary analysis and infrared

spectroscopy indicated that the polymers were not completely cyclised, which is explained by incomplete reduction of tetranitronaphthalene or oxidation of (I) during polycondensation.

Table 4. Conditions of polycondensation in polyphosphoric acid and viscosity of resulting polymers [20,31].

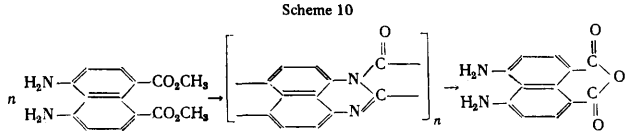
*Total concentration of both monomers in polyphosphoric acid.

The difficulties associated with the instability of (I) are eliminated by effecting the polycondensation of (III) or (IV) in polyphosphoric acid at 100–250°C:

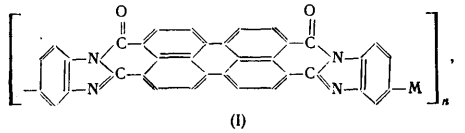
Scheme 10



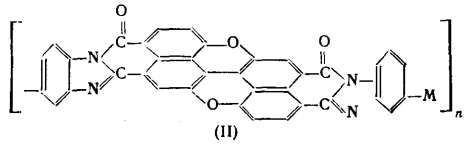
(III) (IV)

Polymers obtained from (III) are soluble in concentrated sulphuric acid. Their elementary composition agrees satisfactorily with calculation. Polymers obtain by the polycondensation of (IV) did not dissolve in concentrated sulphuric acid.

The polycondensation in polyphosphoric acid of the dianhydrides of perylenetetracarboxylic [5,25,31,37] and of 2,8′:2′,8-dioxy-1,1′-binaphthyl-4,4′,5,5′-tetracarboxylic [45] acids with aromatic tetra-amines yields polyaroylene-bisbenzimidazoles having the structures



(I)



(II)

The polymer (V) (M absent, $[\eta] = 0.2–0.3$ dl g^{-1}) was obtained by heating the initial components in polyphosphoric acid to 230°C and maintaining this temperature for 16 h.

When other tetra-amines (M = O, CH_2) were used, the polymers (V) were obtained in low yields and having a smaller value of $[\eta]$. Polymers of structure (VI) (with M absent or representing CH_2) were synthesised at 200 to 210°C. With rise in the temperature and increase in the duration of the synthesis the molecular weight of the polymers (VI) ($[\eta] = 0.6$ dl g^{-1}) increased, but at the same time the yield of insoluble products also increased.

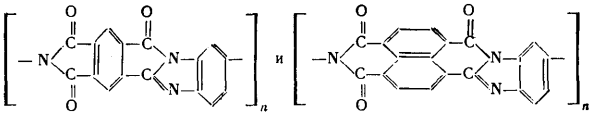
Pyrrones have been obtained also by using for polycondensation in polyphosphoric acid (at 200°C for 8 h) dianhydrides of bisadducts of diene synthesis between maleic anhydride and various bisfuran compounds [26,37,56].

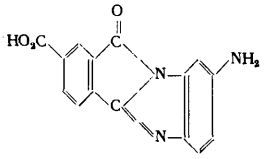
(*d*) Synthesis of polymers akin to pyrrones

D'Alelio and Kieffer [57] obtained high-viscosity polyimidazopyrrolone–imides by the polycondensation of benzene-1,2,4-triamine with the dianhydride pyromellitic and benzophenonetetracarboxylic acids in dimethylacetamide solution followed by thermal cyclisation of the precondensates. The use of naphthalenetetracarboxylic dianhydride gave polymers of very low molecular weight (~ 0.1 dl g^{-1}). The polycondensation of benzene-1,2,4-triamine or its dihydrochloride with pyromellitic or naphthalenetetracarboxylic dianhydride in polyphosphoric acid at 180°C for 12–14 h yielded the polymers



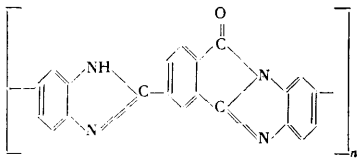
having intrinsic viscosities of 0.63 and 0.88 dl g^{-1} respectively.

The reaction of benzene-1,2,4-triamine with trimellitic anhydride in dimethylacetamide or polyphosphoric acid gave only products of low viscosity, which was attributed to formation of the unreactive compound



Polymers of higher molecular weight ($[\eta] = 0.29–0.45$ dl g^{-1}) have been obtained from trimellitoyl chloride and benzene-1,2,4-triamine in the above solvents in the

presence of triethylamine as acceptor of hydrogen chloride. Polymers ($[\eta] = 0.51$ dl g^{-1}) with the structure



have been obtained by the polycondensation of trimellitic anhydride with biphenyl-3,3′,4,4′-tetra-amine in polyphosphoric acid [57,58].

Copolymers of imidoaroylenebenzimidazole structure were obtained by copolycondensation of the naphthalenetetracarboxylic dianhydride and the biphenyltetra-amine with benzidine or *pp*′-oxydianiline [ODPDA]. [31,59] Various molar proportions of dianhydride, diamine, and tetra-amine (1 : 0.2 : 0.8, 1 : 0.5 : 0.5, 1 : 0.8 : 0.2) were used to synthesise the copolymers. Their synthesis was accomplished either in two stages or as a single-stage process in polyphosphoric acid. The first stage in the two-stage synthesis involved heating the mixture of dianhydride, diamine, and tetra-amine in dimethylacetamide, dimethyl sulphoxide, or 1-methyl-2-oxopyrrolidine at 75–85°C for 6 h. Subsequent vacuum heat-treatment of the precondensates at 200–300°C effects their intramolecular cyclisation to form copolymers of block-ladder imidoaroylenebenzimidazole structure. In the single-stage method polycondensation was conducted in polyphosphoric acid at 200°C for 8 h. Owing to the difference in activity between diamines and tetra-amines the composition of the copolymers differed from that of the initial mixture. The final copolymers were dark, amorphous powders, soluble in polyphosphoric, sulphuric, and formic acids but insoluble in organic solvents. Their intrinsic viscosity was 0.2–0.6 dl g^{-1}.

IV. PROPERTIES OF THE POLYMERS

1. Thermal Stability

The main property which first attracts the attention of research workers to pyrrones is their high heat-resistance and thermal stability. Despite the heightened interest in such polymers, only isolated papers have hitherto been specially concerned with a detailed investigation of their thermal stability. In most publications, however, the thermal stability of the pyrrones obtained is measured by thermogravimetric curves determined with different rates of temperature rise. This makes it difficult to compare the thermal stability of pyrrones differing in structure. Furthermore, very little information is given on the chemistry of the processes occurring in the polymers at high temperatures in oxidising and inert atmospheres and also in a vacuum.

Several workers [60–63], who have investigated the mechanism of the degradation of polymers containing heterocycles in the main chain (polyimides, polybenzimidazoles, polyoxadiazoles, etc.), associate the thermal stability of the polymers mainly with the stability of the heterocycles. This takes no account of the specific natures of the polymers examined, which are governed by the presence of a system of conjugated bonds extending through large sections of the macromolecular chain and by the presence of paramagnetic centres whose structure does not remain constant over a wide temperature range [64,65,67].

Dawans and Marvel [4] used a dynamic thermogravimetric method to study thermal degradation, and showed that polybenzimidazopyrrolones based on pyromellitic dianhydride are stable in an atmosphere of nitrogen up to 450 to 500°C; at 800–900°C they undergo a loss in weight of 25–40%. In air these polymers are oxidised fairly rapidly at 350–400°C. The thermal stability of pyrrones prepared in polyphosphoric acid is superior to that of the same polymers obtained in two stages and in the melt (Fig. 1)‡. The presence of intermediate methylene or oxygen links in the macromolecular chain leads to some diminution in the thermal stability of the polymers (Figs. 2 and 3). Polybenzimidazopyrrolones based on benzophenonetetracarboxylic acid show thermal stability as good as that of the corresponding polymers based on pyromellitic dianhydride (Fig. 3).

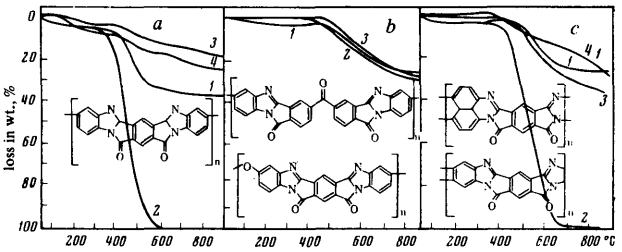


Figure 1. Thermogravimetric curves (rate of rise in temperature $\Delta T = 6$ deg min^{-1}) obtained in air for polymers prepared in: *a*) 1) melt; 2) melt (curve in nitrogen); 3) PPA soln.; 4) two stages; *b*) 1) melt; 2) melt; 3) PPA soln.; *c*) 1) melt; 2) melt (curve in nitrogen); 3) melt; 4) PPA soln.

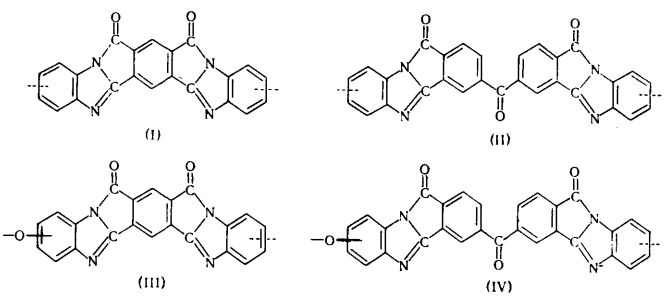
In a study of the thermal degradation under isothermal conditions of films of the pyrrones



Jewell found [66] that the initial losses in weight were due to removal of absorbed moisture (~ 7 wt. % up to 100–150°C) and to further intramolecular cyclisation. Films which had been preheated at 350°C for 2 h did not lose weight until progressive decomposition of the polymer occurred, which began above 400°C (Fig. 4).

‡Pyrrones obtained in the melt under high pressure possess enhanced thermal stability in air and in an inert atmosphere [47].

The effective activation energy of thermo-oxidative degradation, calculated for the polymers (I)–(IV) from the constant-rate sections over the range 440–460°C, was respectively 31, 34, 28, and 30 kcal mole^{-1}. The authors concluded from the results of differential thermal analysis that the polymers had undergone no phase transitions.

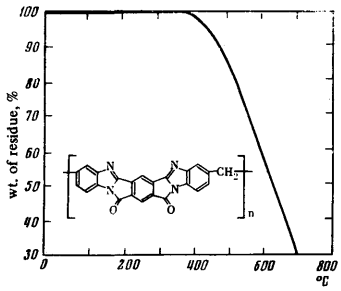


Figure 2. Thermogravimetric curve (ΔT = 4 deg min^{-1}) in air.

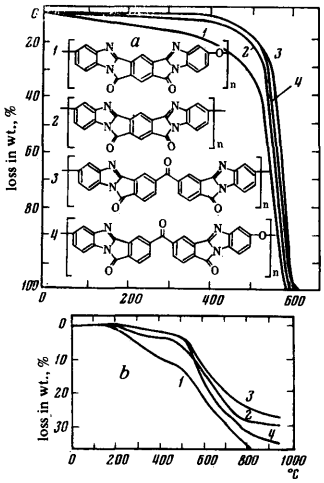

Figure 3. Thermogravimetric curves for pyrrone films (ΔT = 5 deg min^{-1}) in: *a*) air; *b*) vacuum.

When the polymers are heated in a vacuum, the main losses in weight are observed during the initial period of degradation, after which the weight of the residue tends to a limiting value. The total losses in weight of the pyrrones investigated are 28–38 wt. % up to 800°C. The activation energy for degradation of the polymers (I)–(IV) in a vacuum is 47–50 kcal mole^{-1}.

Examination of the products of the degradation of polymer (II) showed that up to 380°C the losses in weight are due to the removal of water. Above 420°C a successive increase in the rate of degradation is observed; it reaches a maximum at 550°C, and drops rapidly at temperatures above 620°C. A large quantity of carbon monoxide and dioxide is evolved in this temperature range. At about 500°C –NCN–groups are also eliminated. With rise in temperature to 650°C these are accompanied by CN– and HCN– groups. Evolution of traces of ammonia is observed only during the main decomposition of the polymer. Thus dehydration occurs in the initial period, and this is followed by thermal rupture of bonds in the macromolecular chain.

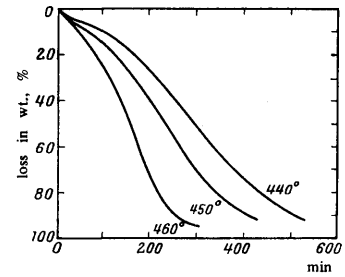

Figure 4. Thermogravimetric curves for pyrrone film (BODA–BPTA) in air.

An investigation of thermo-oxidative degradation undertaken by the Reviewers [5,24,31,35,67] and also by Van Deusen and his coworkers [6,20,40] indicates that polynaphthoylene-bisbenzimidazoles are more stable than the corresponding polyimides and also than pyrrones based on pyromellitic dianhydride (Fig. 5) Their resistance to thermo-oxidative degradation is found to depend, up to a certain limit, on the molecular weight, which is probably an effect of the terminal groups. A particularly substantial decrease in stability was observed with polymers of low molecular weight: when $[\eta]$ = 0.37 dl g^{-1}, progressive breakdown began at a temperature 75 deg lower.

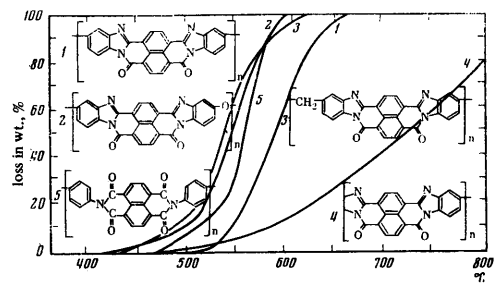

Figure 5. Thermogravimetric curves in air with ΔT = 2 deg min^{-1} (2.5 deg min^{-1} for curve 4).

In a vacuum or in an inert atmosphere the polymers lose 18–30% in weight when heated to 800–900°C. The influence of molecular weight is considerably less evident under these conditions, but even in this case polymers having low molecular weights begin to lose weight at lower temperatures. Polymers obtained from naphthalene-tetracarboxylic dianhydride and biphenyltetra-amine, having intrinsic viscosities of 0.8–1.15 dl g^{-1}, do not

decompose at all when heated in nitrogen to 600°C (Fig. 6), whereas a similar polymer of viscosity 0.12 dl g^{-1} loses up to 10 wt.%. Polymers of completely ladder structure obtained from naphthalenetetracarboxylic dianhydride and benzenetetra-amine, lose 4 wt.% under the same conditions. Several authors [52] explain the lower thermal stability of polymers of ladder structure, probably correctly, by the absence of extensive polyheterocyclisation on rigid macromolecules, i.e. by the presence of a large number of defects.

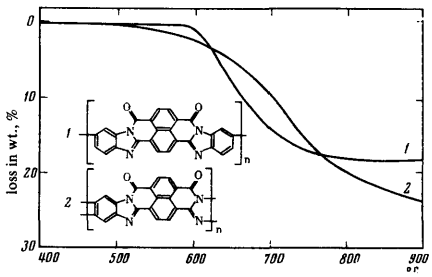

Figure 6. Thermogravimetric curves in nitrogen (ΔT = 2.5 deg min^{-1}).

Differential thermal analysis of a polynaphthoylenebisbenzimidazole (from naphthalenetetracarboxylic dianhydride and biphenyltetra-amine) (Fig. 7) has shown [31] that reactions involving complicated intra- and intermolecular rearrangements occur when the polymer is heated in an inert atmosphere, in an inert atmosphere contaminated with air, and in air. Heating the polymer to 110–120°C reveals an endothermic peak, indicating the evolution of 4–5% of adsorbed water. Raising the temperature to 270–330°C leads to cyclisation of the repeating units that have remained uncyclised, accompanied by the appearance of an exothermic peak on the curves. Further heating of the polymer in air to 540°C and in argon to 655°C produces insignificant losses in weight, but above these temperatures the specimen breaks down rapidly in air, and loses up to 20–25 wt.% in an inert atmosphere. Breakdown of the polymer is accompanied by cross-linking. The most favourable conditions for carbonisation occur in an inert atmosphere. In air and even with a low oxygen content (7%) degradative processes predominate over cross-linking processes, resulting in progressive weight losses by the polymer.

Tests on the isothermal aging of pyrrones (from naphthalenetetracarboxylic dianhydride and biphenyltetra-amine) showed that they lost only 10 wt.% after being heated in air at 315°C for 1500 h. [20] At 400°C the weight losses for a polymer of the same type do not exceed 10% after 7–8 h.

A kinetic study of the thermo-oxidative degradation of this polymer has been made over the range 450–570°C (Fig. 8). [31,67] The process is clearly autocatalytic in character. The effective activation energy, calculated for sections having a constant rate, is 28.8 kcal $mole^{-1}$ in the temperature range 470–502°C. At higher temperatures the process takes place without an induction period, and its activation energy falls to 7.4 kcal $mole^{-1}$, which indicates a change in the mechanism of thermo-oxidative degradation,

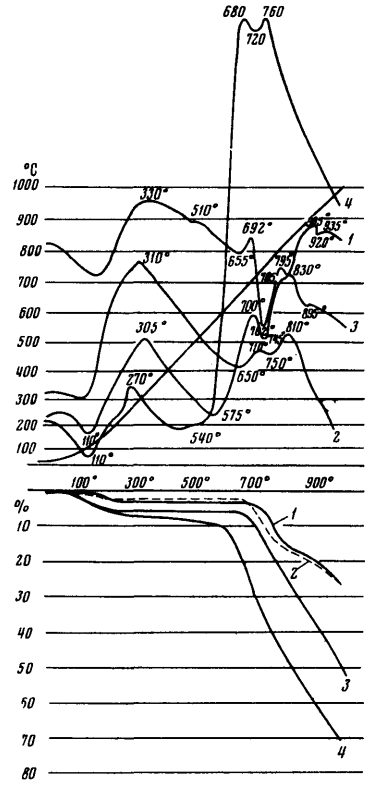

Figure 7. Differential thermal analysis of polynaphthoylenebisbenzimidazole (NDA–BPTA) with ΔT = 6 deg min^{-1} in: 1) argon (under cover); 2) argon (open crucible); 3) argon + 7% O_2; 4) air.

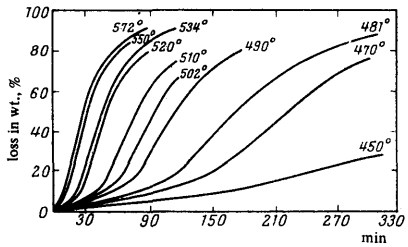

Figure 8. Thermogravimetric curves in air for polynaphthoylenebisbenzimidazole (NDA–BPTA, $[\eta]$ = 1.0 dl g^{-1}).

Small (1%) additions of the previously pyrolysed polymer produce an increase in the maximum rate of degradation. The autocatalytic character of degradation of the polymer and the specific effect of pyrolysed additions are explained in terms of a "local activation effect", which is characteristic of polymers containing a conjugated system [65,67].

Mass-spectroscopic analysis indicates that, when polynaphthoylenebisbenzimidazoles are heated in a vacuum to 800°C, the chief gaseous products are carbon monoxide, nitrogen, and a certain amount of carbon dioxide; hydrogen and steam are also evolved. These results, together with

the composition of the residues (Table 6), indicate the occurrence of processes of carbonisation and the formation of polynuclear fused systems, including conjugated carbocyclic and heterocyclic rings.

Table 6. Change in composition of polymer after being heated in a vacuum [31,37,50].

Repeating unit	Composition	Temperature at which heated, °C				
		300	400	500	600	800
	C/N	5.6	5.8	5.7	9.7	10.9
	C/H	27.7	29.5	30.7	47.5	61.3

Thermogravimetric analysis of the thermal and thermo-oxidative degradation of pyrrones obtained from perylene-tetracarboxylic dianhydride with biphenyltetra-amine, oxydiphenylenetetra-amine, and diphenylmethanetetra-amine respectively (Fig. 9) [24,31,67] indicates that these polymers are less stable in air than are the corresponding polynaphthoylenebisbenzimidazoles of high molecular weight ($[\eta] \geq 1.0$ dl g^{-1}). Nevertheless, they are more resistant to thermo-oxidative degradation than are polynaphthoylenebisbenzimidazoles of low molecular weight ($[\eta] < 0.4$ dl g^{-1}). Such a difference is probably due to the influence of the terminal groups. In a vacuum their thermal stability is equal to or even somewhat surpasses that of polynaphthoylenebisbenzimidazoles of high molecular weight, which is probably due to the stronger intermolecular interaction of polymers containing perylene rings and their greater tendency to cross-linking.

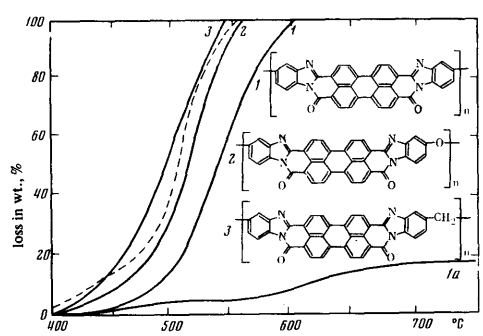

Figure 9. Thermogravimetric curves (ΔT = 2 deg min^{-1}) in: 1)–3) air; 1*a*) vacuum; ---) polynaphthoylenebisbenzimidazole (NDA–BPTA, $[\eta] = 0.37$ dl g^{-1}).

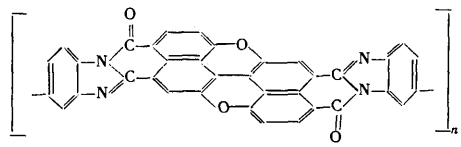
Great thermal stability in air and in a vacuum is shown also by pyrrones prepared in polyphosphoric acid from biphenyltetra-amine and dianhydride bisadducts of maleic anhydride with bisfuran compounds [26,56], and also from this tetra-amine and 2,8′ : 2′,8-dioxy-1,1′-binaphthyl-4,4′,5,5′-tetracarboxylic dianhydride.[45]



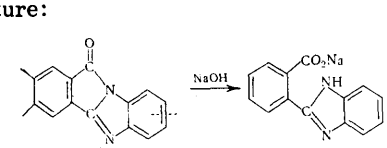
As has been mentioned above, the application of thermostable polymers is most promising in space technology. Such polymers and also compositions based on them are used for the ablation protection of the surfaces of aircraft and propulsion units from the action of high-temperature gas-flows. Prospects have been discussed [68] for the use of heterocyclic polymers of ladder and block–ladder structure as ablation-resistant coatings. Many pyrrones prepared from aromatic tetra-amines and various dianhydrides (of naphthalenetetracarboxylic acid, perylene-tetracarboxylic acid, bisadducts of diene synthesis between maleic anhydride and bisfuran compounds) proved resistant to the action of high-temperature air flows [69–72]. They satisfy such criteria of ablation resistance as low rate of ablation $A_V = \Delta m/\tau F$ kg m^{-2} s^{-1} (where Δm is the loss in weight, F the surface area of the specimen, and τ the duration of the test) and resistance to the action of large temperature gradients. Specimens of the polymers and compositions were prepared by hot pressing.

The rate of ablation of a polymer is almost independent of its molecular weight after the latter has reached a certain value ($[\eta] \geq 0.9$ dl g^{-1}), being determined by its resistance to thermo-oxidative degradation and its tendency to cross-linking. Pyrrones based on naphthalenetetracarboxylic dianhydride, and especially those containing perylene rings, showed the lowest rate of ablation. The introduction of intermediate oxy and methylene groups somewhat increases the rate of ablation. Polymers having a low degree of cyclisation exhibited a sharp drop in ablation resistance. Pyrrones show better ablation resistance than corresponding polyimides and unmodified phenol–formaldehyde resins. The stability of the test specimens to the action of a temperature gradient is greatly improved after they have been heat-treated in an inert atmosphere; it is improved also by hot-pressing polymers containing additives which act as temporary plasticisers.

2. Resistance to Radiation and Chemicals

Pyrrones are extremely resistant to the action of ionising radiation (Table 7). Thus the strength properties of pyrrone films had not deteriorated after exposure to a 10 000-Mrad dose of electrons of energy 2–3 MeV, whereas polyester films are destroyed by a dose of 200 Mrad. [3,19,73,74]

Investigation of the chemical stability of polybenzimidazopyrrolones has shown that the mechanical strength of the films diminishes relatively slowly on standing in 96% sulphuric acid (Table 8). In alkaline solutions the films rapidly lose their strength. The reaction between the polymer and the alkali can be regarded as conversion of the imidazopyrrolone structure into a polycarboxybenzimidazole structure:



Polynaphthoylenebisbenzimidazoles, in contrast to polybenzimidazopyrrolones, are extremely resistant to the action of concentrated sulphuric acid[31,36]. The viscosity of solutions of the polymers is almost unchanged after standing in the acid at room temperature for 700 h. Keeping a polynaphthoylenebisbenzimidazole in 40% alkali (potassium hydroxide) for 2 days produces a decrease in its intrinsic viscosity from 1.8 to 1.1 dl g^{-1}.

Table 7. Effect of radiation on mechanical properties of pyrrone films[3,19].

3. Electrical, Magnetic, and Catalytic Properties

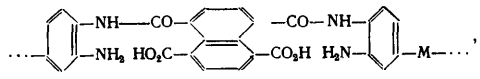
Very little information is available on the electrical properties of polybenzimidazopyrrolones[3,4]. Their resistivity and dielectric strength are typical of insulating organic polymers (Table 9). Polybenzimidazopyrrolones are paramagnetic materials having concentrations of unpaired electrons of 10^{16}–10^{19} g^{-1}.[7]

The magnetic and electrical properties of polymers based on naphthalenetetracarboxylic and perylenetetracarboxylic dianhydrides with aromatic tetra-amines, and also of copolymers of naphthalenetetracarboxylic dianhydride with diamines and tetra-amines, have been studied in greater detail[5,24,25,31,35,50]. The temperature dependence of the conductivity of these polymers is typical of organic semiconductors. Table 10 shows that the conductivity parameters (the activation energy E_σ and the resistance ρ_t) depend substantially on the nature of the dianhydride and the tetra-amine used and on the ratio of diamine and tetra-amine in the case of the copolymers. A break in the conjugated system impairs the conductivity. With increase in the number of fused rings in the initial dianhydride the values of ρ and E_σ for the polymers diminish, probably owing to an increase in intermolecular interaction.

Table 9. Electrical properties of polymers[3,4].

Polymer		Resistivity, ohm cm	Dielectric strength, V cm^{-1}	Dielectric constant
PMDA-ODPTA	PAAA	$6 \cdot 10^9$	$2 \cdot 10^5$	—
	pyrrone	$(3—5) \cdot 10^{12}$	$6 \cdot 10^5$	—
PMDA-NTA	pyrrone	$5 \cdot 10^{10}$	—	4.0

Polyamide-amino-acids have lower conductivities, which depend to a less extent on the nature of M in the formula[31,50]



(where M represents O or CH_2 or is absent).

Table 10. Electrical properties of polyaroylenebisbenzimidazoles and copolymers[31,50].

Polymer		No.	—M—	Conductivity measured up to 200°C: E_σ	Conductivity measured up to 200°C: $\lg \rho_{150°}$
		I	absent	0.47	5.70
		II	—O—	0.67	9.35
		III	$—CH_2—$	0.57	8.35
		IV	absent	0.32	4.60
		V	—O—	0.48	7.10
		VI	$—CH_2—$	0.42	6.50
NDA-BPTA-ODPDA copolymers	1:0.2:0.8	VII	—	0.74	9.75
	1:0.5:0.5	VIII	—O—	0.60	7.60
	1:0.8:02	IX	—	0.59	6.25

Both the final polymers and the precondensates give electron spin resonance signals characteristic of conjugated polymers[5,24,25,31,35,50]. The concentration of paramagnetic centres is considerably lower in polyamide-amino-acids than in cyclised polymers. The paramagnetism of the former compounds has been explained[24] by the possibility of formation of an isoimide structure. In such polymers, moreover, intramolecular and intermolecular transmission of conjugation can be accomplished by complex formation between amino- and carboxy-groups.

A study has been made of the variation in the electrical properties at various stages in the production of polymer molecules when polyamide–amino-acids are heated in a vacuum from 50–100° to 800°C.[31,37,50] The various polyamide–amino-acids show a general tendency for the electrical and magnetic properties to change with the temperature at which they have been heated (Fig. 10). Only intramolecular cyclisation occurs up to 150–200°C. Above 300°C this is accompanied by incipient slight cross-linking (depending on the structure of the polyamide–amino-acid and the polymer), which intensifies at 400°C. In this temperature range the electrical properties of the polymer improve, the narrow e.s.r. signal becomes stronger and narrower, the background in the infrared spectra becomes stronger, and amorphous specimens become polycrystalline.

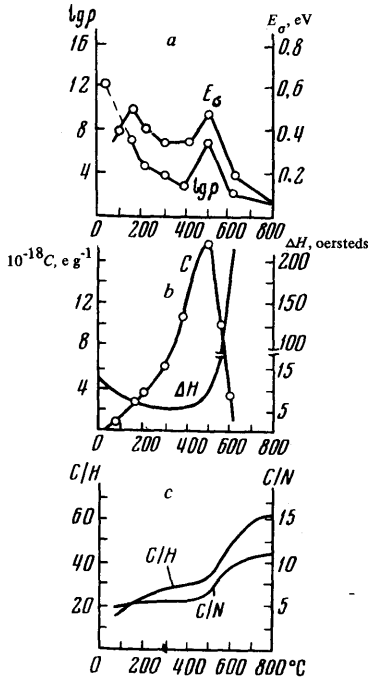


Figure 10. Change in electrical properties—E_σ and ρ_t—and magnetic properties—C (e g^{-1}) and ΔH_{esr} (oersteds)—and in elementary composition of PAAA on heating in a vacuum (for 2 h at each temperature).

Processes involving partial degradation of macromolecules at weak bonds (structural defects) begin at 500°C. They are accompanied by a diminution in the degree of order in the polymer specimen and a sharp deterioration in electrical properties. At 600°C the evolution of gaseous products is accompanied by that of heavier, reactive fragments able to sublime, recombination occurs, blocks previously formed on degradation undergo further cross-linking, the electrical properties of the polymers improve, the intensity of the narrow e.s.r. signal decreases, and a broad e.s.r. signal appears. Raising the temperature of pyrolysis to 800°C leads to a further improvement in the electrical properties and very considerable broadening of the e.s.r. signal of the residues, which contain a notable quantity (up to 8%) of nitrogen and a certain amount of oxygen, and are probably coarse blocks of a polycyclic aromatic including heterocyclic rings.

Pyrrones are catalysts of semiconductor type[7,75,76]. The decomposition of nitrous oxide was found to depend in considerable measure on the type of conjugation in the catalyst macromolecules. Thus the activation energy for this model reaction was 40–52 and 18–27 kcal mole^{-1} when pyrrones of block–ladder and ladder structure respectively were used.

Table 11. Mechanical properties of pyrrone films[19].

Pyrrone	Tensile strength, kg cm^{-2}	Elongation, %	Young's modulus, kg cm^{-2}
PMDA-BPTA	1430	2.8	66 500
PMDA-ODPTA	1530	4.8	57 000
PMDA-DPMTA	975	3.9	37 400
PMDA-BOTA	930	2.6	41 500
BODA-BPTA	1420	4.3	42 000
BODA-ODPTA	1320	3.8	43 800
BODA-DPMTA	680	1.9	41 900
BODA-BOTA	840	3.1	34 800

4. Mechanical Properties

In view of the great thermal stability of pyrrones they show promise for the production of films, adhesives, fibres, and moulded articles. The strength of pyrrone films is high[19], but, as was to be expected with such rigid chains, they have a high modulus of elasticity and low relative elongation (Table 11). The mechanical properties of the films is greatly influenced by the temperature of cyclisation (Table 12) and to a less extent by the atmosphere in which cyclisation occurs (Table 13). The effect of the test temperature on the strength properties of pyrrone films is shown in Table 14.

