IRS continues to be widely used in studies of surface phenomena and adsorption. The most recent papers on these topics deal with the physiochemical processes occurring in the surface layers of polymers during photochemical oxidation[265-267], under the influence of a corona discharge[268], in the presence of ozone[269,270], and they also describe further studies of various processes in polymers[271-274]. Adsorption[234], surface phenomena on semiconductors[275-279], and corrosion inhibitors[280] have also been investigated. In addition, IRS has been used to study the surface orientation of polymers[281] and biopolymers[282,283], the behaviour of surface-active molecules at an interface[284], solutions of alkali metals in liquid ammonia[285], adhesion between epoxy resins and cellulose[286,287], the hydrolysis of glass surfaces[288], and also a number of films and surface coatings[289-291].

Furthermore, the ATR method continues to be widely used to measure optical constants[292-297].

The Pre-exponential Factors for Unimolecular Gas-phase Reactions

G.M.Nazin

The principal concepts and methods whereby the pre-exponential factors for unimolecular gas-phase reactions may be found have been examined. The methods are based on the transition state theory which accounts successfully for all experimental data. The reactions have been classified taking into account the typical structure of the activated complex. The question of the effect of molecular structure on the value of the pre-exponential factor has been examined for each group of reactions. The general postulates have been illustrated by examples. The data employed embrace about 800 reactions.
The bibliography includes 177 references.

I. INTRODUCTION

Extensive information is now available concerning the pre-exponential factor A for unimolecular reactions of polyatomic molecules. The fundamental principles of the theory, which permitted a successful explanation of the experimental data, were formulated many years ago with the aid of the transition state method[1]. However, a detailed quantitative treatment with extension of the theory to different classes of compounds became possible only in the 1960's, in the first place due to the large-scale introduction in practice of the computational method of the Rice–Ramsperger–Kassel–Marcus (RRKM) theory and in the second place due to the marked increase in the number of experimental data. The data of recent years are the most accurate and frequently refer to long series of similar compounds, which is also important. The aim of the present review is to give a general and systematic account of the available data on gas-phase reactions.

II. THE VALUE OF THE PRE-EXPONENTIAL FACTOR

In 1928 Polanyi and Wigner[2] were the first to examine the question of the magnitude of the pre-exponential factor in unimolecular reactions using for this purpose mainly data for reactions in solutions[3] and introduced the concept of the "normal" pre-exponential factor, which has similar magnitude to molecular vibration frequencies (10^{12}–10^{14} s^{-1}). It is remarkable that at that time only three gas-phase reactions were known (decomposition of azomethane and N_2O_5 and the racemisation of pinene), which can now be classified, making certain assumptions, as unimolecular;

Table 1. The range of values of pre-exponential factors and certain other characteristics of unimolecular reactions.

Note. Column 7 lists data on all types of kinetic isotope effects in both thermally and chemically activated systems. The first, second, and third numerals in column 5 indicate the numbers of reactions with lg A less than 12, in the range 12–14, and greater than 14 respectively.

they all have lg $A > 14$. All earlier theories of unimolecular reactions (the Rice–Ramsperger, Kassel, and Slater theories) yielded a normal value of A,[4,5] which to a considerable degree helped to confirm the validity of this concept.

In 1952 the proportion of reactions with normal values of A were 60% according to Kondrat'ev's data[4] and that of reactions with lg $A > 14$ was 16%. At present about 800 unimolecular reactions are known, for which the parameters of the Arrhenius equation have been determined (Table 1). Of these 47% have lg $A = 12$–14, 33% have lg $A > 14$, and 20% have lg $A < 12$. On the whole, pre-exponential factors lie in the range between 10^9 and 10^{17} s^{-1}. The absolute number of reactions with A exceeding 10^{14} or below 10^{12} s^{-1} is very large. Therefore the concept of the "normal" pre-exponential factor is now of purely conventional significance; it reflects the frequently encountered situation where the structure of the activated compound differs little from that of the initial molecule.

III. CALCULATION OF THE PRE-EXPONENTIAL FACTOR

The high or low experimental values of A can only be accounted for with the aid of statistical theories of unimolecular reactions based on the activated complex (AC) method. The modern RRKM theory[9,162,163] yields the following expression for the rate constant at a high pressure:

$$k_\infty = \alpha \frac{kT}{h} \frac{Q^{\neq}}{Q} e^{-E_a/RT}, \qquad (1)$$

which is the same as the classic Eyring formula and is equivalent to the formulation[1]

$$k_\infty = \alpha \frac{kT}{h} e^{\Delta S_0^{\neq}/R} \cdot e^{-\Delta H_0^{\neq}/RT}, \qquad (2)$$

where α is the statistical factor for the reaction, $Q^{\neq}$ and Q are the partition functions of the activated complex and the initial molecule, E_a is the true activation energy, i.e. the height of the potential barrier at 0°K, and $\Delta S^{\neq} = S_0^{\neq} - S_0$ and $\Delta H_0^{\neq} = \Delta H_0^0 + (H_T - H_0^0)^{\neq} - (H_T - H_0^0)$ are the entropy and enthalpy of formation of one mole of activated complex.

The relation between E_a and the activation energy E at a temperature T is illustrated in Fig. 1 (E_{vibr} and $E_{vibr}^{\neq}$ are the vibration energies of the active internal degrees of freedom of the reactant and the activated complex, $E_{t\text{-}r}$ is the energy of the internal translational and rotational motions in the activated complex, r and t are the numbers of internal rotations, and E_0 and $E_0^{\neq}$ are the zero-point energies of the initial molecule and the activated complex respectively).

If it is assumed that the experimental activation energy U, determined from the Arrhenius equation

$$k_\infty = Ae^{-U/RT}, \qquad (3)$$

is equal to E, then the following relations are valid:

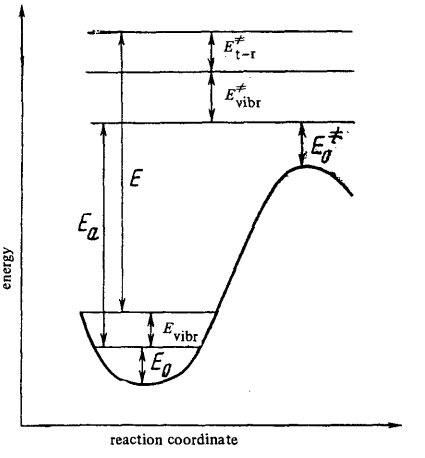
$$U = E_a + E_{t\text{-}r}^{\neq} + E_{vibr}^{\neq} - E_{vibr} = E_a + (r - t + 2)RT/2 + RT^2(d\ln Q^{\neq}/dt - d\ln Q/dT), \qquad (4)$$

$$k_\infty = \alpha \frac{ekT}{h} e^{\Delta S^{\neq}/R} e^{-U/RT}, \qquad (5)$$

$$\ln A = 1 + \ln\alpha + \ln\frac{kT}{h} + \frac{\Delta S^{\neq}}{R}, \qquad (6)$$

$$\ln A = \ln\frac{\alpha ekT}{h} + \ln\frac{Q^{\neq}}{Q} + T\left(\frac{d\ln Q^{\neq}}{dt} - \frac{d\ln Q}{dt}\right). \qquad (7)$$

When account is taken of the changes in the moments of inertia of the overall rotation owing to the greater size of the activated complex, then the term $\frac{1}{2}\ln(I_A^{\neq}I_B^{\neq}I_C^{\neq}/I_AI_BI_C)$ must be added to the right-hand side of Eqn. (7). All the difficulties of the theoretical calculation of A from Eqn. (7) reduce to the necessity of determining the vibration frequencies and the moments of inertia of the overall and internal rotations in the activated complex. Since the same partition function can be obtained with the aid of a wide variety of frequency sets, there is always a considerable uncertainty in the choice of the structure of the activated complex.



Schematic representation of the energy levels in a unimolecular reaction.

The RRKM theory provides the greatest scope for overcoming this uncertainty. On the basis of a single model of the activated complex, it is possible to calculate within the framework of this theory a wide variety of characteristics of unimolecular reactions, which are susceptible to experimental determination. They include the following[5,9].

1. The pressure dependence of the rate constant $k(p)$.
2. The primary and secondary isotope effects in thermally activated systems: $(k_H/k_D)_{prim}$ and $(k_H/k_D)_{second}$.
3. The reverse isotope effect in the region where k varies with p: $(k_H/k_D)_{rev}$.
4. The dependence of the rate of reaction on the excess energy above the threshold value: $k(\epsilon)$.
5. The isotope effect in chemically activated systems: $k(\epsilon)_H/k(\epsilon)_D$.

Unfortunately not all these characteristics are sufficiently sensitive to changes in the vibration frequency in the activated complex. Measurements of the dependence of k on p and of the isotope effects in thermally activated systems are the most useful[9,146,164]. It was shown recently[126,146] that in reactions with a reverse isotope effect the position of the point of intersection of the $k(p)$ curves for isotopic molecules depends greatly on the structure of the

activated complex and thus may be used successfully to test activated complex models.

Reactions involving the decomposition of the molecule into two radicals have yet another extremely important characteristic which makes it possible to infer the structure of the activated complex: the rate constant for the recombination of radicals (see p. 718). Similarly the rate constant for the addition of an atom or a radical to an olefin helps us to understand the structure of the activated complex in the reverse reaction involving the decomposition of the free radical into an olefin and an atom (or a radical).

Calculations for activated complex models based on the RRKM theory using, in addition to the pre-exponential factor, at least one other experimental characteristic have been made for approximately 60 reactions (Table 1). However, in the majority of cases this involves the calculation of the rate of decomposition of chemically activated species, i.e. a characteristic which is relatively insensitive to the activated complex parameters [9]. There are comparatively few calculations concerning the $k(p)$ relation and the isotope effect.

The most complete attempts to determine the structure of the activated complex by adjusting the calculated $k(p)$ curves to coincide with experimental plots have been made for ethane [8,9], hexafluoroethane [165], ethyl chloride [52,95–97,100,101], methyl isocyanide [115,166], ethyl isocyanide [116], cyclopropane [52,126,131,132], 1,1-dichlorocyclopropane [167], cyclobutane [52,126], cyclobutene [126,132,146,147], methylcyclobutene [136], azomethane [35,36], and alkyl [9,28] and certain other radicals [71]. In many cases [100,136,167] it was established that the detailed structure of the activated complex is very difficult to determine, since different models yield similar results. Probably this difficulty will increase with increase of the complexity of the molecular structure and of the activation energy [136,167].

Models using two characteristics, $k(p)$ and the reverse isotope effect at low pressures, have been optimised for the following reactions: decomposition and isomerisation of cyclopropane [126,165] and cyclobutane [126,146], isomerisation of methyl isocyanide [112] and ethyl isocyanide [116], and decomposition of ethyl chloride [100]. One may assume that the interpretation of the structure of the activated complex for these reactions and also for the decomposition of ethane, hexafluoroethane, azomethane, and alkyl radicals has been made fairly reliably. Examples of activated complex models will be quoted below.

One should note that the accuracy of the geometrical structure and of the vibration frequencies of the activated complex achieved in these calculations greatly exceeds the accuracy required for the calculation of the pre-exponential factor. Therefore, from the standpoint of the estimation of A, the importance of calculations based on the RRKM theory consists primarily in a convincing demonstration of the validity of the transition state method for reactions of polyatomic molecules at high pressures and the fact that, for all fundamental types of unimolecular reactions (which will be dealt with below), a detailed analysis has been made of activated complex models in individual examples.

Recently successful attempts have been made to develop semiempirical methods for the calculation of A. [103,168–170] In the main they refer to reactions proceeding via a cyclic transition state. The methods are based on approximate hypotheses concerning the structure of the activated complex and employ experimental values of $\Delta S^{\neq}$ [from Eqn. (5)] in order to find the contributions of the individual structural elements of the activated complex to the total entropy of activation. Either the values of the contributions or the methods of their determination are then standardised.

Mulyava and Shevchuk [168] proposed a method based on the additivity of bond entropies in molecules and activated complexes for the calculation of $\Delta S^{\neq}$. Using the bond classification of the kind usual in additive schemes [171,172] and the concept of the activated bond in the activated complex [173], they calculated the corresponding bond entropies and also corrections for symmetry, cyclisation, conjugation of double bonds, and the presence of cumulative double bonds. A fairly high accuracy in the calculation of $\Delta S^{\neq}$ was demonstrated on a number of examples, but for its large-scale application the method probably requires a more detailed formulation. A similar procedure for the estimation of $\Delta S^{\neq}$ but with a less detailed subdivision into components was proposed by Szabó and Berces [174].

The method of calculation of A for cyclic activated complexes proposed by O'Neal and Benson [103] is less formal. On the basis of a physically clear albeit approximate activated complex model, these workers proposed simple rules for the calculation of individual structural contributions to activation entropy from molecular characteristics. The method is applicable to calculations for more than one hundred reactions and yields an excellent agreement with experiment. Within the framework of this method, it is easy to predict the effect of substituents on $\Delta S^{\neq}$ for the reaction (the method is described in greater detail on p. 720).

The success of the approximate methods of calculation of $\Delta S^{\neq}$ for cyclic activated complexes can be accounted for to some extent by the comparatively low sensitivity of this quantity to changes in the activated complex parameters. In order to predict A to within a factor of three, it is sufficient to take into account the most fundamental changes in the types of motion on formation of the activated complex, i.e. those associated with low-frequency vibrations and internal rotation. Probably the same accuracy can be achieved also in the estimation of A for bond dissociation reactions [170,175].

IV. CLASSIFICATION OF REACTIONS

In terms of the pre-exponential factor and the typical structure of the activated complex, reactions can be divided into the five main groups indicated in Table 2.

Table 2. Classification of reactions.

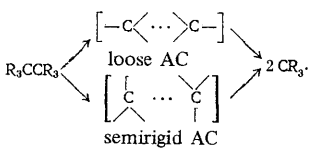
No.	Group of reactions	Reactions investigated	Reactions with lg$A$ in the range			Number of series with different numbers of reactions				
			<12	12–14	>14	1–5	6–10	11–15	16–20	20
1	decomposition into two radicals	171	7	40	124	17	4	2	—	2
2	decomposition into an atom and a radical	52	—	43	9	7	3	1	—	—
3	elimination or isomerisation via a four-membered ring	130	24	93	13	17	2	—	1	1
4	ditto via a five- or six-membered ring	227	98	125	4	8	1	5	2	1
5	reactions via a biradical transition state (ring opening, *cis-trans*-isomerisation)	146	8	50	88	7	5	1	—	3

The assignment of reactions to particular groups is specified in column 4 of Table 1. The classification does not embrace about 50 reactions. The characteristic features of each group of reactions will be examined in subsequent sections.

Table 2 also shows the distribution of reactions with respect to homologous reaction series. Evidently in gas-phase reactions there are comparatively few long reaction series. Nevertheless, large series in which the effect of structure on A is shown (and for which the most reliable experimental data are as a rule available) are in fact the most valuable for understanding the structure of the activated complex and for developing semiempirical methods for calculating A. Studies undertaken specially to investigate the greatest possible number of reactions with the same mechanism and the same reaction centre probably merit attention.

V. DISSOCIATION OF THE MOLECULE INTO TWO RADICALS OR INTO AN ATOM AND A RADICAL

In the decomposition of a molecule into two radicals via homologous bond dissociation, for example the reaction $R_3C-CR_3 \rightarrow 2CR_3$, two types of activated complex structures are distinguished—the loose and semirigid structures. The following notation can be introduced:



(8)

A characteristic feature of the loose activated complex is a considerable extension of the bond undergoing dissociation and free (or almost free) three-dimensional rotation of the separating fragments. The structure of such a complex is close to that of the reaction products. The reverse radical recombination process occurs in almost every collision in the case of a loose activated complex and the recombination rate constant k_r is of the order of $10^{10.5}$ litre mole^{-1} s^{-1}. The recombining radicals are held at a considerable distance by polarisation forces and are oriented arbitrarily reliative to one another [1,15]. The barriers to recombination via a loose activated complex are very small. A loose activated complex is typical in the dissociation of strong bonds between small radicals. It has been demonstrated rigorously for the decomposition of ethane, hexafluoroethane, and certain other compounds.

If $k_r < 10^{10}$ litre mole^{-1} s^{-1}, then the activated complex can be assigned to the semirigid type. In its formation from the molecule, the R_3C-C rocking vibrations do not pass to free rotation but merely undergo a decrease in their frequency. A complete liberation of the rotations of CR_3 radicals does not occur until the critical point has been passed. The formation of a semirigid activated complex from radicals requires a specific orientation of the latter and the transformation of rotational into vibrational motion. Therefore recombination via a semirigid complex involves a loss of entropy.

Judging from the recombination rate constants (Table 3), in most cases the decomposition of molecules into two radicals proceeds via a semirigid activated complex.

In the formation of an activated complex of any type from the initial molecules in reaction (8), the following changes in internal degrees of freedom are possible.

1. A decrease of the frequency of deformation vibrations associated with the dissociating bond (C–C). Two of these pass into the out-of-plane vibrations of the CR_3 radicals formed in the activated complex. The decrease of frequency in this process can be measured with the aid of the secondary α-deuterium isotope effect [164,176]. Judging from the available data, one can assume without much error that in all cases the frequency changes by a factor of two.

The frequencies of the four rocking vibrations of R_3C-C characterising the rocking of the CR_3 groups relative to one another decrease by a factor of 2–3 in a semirigid complex and by a factor of 6–10 in a loose complex. The latter decrease is almost equivalent to free rotation of the fragments about axes perpendicular to the internal axis of inertia. The decrease of the rocking vibration frequencies makes the principal contribution to the entropy of a loose activated complex.

Table 3. Rate constants for the recombination of radicals [45].

Radicals	$\lg k_r$ (litre mole^{-1} s^{-1})	Bond strength, kcal mole^{-1}
R + R R + OR	10—11	80—90
R + NO R + NO_2	9—10	50—60
RO + NO RO + NO_2 RO + OH RO + OR	7—9	35—40

2. The freeing of internal rotation relative to the dissociating bond when the rotation was hindered in the ground state. The increase of activation entropy owing to the freeing of the hindered internal rotation depends little on the partition function for free rotation and factors such as the size of the rotating groups or the symmetry number do not play a significant role. The barrier to internal rotation has the main effect. The maximum contribution to $\Delta S^{\neq}$, which may occur when the height of the barrier is in excess of 10 kcal mole^{-1}, is about 3 Gibbs mole^{-1}.