Table 12. Effect of temperature of cyclisation on mechanical properties of PMDA–BPTA pyrrone films (duration of cyclisation 1 h).[19]

Temp. of cyclisation, °C	Tensile strength, kg cm^{-2}	Stress at flow point, kg cm^{-2}	Young's modulus, kg cm^{-2}	Elongation, %
150	775	1 140	35 600	5.4
225	920	1 200	38 200	4.1
300	1 030	1 320	44 000	3.8

Pyrrone films are far stronger than those obtained from polyamide–amino-acids. For example, the tensile strength of the latter films based on pyromellitic dianhydride and oxydiphenylenetetra-amine is 704–1060 kg cm^{-2}, whereas that of the corresponding pyrrone film[3] is 1060–1550 kg cm^{-2}. Strong films have been obtained from

polyamide-amino-acids prepared from naphthalenetetracarboxylic dianhydride with oxydiphenylenetetra-amine and with diphenylmethanetetra-amine [31,36], their tear strengths being respectively 910 and 850 kg cm^{-2}. After cyclisation at 300°C the strength of the films had improved to 1200 and 1040 kg cm^{-2}. Their mechanical constants can probably be improved by finding optimum conditions for production of the films.

Table 13. Effect of atmosphere on mechanical properties of PMDA–BPTA films (heated at 250°C for 3 h). [19]

Atmosphere	Tensile strength, kg cm^{-2}	Elongation, %	Young's modulus, kg cm^{-2}
Air	1090	4	48 600
Vacuum	1100	3.8	47 600
Nitrogen	990	2.1	60 000

Table 14. Effect of temperature of testing on mechanical properties of PMDA–BPTA films [19].

Temp., °C	Stress at flow point, kg cm^{-2}	Tensile strength, kg cm^{-2}	Elongation, %	Young's modulus, kg cm^{-2}
25	900	1190	2.8	60 000
100	685	1110	3.7	50 000
200	529	800	3.7	36 800

Fibres have been obtained from polymers based on naphthalenetetracarboxylic dianhydride and biphenyltetra-amine [21,54,55,77]. Concentrated sulphuric acid was used as solvent in wet spinning. Polymers having intrinsic viscosity 1.15–2.45 dl g^{-1} have been employed. After drawing (at 360–540°C) the strength of the filaments was 0.85–1.33 g $denier^{-1}$ at draw ratios of 1.10–1.29; the elongation at rupture was 6.8–10.0%. With continuous drawing of filaments at 260–565°C and draw ratios of 1.06–1.31 in an atmosphere of argon and in air their strength reached 2 g $denier^{-1}$ at an elongation of 19%. To obtain strong filaments while preserving high values of the elongation at break, a monofil was subjected to hot drawing in argon. Filaments of strength 4 g $denier^{-1}$ were obtained with 4–5% elongation at break. With a filament which had been drawn at 650°C this elongation had decreased to 3%. According to these workers' results wet spinning from solutions in concentrated sulphuric acid can be used for the practical production of a thermostable fibre. The resulting fibre retains 55% of its initial strength after being kept in air at 600°C for 1 min, and 50% in air at 360°C for 30 h; it is extremely resistant to ultraviolet radiation.

Intensive research is being conducted in the USA into the synthesis of high molecular-weight pyrrones of ladder structure (naphthalenetetracarboxylic dianhydride–biphenyltetra-amine) and the production of fibres from them [21,22].

Methods have recently been found for moulding strong, thermostable articles from pyrrones by adding a temporary plasticiser [31,72]. Polymeric goods obtained directly from the molten monomers under high pressures also possess great strength and hardness [47].

Fluorine-containing Polyethers, polyesters, and polythia-compounds

B.F.Malichenko

Methods of preparation and the influence of fluorine atoms on the principal physicochemical characteristics of fluorine-containing polyethers, polyesters, and polythia-compounds are reviewed. Heterochain and carbochain polyethers and polyesters and their possible regions of practical use in chemistry and technology are discussed. 197 references.

I. INTRODUCTION

The development of atomic energy, chemical technology, radio electronics, high-altitude aviation and space-flight, and other important branches of technology requires the creation of new polymeric materials which can be used under extremely severe conditions. Here the material should not only withstand contact with various aggressive media but also retain a complex of physicochemical and strength characteristics in these media over a wide range of high and low temperatures. One of the promising directions for increasing the thermal and chemical stability of polymeric materials is the replacement of the hydrogen atoms in them by fluorine atoms. Here the maximal effect can be reached when completely fluorinated monomers are used for the preparation. However, in several instances a considerable improvement in physicochemical properties of the polymeric materials can be brought about by the introduction into their chain of individual fluorine atoms or small perfluorinated groups. Polymers in which the fluorine atoms are linked to carbon are of the greatest practical interest. Systems in which fluorine is bound to silicon, phosphorus, nitrogen, etc. usually are not very resistant to hydrolysis and are not of practical interest for the preparation of high-molecular-weight compounds.

Non-fluorinated polyethers, polyesters and polythia-compounds can be readily converted into rubbers, films, fibres, etc. However, their thermal and chemical stabilities are low, which restricts the range of practical use of these comparatively accessible and cheap materials. The preparation and study of the properties of fluorine-containing polyethers and polyesters have been dealt with in a large number of papers. Both completely fluorinated polyethers and polyesters and also polymers having chains containing various lengths of non-fluorinated substituted methylene groups are of interest.

The present review deals with methods of obtaining fluorine-containing polyethers, polyesters, and polythia-compounds which contain oxygen or sulphur atoms in the main or side polymeric chains. The contribution of the fluorine atoms to the change in physicochemical properties of these polymers in comparison with their non-fluorinated analogues is discussed. Without any pretence of a complete survey of the published material, the review nevertheless reflects sufficiently adequately the general state of the problem of fluorine-containing polyethers, polyesters, and polythia-compounds and makes orientation in this important part of polymer chemistry somewhat easier.

II. POLYETHERS

The $-CF_2-O-CH_2-$ grouping of low stability chemically[1,2] and therefore its introduction into polyether chains is undesirable. Completely fluorinated ethers of the $-CF_2-O-CF_2-$ type exhibit high thermal and chemical stability. The energy of the C–O–C bond in non-fluorinated ethers is ~90 kcal mole^{-1}, whereas for fluorinated ethers it is ~10 kcal mole^{-1} greater. If it is assumed that the energy of the C–C bond in polytetrafluoroethylene is also 90 kcal mole^{-1}, then evidently the introduction of oxygen atoms into a chain consisting of difluoromethylene groups does not reduce the thermal stability of the polymer, but confers upon it several new properties. Methods for the preparation of fluorine-containing polyethers and polythia-compounds are given below and some of their physicochemical properties are described.

A. Heterochain Polyethers and Polythia-compounds

1. Reaction of fluorine-containing alkenes with oxygen. At the beginning of this century, Swarts showed[3] that acyl halides are formed in the oxidation of fluorinated alkenes by oxygen. Subsequently[4,5] further investigation of this process disclosed a tendency of perfluoroalkene–oxygen systems to explode. In the oxidation of tetrafluoroethylene with molecular oxygen at atmospheric pressure[6] using ultraviolet radiation or X-rays as initiator or under the influence of elevated temperature, in addition to simple oxidation products (COF_2, CF_2-CF_2 (O), CF_2-CF_2 (CF_2), etc.) a polymer of composition $(-CF_2CF_2-O-O-)_X$ is formed. The latter is an unstable copolymer of tetrafluoroethylene and oxygen. It was suggested that the oxidation of tetrafluoroethylene proceeds by a chain mechanism[7]. In the absence of

initiators liquid tetrafluoroethylene copolymerises with oxygen at elevated pressure, forming an elastic product with 0.76 mole oxygen per mole tetrafluoroethylene[8]. In the presence of ozone the induction period of the reaction between oxygen and tetrafluoroethylene is shortened but the ozone does not affect the composition of the copolymer[9,10]. A study of the ^{19}F NMR spectra showed that the copolymer has a homogeneous structure $(-CF_2CF_2-O-O)_X$. Evidently, the oxidation of halogenated alkenes takes place analogously to copolymerisation[11], when one of the monomers is incapable of homopolymerisation. A study of the kinetics of oxidation of tetrafluoroethylene by molecular oxygen[12], under the influence of γ- or X-rays confirmed the suggestion of the formation of intermediate products of peroxide type. The reaction of tetrafluoroethylene with oxygen is an autoxidation of the alkene, which is accelerated in the presence of traces of ozone, and is evidently linked with the radical copolymerisation of alkenes with oxygen. Chain growth can be represented by the scheme[10]:

$$\ldots -CF_2^{\cdot} + O_2 \rightarrow \ldots CF_2-O-O^{\cdot} + CF_2=CF_2 \rightarrow \ldots CF_2-O-O-CF_2CF_2^{\cdot}$$

The formation of gaseous products—carbonyl fluoride and tetrafluoroethylene oxide—takes place in the decomposition of the copolymer:

$$\ldots -CF_2-O-O-CF_2CF_2-O^{\cdot} - \ldots -CF_2-O-O-CF_2^{\cdot} + COF_2$$

$$\ldots -CF_2-O-O-CF_2CF_2^{\cdot} - \ldots -CF_2-O^{\cdot} + CF\underset{O}{\diagdown\!\diagup}CF_2.$$

The formation of a peroxide polymer with molecular weight up to 1000 as one of the main reaction products was also noted in the oxidation of chlorotrifluoroethylene[13]. The side-products isolated in this process[14] were COF_2, COFCl, $CF_2Cl-COCl$, and evidently

$$CF_2\underset{O}{\diagdown\!\diagup}CFCl \text{ and } \begin{matrix} CF_2-CFCl \\ | \quad | \\ O-\!-O \end{matrix}[14].$$

When peroxide polymers are heated in an atmosphere of nitrogen the polymer $[-CF_2CF_2-O-]_X$ is formed, in addition to the gaseous products[8]; it exhibits high thermal and chemical stability. Poly(tetrafluorooxyethylene) is a crystalline and rather well orientated polymer with a spiral conformation of the macrochains[15].

Polyethers with a large number of successively linked difluoromethylene groups can be obtained in the common pyrolysis of the mercury salts of perfluorodicarboxylic acids[16]:

$$HgOOC-[CF_2]_n-O-[CF_2]_n-O-[CF_2]_n-COOHg + HgOOC-[CF_2]_y-COOHg \rightarrow \rightarrow [-O-[CF_2]_m-]_x$$

In the pyrolysis of this polymer up to 400°C there is partial cross-linking of its chain occurs. By heating iodides in the presence of mercury[17]:

$$O(CF_2CF_2\dot{I})_2 \xrightarrow[UV]{Hg} -[CF_2CF_2-O-CF_2CF_2-]_x$$

polyethers with $\bar{M}_n \simeq 40\,000$ were obtained. Their glass point is $\sim -65°C$, they withstand solvents and exhibit high thermal stability. Appreciable decomposition of these polyethers is observed above 500°C, which not only exceeds the decomposition temperature of non-fluorinated polyethers but even that of such a thermally stable polymer as poly(tetrafluoroethylene). As a result of the investigation of the thermal degradation of poly(tetrafluoroethylene oxide)[18] it was found that its maximal rate of decomposition is observed at 628°C, with the activation energy of the decomposition being 98 kcal mole^{-1}, whereas for poly(tetrafluoroethylene) these values are 568°C and 85 kcal mole^{-1} respectively. Evidently, the higher thermal stability of poly(tetrafluoroethylene oxide) is due to the greater stability of the radicals formed in the degradation.

The polyesters based on perfluoropropene are of considerable interest and have already found practical application. The nature of the initiator employed has a considerable influence on the course of the reaction between oxygen and perfluoroethylene. With γ-rays, gaseous products are mainly formed[19], the bulk of which consists of COF_2 and CF_3-COF, and there is a small quantity of an explosive polymer with M = 120–330. A high yield of polymeric products could be obtained by using ultraviolet light as initiator. The oxygen in the copolymer depends on the reaction temperature and the wavelength of the radiation used[20]. In the photochemical copolymerisation of perfluoropropene and oxygen at −60°C the copolymer $[-CF_2-CF(CF_3)-O-]_X$ is formed, but with increase in the copolymerisation temperature the number of peroxide groups in the copolymer decreases[21]. On heating or further irradiation the proportion of oxygen in the copolymer drops. Copolymers of this type contain reactive terminal –COF groups. The stability of the polyether can be greatly increased by converting the terminal acyl fluoride groups into carboxyl groups followed by decarboxylation of the latter. Oligomers of composition $[-C_3F_6-O-]_X$ exhibit high thermal and chemical stability. They are unchanged on heating to 350°C. The structure of the elementary unit of the polymer,

$$(-\underset{CF_3}{\underset{|}{CF}}-CF_2-O-),$$

was deduced from the ^{19}F NMR spectra and chemically[22].

2. Polymerisation of oxides and thio-oxides of fluorine-containing alkenes.

The polymerisation of oxides of fluorinated alkenes has been a more convenient method of making polyethers. It has allowed the process to be simplified and the formation of explosive peroxide polymers to be avoided. Oxides of the type

$$CF_3-CH\underset{O}{\diagdown\!\diagup}CH_2$$

have been polymerised in the presence of catalysts of the Lewis acid type[23] with the formation of a thermally stable polyether with $M \simeq 230\,000$. Peroxide initiators and γ-rays do not bring about polymerisation of this monomer[23]. Oligoethers with $M = 1000-4000$ were obtained from 2,3-epoxy-1,1,1-trifluoro-propane in the presence of anionic or cationic catalysts[24,25]. The nature of the terminal groups of the polyether depends on the polymerisation catalyst employed. The use of aluminium chloride as a catalyst facilitates the formation of terminal hydroxyl groups whereas when alkaline catalysts or boron trifluoride are used double bonds are formed as terminal groups[24]. High-molecular-weight polyethers are also formed from other oxides in the presence of cationic catalysts, for example, from epoxy-2,2,3,3-tetrafluoro-1-vinylbutane[26,27].

Active carbon[28–30], alkali metal fluoride[29,31], or γ-rays[32] have been used as catalysts for the polymerisation of perfluorinated oxides. The polyethers from perfluoro(epoxypropane) have the composition:

$$F-[C_3F_6O-]_x-\underset{CF_3}{\underset{|}{CF}}-COF.$$

To increase the stability of this polyether [30] or of the copolymer of perfluoroepoxypropane with epoxytetrafluoroethylene [33], the terminal –COF groups are decarboxylated. To do this, the polyether with terminal functional groups is treated with elemental fluorine and if double bonds are present ultraviolet light is used, which leads to doubling of the molecular weight of the polyether. If the ammonium salts of these acids are decarboxylated the polyethers will also contain rather stable $-CF_2H$ terminal groups [34].

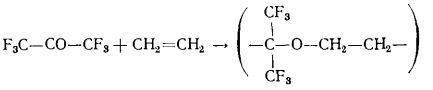
Fluorine-containing thio-oxides form homopolymers or copolymers in the presence of initiators of the radical type or under the action of ultraviolet radiation [35]. Fluorine-containing polythia-compounds exhibit increased fire resistance and chemical stability, and can also be used as plasticisers, for example, for poly(tetrafluoroethylene).

The polyethers from perfluoro(epoxypropane) exhibit extremely valuable properties [21] and are greatly superior to their non-fluorinated analogues. They are insoluble in various solvents, resistant to the action of oxidants such as O_2, O_3, and Cl_2 up to 250°C; stable to radiation, which distinguishes them favourably from poly(tetrafluoroethylene); incombustible, and of low toxicity. Liquid polyethers retain their viscosity over a wide range of temperatures and are used as lubricants. These polyethers withstand heating up to 410°C and low-molecular-weight polyethers can even be distilled at 490°C without decomposition. Films of fluorinated polyethers exhibit satisfactory mechanical strength and do not lose their elasticity at –80°C [36]. Attempts to use these polymers for obtaining rubbers were unsuccessful since no reliable methods for their vulcanisation have yet been discovered. The copolymerisation of perfluoroepoxyalkanes and perfluorodiepoxyalkanes (the preparation of the first representatives of fluorine-containing diepoxides and their polymers has been mentioned [37,38]), or the cross-linking of polyether macrochains at the stage of the decarboxylation of the terminal groups can probably be used for this purpose.

3. Copolymerisation of oxides and alkenes. Copolymers of fluorinated oxides and non-fluorinated alkenes are interesting. Perfluoroepoxyalkanes readily form block-copolymers with non-fluorinated vinyl monomers (styrene, butadiene, isoprene, methyl methacrylate, etc.) in the presence of alkali metals or their complexes with aromatic compounds [39]. Block-copolymers exhibit increased resistance to the action of organic solvents, increased impact strength, fire resistance, and low gas permeability. Fluorine-containing polyethers can also be obtained by the copolymerisation of non-fluorinated oxides, for example, ethylene oxide and highly fluorinated alkenes (perfluoropropene, chlorotrifluoroethylene) in the presence of peroxide initiators or on irradiating a mixture of monomers with ultraviolet light [40]. Copolymers soluble in organic solvents are formed thereby, and their composition and properties can be regulated readily by means of the composition of the initial mixture of monomers. Unlike poly(ethylene glycol), when exposed to the action of sulphuric acid at 150°C, the above copolymer is stable under these conditions.

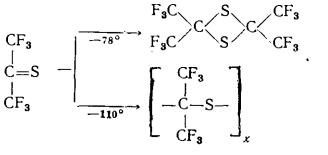
4. Polymerisation of ketones or thioketones and their copolymerisation with alkenes. The carbonyl groups of aldehydes and ketones are usually stable to the action of free radicals, although in some instances such reactions have been effected [41,42]. However, fluorinated ketones, the carbonyl group of which is under the inductive influence of electron-withdrawing perfluoroalkyl radicals, are capable of adding compounds of the R–H type at the carbonyl group under conditions for free-radical processes [43]. The carbonyl group of fluorinated ketones is reminiscent of the weakly polarised double bond of alkenes, which facilitates their participation in reactions which take place according to a free radical mechanism in comparison with non-fluorinated analogues. In the presence of t-butyl peroxide, hexafluoroacetone is capable of adding either simple low-molecular-weight substances (hydrocarbons, ethers, aldehydes, etc.) or high-molecular-weight compounds, for example, polyethylene [43]. It is noteworthy that fluorinated ketones are readily broken down into radicals under the influence of ultraviolet light. The least stable of them under these conditions is evidently hexafluorocyclobutanone. Even at room temperatures this loses the carbonyl group, being converted into perfluorocyclopropane [44]. At low temperatures hexafluorocyclobutanone polymerises in the presence of sodium acetate with the formation of a linear polyether.

Alkenes are readily copolymerised with hexafluoroacetone in the presence of peroxide initiators [45,46]:



Such copolymers exhibit reduced combustibility and water-repellant properties and can be used as protective coatings on metals. The copolymer of ethylene and hexafluoroacetone is sufficiently thermostable. When the copolymer has 11% hexafluoroacetone its loss in weight at 400°C is 1.5%, that at 470°C is 8.7%. The copolymer is readily formed into films [45]. Not only alkenes can undergo copolymerisation with polyfluorinated ketones, but also several other substances which do not form homopolymers (CO, SO_2, etc.). Such copolymers can be used for protecting metals, as adhesives for sheet materials, and for increasing the elasticity of polymers [47]. Polymeric fluorinated ketones copolymerise with polyalkenes, polyethers or polyamides, in the presence of peroxide initiators, improving the fire-resistance, adhesion, and dye receptivity of the latter [48]. However, nothing has been published on the possibility of vulcanising these copolymers.

Fluorine-containing thioketones readily undergo polymerisation both in the presence of special catalysts (boron trifluoride–diethyl ether, dimethylformamide, benzthiols [49,50], aluminium or titanium isopropoxides [51]) and without them [52]. The course of the reaction is greatly affected by the temperature. In the presence of dimethylformamide a dimer is formed from hexafluoroacetone at –78°C, whereas at –110°C the sole product of the reaction is a polymer of linear structure:



Thioketones with 5–10 carbon atoms polymerise with difficulty, forming dimers or liquid products. With decrease in the number of carbon atoms in the thioketone the polymerisation is facilitated and solid, high-molecular-weight polymers with comparatively moderate melting

points are formed. The polymers of fluorinated thioketones are of low stability: their depolymerisation takes place at −78°C [51,53] or at room temperature [50]. However, in some instances their stability is high, which allows elastic films or fibres, resistant to the action of solvents, to be obtained from them [49,52].

Hexafluoroacetone readily forms addition compounds of 1:1 composition with alkenes having an allyl hydrogen atom [54], which made possible the modification of natural polyisoprene [54] and other polydienes, such as polybutadiene and neoprene [55], with hexafluoroacetone. After such treatment the fluorine content of the polymer is 43%.

5. Polymerisation of aldehydes and thioaldehydes. Fluorine-containing aldehydes of the R_f-COH type polymerise extremely readily both in the presence of various catalysts or initiators and without them. For this reason it has been impossible to determine the precise boiling point of thioacetaldehyde, as this polymerises during distillation [56,57]. The polyether formed as a result of the spontaneous polymerisation of the fluoral melts at ~50°C and depolymerises on heating. During a more detailed investigation of the conditions for the polymerisation of fluorinated aldehydes certain regularities were found [58]. In the polymerisation of the lower aldehydes peroxide initiators were more active than acid catalysts (H_2SO_4, Ac_2O). The higher fluorinated aldehydes polymerise more easily under the action of acid catalysts.

The structure of poly(fluoroaldehydes) is that of substituted poly(oxymethylenes) with terminal hydroxyl groups. Their thermal stability can be enhanced by replacing the terminal hydroxyl groups by halogen [59]:

$$HO-\underset{R_f}{CH}-\left[O-\underset{R_f}{CH}\right]_x OH + SOCl_2 \rightarrow Cl-\underset{R_f}{CH}-\left[O-\underset{R_f}{CH}\right]_x-Cl$$

Polyaldehydes containing fluorine and chlorine atoms, for example, poly(chlorodifluoroacetaldehyde), are less stable to the action of elevated temperatures than poly(perfluoroaldehydes) [60] and are depolymerised even at 180°C, forming the monomeric aldehyde.

Poly(fluoroaldehydes) can be used as coatings for metals. They are insoluble in organic solvents, oligophobic and hydrophobic, and do not decompose in contact with fuming nitric acid, or boiling alkalis, but break down in boiling sulphuric acid. Their depolymerisation was observed at 380−400°C, but other studies gave a considerably lower depolymerisation temperature [57,60].

Copolymers of formaldehyde and fluorinated aldehydes are very interesting. The copolymerisation of these monomers proceeds at low temperatures in the presence of quaternary ammonium salts [61]. After protection of the terminal hydroxyl groups a sufficiently stable polymer, which exhibits good mechanical properties in the temperature range from −78° to +200°C, is obtained.

Fluorine-containing polythia-compounds can be obtained readily by the polymerisation of such fluorine-containing thiocarbonyl compounds as thioaldehydes or thioacyl halides. In certain instances the polymerisation of these compounds proceeds spontaneously [62]. Thiocarbonyl fluoride is the simplest monomer which can be used for this purpose. It can be polymerised both by anionic [63,64] and by free-radical [65] mechanisms. Dimethylformamide [50,63], titanium or aluminium isopropoxides [63,64], and boron trifluoride−diethyl ether [50] have been used as catalysts for the polymerisation of thiocarbonyl compounds. Ultraviolet light [65,66] or organoboron compounds in conjunction with oxygen or oxidants [65] can be initiators of the free-radical polymerisation of fluorothiocarbonyl compounds.

Poly(thiocarbonyl fluoride) with $M = 2000-5000$ is formed even on storage of the monomer [50]. In the presence of catalytic amounts of dimethylformamide at −78°C thiocarbonyl fluoride is readily converted into a polymer of structure $[-CF_2-S-]_x$. The initiation of the anionic polymerisation of thiocarbonyl fluoride, chain growth, and chain breaking can be represented by the following scheme:

$$CF_2=S \xrightarrow{\text{solvent}} (CF=S)^+ + F^- + CF_2=S \rightarrow CF_3-S^-;$$
$$CF_3-S^- + CF_2=S \rightarrow CF_3-S-[CF_2-S]_x-CF_2-S^-;$$
$$CF_3-S-[CF_2-S-]_x CF_2-S^- \rightarrow CF_3-S-[CF_2-S]_x-CF=S + F^-.$$

This polythia-compound contains terminal thiocarbonyl groups −CF=S and a small number of −CF=O carbonyl groups, observable in the infrared spectrum of the polymer [50]. The value of the characteristic viscosity, measured for a 0.1% solution of the polymer in chloroform, varied from 3 to 6 [50,64], and the molecular weight, determined by an osmometric method, reached 300 000−400 000 [67]. Poly(thiocarbonyl fluoride) is an elastic and hard polymer, m.p. ~35°C, glass point −118°C, decomp. temp. 175°C. It can readily be formed into films (σ = 770 kgf cm^{-2}, ϵ = 90%). This polymer is stable to the short-time action of boiling nitric acid and boiling solutions of alkalis. Under the action of amines, poly(thiocarbonyl fluoride) is destroyed very rapidly [63]. Alkali brings about the slow destruction of this polythia-compound by acting on the terminal groups. The ability of the polymer to withstand high temperatures and alkalis can be considerably increased by conversion of the terminal thiocarbonyl groups into trifluoromethyl groups. To do this the polymer is treated with antimony(V) fluoride [50], after which the resistance of the polymer to the action of amines is also increased:

$$CF_3-S-[CF_2-S]_x-CF=S \xrightarrow{SbF_5} CF_3-S-[CF_2-S-]_x-CF_3$$

Another method of increasing the stability of this type of polythia-compound to the action of heat or amines is the copolymerisation of thiocarbonyl fluoride with certain halogenated thioacyl fluorides [63], for example, with CHFCl−CF=S. It is interesting to note that the homopolymers of thioacyl fluorides [51] are destroyed by alkalis even at room temperature [50].

The higher fluorinated thioaldehydes readily polymerise with the formation of liquid or solid high-molecular-weight compounds [68]. Crystalline polythia-compounds with branched fluorinated radical, which reduces their solubility in organic solvents, were obtained in the polymerisation of fluorinated thiobutyraldehyde [69]:

$$(CF_3)_2CF-CHS \rightarrow \underset{\underset{CF(CF_3)_2}{|}}{[-CH-S-]_x}$$

The decomposition temperature of this polymer is ~200°C.

A series of copolymers of fluorinated thiocarbonyl compounds with other monomers has been obtained. Elastomers which do not crystallise at low temperatures are formed in the copolymerisation of thiocarbonyl fluoride with various alkenes [70] (ethylene, but-2-ene, styrene, butadiene, vinyl fluoride). These copolymers are more resistant to thermal destruction and are fabricated more readily. Copolymers of thiocarbonyl fluoride are extremely resistant to the action of concentrated nitric acid [66]. To reduce the tendency towards crystallisation of poly(thiocarbonyl fluoride) it was copolymerised with a thioacyl fluoride in the presence of catalytic amounts of aluminium or titanium alkoxides [71].

5. Aromatic polyethers and polythia-compounds. In the preparation of *p*-trifluoromethylphenol it was noted that in an alkaline medium in the cold it is converted into a polymer of structure $[-CF_2-C_6H_4-O-]_x$ [72]. Potassium perfluoro-*p*-tolyl oxide was more stable under these conditions; its polycondensation in the cold was very slow. At elevated temperatures a polyether with $M = 1500-3000$ is formed[73]:

$$CF_3-C_6F_4-OK \rightarrow [-CF_2-C_6F_4-O-]_x$$

Such a structure was attributed to the polyether from the ^{19}F NMR spectra. This polyether melts at ~100°C and starts to decompose at ~300°C.

A number of aromatic polyethers are of great interest. The tendency of perfluorinated aromatic compounds to undergo nucleophilic substitutions has been utilised for their preparation. When hexafluorobenzene is heated with alkalis, alkali metal pentafluorophenoxides are formed and on further heating they are converted into polyethers:

$$C_6F_5OK \rightarrow C_6F_5\ O-[C_6F_4-O-]_x-C_6F_4-OK$$

The softening temperature of poly(perfluoro-*p*-phenylene oxide) with $M \simeq 12\,000$ exceeds 100°C.[74]

Poly(perfluoro-*p*-phenylene sulphide), which melts at temperatures above 300°C, was obtained by the same scheme. Its structure is clearly shown by its desulphidation on Raney nickel, which gives only 1,2,4,5-tetrafluorobenzene (structural units) and a little pentafluorobenzene (terminal units).

However, the thermal stability of these polyethers and polythia-compounds was less than that of their non-fluorinated analogues. A similar relation was also noted in investigating the thermal destruction of the perfluoropolyphenylenes[75]. Evidently, the introduction of fluorinated phenyl nuclei into the chains of the polymers does not give a product more stable thermally than its non-fluorinated analogue. The presence of terminal hydroxyl or phenoxide groups should also facilitate subsequent processes which are accompanied by the release of alkali metal fluorides or of hydrogen fluoride.

B. Carbochain Polyethers and Polythia-compounds

There have been many publications, mainly patent specifications, describing polyethers obtained by the polymerisation of vinyl or allyl ethers and also of glycide ethers, that is, polyethers in which the oxygen atoms are in side-chains. Fluorine atoms were introduced into the alkyl (aryl) or vinyl part of these monomers or in both parts simultaneously.

1. Polymers and copolymers of fluoroalkyl vinyl or allyl ethers. This section will consider polymers made from monomers of structure $R_f-O-CH=CH_2$ or $R_f-CH_2-O-CH=CH_2$. The polymerisation of the non-fluorinated double bond of this type of monomer can be brought about by initiators of free-radical processes or catalysts of ionic type. The ability to polymerise under conditions of free-radical initiation depend on the structure of the original monomer. Perfluoroisopropyl allyl ethers[76] or $\alpha\alpha$-dihydroperfluoro-*n*-alkyl vinyl ethers[77] can be polymerised in the presence of benzoyl peroxide or ultraviolet light, whereas pentafluorophenyl vinyl ether does not polymerise[78] in the presence of free-radical initiators. It is noteworthy that the polymerisation of fluoroalkyl vinyl ethers has been studied insufficiently. There have been contradictory statements about the ability of peroxide initiators to bring about the polymerisation of some of these monomers[79]. In recent studies it has been noted[80] that the catalysts mentioned in earlier studies are either inactive generally or exhibit a very low activity.

In this respect fluoroalkyl vinyl ethers are reminiscent of their non-fluorinated analogues, which under the action of light or of initiators of the free-radical processes are slowly polymerised with the formation of low-molecular-weight products.

Catalysts of the Friedel–Crafts type are more effective for the polymerisation of fluoroalkyl vinyl ethers (as for their non-fluorinated analogues. Aluminium chloride[78], boron trifluoride–diethyl ether[77,80-82], or gaseous boron trifluoride[78,80] at low temperatures have been used as such catalysts. The polymerisation rate and the molecular weight of the polymer depend on the type of catalyst. Evidently, the most active is gaseous boron trifluoride; when this is used, trifluoroethyl vinyl ether is polymerised very rapidly with the formation of a high-molecular-weight product, whereas with boron trifluoride–diethyl ether the polymerisation is slow and a low-molecular-weight polyether is formed [80].