3. The change in the frequency of torsional vibrations relative to the R–C bonds, i.e. the change in the rotational motion of the groups R adjoining the reaction centre. The decrease of the torsional vibration frequency, which may accompany a change in the geometry of the R_3C fragment and a decrease of the repulsion between the groups R and which can be very large in principle, occurs comparatively rarely, since usually adjacent groups inhibit fairly strongly their mutual rotation both in tetrahedral and in planar CR_3 structures.

On the other hand an increase of the frequency of the torsional vibrations of an adjacent group (and hence a decrease of A) are frequently observed in the decomposition of free radicals or olefins, when the barrier to internal rotation relative to the terminal bond being formed increases owing to the conjugation of the free valence produced. Usually one bond is involved in such conjugation and therefore the effect is small.

When account is taken of all three factors enumerated above, it is usually possible to explain satisfactorily the experimental data.

The decomposition of the molecule into an atom and a radical, $R_3CX \rightarrow R_3C\cdot + \cdot X$, is analogous to the decomposition into two radicals. The difference is that in the

elimination of an atom the number of deformation vibrations which are altered in the activated complex is a factor of two less than in the elimination of a radical and moreover the effect associated with rotation relative to the bond undergoing dissociation is missing. For the majority of reactions investigated, the activated complex has a semirigid structure and the entropy change $\Delta S^{\neq}$ is small. A loose activated complex has been postulated only for the decomposition of methane [9]. However, in this case too A exceeds 10^{14} s^{-1} only slightly owing to the small total number of parameters which are altered.

Table 4. Dissociation of the C–C bond.

Compound	Activated complex	$\lg A$ (s^{-1})
$H_3C—CH_3$	loose	16.3—17
$F_3C—CF_3$	ditto	17.6
$Me_3C—CMe_3$	semirigid	16.3
$CH_3—CH_2CH=CH_2$	ditto	15.8
$CH_3—CH_2Ph$	»	14.5
$CH_3—CH_2CHCH_3$	»	13.5—15

Example 4. Dissociation of the C–C bond. In C–C bond dissociation reactions, A varies from $10^{13.5}$ to 10^{17} s^{-1}. Typical cases are presented in Table 4. [6]

The ethane and hexafluoroethane decomposition reactions provide a classic example of a loose activated complex and have the highest values of A. In the case of hexamethylethane the complex is semirigid, but A is also very high. Possibly in this case the rotation of adjacent groups, i.e. the decrease of the frequencies of the torsional vibrations of the CH_3 groups in the transition state, has an effect. Much lower values of A are observed in the decomposition of unsaturated and aliphatic-aromatic compounds and also of free radicals, owing to conjugation and the increase of the barriers to internal rotation in the radical formed (Table 5 presents a model which explains quantitatively the observed pre-exponential factors).

Example 2. Azo-compounds. The high values of A (10^{17} s^{-1}) observed in the decomposition of azo-compounds can be explained by the simultaneous dissociation of two C–N bonds and by a loose structure of the activated complex. Table 6 presents a model of such a transition state for the decomposition of azomethane [35] ($\lg A = 17.3$). A free activated complex probably occurs also in the decomposition of $C_2H_5N_2C_2H_5$.

However, for large groups R in R–N=N–R, free activated complexes are unlikely and therefore the corresponding values of A should not exceed 10^{15} s^{-1}. The values of A of the order of 10^{17} s^{-1} quoted in the literature for large molecules of azo-compounds are probably erroneous. Recent data confirm this [34].

Example 3. Peroxides, hydroperoxides, nitrites, and nitrates (Table 7). A general characteristic of all these compounds is a comparatively rigid structure of the activated complex (recombination rate constant 10^7–10^9 litre $mole^{-1}$ s^{-1}) and the fact that the dissociation of O–O or O–N bonds results not only in a freeing of rotation about these bonds but also in a decrease of the barrier to the internal rotation of the group R, i.e. the effect of adjacent groups is bound to be shown to some extent in this case. It can be particularly appreciable for peroxides. Unfortunately accurate calculations have not been made for these compounds. The attempts to explain the high values of A in the decomposition of peroxides without taking into account the rotation of R were unsuccessful [47].

Table 5. Models of the transition states for the dissociation of the C–C bond [8, 28, 52] (vibration frequency, cm^{-1}).

Vibration	$C_2H_6 \rightarrow \left[-\overset{\cdot}{C}\cdots\overset{\cdot}{C}-\right]$		$H_3C—CH_2CH=CH_2 \rightarrow \left[{}^{1}H_3C\cdots{}^{2}CH_2\cdots{}^{3}CH\cdots{}^{4}CH_2\right]$		$H_3C—CH_2CHCH_3 \rightarrow \left[{}^{1}H_3C\cdots{}^{2}CH_2\cdots{}^{3}CH—{}^{4}CH_3\right]$

Example 4. Aliphatic nitro-compounds. In the study of the pyrolysis of aliphatic nitro- and α-halogenonitro-compounds, data were obtained for bond dissociation in the longest reaction series in the group of reactions involving decomposition into two radicals [37]. Here all the theoretically predicted contributions to the increase of $\Delta S^{\neq}$ and in particular the effect of the free rotation of the alkyl groups in the radical formed have been detected and measured experimentally (Table 8).

Table 6. Decomposition of azomethane

$$CH_3—N=N—CH_3 \rightarrow \left[-C\cdots N=N\cdots C-\right] \rightarrow N_2 + 2CH_3.$$

$I_A \cdot I_B \cdot I_C$	$2.85 \cdot 10^{-115}$	$4.33 \cdot 10^{-115}$

In all cases the activated complexes have a semirigid structure (the $CH_3 + NO_2$ recombination rate constant is $10^{9.5}$ litre $mole^{-1}$ s^{-1}). In nitromethane the barrier to internal rotation about the C–N bond is very low and the only factor which alters $\Delta S^{\neq}$ is the decrease of the deformation vibration frequencies of CH_3–N and C–NO_2. In all

Table 7.

4	$RCXNO_2—^{*}NO_2$, (X = H, F, NO_2)	7	+	+	+	+	13.7—15
5	RCX_2NO_2 (X = Cl, Br)	3	+	+	—	—	6.2—8.0

other compounds the effect associated with the freeing of hindered internal rotation is shown. In the absence of large halogen atoms (Cl, Br, and I) from the α-position (third row in Table 8), $\Delta S^{\neq}$ increases slightly, which may be attributed to a decrease of the torsional vibration frequencies of the NO_2 groups in the radicals formed [$\cdot C(NO_2)_3$, $\cdot CH(NO_2)_2$, $\cdot CHFNO_2$]. A similar but much larger effect is observed for the alkyl group the rotation of which in the transition state becomes completely free (fourth row in Table 8). This conclusion has been confirmed by a number of independent findings[38].

VI. REACTIONS INVOLVING A CYCLIC TRANSITION STATE

In reactions which proceed via a cyclic activated complex, the loss of free or partly hindered internal rotation has the greatest influence on A. There is no fundamental difference between the third and fourth groups of the proposed classification (Table 2). The difference is merely quantitative. In a four-membered transition state, only one or two internal rotations can be lost and in a six-membered state the loss of 2–4 rotations is possible. Accordingly, in the fourth group of reactions (Table 2), low values of A are encountered much more frequently than in the third group. Certain cases where it is possible to follow clearly the change in A owing to the increase of the number of restricted internal rotations are presented in Table 9.

In a cyclic transition state the decrease of entropy due to the disappearance of internal rotations is partly compensated by the appearance of low-frequency out-of-plane ring vibrations. It is not possible to determine by any simple method the frequency of these vibrations taking into account all the ring atoms. Therefore O'Neal and Benson[103], who developed a method for the calculation of A in four- and six-centre unimolecular reactions, proposed for the activated complex a model with a so called loose cyclic structure in the formation of which internal rotations are transformed into semifree partial torsional bond vibrations, It is assumed further that the order of the bonds being loosened and formed changes by 1/2 with a corresponding change in the deformation, stretching, and torsional vibration frequencies. This hypothesis standardises the method of calculation of $\Delta S^{\neq}$. To simplify the calculation, the activation entropy is divided into four parts:

1. $\Delta S^{\neq}_{vibr}$—the entropy change owing to the change in the deformation and stretching vibration frequencies. For each principal cyclic framework, $\Delta S^{\neq}_{rot}$ is constant.

Table 9. Four- and six-membered rings.

Reaction	No. of rotations lost	lg$A$ (s^{-1})
 (X = Cl, Br I)	1	12—13
	2	11—11.8
	2	11—12
	3	10—11.5
	4	9—10.5

2. $\Delta S^{\neq}_{rot-vibr}$—the entropy arising owing to the restriction of the free internal rotations (which are converted into torsional vibrations about bonds with an order of 3/2).

3. $\Delta S^{\neq}_{sym}$—the overall symmetry correction: $\Delta S^{\neq}_{sym} = R \ln \sigma$, where σ is the statistical factor of the reaction.

4. $\Delta S^{\neq}_{cor}$—a correction term which must be introduced into $\Delta S^{\neq}_{r-t}$ in order to take into account the barriers to internal rotation in the initial molecule. The effect of substituents on A is in fact taken into account in terms of $\Delta S^{\neq}_{cor}$.

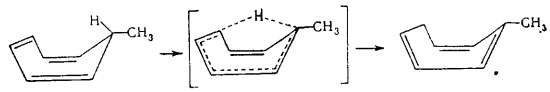
Despite the considerable simplifying assumptions made in the calculation of activation entropy, in most cases the calculated A differ by not more than a factor of two from the average experimental values[103]. Within the framework of a single reaction series, where the main variable parameter is $\Delta S^{\neq}_{cor}$, the accuracy of the prediction of A may be very high.

In many cases a purely qualitative examination of the direction of change in the barrier to rotation makes it possible to explain fine effects of the structure and substituents on A. The examples quoted, the experimental data for which were taken from Refs. 6 and 103, illustrate this.

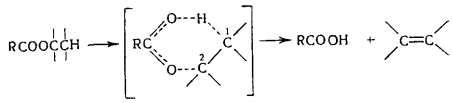
Example 5. 1,5-Migration of hydrogen. Ten cases of hydrogen migration [reaction (9)] have been investigated[9]. Two rotations are lost in the activated complex and $\lg A = 11-11.8$:

(9)

However, for 7-methylcyclohepta-1,3,5-triene, where there is no internal rotation, $\lg A$ has the normal value of 12.6:



Example 6. Esters. The value of A. In the transition state for the reaction



the rotations about the $O-\overset{2}{C}$ and $\overset{1}{C}-\overset{2}{C}$ bonds disappear, which explains the decrease of the pre-exponential factor to $10^{11}-10^{11.8}$ s^{-1}. The substituents in the 1- and 2-positions increase the barrier to internal rotation and smooth out the differences between the initial state and the activated complex. Substituents in the 2-position may be expected to have a greater effect, since they influence also the $\overset{1}{C}-\overset{2}{C}$ bond and what is particularly important, the $O-\overset{2}{C}$ bond, which has a very low barrier to internal rotation (Table 10).

Table 10. Effect of substituents on A for the decomposition reactions of esters.

Substituent	lg A
1-Phenyl	12.0
2-Phenyl	12.4
1,2-Diphenyl	12.7
1-Alkyl (linear)	12.0
1-Alkyl (branched)	12.6
1,1-Dialkyl	12—13

Table 11.

Reactant	Observed ratio	Statistical ratio
	 =3	0.67
	$\frac{CH_3CH=CHCl}{CH_2=CHCH_2Cl} = 1.1$	0.67

Example 7. Esters. Mode of Cleavage. When the elimination reaction can occur in two ways, the pathway for which the transition state includes bonds with highest barriers to internal rotation is preferred. On the basis of this simple postulate, one can explain all cases where the composition of the products differs from their relative proportions based on a purely statistical distribution (Table 11).

In the first example quoted in Table 11, the transition state involves preferentially the $\overset{1}{C}-\overset{2}{C}$ bond of the cyclohexane ring instead of the $C-CH_3$ bond and the second includes the $C-CH_2Cl$ bond instead of $C-CH_3$.

Example 8. Acetals.

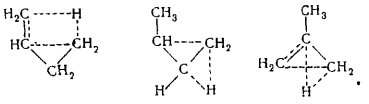
H	alkyl	11.9—12.2
alkyl	alkyl	12.5—12.8

VII. REACTIONS INVOLVING A BIRADICAL TRANSITION STATE

The first elementary step in the geometrical isomerisation of olefins and cyclic hydrocarbons and also in the decomposition and structural isomerisation of the latter consists in the dissociation of a C-C bond and proceeds via an activated complex which has the properties of a biradical [112,169,170]. In many cases an excited biradical is probably an intermediate, which can lead to the formation of products and to the reverse reaction

The reversibility of the first stage hinders the interpretation of the kinetic data [126]. For certain structural isomerisations, it is postulated that the dissociation of a C–C bond and hydrogen migration can occur in a single elementary step via a transition state which differs from the biradical state [132]. From this standpoint, the following activated complex structures are possible for the structural isomerisation of methylcyclobutane:



Product but-1-ene but-2-ene isobutene

However, it is assumed that the cyclisation, associated with hydrogen transfer, involves a very loose structure and does not prevent rotation about the C–C bond.

In most cases the pre-exponential factors for these reactions are enhanced (up to $10^{15.5}$ s^{-1}), the main reason for which is the appearance of internal rotations about single bonds in the linear system produced.

The presence of substituents prevents internal rotation and limits the increase of A. A double bond in the α-position relative to the free valence has a similar effect, since conjugation leads to an increase of the barrier to internal rotation. On the basis of these general considerations, even when the treatment is confined for simplicity to the hypothesis of a purely biradical structure of the activated complex, it is possible to understand the typical values of A observed in these reactions, which are listed in Table 12.

Quantitative calculations based on the RRKM theory have been made for only a few reactions of this type [52,126,132], but these confirm satisfactorily the decisive role of internal rotations. Pre-exponential factors have been evaluated by semiempirical calculations of activation entropies for reactions involving a biradical state [169,170,175]. A recent handbook [177] describes methods for the semiempirical calculation of A for all types of unimolecular reactions.

In conclusion one may note yet again that, despite the large number of theoretical treatments of unimolecular reactions, the real possibility of estimating pre-exponential factors of decomposition and isomerisation rate constants for polyatomic molecules at high pressures is nowadays based almost entirely on the classical formula (1) of the transition state theory. The more detailed RRKM statistical theory, the general validity of which has been confirmed by the success of its application, yields for k_∞ a formula identical with Eqn. (1). The possibility of taking into account anharmonic interactions in the activated molecule by postulating an activated complex with a somewhat predetermined structure in the RRKM theory) and the explanation on this basis of the high values of the pre-exponential factor constitute a brilliant achievement of the statistical theory. As a result, among problems concerning unimolecular reactions, that of the pre-exponential factor is the most completely resolved. Its solution is based on hypotheses concerning the structure of activated complexes in various elementary processes, which have arisen as a result of long experience gained in the application of the transition state theory to real systems. Despite their qualitative nature, in the vast majority of cases these hypotheses are sufficient to estimate correctly the critical values of A for reactions of the given type and to predict the dependence of A on molecular structure. Recently, in connection with the development of the RRKM theory, the possibility of a quantitative approach to the modelling of the activated complex structure has also appeared.

In the calculation of the pre-exponential factor, one may restrict the treatment to specifying the geometrical structure, the vibration frequencies, and the barriers to internal rotation in the activated complex, which can be frequently done using the corresponding characteristics

Table 12.

No.	Reaction	lg A	No.	Reaction	lg A
1		15.45	7		15.63
2		14.05 14.13	8		14.61
3		13.28 13.21	9		14.50
4		13.89	10		14.50
5		13.29	11		13.26
6		15.62	12		14.10

of the reactants and the reaction products or any of their analogue among stable compounds. When the reaction mechanism is well known, A can be in its turn an important source of information about the structure of the activated complex. This factor has been used successfully to develop empirical and semiempirical methods for the calculation of A, which nowadays play a dominant part in the interpretation and prediction of pre-exponential factors[168,170,177]. The scope of these methods depends entirely on the accumulation of experimental data and their reliability depends on fundamental studies involving the calculation of activated complex structures (for example within the framework of the RRKM theory). Together with considerable achievements in this field, the experimental and particularly theoretical studies which have been made are still inadequate and require further development.

Formation of Free Radicals from Molecular Complexes

G.B.Sergeev and I.A.Leenson

The Review summarises results from various branches of chemistry having as a common theme the part played by donor-acceptor molecular complexes in the generation of free radicals. Attention is paid mainly to liquid-phase reactions. One section deals with polymerisations involving molecular complexes. A list of 200 references is included.

I. INTRODUCTION

The theoretical importance of the formation of free radicals by the interaction of valency-saturated molecules was at one time pointed out by Semenov[1], but the experimental information which has been accumulated on this problem is still very limited[2]. Processes in which the appearance of radicals is preceded by preliminary donor–acceptor interaction of the molecules, leading to the formation of various types of complexes, have been better studied.

The importance of molecular complexes in chemistry is immense. During the twenty years that have elapsed since Mulliken worked out the principles of the modern theory of donor–acceptor interaction in complexes great progress has been made in elucidating the structure, geometry, and thermodynamic and spectral characteristics of the complexes. Detailed accounts of these topics are to be found in monographs[3,4]. Nevertheless, relatively few studies have been made of the part played by complexes in chemical reactions.

Reviews on the production of free radicals from complexes cover the literature up to 1963–1964.[5-7] In the present Review attention is paid mainly to various mechanisms by which free radicals are formed and to possible explanations of such processes in energetic terms. Use is made chiefly of results published during 1965–1970. Complexes formed by metal salts are not considered, nor are stable free radicals, aspects which have already been discussed in detail[8-11]. However, we have considered several papers in which free radicals were recorded and the existence of a complex can be inferred from the properties of the reactants.

II. MECHANISMS OF THE FORMATION OF FREE RADICALS FROM MOLECULAR COMPLEXES

1. Involvement of Complexes in Radical Reactions

Three tasks are involved in studying the part played by molecular complexes in the formation of free radicals: the existence of molecular complexes in the system must be proved, then free radicals must be detected or a radical reaction mechanism demonstrated, and finally a connection must be established between complex formation and the appearance of radicals. The last task is usually the most complicated.