The presence of fluorinated substituents as side-chains confers a series of valuable properties upon the polymer: fire resistance, water- and oil-repellance, which enables it to be used as protective coatings for metals, cloth, paper, etc. An extremely interesting property of such polyethers, especially polyethers obtained from monomers with branched fluorinated radicals, is the extremely small critical surface tension for wetting. For example, for poly(heptafluoroisopropyl vinyl ether) $\gamma_w = 14.2$ dyne cm^{-1} [79]. It has been proposed to use a series of fluorine-containing polyethers as adhesives, like their non-fluorinated analogues[77].

Copolymers of fluoroalkyl vinyl ethers with various vinyl monomers are interesting. The copolymerisation can be carried out blockwise, in emulsion, or suspension in the presence of initiators of free-radical polymerisation[83]. Lauryl peroxide[84] or redox systems based on ammonium persulphate[85-87] have been used as polymerisation initiators. Usually, in the copolymer there is a smaller amount of the fluoroalkyl vinyl ether than there was in the monomer mixture[84]. The presence of polyfluoroalkoxide substituents in the copolymer chain increases the plasticity of the polymers. Copolymers of trifluoroethyl vinyl ether and tetrafluoroethylene can be fabricated into articles by the usual methods[85]. The introduction into the polyvinyl chloride chain of this same monomer increases its thermal and chemical stability which allows these copolymers to be used for protective coatings for metals[85]. Even small quantities of trifluoroethyl vinyl ether give its copolymers with vinyl chloride and other vinyl monomers increased thermal stability and improve their resistance to attack by solvents[84,86]. The use of these monomers for the preparation of special-purpose rubbers can be extremely promising. Copolymers of perfluorobutadiene and poly(fluoroalkyl vinyl ethers) compounded with carbon black are readily vulcanised with the formation plastics which withstand oil and petrol. Their resistance to oxygen at high temperatures is higher than that of rubbers based on copolymers of non-fluorinated butadiene and acrylonitrile[87]. Vinyl ethers, especially those which also contain other functional groups, for example, the ethylvinyl ether of 2-*N*-ethylperfluorooctanesulphonamide are used for the special treatment of fabrics to confer on the latter resistance to oil and water[88].

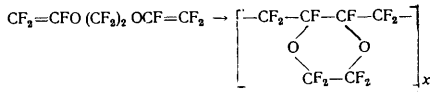
3. Polymers and copolymers of alkyl-perfluorovinyl and allyl ethers and sulphides. Unlike vinyl ethers with a non-fluorinated double bond, perfluorovinyl ethers are readily polymerised in the presence of initiators of free-radical processes. The following initiators were used for the polymerisation of these monomers: benzoyl peroxide[89], γ-radiation[90], or tetrafluorohydrazine[91]. Perfluorovinyl sulphides do not polymerise in the presence of benzoyl peroxide[89]. In the general case the ability of these monomers to polymerise decreases in the order[90]:

$$R_f{-}CH_2{-}O{-}CF{=}CF_2 > R_f{-}O{-}CF{=}CF_2 > R_f{-}S{-}CF_2{=}CF_2 .$$

The molecular weight of the polymers changes in the same order. It is noteworthy that the sulphides $R_f{-}S{-}CF{=}CF_2$ not only polymerise badly themselves but also inhibit the polymerisation of other vinyl monomers[90], probably because of capture of the electron by the vacant orbital of the sulphur atom. Polyethers of fluorine-containing allyl ethers were obtained from the corresponding monomers in the presence of persulphates[92]. They are used as adhesives for attaching halogenated polymers to metals.

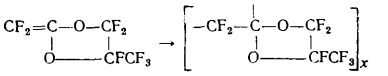
Alkyl- and polyfluoroalkyl-perfluorovinyl ethers are readily copolymerised with various vinyl monomers[93] to form liquid or solid copolymers[89]. High-melting copolymers of perfluoromethyl vinyl ether with tetrafluoroethylene can be converted into articles by the usual methods, for example, into stiff colourless and transparent films[90,91]. High-molecular-weight copolymers are formed when perfluoropropyl vinyl ether and tetrafluoroethylene are polymerised together[94,95]. The preparation of copolymers with various fluorine-containing alkenes is of interest for the production of elastomers with increased thermal stability and excellent resistance to frost. For example, a copolymer of vinylidene fluoride and perfluoroethyl vinyl ether, strengthened with magnesium oxide and hexamethylenediamine, retains its flexibility at $-25°C$ and its loss in weight after 200 h at 288°C totalled 10%[96]. Such materials were proposed for use for fuel cells and diaphragms working in contact with liquid fuel.

Perfluorinated bisvinyl ethers of the type $CF_2{=}CFO[CF_2]_n{-}OCF{=}CF_2$ are polymerised or copolymerised with fluorine-containing alkenes block-wise, in solution, or suspension in the presence of peroxide-type initiators. These monomers are interesting because their polymerisation can be effected at one vinyl group and then the fore-polymer obtained is converted into a cross-linked product by subsequent polymerisation in moulds[97]. In the polymerisation of such monomers ($n = 2$) in the presence of peroxides, for example, peroxides of the $(C_3F_6O_2)_x$ type[98], polyethers with rings in the chain are formed[99]:

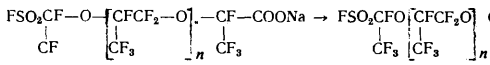


these exhibit high chemical stability and good electrical insulating properties. They are thermoplastic and can be extruded or cast under pressure. These polyethers withstand boiling nitric and sulphuric acids and boiling alkali solutions. Perfluorodivinyl ethers copolymerise with perfluoroalkyl vinyl ethers or perfluoroalkenes to give a fore-polymer. After additional polymerisation a rigid, chemically inert material is obtained[100].

The polymerisation of perfluoro-4-methyl-2-methylene-1,3-dioxolane in the presence of tetrafluorohydrazine gave a polymer with unusually high gas permeability[101], which allowed it to be used for the separation of many gases:

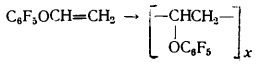


Perfluorovinyl ethers with several ether bonds are obtained by the pyrolysis of the alkali salts of carboxylic acids[102]:

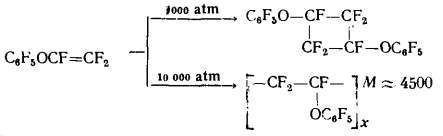


Polymers or copolymers of these vinyl ethers with vinylidene fluoride are plates or elastomers.

Of the fluorine-containing vinyl ethers, that with the least ability to polymerise is probably the phenyl vinyl ethers. Pentafluorophenyl vinyl ether[103] and its derivatives which contain a single hydrogen atom in the vinyl group[104] can be polymerised in the presence of Friedel-Crafts type catalysts. The molecular weights of these polymers are low (2300–17 000), and their melting points lie in the range 120–180°C.



Phenyl perfluorovinyl ethers[105] or perfluorophenyl vinyl ethers[106] are polymerised with difficulty even at 230°C after 10 days[107], the yield of polymers with characteristic viscosity 0.03 totalling 2–3%. However, on irradiation of these monomers with γ-rays at high temperatures a polyether soluble in perfluorobenzene and of increased thermal stability could be obtained in 6–7% yield. These monomers were polymerised by using high pressure (10 000 – 15 000 atm [106]) since at a pressure of 1000 atm dimers are formed exclusively:



3. Polymerisation and copolymerisation of glycide ethers. Fluoroalkyl glycide ethers became available monomers after the ability of perfluoroketones to react with alkali metal fluorides to form alkoxides of perfluoroalcohols had been observed. When the latter react with epichlorhydrin or epibromohydrin they are converted into the corresponding glycide ethers[109,110]. Glycide ethers based on hexafluoroacetone are polymerised in the presence of catalytic amounts of water and diethylzinc at $-70°C$ [109], whereupon a highly elastic polymer with $M \simeq 84\,000$, insoluble in ordinary and soluble in fluorinated solvents is formed[110]. The glass point and decomposition temperature of these polymers are $-43°$ and $+270°C$ respectively. When the glycide ethers are polymerised in the presence of boron trifluoride–diethyl ether, low-molecular-weight liquid products were isolated. Homopolymers and also copolymers of these monomers with the oxides of other alkenes are used for obtaining resins, coatings, adhesives, and also for special treatment of fabric to confer oil- and water-repelling properties upon it. For impregnation of overalls, glycide ethers of pyrans are also used[111], the polymerisation of which is effected in the presence of iron(III) chloride. Thermoreactive resins are obtained from glycide ethers, the molecules of which contain an additional vinyl group[112].

These resins were hardened by using amines, for example, diethylenetetramine. Perfluorinated epoxyalkenes of structure

$$CF_2=CF[CF_2]_n-CF-CF_2$$
$$\qquad\qquad\quad \backslash O /$$

are of considerable interest[113]. Monomers of this type can be polymerised or copolymerised with various fluorinated alkenes or their oxides to form polyethers capable of being hardened by polymerisation of the second functional group. These polymers have high thermal and chemical stability and can be used to obtain fibres, films, and moulded articles.

4. Modification of celluloses by fluoride-containing compounds. There have been descriptions of attempts to introduce fluorine atoms into cellulose or manufactured articles made on its basis. Attempts were made to introduce isolated fluorine atoms into cellulose by the action of the tosyl ethers of alkali metal fluorides upon it[114]. This method gives good results with several of the simplest esters of toluenesulphonic acids, but only small quantities of fluorine could be introduced into cellulose by this method. A method based on reactions of nucleophilic addition of alcohols to perfluoroalkenes, for example, to perfluoropropene, was more effective[115]. In alkaline medium cellulose reacts with perfluoropropene to form ethers of the $R-O-CF_2-CFH-CF_3$ type and a certain amount of ethers of the $R-O-CF_2-CF=CF_2$ type, products of the substitution of fluorine atoms in the allyl position. The ether bonds of such types were stable in acid and alkaline media, probably because of the increase in the hydrophobic nature of such fluorine-containing polymers. Up to 13% fluorine could be introduced into cellulose by this method and the polymer itself acquired water-repelling properties. Other fluorinating media can be used for introducing fluorine atoms, for example, sulphur tetrafluoride[116]. This fluorinating agent readily replaces hydroxyl, carbonyl, or carboxyl groups by fluorine atoms with the formation of C–F, CF_2, or CF_3 groupings respectively. This method is suitable for making paper or cardboard water-repellent.

III. POLYESTERS

Nonfluorinated polyesters are readily formed in reactions between dicarboxylic acids and diols or polyols. In several instances re-esterification between the dimethyl or other diethers of dicarboxylic acids and diols has been used successfully. In certain instances (mainly in working with diols with increased acidic properties, for example, with various bisphenols) acyl halides of dicarboxylic acids are used. Polyesters are interesting for obtaining fibres, films, etc. or are intermediates for further syntheses, for example, for obtaining polyurethanes, etc.

In comparison with carboxylic acids their fluorinated analogues are stronger. The dissociation constant of acetic acid is 1.8×10^{-5}, whereas that for trifluoroacetic acid is several orders of magnitude greater (5.9×10^{-1}). This strengthening of the acidic properties is due to the inductive influence of the electron-withdrawing fluorinated radical. A similar effect of fluorinated radicals is seen in the acidic properties of fluorine-containing alcohols. Alcohols with the $-CF_2OH$ grouping are unknown. Alcohols with $-CF_2CH_2OH$ groups are completely stable. They are obtained in the telomerisation of tetrafluoroethylene and methanol (monohydric alcohols) or in the reduction of diesters of perfluorodicarboxylic acids (diols). The acidic properties of 1,1-dihydroperfluoro-alcohols are comparable with those for phenols. Therefore the direct esterification of such alcohols is difficult. To obtain esters under such conditions the anhydrides or acyl halides of fluorinated or non-fluorinated carboxylic acids are used.

The polyethers obtained from dicarboxylic acids and diols and also the polyesters made by the polymerisation of unsaturated esters are of practical interest. Both types of fluorine-containing polyester will be considered below.

A. Heterochain Polyesters

The available aliphatic fluorine-containing dicarboxylic acids at present are perfluoroadipic and perfluoroglutaric acids. They are obtained by the oxidation of dichlorooctafluorocyclohexene or dichlorohexafluorocyclopentene respectively. The electrochemical fluorination of dicarboxylic acids to perfluorodicarboxylic acids is extremely promising. Despite the comparatively low yields of valuable products (up to 20%) the electrochemical fluorination is simple and allows the process to be effected in a single stage. The preparation of the higher perfluorodicarboxylic acids is extremely difficult, which hinders the investigation of these products as monomers at present. Dimethyl or diethyl perfluorodicarboxylates are readily reduced to $\alpha\alpha\omega\omega$-tetrahydroperfluoroglycols of the type $HOCH_2[CF_2]_nCH_2OH$. Diols with $n = 3$ and 4 were used to obtain polyesters.

1. Polyesters from dicarboxylic acids and diols. Fluorine-containing polyesters have been studied in sufficient detail for some of them to be put into industrial production, whereas poly(thioesters) have hardly been investigated at all. The preparation of poly(thioesters) from the anhydrides of perfluorodicarboxylic acids and of non-fluorinated dithiols have been mentioned in the literature, but the properties of the polymers were not given[117].

Fluorine-containing polyesters can be obtained by all the methods employed for the preparation of their non-fluorinated analogues. However, high molecular weights could not always be attained. Polyesters with moderate molecular weights are readily formed from the anhydrides of perfluorodicarboxylic acids and fluorinated diols[118]. High-molecular-weight polyesters also could not be obtained by heating the disilver salts of perfluorodicarboxylic acids with $\alpha\omega$-polymethylene di-iodides[119] or by the esterification of non-fluorinated diols with perfluorodicarboxylic acids[119].

Best results were obtained on using the bisacyl chlorides of perfluorodicarboxylic acids. When the latter were heated with fluorinated diols polyethers with molecular weights up to 17 000 could be obtained[120]. Polyethers with even higher molecular weights are formed on using bis(acyl chlorides) of non-fluorinated dicarboxylic acids[121]. Polyesters can be obtained by re-esterification between the dimethyl esters of non-fluorinated dicarboxylic acids and fluorinated diols. Alkali metal alkoxides, metal oxides, and strong acids have been used as catalysts for the re-esterification[122]. The second stage (polycondensation) takes place at 200–300°C in the presence of catalytic amounts of oxides of Sb, Bi, Ti, or Mg.

Aliphatic or aromatic dicarboxylic acids can be used as the acidic constituent. Aliphatic dicarboxylic acids form low-melting or liquid polyesters[117-120], which exhibit high thermal stability and elasticity at low temperatures. Their glass points lie in the range from −30° to −57°C. Such polyesters are capable of being cross-linked at the stage of their preparation with polyols (glycerol)[120], or at the stage of subsequent retreatment with peroxides or calcium carbonate[121], or by other functional groups, for example, hydroxyl groups, found in the dicarboxylic acid molecule[122]. One of the most valuable polyesters of this type is poly(hexafluoropentamethyleneadipate). The oil- and petrol-resistant rubbers from this polyester, which exhibit good low-temperature characteristics, are produced on an industrial scale[123,124]. They can be used at temperatures from −72° to +150°C. Despite the fact that their mechanical properties are not outstanding (σ = 160 kgf cm^{-2}, ϵ = 120−230%), these rubbers have found practical application in the aviation industry.

Attempts have been made to increase the thermal stability of aliphatic polyethers by using terephthalic acid in place of part of the adipic acid. The resistance of low-molecular-weight polyesters ($M \simeq 1800-2700$) to heating was improved to some extent by replacing 30% of the adipic acid by terephthalic. The other properties of the polyesters changed insignificantly[125]. A further increase in the proportion of terephthalic acid leads to an increase in the melting points of the mixed polyester and a deterioration in its low-temperature characteristics[126]. Polyesters based on terephthalic acid and fluorinated diols are plastics themselves; they are readily soluble in organic solvents and are used as heat-resistant protective coatings or as cast resins[127].

In certain instances, when both the acid and diol are fluorinated, it is desirable to introduce a certain proportion of non-fluorinated diol or non-fluorinated hydroxy-acid into the polyester. These additions favour an increase in the molecular weights of the polyesters[128].

All the aliphatic fluorine-containing polyesters undergo hydrolysis to a considerable extent. Their hydrolytic stability is considerably less than that of their non-fluorinated analogues.

2. Polyesters from fluorinated aromatic dicarboxylic acids. Nothing has been published about polyesters obtained from aromatic dicarboxylic acids having fluorinated phenyl nuclei. Only the use of fluorophthalic anhydride for the preparation of glyptal resins has been described[129]. Evidently, the use of fluorinated aromatic dicarboxylic acids for the preparation of polyesters does not lead to an increase in their thermal and hydrolytic stabilities. The fluorine atoms, like those of any other halogen, will be comparatively easily displaced by nucleophilic agents under the influence of electron-withdrawing carboxyl groups even during the preparation of polyesters at 150−200°C. Furthermore, fluorinated aromatic acids themselves are readily decarboxylated on heating. Pentafluorobenzoic acid starts to decompose even at 190°C, and tetrafluoroisophthalic acid is decarboxylated at 203°C [130].

There is also considerable interest in aromatic dicarboxylic acids in which the fluorine atoms are not in the phenyl nuclei but in the side-chains. The acids of this type are devoid of the above drawbacks. Their thermal and chemical stabilities should be close to those for benzoic and terephthalic acids. The recently synthesised dicarboxylic acids of the type $HOOC-C_6H_4[CF_2]_n-C_6H_4COOH$ [131,132] and acids of the type $HOOC-C_6H_4-C(CF_3)_2-C_6H_4COOH$ can be regarded as promising monomers for the preparation of fluorine-containing polyesters. The latter acids have already been used for the preparation of polyesters[133]. The diols were aliphatic fluorinated diols or bisphenols of aromatic or aliphatic−aromatic series. The bis(acyl chlorides) of the dicarboxylic acids and bisphenols form polyesters (polyarylates) under interphase polycondensation conditions[134]. Table 1 gives certain properties of the fluorine-containing polyarylates with those their non-fluorinated analogues for comparison. As Table 1 shows, the replacement of methyl groups at the central atom of the bisphenol by trifluoromethyl groups leads to some increase in the thermal stability of the polyesters. Fluorine-containing polyarylates exhibit greater elasticity than their non-fluorinated analogues and are readily converted into films with satisfactory strength characteristics. Their breaking strength reaches 700−1000 kgf cm^{-2} and the elongation is 30−70%. Polyesters made from bisphenols fluorinated in the aromatic nucleus decompose at ~300°C [140].

A detailed study of the kinetic features of the thermal degradation of polyesters based on adipic, fumaric, or terephthalic acid and octafluorohexane-1,6-diol was made at 260−420°C. The replacement of part of the adipic acid by isophthalic acid in the preparation of the polyesters, or the use of fumaric acid, did not lead to an improvement in the thermal stability of the polyester[141]. A considerable increase in the thermal stability was noted for polyesters based on terephthalic acid. The release of volatile degradation products was observed here at 360−380°C, whereas polyesters from aliphatic acids released gaseous products at much lower temperatures (220−260°C). It is interesting to note that the hydrogen fluoride or silicon tetrafluoride formed in the reaction of the latter with glass were not observed in the degradation products[142]. The temperature for the start of the degradation of the fluorine-containing polyester based on terephthalic acid exceeds these values for poly(chlorotrifluoroethylene) and copolymers of vinylidene fluoride with chlorotrifluoroethylene or perfluoropropene and also for poly(ethylene terephthalate) for which degradation in nitrogen atmosphere was observed even at 280−320°C. A similar series of relations was also found for the degradation of fluorine-containing polyesters in the presence of oxygen[143], but the temperatures at which the polymer loses 25% of its weight in oxygen atmosphere is lower than for the same temperatures in a vacuum.

3. Polyesters based on carbonic acid (polycarbonates). Non-fluorinated polycarbonates have found application for the production of fibres, films, etc. There have been few studies of fluorinated polycarbonates. Aliphatic fluorine-containing polycarbonates were made from octafluorohexane-1,6-diol and octafluorohexamethylenebis(chloroformate) in the presence of an acceptor of hydrogen chloride[144]. This polycarbonate has a lower melting point than its non-fluorinated analogue, but it is 7−8 times more resistant to heating and hydrolyses somewhat more slowly in acid medium than the same non-fluorinated polycarbonate. Mixed polycarbonates of hexafluoropentane-1,5-diol and 2,2-bis-(*p*-hydroxyphenyl)-propane exhibit high chemical stability, good dielectric and water-repellant properties, and low coefficients of friction[145]. Polycarbonates from fluorinated aromatic bisphenols are obtained by interfacial polycondensation. Some improvement in the physicochemical characteristics of polycarbonate can be brought about by the introduction of individual fluorine atoms into the aromatic nuclei of the

bisphenol. For example, the replacement of hydrogen atoms by fluorine in the *ortho*-position to the hydroxyl group of 2,2-bis(*p*-hydroxyphenyl)propane improves its Vik heat resistance from 164–166° to 170–175°C, and appreciably increases its volume resistivity in comparison with its non-fluorinated analogue[146,147]. However, the mechanical characteristics of the polymers and their melting points are almost unchanged, although the flame resistance of the fluorinated polycarbonates is improved.

The melting point of a polycarbonate can be raised considerably by substituting fluorine for the hydrogens of the methyl groups in the bisphenol molecule. The polycarbonate based on 2,2-bis(*p*-hydroxyphenyl)-1,1,3,3-tetrafluoro-1,3-dichloropropane melts at 295–315°C [147], whereas the melting point of crystallites of its non-fluorinated analogue is 263°C [147]. Polycarbonates of this type are distinguished by increased heat resistance and low steam permeability.

B. Carbochain polyesters

Methods of preparation and certain physicochemical properties of fluorine-containing polyesters in which the ester grouping is found in the side-chain of the polymer will be considered in this section. Polyesters of this type are of great practical interest. The starting monomers for certain types of carbochain polyesters are now available on an industrial scale. Their polymerisation, further treatment, and vulcanisation is carried out by the usual equipment of the synthetic rubber industry. Oil- and petrol-resistant rubbers with good frost resistance are processed on an industrial scale.

1. Polymers and copolymers of acrylic and methacrylic acids. Non-fluorinated esters of acylic or methacryllic acids are readily polymerised with other vinyl monomers in the presence of initiators of free-radical type. Esters of fluorinated acrylic acid polymerise badly under these conditions. Yakubovich and coworkers[148] explain such a sudden decrease in the activity of these monomers by the presence of a double bond conjugated with a carbonyl group in molecules of the type $CF_2=CF-COOR$, which leads to the formation of radicals of low activity and hinders the homopolymerisation of these esters. In the presence of other non-fluorinated vinyl monomers the esters of perfluoroacrylic acid form copolymers with high molecular weights. The introduction of fluorine atoms into the methyl group of methacryllic acid has little effect on the reactivity of the monomers but somewhat reduces the decomposition temperature of these polymers in comparison with their non-fluorinated analogues[149].

There is great interest in polymers obtained from esters of acrylic acid and fluorinated alcohols. These monomers readily polymerise spontaneously[150] or in the presence of various initiators: the light of an incandescent lamp[151], benzoyl peroxide[150,152,153], the lauryl[150] or acetyl[150] radicals, azoisobutyronitrile[150], ultraviolet light[150,154], high-energy electrons[155], hydrogen peroxide[152], aqueous solutions of potassium[151,152,156,157] or sodium[151,158,159] persulphate in the presence of various emulsifiers. The polymerisation of 1,1-dihydroperfluoroalkyl acrylates can be effected blockwise, in solution, or in emulsion[160]. Emulsion polymerisation is the most convenient method of polymerisation of such monomers. The molecular weight of the homopolymers reaches 10 000 000. The low-temperature properties, and also their resistance to swelling, depend considerably on the structure of the monomers. The glass points of the fluorine-containing polyesters are higher than those of their non-fluorinated analogues. The glass points in the polyfluoroalkylacrylates depend on the number of difluoromethylene groups in the alcohol residue.

They fall gradually and reach a minimum for the polymer with an alcohol residue with 6 carbon atoms. The polymer with 8 carbon atoms in this residue is already crystalline. It is interesting to note that in the series of non-fluorinated acrylates crystallisation is observed only for those polymers, the alcohol residues of which consist of 14 or more carbon atoms[161]. Nothing has been published on the minimal glass point for non-fluorinated acrylates, but the values for the brittle points[162] suggest that it will be for the polymer with an alcohol residue with 8 carbon atoms. The segment length for 1,1-dihydroperfluorobutyl acrylate, polymerised in the presence of potassium persulphate, has been found to be 15 carbon atoms[163]. This exceeds the values for other elastomers (seven carbon atoms for polyisobutene, eleven for polystyrene), but could not be connected with the glass point.

The frost resistance of fluoroalkyl acrylates was increased by the introduction of an ether bond into the chain of the alcohol residue.[164,165] Side-radicals with an ether bond increase the flexibility of the polymeric chain, playing the part of a plasticiser.

The resistance of these polymers to swelling in organic solvents also depends on the number of fluorine atoms in the alcohol residue and is rather high for a large degree of fluorination of the latter.

The most valuable polymers are those from 1,1-dihydroperfluorobutyl acrylate which have been named 1F4, or polyFBA [166-168], and the polymers from 3-(perfluoromethoxy)-1,1,-dihydroperfluoropropyl acrylate, called 1F2. These polymers were vulcanised by all the methods used for the vulcanisation of polyester rubbers. When the salts, oxides, or hydroxides of bivalent metals are used as vulcanising agent, these polyesters acquire increased mechanical strength. The use of magnesium oxide has maximal effect. In the vulcanisation of fluoroacrylate polyesters by polyamines[165,169,170] the vulcanisate acquires a resistance to the action of high temperatures, mineral acids, and oxygen. The vulcanisation of polyesters by the above agents evidently proceeds by the formation of salt bridges between the carboxyl groups which appear as a result of the hydrolysis of ester groups, and by bivalent metals owing to the formation of amide bridges. Strongly alkaline agents, for example, sodium silicate[165,169], can bring about ester condensation, which also leads to cross-linking of the macro-chain of the polyester.

Certain properties of 1F4 and 1F2 resins are given in Table 2.

Fluorinated rubber of grade 1F4 exhibits high resistance to the action of organic solvents of various classes (aliphatic and aromatic hydrocarbons, chlorinated hydrocarbons, ketones, etc.) which allows them to be used in the chemical industry[171] as coatings, and as liquids in aeroplane hydraulic systems[170]. They can be used at temperatures up to 200°C [168] in fuel and lubricant systems, that is, where copolymers of butadiene and acrylonitrile are unsuitable[166]. 1F2 rubber, which has better frost resistance, can be used in the same branches of technology[172].

A large number of publications, mainly patent specifications, deal with the production of copolymers of 1,1-dihydroperfluoroalkyl acrylates with various vinyl monomers. To obtain copolymers with dienes, block copolymerisation is not very suitable since the polymerisation is complicated by a Diels–Alder condensation[173]. The latter can be avoided by carrying out the copolymerisation in emulsion and in the absence of oxygen. Copolymers with butadiene exhibit increased frost resistance[158,174] (glass point = −75°C), but tend to swell[167]. They are readily vulcanised by the agents listed above, and also by sulphur[151,165,169].

Methods of making copolymers of 1,1-dihydroperfluoroalkyl acrylates with ethyl acrylate[154,175], acrylamide[153], acrylonitrile[153,157], methacrylamide[152], ethylene[176], and trifluoroethyl vinyl ether[159]. The presence in the copolymer of fluorinated groupings confers noninflammibility on the polymer[177], and the joint presence of fluorine and chlorine allows the polymers also to be used as adhesives[178]. Copolymers with methacrylyl chloride are used for the chemical modification of wool[179] and copolymers with butadiene and acrylic acid have been proposed for use as regulators of the combustion of rocket fuel[180].

Elastomeric properties are also exhibited by copolymers of allyl esters of fluorine-containing acids[181]. Polyesters with branched fluorinated radicals[182] and also polyesters the alcohol residues of which contain ester[183], amide[184], or sulphamide[185] groups have been proposed for use for the protection of cloth or leather from the action of solvents, dyes, oil, etc.

Fluorine-containing polyacrylates or polymethacrylates exhibit good water-, oil-, and dirt-repelling properties[186]. The investigation of polymers with fluorinated radicals of various lengths showed that groupings in which the number of fluorinated carbon atoms is less than 5 do not give rise to an oil-repelling effect, whereas increasing the number of these atoms to 8 gives the polyesters superlative oil repellance[187]. On replacing even a single fluorine atom in the ω position by hydrogen, the oil repellence effect disappears completely and the surface tension rises sharply. Thus for polyacrylates with perfluoroalkyl substituents, in the composition of which there are eight carbon atoms[188], γ_S is ~11 dyn cm^{-1}, which is comparable with values of γ_S for perfluorohexan-1-oic acid (8.6 dyn cm^{-1}) and perfluoro-octan-1-oic acid (7.9 dyn cm^{-1}). In investigating copolymers of fluoroalkyl acrylates with non-fluorinated vinyl monomers γ_S increases in proportion to the number of the latter introduced[189]. If the second monomer contains fluorine atoms, then γ_S decreases. Evidently, lateral fluorinated substituents are orientated vertically (in relation to the polymer chain) and packed densely, like the packing in the molecular layers of perfluorocarboxylic acids. The capability for orientation and close packing in the surface layer depends on the length of the fluorinated parts of the chain and on the structure and dimensions of the side-chains as a whole.

The influence of the lateral fluorinated substituents on the formation of ordered (syndiotactic) structure was noted in the investigation of polymers, synthesised from esters of methacrylic acid and fluorinated monohydric alcohols[190]. Polymethacrylic acid obtained after the hydrolysis of such polyesters is found in syndiotactic form. The vinyl esters of fluorocarboxylic acids are readily polymerised by a radical mechanism, and the poly(vinyl alcohol) obtained as a result of hydrolysis contains ~80% syndiotactic diads[190-193].

The value of γ_S is somewhat increased on replacing a linear fluorinated radical by a branched one[194] in those instances when the latter is separated from the chain by several methylene groups but the oil-repelling properties of the polymer disappear[195]. When the branched radical is directly connected with acrylic acid, the γ_S is less[196]. Such polyesters have been suggested for use to give wool oil- and water-repelling properties[197].

The Anomeric Effect

N.S.Zefirov and N.M.Shekhtman

One of the problems of dynamic stereochemistry and conformational analysis—the anomeric effect—is surveyed, and is shown to be a general conformational phenomenon occurring widely in acyclic and heterocyclic compounds. A theoretical discussion is given of the nature of this effect. The bibliography comprises 189 references.

I. INTRODUCTION

At the present time conformational analysis is based, in its most general form, on examination of the energy contributions made by changes in bond angles and lengths, by eclipsed conformations, and by interaction between non-bonded atoms. The energy of the molecule can be written as a sum

$$E_{mol} = E_l + E_p + E_Q + E_V,$$

where E_l is the sum of the energies due to change in bond lengths from the normal to the observed value, E_p the sum of "Pitzer stresses", E_Q the sum of the angular stresses, and E_V the sum of the van der Waals interaction energies of non-bonded atoms. An additive scheme involving all these steric factors enables the conformations of a wide range of compounds to be calculated fairly accurately[1-4].

Quite a large number of cases have now accumulated in the literature in which the stability of the conformations actually observed cannot be explained solely by steric factors. This type of discrepancy is usually regarded as specific to a given grouping, and is often given a special name, e.g. "anomeric effect"[5,6], "the rabbit's-ears effect"[7-10], the Δ^2 instability factor[5,11], etc. In principle these factors can be taken into account by introducing new terms into the expression for the energy of the molecule.

The present paper examines one such effect—the so called "anomeric" effect.