Donor–acceptor interaction between reactant molecules changes their electronic structure and reactivity. Complex formation may be expected to increase the reaction velocity when interaction between donor and acceptor lowers the free energy of the transition state more than the energy of the ground state[12]. Such changes obviously occur in many biochemical processes, in particular in enzymic reactions, where the entropy factor plays a large part in the transition state[13]. The existence of molecular complexes can often be shown in the reactions of relatively small organic molecules, but it is not easy to prove that they are involved in forming the product[14]: the complex may be produced in parallel with the main reaction.

Let us examine the simple schemes of consecutive and parallel reactions

$$A + D \overset{K}{\rightleftarrows} \pi \xrightarrow{k_1} P, \qquad (I)$$

$$\pi \overset{K}{\rightleftarrows} A + D \xrightarrow{k_2} P, \qquad (II)$$

where A is an acceptor, D a donor, π the complex, and P the product. A choice between (I) and (II) cannot be based on the usual kinetic measurements[14,15]. Indeed, the low activation energy leads to rapid and reversible formation of a complex in solution at room temperature[14]. Rate constants for the formation and the dissociation of π–π complexes of 1,3,5-trinitrobenzene with deuterated fluorenes have been measured recently by quadrupole relaxation as respectively $(0.61–1.7) \times 10^{10}$ M^{-1} s^{-1} and $(0.53–1.5) \times 10^{10}$ s^{-1}.[16]

If a reaction occurs and a complex is formed in a system, and the latter can be monitored e.g. by means of its optical absorption, the disappearance of the complex in the system according to Eqn. (I) is described, for the normally chosen experimental conditions $[D]_0 \gg [A]_0$, by the equation

$$\ln\frac{[\pi]_0}{[\pi]} = \ln\frac{[A]_0}{[A]} = \frac{k_1 K [D]_0}{K[D]_0 + 1} t. \qquad (1)$$

If the complex coexists with formation of the final product [Eqn. (II)], we have

$$\ln\frac{[\pi]_0}{[\pi]} = \ln\frac{[A]_0}{[A]} = \frac{k_2 [D]_0}{K[D]_0 + 1} t. \qquad (2)$$

In both cases the reaction follows a first-order law, and the mechanisms cannot be distinguished[15].

Direct evidence of the formation of intermediate complexes has been obtained only for certain reactions in the gas phase[17].

With liquid-phase processes the problem of the participation of complexes in the reaction can be solved by a detailed study of the intermediate species. Correlations between various properties of the complexes and the reaction rate constants are also usually regarded as evidence of their involvement in the chemical process. Correlations have been observed between the reactivity of donor and acceptor and the stability of their complexes with substances which do not react with them [18]. The equilibrium constants of complex formation have been found to correspond with the rate constants in the interaction of a given acceptor with a series of donors [11,15]. A correlation exists between reactivity and changes in optical charge-transfer spectra [19].

A kinetic method, in which the reaction is conducted in different solvents, has also been proposed [20] for making a choice between schemes (I) and (II). The reaction of tetrachlorophthalic anhydride with triethylamine, which resembles the Menshutkin reaction and depends on the polarity and the polarisability of the solvent molecules, was investigated. The apparent first-order rate constant, determined experimentally from the decrease in the acceptor concentration, is connected with the equilibrium constant of complex formation and with the concentration of the donor, present in excess, by the relation $k_{exp} = k'[D]_0/(1 + K[D]_0)$. If the complex takes part in the reaction, we have $k' = k_1 K$. The values of k_1 and K can be obtained by reducing the above equation to the form [15,20]

$$1/k_{exp} = 1/k_1 + 1/k_1 K \cdot 1/[D]_0 . \qquad (3)$$

With parallel formation of the complex (scheme II) we have $k' = k_2$. If the rate constant of the Menshutkin reaction k^M is used to characterise the solvent, a definite regularity in the dependence of $\lg k_1$ on $\lg k^M$ should be observed if the complex takes part in the reaction. If, however, the complex is not involved in the reaction, a large scatter of the points should be obtained in the corresponding dependence of $\lg k_2$ on $\lg k^M$. On this basis it was concluded [20] that the charge-transfer complex is an intermediate product, and that the reaction occurs according to scheme (I).

Another approach to elucidating the part played by the complex in the reaction consists in lowering the temperature. This permits the study of intermediate products that are unstable at room temperature [21-23] and also diminishes the rate of all stages in schemes (I) and (II). With sufficient retardation of the most rapid stage of the reaction, an S-shaped rate curve representing accumulation of the reaction product may be observed experimentally if the product is formed from the complex (consecutive reaction). Here it is desirable that none of the elementary rate constants should differ too greatly in absolute magnitude. A negative temperature coefficient is also of interest: if the acceleration of the reaction when the temperature is lowered is associated with formation of an intermediate complex, this agrees with schemes (I)—not with (II). [15]

We have been discussing above the simplest consecutive and parallel reactions (schemes I and II). It is often suggested that two intermediate species, e.g. π- and σ-complexes [6,14], are involved in formation of the products. Thus for the scheme

$$A + D \overset{K}{\rightleftarrows} \pi \xrightarrow{k_3} R \xrightarrow[+D]{k_4} P \qquad (III)$$

(in which R is the second complex or free radical) the time variation in the concentration of the product P is expressed by the equation

$$[P] = \frac{k_3 k_4 [D]_0 [\pi]_0}{k_3 - k_4 [D]_0} \left[\frac{1 - e^{-k_4 [D]_0 t}}{k_4 [D]_0} - \frac{1 - e^{-k_3 t}}{k_3} \right] \qquad (4)$$

provided that $[D]_0 \gg [A]_0$ and with rapid equilibrium formation of π. In this case a sigmoid curve for the product can be observed comparatively easily. Fig. 1 shows theoretical rate curves for the accumulation of P with different ratios of k_3 to $k_4[D]$. [24] Schemes of type (III) should be found especially frequently with radical reactions, since the free radicals formed from the complex react readily with the starting materials to give the reaction products.

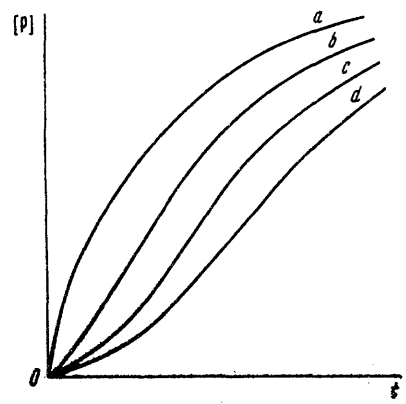

Figure 1. Theoretical rate curves for the accumulation of the reaction product according to: *a*) scheme (I); and according to scheme (III) with different values of $k_4[D]$: *b*) $8k_3$; *c*) $2k_3$; *d*) $1.2k_3$.

Evidence of the formation of the σ-complex from the π-complex—not directly from the original molecules—has been obtained from a spectrophotometric investigation of the reaction between N-substituted aromatic amines and chloranil in solution [22]. A kinetic study has been made of this process [23]. With low concentrations of donor and acceptor very little of the "external" (π) complex is present at room temperature, but it is observed on cooling to −80°C (the process is reversible). Formation of the "internal" (σ) complex in this case requires a further drop in temperature (to −196°C) in order to accumulate the π-complex, followed by a return to −80°C. When the π-complex is present in appreciable concentrations at room temperature, cooling to −80°C is sufficient for the σ-complex to be formed. Thus there exists a critical concentration of the π-complex necessary for further reaction [22]. A similar phenomenon is observed in several radical reactions involving an intermediate complex [25,26].

Formation of the same products by photoexcitation of the complex in the charge-transfer band as in the dark thermal reaction may be used as an argument that the complex is involved in the reaction even in the absence of illumination. This criterion has been applied, for example, to the reaction of acid chlorides with aromatic

amines[27] and to free-radical reactions involving tetranitromethane[25]. The formation of donor–acceptor complexes also favours photochemical reactions. Complex formation usually shifts the absorption maximum to longer wavelengths, and absorption may increase at a given wavelength. Thus complex formation has the effects firstly of increasing the efficiency of the absorption of light and secondly of permitting the use of irradiation with photons of lower energy and the avoidance of several side-reactions.

2. Possible Modes of Breakdown of the Complex into Radicals

The wave function of a donor–acceptor complex in the ground state is given by a linear combination of wave functions of non-bonding and bonding configurations. There exist complexes with weak interaction, when the term describing a structure without charge transfer has the highest value in the wave function; and complexes with strong interaction, which are represented mainly by a structure with a transferred charge. In our opinion the nature of the ground state of the complex and of the radicals formed after charge transfer indicate that four main cases can be distinguished. These are given in Table 1 together with actual examples illustrating the general schemes.

Scheme 1. This shows that, if a complex consists in the ground state of two neutral molecules, an electron transition in the complex will lead to an excited state that is more polar than the ground state. In this case replacement of a less by a more polar solvent will shift the charge-transfer band to longer wavelengths. The effect is usually small, since solvent molecules require a finite time for reorientation around the polar excited state, while the ground state is only slightly solvated. Complete transfer of charge in such cases will yield two oppositely charged radicals.

Scheme 2a. In the ground state the complex consists of charged particles. Most complexes of this type that have been studied are pyridinium halides[6]. The position of the charge-transfer band in such complexes is strongly dependent on the polarity of the solvent. In polar solvents the ionic ground state is more strongly solvated than is the excited state, and this leads to a short-wavelength shift of the charge-transfer band. In this case complete transfer of an electron from donor to acceptor yields two uncharged radicals.

Scheme 2b. Free radicals are produced most easily in the case of complexes having strong interaction, when an electron is transferred spontaneously from the highest occupied orbital of the donor to the lowest vacant orbital of the acceptor. The radical pair thus formed can be regarded in some cases as a new ground state of the complex. When it is excited, charge transfer takes place in the opposite direction, and the excited state corresponds to the original structure[30]. Such cases are usually observed in solid crystalline paramagnetic complexes. Salts of radical-ions have been most thoroughly studied among solid-phase complexes. Such complexes have high electrical conductivity and are usually strongly paramagnetic[34]. Salts of radical-ions can be obtained both by the complete transfer of an electron from donor to acceptor and from "ready made" ions of the substances involved[35]. Such complexes show interesting behaviour in solution. In media of low polarity charge-transfer bands can be observed corresponding to the transfer of an electron from anion to cation. With increase in polarity of the solvent this band moves to shorter wavelengths[36], i.e. in the opposite direction to that for neutral complexes. The position of the charge-transfer band in such complexes corresponds to low energies, and can be observed in the infrared[30,36–40]. Assignment of the charge-transfer band may be made difficult by the absorption due to radical-ions. It should be noted that the ionic ground state of a complex in the solid phase is not necessarily preserved in solution. The electron spin resonance signal also frequently vanishes on passing into solution[41].

Table 1. Mechanisms and examples of the formation of free radicals from molecular complexes.

No.	Starting materials	Complex: gound state	Complex: excited state	Example	Ref.
1	A+D	(A, D)	$(A^{\cdot-}, D^{\cdot+})$	$C_6H_5NH_2$, $(NC)_2C{=}C(CN)_2 \rightleftarrows [C_6H_5\dot{N}H_2]^{\cdot+}$, $[(NC)_2C{=}C(CN)_2]^{\cdot-}$	28
2a	$A^+ + D^{\cdot-}$	$(A^+, D^{\cdot-})$	$(A^{\cdot}, D^{\cdot})$	$C_6H_5\overset{+}{N}CH_3I^{\cdot} \rightleftarrows C_6H_5\dot{N}CH_3$, $I^{\cdot}$	29
2b	A + D	$(A^{\cdot-} D^{\cdot+})$	(A, D)	$[(CH_3)_2NC_6H_4\overset{+}{N}(CH_3)_2]^{\cdot+}$,  $\rightleftarrows (CH_3)_2NC_6H_4N(CH_3)_2$, 	30
3a	A + $D^{\cdot-}$	$(A, D^{\cdot-})$	$(A^{\cdot-}, D^{\cdot})$	$C(NO_2)_4$, $C_6H_5O^{\cdot} \rightleftarrows [C(NO_2)_4]^{\cdot-}$, $C_6H_5O^{\cdot}$	31
3b	$A^+ + D$	(A^+, D)	$(A^{\cdot}, D^{\cdot+})$		32
4	D+X—Y	(D, X—Y)	(D, X˙ Y˙)		33

Spontaneous electron transfer usually occurs with donors of low ionisation potential I_D and acceptors of high electron affinity E_a. The best known donors, e.g. tertiary aromatic amines, have I_D = 6–7 eV. The electron affinity of such acceptors as tetracyanoethylene, tetracyanoquinodimethane, and chloranil is 2.4–2.6 eV according to the most recent results[42,43].

Schemes 3a and 3b. If the complex is formed by neutral and ionic components, one of the radicals will be neutral after electron transfer, and the other charged. Relatively few such examples are known[44].

Scheme 4. Cases are also possible in which one of the components of the complex breaks down into radicals in the course of complex formation, while the other remains unchanged, at least initially. Such a scheme corresponds formally to homolysis of the molecule as a consequence of its bonding into a complex, and will be examined in greater detail in Section III, 2.

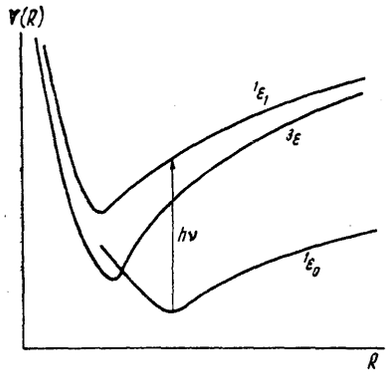

Figure 2. Potential-energy curves of ground and excited states of complex.

Study of the detailed mechanism of the formation of radicals from complexes has begun during recent years. Use is made mainly of the excitation of neutral molecules in the charge-transfer band combined with methods enabling short-lived intermediate species to be investigated. When the complex absorbs light of energy corresponding to the charge-transfer band and insufficient to excite the starting materials, it passes into the lowest excited singlet state (Fig. 2, curve $^1\epsilon_0$). This involves passage of an electron from a donor orbital to the lowest unoccupied orbital of the acceptor, while the total spin multiplicity is maintained. The electronic constitution and the structure of ground and excited states of the complex differ greatly. This leads to a considerable difference between the excited state formed in conformity with the Franck–Condon principle and the equilibrium excited state. As a result, mirror-image symmetry may not be satisfied between the absorption spectrum (i.e. the charge-transfer band) and the fluorescence spectrum[45]. The structure of the excited state of the complex is greatly influenced by the solvent. The excited complex is strongly polar, and the radical-ions formed may be stabilised in a medium of high dielectric constant. The whole process can be represented by the scheme

$$(D,\ A)_0 \xrightarrow{h\nu} (D^+,\ A^-)^*_S \xrightarrow{\text{solvent}} D^+_{\text{solvate}} + A^-_{\text{solvate}}\ .$$

If the complex does not dissociate, it is deactivated. The radiating transition to the ground state is registered as fluorescence of the complex:

$$(D^+,\ A^-)_S{}^* \longrightarrow (D,\ A)_0\ .$$

Intersystem conversion is possible with population of the lowest triplet level of one of the components of the complex, e.g. the donor:

$$(D^+,\ A^-)^* \longrightarrow (D_T{}^*,\ A).$$

Sometimes the lifetime of D_T is shorter in the complex than in the free molecule. Its values for naphthalene and its trinitrobenzene complex, for example, are respectively 20 and 2 s:[46] i.e. typical quenching occurs. The quantum yields of the phosphorescence of aromatic molecules may be increased by the presence of donor–acceptor interaction. Since acceptor molecules do not usually contain heavy atoms, the increase in the spin–orbital interaction, which increases the probability of a singlet–triplet transition, obviously originates in the bonding of the donor into a complex[46,47]. This involves deformation of the molecular orbitals, mixing of s- and p-orbitals, and increase in the spin–orbital interaction. The relative arrangement of energy levels in the complex that is necessary for fluorescence to occur has been analysed[48].

Conversion from the lowest singlet excited state of the complex can theoretically produce a triplet state of the complex itself (Fig. 2, curve $^3\epsilon$). After this, phosphorescence of the complex becomes possible:

$$(D^+,\ A^-)^*_S \rightarrow (D^+,\ A^-)^*_T \rightarrow (D,\ A)_0.$$

Such a process is still the least studied, and interpretation of the experimental results is not always unambiguous.

Great progress has recently been made in the experimental detection of excited states in donor–acceptor complexes. When complexes of tetracyanobenzene and pyromellitic dianhydride with aromatic compounds were illuminated in the charge-transfer band with laser light of wavelength 3371 Å, the absorption spectrum of the undissociated complex in an excited singlet state could be recorded for a few tens of nanoseconds[49]. Excited states have been studied also by the laser photolysis of complexes of tetracyanobenzene with toluene in acetonitrile. The absorption spectrum of the species obtained by exposure to a ruby laser is closely similar to that of the radical-anion of the acceptor. Kinetic analysis has established that the photoinduced species are formed within 10 ns.[50] Fluorescence of the excited singlet complex in solution is observed comparatively rarely. It has been studied in complexes of acid anhydrides with aromatic compounds[51,52] and of tetracyanobenzene with toluene[53]. A systematic investigation[54] of the spectral characteristics of the complexes of tetrachlorophthalic and pyromellitic anhydrides with hexamethylbenzene involved study of the absorption and fluorescence spectra, together with determination of the quantum efficiency of fluorescence in various solvents at room temperature.

Detection of the triplet state of a complex was first reported in 1967, when complexes of tetracyanobenzene with aromatic compounds were illuminated in frozen solutions: both phosphorescence of the complexes in the triplet state[55] and their triplet electron spin resonance signal[56,57] were claimed to have been observed. However, it has since been shown[58,59] that the observed phosphorescence was due to a triplet excited state of the acceptor (tetracyanobenzene). The role of the triplet state of the complex in photoionisation has been studied also by low-temperature flash photolysis: this provided the first experimental detection of the spontaneous ionisation of the triplet state of the complex of pyromellitic dianhydride with mesitylene[60]. It was also concluded that the triplet state may be populated by direct excitation of the complex in the ground state.

Strong attraction between an excited ion-pair and a donor molecule may lead to association (formation of an exciplex)

$$D \cdots (D^+,\ A^-)^*_S.$$

After intersystem conversion, phosphorescence of the triplet eximer is observed [61]:

$$D - - - (D^{+}, A^{-})_{S}^{\bullet} \rightarrow (D, D_{T}^{\bullet}A) \rightarrow D + .$$

With regard to the possibility of radical formation by thermal excitation of the complex, the lowest excited singlet state is energetically too high and is unattainable thermally. Theoretical examination of the energetics of complexes leads to the conclusion that, in the case of the uncharged ground state of the complex in systems comprising a donor of low ionisation potential and an acceptor having a positive electron affinity, the potential-energy curves of ground and triplet states of the complex may intersect [62,63]. If the point of intersection is sufficiently low energetically, thermal population of the triplet state of the complexes is possible (Fig. 2, passage from curve $^{1}\epsilon_{0}$ to curve $^{3}\epsilon$). In the case of a low-lying triplet state such electron transfer does not involve any considerable consumption of energy. Because of this, the thermal formation of radicals from molecular complexes can occur even when the charge-transfer band lies in the short-wavelength region.

III. RADICAL REACTIONS INVOLVING MOLECULAR COMPLEXES IN SOLUTION

Electron spin resonance can in many cases be conveniently used to demonstrate the radical nature of a reaction in solution. However, difficulties arise in assigning the e.s.r. signal to the complex itself. Formation of a triplet state, equivalent to a biradical, precedes the production of radicals by thermal or photoinduced electron transfer in the complex. After dissociation of the biradical, two e.s.r. spectra of equal intensity—due to donor and acceptor radicals—should both be present. Usually, however, only one radical is recorded in the e.s.r. spectrum after electron transfer in the complex and the formation of radical-ions [64]. This is probably due to dissociation of a radical-ion pair in solution into free radical-ions, one of which is more stable than the other. When e.s.r. spectra having a hyperfine structure are observed, they must evidently be assigned not to the complex but to radical electron-transfer reaction products; with a stable radical-ion pair, however, a wide signal should be observed, and at low temperatures the spectrum of the triplet state is registered [6]. The triplet state of a complex is in certain respects analogous to the radical pairs formed e.g. by solid-phase photolysis or radiolysis. The paramagnetism of such pairs has been studied quite thoroughly [65]. As already mentioned, the e.s.r. spectrum of the triplet state of a complex could be detected only in the solid phase. With regard to transitions having $\Delta m = 1$ and $\Delta m = 2$, exposure e.g. of complexes of tetracyanobenzene with methylated benzene derivatives at 77°K produces an e.s.r. signal in the region $g \simeq 4$. [56,57] An e.s.r. spectrum has been observed also in an analogous system on the irradiation of complexes placed in liquid crystals cooled to a vitreous state in a strong electric field. On excitation in the charge-transfer band, transitions were observed having $\Delta m = 1$ and $\Delta m = 2$. Each spectrum consisted of two groups of lines due to the triplet states of the donor and of the complex. This indicates the migration of energy from $(D, A)_{T}^{*}$ to D_{T}^{*}. The type of spectrum depends on the angle between the constant magnetic and electric fields; the method allows the orientation of complexes in the specimen to be studied [66]. The same paper reports observation of the e.s.r. spectrum of the triplet state of the complex in a tetracyanobenzene–naphthalene single crystal. At the same time both of the above transitions in the e.s.r. spectrum on the photochemical breakdown of the complex into radicals were detected also when the acridine–acridan system was illuminated in the charge-transfer band. Two types of radical pairs are formed in this system [67,68].

The use of electron spin resonance to investigate the radical reactions of complexes in solution is restricted by the low concentration and slow rates of conversion of complexes into radicals. The steady-state concentration of short-lived radical species in such reactions is often below the limit of sensitivity of the e.s.r. method.

1. Radicals with Electron Transfer from Donor to Acceptor in the Complex

In several cases increasing the polarity of the solvent does not produce the usual shift in the absorption band of neutral complexes in solution to lower frequencies, but a slight displacement in the opposite direction [69]. This effect is due to the influence of the solvent, which plays an extremely important part in reactions involving molecular complexes. Even in such solvents as hexane and carbon tetrachloride the reactant species which form the complex and the complex itself are in a state which is energetically greatly different from the gas phase [43,70]. The corresponding potential-energy curves will be found in Ref. 71, where the effect of the solvent on the thermodynamic characteristics of the complexes of tetracyanoethylene and iodine with several donors is discussed.

Dissociation of a neutral complex into radical-ions is facilitated by the lowering of the free energy of the latter state consequent on interaction with the solvent [72]. Solvation by a polar solvent makes dissociation into radical-ions energetically advantageous. If a complex is ionic in character in the ground state, a polar solvent tends to stabilise such state, and dissociation into radicals now occurs more easily in a non-polar solvent. This process can be represented as a chemical reaction involving the solvent S:

$$(D, A) + S \rightleftarrows D_{S}^{+} + A_{S}^{-} . \qquad (IV)$$

The equilibrium shifts to the right when the charge-transfer energy is less than the total energy of solvation of the two ions. The stability of the radical-ions towards recombination increases with the polarity of the solvent [73]. Thus it is important to know the energies of solvation of the species formed by dissociation in order to estimate the reactivity of complexes.

In solvents of low polarity the degree of charge transfer in most organic complexes, even those formed by strong donors and acceptors, is small. In polar solvents, however, ionic species may be formed. The reversibility of the process (IV) and the dependence of the position of equilibrium on the polarity of the solvent are supported by results reported in Ref. 74. The spectrum of an equimolecular mixture of tetramethyl-*p*-phenylenediamine and chloranil in acetonitrile exhibits bands corresponding to an anion (at 428 and 448 nm) and to a cation (568 and 618 nm) together with a band (843 nm) due to charge transfer in the complex. Addition of the non-polar carbon tetrachloride diminishes the absorption by the ionic species relative to that due to the complex. This change is reversible: addition of excess of acetonitrile again leads to a relatively greater intensity of absorption by the ions. Analogous results are obtained when the corresponding

ions—the perchlorate of the radical-cation of the amine (Wurster's salt) and the sodium salt of the radical-anion of chloranil—are taken as starting materials.

The effect of the solvent on a reaction may provide a definite criterion of a radical mechanism. With systems in which specific solvation is not of fundamental importance a weak solvent effect may indicate a reaction involving transfer of an atom, whereas a strong solvent effect usually indicates a reaction with transfer of an electron [75].

Electron spin resonance combined with ultraviolet spectroscopy will give a great deal of information on solvation effects in complexes. Taking the behaviour of the tetramethylhydrazine–iodine complex as example [76], we can divide the solvents investigated into three groups. In non-polar solvents (n-hexane, cyclohexane, carbon tetrachloride) there is no e.s.r. signal, but the ultraviolet spectrum contains a strong band due to the complex together with absorption by free and complexed iodine, the equilibrium constant being 450 ± 170 M^{-1} at 25°C. In solvents of intermediate polarity (chloroform, dichloromethane, isopropyl and isobutyl alcohols, dimethoxyethane) e.s.r. signals have already appeared with broad lines (1.7–4.4 G) due to the radical-cation of tetramethylhydrazine. In polar solvents (acetonitrile, acetone, methanol, water) fully resolved e.s.r. spectra are obtained with narrow lines (0.35 ± 0.03 G). In aqueous dioxan the e.s.r. spectral lines become narrower with increase in the radical concentration: i.e. the broadening is not due to spin–spin exchange, but results from electron exchange with tetramethylhydrazine not bound in the complex. The width of the e.s.r. spectral lines is constant in all polar solvents. In chloroform the e.s.r. signal slowly disappears, and the addition of polar solvents accelerates the destruction of radicals. No e.s.r. signal due to iodine is observed. When iodine is replaced by tetracyanoethylene the e.s.r. spectra of both radical-cation and radical-anion are observed in acetonitrile. From the results we arrive at the scheme

$$\begin{gathered}(CH_3)_2N{-}N(CH_3)_2 + I_2 \rightleftarrows (CH_3)_2N{-}N(CH_3)_2 \cdot I_2 \rightleftarrows \\ \rightleftarrows [(CH_3)_2N{-}\dot{N}(\overset{+}{C}H_3)_2\bar{I}\cdot]_S \rightarrow \\ \rightarrow [(CH_3)_2N{-}N(CH_3)_2]^+_S + [I_2]^-_S;\ [I_2]^-_S \rightarrow [I]_S + I^-\ .\end{gathered} \qquad (V)$$

In non-polar solvents the complex is undissociated. In solvents of moderate polarity the complex exists as solvated radical-ion pairs. In polar solvents the radicals are in the free form: the pairs are dissociated and the ions are solvated independently. The instability of the radical-anion of iodine makes the overall process irreversible.

Electron spin resonance spectra have been observed also in complex formation between iodine and tetraarylhydrazines in solution and in the solid state, each molecule of the complex being associated in the latter case with one unpaired electron [77]. Thus the e.s.r. method enables intermediate species to be studied in electron-transfer reactions, and free radical-ions to be distinguished from those combined in pairs.

Photochemical and kinetic studies provide valuable information on the mechanism of one-electron transfer in a complex with the formation of free radicals. When, for example, the tetracyanoethylene–oxolan complex was illuminated in its absorption band, the steady-state concentration of tetracyanoethylene radical-anions, with a characteristic nine-line spectrum, varied as the square root of the light intensity. The increase in the signal in the light was proportional to the square of the time, and the decay of the signal after the light had been switched off conformed to a second-order equation [78]. On the basis of the kinetic measurements it was suggested [78] that on the absorption of light the complex π is excited to a singlet state: $\pi \xrightarrow{I} \pi^S$, the rate of this process being proportional to the light intensity I. Transitions to the ground state $\pi^S \xrightarrow{k_2} \pi$ and to the triplet state $\pi^S \xrightarrow{k_3} \pi^T$ are unimolecular. However, the triplet state is converted into the ground state according to a first-order law: $\pi^T \xrightarrow{k_4} \pi$. If the singlet π^S had dissociated directly into radical-ions

$$\pi^S \longrightarrow D^+ + A^-,$$

solution of the corresponding kinetic equations would have led to a time dependence of the radical concentration involving a hyperbolic tangent. Such a relation was not observed experimentally. It was therefore concluded that the reaction proceeds through a triplet state:

$$\pi^T \xrightarrow{k_5} D^+ + A^-.$$

The most rapid among the various reactions of the radical-ions is recombination

$$D^+ + A^- \xrightarrow{k_6} \pi.$$

Solution of the kinetic equations with $[\pi^S]$ constant leads to direct proportionality between the observed steady-state concentration of radical-anions and the square root of the light intensity.

Photoinduced e.s.r. signals are detected in many complexes of acceptor molecules with donor solvents [79,80]. A more detailed study has been made of the chloranil–dioxan complex [79], on whose illumination the concentration of radicals reached its maximum value (10^{17} spins ml^{-1}) in 1–1.5 min, after which it decreased. This work is interesting also in the use of a rapid-response e.s.r. spectrometer (time constant ~0.03 s), in combination with a cumulative store to improve the signal noise ratio for the kinetic curves, in studying the kinetics of "rapid" e.s.r. signals (time to reach maximum concentration 0.1 s and time to die out after light switched off 0.05–0.15 s). The "rapid" e.s.r. signals are probably due to the primary products of photoexcitation of the complex. A more unambiguous interpretation is obtained in such cases e.g. by flash photolysis of the complex [29,60] or by investigations at low temperatures, when recombination of the radical-ions is much slower [80].

Electron transfer accompanying photolysis of a complex with formation of free radicals has been studied also in the reaction of amines with halogenated methanes [81] and with acid chlorides [27], oxolan with maleic anhydride [82], and ether with oxygen [83]. Detailed studies have been made of the low-temperature reactions of alcohols with halogens, which give radicals on photolysis of the unstable molecular complexes [84–86].

The spontaneous formation of radicals by thermal electron transfer in the complex is especially interesting. Thus on the dissolution of tetracyanoethylene in strong donors the e.s.r. signal of its radical-anions appears immediately, sometimes corresponding to up to 20% conversion of the original substance. An e.s.r. signal has been recorded on the dissolution of tetracyanoethylene in pyridine and its derivatives [87,88], in aromatic amines [28], dimethyl sulphoxide [73,89], *NN*-dimethylacetamide [73], and acetone [73,90], and also on its interaction with cyclopropylated ethylenes [91]. No e.s.r. signal appears in aprotic solvents [90], nor in the presence of oxygen [92]. The corresponding radical-cation is not usually observed, and the kinetics of the reaction can be followed conveniently

by means of the e.s.r. signal or the characteristic spectrum of the radical-anion of tetracyanoethylene in the ultraviolet and visible regions[28]. The formation of radicals depends on the polarity and the viscosity of the medium, since these factors influence the stabilisation of the resulting radical-ions and their rate of recombination[73,90]. In polar dimethyl sulphoxide, for example, tetracyanoethylene forms a strong 1 : 1 complex having an equilibrium constant of 95.4 ± 1.9 M^{-1} at 25°C and a heat of formation of $\Delta H = -11.3$ kcal $mole^{-1}$.[89] At low donor and acceptor concentrations the intensity of the e.s.r. signal is proportional to their concentration.

The following mechanism has been suggested for the formation of radicals[73]:

$$D + A \underset{k_2}{\overset{k_1}{\rightleftarrows}} \pi \overset{k_3}{\underset{k_3}{\rightleftarrows}} \pi^T \xrightarrow{k_4} D^+ + A^- \xrightarrow{k_5} \pi \ . \qquad \text{(VI)}$$

The complex is in a singlet ground state, but its formation involves partial thermal excitation to a triplet state. The singlet excited state is not formed, since it lies considerably above the ground state (3.34 eV); attempts to record fluorescence of the complex were unsuccessful. The triplet state either breaks down into radicals or returns to the ground state; the latter process involves a change in spin, and therefore occurs at a lower rate. With a large excess of the donor the recombination of radical-ions will also be a slow process. The absence of signals from the triplet state of the complex and from the radical-cation is explained by exchange broadening by collisions between π^T and π and also between $D^{\cdot+}$ and D.

The stability of the complexes formed by tetracyanoethylene varies in the sequence

dimethyl sulphoxide ($\Delta H = -11.3$ kcal $mole^{-1}$) > > *NN*-dimethylacetamide (−9.17) > acetone > > oxolan (−1.14).

In the first three solvents the formation of radical-anions is observed, a strong e.s.r. signal being obtained in dimethyl sulphoxide and dimethylacetamide ($[C_2(CN)_4^{\cdot-}] = 0.001$ M and $[C_2(CN)_4]_0 \simeq 0.0007$ M), in acetone the signal is weak, and in oxolan radicals are not detected. Thus a correlation exists between the stability of the complex, as measured by the change in enthalpy ΔH, and the e.s.r. signal. The high heat of formation of the complex with dimethyl sulphoxide displaces downwards all the levels in Fig. 3 due to the complex relative to the level of the free donor and acceptor molecules.

The triplet state of the complex is assumed to be populated thermally[73,89,90,92], which is confirmed by the proportionality of the e.s.r. signal intensity to $\exp(-\delta/kT)$. Calculation for the dimethyl sulphoxide complex with a Boltzmann distribution between the states (D + A) and $(D, A)^T$ gave $\delta \simeq 0.18$ eV and $J = 0.65$ eV, where $J = \delta + \Delta H$ is the singlet–triplet splitting. The corresponding energy diagrams for various solvents and a theoretical interpretation of the observed phenomena will be found in Refs. 73 and 89. According to the theory the rapid appearance of a dark e.s.r. signal is a general property of stable complexes. The signal intensity is closely connected with the heat of complex formation, which can thus be estimated. With ΔH determined by an independent method, the temperature dependence of the e.s.r. signal enables the activation energy δ to be found and hence J to be calculated. Because of the lack of convenient methods of measurement, the magnitude of this splitting is usually unknown for liquid-phase complexes.

Most complexes exhibit no electron spin resonance or else give only a very weak signal. In terms of the above scheme this is explained by the small heats of complex formation. The ground state of the complex is then close to the (D + A) level, and hence δ/kT is too large for appreciable thermal population of the $(D, A)^T$ level. It has been computed e.g. that the e.s.r. signal for the dimethyl sulphoxide–iodine complex ($\Delta H = -4.4$ kcal $mole^{-1}$) should be around 1% of that due to the dimethyl sulphoxide–tetracyanoethylene complex, and therefore is not observed.

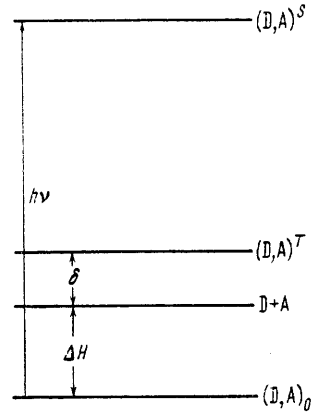

Figure 3. Energy diagram of various states of complex.

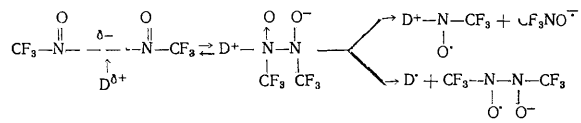
Thermal breakdown of a complex into radical-ions with transfer of an electron has been investigated in detail also in the reactions of nitroso-compounds with various electron donors[93–103]. The mechanism



(VII)

where D is a donor molecule, has been suggested e.g. for the dimer of trifluoronitrosomethane.

Electron transfer in a complex with the formation of radicals has been assumed also in the ozonisation of alkenes[104], the reaction of iodine with tertiary amines[105] and of tetranitromethane with tetra-alkyltetrazenes[106,107] and with 1,1-diphenylethylene[108], in the irradiation of the tetranitromethane–*N*-vinylcarbazole complex[26], and in the dissolution of chloroanil and benzoquinone in donor solvents[109]. An analogous mechanism of one-electron transfer in an intermediate complex probably operates in the reactions of peroxy-compounds with phosphites, sulphides, and aromatic amines. The kinetics and the mechanism of such processes have been discussed in a review[110]. The main part in the formation of peroxide complexes is played by hydrogen bonds[111]. Charge-transfer complexes may have an important role in biochemical processes[112]. Formation of free radicals from complexes takes place, for example, in the interaction of dihydroxyacetone with phenazine[113], of several medicinals (including antibiotics) with chloranil and other acceptors[114], and of flavins with phenols[115,116].