II. HISTORICAL SURVEY

The oxan ring is able to exist as conformational isomers differing in stability. In contrast to cyclohexane, the

asymmetry of the oxan ring increases the number of possible conformational isomers for derivatives of this series [12]: whereas two conformations (chair and boat [13-15]) are possible for cyclohexane, the oxan ring can exist as two chair conformations (1C and C1) and several boat conformations [16], e.g. (see Ref. 12 for greater detail)

As with cyclohexane the boat conformations are energetically less advantageous. Taking the barrier to rotation in methanol as 1.1 kcal mole^{-1} indicated that for oxan the energy of the boat form exceeded that of the chair form by 3.9 kcal mole^{-1}. [17] As a comparison, ΔH for the chair $\rightleftharpoons$ boat equilibrium in cyclohexane is 5.9 kcal mole^{-1}. [18] This estimate is undoubtedly too low, since it would be more logical to base it on the barrier to rotation in dimethyl ether [19], which is 2.7 kcal mole^{-1}. [20,21] This is confirmed by the estimate of 2.2 kcal mole^{-1} for the difference in energy between chair and boat conformations of 1,3-dioxan, based on the barrier to rotation in methanol, whereas experimental determination gives ΔG = 5.7 kcal mole^{-1}, ΔH = 7.1 kcal mole^{-1}, and ΔS = 4.8 e.u. [22-24]

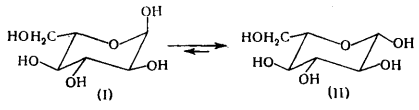
The barrier to chair $\rightleftharpoons$ boat conversion for oxan is 9.9 kcal mole^{-1}, [25,26] which is close to the value (10.3 kcal mole^{-1} [25]) found for cyclohexane.

The presence of chairlike conformations in a large number of pyranoses has been shown by X-ray examination [27-29], microwave spectroscopy [30], and nuclear magnetic resonance spectroscopy [25,26]. The R-factor which enables the departure from a chairlike conformation to be assessed, also has similar values—1.9 in oxan [31] and 2.2 in cyclohexane [32].

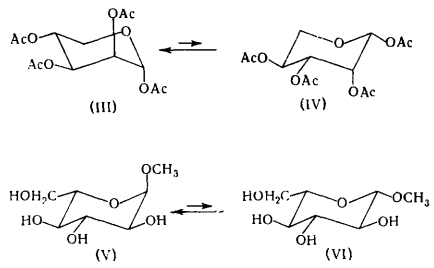
Thus the similarity in the geometry of oxan and cyclohexane enables us to apply general conformational rules to derivatives of the former compound.

The introduction by Reeves of conformational ideas into carbohydrate chemistry showed their complete applicability to this class of compounds, but also revealed the influence of specific "factors" on the relative stability of the conformations [16]. In particular we may mention e.g. the so called Δ^2 instability factor [11,16].

With free sugars both α- and β-forms are usually stable in solution (see Ref. 33 for a detailed scheme of the conformations of pyranoses). For the mutarotation of glucose in aqueous solution, for example, the equatorial form (II) has been shown to be the more stable, with ΔG_{OH} = 0.34 kcal mole^{-1}. [34,35] However, Lemieux [5] and other workers [36-39] have shown that several simple aglycones among pyranose derivatives tend in general to occupy the axial position. Lemieux termed this phenomenon the "anomeric effect" [6].



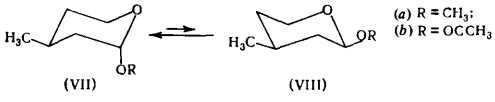
Detailed studies of the anomeric effect have been made on the $\alpha\beta$-anomerisation of pentose acetates [5], methyl pentosides [36,37,40-42], and halogeno- and acetoxy-derivatives of carbohydrates [38,43-46]. For example, 1,2,3,4-tetra-*O*-acetyl-α-D-lyxopyranose exists predominantly as the conformation (III), [5] whereas with methyl glucoside the α-anomer (V) is more stable than the β-anomer (VI). [42]



The first attempt to explain the anomeric effect was made by Edward [42], whose main idea was to examine the dipole–dipole interaction between the electronegative substituent and the ring oxygen atom. Such electrostatic interaction should be fairly large for an equatorial substituent, and slight for an axial substituent, in position 2.

Several quantitative estimates have been made of the anomeric effect in derivatives of monosaccharides. For example, Bishop [40] found a value of ~ 1.2 kcal mole^{-1} for the anomerisation of methyl pentosides in methanol. The most complete estimates of the anomerisation of sugars were given by Lemieux [5], with 1.5 and 1.3 kcal mole^{-1} respectively for the anomeric effect of the acetoxy-group in hexoses and in pentapyranoses. On the bases of these results he proposed a convenient additive scheme for calculating the preferential conformations of derivatives of monosaccharides.

In 1964 Anderson and Sepp found that the equilibrium mixtures of 2-methoxy- and 2-acetoxy-4-methyloxans contain 65% and 70% respectively of the axial forms of the compounds (VII*a*) and (VII*b*), [47] and thus showed that the anomeric effect should be a general phenomenon.



The impossibility of allowing for all the factors—all the dipole–dipole interactions, solvation, hydrogen bonds, deviations in the conformations from the standard chair forms in polysubstituted compounds, etc.—also makes it difficult to study the anomeric effect on models of monosaccharides. During recent years, therefore, various aspects of the anomeric effect have been studied extremely intensively on simple models. The investigations have shown without question that the anomeric effect is a general conformational phenomenon, unconnected with the specific structure of sugars and extremely widespread among heterocyclic compounds.

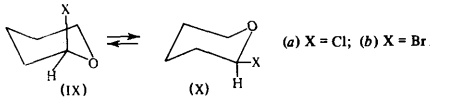
The literature on the anomeric effect has grown very rapidly since 1965. Several reviews have been published during recent years [5,33,48-50], but they are very concise and do not contain the full results. It therefore appeared to us useful to summarise in a special review the existing literature on the anomeric effect. It is systematically based on differences in the structural fragments comprising the cyclic heteroatom and the substituent atom directly attached to the ring.

III. THE ANOMERIC EFFECT IN SIX-MEMBERED CYCLIC STRUCTURES

1. The O–C–Hal Fragment

(*a*) Halogenated oxans

The conformational equilibrium of 2-halogeno-oxans can be represented by the equation



(*a*) X = Cl; (*b*) X = Br

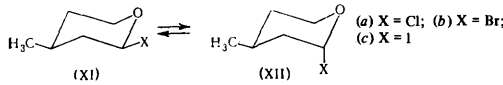
The conformational free energy of chlorine and bromine in the cyclohexane series is 0.43 [51] (0.53 [52]) and 0.38 [51] (0.48 [52]) kcal mole^{-1} in favour of predominance of the equatorial form.

Nuclear magnetic resonance has been used by Booth and Ouellette [53] and by Zefirov and Shekhtman [54,55] to study the conformational equilibrium of 2-chloro- and 2-bromo-oxans. They showed that the proportion of the equatorial form is very small in both compounds, the equilibrium being displaced almost completely towards the axial isomer (IX). The free energy of the conformational equilibrium (IX) $\rightleftharpoons$ (X) was estimated as 1.8 kcal mole^{-1}. The magnitude of the anomeric effect can be written

$$\Delta G_{AH} = \Delta G_0 - \Delta G_x,$$

where ΔG_0 is the equilibrium free energy and ΔG_X the conformational free energy of the substituent in the cyclohexane series [47] (this view has been criticised [56]). In this case the anomeric effect is estimated as 2.3 kcal mole^{-1}. Variation in the polarity of the solvent has very little influence on the position of the conformational equilibrium (IX) $\rightleftharpoons$ (X). [53] It is interesting that the n.m.r. spectrum of (IX*a*) shows a reversal of the chemical shifts of the signals from the axial and the equatorial proton attached to $C_{(6)}$. [55]

The above results [53–55] were based on a semi-quantitative estimate of the equilibrium position from the spin–spin interaction constants. A more exact estimate of the anomeric effect was made by Anderson and Sepp [57] in a study of the epimerisation of 2-halogeno-4-methyloxans (XI) and (XII) (*a*–*c*)

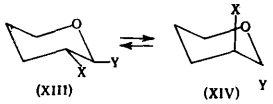


(*a*) X = Cl; (*b*) X = Br; (*c*) X = I

From data on the epimerisation equilibrium the anomeric effect for chlorine was estimated as 2.65 and 2.0 kcal mole^{-1} for non-polar and polar solvents respectively. The anomeric effect for bromine and iodine was ~ 3.1 kcal mole^{-1}.

Gas chromatography showed that 2-chloro-oxan comprises a mixture of equal quantities of axial and equatorial forms (IX*a*) and (X*a*). [58] However, this conclusion is undoubtedly erroneous, since it contradicts all the work cited above. Furthermore, the preferred axial conformation of this compound has recently been proved by measuring the Kerr constants and the dipole moments [59].

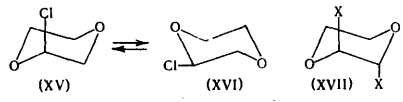
Lemieux and Fraser-Reid [43] found that *trans*-2,3-dichloro- and bromo-oxans exist predominantly as the *trans*-diaxial conformation (XIV).



In this case the position of the conformational equilibrium is determined not only by the anomeric effect but probably also by 1,2-repulsion of the halogen atoms in the diequatorial conformation. This effect has been studied in some detail among cyclohexane derivatives [60–62].

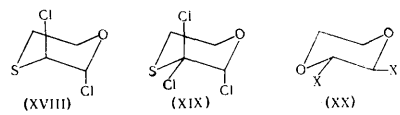
(*b*) Halogenated dioxans and oxathians

Zefirov and Fedorovskaya [63] observed a distinct anomeric effect with 2-chloro-1,4-dioxan. The equilibrium (XV) $\rightleftharpoons$ (XVI) was extensively displaced towards the axial isomer (XV), the position of the conformational equilibrium being as little affected by the polarity of the solvent as in the case of 2-halogeno-oxans.

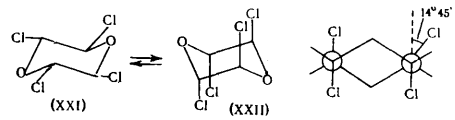


(X = Cl, Br)

Much work has been done on elucidating the configurations and preferred conformations of 2,3-dihalogeno-1,4-dioxans [64–68]. X-Ray examination has shown that the *trans*-isomers of 2,3-dichloro- and 2,3-dibromo-1,4-dioxans exist in the diaxial conformation (XVII). [64,65] Nuclear magnetic resonance has shown that in solution *trans*-2,3-dichloro-, -2,3-dibromo-, and -2,5-dichloro-1,4-dioxans also occur in the diaxial conformation [64,65,67–70]. Wolf and his coworkers [71,72] have studied the conformations of many polychlorinated oxathians and established a distinct anomeric effect in the halogenated derivatives. For example, *trans*-2,3-dichloro-oxathian and 2,3,3-trichloro-oxathian have the more stable conformations (XVIII) and (XIX) respectively.



It is probable that, as with 2,3-dichloro-oxan, the axial conformations of 2,3-dihalogenodioxans and 2,3-dichloro-oxathian are due not only to an anomeric effect but also to repulsion of the halogen atoms in the diequatorial conformation (XX).

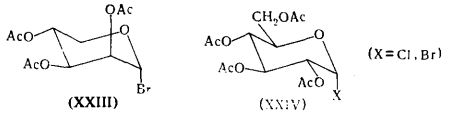


Extraordinarily interesting results have been obtained in a study of the crystalline structure of *trans*-2,3,5,6-tetrachloro-1,4-dioxan [73]. In spite of strong 1,3-interactions, the stable conformation is (XXII), in which all four chlorine atoms are axial. The C–Cl bond is inclined at an angle of 14°45′ to the vertical position.

(*c*) Pyranosyl halides

Numerous examples of pyranosyl halides have shown that the form in which the halogen is in an axial position is usually the more stable [5,11,38,39,45,74]. Thus (XXIII) and

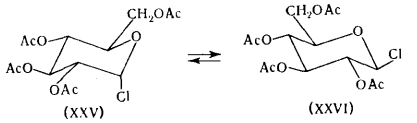
(XXIV) are the stable conformations of tri-*O*-acetyl-D-lyxopyranosyl bromide and tetra-*O*-acetyl-α-D-glucopyranosyl halides respectively.



(XXIII) (XXIV)

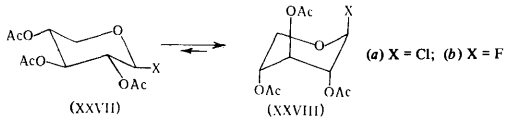
The anomerisation of pyranosyl halides should occur extremely readily, since the halogen atom is capable of nucleophilic detachment and the cyclic oxygen atom greatly stabilises the resulting carbonium ion. Since anomerisation occurs smoothly, therefore, the main factor determining the relative stability of the epimers is the anomeric effect.

Lemieux and Hayami [75] estimated the anomeric effect of the chlorine atom attached to $C_{(1)}$ in acetochloroglucose as ~ 2 kcal mole^{-1} in acetonitrile (taking into account ΔG_{Cl}), which corresponds to the presence of 93–95% of the α-anomer (XXV) in the equilibrium mixture.



(XXV) (XXVI)

In several cases the anomeric effect is sufficiently large to displace the equilibrium to a "completely" axial conformation. Very interesting examples of this type are provided by β-D-xylopyranosyl chloride and fluoride, the most stable conformations of which are (XXVIII*a*) and (XXVIII*b*), in which all four constituents are in axial positions [33,76–79]:

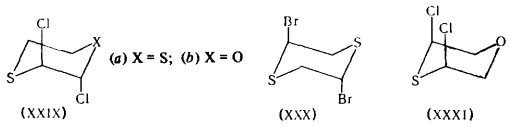


(XXVII) (XXVIII)

The 1,3-diaxial repulsion of two acetoxy-groups in the cyclohexane series has been estimated as 2.0 kcal mole^{-1}. [80] Although the structure (XXVIII) involves two 1,3-diaxial repulsions, this conformation is the more stable.

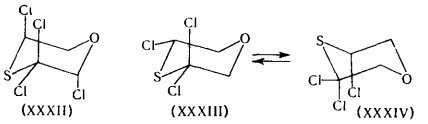
2. The S–C–Hal Fragment

The repulsion between sulphur and halogen atoms is sufficient to destabilise the equatorial conformation. Kalff and Romers [81,82] made an X-ray examination of *trans*-2,3-dichlorodithian and *trans*-2,5-dibromodithian, and found them to have the conformations (XXIX*a*) and (XXX) respectively.



(XXIX) (XXX) (XXXI)

Few data are available on the conformations of compounds of this type in solution. Study of the infrared spectra and dipole moments of *trans*-2,3-dichloro- and *trans*-2,5-dibromo-1,4-dithians has shown [72] that these compounds have the same conformations as in the crystal. It has been found [71,72,83] that *trans*-2,3-dichloro-, *cis*-3,5-dichloro-, *trans*-2,3,3,5-tetrachloro-, and 3,3,5-trichloro-oxathians have the preferred conformations (XXIX*b*) and (XXXI)–(XXXIII) respectively.



(XXXII) (XXXIII) (XXXIV)

These results are based on the vicinal spin–spin splitting constants. When compounds (XXXI)–(XXXIII) are compared, however, it remains obscure why the diaxial repulsion of the halogen atoms destabilises the conformation (XXIV), although this does not occur with compound (XXXI). It is also noteworthy that in several cases the quantity J_{ee} was of the order of 6–8 c/s, which perhaps indicates the presence of a mobile equilibrium, e.g. (XXXIII) ⇌ (XXXIV).

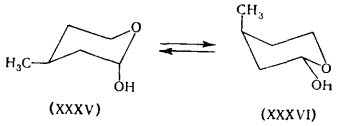
3. The O–C–OR Fragment

(*a*) Hydroxy-derivatives (R = H)

Oxan-2-ol is a cyclic tautomer of hydroxyvaleraldehyde, and according to the infrared spectra [84] exists in the hemiacetal form. It is well known that cyclic hemiacetal forms predominate with monosaccharides. It has already been remarked that the polarity of the solvent has relatively little effect on the position of the conformational equilibrium in 2-halogenated oxans, but the situation is quite different with the 2-hydroxylated derivatives.

The position of the conformational equilibrium is considerably changed by transfer from aprotic solvents to water, being displaced towards the equatorial form. This applies also to cyclohexanols, for which the mean values of ΔG_{OH} are 0.54 and 0.87 kcal mole^{-1} in aprotic solvents and in water respectively [51]. Stabilisation of the equatorial conformation of 2-hydroxylated oxans in water may be due either to an increase in the dielectric constant of the medium, which diminishes the anomeric effect, or to strong solvation of the hydroxy-group, which increases its effective volume.

In fact, Anderson and Sepp [85] found that the transfer from aprotic solvents to water produces a marked change in the conformational equilibrium for *trans*-4-methyloxan-2-ol: in water this compound exists to the extent of 66% in the equatorial conformation, whereas in carbon tetrachloride the conformation (XXV) with an axial hydroxyl predominates (60%):



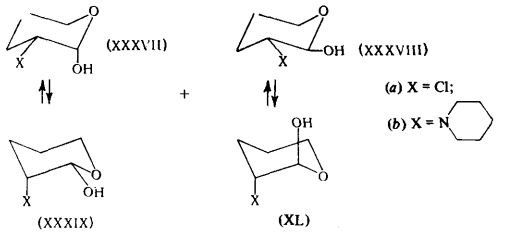
(XXXV) (XXXVI)

Pierson and Runquist showed by means of n.m.r. spectroscopy that the proportion of the axial isomer in oxan-2-ol is 77% in non-polar solvents [86]. This result is confirmed by infrared spectroscopy. Thus in 5% solution in carbon tetrachloride, for example, the conformation having an axial hydroxyl predominates, its proportion increasing further with dilution [85].

It is interesting that a distinct anomeric effect has been observed [87] with chroman-2-ol both in acetonitrile and in carbon tetrachloride, the proportion of the axial isomer (80–85%) being independent of the concentration.

The equilibrium mixture of oxan-2,3-diol in deuterochloroform has been shown by the n.m.r. spectra to comprise 30% of *cis*- and 70% of *trans*-diequatorial isomers[88]. The decisive part in stabilisation is probably played by an intramolecular hydrogen bond[89].

In dimethyl sulphoxide the addition product of hypochlorous acid and dihydropyran comprises a mixture of *cis*- and *trans*-isomers in the proportions 37 : 63, with $J_{2,3} = 5.6$ c/s for the *trans*-isomer, which suggests the presence in conformational equilibrium (XXXVIII) ⇌ (XL*a*) of an appreciable fraction of the diaxial form (XL*a*).[90]



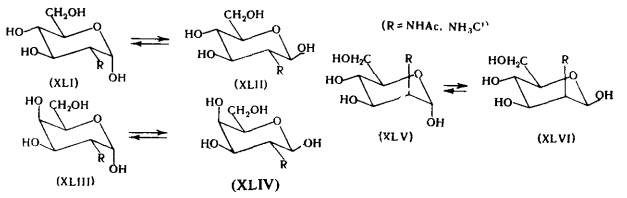
The equilibrium mixture of 3-piperidino-oxan-2-ol comprises 46% of the *cis*-isomer (XXXVII) ⇌ (XXXIX*b*) and 54% of the *trans*-isomer (XXXVIII*b*) ⇌ (XL*b*). For the *trans*-isomer $J_{2,3} = 6.6$ c/s,[91] which also indicates predominance of the diequatorial conformation (XXXVIII*b*).

Thus with oxan-2-ol derivatives in protic solvents the conformation in which the hydroxyl is in an equatorial position is usually the more stable.

The conformation of sugars and their $\alpha\beta$-anomerisation are well known[5,33,40,48,74,92,93], and we shall not discuss this subject in detail. We note merely that the magnitude of the anomeric effect in monosaccharides may be affected by a far larger number of factors than in the case of oxan-2-ol. As with the latter, the anomeric effect is influenced primarily by the nature of the solvent. Thus the equilibrium mixture of glucose in absolute methanol contains equal quantities of α- and β-forms, which gives an anomeric effect of 0.9 kcal mole^{-1},[94] but in water the proportions of the two forms are 36 : 64.[48,95] In a pyridine solution of mannose the equilibrium mixture contains 85% of the α-form[96] (the calculated anomeric effect is 1.15 kcal mole^{-1} [94]). The magnitude of the effect increases in non-polar solvents[94].

It has been found with aldopyranoses that the configuration of the hydroxyl attached to the $C_{(2)}$ atom greatly influences the magnitude of the anomeric effect[48]. Angyal showed that, in the absence of a 2-hydroxyl, the effect in pyranoses is 0.85 kcal mole^{-1}; if the hydroxyl is axial the effect is 1.0 kcal mole^{-1} (except when the 3-hydroxyl is also axial); and finally the anomeric effect is 0.55 kcal mole^{-1} when the 2-hydroxyl is equatorial (all values of the anomeric effect were calculated with ΔG_{OH} taken into account).

Polarimetric data and n.m.r. spectra have shown that replacement of the 2-hydroxyl in a series of D-gluco- and D-galacto-pyranoses by an acetamido-group or by an ammonium group results in greater stability of the α-forms (XLI) and (XLIII), whereas with D-mannose the β-form (XLVI) is stabilised[97,98].



Thus a great variety of factors—solvent, intramolecular hydrogen bonds, specific solvation, nature of substituent adjacent to anomeric centre, etc.—influence the conformational equilibrium of oxanols.

(*b*) Alkoxyoxans

Alkoxyoxans are very convenient models for examining various factors influencing the anomeric effect, as a consequence of which they are probably the most thoroughly studied. Zefirov and Shekhtman[54,55] and Pierson and Runquist[86] have made semi-quantitative assessments of the position of the conformational equilibrium and the magnitude of the anomeric effect for a wide range of 2-substituted oxans. These workers have found that 2-alkoxyoxans do exhibit an anomeric effect, whose value varies somewhat with the polarity of the solvent. Thus the anomeric effect for a series of 2-alkoxyoxans varies over the range 1.3–2.8 kcal mole^{-1} in non-polar solvents, and over the range 1.25–1.9 kcal mole^{-1} in acetonitrile[49,54,55].

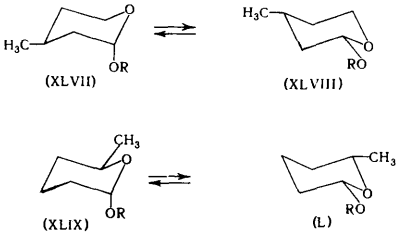
The electronegativity of the substituent undoubtedly affects the position of conformational equilibrium. There is probably a general tendency for the anomeric effect to increase slightly with electronegativity. Quantitative correlation is difficult, however, because of the lack of reliable and accurate data on the position of conformational equilibrium for a wide range of substituents. Pierson and Runquist[86] tried to correlate the free energy for the equilibrium in a series of 2-alkoxyoxans with the Taft inductive σ^*-constants for the radical in the alkoxy-group. However, the resulting correlation can hardly be regarded as in any way reliable owing to the crudity with which the equilibrium position was estimated.

The position of conformational equilibrium in 2-alkoxyoxans appears to be relatively insensitive to the size of the radical in the alkoxy-group[7,54,55,86,99].

It is interesting that α-fenchol reacts with dihydropyran to yield two compounds, which have been regarded as conformational isomers containing an axial and an equatorial fenchyloxy-group[100]. Such separation of conformers is obviously unprecedented, and it is probable that these workers were actually dealing with structural isomers.

The nature of the solvent has a relatively weak influence on the anomeric effect, although a certain tendency is observed for the content of the axial form to increase with decrease in the polarity of the medium[7,47,54,85,86,101].

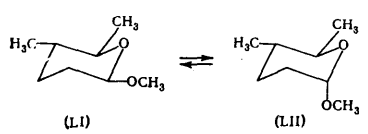
More exact data were obtained by Anderson and Sepp[57,101] and also by Eliel and Giza[56] in a study of the epimerisation of 2-alkoxy-4-methylpyrans (XLVII) ⇌ (XLVIII) and 2-alkoxy-6-methylpyrans (XLIX) ⇌ (L). They found a distinct dependence of the anomeric effect on the solvent. Thus ΔG for 2-methoxy-4-(and 6)-methyloxans in carbon tetrachloride is respectively 0.83 and 0.73 kcal mole^{-1} (corresponding to 80% and 67% of the anomer XLVII), whereas in acetonitrile the values are 0.42 and 0.35 kcal mole^{-1} (67% and 64% of the anomer XLVII).[56,102]



The size of the alkoxy-group has been considered[85] to have no significant influence on the position of the conformational equilibrium. In fact, the proportion of the *trans*-form (XLVII) remains almost unchanged on passing from the methoxy- to the isobutoxy-group. Thus in acetonitrile, for example, 65% of (XLVII) is present in the case of 2-methoxy-4-methyloxan, and 70% with 2-isobutoxy-4-methyloxan. Other workers[56], however, have noted a definite and monotonic decrease in the proportion of axial conformations (XLVII) and (XLIX) with increase in the bulk of the radical in the alkoxy-group. Thus $\Delta G(CCl_4)$ has the values 0.73, 0.64, and 0.5 kcal mole^{-1} for the methoxy-, isopropoxy-, and t-butoxy-groups in the 2-alkoxy-6-methyloxans.

The position of the conformational equilibrium in alkylated 2-alkoxyoxans is relatively insensitive to the location of the alkyl substituent in the ring[56,85,101]. Thus 2-methoxy-4-methyloxan in methanol contains 69% [101] (67.3% [56]) of the conformation (XLVII), while in 2-methoxy-6-methyloxan the content of the axial isomer (XLIX) under the same conditions is 70% [101] (62.5% [56]).

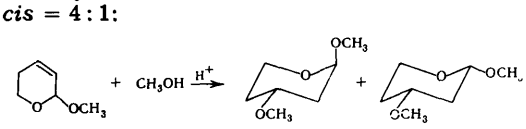
It has been pointed out[101] that the proportion of the axial form is greater with methyl glucoside than with methyl xyloside and 2-methoxyoxan. The explanation offered was that the presence of two bulky groups in positions $C_{(5)}$ and $C_{(6)}$ of the oxan ring in the equatorial position results in their steric repulsion, which may lead to a slight flattening of the ring and hence an increase in the distance between the axial 6- and 2-substituents, so that the steric repulsion of the 2-substituents is diminished. This effect has been confirmed experimentally on the isomeric 2-methoxy-5,6-dimethyloxans[101]. It was observed that the epimerisation of 2-methoxy-*trans*-5,6-dimethyloxans yields an equilibrium mixture in which the content of the isomer (LII) reaches 77%.



(LI) (LII)

Distinct anomeric effects have been observed also with oxanyloxy-,[103] trimethylsiloxy-,[54] t-butylperoxy-,[104] and alkylthio-oxans[103].

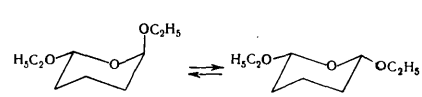
Sweet and Brown[105] showed that the addition of methanol to 5,6-dihydro-2-methoxy-2*H*-pyran yields a mixture of 2,4-dimethoxyoxans in which the ratio of the isomers is *trans* : *cis* = 4 : 1:



(LIII) (LIV)

Since the reaction was conducted in acid medium, the composition of the mixture was probably controlled thermodynamically. The n.m.r. spectra showed that the 4-methoxy-group occupied an equatorial position, while the anomeric effect in methanol was 1.4 kcal mole^{-1}. The difference in magnitude of the anomeric effect in (LIII) and (XLVII)—that of the latter compound in methanol is[85] 0.9 kcal mole^{-1}—was regarded[105] as a good illustration of the polar nature of the anomeric effect.

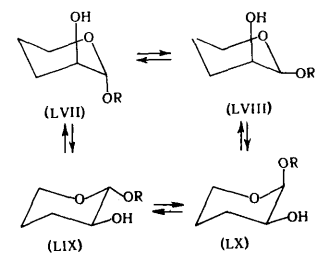
The anomeric effects of 2,6-diethoxyoxans



(LV) (LVI)

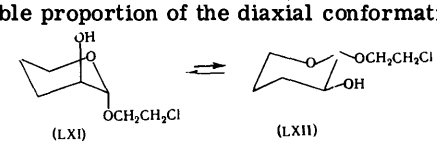
and of 2-ethoxy-4(or 6)-methyloxans are almost the same[56,108] when it is remembered that the *trans*-isomer (LV) is a DL-pair, so that ΔG is increased by $RT\ln 2 = 0.41$ kcal mole^{-1}. It is found also that with increase in the polarity of the solvent the equilibrium (LV) $\rightleftharpoons$ (LVI) is displaced towards the *cis*-isomer. Thus ΔG for this equilibrium has the values 1.16, 0.76, and 0.89 kcal mole^{-1} in carbon tetrachloride, acetonitrile, and ethanol respectively[56].

There is no published information on the conformations of 2,3-dialkoxyoxans, but 2-alkoxyoxan-3-ols have been studied by several workers. Although the n.m.r. data[107,108] are somewhat contradictory, there is no doubt about the predominance of the *trans*-diaxial form (LVII) and the presence of an anomeric effect; the size of the alkoxy-group has hardly any influence on the position of the conformational equilibrium[108].



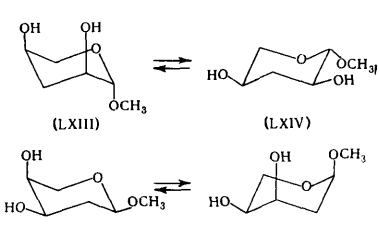
(LVII) (LVIII) (LIX) (LX)

The *trans*-isomer of 2-2′-chloroethoxyoxan-3-ol has $J_{3,2} = 5$ c/s in deuterochloroform[88], which also suggests a considerable proportion of the diaxial conformation (LXI).



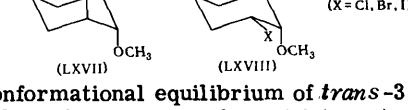
(LXI) (LXII)

Lemieux and Pavia[109] found that the nature of the solvent was the main factor determining the conformations of methyl 3-deoxy-β-L-erythropentapyranoside and 2-deoxy-L-erythropentapyranoside. In deuterium oxide the compounds exist in the conformations (LXIV) and (LXV), but in deuterochloroform as (LXIII) and (LXVI) respectively. The n.m.r. data correlate well with the specific rotations.



(LXIII) (LXIV) (LXV) (LXVI)

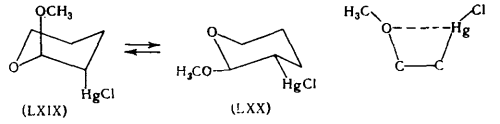
The halogenomethoxylation of dihydropyran yields a mixture of 3-halogeno-2-methoxyoxans. The *trans*-isomer exists in the diaxial conformation (LXVII), and the *cis*-isomer in the equatorial–axial conformation (LXVIII).[43] Iodomethoxylation results in the formation of 100% of (LXVII), whereas chloromethoxylation gives 75% of (LXVII) and 25% of LXVIII).



(LXVII) (LXVIII) (X = Cl, Br, I)

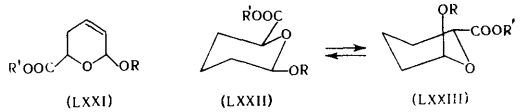
The conformational equilibrium of *trans*-3-chloromercuri-2-methoxyoxan is of great interest. Since $\Delta G_{HgCl} \simeq 0$ (the value of ΔG for the $HgOCOCH_3$ group is[52]

0 ± 0.09 kcal mole^{-1}), and also because of the anomeric effect of the methoxy-group, the conformation (LXIX) should predominate. According to Zefirov and Shekhtman[55], however, the diequatorial conformation (LXX) is stable. This was explained by the additional effect of coordination of the methoxyl oxygen and the mercury atom, which stabilises (LXX). The magnitude of this effect is 0.95 kcal mole^{-1} with ΔG^{OCH_3} taken into account.



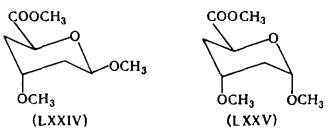
(LXIX) (LXX)

The n.m.r. spectra of Δ^3-dihydropyrans (LXXI) (obtained by Diels–Alder condensation of 1-alkoxyalka-1,3-dienes with carbonyl-containing compounds) and of the corresponding oxans indicate that isomers having shorter retention times in gas–liquid chromatography comprise more than 90% *trans-ax,eq*-isomers with the alkoxy-group in the axial position, whereas isomers having longer retention times comprise not less than 90% of *cis-eq,eq*-isomers[110,111]. Epimerisation in the presence of boron trifluoride leads to the conversion of *cis*-isomers (LXXII) into *trans*-isomers (LXXIII).



(LXXI) (LXXII) (LXXIII)

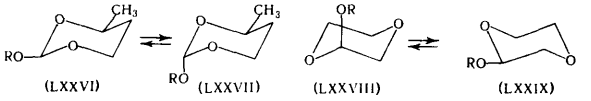
It is interesting that, in the case of methyl 4,6-dimethoxyoxan-2-carboxylate, the *ribo*-configuration (LXXV) is more stable than the *arabino*-isomer (LXXIV), in spite of the 1,3-diaxial arrangement of the methoxy-groups[112].



(LXXIV) (LXXV)

(*c*) Alkoxy-derivatives of saturated six-membered heterocycles containing two heteroatoms

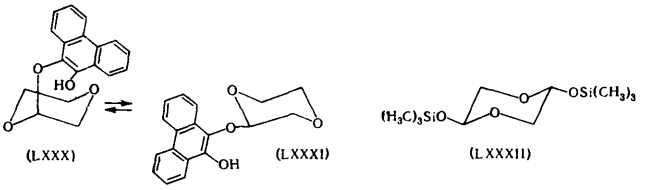
Eliel and Giza[10,56] observed a distinct anomeric effect with 2-alkoxy-1,3-dioxans. The epimerisation of 2-methoxy(and ethoxy)-4-methyl-1,3-dioxans (LXXVI) ⇌ (LXXVII) results in predominance of the *cis*-isomer (LXXVII), with $\Delta G^{OR} = 0.35$ kcal mole^{-1} in carbon tetrachloride. For 2-methyl-1,3-dioxan $\Delta G^{CH_3} = 3.6-4.1$ kcal mole^{-1}, which far exceeds the value of 1.7 kcal mole^{-1} observed for methylcyclohexane[51].



(LXXVI) (LXXVII) (LXXVIII) (LXXIX)

Zefirov and Fedorovskaya used the n.m.r. method to show that the anomeric effect applies to 2-alkoxy-1,4-dioxans[63,113]. In contrast to 2-alkoxyoxans[7,54,55,86,99], however, their conformational equilibrium (LXXVIII) ⇌ (LXXIX) is more sensitive to the volume of the substituent in the alkoxyl. Thus the (LXXIX) content increases by about 25% on passing from the methoxy- to the t-butoxy-group at position 2.[63]

Similar results have been obtained for 2-phenanthryloxy-1,4-dioxan, in which the steric effect predominantes over the polar effect, so that the conformational equilibrium is displaced towards the equatorial isomer (LXXXI):[114]



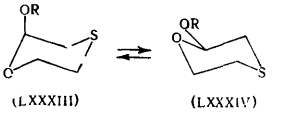
(LXXX) (LXXXI) (LXXXII)

A general explanation of this phenomenon can be given in terms of the "hockey-stick effect" (see below).

It is interesting that in the n.m.r. spectrum of 2,5-bis-trimethylsiloxy-1,4-dioxan $J_{AX} = 6.0$ c/s and $J_{BX} = 2.4$ c/s (in carbon tetrachloride), so that a diequatorial conformation (LXXXII) was adopted for this compound[115]. For 2-t-butoxydioxan $J_{AX} + J_{BX} = 8.4$ c/s,[62] and in both cases the content of the diaxial conformation is ~ 45%.

Another pecularity of alkoxy-1,4-dioxans is that the effect of the solvent on the position of conformational equilibrium is opposite to that observed with oxan derivatives[7,47,54,85,86,101]. With 2-alkoxy-1,4-dioxans the proportion of the axial conformation increases somewhat on passing from carbon tetrachloride to acetonitrile, which may be due to fine solvation effects at the 4-oxygen atom[63].

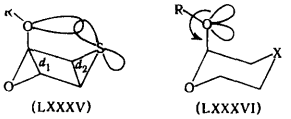
As already noted, introduction of the second heteroatom on passing from 2-alkoxyoxans to 2-alkoxydioxans has no great qualitative effect on the conformational behaviour. However, the situation changes radically on passing to 2-alkoxyoxathians, as Foster et al.[116] and Zefirov et al.[113,117] have shown. Thus with 2-methoxy- and 2-butoxy-oxathians at least 50% of the equatorial conformation (LXXXIV) is present at equilibrium.



(LXXXIII) (LXXXIV)

A strict interpretation of this phenomenon is difficult because of the absence of experimental conformational analyses of other, analogous heterocyclic systems. However, it is obvious that destabilisation of the axial conformation cannot be explained simply by dipole–dipole repulsion of the 4-heteroatom and the substituent, for such repulsion should be more strongly developed in 1,4-dioxan than in 1,4-oxathian derivatives.

A general explanation of this phenomenon can evidently be based on the "hockey-stick effect"[118]. For the R–O–C–C–S fragment, in particular, the orbital of the oxygen atom (p or sp^3) may overlap an orbital of the sulphur atom (p- or sp^3-hybrid), as shown in formula (LXXXV). Since these orbitals are populated by four electrons, such overlap should lead to repulsion. Such repulsion will evidently depend on the geometry of the molecule, in particular on the relative distances d_1 and d_2, and also on the nature of the atoms having lone pairs of electrons. Experimental results must be accumulated for a more detailed study of this phenomenon.



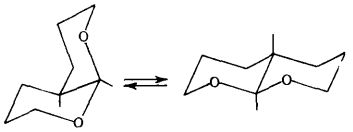
(LXXXV) (LXXXVI)

However, the "hockey-stick effect" enables an acceptable explanation to be given for the greater sensitivity noted above of the conformational equilibrium to the volume of the alkoxy-substituent in the 1,4-dioxan series than in

alkoxyoxans. In fact the most stable rotational conformation of the axial alkoxy-group is (LXXXVI), in which the radical R is directed outside the ring, and hence the orbitals of the oxygen atom containing lone pairs are directed inside the ring. Hence arises the possibility of repulsion of the 4-oxygen atom and the alkoxyl oxygen as a consequence of the "hockey-stick effect". If, however, the size of R is small, the group OR may adopt a more favourable rotational conformation, which will diminish such repulsion. When R is a bulky group, e.g. t-butyl, the mobility of OR is restricted significantly, and the orientation of OR observed with respect to $O_{(4)}$ leads to repulsion, which partly destabilises the axial conformation (LXXXVI).

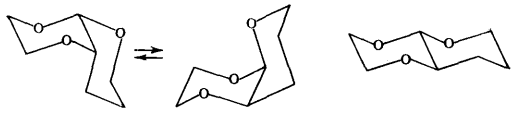
(*d*) Fused saturated systems

The axial forms of 3-alkoxy-4-oxa-5α-cholestanes and 3-methoxy-4-oxa-5α-oestranes are the more stable[119,120]. Thus an anomeric effect is clearly evident for the group O–C–O–C, which is a fragment of the polyfunctional fused systems.



(LXXXVII) (LXXXVIII)

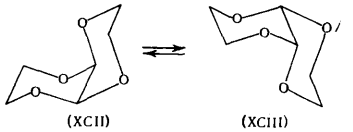
Descotes et al.[121] have shown by the n.m.r. method that the epimerisation of decahydro-1,8-dioxanaphthalene yields an equilibrium mixture of 57% of the *cis*-form (LXXXVII) and 43% of the *trans*-form (LXXXVIII), which differs markedly from the behaviour of decalin[122]. The relative stabilisation of the *cis*-isomer is explained by the anomeric effect, since the fragment O–C–O–C in this compound is analogous in (LXXXVII) to the O–C–O–R observed for the axial conformation of 2-alkoxyoxan, and the anomeric effect is of the same order in this case (1.4 kcal mole^{-1} [121]) as for simple 2-alkoxyoxans[84,101].



(LXXXIX) (XC) (XCI)

cis-Decahydro-1,4,5-trioxanaphthalene (LXXXIX) $\rightleftharpoons$ (XC) and the *trans*-isomer (XCI) were prepared by Sweet and Brown[88], and their structures proved by means of the n.m.r. spectra. Unfortunately these workers did not study the acid epimerisation, but it can be confidently stated that here the *cis*-isomer (XC) should be the more stable, as a consequence of the anomeric effect.

A *trans*-configuration was originally attributed to decahydro-1,4,5,8-tetraoxanaphthalene on the bais of X-ray data on its complex with mercurous chloride[123]. However, low-temperature n.m.r. spectroscopy has shown that this possesses a *cis*-configuration; the latter is more stable owing to the anomeric effect. The compound exists as two rapidly interconvertible conformations



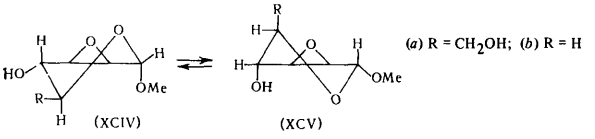
(XCII) (XCIII)

with $\Delta G^{\neq} = -11.5$ kcal mole^{-1}. [124–126]

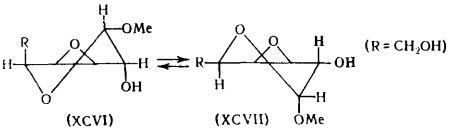
(*e*) Alkyl pyranosides

We have already mentioned in the Introduction that many examples have been shown of the preferential axial orientation of polar aglycones in the sugar series[36,37,40–42,67]. Lemieux[5] observed equilibrium proportions of 3 : 1 of α- and β-anomers in methyl 2,3,4,6-tetra-O-methyl-α- and -β-glucopyranosides in methanolic solution. Intramolecular rearrangement of methyl β-D-glucopyranoside triacetate catalysed by boron trifluoride and titanium tetrachloride gave a 90% yield of the α-anomer with an axial methoxy-group[127].

Methyl pyranosides contain approximately the same content (70%) of the axial isomer in conformational equilibrium[101] and exhibit a similar anomeric effect (1.2 kcal mole^{-1})[40] as the analogous 2-alkoxyoxans. The presence of many functional groups in alkyl pyranosides has enabled a broad study to be made of the various factors influencing the position of conformational equilibrium. Since most of the results of the large amount of work done on this problem can be found in review papers[5,33,48,50,101,128], we will not discuss it at length. We remark merely that an anomeric effect has been found also in polyacetylenic alcohols of glucosides[129].



(XCIV) (XCV) (*a*) R = CH_2OH; (*b*) R = H



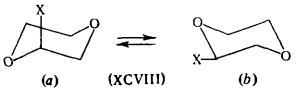
(XCVI) (XCVII) (R = CH_2OH)

In several cases the anomeric effect makes conformations having an axial alkoxy-group stable with 2,3- and 3,4-anhydroglucopyranosides[130–134]. In the case of the conformational equilibrium of methyl 2,3-anhydro-α-D-manno- and -lyxo-pyranosides, for example, the latter being especially interesting, (XCIV*a*) and (XCIV*b*) respectively are the stable conformations, but with methyl 3,4-anhydro-α-D-galactopyranoside the conformation (XCVII) is stable.

(*f*) Acetoxy-derivatives

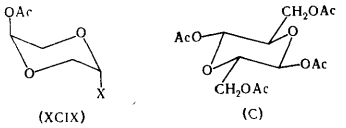
Anderson and Sepp[47,57,85] and Zefirov and Shekhtman[54] have shown that oxan-2-yl acetate and its alkyl derivatives have almost the same anomeric effect and similar contents (85–90%) of the axial form. The proportion of the axial isomer in the equilibrium mixture diminishes with increase in the polarity of the solvent.

The difference in electronegativity between the acetoxy- and the methoxy-group has a stronger influence on the position of conformational equilibrium in 2-alkoxy-1,4-dioxans. According to Zefirov and Fedorovskaya[63] the compound (XCVIII) in carbon tetrachloride consists of 68% of (XCVIII*a*) if X = OCH_3, and 95% if X = $OCOCH_3$.



(*a*) (XCVIII) (*b*)

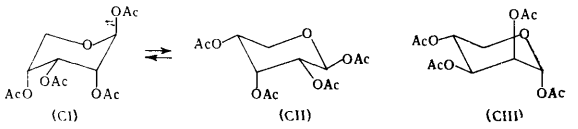
According to n.m.r. data 1,4-dioxan-2,5-diyl *trans*-diacetate consists almost entirely of the diaxial conformation (XCIX: X = $OCOCH_3$).[135] Nevertheless, the tetraequatorial conformation (C) of *trans*-2,5-diacetoxy-3,6-bisacetoxymethyl-1,4-dioxan is stable[135].



(XCIX) (C)

From results for the anomerisation and conformational equilibrium of pyranose acetates Lemieux[5] calculated the anomeric effects for hexoses and pentoses as 1.5 and 1.3 kcal mole^{-1} respectively. The difference between these values is probably due to the electronegativity of the 5-substituents and in particular the inductive effect of the 6-oxygen atom.

The increased content (88%) of the axial isomer in glucose penta-acetate in comparison with xylose tetra-acetate (78.5%) and oxan-2-yl acetate (75%) is attributed by Anderson and Sepp[101] not only to the polar effect of the 6-hydroxymethyl group but also to interaction of the 3- and 4-acetoxy-groups.

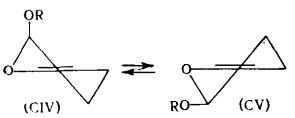


(CI) (CII) (CIII)

The conformational equilibrium of β-D-ribopyranose tetra-acetate (CI) ⇌ (CII) is displaced towards the *trans*-axial conformation (CII) by an anomeric effect[136]. α-D-Lyxopyranose tetra-acetate exists to the extent of 98% as the conformation (CIII).[138]

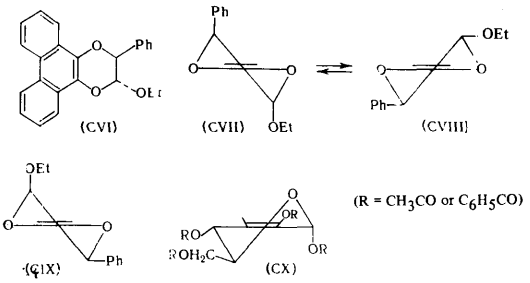
(*g*) Alkoxy-derivatives of dihydropyrans and dihydrobenzopyrans

The half chair is the preferred conformation of unsaturated and fused pyran derivatives containing a 5–6 double bond. Since ΔG_R decreases on passing from derivatives of cyclohexane to those of cyclohexene[137], a distinct anomeric effect was to be expected in dihydropyran derivatives. In fact Zefirov and Shekhtman found[54,87] with 2-alkoxy-3,4-dihydropyrans that the axial conformation (CIV) is predominant.



(CIV) (CV)

An anomeric effect has been demonstrated by nuclear magnetic resonance in 2-alkoxy-derivatives of chroman[86,139,140], 5,6-benzochroman[139], and dihydrophenanthro-1,4-dioxan[114]. Pfundt and Farid[114] observed with *trans*-2-ethoxy-5,6-dihydro-3-phenyl-5,6-phenanthro-1,4-dioxan (CVI) a mobile equilibrium with a considerable proportion of the diaxial conformation (CVII). Such a position of conformational equilibrium is undoubtedly due to a considerable decrease in ΔG_{Ph} on passing from oxan to dihydropyran derivatives. The *cis*-isomer exists as the conformation containing an axial ethoxy-group (CIX).



(CVI) (CVII) (CVIII)

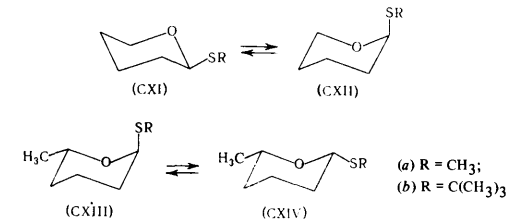
(CIX) (CX) (R = CH_3CO or C_6H_5CO)

Ferrier and Sankey[141] used nuclear magnetic resonance to show that, in esters of 2,3-didehydro-3-deoxyaldoses (CX), the allyl ester groups occupy preferentially (with respect to the double bond) a quasi-axial position, and the anomeric effect is 0.8 and 1.3 kcal mole^{-1} for the acetoxy- and benzoyloxy-groups respectively.

4. The O–C–S Fragment

(*a*) Alkylthio-derivatives of oxygen-containing heterocycles

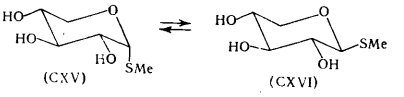
Semi-quantitative n.m.r. data have shown that 2-phenylthio- and 2-ethylthio-oxans possess an anomeric effect, although it is considerably weaker than in alkoxy-derivatives[54]. With 2-ethylthio-oxan, for example, the equilibrium mixture (in carbon tetrachloride) contains 65% of the axial isomer (CXII). This value agrees satisfactorily with results for the epimerisation of 2-methylthio- and 2-t-butylthio-6-methyloxans[56], the proportion of the axial *trans*-isomers (CXIII) being ~ 65% for both compounds. In acetonitrile, however, the equilibrium (CXIII) ⇌ (CXIV) is displaced in favour of the equatorial epimer, with values of ΔG of −0.08 and −0.12 kcal mole^{-1} for cases (*a*) and (*b*) respectively.



(CXI) (CXII)

(CXIII) (CXIV) (*a*) R = CH_3; (*b*) R = $C(CH_3)_3$

The epimerisation of methyl 1-deoxy-1-mercapto-β-D-ribopyranoside yields a mixture containing 18.5% and 7.4% respectively of the α- and β-epimers (CXV) and (CXVI), and thus suggests the presence of an anomeric effect. However, these results are not very exact, since the mixture contains a considerable proportion of furanoside forms[142]. 2-Ethylthiodihydrophenanthro-1,4-dioxan also exhibits an anomeric effect[114], the equilibrium content of the axial conformation being ~ 60%.

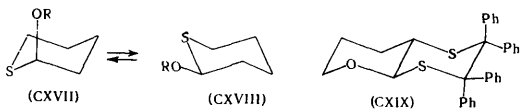


(CXV) (CXVI)

The above results show that the dipole interaction of oxygen and sulphur atoms is sufficient to destabilise the equatorial conformation.

(*b*) Alkoxythians

Since an anomeric effect is found with 2-alkylthio-derivatives of oxan, it should obviously occur also with alkoxylated six-membered sulphur-containing heterocycles. Zefirov et al. have shown[117,143] a distinct anomeric effect with 2-alkoxythians (CXVII) ⇌ (CXVIII). Thus the n.m.r. spectra indicate at least 90% of the isomer having the conformation (CXVII) at equilibrium in the cases of 2-methoxy- and 2-n-butoxy-thians, and the effect of solvents on the conformational equilibrium coincides with that observed for 2-alkoxyoxans[54,55].



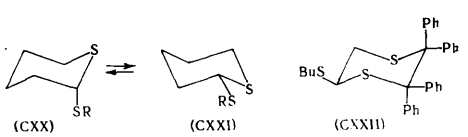
(CXVII) (CXVIII) (CXIX)

Distinct predominance of the axial conformation of alkoxy-derivatives has been found with 2-ethoxy- and 2-butoxy-5,5,6,6-tetraphenyl-1,4-dithians[144]. Thiobenzophenone reacts with dihydropyran to form *trans*-3,3,4,4-tetraphenyl-7-oxa-2,5-dithiabicyclo[4,4,0]decane (CXIX), the structure of which has been proved by n.m.r. spectroscopy[144,145]. In this connection it is of great interest to obtain the *cis*-isomer and also to study epimerisation.

It is interesting that according to the n.m.r. spectra[146] an anomeric effect occurs with thian-2-ol in deuterochloroform.

5. The S–C–S Fragment

Alkylthiothians (CXX) ⇌ (CXXI) exhibit a distinct anomeric effect[117], which has been estimated as 0.7 and 0.5 kcal mole^{-1} in carbon tetrachloride and in acetonitrile respectively.

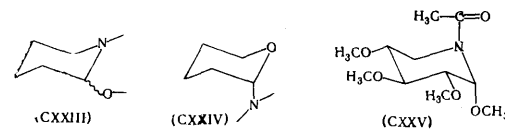


(CXX) (CXXI) (CXXII)

According to n.m.r. data, however, 2-butylthio-5,5,6,6-tetraphenyl-1,4-dithian exists predominantly as the equatorial conformation (CXXII).[144] This is probably due to strong 1,3-repulsion between phenyl and butylthio-groups, which predominates over the anomeric effect.

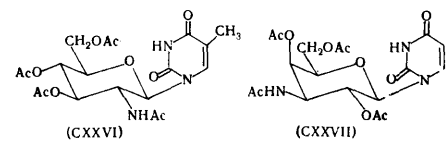
6. The N–C–O Fragment

The N–C–O fragment, containing an amino-nitrogen atom, can occur in two forms (CXXIII) and (CXXIV). In view of the variety of functional nitrogen groups, moreover, the conformational equilibrium of compounds of type (CXXIV) will obviously depend on the kind of nitrogen group present. Very few data are available on compounds of type (CXXIII).[147–149] Thus methyl *N*-acetyl-2,3,4-tri-*O*-methyl-α-D-xylopiperidinose occurs predominantly in the form (CXXV).[147] However, this effect may be due to purely steric factors (the conformation of 2-substituted *N*-acetylpiperidines will be discussed below). Compounds of type (CXXIV) containing an amino-group have been studied fairly thoroughly, but few data are available on the conformational equilibrium of such systems.



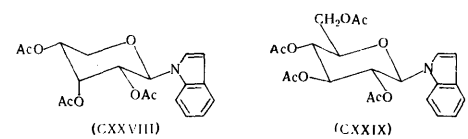
(CXXIII) (CXXIV) (CXXV)

A quite large number of examples have shown that substituents having an sp^2-hybrid nitrogen atom do not develop an anomeric effect. Thus epimerisation data for 1-(2-acetamido-3,4,6-tri-*O*-acetyldeoxy-β-D-glucopyranosyl)-thymine[150] and 1-(3-acetamido-2,4,6-tri-*O*-acetyl-3-deoxy-β-D-galactopyranosyl)uracil[151] indicate that the equatorial conformations (CXXVI) and (CXXVII) respectively are the more stable.



(CXXVI) (CXXVII)

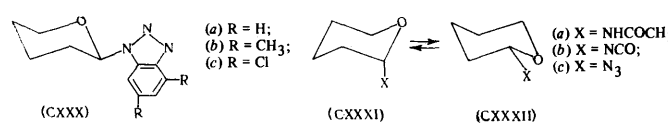
In a study of analogues of nucleosides Cushley et al.[152] discovered that an *N*-indolyl substituent on the $C_{(1')}$ atom of the pyranose ring also occupies the equatorial position, e.g. in



(CXXVIII) (CXXIX)

Similarly, the equatorial conformation (CXXX) is stable with benzotriazolyloxans[153].

A semi-quantitative estimate of the position of conformational equilibrium in *N*-oxan-2′-ylacetamide shows[104] that at least 85% of the conformation (CXXXII*a*) is present in the equilibrium (CXXXI) ⇌ (CXXXII).



(CXXX) (CXXXI) (CXXXII)

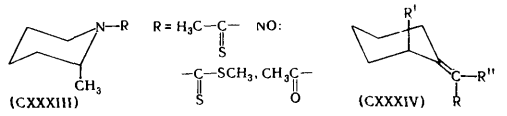
However, the situation changes markedly on passing to 2-substituted oxan derivatives containing linear functional groups in which nitrogen is present in the *sp*-hybrid state. Thus Zefirov and Shekhtman[104] showed by an n.m.r. method that the axial conformations (CXXXI*b*) and (CXXXI*c*) predominate at equilibrium in oxan-2-yl azide and isocyanate respectively, their proportions lying in the range 70–80%. It is interesting that, in the case of the azide, the proportion of the axial conformation diminishes on passing from acetonitrile to carbon tetrachloride.

7. The Fragments O–C–C, S–C–C, and N–C–C

The varied character of the functional groups containing a carbon atom makes it necessary to examine the conformational behaviour of compounds as a function of the type of hybridisation of the carbon atom. Consideration of the volume and electronegativity of the functional groups containing a tetrehedral carbon atom indicates absence of an anomeric effect with compounds containing simple alkyl groups. This principle is confirmed experimentally[154,155].

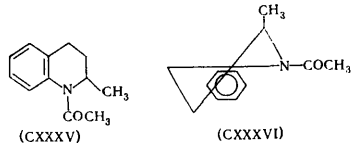
Anomalies might be expected with strong electron-acceptor groups such as trifluoromethyl and trichloromethyl, but experimental data on this aspect are lacking.

A very interesting phenomenon was discovered by Paulsen et al.[147,156,157], who found that a 2-methyl group in *N*-thioacetyl-, *N*-*syn*-nitroso-, *N*-methylthiothiocarbonyl-, and *N*-acetyl-piperidines occupies an axial position (CXXXIII). This phenomenon is most probably due not to a polar but to a steric effect. In fact, the cyclic nitrogen atom is trigonal in all the compounds, which produces strong steric repulsion between the *N*-substituents and the equatorial 2-methyl group.

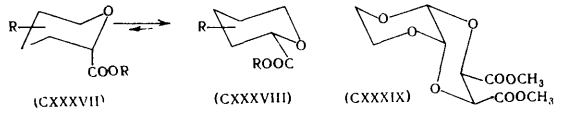


A similar effect has been found with cyclohexanes having an exocyclic double bond. Thus for compounds of type (CXXXIV) in which R = R′ = CH_3 the equilibrium mixture contains 85% of the axial conformations (CXXXIV).[158,159]

The methyl group in *N*-acetyltetrahydroquinaldine (CXXXV) has the axial conformation (CXXXVI).[155]



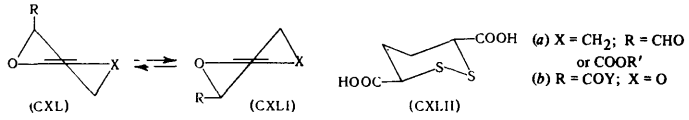
Available published data indicate that an anomeric effect is absent also from functional groups containing an sp^2-hybrid carbon atom. Thus epimerisation data on methyl alkyloxan-2-carboxylates (CXXXVII) ⇌ (CXXXIII) indicate that for the methoxycarbonyl groups ΔG = 1.62 kcal $mole^{-1}$.[160]



Using n.m.r. data Bramley et al.[161] showed that dimethyl decahydro-1,4,5,8-tetraoxanaphthalene-2,3-dicarboxylate has *cis*-fusion of the rings with a diequatorial arrangement of the methoxycarbonyl groups (CXXXIX).

A preferred equatorial position of methoxycarbonyl groups has been found also with isomeric methyl 6-alkoxyoxan-2-carboxylates[110,112].

Nuclear magnetic resonance has shown that the conformational equilibrium of 2-formyl- and 2-methoxycarbonyloxans is shifted towards the equatorial form (CXLI*a*).[137,162]



The absence of an anomeric effect in *trans*-1,2-dithian-3,6-dicarboxylic acid (CXLII) has been demonstrated by X-ray examination[163].

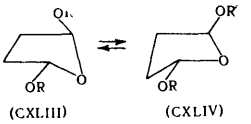
However, very interesting results have been obtained from a study of the conformational equilibrium of benzo-1,4-dioxan-2-carboxylic acid and its derivatives. The proportion of the axial conformation (CXL*b*) is 70%.[162,164] In this case the conformation is probably determined either by dipole–dipole attraction between the 4-heteroatom and the 2-functional group or by the inverse "hockey-stick effect", in which overlapping of the *p*-orbital of the carbon atom of the methoxycarbonyl group and the orbital of the 4:oxygen atm, which has a lone pair of electrons, leads to stabilisation of the axial conformation.

We may note in conclusion that data on functional groups having an *sp*-hybrid carbon atom are lacking, and therefore an experimental study of this question would be welcome.

IV. THE ANOMERIC EFFECT IN ACYCLIC AND NON-SIX-MEMBERED CYCLIC STRUCTURES

The anomeric effect should obviously apply to other types of structures containing an X–C–Y fragment.

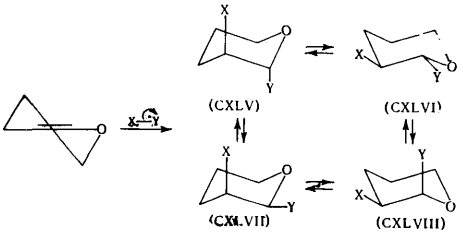
With cyclic structures interaction of this type should lead to stabilisation of the gauche conformation. Experimental data have shown that acetals exist predominantly in the gauche–gauche conformation[165], and a chloromethyl ether as a gauche conformation[166]. Polyformaldehyde, in contrast to polyethylene, forms a spiral chain[56,167].



A clear anomeric effect has been found in 2,5-dimethoxyoxolan[106]. Epimerisation in benzene yields an equilibrium mixture containing 63% of the *trans*-isomer (CXLIII). Increase in the polarity of the solvent shifts the equilibrium in favour of the *cis*-isomer (CXLIV). A similar situation has been found in 2-substituted 1,3-dioxolans[168]. This effect will obviously hold also for non-six-membered rings.

V. THE ANOMERIC EFFECT AS A FACTOR DETERMINING THE STEREOCHEMICAL COURSE OF REACTIONS

If a reaction is controlled thermodynamically, the anomeric effect will obviously be one factor determining the configuration of the products. This has already been shown in the examples of epimerisation. However, it applies also to certain other types of reactions. In particular, electrophilic addition at the double bond in Δ^2-dihydropyrans will lead under conditions of thermodynamic control to an appreciable quantity of a product having a *cis*-configuration. If a mechanism of *trans*-addition via the intermediate formation of an onium ion is accepted (for an alternative view see Ref. 169), the product will exist in the two conformations (CXLV) and (CXLVI). In this case epimerisation will yield the *cis*-isomer, which exists in the conformations (CXLVII) and (CXLVIII). In the absence of strong 1,2-repulsion between substituents X and Y to stabilise the conformation (CXLV), the conformation (CXLVIII) should obviously be the most stable. In fact, the halogenation of dihydropyran gives a mixture of *cis*- and *trans*-isomers[143,170], as discussed above, the proportion of the *cis*-isomer being greater in the dibromide than in the dichloride.



The addition of such electrophilic agents as nitrosyl chloride, oxalyl chloride, and acetals in the presence of boron trifluoride yields products having a *cis*-configuration of the type (CXLVIII).[169] The addition of ethanesulphenyl chloride to dihydropyran at low temperatures conforms to kinetic control and gives a normal product of *trans*-configuration, but at high temperatures the *cis*-isomer is obtained[171]. In the absence of added acid agents, which promote thermodynamic control, the formation of *trans*-products is more probable. In particular, as already noted above[55], the oxymercuration of dihydropyran yields the *trans*-isomer. It is noteworthy that *cis*-addition is very often observed in electrophilic additions at the double bond in polyfunctional derivatives of dihydropyran (glycals).[78,172-177]

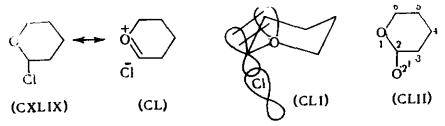
VI. THE NATURE OF THE ANOMERIC EFFECT

It is evident from the above discussion that an "anomeric effect" is exhibited by an extraordinarily wide range of compounds of various types and covers quite diverse phenomena. It therefore becomes necessary to refine this concept.