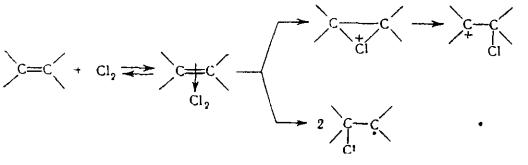
2. Radicals formed by Rupture of a Bond in One of the Components of the Complex

Free radicals are formed in several reactions of valency-saturated molecules at rates sometimes exceeding a hundredfold those calculated theoretically from the dissociation energy of the least stable bond. Such processes are sometimes termed *molecularly induced homolysis*, and their mechanism is not yet entirely clear [117,118]. In many cases such reactions have a radical-chain mechanism. A kind of feedback occurs in these processes: the energy required for dissociation of the molecule is partly or completely returned on the formation of new bonds after homolysis [2,119]. The solvent plays an important part in such reactions [120].

The formation of complexes in molecularly induced homolyses has been proved only in a series of reactions. In some cases their existence can be expected, since one of the reactants (often an alkene) has donor properties, while the other (e.g. a halogen) has acceptor properties. The formation of halogen–alkene complexes has been demonstrated experimentally [121,122].

Molecular complexes are probably involved in the formation of radicals in the liquid-phase chlorination of alkenes [119,123-128]. In the absence of light, oxygen, or a solvent the chlorination is a radical process with straight-chain alkenes and an ionic process with branched-chain alkenes. The radical reaction does not occur with tri- and tetra-alkylated alkenes. Oxygen strongly inhibits the radical reaction, which is then replaced by the slower ionic process. Dilution with a non-polar solvent also promotes the ionic reaction. Illumination increases the relative proportion of the radical reaction. The spontaneous formation of radicals in an alkene in the absence of a solvent and of oxygen is a rapid process unaffected by illumination. The reaction with cyclohexene goes readily even at −78°C. [119] The introduction of cyclohexane into the reacting mixture results in its chlorination, which proves the presence of chlorine atoms.

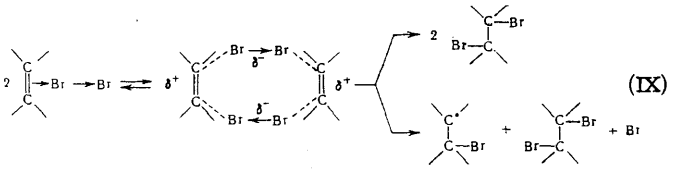
It is supposed that the reaction begins with the formation of an alkene–chlorine complex, which may either rearrange into ionic intermediate products or react with a second alkene molecule to form radicals:



(VIII)

Thus the classic scheme of the polar addition of chlorine to alkenes disregards all the specific features of the reaction. The low rate of initiation of free radicals is already sufficient for the radical-chain reaction to compete successfully with the ionic reaction [127].

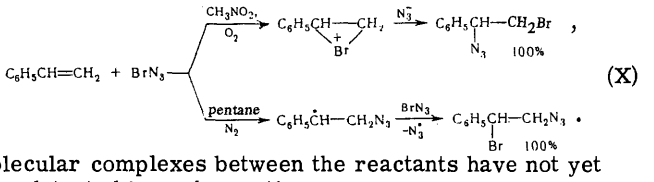
Schemes analogous to (VIII) have been suggested for the radical bromination [33] and nitration [86] of alkenes. A mechanism involving a complex containing two halogen molecules has been assumed [129] from kinetic results on the bromination of alkenes:



(IX)

Calculation shows that in this case the production of radicals is weakly endothermic ($q = -5$ kcal mole^{-1}), and therefore this mechanism has energetic advantages over the direct breakdown of a bromine molecule into atoms, which requires 46 kcal mole^{-1}. According to the above scheme polar and radical mechanisms of the halogenation of alkenes may involve closely similar transition states.

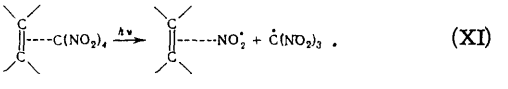
Complexes are probably involved also in the formation of radicals by the reaction of unsaturated compounds with iodine [130,131] alkyl hypohalites [120,132,133], halogen azides [134-137], peroxides [118], compounds containing a cyano-group [138], and ozone [104]. Spontaneous formation of radicals without initiation was observed in all these reactions. The possibility that molecular complexes are involved in directing the radical and ionic reactions is especially interesting. On the addition of bromine azide to alkenes, for example, theoretical yields of products of either the ionic or the radical reaction can be obtained depending on the conditions [135]. In the case of styrene, for example, the process can go according to the equations



(X)

Molecular complexes between the reactants have not yet been detected in such reactions.

The electronic rearrangement accompanying complex formation may tend to weaken a bond in one of the components [139]. In several cases the participation of complexes in the reaction is confirmed by combining photochemical decomposition with subsequent analysis of the resulting radicals by e.s.r. at low temperatures. In the photolysis of the complex of tetranitromethane with an alkene, for example, the energy of the quanta corresponding to the long-wavelength edge of the charge-transfer band is insufficient to rupture a bond in either component. In a mixture of the substances, however, tetranitromethane undergoes homolytic breakdown [25]. The latter is assumed to occur in conformity with the equation



(XI)

The free radicals formed by photolysis of the complex were identified by electron spin resonance at low temperatures. A similar reaction may occur even without illumination, obviously as a result of thermal excitation of the complex [140]. Under appropriate conditions the free radicals generated by the homolytic breakdown of tetranitromethane in the complex may lead to chain processes. The high quantum efficiency of the consumption of alkene and formation of a crystalline product on reaction with 1-phenylcyclohexene with illumination in the charge-transfer band, for example, indicates that the reaction has a chain mechanism [141].

Thus a detailed study of molecular complexes in such systems provides a deeper understanding of certain aspects of the mechanism of these reactions.

IV. RADICAL POLYMERISATION INVOLVING COMPLEXES

Many investigations have shown that a very promising method of polymerisation, besides the use of such

classical initiators as peroxides, diazo-compounds, etc., is the radical breakdown of molecular donor–acceptor complexes. Several facts indicate that complexes are involved in such reactions. Dilution of the reaction mixture with the solvent has been found to influence the composition of the polymer, a previously unknown effect. If the complex is responsible for the formation of a regular copolymer in the system, a diminution in this regularity is to be expected on dilution, which lowers the relative concentration of the complex. In the copolymerisation of divinyl ether with fumaronitrile, for example, dilution not only decreases the rate of polymerisation but also lowers the nitrile content of the copolymer [142].

If polymerisation takes place under the influence of active species formed by slow breakdown of a complex (e.g. according to scheme III), sigmoid kinetic curves should be obtained for the accumulation of the reaction product, as already mentioned. Such curves have been observed in several cases [143,144]. Finally, formation of a polymer having mainly a *cis*-1,4-microstructure by the interaction of butadiene with maleic anhydride confirms the involvement of a complex in the polymerisation [9,145]. The usual radical polymerisation of butadiene yields mainly the *trans*-1,4-microstructure. Thus the complexed diene—not the free compound—evidently takes part in the reaction, since precisely in the complex the strongest interaction with charge transfer should occur with a monomer having a *cis*-structure [145].

Complexes have a dual role in radical polymerisation: they are able firstly to initiate the reaction by breaking down into free radicals, and secondly to take part in chain growth by the bonding of free radicals into the complex. The Review considers mainly the process of initiation. The second aspect is also very interesting from both theoretical and practical points of view. The medium greatly affects the properties of free radicals, and solvation or bonding of the free radical into a complex may in considerable measure determine its reactivity in solution [8,11,146,147].

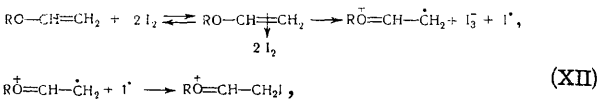
Examination of the literature reveals the following features of polymerisation initiated by molecular complexes. Such a reaction may occur at an extremely high rate, not attained with the usual initiators [148]. In some cases regular copolymers are formed, with a regular alternation of monomer units; independently of the proportions of the reactants, a 1 : 1 copolymer is usually obtained. The reaction mechanism cannot be described in terms of the laws of normal radical polymerisation. Sometimes the complex formed by the starting materials can be regarded as a monomer that is considerably more reactive than the usual monomers. Cases have been described in which neither component monomer of the complex is capable of polymerisation even in the presence of a radical initiator, whereas a mixture of the monomers is easily copolymerised even in the absence of an initiator [149]. On the other hand, the formation of a stable complex may so inactivate the monomer that polymerisation does not occur even in the presence of a radical initiator [150].

All cases of polymerisation initiated by the breakdown of a molecular complex into radicals can be divided into two groups. The complex may be a foreign reagent with respect to the monomers: i.e. its function is identical with that of the usual radical initiators. On the other hand, the initiating complex may include one or more monomer molecules. In the latter case the composition of the polymers can be varied by changing that of the complex, e.g. by the addition of various complexing agents [151,152].

The specific features of polymerisation initiated by a complex are due to the formation by electron transfer of two radical-ions

$$(A,\ D) \rightarrow A^{\cdot-} + D^{\cdot+},$$

which have different destinies. The ions may recombine, when it is supposed that polymerisation is begun by a biradical [148,153]. Recombination of the radicals yields a dipolar zwitterion $^{-}A-D^{+}$, which initiates ionic polymerisation [153]. Recombination of the radical centres may occur as a result of various secondary processes [143,149]. In the ionic polymerisation of vinyl ethers in the presence of iodine, for example, the reactions



(XII)

are possible [149].

Thus ionic and radical mechanism are closely connected, which explains the influence on radical polymerisation exerted by inhibitors of the ionic reaction [154]. When radical-ions are formed, ionic polymerisation is possible; this may be greatly accelerated by light, which facilitates electron transfer in the complex [155–157]. The mechanism of the conversion of radical-ions into carbonium ions has not yet been finally elucidated [158,159]. When one or both radical-ions obtained from the complex react with monomer molecules, the addition of the very first monomer molecule leads to the separation of ionic and radical centres, and here also both ionic and radical polymerisation is theoretically possible [153].

By no means all the above mechanisms are realised in practice. Thus the monomeric radical-cations studied hitherto do not exhibit simultaneous cationic and free-radical activity during polymerisation; no examples have yet been found of the formation from $D^{\cdot+}$ of bications $^{+}D-D^{+}$ to lengthen the chain. Many electron acceptors present in a complex are inhibitors of free-radical reactions, and perhaps suppress the radical activity of $D^{\cdot+}$. [149]

The dissociation of weak complexes into radicals cannot be detected experimentally by electron spin resonance, but the concentration of radicals is nevertheless sufficient for polymerisation to occur [160]. Examination of the kinetics of polymerisation is then a convenient method for studying the rate of breakdown of the initiating complex. In many cases in which the complex served merely to generate radicals, for example, the reaction velocity was proportional to the square root of the concentration of the complex [161–164]. The simplest explanation of this relation is the formation of an equilibrium complex, whose consumption is accompanied by the appearance of free radicals that react with the monomer [161]. More complicated mechanisms have also been suggested [163,165].

The most detailed study has been made of the initiation of polymerisation by complexes of aromatic amines with carboxylic acids and their derivatives. A relation has been established between the energetics of formation of the complexes and the kinetic parameters of the polymerisation initiated by them. The results are presented in Table 2.

The reactions between amines and acid chlorides are rapid. With an initial concentration of 0.1 M, for example, the half-conversion time is of the order of milliseconds [167]. A low-temperature technique is used [168] to study such complexes and their reactions. Bands due to complexes of anhydrides with amines have been detected at –196°C.

When the temperature rises by a few tens of degrees, chemical reaction occurs with disappearance of the complex. The infrared spectra indicate a decrease in the concentration of anhydride and amine groups, together with the formation at low temperatures of an ammonium salt [168].

Table 2. Influence of reaction conditions on the activation energy E_a for the polymerisation of methyl methacrylate initiated by the complexes of dimethylaniline with various acceptors.

Acceptor*	Parameters of complex			E_a, kcal mole^{-1}				Ref.
				no solvent		in acetonitrile		
	$h\nu_{max}$, kcal mole^{-1}	K_{eq} (25°C)	$-\Delta H$, kcal mole^{-1}	dark reaction	photochemical reaction	dark reaction	photochemical reaction	
TCPA	62.3	10.85	3.6	—	—	7.2	—	164
PA	76.2	4	2.0	—	12.0	11.5	11.5	164, 166
IPC	79.5	6.65	1.8	—	—	8.8	—	164
BAn	84.5	3.51	1.2	—	13.2	11.0	11.0	164, 166
BC	84.6	9.5	1.1	13.5	—	7.0	—	162, 164
BAc	—	—	—	13.2	6.4	—	—	161

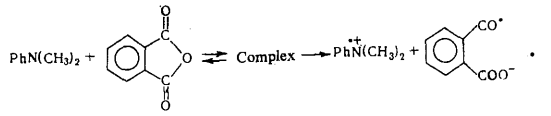
*TCPA = tetrachlorophthalic anhydride
PA = phthalic anhydride
IPC = isophthaloyl chloride
BAn = benzoic anhydride
BC = benzoyl chloride
BAc = benzoic acid

The following schemes have been suggested for the formation of radicals by electron transfer in complexes of aromatic amines [161,169]:

$$PhN(CH_3)_2 + PhCOOH \rightleftarrows \text{Complex} \longrightarrow Ph\overset{\cdot+}{N}(CH_3)_2 + PhCO^{\cdot} + OH^-,$$

$$PhN(CH_3)_2 + PhCOCl \rightleftarrows \text{Complex} \longrightarrow Ph\overset{\cdot+}{N}(CH_3)_2 + PhCO^{\cdot} + Cl^-,$$

$$PhN(CH_3)_2 + (PhCO)_2O \rightleftarrows \text{Complex} \longrightarrow Ph\overset{\cdot+}{N}(CH_3)_2 + PhCO^{\cdot} + PhCOO^-,$$



Breakdown of the complex is facilitated by ionic solvation, the effect being most strongly developed when the chloride ion is formed, and weakest with the radical-anion from phthalic anhydride. With strong complexes in a polar solvent it is sometimes possible to record the e.s.r. spectrum of the radical-cation of the amine [170,171]. However, it has been shown that polymerisation is initiated by the hydrocarbon radicals [172]. The rate of breakdown of the complex is strongly affected by light and the presence of oxygen, as well as the polarity of the medium [160,170,171,173-175].

As well as the complexes of amines with acid derivatives, polymerisation has been initiated by the use of complexes of nitrogen heterocycles with sulphur dioxide and with halogenated methanes [150], complexes of polymers with sulphur dioxide and carbon tetrachloride [150,185], and previously illuminated complexes of maleic anhydride with amides [176-178] and oxolan [179,180].

The mechanism of polymerisation initiated by complexes containing monomers has not yet been finally elucidated. Several authors hold the view that the determining factor is radical–monomer interaction in the transition state: others consider that the formation of copolymers of alternating structure is due to the involvement of molecular donor–acceptor complexes in initiation and chain growth [9]. Only one monomer—the donor—can enter the complex, and the second component is then an acceptor of electrons [149,181]. It is usually supposed that such a mechanism applies e.g. to the polymerisation of *N*-vinylindole and *N*-vinylpyrrole under the influence of chloranil, tetracyanoethylene, and other acceptors [182], and also the polymerisation of *N*-vinylcarbazole in the presence of chloranil and tetranitromethane [143,183]. In some cases initiation has been effected by illuminating the complex in the charge-transfer band [184].

The complex may also consist of two monomers, one with donor properties and the other with acceptor properties. Examples of reactions of this type that have been investigated are the copolymerisation of dioxen with maleic anhydride [185-187], of 1,2-dimethoxyethylene with maleic anhydride [187], of styrene and butyl vinyl ether with maleic anhydride [188], of butyl vinyl ether with acrylonitrile and maleic anhydride [189,190], of methyl methacrylate with the dimer of methyl vinyl ketone [191] and with *N*-vinylpyrrolidone [192], and also of sulphur dioxide with several olefinic compounds—1-methylcyclopropene [144], cyclopentene [193], bicyclo[2,2,1]hept-2-ene [148], styrene, and methyl methacrylate [194].

The possibility of polymerisation with weak complexes, incapable of complete electron transfer with dissociation into radicals, is explained on the assumption of mutual activation of donor and acceptor in the complex [149].

Valuable information on the reactivity of the complex is obtained from a study of ternary copolymerisation. In several cases the reaction in which donor and acceptor monomers enter the polymer chain alternately can be regarded as the binary copolymerisation of the complex formed by these monomers with a molecule of the third monomer [195]. Ternary copolymerisation has been studied on the systems

- styrene–maleic anhydride–sulphur dioxide [151]
- 2-chloroethyl vinyl ether–maleic anhydride–acrylonitrile, dioxen [145,196,197]
- methyl methacrylate–methyl vinyl ketone dimer–styrene, acrylonitrile [191]
- methyl methacrylate–maleic anhydride–*N*-vinylpyrrolidone [198]
- cyclopropene–acrylonitrile–sulphur dioxide [199]
- dioxen–maleic anhydride–2-chloroethyl acrylate [200]
- anethole–maleic anhydride–2-chloroethyl methacrylate, methacrylonitrile, acrylonitrile [195]

in the last three of which a kinetic study was made.

An interesting investigation has recently been made of the relation between the thermodynamic constants of the complexes formed by two monomers in various solvents and the reactivity of these complexes [197]. Increase in the equilibrium constant of the complex as the solvent is changed leads to an increase in the reaction velocity. When different complexes are compared, however, the main factor is not the concentration but their reactivity. For example, 1,4-dioxen and 2-chloroethyl vinyl ether become more reactive by factors of 31 and 11 respectively when they enter a complex with maleic anhydride. The same paper proposes a classification according to which all polymerisation reactions involving complexes are divided into several classes according to the equilibrium constant K_{eq} of the complex. When $K_{eq} \simeq 0.01$, reaction either does not take place at all or occurs only in the presence of an initiator. When K_{eq} increases to 0.1–1, the radical or

ionic reaction may occur spontaneously. A stable complex ($K_{eq} \to \infty$) is unable to initiate polymerisation.

Thus the above results indicate the wide possibilities for varying the rate and the selectivity of polymerisation processes and the structure of the polymers by combining the initial monomers into complexes.

Examination of the literature thus reveals only a small number of investigations, based on kinetic results, of the conversion of molecular complexes into free radicals. The mechanism of the process, especially in the absence of light, is still obscure. Rearrangement of the electronic structure accompanying complex formation may obviously weaken a bond in one of the components. In several cases a correlation has been established between the e.s.r. signal and the enthalpy of formation of the complex. Investigation of the entropy contributions in such processes is extremely important.

The high rate and the reversibility of complex formation often lead to ambiguity in the kinetic results. Processing the experimental data on electronic computers would enable the reliability of the proposed mechanisms to be assessed.

Fresh correlations must be sought between the thermodynamic characteristics of complex formation (K_{eq}, ΔH, ΔS) and the reactivity of the molecular complexes. In our view, a promising line of research would be the kinetic investigation of systems in which several complexing processes are competing (e.g. the interaction of reactant molecules with themselves and the solvent). Knowledge of the energies of solvation of the species formed from the complex would facilitate a quantitative estimate of the reactivity of the complexes. Such data could usefully be obtained by means of nuclear magnetic resonance, a method which in several cases gives reliable information also on the thermodynamic characteristics of molecular complexes. Thus the most effective way of solving the problem discussed in the Review, is to combine various methods of investigation (kinetic, photochemistry, in particular flash, e.s.r., and n.m.r.). When analysing the mechanism of the formation of radicals from valency-saturated molecules, we must take into account the possibility of competition between the appearance of radicals by electron transfer in the complex and directly from the original molecules under the influence of the solvent.

Examination of the role of molecular complexes in the formation of free radicals, especially in the case of polymerisation processes, shows that radical and ionic mechanisms are more closely connected than had been assumed. This connection is understandable if the initial stage is electron transfer in the molecular complex with the formation of radical-ions. Study of the laws of the conversion of molecular complexes into other active intermediate products will permit control of the rate and the selectivity of the most diverse processes.

Preparation of Vicinal Difunctional Compounds by the Converted Electrophilic Halogenation of Multiple Bonds

L.S.Boguslavskaya

The halogenation of unsaturated compounds in various reactive solvents (water, mineral acids, lower aliphatic alcohols and acids, etc.), involving the addition of halogen and a solvent fragment at the multiple bond, is discussed. The reasons for the varying orientation in the addition of unlike species at the multiple bond, as a function of the structure of the unsaturated compound, the type of electrophilic halogen, and the nucleophile, are considered in terms of the theory of halogenonium ions. The list of references contains 132 items.

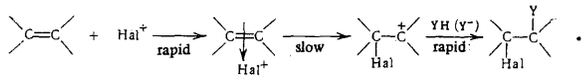
1. INTRODUCTION

Consideration is given to electrophilic additions to unsaturated compounds, in which the electrophilic species is a positively charged halogen, and the nucleophilic species either a different halogen ion or a neutral molecule. These reactions can be represented by the general scheme



The interest of such processes is that they provide convenient methods for obtaining in a single stage saturated compounds with different substituents in vicinal positions, providing a route to further syntheses. Furthermore, such reactions enable us to establish the sequence of attack by reagents at a double bond and the orientation of the addition of the attacking species to unsymmetrical unsaturated compounds, which makes it possible to assess the mechanism of the processes quite objectively.

Among the immense number of studies on electrophilic addition the least attention has been paid to these reactions[1-4]. The reason is that until recently methods for the quantitative determination of structural isomers were lacking, and therefore great difficulties arose in determining the direction of the addition of unlike species at the double bond in an unsymmetrical unsaturated compound. With the appearance of new methods of analysis (gas–liquid chromatography, nuclear magnetic resonance) interest in concerted additions grew considerably. Several products that had previously been regarded as pure compounds were found to be mixtures of isomers[3].

The selectivity of additions is the most important factor determining the subsequent preparative utilisation of the products. In planning a synthesis it is necessary to know the orientation of addition to be expected from an unsaturated compound of specified structure with a particular electrophilic halogen and nucleophile. Summarising available information on reactions of this type has revealed several of their general features, which can serve as a guide in the development of methods of synthesis. The experimental results have been interpreted in terms of the theory of halogenonium ions[3].

2. ADDITION OF ELEMENTS OF HYPOHALOUS ACIDS

These reactions constitute the most thoroughly studied class of concerted halogenations[3,5]. The hypochlorination of ethylene forms the basis of the hitherto industrially important method of obtaining oxiran via 2-chloroethanol[6]:

$$CH_2{=}CH_2 + Cl_2 + H_2O \rightarrow \underset{85\%}{ClCH_2CH_2OH} + \underset{10\%}{ClCH_2CH_2Cl} + \underset{1\%}{ClCH_2CH_2OCH_2CH_2Cl}\ ,$$

$$ClCH_2CH_2OH \xrightarrow{-HCl} CH_2{-}CH_2 \quad (O)$$

Analogous methods give high yields of propylene chlorohydrin[7], glycerol chlorohydrins from allyl chloride[8], and butylene chlorohydrins from a mixture of butenes[9].

Vinyl chloride adds the elements of hypochlorous acid in conformity with Markovnikov's rule to form the unstable intermediate 1,2-dichloroethanol, which is dehydrochlorinated to give a high yield of chloroacetaldehyde[10]:

$$CH_2{=}CHCl \xrightarrow{HOCl} ClCH_2CH(Cl)OH \xrightarrow{-HCl} \underset{96\%}{ClCH_2CHO}\ .$$

Cyclohexene reacts with an equimolecular quantity of hypochlorous acid in the presence of mercuric oxide in water to give a 70% yield of 2-chlorocyclohexanol[11]. The action of t-butyl hypochlorite on styrene in aqueous acetic acid at room temperature yields 2-chloro-1-phenylethanol, but in the absence of acetic acid the t-butyl ether of this alcohol is obtained[12] (addition products conforming to Markovnikov's rule):

$$C_6H_5CH{=}CH_2 \xrightarrow[H_2O,\ CH_3CO_2H]{t\text{-}BuOCl} \underset{84\%}{C_6H_5CH(OH)CH_2Cl}\ .$$

Diallyl ether reacts with an aqueous solution of bleaching powder to give an almost theoretical yield of 1,7-dichloro-4-oxaheptane-2,6-diol[13]:

$$(CH_2{=}CHCH_2)_2O \xrightarrow{HOCl} [ClCH_2CH(OH)CH_2]_2O\ .$$

$\alpha\beta$-Unsaturated acids (or their esters), nitriles, aldehydes, and ketones containing an unsubstituted hydrogen atom in the α-position relative to the functional group add hypohalous acids predominantly (but not exclusively) with

the halogen becoming attached to the α-carbon atom, and the hydroxyl to the β-carbon atom[14-27]:

$$CH_2{=}CHCO_2H \xrightarrow{HOCl} HOCH_2CHClCO_2H^{15-17}$$

$$CH_3CH{=}CHCO_2H \xrightarrow{HOCl} \underset{74\%}{CH_3CH(OH)CHClCO_2H} + \underset{26\%}{CH_3CHClCH(OH)CO_2H^{20}}$$

$$CH_2{=}CH{-}CN \xrightarrow{HOCl} \underset{79\%}{HOCH_2CH(Cl)CN} + \underset{21\%}{ClCH_2CH(OH)CN^{27}}.$$

The yields in such reactions are usually 40–67%[22-27], but may reach 90–95% in individual cases (e.g. in the hypochlorination of certain β-substituted $\alpha\beta$-unsaturated acids and their salts)[23].

The orientation of addition changes when a methyl substituent is present at the double bond in the α-position with respect to an electron-accepting functional group: the halogen goes mainly to the β-carbon atom and the hydroxyl to the α-carbon atom[23,27]. The yields (%) are respectively

$$\underset{CH_2=CY}{\overset{CH_3}{|}} \xrightarrow{HOCl} \underset{ClCH_2C(OH)Y}{\overset{CH_3}{|}} + \underset{HOCH_2CClY}{\overset{CH_3}{|}}$$

(Y=COOH 90 and 10; Y=$COOC_2H_5$ 70 and 30; Y=CN 58 and 42).

The direction of the addition of hypochlorous acid to hexenoic acids has been studied as a function of the position of the double bond relative to the carboxyl[22]. Hex-2-enoic acid reacts so slowly that a considerable proportion of the hypochlorous acid decomposes, and a single product—2-chloro-3-hydroxyhexanoic acid—is formed in low yield (15%). Hex-3-enoic acid reacts considerably more readily and gives a good yield of a mixture of addition products—3-chlorohexan-4-olide and 4-chloro-3-hydroxyhexanoic acid:

$$CH_3CH_2CH{=}CHCH_2CO_2H \xrightarrow{HOCl} \underset{80\%}{CH_3CH_2CH(O{-}CHClCH_2CO)} + \underset{20\%}{CH_3CH_2CHClCH(OH)CH_2CO_2H}.$$

Hex-4-enoic acid on hypochlorination gives an almost theoretical yield of 5-chlorohexan-4-olide, with a less than 5% yield of the addition product of opposite orientation:

$$CH_3CH{=}CHCH_2CH_2CO_2H \xrightarrow{HOCl} \underset{95\%}{CH_3CHClCH(O{-}CH_2CH_2CO)}.$$

Hypohalous acids add to butadiene preferentially at the 1,2-position[28,29]:

$$CH_2{=}CH{-}CH{=}CH_2 \xrightarrow[H_2O,CH_3CO_2H]{t\text{-}BuOCl} \underset{20\%}{ClCH_2CH(OH){-}CH{=}CH_2} + \underset{14\%}{ClCH_2CH{=}CHCH_2OH}.$$

Aqueous bromoacetamide acts on chloroprene and bromoprene to give 30–35% yields of products exclusively of 3,4-addition[30-32]:

$$CH_2{=}CCl(Br){-}CH{=}CH_2 \xrightarrow{HOBr} CH_2{=}CCl(Br){-}CH(OH)CH_2Br.$$

1-Bromobutadiene and 1,2-dichlorobutadiene also add hypobromous acid at the unsubstituted double bond[32,33]. 1,4-Addition products to halogenated butadienes have not been detected. This was explained by steric hindrance by the halogen substituent to the approach of the attacking electrophilic halogen[34].

Fundamental researches on the addition of hypohalous (hypochlorous, hypobromous, and hypoiodous) acids to unsaturated compounds have been undertaken by the English school of chemists[3]. As will be shown below, the main features discovered in the study of these reactions are of general significance. An immense volume of data have been obtained on the direction of the addition of hypochlorous acid to propene compounds in dilute aqueous solutions of perchloric acid and silver perchlorate (to combine with the chloride anion) in conformity with scheme 1 (Table 1).

Table 1. Products of the hypochlorination of propene derivatives according to scheme 1.

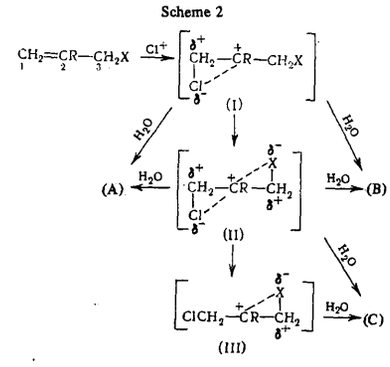
R	X	Products, % (A)	(B)	(C)	Ref.
H	H	91	9	0	15, 36
H	OH	73	27	0	37, 39
H	^{36}Cl	30	66	4	38, 40
H	Br	32	40	28	41
H	I	30	22	48	42
CH_3	H	100	0	0	35
Cl	^{36}Cl	96	4	0	43, 44
CH_3	^{36}Cl	94	4	2	40

The chlorine cation is found to add either at $C_{(1)}$ or at $C_{(2)}$, the selectivity of the reaction depending on the presence of substituents at $C_{(2)}$ and $C_{(3)}$. Migration of halogen from $C_{(3)}$ to $C_{(2)}$ is observed in allyl halides. The percentage of the product of migration increases in the sequence Cl < Br < I; the hydroxy-group at $C_{(3)}$ does not migrate. The presence of methyl or halogen at $C_{(2)}$ favours preferential addition in conformity with Markovnikov's rule.

Scheme 1

$$CH_2{=}\overset{1}{C}(R){-}\overset{2}{C}H_2\overset{3}{C}H_2X + HOCl \longrightarrow \underset{\text{(A) according to Markovnikov's rule}}{ClCH_2\overset{OH}{\overset{|}{C}}(R)CH_2X} + \underset{\text{(B) contrary to Markovnikov's rule}}{CH_2(R){-}\overset{OH}{\overset{|}{C}}ClCH_2X} + \underset{\text{(C) formally contrary to rule (with 3 → 2 migration of substituent X)}}{ClCH_2\overset{X}{\overset{|}{C}}(R)CH_2OH}$$

Scheme 2

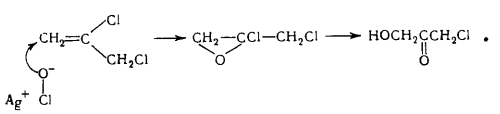


The results suggest a reaction mechanism (scheme 2) in which the chlorine cation, added at the site of highest electron density in the unsaturated compound, forms a chloronium cation (I) by coordination of its lone pairs of electrons with the cationic carbon centre. This stage determines the rate of the reaction. If the substituent X is likewise capable of such coordination, structures (II) and (III) are also possible. Further reaction of these ions

with water yields the adducts (A) (in conformity with Markovnikov's rule), (B) (unrearranged adduct contrary to the rule), and (C) (rearranged adduct contrary to the rule). A methyl group at the cationic carbon centre stabilises the intermediate cation and favours orientation of addition according to rule[35,45,46]: with 3-chloro-2-methylpropene 2% of the 6% of adduct formed contrary to Markovnikov's rule corresponds to the rearranged product (C).[40] A chlorine atom at the cationic carbon centre also promotes orientation according to the rule[43,45], but 3 → 2 migration of the allyl halogen does not occur[43].

Polar solvents stabilise the intermediate carbon cation and thereby promote the 3 → 2 displacement of the allylic halogen. Thus in the hypochlorination of allyl bromide not in water but in a less ionised solvent—40% and 70% aqueous dioxan[41]—the quantity of rearranged adduct has fallen from 28% to 18% and 11% respectively. A similar phenomenon has been observed with allyl iodide[42].

When 2,3-dichloropropene undergoes hypochlorination in the presence of silver perchlorate, the yield of normal addition products (Table 1) decreases, and a new product, 1-chloro-3-hydroxyacetone, appears[44,48,49]. When an alkene labelled with chlorine-36 at position 3 was used, 1-chloro-3-hydroxyacetone was obtained containing all the labelled chlorine. Kinetic measurements in the presence of excess of silver ions and of the alkene showed the occurrence of autocatalysis, which is promoted by increasing the concentration of hypochlorous acid and of the alkene together with low concentrations (preferably the absence) of mineral acid. Analysis of the products under kinetically controlled conditions showed that the autocatalysis was due to the formation of 1-chloro-3-hydroxyacetone. The explanation offered[49] for these results was that, in the presence of silver ions, the usual electrophilic addition was accompanied by nucleophilic attack on the double bond by the hypochlorite anion with subsequent formation of an epoxide. Under the reaction conditions the epoxide ring was opened with formation of the hydroxyketone:



This reaction is favoured by the presence of electron-accepting substituents attached at the double bond.

Orientation contrary to Markovnikov's rule occurs to a greater extent with electrophilic bromine and iodine than with electrophilic chlorine[41,42,50-52] (cf. Table 1):

$$CH_3{=}CH{-}CH_3 \xrightarrow[Cl^-]{Br^+} \underset{54\%}{BrCH_2CHClCH_3} + \underset{46\%}{ClCH_2CHBrCH_3}\ .$$

The presence of strongly electron-donating or electron-accepting groups at the double bond promotes the selective occurrence of concerted addition[50-52]:

$$C_6H_5CH{=}CH_2 \xrightarrow[Cl^-]{I^+} C_6H_5CHClCH_2I \quad (95\%)$$

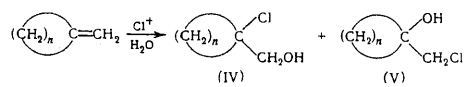
$$CH_3CH{=}CHSO_3H \xrightarrow[Cl^-]{I^+} CH_3CHClCHISO_3H \quad (90\%)\ .$$

The addition of hypobromous acid to 3,3,3-trichloropropene takes place selectively contrary to the rule[53]:

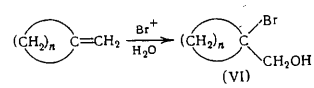
$$CH_2{=}CHCCl_3 \xrightarrow[H_2O]{Br^+} HOCH_2CHBrCCl_3\ .$$

The orientation of addition is similar in the hypochlorination of 3,3-di- and 3,3,3-tri-chloropropenes[54].

The addition of hypochlorous acid to methylenecycloalkanes yields two structural isomers, whereas the addition of hypobromous acid gives almost entirely a single isomer formed contrary to Markovnikov's rule[45,55,56]:



with n = 4–7 the respective percentages of (IV) are 60, 41, 67, and 35, accompanied by (V)—40, 50, 32, and 64;



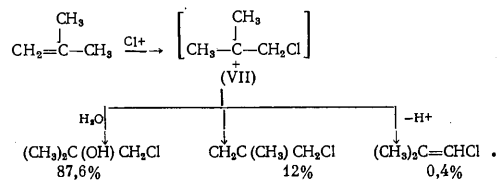
the percentages of (VI) with n = 4–7 are respectively 99, 91, 98, and 87. The predominance of the anomalous orientation in the case of the cyclopentane and cycloheptane rings is attributed[55] to steric hindrance of the trigonal carbon atom in these rings, but it is acknowledged that such an explanation does not completely account for the influence of the ring on the orientation in this reaction, since the addition of hydrogen bromide to such compounds yields an adduct strictly according to Markovnikov's rule[57].

When allene hydrocarbons react with an aqueous suspension of calcium hypochlorite in an atmosphere of carbon dioxide, addition takes place with the chlorine cation going to the central carbon atom, and the hydroxyl to the adjacent atom having the largest number of alkyl substituents[58]:

$$CH_2{=}C{=}CH{-}C_2H_5 \xrightarrow[H_2O]{Cl^+} \underset{\substack{OH\\63\%}}{CH_2{=}CClCHC_2H_5} + \underset{\substack{OH\\7\%}}{CH_2CCl{=}CHC_2H_5}\ .$$

In no case was the formation of α-chloro-ketones observed, which should have been obtained with the opposite orientation of addition. An earlier publication[59] had reported that chloroacetone was obtained by the action of hypochlorous acid on allene.