In a broad sense the term "anomeric effect" can be understood purely phenomenologically as the predominance of the axial conformation of a substituent in the α-position with respect to a heteroatom. Such an effect can obviously be due to a wide variety of causes, including purely steric factors, as has been discussed above for acetyl derivatives of piperidine.

In a narrower sense the anomeric effect can be understood as the predominance of an axial form as a consequence of specific non-steric interaction of a substituent with an adjacent heteroatom. This definition eliminates from discussion the effect of interaction of the substituent with a remote heteroatom, as discussed above for benzodioxan-2-carboxylic acid. In this sense the problem of the nature of the anomeric effect reduces to studying the interaction between the substituent and the heteroatom.

Two views are held on the nature of such interaction, according to one of which an explanation of the anomeric effect is to be sought in stereoelectronic factors. The concept of "double bond–no bond resonance"[178,180] is applied for this purpose. This concept has been used to explain various anomalies in the physical properties of compounds in which two electronegative substituents are attached to the same carbon atom. On this basis the resonance structures of 2-halogeno-oxans will be (CXLIX) and (CL).

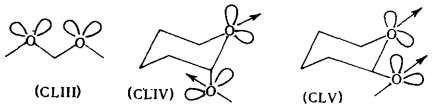


(CXLIX) (CL) (CLI) (CLII)

Such resonance is due to overlapping of the p_Z-orbital of the oxygen atom and the σ^*-orbital of the C–X bond (CLI).[7] The interaction between the p-electrons of the oxygen atom and the framework of σ-bonds for the fragment CH_2-O-CH_2-X has been examined[180-182]. Such overlapping will obviously be greatest with the halogen atom in the axial position. Therefore mixing of e.g. the p_Z-orbital of the ring oxygen atom and the σ^*-orbital of the carbon–halogen bond should result in stabilisation of the axial conformation. Conjugation of this type is supported by the shortening of the carbon–oxygen bond and lengthening of the C–X bond which are observed experimentally in several cases[183,184].

The situation is far more complicated, however, with alkoxy-derivatives[185-187]. Both the exocyclic $C_{(2)}-O_{(2')}$ bond (CLII) and in several cases also the $C_{(2)}-O_{(1)}$ bond are shortened. Shortening of the former bond has been observed also for the equatorial conformation[186,187].

Attempts have been made to relate the variation in bond lengths with the variation in angles and hence in hybridisation[187,188]. On the whole, however, this is a very complicated question, and a more detailed examination of this aspect of the "anomeric effect" encounters certain difficulties.



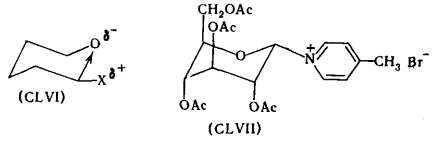
(CLIII) (CLIV) (CLV)

The second view relates the "anomeric effect" to dipole–dipole repulsion of substituent and heteroatom. The first to apply this idea was Edward[42]. Formulae (CLIV) and (CLV) show that dipole interaction is stronger in the equatorial than in the axial conformation. This view has been adopted in most papers. It is consistent with the influence of the solvent on the magnitude of the anomeric effect and with the qualitative changes observed with variation in the electronegativity of the substituent and the introduction of addition substituents[105,107,132]. Attempts have been made to calculate the electrostatic repulsion due to the dipole interaction[7]. However, although these calculations are consistent with the qualitative picture, they are unable to provide serious support for this view owing to the crudeness of the postulates involved.

A somewhat refined picture of such dipole–dipole interaction has recently become widespread. Since a considerable part of the negative charge is concentrated in the region of the lone pairs of the oxygen atoms, a rotational conformation of the type (CLIII) for the acetal fragment would be unstable. This phenomenon has been termed the "rabbit's-ears effect"[7-10]. An example is provided by the anomeric effect in alkoxyoxans. In several cases the "rabbit's-ears effect" enables the rotational conformations of alkoxy-groups to be predicted correctly, and it is applicable also to several nitrogen heterocycles and aliphatic compounds. In essence, however, this effect is also phenomenological, since the detailed causes of the instability of the conformation (CLIII) are unknown.

VII. THE INVERSE ANOMERIC EFFECT

In view of the polar nature of the anomeric effect, the converse effect can be imagined, in which there is dipole–dipole attraction between substituent and heteroatom of the type (CLVI). For a methyl alkyloxan-2-carboxylate, as noted above, $\Delta G_{COOR} = 1.62$ kcal mole^{-1},[160] which exceeds the value in methyl cyclohexanecarboxylate by 0.5 kcal mole^{-1}. Such an increase in the value of ΔG can be explained by two factors: a decrease in the distance between the atoms $C_{(2)}$ and $C_{(6)}$ in oxan will lead to an increase in 1,3-diaxial repulsion between the 6-hydrogen atom and the 2-substituent; it is also possible that this difference is due to an inverse anomeric effect.



(CLVI) (CLVII)

The clearest example of an inverse anomeric effect was observed by Lemieux and Morgan[189] with a glucopyranosylpyridinium salt. According to n.m.r. data this compound exists as the conformation (CLVII), in which the three acetoxy-groups and the acetoxymethyl group are present in axial conformations. Stabilisation of such a conformation is obviously due to an inverse anomeric effect—attraction of the heteroatom and the equatorial pyridinium group. Obviously, although very little study has been made of the inverse anomeric effect, it should also be a general phenomenon, applying to a wide range of compounds.

---o0o---

As the present Review has shown, the anomeric effect is a general conformational phenomenon covering an extraordinarily wide range of compounds. Although the nature of this effect is a matter of controversy, we are able to predict it with a considerable degree of probability for a large number of compounds which have not yet been studied. It is quite obvious that further investigation of this effect with the use of new model compounds and a more profound study will lead to progress in understanding the nature of the forces determining the conformations of molecules.

Advances in the Synthesis of Glycerol Phosphatide Esters

V.I.Shvets

CONTENTS

I. Introduction	330
II. Synthesis of glycerophosphatides from 1,2-diglyceride structures	330
III. Synthesis of glycerophosphatides by the acylation of substituted glycerophosphoric acids	336
IV. Synthesis of complex glycerophosphatides	337
V. Methods of synthesis of optically active phosphoinositides	338

A survey is given of the present position in the synthesis of glycerol phosphatide esters—phosphoric esters in which the glycerol residue is esterified—some of the principal representatives of the biologically important class of substances, the lipids. The main principles and recent advances are discussed in the synthesis of classical glycerol phosphatide diesters of the type of cephalins, lecithins, phosphatidylserines, cardiolipins, phosphatidylglycerols and their amino-acid derivatives, etc., and also complex phosphatides containing amino-acids, peptides, and sugars. Special attention is paid to the synthesis of optically active unsymettrically substituted myoinositols, which include such glycerol phosphatides as mono-, di-, and tri-phosphoinositides and complexes based on them. The list of references includes 246 items.

I. INTRODUCTION

During the past twenty years the chemistry of the important natural compounds the lipids, including that of glycerol phosphatide esters, has made great advances, with the possibility of finally determining the structure of the principal classical glycerophosphatide esters—phosphatidic acids, phosphatidylaminoethanols (cephalins), phosphatidylcholines (lecithins), phosphatidylserines, phosphoinositides of various types (mono-, di-, and tri-phosphoinositides) phosphatidylglycerols, diphosphatidylglycerols (cardiolipins), amino-acid derivatives of phosphatidylglycerol, etc.[1,2]

To a considerable extent this enabled the problem of studying the part played by glycerophosphatides in processes occurring in the living cell (membrane processes, the chain of electron transfer, the transmission of nerve impulses, metabolic mechanisms, etc.) to be raised to the molecular level, which promises in the near future to solve many fundamental questions of biology where an important role is assigned to glycerophosphatides[3].

Synthetic work in the field of glycerophosphatides has made one of the principal contributions to their chemical investigation. The main lines of these researches were shown in several reviews[4-12], which were devoted to individual aspects of the synthetic chemistry of glycerophosphatides and hence did not give a complete picture. Furthermore, most of them almost completely ignore work in the Soviet Union on the synthesis of glycerophosphatides, which is being widely developed at the present time and in many respects has enriched considerably our knowledge of their chemistry. These were the main reasons for publishing the present Review.

The synthesis of glycerophosphatides reached its present level in effect only during the past decade in connection with the widespread introduction into the chemistry of lipids of physicochemical methods for purifying and identifying organic compounds and establishing their structure. In this sense an important part in the advances of recent years has been played by adsorption, paper, thin-layer, and gas–liquid chromatography, infrared spectroscopy, and recently mass spectroscopy, nuclear magnetic resonance (n.m.r.), and optical rotatory dispersion.

Nowadays the synthesis of diester glycerophosphatides such as cephalins, lecithins, and phosphatidylserines—which are often termed classical—presents no difficulty, largely owing to recent advances in the synthesis of triester glycerophosphatides[13-15], phosphatidopeptides[16-21], and other complex glycerophosphatides[22-26], papers on whose isolation from natural sources have begun to appear.

The methods now used for the preparation of glycerophosphatides consist in the successive building up of individual structural parts of the molecule (phosphoric esters of the nitrogen bases and amino-acids, aliphatic acids, etc.) from various derivatives of unsymmetrically substituted glycerol.

All the methods which have been described for synthesising glycerophosphatides can be divided into two broad groups: (1) synthesis from 1,2-diglyceride structures presupposes the initial production of the 1,2-diglyceride part of the molecule, so that in this case the introduction of aliphatic acids into a substituted glycerol molecule precedes phosphorylation; (2) the synthesis from glycerophosphoric esters is characterised by the opposite sequence of esterification and phosphorylation.

II. SYNTHESIS OF GLYCEROPHOSPHATIDES FROM 1,2-DIGLYCERIDE STRUCTURES

This group of preparations includes two independent methods. A common feature is the initial production of a 1,2-diglyceride structure either in the form of a 1,2-diacyl-*sn*-glycerol† or as a 1,2-diacyl-3-deoxy-3-iodo(or bromo)-*sn*-glycerol. Phosphoric ester bonds are formed with the first group of compounds by well known methods of phosphorylation[27], and with the second group by reaction with the silver salts of substituted phosphoric acids[28].

† The nomenclature of optically active unsymmetrically substituted glycerol derivatives conforms to the IUPAC–IUB rules—European J. Biochem., 2, 127 (1967).

1. Synthesis of 1,2-Diglycerides

The preparation of 1,2-diglycerides presents considerable difficulties, owing to the greater reactivity of the 1,3-hydroxy-groups of glycerol in comparison with the 2-hydroxyl, and also because of the ease of migration of acyl groups from the 2-position to the 1- and 3-positions[29]. Therefore many of the earlier published syntheses of 1,2-diglycerides did not yield pure compounds but mixtures of 1,2- and 1,3-diglycerides. These facts have necessitated special approaches to the preparation of 1,2-diglycerides which would avoid these difficulties.

One approach is the temporary protection of the 3-hydroxyl. The methods used most frequently have been benzyloxycarbonyl[30], trityl[31-35], benzyl[39], oxanyl[34,37], ethoxyethyl[34], and 2,2,2-trichloroethoxycarbonyl[38,39] protection. The 3-*O*-derivatives of glycerol were esterified either in stages or exhaustively, and at the last stage the protecting group was removed by catalytic hydrogenolysis[30-32,36] or mild acid hydrolysis, excluding migration of the aliphatic acid radicals[33-35,38,39]. This yielded 1,2-diglycerides containing the same or different acids. The problem of the selective introduction of different aliphatic acid radicals and also the possibility of obtaining highly unsaturated 1,2-diglycerides will be specially considered in subsequent sections.

Another approach to the preparation of 1,2-diacylglycerols consists in using 2-monoglycerides obtained by removing benzylidene protecting groups by catalytic hydrogenolysis[40,41] or mild hydrolysis with boric acid[42,43] of the corresponding acyl derivatives of 1,3-*O*-benzylideneglycerol. 2-Monoglycerides are selectively esterified to 1,2-diglycerides. The method makes it possible to obtain racemic 1,2-diglycerides of any structure and degree of unsaturation.

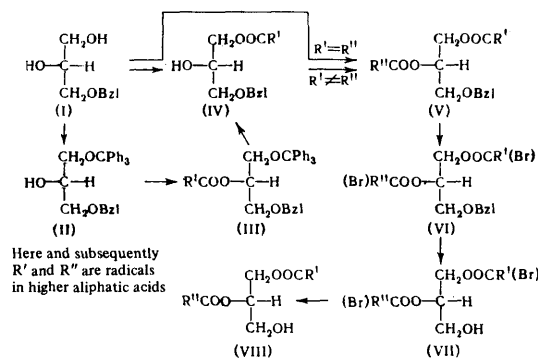
None of the above methods is universally applicable: with some of them it is impossible (or possible in only a few cases) to obtain 1,2-diglycerides containing the radicals of highly unsaturated aliphatic acids[30-32,36], which are widely distributed in natural sources and are of the greatest biological value[1,2]; other methods are unsuited to the preparation of optically active 1,2-diacyl-*sn*-glycerols[30-33,37,44-47], in the form in which they are involved in various biological processes in the living cell[1,2].

Further discussion of synthetic approaches to 1,2-diglycerides will be arranged to show which methods are most suitable for the preparation of saturated and unsaturated 1,2-diacyl-*sn*-glycerols containing the same and different acid radicals. These compounds have been prepared most often by the benzyl method, which was proposed for saturated 1,2-diglycerides[36].

Hydrogenation of ethylenic double bonds in acyl radicals during the preparation of unsaturated 1,2-diglycerides, which would occur on catalytic debenzylation (VI) → (VII), is avoided by preliminary protection with bromine (V) → (VI). Debenzylation is followed by debromination with zinc dust (VII) → (VIII), which restores the original double bonds, without change in their configuration, to give the 1,2-diacyl-*sn*-glycerols (VIII)[48-57] (Scheme 1).

Diglycerides containing different acid radicals can be prepared in two ways, distinguished by the methods used to introduce aliphatic acids into the 1- and 2-positions—(i) acylation in stages (I) → (IV) → (V)[51,52,54,56,57] [direct esterification (I) → (V) yields diglycerides containing the same acid radicals[48,50,52,55]], and (ii) preliminary protection of the 1-hydroxyl with a trityl radical (I) → (II), which, after introduction of an aliphatic acid radical on the 2-hydroxyl (II) → (III), is removed by means of hydrogen chloride with migration of the acyl radical from the 2- to the 1-position (III) → (IV), this being followed by esterification of the freed 2-hydroxyl (IV) → (V).[49,53,54]

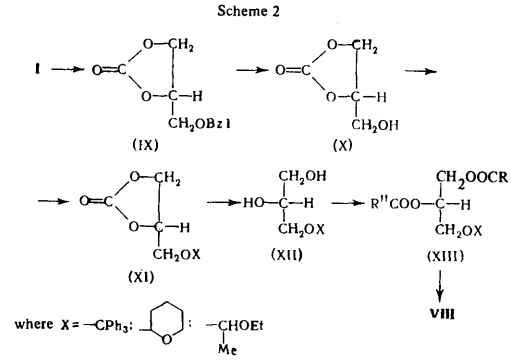
Scheme 1



With highly unsaturated aliphatic acids such as linoleic and linolenic acids the benzyl method of preparing diglycerides has considerable limitations[50-57], and it is entirely unsuitable for the preparation of 1,2-diacyl-*sn*-glycerols containing still more highly unsaturated acid radicals, e.g. from arachidonic acid. This is because a large quantity of bromine introduced at the double bonds in the aliphatic acid leads to difficulties in debenzylation owing to poisoning of the catalyst, and also because of the poor solubility of the bromides which are formed. Several attempts have been made recently to modify the benzyl method of preparing 1,2-diglycerides with the aim of applying it to obtain 1,2-diacyl-*sn*-glycerols of any degree of unsaturation.

The first of these attempts consists in replacing the benzyl protection in 3-*O*-benzyl-*sn*-glycerol (I) by a trityl, an oxanyl, or an ethoxyethyl group (I) → (XII). These groups are easily removed by mild acid hydrolysis of compounds of type (XIII)—obtained by the esterification of 3-*O*-derivatives of *sn*-glycerol (XII)—with the formation of 1,2-diglycerides (VIII) (Scheme 2).[34]

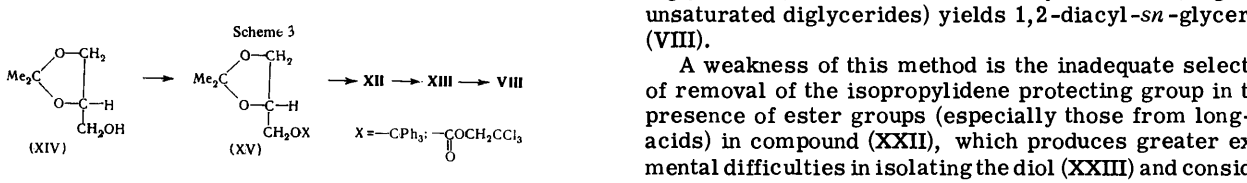
Scheme 2



Other papers[35,38,39] also propose replacing the benzyl group in 3-*O*-substituted glycerol (XII) by groups more suitable for the preparation of highly unsaturated 1,2-diglycerides, such as trityl[35] and 2,2,2-trichloroethoxycarbonyl[38,39] (the former is removed by chromatography on

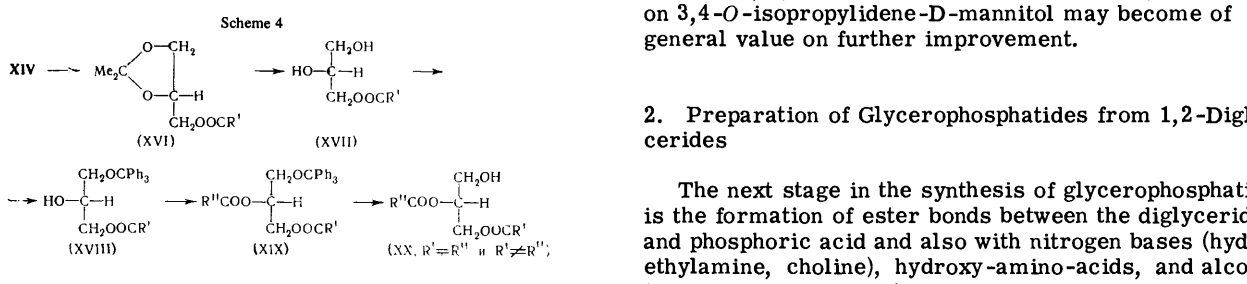
silicic acid[33], and the latter with zinc in acetic acid[38,39]) (Scheme 3).

Scheme 3



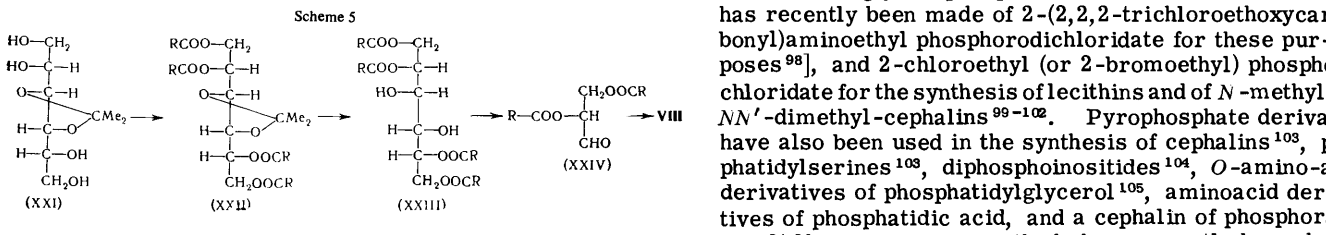
The chief difficulty in these syntheses is to remove isopropylidene protecting groups‡ in the presence of trityl and 2,2,2-trichloroethoxycarbonyl groups (XV) → (XII): in the first case[35] this is achieved by the action of trichloroacetic acid, and in the latter case with boric acid[38,39]. Since both isopropylidene and the two other protective groups[35,38,39] are sensitive to acid hydrolysis, although in differing degrees, it is difficult to rely on complete selectivity of removal of the acetal group, which considerably diminishes the potentialities of this method.

Scheme 4



Attempts to replace benzyl by trityl protecting groups had been made earlier (Scheme 4).[56,58] The diglycerides were prepared from 1,2-*O*-isopropylidene-*sn*-glycerol (XIV), which was converted into the 3-monoglyceride (XVII), then subjected to tritylation and complete acylation (XVII) → (XVIII) → (XIX), and after removal of the trityl protecting group under mild conditions[33] converted, as was to be expected, into the enantiomer of the natural diglyceride, 2,3-diacyl-*sn*-glycerol (XX). The preparation of 1,2-diacyl-*sn*-glycerols by this method from L-mannitol as starting material (D-mannitol was used in the other preparations) was impracticable because of the great shortage of L-mannitol.

Scheme 5



Finally, a new method has recently been suggested for preparing 1,2-diacyl-*sn*-glycerols[59], in which the starting material is 3,4-*O*-isopropylidene-D-mannitol (XXI), which is obtained from D-mannitol via the intermediate formation of 1,2 : 3,4 : 5,6-tri-*O*-isopropylidene-D-mannitol (Scheme 5).[60] Esterification converts (XXI) into the tetra-acyl derivative (XXII). After mild acid hydrolysis of the acetal protecting group the diol (XXIII) is oxidised with lead tetra-acetate to the 1,2-diacyl-*sn*-glyceraldehyde (XXIV). Reduction of (XXIV) with hydrogen in the presence of Raney nickel (for the preparation of saturated diglycerides) or with sodium tetrahydroborate (to give unsaturated diglycerides) yields 1,2-diacyl-*sn*-glycerols (VIII).

A weakness of this method is the inadequate selectivity of removal of the isopropylidene protecting group in the presence of ester groups (especially those from long-chain acids) in compound (XXII), which produces greater experimental difficulties in isolating the diol (XXIII) and considerably diminishes the overall yield of the diglyceride (VIII).

Summarising this Section, we can say that, in spite of the great amount of work on the preparation of 1,2-diacyl-*sn*-glycerols, no method can be suggested at the present time which would be universally applicable to products of any structure and degree of unsaturation. Nevertheless, some specialisation of methods is possible. The benzyl method is the most suitable for obtaining saturated and slightly unsaturated diglycerides. The carbonate method is to be recommended for the preparation of highly unsaturated diglycerides. Finally, methods based on 3-*O*-trityl- or 3-*O*-2′,2′,2′-trichloroethoxycarbonyl-*sn*-glycerols and on 3,4-*O*-isopropylidene-D-mannitol may become of general value on further improvement.

2. Preparation of Glycerophosphatides from 1,2-Diglycerides

The next stage in the synthesis of glycerophosphatides is the formation of ester bonds between the diglycerides and phosphoric acid and also with nitrogen bases (hydroxyethylamine, choline), hydroxy-amino-acids, and alcohols (glycerol, myoinositol).

Phosphorylation is most often effected with phenyl phosphorodichloridate[61-74] and phosphoryl chloride[39,57,75-93] in the cases of saturated and unsaturated compounds respectively. Use of the latter agent lowers the yield of the final glycerophosphatides owing to formation of a large quantity of by-products. Compounds of the required structure are isolated from the complicated reaction mixture mostly by chromatography on silicic acid.

There are several modifications of phosphorylation, which make it possible to achieve unambiguous results in certain particular cases. Thus 2-phthalimidoethyl phosphorodichloridate has been used for the synthesis of cephalins and triester glycerophosphatides[13-15,21,44,47,55,58,94-97] [use has recently been made of 2-(2,2,2-trichloroethoxycarbonyl)aminoethyl phosphorodichloridate for these purposes[98]], and 2-chloroethyl (or 2-bromoethyl) phosphorochloridate for the synthesis of lecithins and of *N*-methyl- and *NN*′-dimethyl-cephalins[99-102]. Pyrophosphate derivatives have also been used in the synthesis of cephalins[103], phosphatidylserines[103], diphosphoinositides[104], *O*-amino-acid derivatives of phosphatidylglycerol[105], aminoacid derivatives of phosphatidic acid, and a cephalin of phosphoramide type[24,26]. Interesting methods have recently been developed for producing bonds of the type P—O—nitrogen base (the latter is usually aminoethanol). Among them are the reactions of phosphatidic acids with aziridine and its derivatives[106,107], and also with nitrogen bases in the presence of trichloroacetonitrile[39], 2,4,6-tri-isopropylbenzenesulphonyl chloride[108], and dicyclohexylcarbodiimide[109]. This last reagent has also been used to obtain phosphatidylglycerol and dipyrophosphatidic acid from phosphatidic acid[93,100].

In order to ensure an unambiguous result of phosphorylation, all the functional groups, other than the hydroxyls

‡ See next paragraph (Editor of Translation).

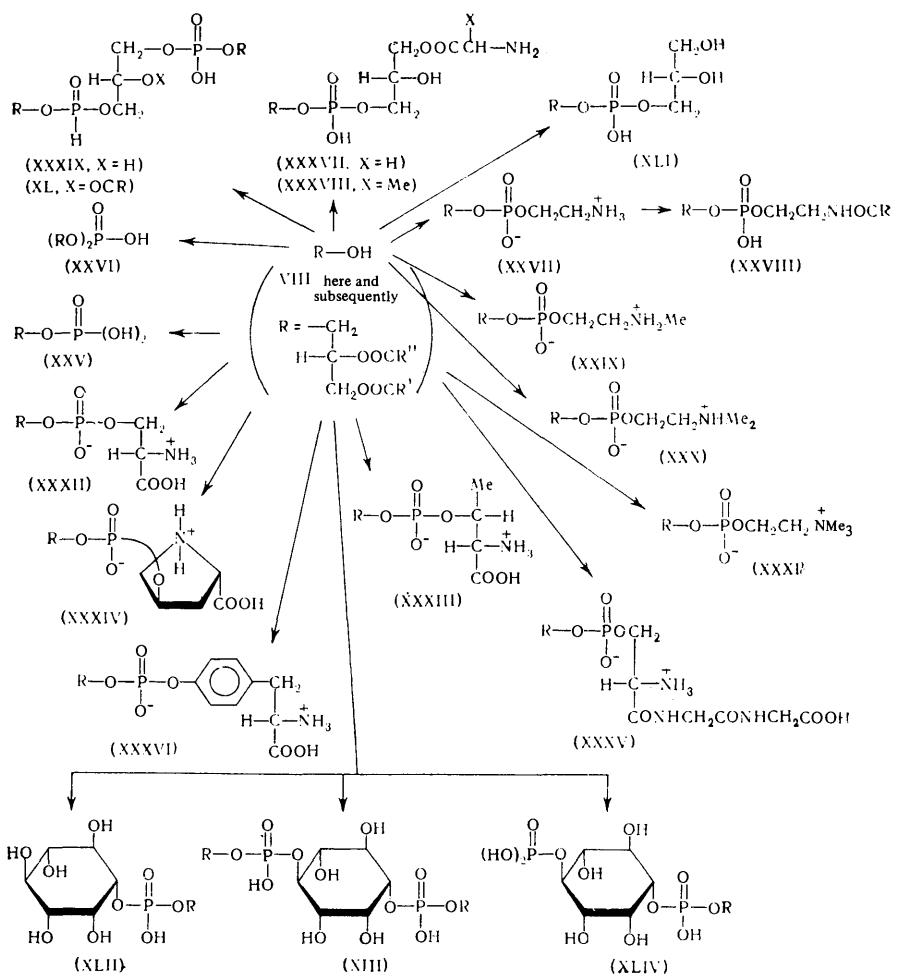
to be phosphorylated, in the nitrogen bases, hydroxy-amino-acids, glycerol, and myoinositol are blocked with protective groups. Amino-groups are protected with benzyloxycarbonyl [13,14,19,25,64,66-72,85], phthaloyl [13-15,44,45,47,55,58,77,78,84,86,94-97,105], t-butoxycarbonyl [39,81,83,90,91,109], methoxybenzyloxycarbonyl [92], 2,2,2-trichloroethoxycarbonyl [98], and γ-chlorobutyroyl [87] groups. The carboxy-groups of the amino-acids are blocked with benzyl [15,24,26,66,67,69,70,103], t-butyl [83,86,90], and phthalimidomethyl [81,87,92] protecting groups; and the hydroxyl of glycerol and myoinositol with benzyl [73,88,105,111-113], t-butyl [91], isopropylidene [75], cyclohexylidene [104,114], acetyl [13,16,21,115], benzoyl [104,116,117], toluene-*p*-sulphonyl [118,119], and oxanyl [111,116] groups.

Protective benzyloxycarbonyl, benzyl, and toluene-*p*-sulphonyl groups are removed in the last stages of hydrogenolysis, which excludes their application to the preparation of unsaturated glycerophosphatides. However, the methods which have appeared for the mild electrochemical removal of these groups will undoubtedly enable the limitations on their protective use to be overcome [20,120,121]. The conditions under which the remaining protective groups are eliminated enables them to be recommended for the preparation of both saturated and unsaturated glycerophosphatides. Thus phthaloyl, phthalimidomethyl, acetyl, and benzoyl groups are split off by mild hydrazinolysis, t-butyl, t-butoxycarbonyl, methoxybenzyloxycarbonyl, γ-chlorobutyroyl, isopropylidene, cyclohexylidene, and oxanyl groups by mild acid hydrolysis; and the 2,2,2-trichloroethoxycarbonyl radical with zinc in acetic acid.

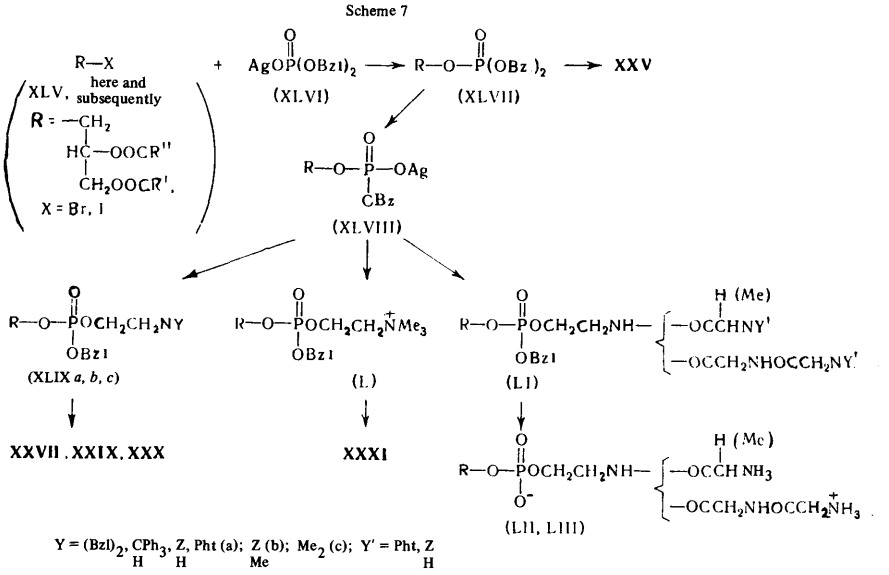
The wide choice of means of protection and phosphorylating agents enables glycerophosphatides of any structure to be obtained, provided that such structure was present in the initial diglycerides and also in the second structural unit of the phosphatide (nitrogen base, hydroxy-amino-acid, glycerol, myoinositol, etc.).