Concerted addition to unsaturated compounds having a quaternary carbon atom at the double bond is accompanied by the formation of small amounts of unsaturated substitution products[4,43,44,46,47]:



Possible reasons why particularly ions of type (VII), having electron-donating substituents at the cationic carbon centre, tend to undergo the competing loss of a proton have been discussed[4,60-62].

3. ADDITION OF HALOGENS IN ORGANIC SOLVENTS

The reaction of unsaturated compounds with molecular halogens, N-halogeno-amides, or t-butyl hypochlorite in certain organic solvents (alcohols, acids, acid anhydrides) or mineral acids (sulphuric, phosphoric, etc.) results in concerted addition of halogen and a solvent fragment at the multiple bond. Comprehensive investigations on the halogenoalkoxylation of ethylenic, diene, and enyne hydrocarbons and the properties of the resulting ethers of β-halogeno-alcohols have been reported in detail in a monograph[63].

When ethylene and chlorine are passed simultaneously into a solution of sodium acetate in acetic acid, a mixture of dichloroethane and 2-chloroethyl acetate is obtained[64]:

$$CH_2=CH_2 \xrightarrow[CH_3CO_2H,\ CH_3CO_2Na]{Cl_2} \underset{47\%}{ClCH_2CH_2OCOCH_3} + \underset{45\%}{ClCH_2CH_2Cl}\ .$$

Conducting this reaction in acetic anhydride increases the yield of the chloro-ester to 87%. The use of methyl acetate as solvent raises the yield of dichloroethane. Chlorination (or bromination) of ethylene in the presence of mercuric acetate in formic, acetic, and chloroacetic acids also leads to the formation of 2-halogenoalkyl esters[65].

The action of *NN*-dichlorobenzenesulphonamide in methanol on but-2-ene gives 2-chloro-3-methoxybutane together with a small quantity of 2,3-dichlorobutane[66]:

$$CH_3CH=CHCH_3 \xrightarrow[CH_3OH]{Cl^+} \underset{70-80\%}{CH_3CHClCH(OCH_3)CH_3} + CH_3CHClCHClCH_3\ .$$

The same reaction with but-1-ene probably leads to a mixture of isomers with the substituents in the 1,2-positions[66,67].

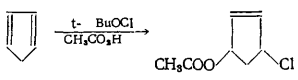
t-Butyl hypochlorite acts on alkenes (ethylene, propene, pent-2-ene, hex-3-ene, hept-1-ene, cyclohexene) in methanol, ethanol, phenol, and acetic acid in the presence of catalytic quantities of toluene-*p*-sulphonic acid to give satisfactory yields (from 30–40% to 60–70%) of the corresponding β-chlorinated ethers and esters[68]. It must be supposed that, in the case of unsymmetrical alkenes, the products are mixtures of isomers. The preparation of β-halogeno-esters of strong acids by the concerted halogenation of alkenes in these acids has been reported[69,70].

The addition of methyl hypochlorite to buta-1,3-diene by the action of *NN*-dichlorobenzenesulphonamide in methanol gives a total yield of 46% of 1,2- and 1,4-addition products, in which the former strongly predominates[71]:

$$CH_2=CH-CH=CH_2 \xrightarrow{ClOCH_3} \underset{OCH_3\quad 83\%}{ClCH_2CH(OCH_3)-CH=CH_2} + \underset{17\%}{ClCH_2CH=CHCH_2OCH_3}\ .$$

The bromo- and iodo-alkoxylation of butadiene yields almost exclusively 1,2-addition products[28,71-73]. Thus the action of a methanolic solution of bromine on butadiene forms 4-bromo-3-methoxybut-1-ene (63%) slightly contaminated with 1-bromo-4-methoxybut-2-ene (4%) and products of the addition of two bromine atoms[73].

The chloro-acetoxylation of cyclopentadiene by the action of t-butyl hypochlorite dissolved in acetic acid gives a 47% yield of a conjugate 1,4-addition product—*trans*-5-chlorocyclopenten-3-yl acetate[74]:



The chloro- and bromo-methoxylation of isoprene always involves the attachment of halogen at position 1. In the case of chloro-alkoxylation this leads to 1,2- and 1,4-addition products in the proportions 2 : 1:[75,76]

$$\overset{1}{CH_2}=\overset{2}{C}(CH_3)-\overset{3}{CH}=\overset{4}{CH_2} \xrightarrow{ClOR} \underset{OR}{ClCH_2C(CH_3)=CH_2} + \underset{CH_3}{ClCH_2C(OR)=CH-CH_3}\ .$$

Only 1,2-addition products—3-alkoxy-4-bromo-3-methylbut-1-enes—have been identified on bromo-alkoxylation[63,75]. The bromo- and iodo-alkoxylation of chloroprene and bromoprene, unlike those of isoprene, take place mainly at the 3,4-positions[77-79]:

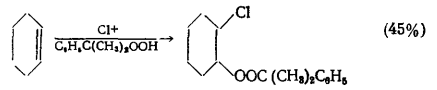
$$\overset{1}{CH_2}=\overset{2}{C}(Cl)-\overset{3}{CH}=\overset{4}{CH_2} \xrightarrow{BrOR} CH_2=C(Cl)-CH(OR)-CH_2Br$$

The chloro-alkoxylation of the same compounds yields 1,4- and 3,4-addition products in the proportions 4 : 1.[80] Thus in isoprene the substituted double bond is the more reactive, whereas in halogenoprenes this applies to the unsubstituted double bond.

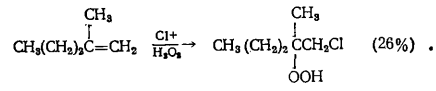
The halogeno-alkoxylation of butenyne and its homologues takes place mainly in the vinyl group[81,82]:

$$CH_2=CH-C\equiv CH \xrightarrow{HalOR} HalCH_2-\underset{OR}{CH}-C\equiv CH\ .$$

The action of t-butyl hypochlorite and alkyl hydroperoxides or hydrogen peroxide on certain ethylenic compounds (2-methylpent-1-ene, hex-3-ene, cyclohexene, etc.) forms β-chlorinated peroxides in 20–50% yields[83]:



(45%) ;

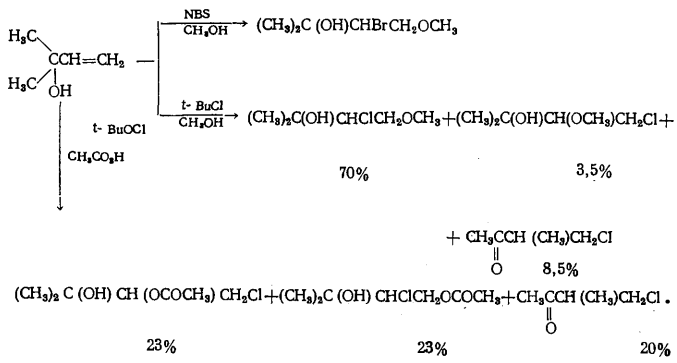


(26%) .

Vinyl ethers react with t-butyl hypochlorite in the presence of primary or secondary alcohols, alkyl hydroperoxides, or hydrogen peroxide to give moderate yields of chlorinated acetals, peroxy-acetals, and hydroperoxy-acetals respectively[83].

The chloro-methoxylation of allyl alcohol with methanolic molecular chlorine[84] or hexachloromelamine[85] yields a mixture of isomeric methoxychloropropanols together with 2,3-dichloropropan-1-ol. The addition product conforming to Markovnikov's rule predominates in the isomeric mixture.

The bromo-methoxylation of 1,1-dimethylpropanol with methanolic *N*-bromosuccinimide (NBS)[86] gives a 46% yield of the non-Markovnikov selective addition product. The chloro-methoxylation of this compound with t-butyl hypochlorite in methanol[86] gives a mixture of structural isomers with the same isomer strongly predominating. The addition of chlorine acetate $ClOCOCH_3$ gives a mixture of equal quantities of structural isomers, accompanied by β-chloro-ketones resulting from a pinacoline type of rearrangement[87]:



The chloro- and bromo-methoxylation of 1,1,2-trimethylpropenol also gives a mixture of the two isomeric addition products, together with considerable quantities of β-halogeno-ketones[87-92]. Rearrangement with the formation of β-halogeno-ketones becomes the main reaction of this propenol and of 1-aryl-1,2-dimethylpropenols with t-butyl hypochlorite when protic are replaced by aprotic solvents (dichloromethane, nitromethane)[93-97].

3,3,3-Trifluoropropene reacts readily with an acetic-acid solution of bromine in the presence of mercuric acetate or sulphate to give a high (78%) yield of the non-Markovnikov concerted addition product[98]:

$$CF_3CH{=}CH_2 \xrightarrow[CH_3CO_2H,\,Hg(OCOCH_3)_2]{Br^+} CF_3CHBrCH_2OCOCH_3 .$$

The dibromide is the main product in the absence of mercury salts. An analogous orientation of electrophilic addition is found in the concerted chlorination of 3,3,3-trichloropropene[99] and 3,3,3-trichloro-2-methylpropene[100].

The chlorination of compounds containing a 2,2-dichlorovinyl group, in mixtures of acetic acid and mercuric acetate, formic and concentrated sulphuric acids, gives high yields of α-chlorinated carboxylic acids[101]:

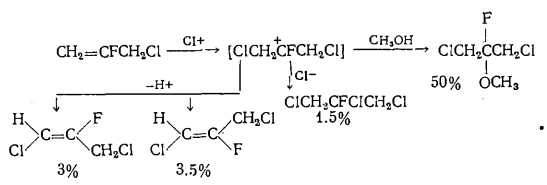
$$R(CH_2)_nCH{=}CCl_2 \xrightarrow[HCO_2H]{Cl^+} [R(CH_2)_nCHClCCl_2OCOH] \xrightarrow[(60-80\%)]{H_2O} R(CH_2)_nCHClCO_2H .$$

Thus the presence of three fluorine or chlorine atoms in the allyl position promotes non-Markovnikov addition. The presence of two halogen atoms in the 1-vinyl position favours the addition of halogen at the adjacent carbon atom forming the double bond[98,101].

Allyl chloride and bromide with methyl hypochlorite form every possible addition product, with the non-Markovnikov products predominating[102]: e.g.

$$CH_2{=}CHCH_2Cl \xrightarrow[CH_3OH]{Cl^+} \underset{12.5\%}{ClCH_2CH(OCH_3)CH_2Cl} + \underset{18.5\%}{CH_3OCH_2CHClCH_2Cl} .$$

The chloro-methoxylation of 2-halogenoallyl chlorides conforms to Markovnikov's rule[103], as was to be expected by analogy with the hypochlorination of 2-chloroallyl chloride[43,44]; unsaturated substitution products are also formed:



The concerted halogenation of double bonds in cholesterol[104,105] and in corticosteroids[106] provides an example of selective addition contrary to Markovnikov's rule.

4. HALOGENOFLUORINATION

In 1959 the first papers were published on the concerted halogeno-fluorination of steroids by *N*-halogeno-amides and anhydrous hydrogen fluoride in the presence of organic acceptors of protons (alcohols or ethers) in chloroform[107–110]. The bromo-fluorination of Δ^5-steroids with *N*-bromoacetamide and hydrogen fluoride forms 5α-bromo-6β-fluorosteroids (contrary to Markovnikov's rule), whereas iodo-fluorination with *N*-iodosuccinimide and hydrogen fluoride gives 5α-fluoro-6β-iodosteroids[110]. Halogeno-fluorination involves *trans*-addition[106,108,109]. Thus vicinal *trans*-bromofluoro- and *trans*-fluoroiodo-cyclohexanes are obtained in satisfactory yields from cyclohexene under the above conditions[109].

This method has since been used to prepare simpler bromofluoro- and chlorofluoro-derivatives. The bromo-fluorination of esters of $\alpha\beta$-unsaturated carboxylic acids unsubstituted in the α-position gives 50–70% yields of 2-bromo-3-fluoroalkanoic esters[111,112]:

$$CH_2{=}CHCO_2CH_3 \xrightarrow[F^-]{Br^+} FCH_2CHBrCO_2CH_3 .$$

The chloro-fluorination of ethylene, propene, vinylidene chloride and fluoride, and methyl acrylate has been accomplished with moderate (30–60%) yields by chlorinating these compounds with gaseous chlorine in liquid hydrogen fluoride or with hexachloromelamine and hydrogen fluoride in ether[113]: e.g.

$$CH_2{=}CHCO_2CH_3 \xrightarrow[F^-]{Cl^+} FCH_2CHClCO_2CH_3 .$$

The intermediate formation of a β-chloro-cation in the concerted addition of chlorine and fluorine to alkenes has been proved[113] in the case of the chloro-fluorination of ethylene in the presence of benzene. Formation of 1-chloro-2-fluoroethane and mono- and dichlorobenzenes is then accompanied by an 8% yield of phenethyl chloride:

$$CH_2{=}CH_2 \xrightarrow{Cl^+} [ClCH_2\overset{+}{C}H_2] \begin{cases} \xrightarrow{F^-} ClCH_2CH_2F , \\ \xrightarrow{C_6H_6} ClCH_2CH_2C_6H_5 . \end{cases}$$

The bromo-fluorination of C_2–C_{18} alk-1-enes by means of *N*-bromoacetamide and hydrogen fluoride in an ether–chloroform mixture gives good (up to 60–70%) yields of 1-bromo-2-fluoroalkanes, together with a certain amount (3–8%) of the isomeric 2-bromo-1-fluoroalkanes[114]. In some cases the addition of pyridine to the solvent increases the yield of the addition product. Thus the bromo-fluorination of styrene in ether produces a 25% yield of β-bromo-α-fluoroethylbenzene, but in a 4 : 1 ether–pyridine mixture the yield rises to 68%. The bromo-fluorination of allyl bromide gives both isomeric dibromofluoropropanes, with the addition product contrary to Markovnikov's rule predominating:

$$CH_2{=}CHCH_2Br \xrightarrow[F^-]{Br^+} \underset{22\%}{BrCH_2CHFCH_2Br} + \underset{32\%}{FCH_2CHBrCH_2Br} .$$

When methyl acrylate undergoes bromo-fluorination by the above method in ethereal pyridine, the expected methyl α-bromo-β-fluoropropionate is accompanied by small quantities of methyl β-bromo-α-fluoropropionate and methyl β-bromo-α-ethoxypropionate[112]. The bromo-fluorination of methyl methacrylate yields the single addition product—methyl β-bromo-α-fluoro-α-methylpropionate[115]:

$$CH_2{=}C(CH_3)CO_2CH_3 \xrightarrow[F^-]{Br^+} BrCH_2\overset{CH_3}{\overset{|}{C}}FCO_2CH_3 .$$

The chloro-fluorination of methyl α-methoxyacrylate by hexachloromelamine and hydrogen fluoride goes similarly[116].

The bromo-fluorination of allyl acetate by means of *N*-bromoacetamide and hydrogen fluoride gives 3-bromo-2-fluoropropyl acetate in low yield. The presence of the isomeric product formed contrary to Markovnikov's rule was not established[115].

The chloro-fluorination of allyl alcohol by hexachloromelamine and hydrogen fluoride in methanolic chloroform yields both possible isomers[85]:

$$CH_2{=}CHCH_2OH \xrightarrow[F^-]{Cl^+} \underset{45\%}{ClCH_2CHFCH_2OH} + \underset{5\%}{FCH_2CHClCH_2OH} .$$

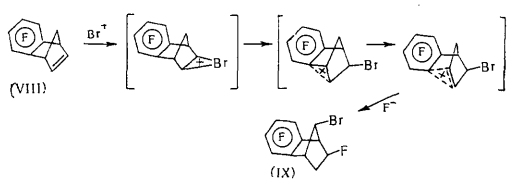
The chloro-fluorination of 2-fluoro- and 2-chloro-allyl alcohols, as well as that of the corresponding chlorides, leads to selective addition of chlorine fluoride in conformity with the Markovnikov rule[103,117]:

$$CH_2{=}CHalCH_2OH \xrightarrow[F^-]{Cl^+} ClCH_2CFHalCH_2OH$$

Hal=F (yield 76%), Cl (50%) .

In the case of the allyl chlorides this is accompanied by small quantities of products of substitution and of the addition of two chlorine atoms[103]. Allyl chloride and bromide are chloro-fluorinated with the formation of every possible addition product; in the case of allyl bromide a product is also detected in which the bromine atom has migrated. Products of substitution by chlorine were not found[102].

Several specific aspects of the addition to fluoroalkenes of interhalogen compounds, and in particular of halogens, have been discussed in review papers[118,119]. The bromofluorination of (VIII) by *N*-bromosuccinimide and hydrogen fluoride in ether yields the Wagner–Meerwein rearrangement product (IX):



(VIII) (IX)

Rearrangement takes place also on the addition of bromine chloride and methyl hypochlorite to (VIII); the addition of iodine chloride, however, is not accompanied by rearrangement[120].

5. MECHANISM OF CONCERTED ELECTROPHILIC HALOGENATION

Examination of the experimental work surveyed in Sections 1–3 shows that the observed orientation of concerted addition at a multiple bond can in most cases be explained satisfactorily by scheme 2 (Section 2). Summarising the experimental results on various reactions involving the concerted electrophilic chlorination of allylic systems makes it possible to elucidate the influence of the nucleophile and the structure of the original unsaturated compound on the orientation of addition.

When position 2 in the initial alkene is unsubstituted, addition of a nucleophile Y is preceded by an intermediate halogenonium cation, the structure of which (I–III in scheme 2) is influenced by neighbouring groups (in particular the substituent X in the compounds surveyed in Table 2).

Attack by the nucleophile Y on the cations results in the formation of—(A) a product of addition according to Markovnikov's rule, (B) an unrearranged product of addition contrary to this rule, and (C) a rearranged product of addition contrary to the rule. When X = H addition both of hypochlorous acid and of chlorine fluoride takes place almost entirely according to rule. When X = OH, Cl, Br, the quantity of anomalous products (B) + (C) increases with increase in the relative participation of the groups X in the formation of onium structures of types (II) and (III). This regularity is observed with all three reactions examined (hypochlorination, chloro-methoxylation, and chloro-fluorination).