As is shown by Scheme 6, many glycerophosphatides have now been prepared, including phosphatidic acids (XXVI), [65,75,76,82,89,92,93,110,122,123] cephalins (XXVII), [39,44,45,47,55,58,63,64,77,78,84,85,94-98,103,107-109] on the basis of which have recently been obtained *N*-acyl-cephalins (XXVIII), [124] *N*-methylcephalins (XXIX), [68,101,108] *NN'*-dimethylcephalins (XXX), [57,101,108] lecithins (XXXI), [61,62,79,80,99,100,102] phosphatidylserines (XXXII), [66,81,83,89,87,130] and also several phosphatides containing threonine (XXXIII), [70] hydroxyproline (XXXIV), [69,92] and serylglycylglycine (XXXV). [97] Effectively the same methods have been used to obtain the highly unsaturated compounds phosphatidyltyrosine (XXXVI), [90] *O*-amino-acid derivatives of phosphatidylglycerol (XXXVII) and (XXXVIII), [73,91,105]

Scheme 6



Scheme 7



cardiolipin and its acyl derivatives (XXIX) and (XL),[88,89] phosphatidylglycerols (XLI),[75,88,110] and also racemic monophosphoinositides (XLII)[115] and diphosphoinositides of various structures (XLIII) and (XLIV)[104,114] (the preparation of optically active phosphoinositides will be discussed separately).

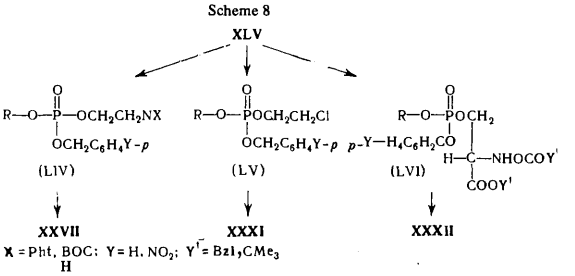
This method has also been used to prepare several modified glycerophosphatides containing 2-aminopropan-1-ol,[72] 2-amino-2-methylpropan-1-ol,[71] α-methylcholine[74], and certain cytotoxic groups[125].

3. Preparation of Glycerophosphatides based on 1,2-Diacylhalogenohydrins of *sn*-Glycerol

The preparation of 1,2-diacylhalogenohydrins of *sn*-glycerol presents considerably fewer difficulties than that of 1,2-diglycerides. They are prepared from 1,2-*O*-isopropylidene-*sn*-glycerol (XIV) in a series of stages, the last of which is esterification. Replacement of the hydroxyl by a halogen (iodine, bromine) is accomplished by the use of toluene-*p*-sulphonyl derivatives as intermediates[28,126-130]. Phosphoric ester bonds are then produced by the reaction of 1,2-diacylhalogenohydrins of *sn*-glycerol with silver salts of substituted phosphoric acids[28].

The synthesis can be effected in two ways. In the first case (Scheme 7) the reaction of 1,2-diacylhalogenohydrins of *sn*-glycerol (XLV) with silver dibenzyl phosphate (XLVI) yields dibenzyl phosphatidates (XLVII), which after anionic monodebenzylation with sodium iodide, lithium fluoride, or a similar reagent[131] are converted into alkali-metal salts, and then into the silver benzyl phosphatidates (XLVIII). These last products react with halogeno-derivatives of nitrogen bases to form protected glycerophosphatides (XLIX)–(LI). The benzyl group (sometimes *p*-nitrobenzyl is used instead) is removed by catalytic hydrogenolysis or by further anionic debenzylation, which in this case can be conveniently accomplished with a tertiary base such as *N*-methylmorpholine. The same groups are used to block amine and carboxyl functions as in the preparation of glycerophosphatides from 1,2-diglycerides. The benzyl[132-134] and trityl[135] groups are also used to protect amino-groups. This variant has proved most convenient for preparing several phosphatidic acids (XXV),[28,130,136-140] cephalins (XXVII),[128,132-135,141] *N*-methylcephalins (XXIX),[135] *NN'*-dimethylcephalins (XXX),[142] lecithins (XXXI),[127,128,143-145] and also phosphatidopeptides (LII) and (LIII).[17-20] Series of lysophosphatides such as lysocephalins and lysolecithins have been obtained similarly[146,147].

Scheme 8



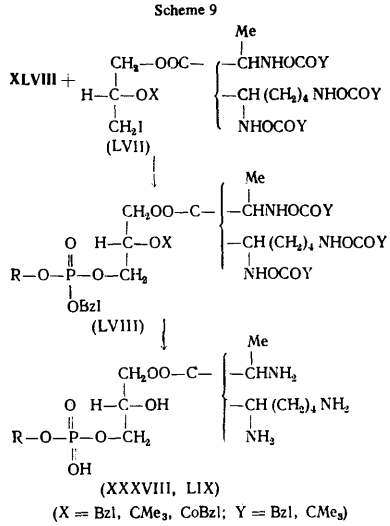
In the second form of the method (Scheme 8) molecules of protected glycerophosphatides (LIV)–(LVI) are produced by condensing the 1,2-diacylhalogenohydrin of *sn*-glycerol (XLV) with a silver salt of a substituted phosphoric acid in which a phosphoric ester bond has already been established with a nitrogen base or with serine.

Differences in principle between these methods are slight. The latter variant has found application also in the synthesis of cephalins (XXVII),[129,127,148-153] lecithins (XXXI),[154] and also, in contrast to the first variant, to obtain phosphatidylserines (XXXII).[126,155,156] This method of synthesis has proved especially convenient for obtaining highly unsaturated phosphatides[148-154,156], amino-groups being protected by means of the t-butoxycarbonyl group[151,156], and the carboxyl function by means of a t-butyl group[156].

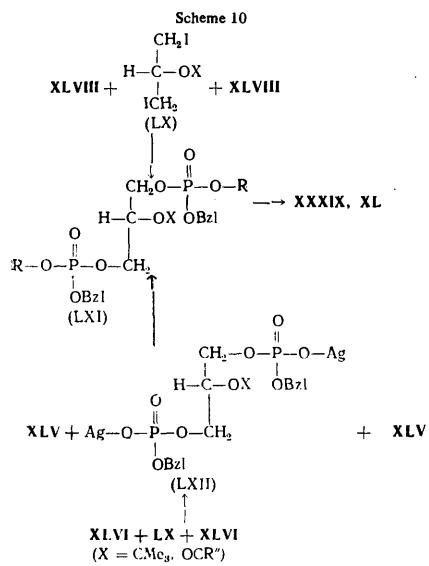
Double decomposition between derivatives of glycerol iodohydrin and silver salts of phosphoric acids is widely used in the preparation of *O*-amino-acid derivatives of phosphatidylglycerol. The method has found application in obtaining both unsaturated[91,157,158] and saturated compounds with individual parts of the molecule differing in configuration[159-161]. It consists in condensing silver benzyl phosphatidates (XLVIII) with glycerol iodohydrins

protected in the 2-position and esterified in the 1- or 3-position with protected amino-acids (LVII). As usual, the protected groups are removed at the last stage: (LVIII) → (XXXVIII), (LIX) (Scheme 9).

Scheme 9



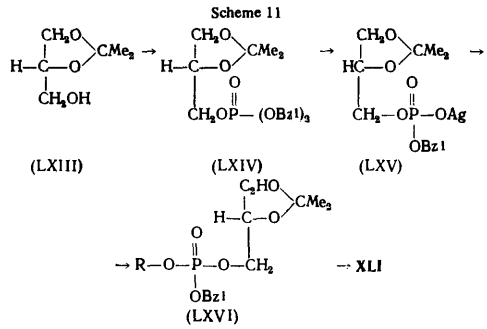
Scheme 10



The same principle forms the basis of a synthesis of cardiolipin (XXXIX) and its *O*-acyl derivatives (XL) [162,163] (Scheme 10). The molecular structures (LXI), containing three glycerol residues linked by phosphoric acid, were produced either by the reaction of two molecules of silver benzyl phosphatidate (XLVIII) with 2-*O*-t-butyl(or acyl)-1,3-deoxy-1,3-di-iodoglycerol (LX) or by combining two molecules of 1,2-diacyliodohydrins of *sn*-glycerol (XLV) with the disilver salt of 2-*O*-t-butyl(or acyl)glycerol 1,3-bis(benzyl phosphate) (LXII), obtained by the reaction of (LX) with silver dibenzyl phosphate (XLVI) followed by partial debenzylation and conversion into the corresponding silver salt (LXII). The protecting groups were removed in the usual way as the final stage: (LXI) → (XXXIX), (XL).

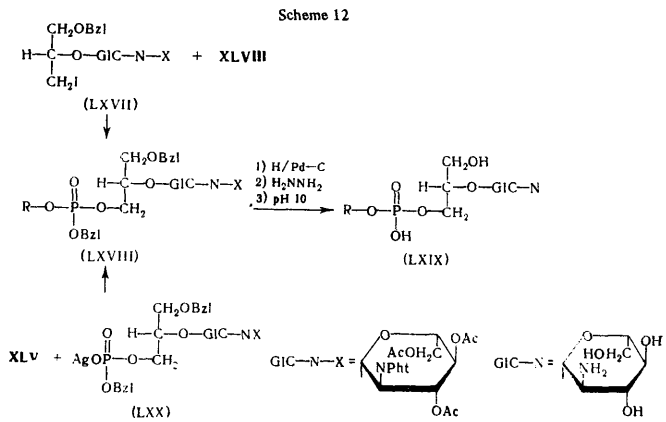
Phosphatidylglycerol (XLI) has been synthesised by a similar method [164] (Scheme 11).

Scheme 11



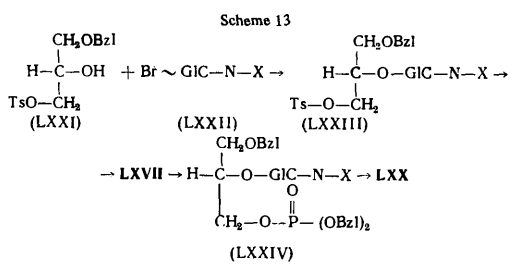
During recent years the present method has been used for the preparation of several glycolipids. The first synthetic work on these lines was concerned with a glucosamine derivatives of phosphatidylglycerol (LXIX) [22]—a glycolipid found in *Bacillus megatherium* [23,165] (Scheme 12).

Scheme 12



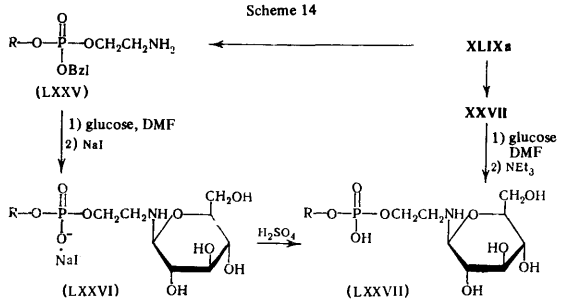
A glycosidic bond between the anomeric hydroxyl of the glucosamine and the 2-hydroxyl of glycerol was formed by the Koenigs–Knorr reaction of the corresponding glycerol derivatives (LXXI) and the glucosamine bromide (LXXII). The product (LXXIII) was converted by well known methods into the halogenohydrin (LXVII) and the silver salt (LXX), which were used as the chief intermediates in the synthesis of a glucosamine derivative of phosphatidylglycerol (LXIX) (Scheme 13).

Scheme 13



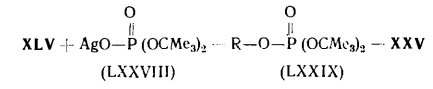
Another example is the synthesis of the *N*-glycoside of aminoethyl phosphatidate (LXXVII) [166] based on synthetic cephalin (XXVII) [135] (Scheme 14).

Scheme 14



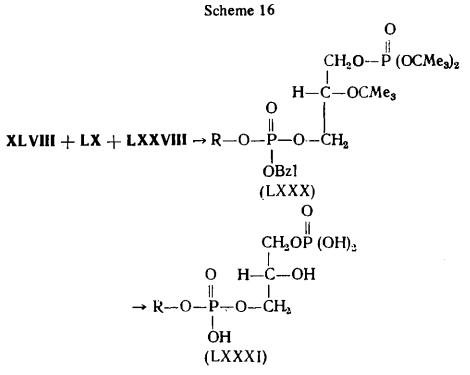
A further development of the method is to use silver di-t-butyl phosphate (LXXVIII) as phosphorylating agent in cases in which phosphoric monoesters are to be prepared, because of the ease of removal of a t-butyl group with hydrogen chloride (Scheme 15). Thus phosphatidic acid (XXV) has been obtained by the reaction of 1,2-diacyliodohydrin of *sn*-glycerol (XLV) with the above silver salt (LXXVIII). [167]

Scheme 15



The same silver salt (LXXVIII) has been used for the synthesis of phosphatidyl glycerophosphate (LXXXI) [167] by condensation with silver benzyl phosphatidate (XLVIII) and glycerol di-iodohydrin (LX) followed by removal of the protecting group (Scheme 16).

Scheme 16



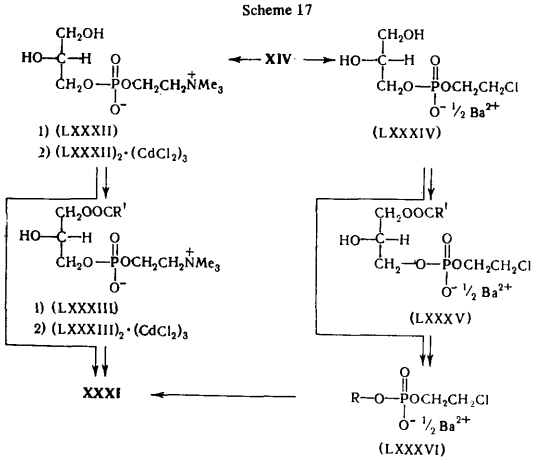
The method of preparing phosphatides by double decomposition of various glycerol halogenohydrins with silver salts of derivatives of phosphoric acids is distinguished from syntheses based on 1,2-diacyl-*sn*-glycerols by its directional character and hence by higher yields of reactions involving the formation of phosphoric ester bonds. However, it is also characterised by many stages and serious experimental difficulties in obtaining many of the starting materials, which often prevent it from competing with the preparation of phosphatides from 1,2-diglycerides.

III. SYNTHESIS OF GLYCEROPHOSPHATIDES BY THE ACYLATION OF SUBSTITUTED GLYCEROPHOSPHORIC ACIDS

The first group of methods for synthesising glycerophosphatides is characterised by several stages, which often diminishes its preparative possibilities. The second type of synthesis, in which the sequence of phosphorylation and acylation is reversed compared with the first group, enables diester glycerophosphatides to be obtained by a shorter route and in high yields directly from 1,2-*O*-isopropylidene-*sn*-glycerol (XIV).

It must be borne in mind that the esterification of glycerophosphoric esters of protected aminoethanol, choline, and serine occurs with considerable difficulty and yields mainly lysophosphatides [62,168,169]. During recent years, however, methods have been found which have permitted the selective or exhaustive esterification of glycerophosphoric esters of nitrogen bases [145,169-192]. The starting material mostly used for this purpose in the synthesis of lecithins (XXXI) has been either the cadmium complex of 3-*sn*-glycerylphosphorylcholine 2(LXXXII).$.3CdCl_2$ [145,169,171-177,179] or barium chloroethyl 3-*sn*-glyceryl phosphate (LXXXIV), [170,178] both obtainable by accessible methods from 1,2-*O*-isopropylidene-*sn*-glycerol (XIV). The compounds—(LXXXII), 2(LXXXII).$3CdCl_2$, (LXXXIII), 2(LXXXIII).$3CdCl_2$, (LXXXIV), and (LXXXV)—were acylated either selectively or exhaustively with aliphatic acid chlorides [169-179] or by enzymatic esterification [180,181]. In the case of the cadmium complexes [145,169,171-177,179] this immediately yields lecithins (XXXI) or lysolecithins (LXXXIII) depending on the degree of esterification. When the barium salts (LXXXIV) and (LXXXV) are used [170,173], the quaternary ammonium group of the lecithins (XXXI) is introduced by reaction between the acylated barium salt (XXXVI) and trimethylamine (Scheme 17).

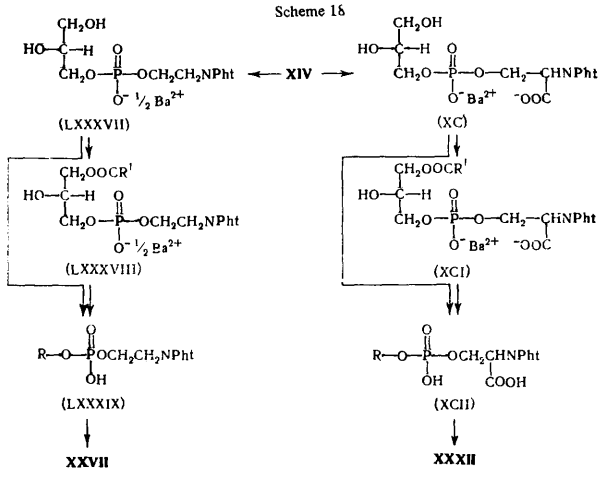
Scheme 17



In the synthesis of cephalins (XXVII) [182-185] and phosphatidylserines (XXXII) [186] from 1,2-*O*-isopropylidene-*sn*-glycerol (XIV) barium 3-*sn*-glyceryl *N*-phthaloylaminoethyl phosphate (LXXXVII) and the corresponding *N*-phthaloylserine salt (XC) are obtained. These are converted by stepwise esterification—(LXXXVII) → (LXXXVIII) → (LXXXIX) or (XC) → (XCI) → (XCII)—or complete esterification—(LXXVII) → (LXXXIX) or (XC) → (XCII)—into phthaloyl derivatives of cephalin (LXXXIX) or

phosphatidylserine (XCII), from which the protective groups are removed by mild hydrazinolysis (XXVII) or (XXXII) (Scheme 18). A similar principle has been used to obtain an unsaturated phosphatidylserine from barium glyceryl *N*-methoxybenzyloxycarbonylserine phosphate or the phthalimidomethyl ester[187].

Scheme 18



Besides being shorter than the first group of methods, the present route for the synthesis of glycerophosphatides has the advantage of being universally applicable for the preparation of phosphatides containing either saturated or unsaturated aliphatic acids.

Attempts have been made at the direct acylation of glycerophosphoric esters of nitrogen bases by means of acid anhydrides. Although the first work of this type[188] has only historic significance, later investigations on the acylation of 3-*sn*-glycerophosphate[189], 3-*sn*-glyceryl-phosphoryl-*N*-phthaloylaminoethanol[190] obtained by saponifying natural cephalins and then protecting the amino-group with a phthaloyl group, and 3-*sn*-glyceryl-phosphorylcholine[191,192] with aliphatic acid anhydrides in the presence of their tetraethylammonium salts can make full claim to preparative use.

IV. SYNTHESIS OF COMPLEX GLYCEROPHOSPHATIDES

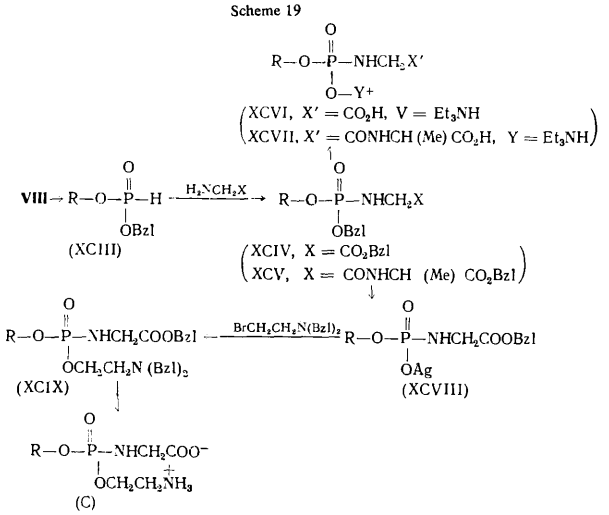
All the papers discussed have been concerned mainly with the synthesis of the so called classical diester glycerophosphatides. An exception is provided by the syntheses of amino-acid derivatives of certain phosphatides (XXXIII), (XXXIV), (XXXVI)–(XXXVIII), and (LIX)[69,70,73,90-92,105,157-161], phosphatidopeptides (XXXV), (LII), and (LIII),[16-21,67] the glucosamino-derivative of phosphatidylglycerol (LXIX),[22] and an *N*-glycoside of phosphatidylaminoethanol (LXXVII);[166] the need to discuss them in preceding Sections was dictated solely by methodological considerations. These compounds cannot be included among classical glycerophosphatides. Phosphatides which contain, besides the traditional structural units, amino-acids, peptides, carbohydrates, etc. are often termed complex phosphatides, and perhaps classical glycerophosphatides are fragments of these complex lipid structures, which are present in natural tissues and are easily decomposed in the course of isolation[193-199]. Another feature of these compounds is presumably a triester structure of the phosphate portion[193-199]. Progress in the synthesis of classical glycerophosphatides has enabled a close approach to be made to obtaining certain classes of complex phosphatides. The chief researches on these lines, other than the few discussed in the previous Sections, will be described below.

Among the most widely distributed complex phospholipids are amino-acid and peptide derivatives of glycerophosphatides. Besides the amino-acid derivatives of phosphatidylglycerol (XXXVII), (XXXVIII), and (LIX), phosphatidylpeptides based on cephalins and phosphatidylserines (XXXV), (LII), (LIII), and also cardiolipin[199] we may assume the possibility of the covalent addition of amino-acids and peptides to the phosphoric acid in glycerophosphatides by means of phosphoramide and acyl–phosphate bonds. Definite indications of the possibility of such complex formation have now been obtained[200].

1. Synthesis of Amino-acid and Peptide Derivatives of Phosphatidic Acid and Phosphatidylaminoethanol of Phosphoramide and Acyl Phosphate Types

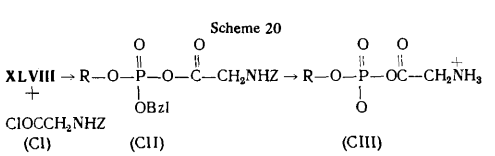
Phosphatidylamino-acids (XCVI)[24] and phosphatidylpeptides (XCVII)[24] containing a phosphoramido-bond are obtained (from 1,2-diglycerides) by a method widely used in the chemistry of nucleotide amino-acids and peptides[201] with synthetic procedures characteristic of glycerophosphatides. In order to obtain (P→N)-glycylphosphatidylaminoethanol (C) the corresponding protected derivative of phosphatidic acid (XCIV) is converted, by the methods described in Section II, into the silver salt (XCVIII), from which the cephalin (XCIX) is formed[26] (Scheme 19).

Scheme 19



A glycine derivative of phosphatidic acid of acyl phosphate type (CIII) is formed by reaction of silver benzyl phosphatidate (XLVIII) with *N*-benzyloxycarbonylglycyl chloride (CI) followed by removal of the protective groups (CII) → (CIII)[25] (Scheme 20).

Scheme 20

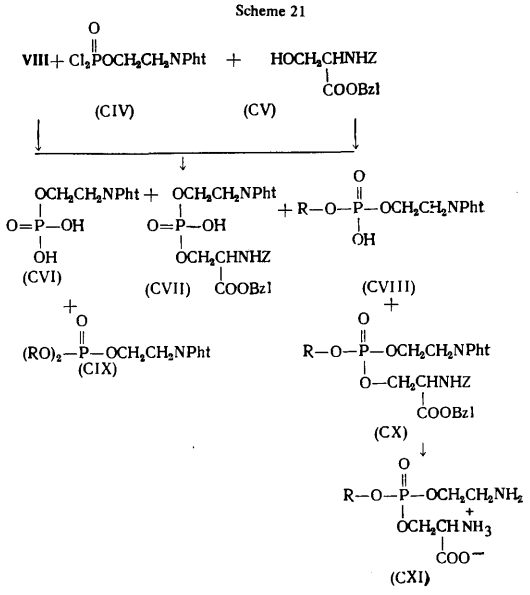


Investigations of the properties under comparable conditions of classical glycerophosphatides and of amino-acid and peptide derivatives of phosphatidic acid and phosphatidylaminoethanol—(XCVI), XCVII), (C), and (CIII)—have shown[24-26] the lower hydrolytic stability of the latter compounds. Both acyl–phosphatide and phosphoramide bonds are labile even in weakly acid media. Study of the structure and properties of the synthetic amino-acid and peptide derivatives of glycerophosphatides—(XCVI), (XCVII), (C), and (CIII)—suggests that such complex formation may occur in natural lipoproteins, but the exceptional lability of these structures creates serious difficulties in their isolation from natural sources in the native state, so that the question of the presence of compounds of this type in natural lipid–protein complexes is still a matter of controversy.

2. Synthesis of Triester Phosphatides and Phosphatidopeptides

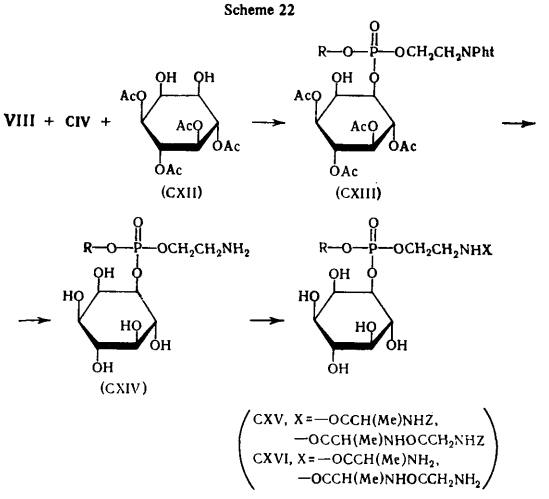
The preparation of triester phosphatides and phosphatidopeptides has been based on the method of synthesising diester glycerophosphatides from 1,2-diglycerides. Aminoethylphosphatidylserine (CXI)—a triester glycerophosphatide assumed to be present in the microsomes of brain tissue[202,203]—has been synthesised by reaction among the 1,2-diglyceride (VIII), 2-phthalimidoethyl phosphorodichloridate (CIV), and the dibenzyl ester of *N*-carboxyserine (CV), with subsequent removal of the protective groups (CX) → (CXI)[15] (Scheme 21). The course of the reaction is ambiguous, being accompanied by the formation of a series of phosphoric mono-, di-, and tri-esters (CVI)–(CIX), as a consequence of which the yield of aminoethylphosphatidylserine (CXI) after removal of the protective groups does not exceed 2–3%.

Scheme 21



The 1-*O*-aminoethylphosphatidylmyoinositol structure (CXIV) has been formed similarly[13]. The synthetic triester (CXIV) has been used to obtain phosphatidopeptides (CXVI)[16,21]—structural units in the lipid complex of ox brain[198]—by condensation of the amino-group in the aminoethyl residue of (CXIV) with the azides of *N*-benzyloxycarbonyl-alanine and -glycylalanine followed by removal of the protective groups by known methods (CXV) → (CXVI) (Scheme 22).

Scheme 22



Study of the stability of the synthetic triester phosphatides—(CXI), (CXIV), and (CXVI)—has shown that they are labile compared with the cephalins, phosphatidylserines, and phosphatidylinositols which they contain[13,15,16,21], this being fully consistent with published data[193-199] on the properties of triester phosphatides. The triester (CXIV) and (CXVI) containing myoinositol are considerably more stable than the triester (CXI),[13,15,16,21] which is supported by the assumed special role of myoinositol in the formation and functioning of complex phosphatides and phosphatidopeptides[198].

V. METHODS OF SYNTHESIS OF OPTICALLY ACTIVE PHOSPHOINOSITIDES

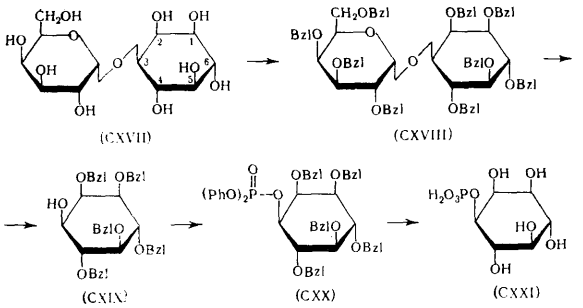
The problem of obtaining optically active phosphoinositides requires special consideration (all those mentioned hitherto were synthesised in optically inactive form). In naturally occurring phosphoinositides the myoinositol molecule is asymmetrically substituted in the 1-equatorial position by the phosphatidyl radical, and hence possesses optical activity. This has been proved both for inositophosphatides of simple structure[204-208] and for the complexes[209-212].

The problem of synthesising optically active phosphoinositides is in essence a particular case of the wider problem of obtaining optically active myoinositol derivatives. At the present time there are two approaches to a solution—(1) the use of natural substances (galactin, quebrachitol, bornesitol, etc.), in which molecular asymmetry is already established, for their further conversion into optically active asymmetrically substituted myoinositols of specified structure; and (2) the resolution of racemic asymmetrically substituted myoinositols, prepared from myoinositol itself, into enantiomers.

1. First Method

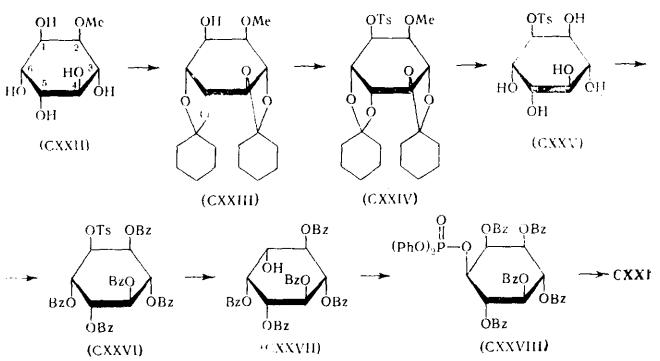
In 1959 Ballou reported[207] the synthesis of optically active *sn*-myoinositol 3-phosphate§. The starting material was galactin, which was completely benzylated (CXVII) → (CXVIII); methanolysis with 1% hydrochloric acid led to cleavage of the α-glycosidic bond in the nonabenzylgalactin (CXVIII); the resulting 1,2,4,5,6-penta-*O*-benzyl-*sn*-myoinositol (CXIX) was phosphorylated with diphenyl phosphorochloridate; and after removal of the protective groups *sn*-myoinositol 3-phosphate (CXXI) was isolated (Scheme 23).

Scheme 23



Gero[117] has recently proposed another route to the optically active 3-phosphate (CXXI), starting from quebrachitol (2-*O*-methyl-(−)-inositol) (CXXII). This was converted into 3,4 : 5,6-di-*O*-cyclohexylidenequebrachitol (CXXIII), which was then transformed into 3,4 : 5,6-di-*O*-cyclohexylidene-2-*O*-methyl-1-*O*-tosyl-(−)-inositol (CXXIV). The latter after elimination of the methyl group with boron trichloride gave 1-*O*-tosyl-(−)-inositol (CXXV). After benzoylation (CXXV) → (CXXVI) and removal of the tosyl group with inversion of the configuration of the 3-hydroxyl the product was 1,2,4,5,6-penta-*O*-benzoyl-*sn*-myoinositol (CXXVII), which was converted by the methods described by Ballou[207] into *sn*-myoinositol 3-phosphate (CXXI) (Scheme 24).

Scheme 24

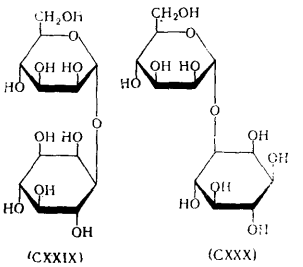


However, these syntheses[117,207,215] possess extremely serious limitations, and hence cannot be recommended for obtaining optically active phosphoinositides of natural structure. Apart from the difficult availability of galactin and quebrachitol, which are isolated from vegetable sources inaccessible in the Soviet Union, the many stages in the syntheses, and the low yields of optically active asymmetrically substituted myoinositols, a further significant defect must be mentioned. It is readily observed that the application of asymmetrically substituted myoinositols, obtained from galactin and quebrachitol, to the synthesis of optically active phosphoinositides will yield phosphatides containing the phosphatidyl group at the 3-position of myoinositol, i.e. of unnatural configuration.

The method of obtaining 2,3,4,5,6-penta-*O*-tosyl-*sn*-myoinositol from (−)-bornesitol (1-*O*-methyl-*sn*-myoinositol),[118,119] based on its exhaustive tosylation with subsequent removal of the methyl group with boron tribromide, does not possess this disadvantage. However, attempts to prepare phosphatidylinositol from 2,3,4,5,6-penta-*O*-tosyl-*sn*-myoinositol have encountered insuperable difficulties[118].

2. Second Method

Purely chemical methods for obtaining the two series of optically active derivatives of myoinositol have not been developed hitherto because of the great difficulty of resolving their racemic mixtures. Isolated papers have been published on unsuccessful attempts at separation[113]. Nevertheless, mention must be made of Angyal's work[216] on the preparation of mannosylmyoinositols, which were obtained in low (4.5%) yield by the Koenigs–Knorr reaction¶ and separated by crystallisation into two diastereomers—1- and 3-*O*-α-D-mannopyranosyl-*sn*-myoinositols



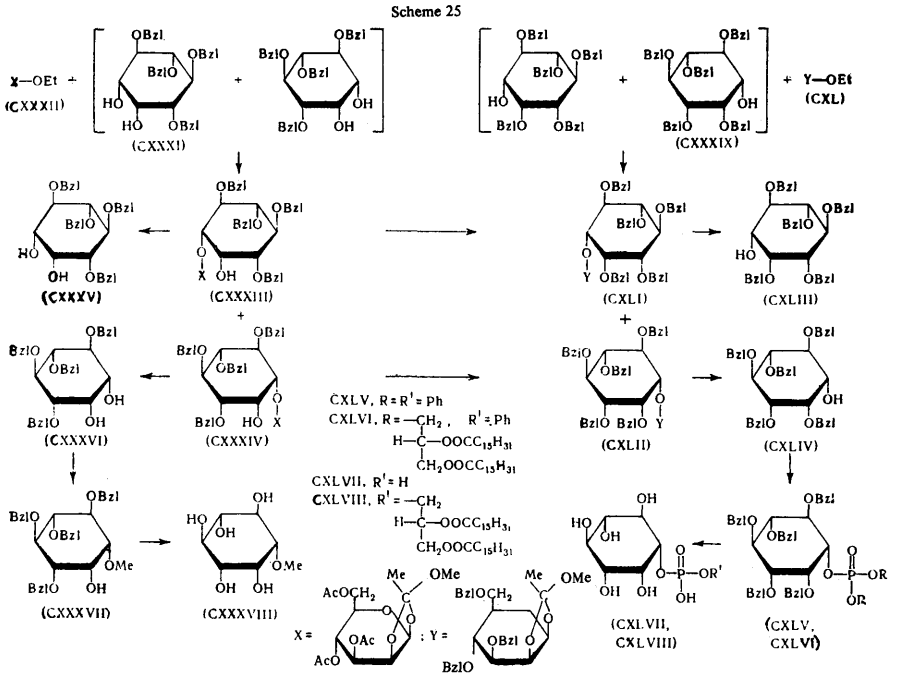
Use of the orthoester method of glycosylation[217] to form a glycosidic bond enabled the yield of diastereomeric mannosylmyoinositols (CXXIX) and (CXXX) to be raised considerably (to 10–12%).[218] The mannoside (CXXIX) might have served as initial compound for obtaining optically active 1-*O*-substituted derivatives of myoinositol, but this was prevented by its low yield in the main reaction.

A procedure has been developed recently in our laboratory for separating racemates of asymmetrically substituted myoinositols via the diastereomeric orthoacetates with D-mannose[219], which has opened a path to obtaining optically active phosphoinositides. Transesterification of 1,4,5,6-tetra-*O*-benzylmyoinositol (CXXXI) with D-mannose orthoacetate (CXXXII) gave the diastereomeric orthoesters (CXXXIII) and (CXXXIV), which were separated by crystallisation or by chromatography. Acid hydrolysis of these orthoesters yielded 1,4,5,6- and 3,4,5,6-tetra-*O*-benzyl-*sn*-myoinositols (CXXXV) and (CXXXVI). The absolute configuration of these products was established by conversion of (CXXXVI) into the methyl ether (CXXXVIII), which was compared with specimens of (+)- and (−)-bornesitols[220] (Scheme 25).

§ Our proposed nomenclature[213,214] is used for optically active myoinositol derivatives.

¶ The Koenigs–Knorr reaction has been used also to prepare galactin in 2.1% yield. In this case the diastereomers were separated by seeding with crystalline natural galactin[216].

Scheme 25



An attempt to use 3,4,5,6-tetra-*O*-benzyl-*sn*-myoinositol (CXXXVI) to synthesise the monophosphoinositide was unsuccessful owing to the presence of vicinal hydroxy-groups in (CXXXVI), which made it necessary to seek ways of synthesising the corresponding pentabenzyl derivatives. 2,3,4,5,6-Penta-*O*-benzyl-*sn*-myoinositol (CXLIV) was obtained from 1,2,4,5,6-penta-*O*-benzylmyoinositol (CXXXIX)[111,113,221] by the method developed for separating 1,4,5,6-tetra-*O*-benzylmyoinositol (CXXXI)[221] (Scheme 25).

Since the orthoesters (CXLI) and (CXLII) have very similar physicochemical properties and are therefore difficult to separate, the synthesis of the pentabenzyl ethers (CXLIII) and (CXLIV) was modified[222]. The orthoesters (CXXXIII) and (CXXXIV), easily obtained by the transesterification of 1,4,5,6-tetra-*O*-benzylmyoinositol (CXXXI),[220] were taken as starting materials. In this case formation of the orthoacetate with D-mannose was used both the resolve racemic compounds and to protect temporarily the 1- and 3-hydroxyls in myoinositol. The stability of the orthoester grouping under alkaline conditions was exploited by exhaustively benzylating (CXXXIII) and (CXXXIV) to (CXLI) and (CXLII), and hydrolysing in the usual way to the pentabenzyl ethers (CXLIII) and (CXLIV). Application of the new carbohydrate orthoester protection enabled optically active pentabenzyl ethers of myoinositol to be obtained in preparative quantities (Scheme 25).

2,3,4,5,6-Penta-*O*-benzyl-*sn*-myoinositol (CXLIV) has been used as starting material for the directed synthesis (Scheme 25) of the structural unit of all phosphoinositides—*sn*-myoinositol 1-phosphate (CXLVII)[221]—which proves to be identical with the *sn*-myoinositol 1-phosphate isolated from soya-bean phosphatides[207].

These investigations culminated in the first chemical synthesis of an optically active phosphatidylinositol[222,223] (Scheme 25). To obtain the monophosphoinositide (CXLVIII) the pentabenzyl ether (CXLIV) was condensed with 1,2-dipalmitoyl-*sn*-glycerol and phenyl phosphorodichloridate to give a compound (CXLVI) which on hydrogenation yielded phosphatidylinositol (CXLVIII). The properties of the synthetic phosphatidylinositol (CXLVIII) were closely similar to those of monophosphoinositides isolated from various natural sources[224,225].

---o0o---

During preparation of the manuscript for press several papers have been published on the synthesis of glycerophosphatides and their structural units.

A new method has been developed for the synthesis of 1,2-diacyl-*sn*-glycerols from *sn*-glycerol 1,2-carbonate[226,227], obtained by a shorter route than the existing method[34] from 3,4-*O*-isopropylidene-D-mannitol. The preparation of 1,2-diglycerides by the direct esterification of this last compound[59], which was unsuitable for compounds containing higher aliphatic acid radicals, has been freed from this defect[228].

The natural glycolipids[229]—mannosyl and glucosyl diglycerides[230]—have been synthesised from the diglycerides obtained[226-228]. Galactosyldiglycerides have been prepared from 2,5-*O*-methylene-D-mannitol[231]. This same compound has been the starting material for a new synthesis of 1,2-diacyl-*sn*-glycerols undertaken in our laboratory, by means of which saturated and unsaturated 1,2-glycerides containing the same and different acid radicals can be obtained.

No fundamentally new work on the synthesis of nitrogen-containing glycerophosphatides has appeared recently, although several papers make a definite contribution to the further development of synthetic methods. Thus the use of 2,4,6-tri-isopropylbenzenesulphonyl chloride as condensing agent to produce a phosphoric ester bond[108] has been extended to the phosphatidyl derivative of L-threonine[232], this synthesis comprising initially the formation of the glycerophosphoric structure and then introduction of ester radicals by means of Lapidot's method using aliphatic acid anhydrides[189].

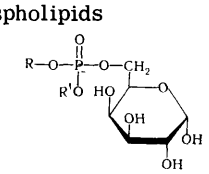
Several papers have appeared on the direct acylation of 3-*sn*-glycerylphosphorylcholine. Thus the cadmium complex of the 1-substituted compound has been used for exhaustive esterification of the 2-position with ^{14}C-labelled oleic acid[233]. Aneja and Chadha[234] have investigated the

mechanism of the esterification of 3-*sn*-glycerylphosphorylcholine by higher aliphatic acid chlorides. The formation of lecithin is shown to be accompanied by that of several more polar secondary products, which has a considerable effect on the overall yield of lecithin[6]. One of them is lysolecithin, and another—previously regarded as a cyclic lysolecithin[6]—is a mixture of isomeric monoacyldeoxychloroglycerylphosphorylcholines, the secondary products being formed from a common intermediate compound.

Among methodological papers mention must be made of the development of the mild removal, by means of zinc in acetic acid, of the phthalimidomethyl group[235], which is widely used for blocking the carboxyl function of amino-acids in the synthesis of phosphatidylserines and phosphatidylhydroxyprolines[81,87,92].

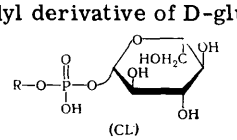
A series of syntheses of certain modified glycerophosphatides was designed to prepare materials for the investigation of enzymatic reactions with phosphatides, the part they play in the formation of biological membranes, etc. Thus, for the purpose of studying lipid–protein interactions by means of electron spin resonance spectroscopy in the investigation of lipolytic enzymes, *O*-(1,2-distearoyl-*sn*-glycerol-3-phosphoryl)-3′-oxymethyl-2′,2′,5′,5′-tetramethylpyrrolidine 1′-oxide has been synthesised by reaction between the corresponding phosphatidic acid and 3-hydroxymethyl-2,2,5,5-tetramethylpyrrolidine 1-oxide in the presence of 2,4,6-tri-isopropylbenzenesulphonyl chloride[236]. 3-Palmitoyl-*sn*-glyceryl-1-phosphorylcholine (lysolecithin of unnatural structure)[237] and also 2,3,4,5-tetrastearoyl-1,6-diphosphorylcholine-D-mannitol (an analogue of lecithin of unnatural structure)[238] have been prepared from 3,4-*O*-isopropylidene-D-mannitol and D-mannitol itself by methods which leave much to be desired from the viewpoint of the present-day chemistry of the glycerophosphatides. The glycerophosphatides obtained were investigated as substrates for phospholipases and acyltransferases. Similar methods have been used to obtain analogues of lysolecithins based on trimethylene glycol[239], which have been examined as components of artificial membranes.

Several papers deal with the synthesis of new glycerophosphatides. Thus the method of silver salts has been used for diester and triester glycophospholipids, which are assumed to be present in natural sources[196–198]. The synthetic glycophospholipids



(CXLIX, R′ = H, $CH_2CH_2NH_2$)

contain D-galactose attached by an ester link to the phosphatidyl group[240,241]. The same method has been used to obtain a phosphatidyl derivative of D-glucose



(CL)

but in this case the phosphatidyl group is attached at the anomeric hydroxyl (CL).[242]

In the field of the synthesis of phosphoinositides the resolution has been accomplished of racemic 1,2:5,6-di-*O*-cyclohexylidenemyoinositol[243], and each of the enantiomers—of 1,2:5,6- and 2,3:4,5-di-*O*-cyclohexylidene-*sn*-myoinositols—can be used as principal starting material for obtaining di- and tri-phosphoinositides and also other members of this class of phosphatides. Attempts to separate 1,2:4,5-di-*O*-cyclohexylidenemyoinositol into enantiomers[244], and also to use D-glucose orthoacetate instead of D-mannose orthoacetate for the resolution[244], have been unsuccessful.

Molotkovskii[245] has accomplished the synthesis of racemic phosphatidylinositol with unsaturated acids using 1,2,4,5,6-penta-*O*-acetylmyoinositol as inositol component. A phosphoric diester bond was formed by reaction of the 1,2-diacyl-3-deoxy-3-iodoglycerol with silver benzyl 1,2,4,5,6-penta-*O*-acetylmyoinositol phosphate.

Gigg and his coworkers[246] have examined in detail the possibility of producing a racemic phosphatidylinositol structure using—(1) the reaction of a 1,2-diacyl-3-deoxy-3-iodoglycerol with various silver phosphates containing 1,2,4,5,6-penta-*O*-benzylmyoinositol attached by a phosphoric ester bond, with subsequent removal of the protective groups by hydrogenolysis and anionic debenzylation; and (2) the reaction of 2,3,4,5,6-penta-*O*-benzylmyoinositol 1-phosphate (obtained by phosphorylation of the corresponding penta-substituted myoinositol with bis-2,2,2-trichloroethyl phosphorochloridate, the protective groups being removed with zinc dust in methanol) with a 1,2-diglyceride in the presence of 2,4,6-tri-isopropylbenzenesulphonyl chloride. The latter method is shown to have considerable advantages over the former.

I. INTRODUCTION

Although 125 years have elapsed since the discovery by Faraday[1] in 1845 of the phenomenon of the rotation of the plane of polarisation in a magnetic field and although numerous investigators both in France and abroad devoted their lives to a profound study of this phenomenon and its applications in structural chemistry, in 1970 the Faraday effect is quite unfamiliar to chemists as a research technique.

The literature, which includes more than 200 papers, clearly shows that a powerful technique now exists whereby it is possible to solve, sometimes very successfully, a large number of problems in structural chemistry. Numerous meetings with investigators from different countries at conferences have revealed a considerable interest in this method. The question thus arises why the Faraday effect is known only to a limited circle of specialists while NMR, infrared, and ultraviolet spectroscopic techniques have become common and classical procedures. The answer is probably that all the papers describing the principles of the method and its applications have been published in French and, with rare exceptions, in French periodicals. It is therefore an urgent necessity to overcome the language barrier in order that the Faraday effect may become internationally known. Our attempt to solve this difficult problem was stimulated by the invaluable support of many well known investigators such as C. A. Coulson, H. D. Ballhausen, C. K. Jorgensen, A. Julg, R. Daudel, A. Sladkov, and J. R. van Wazer, to whom we are indebted for their assistance and advice in the compilation of this review.

II. WHAT IS THE FARADAY EFFECT?

As early as 1845, Faraday[1] made the following fundamental discovery: any transparent substance placed in a magnetic field H rotates the plane of polarisation when monochromatic light is passed through it. This phenomenon may be called magnetic rotation by analogy with natural rotation, although molecular asymmetry is evidently important for the latter, while the former is shown by any substance in a magnetic field. Faraday's experiments were repeated and extended by Becquerel[2], Mathiessen[3], and especially Verdet[4], who was the first to find a quantitative expression for the effect in the form

$$\alpha = \rho \int_0^l \boldsymbol{H} d\boldsymbol{l},$$

where l is the optical pathlength in the test substance and ρ a characteristic constant for the substance, which has been called the Verdet constant. Thus measurement of the angle α permits in principle the determination of the Verdet constants of the relevant compounds and also the corresponding molecular magnetic rotation $(\rho)_M$, defined by the expression

$$(\rho)_M = \frac{\rho}{d} \cdot M,$$

where M and d are the molecular weight and specific gravity of the substance.

This in broad outline is the observed phenomenon and about a century elapsed since its discovery before the following two fundamental questions were formulated:

1. What is the reason for the rotation of the plane of polarisation?
2. Is the Verdet's formula rigorously valid?

The answer to the first question in terms of classical quantum mechanics has been given in publications which are virtually inaccessible to physical chemists without sufficient experience in quantum-chemical calculations. Indeed the theoretical aspect of the magnetic rotation of the plane of polarisation (the electromagnetic wave, the magnetic field, and the set of molecular orbitals in the strong interaction condition) is so complex that, listening to lectures by theoretical physicists developing the formal mathematical side of the problem, one might sometimes ask whether the effect under discussion is indeed the one first observed by Faraday. To see this, it is sufficient to read only a few pages in papers by Kronig[5], Rozenfeld[6], Kramers[7], Groenewege[8], Smet[9-11], or I'Haya[12]. The concept which we shall now develop in a few words will undoubtedly arouse protests by theoreticians but it has the

advantage of a simple description of the basis of the phenomenon.

The presence of a magnetic field leads to complete loss of symmetry by molecular orbitals. If Ψ_0 denotes the wave function in the absence of the field, the perturbed wave function is

$$\psi = \psi_0 + \sum_k c_k \psi_k ,$$

where Ψ_k are the wave functions of the excited molecular states.

The change of Ψ_0 under the influence of the field H appears to involve the mixing of the ground and excited molecular states. It has been shown[13] that in first-order perturbation theory

$$c_k = \frac{-aH \int \psi_0 \frac{\partial}{\partial \theta} \psi_k d\tau}{E_0 - E_k} ,$$

where θ is the polar angle reckoned from the direction of H and E_0 and E_k are the energies of the levels corresponding to Ψ_0 and Ψ_k. It is immediately clear that the contribution by Ψ_k to perturbation will be non-zero only when Ψ_k includes symmetry elements antisymmetric to Ψ_0. This is in fact why, when Ψ_0 is the $2p_z$ orbital, only the $3d_{xy}$ orbital makes an appreciable contribution to the deformation of Ψ_0 and, when Ψ_0 is an s orbital, no orbital with an energy lower than that of the $4f$ orbital can be involved in the perturbation. As a result, one may say *a priori* that the Faraday effect due to the π electrons in the molecule is much greater than that due to the σ electrons, since $E_{2p_z} - E_{3d_{xy}}$ is always much smaller than $E_s - E_{4f}$. Subsequently we shall see that this is in fact so. Thus in a magnetic field molecular orbitals completely lose their symmetry and this is the reason for the optical anisotropy and the further consequences are fully analogous to those in the natural rotation of the plane of polarisation[14].

The second question posed above is no less important: one can show that the rotation α is not in fact strictly proportional to H but is expressed by a limited series

$$\alpha = aH + bH^2 + cH^3 + \ldots$$

Usually the "double rotation 2α", i.e. the sum of the rotations $+\alpha$ and $-\alpha$ observed for two opposite values of the field $+H$ and $-H$ is measured experimentally. This procedure eliminates terms proportional to the even powers of H in the expression for α. Therefore, if cH^3 is negligibly small, then $\alpha \propto H$, in agreement with Verdet. Detailed calculation of the quantities a and c shows that this is true, provided that H does not exceed 2.5×10^4 gauss. This limits has not so far been attained in classical apparatus for the measurement of the Faraday effect in the transparency range; the most powerful of these, which we have in our laboratory, has $H_{max} = 1.5 \times 10^4$ gauss. However, one must recognise that an increase of H_{max}, which might nowadays be expected by specialists in the field of the Faraday effect, would face the boldest investigators with the difficulties of non-linear quantum electrodynamics; their results could not be compared directly with the data of their colleagues, who, unable to use the new facilities for practical reasons, would continue to work in the region where α is fairly exactly proportional to H. This is indeed the case, but, having made these philosophical remarks, we shall now turn to the actual experimental technique and the results which it can yield.

III. EXPERIMENTAL ARRANGEMENT AND ACCURACY OF MEASUREMENTS

The optical system consists of a mercury lamp S emitting a characteristic spectrum from which the required line may be isolated by a monochromator M of TREGOR type. The monochromatic light beam passes through a polariser P and then through a polarimetric cuvette C in the gap of the electromagnet (Fig. 1). The rotation of the plane of polarisation is read off to within 0.01° with the aid of a Lippich polarimeter. The electromagnet is supplied with currents up to 200 A stabilised to within 1%, from a 150 V supply. The maximum magnetic field strength in the centre of the gap is of the order of 1.5×10^4 gauss for a homogeneity of 10^{-5} gauss cm^{-1} and a gap of 7 cm wide. The polarimetric cuvette, with an average length of 3 cm and a working volume of 2 cm^3, is thermostatted and located in the gap by means of adjustable brass holders clamped to the yoke of the electromagnet.

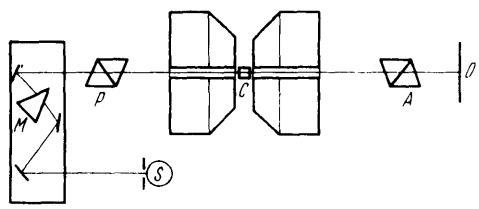

Figure 1.

The polarimetric readings can be made with two opposite directions of H and the resulting "double rotations 2α" reach on average 75°. To obviate the necessity for an accurate determination of the magnetic field gradient along the cuvette, relative measurements are usually made. If we denote by subscripts e and i the standard and test substances respectively, then

$$\frac{\alpha_i}{\alpha_e} = \frac{\rho_i}{\rho_e}$$

or, introducing the specific rotatory power (ρ_i) and the molecular rotatory power $(\rho_i)_M$:

$$(\rho_i)_M = \frac{\rho_e}{\alpha_e} \alpha_i \frac{M_i}{d_i} ,$$

where M and d denote the molecular weight and the specific gravity of the test substance. Doubly distilled water is used as a classical reference standard, since its Verdet constant at 20°C and a wavelength of 546 nm (the green line in the discharge spectrum of mercury) has been measured with a high accuracy by de Mallemann et al.[15] as 4.482 μrad (microradians). It was established that the magnetic rotation of the substance depends on the wavelength at which the measurements are made[16], on temperature[17,18], and on the physical state of the test substance[19]. As regards the first factor, it is assumed that the substance exhibits *normal dispersion*, provided that the measured Verdet constants at $\lambda_1 = 578$ nm, $\lambda_2 = 546$ nm, and $\lambda_3 = 436$ nm satisfy the relations

$$\frac{\rho(\lambda_3)}{\rho(\lambda_1)} = 1.86 \text{ and } \frac{\rho(\lambda_2)}{\rho(\lambda_1)} = 1.13 .$$

The dispersion for covalent and diamagnetic molecules and molecules without transition elements is always normal as long as the first vertical transition for these compounds in the ultraviolet region lies below 280 nm.

The effect of temperature and the physical state on the magnetic rotation of a given substance has been the subject of numerous investigations. In particular, de Mallemann established that

$$(\Omega)_M = \frac{9n}{(n^2+2)^2}(v)_M$$

is an invariant quantity for all changes [in the system]. In this formula n is the refractive index at the experimental wavelength and temperature[19]. Recently Dagnac-Amans[20] showed that molecular magnetic rotation can always be used over a wide temperature range centres on 20°C for a satisfactory description of the magneto-optical properties of a single molecule. She also succeeded in showing, having confirmed the individual results of the work of Dupouy and Fert[17], that magnetic rotation decreases slightly (and linearly) with increasing temperature (except for H_2O and D_2O). Table 1 lists specific data confirming this finding.

Table 1.

CS_2	$y=-0.658\ t+781.6$	$CH_3(CH_2)_2CH_2OH$	$y=-0.024\ t+342.0$
C_6H_6	$y=-0.216\ t+811.8$	CH_3COCH_3	$y=-0.024\ t+249.3$
CCl_4	$y=-0.073\ t+472.0$	CH_3OCH_3	$y=-0.020\ t+191.7$
$CH_3CH_2CH_3$	$y=-0.071\ t+258.0$	D_2O	$y=+0.012\ t+77.8$
SO_2	$y=-0.066\ t+219.5$	H_2O	$y=+0.006\ t+71.6$

On our apparatus, it is possible to investigate either liquids in the temperature range between −120° and +120°C or solutions of sparingly soluble substances in a suitable solvent. The optical measurements do not present any difficulties in the first case and one can be certain that the accuracy attained in the measurement of molecular rotation is about 0.3%. In the second case fundamental difficulties arise because of the importance of the choice of solvent. Initially one must make sure that in the test solution there are no chemical or physical interactions between the solute and solvent and that one may employ the relations established by Verdet[4] for ideal mixtures, according to which each component makes an additive contribution to the overall magnetic rotation. Then it is necessary to select a solvent whose Verdet constant differs sufficiently from the analogous constant of the test solution. This factor, which is very sensitive in practice, must be satisfied with great precision, since it determines the success of the measurements. In view of all these considerations, measurements in solutions must be resorted to only in extreme cases and the accuracy of the molecular rotation thus obtained does not exceed 1%. In an attempt to obviate this difficulty, Zarzycki and Naudin[21] devised a special apparatus permitting observations on compounds in the liquid state, whose melting points may reach 1100°C.

After this brief description of the classical experimental arrangement, we proceed to the review of the fundamental applications of the method in studies on problems in structural chemistry, which are of the most immediate interest.

IV. THE FARADAY EFFECT AND THE ADDITIVE PROPERTIES OF MATTER

We have just seen how magnetic molecular rotation (a generalised property) characterising the test substance may be determined by a simple polarimetric measurement, provided that the specific gravity is known. Because of this generality, non-specialists believed for a long time that the Faraday effect constitutes a less powerful method than NMR or infrared spectroscopy, since the latter make it possible, in principle, to determine the essential characteristics of the nucleus or a given bond. We shall now see that in fact such discrimination is invalid and is based solely on the ignorance of the magneto-optical phenomenon. Magnetic rotation of polarisation is an additive property of matter: the question arises of the significance of this assertion and its basis. All the experimental data accumulated during the period since the Faraday effect has been known indicate a systematic additivity of magnetic rotation, similar to that discovered by Pascal and coworkers[22] in diamagnetism, which frequently makes it possible to calculate with surprising accuracy the molecular rotation of a compound, provided that two conditions are satisfied: (1) only covalent, normal, diamagnetic, σ, or π localised bonds are present; (2) the bond constant has been explicitly defined.

In 1960 Gallais and Voigt[23] first suggested that additivity may be expected for magnetic rotation per bond. The difficulty of determining the magnetic rotation parameters referred to individual bonds consists in the necessity of separating a generalised quantity for the atom into components characterising individual bonds in such a way that each bond constant is independent of the individual characteristics of the others. Moreover, the quantity characteristic of the atom as a whole must evidently be the same every time. This problem hardly exists in organic chemistry, since carbon almost always exhibits the same coordination and employs four valence electrons. However, it is important for inorganic chemistry, where atoms can have significantly different coordinations. In order to overcome this difficulty, it is necessary (1) to define bond constants in such a way that they are independent of the coordination of the atoms involved in the given bond and (2) account must be taken of the behaviour of lone electron pairs not involved in any interatomic bond.

The first conditions may be satisfied simply by dividing the generalised quantity characterising the atom into equal parts among the n_E valence electrons, assuming that they are all equally active as regards the optical, magnetic, and magneto-optical properties. The modulus α (for refraction, magnetisation, and magnetic rotation) of a single σ or π bond between two atoms A and B is then uniformly represented by the symbol

$$\alpha\left(\frac{A}{n_A}-\frac{B}{n_B}\right)$$

and if the atom X contributes two electrons to the bond (a double bond, or a donor–acceptor bond in which X is an electron-donating atom), its contribution to a bond of this kind becomes $2X/n_X$, etc.

Tables 2–4 present data on the magnetic rotation due to the commonest bonds, determined in accordance with the above principles from chemical data for carbon[23,24], boron[25-30], aluminium[31,32], gallium[33], nitrogen[23,34], sulphur[20,35], and phosphorus[36,37]. Having at one's disposal the required set of bond constants, it is easy to calculate the magnetic rotation, provided that, taking into account Eqn. (2), the contribution $\alpha(e)$ by lone electron

pairs is added. This condition is so important that its neglect immediately leads to considerable errors: unfortunately, in most studies on molecular interaction and almost always in the field of dipole moments, the contribution by lone electron pairs of atoms in the molecule is disregarded in the calculation of molecular quantities. Soon we shall see that the magnetic rotation which may be attributed to lone electron pairs is usually very considerable. There exists a simple method of estimating their contribution to a first approximation: it was used for the first time in the field of molecular refraction by Le Fevre and coworkers[38] at the time when we were preparing to publish analogous reports on the Faraday effect[39]. For this purpose, one must consider the changes in the magnetic rotation $\rho(C-E)$ due to the carbon–element bond as a function of the position of E in the Periodic System.

Table 4.

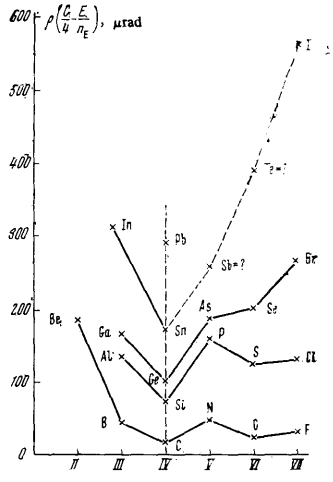

Figure 2.

Fig. 2 shows that the rotation increases rapidly within each Group, whereas in each horizontal Period it passes through a minimum when E belongs to Group IV. A detailed study of these changes leads to progress in the solution of the problem, which consists in the separation of the effects of various factors on the magnetic rotation due to the bond. Four factors may be regarded *a priori* as important: (1) the change in the overall value for the atom E involved in the bond $(C/4-E/n_E)$, while the analogous quantity for carbon remains constant; (2) proportionality to the amount

of ionic character of the bond; (3) the type of hybridisation of the atom E; (4) and, evidently, the activity of the corresponding lone electron pair of the atom E.

Simple considerations demonstrate that the third and fourth factors are dominant in the variation of $\rho(C-E)$. On the other hand, the decrease of the magnetic rotation due to the bond, on passing from Group II to IV, may be attributed only to the first and second factors and the minimum in the observations when E belongs to Group IV must be caused by the simultaneous operation of the first and second factors, the second predominating. Analysis of the left-hand part of the plot in Fig. 2 shows how $\rho(C-E)$ changes as a function of the hybridisation of the atom E. On passing from Group II to Groups III and IV, the fraction of s character of the atomic orbitals involved in the bond increases from 50 to 75 (in accordance with the change in hybridisation: $sp-sp^2-sp^3$). One must assume that the s character of the atomic orbitals of E and the rotation due to the (C–E) bond vary in parallel. Thus we arrive at the hypothesis, put forward by Le Fevre and coworkers[38] and Gillis[40] to account for the decrease of the (C–E) bond refraction in the given case. However, contrary to the postulates of these investigators, there is no doubt that the fraction of s character of the bond and refraction or rotation are not linearly related. Admittedly, in any type of linear relation between $\rho(C-E)$ and the amount of s character there should be no change in $\rho(C-E)$ on passing to Groups V, VI, and VII, since the hybridisation of nitrogen atoms in NH_3, of oxygen atoms in OR_2, and of fluorine atoms in FR remains close to sp^3. The increase of $\rho(C-E)$ actually observed appears to be caused, under these conditions, by the contribution from the lone electron pairs of the atom E, which may be calculated using the definition of bond rotation and the symbolism of the systematic additive scheme. Thus for phosphorus (a Group V element), we have