In comparison with methanol and water molecules, the fluoride anion, acting as a nucleophile, enhances the selectivity of addition in favour of the adduct (A). This is probably due to the high nucleophilic activity and small size of the fluoride anion, as a consequence of which it is less subject to steric hindrance than are neutral methanol and water molecules, and easily penetrates the shielded cationic carbon centre situated at the central carbon atom.

Nevertheless, in the presence of bulky electronegative substituents (Cl, Br) the proportional attack by the fluoride anion at the less hindered 1-carbon atom (cations I and II) and the 3-carbon atom (cations II and III) increases, and the relative quantity of non-Markovnikov adducts becomes larger. It is noteworthy that the ratio of rearranged to unrearranged adduct is considerably larger in the chloro-fluorination than in the hypochlorination of allyl bromide (C/B = 1.6 and 0.7), which is probably due to the higher polarity of the environment produced by liquid hydrogen fluoride. When the nucleophiles are bulky and possess less nucleophilic activity than methanol and water molecules, attack on the intermediate cation is more intense at the less hindered 1,3-carbon atoms. For these nucleophiles with X = Cl, Br the non-Markovnikov isomers predominate.

Table 2. Concerted electrophilic chlorination of allylic derivatives according to scheme 2:

$CH_2{=}CHCH_2X + Cl^+ + Y \rightarrow (A) + (B) + (C)$

X	Y	Products, % (A)	(B)	(C)	Ref.
H	H_2O	91	9	0	35–37
H	F^-	100	—	—	113
OH	H_2O	73	27	0	39
OH	CH_3OH	71	29	0	102
OH	F^-	90	10	0	84, 102
^{36}Cl	H_2O	30	66	4	38, 40
Cl	CH_3OH	41	—	59*	85, 102
Cl	F^-	68	—	32*	102
Br	H_2O	32	40	28	41
Br	CH_3OH	26	—	74*	102
Br	F^-	60	15	25	102

* Sum of (B) + (C).

These ideas suggest that passing from allyl alcohol to the acetate and especially the trihalogenoacetates will produce a change in the orientation of concerted addition in favour of the non-Markovnikov adduct. The expected effect has in fact been observed[121] in the chloro-fluorination and chloro-methoxylation of these derivatives (Table 3). For the addition of chlorine fluoride the relative quantity of the non-Markovnikov adduct 2-chloro-3-fluoropropan-1-ol increases in the sequence

$$OH < OCOCH_3 < OCOCCl_3 < OCOCF_3,$$

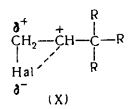
for the addition of methyl hypochlorite the quantity of the corresponding adduct 2-chloro-3-methoxypropan-1-ol increases in the sequence

$$OH < OCOCH_3 < OCOCF_3 < OCOCCl_3.$$

This fact is consistent with the concept of steric hindrance to attack by the nucleophile. The bulky trichloroacetate group proves a greater obstacle than the trifluoroacetate group to the electrically neutral nucleophilic methanol molecule. The small, negatively charged fluoride ion is probably more subject to electrostatic repulsion than to actual steric hindrance, so that the trifluoroacetate group then exerts a stronger orienting influence than does the trichloroacetate group.

It is probable that the role of steric factors is in general large in electrophilic halogenation. This principle is illustrated by the preferential non-Markovnikov halogenation of propene derivatives in which all the allylic hydrogen

atoms have been replaced by other groups— $CH_2:CH.C(CH_3)_3$,[122] $CH_2:CH.CCl_3$,[53,54] $CH_2:CH.CF_3$,[98] and $CH_2:CH.COOR$.[111-113] These results cannot be explained solely by the distribution of electron density in the ground state of the unsaturated compounds, for otherwise the opposite orientation would have been expected with t-butylethylene (n-butylethylene gives 80% of the Markovnikov addition product[122]). It must be assumed that the most important factor here is the shielding effect of β-substituents, which block the cationic carbon centre in the ion



(X)

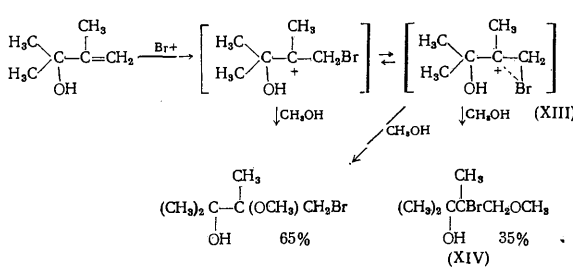
leaving the terminal carbon atom more accessible to attack by the nucleophile[122,123].

Table 3. Concerted chlorination of allyl acetates[121].

Initial compound	Addition products, %	
	according to Markovnikov	contrary to Markovnikov
Chloro-fluorination	$ClCH_2CHFCH_2OH$	$FCH_2CHClCH_2OH$
$CH_2=CHCH_2OH$	90	10
$CH_2=CHCH_2OCOCH_3$	82	18
$CH_2=CHCH_2OCOCCl_3$	74	26
$CH_2=CHCH_2OCOCF_3$	67	33
Chloro-methoxylation	$ClCH_2CH(OCH_3)CH_2OH$	$CH_3OCH_2CHClCH_2OH$
$CH_2=CHCH_2OH$	71	29
$CH_2=CHCH_2OCOCH_3$	54	46
$CH_2=CHCH_2OCOCCl_3$	36	64
$CH_2=CHCH_2OCOCF_3$	50	50

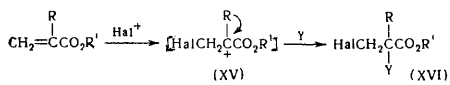
The concerted chlorination of 2-methyl- and 2-halogeno-allyl compounds takes place almost entirely according to Markovnikov's rule (Table 4). With an electron-donating substituent (α-substituent) present in the resulting cationic carbon centre, both addition of the nucleophile and detachment of a proton are probably preceded by a classic carbonium ion (XI) [scheme 3]. The decrease in the positive charge in the cationic carbon centre due to the electron-donating influence of the substituent R prevents formation of the halogenonium cation (XII) by coordination of the p-electrons of the β-halogen (this applies mainly to chlorine, which interacts feebly with the cationic carbon centre[3]). However, the intermediate state (XII) is not excluded in chlorination, since small quantities (4–6%) of non-Markovnikov adducts are nevertheless formed (Table 4 and also Refs. 84–89).

In the concerted bromination of 1,1,2-trimethylpropenol the equilibrium is already considerably displaced towards the halogenonium ion (XIII), and the quantity of non-Markovnikov adduct (XIV) is large[87-89]:



(XIV)

In this case the β-substituents also favour orientation contrary to Markovnikov's rule. The strong orienting influence of α-substituents capable of donating electrons to the cationic carbon centre is apparent in electrophilic addition to α-substituted acrylaldehydes[124] and acrylates[23,115,116], which in the absence of an α-substituent tend to add contrary to the rule[5,15-17,22,23,111-113].



(XV) (XVI)

Table 4. Concerted chlorination of 2-substituted allylic derivatives according to scheme 3:

$CH_2=CRCH_2X+Cl^++Y\rightarrow(D)+(E)$

R	X	Y	Products, % (D)	Products, % (E)	Ref.
CH_3	H	H_2O	100	0	35
CH_3	Cl	H_2O	94	6	40
F	OH	F^-	100	0	117
Cl	OH	F^-	100	0	117
F	Cl	CH_3OH	100	0	103
F	Cl	F^-	100	0	103

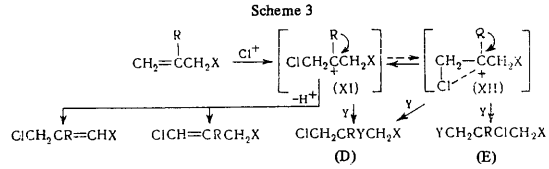
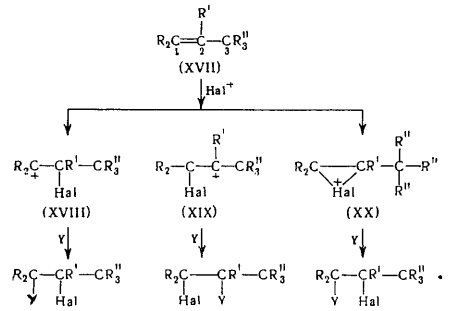
Cl	Cl	CH_3OH	>96	<4	103
Cl	Cl	F^-	100	0	103

Scheme 3



The substituents (methyl[14,15,23,115], methoxyl[116,124,125], and probably halogen[126]) enhance the nucleophilic character of the double bond in acrylates and thereby promote formation of a stable carbonium ion (XV) and hence the Markovnikov adduct (XVI). Thus the distribution of electron density in the ground state of the unsaturated molecule is not the dominant factor determining the direction of concerted electrophilic addition[2]. The orientation of addition obviously depends mainly on the structure of the transitional cation, in which an important part is played by the electronic and steric effects of substituents in α- and β-positions relative to the cationic carbon centre[3,61,102,103].

Let us consider as unsaturated compound the propene system (XVII) (in which R and R′ are substituents capable of donating electrons to the cationic carbon centre). Three main types of intermediate carbon cations (XVIII)–(XX) may be formed as a result of electrophilic attack by the halogen:



The presence of 1-vinyl substituents R favours formation of the stable classic ion (XVIII) and hence addition of halogen to $C_{(2)}$ while the nucleophile Y goes to $C_{(1)}$. The presence of a 2-vinyl substituent R′ favours the classic ion (XIX) with addition of halogen to $C_{(1)}$ and the nucleophile Y to $C_{(2)}$. Allylic substituents R″ shield the central carbon atom in the cation (XX) and promote attack by the nucleophile at $C_{(1)}$ with addition of halogen at $C_{(2)}$†. Which addition product predominates depends also on the nucleophilic activity and the steric radius of the attacking reagent Y. This effect is most strongly developed when R = R″ = H, i.e. when an intermediate cation of halogenonium type (XX) is dominant.

In the simple cases discussed above we observe selective addition either according or contrary to Markovnikov's rule. There are other views on the mechanism of the electrophilic halogenation of unsaturated compounds, developed by Shilov[127-131], which envisage the formation of a different type of donor–acceptor complexes of the substrate with the attacking molecules. However, the suggested schemes cannot explain the varying orientation of the addition of unlike species at a double bond, nor the rearrangement usually observed in such reactions.

Theoretical aspects of the electrophilic halogenation of diene hydrocarbons with conjugated multiple bonds have been considered[3,72,132]. There is insufficient clarity in this question[3,132], and the problem requires further study.

Intramolecular Rearrangements of Hydrocarbon Radicals in the Gas Phase

A.D.Stepukhovich and V.I.Babayan

The review deals with the rearrangements of alkyl radicals occurring in various gas-phase processes. Intramolecular isomerisations involving the migration of a hydrogen atom with formation of three-, four-, five-, and six-membered transition states are examined. The possibility of the isomerisation of small alkyl radicals (ethyl and propyl radicals) and of the transfer of hydrogen to a neighbouring carbon atom in long-chain radicals is discussed. The process mechanism is considered. The bibliography includes 82 references.

CONTENTS

I. Introduction	750

IV. Migration of a hydrogen atom to a more remote carbon atom with a free valence	754
V. The mechanism of the migration of hydrogen in alkyl radicals	756

I. INTRODUCTION

Among reactions of free radicals, those involving their intramolecular isomerisation and leading to the migration of the free valence along the carbon skeleton of the species from one carbon atom to another are of special interest. Owing to isomerisation, the structure of the products of reactions involving free radicals can differ appreciably from that of the products which might have been expected in the absence of radical rearrangements. In many chain processes the isomerisation of the initially formed radicals can lead to the replacement of less active intermediate centres by more active ones. In polymerisation processes such rearrangements result in branching and cross-linking of the polymer chains.

The concept of radical isomerisation arose and began to be developed immediately after the discovery of free radicals and the elucidation of the role which they may play in various chemical reactions. In the 1940's–1950's, radical isomerisation was already adduced to explain experimental data for the thermal decomposition[1,2], isomerisation[3], oxidation[4-6], and other reactions[7,8] of organic compounds involving free radicals. However, one should note that at that time there was in fact no proof of the reality of processes of this kind.

This deficiency was eliminated to a considerable degree in the 1960's when studies on radical isomerisation were directed to the identification of radical centres. The first quantitative data for the kinetic characteristics of isomerisation processes have now also been obtained. In thermal or photolytic decomposition of various organic compounds, two or more isomeric radicals are formed via almost equally probable independent pathways and even the identification of the radicals and the use of tracer atoms do not always make it possible to state unambiguously whether radical rearrangements occur in the system. The fairly frequent formation in the system of structurally isomeric radicals can be explained by a sequence of bimolecular radical substitution, addition, and decomposition reactions without resorting to the hypothesis of radical isomerisation. Therefore numerous contradictory data and conclusions concerning the possible isomerisation of alkyl radicals by the migration of hydrogen atoms have accumulated in the literature dealing with gas-phase free-radical processes.

The present review is concerned with rearrangements of alkyl radicals in the gas phase. The review literature on this question is scanty. We can only point to one review in Czech[9] and a brief description of gas-phase radical rearrangements in monographs by Semenov[10], Pryor[11], Magaril[12], and Freidlina et al.[13] The well tested structural chemical principle of 1 — 2, 1 — 3, 1 — 4, 1 — 5, ... migrations of hydrogen atoms has been adopted in the present review for the classification of rearrangements. The numerical values indicate the relative positions of two rearrangement centres. However, wherever convenient, we have employed the approach of Rabinovitch and coworkers[14], designating the hydrogen atom shift as an *Nab* process, where *N* is the number of units in the ring of the cyclic transition state equal to 3, 4, 5, ..., *a* = *p*, *s*, or *t* refers to primary, secondary or tertiary C — H bonds undergoing dissociation, and *b* = *p*, *s*, or *t* refers to C — H bonds being formed.

Thus the isomerisation

$$CH_3-CH_2-CH_2-CH_2-\dot{C}H-CH_3 \rightarrow \dot{C}H_2-CH_2-CH_2-CH_2-CH_2-CH_3$$

will be designated as a 6*ps* reaction, which corresponds to a 1 — 5 migration of hydrogen according to the first classification. The Rabinovitch notation has the advantage that it reflects two important factors responsible for the occurrence of the rearrangement: the ring size of the transition state and the thermochemistry of the process, i.e. the conversion of less stable radicals into more stable radicals (the conversion of a primary into a secondary or tertiary radical) or conversely.

Intramolecular rearrangements of radicals are usually regarded as reactions of the radical with itself. Accordingly, the present review deals with intramolecular substitution reactions of alkyl radicals which can be represented schematically in the following way:

$$R-\dot{C}H-(CH_2)_n-\overset{H}{\underset{|}{C}}H-R' \rightarrow R-\overset{H}{\underset{|}{C}}H-(CH_2)_n-\dot{C}H-R',$$

where R, R′ is either a hydrogen atom or a hydrocarbon group.

II. 1 — 2 MIGRATION OF A HYDROGEN ATOM

Contradictory views have been expressed in the literature concerning the possibility that alkyl radicals can rearrange by the transfer of a hydrogen atom from a carbon atom adjoining the atom with an unpaired electron.

In order to account for the reaction products, many investigators had to resort to the hypothesis of 1 — 2 migration of a hydrogen atom; however, no one has succeeded in justifying rigorously a rearrangement of this type.

Glazebrook and Pearson[1] investigated the photolysis of di-isopropyl ketone, trapping the radicals formed with metallic mercury. When mercury iodide was added to the system, *n*-propylmercury iodide was obtained unexpectedly. This led the investigators to the conclusion that the isopropyl radicals formed in the primary photolytic step isomerise via a 3*ps* reaction into n-propyl radicals, the isomerisation probably occurring at the instant of the combination of the radical with mercury, since in the absence of the latter the rearrangement does not occur:

$$CH_3\dot{C}HCH_3 \rightarrow \dot{C}H_2CH_2CH_3\,. \qquad (1)$$

This conclusion was questioned by Kharasch and coworkers[15,16], who investigated the thermal decomposition of n-propyl and isopropyl peroxides in carbon tetrachloride but failed to detect rearrangements of the alkyl radicals formed and concluded that there is no isomerisation in the gas-phase reactions either.

The decomposition of alkyl radicals is known to involve bonds in the β-position relative to the free valence[17] (the β-rule). In the presence of radical isomerisation, apparent deviations from this rule should be observed. Thus in the decomposition of isopropyl radicals, ethylene and a methyl radical should be formed, in the decomposition of n-butyl radicals—a methyl radical and propene, etc. The detection in the system of products of such "anomalous" decomposition might constitute serious evidence in support of the occurrence of radical rearrangements in the system.

Heller and Gordon[18] studied the photolysis of [D_2]di-isopropyl ketone at temperatures in the range 200 — 500°C and pressures of 14 — 16 mmHg. In the high-temperature range (407 — 504°C), they detected ethylene and methane in proportions close to 1 : 1. They suggested that under these conditions the anomalous decomposition of the isopropyl radical

$$CH_3\dot{C}DCH_3 \rightarrow CH_3CDH\dot{C}H_2 \rightarrow CH_2{=}CHD + \dot{C}H_3 \qquad (2)$$

plays an important role.

The presence in the system of n-propyl radicals is also indicated by the appearance on the chromatogram of a peak corresponding to 2-methylpentane, which is a product resulting from the combination of n-propyl and isopropyl radicals. The formation of the n-propyl radical via other pathways, namely by the attachment of H· to propene or the intermolecular isomerisation

$$CH_3\dot{C}DCH_3 + CH_3CH_2CH_3 \rightarrow CH_3CDHCH_3 + CH_2\dot{C}H_2CH_3$$

and "atomic cracking", did not occur under these conditions. If reaction (2) proceeds via two stages (rearrangement and decomposition), then, according to the authors, isomerisation is rate-limiting.

The anomalous decomposition of isopropyl radicals, $CH_3\dot{C}HCH_3 \rightarrow \dot{C}H_3 + CH_2 = CH_2$, is believed[18] to be responsible for the formation of part of the ethylene which is a side product in the pyrolysis of isobutane. The rate constant obtained for this reaction in the temperature range 440 — 541°C and in the pressure range 50 — 150 mmHg agrees to some extent with Heller's results[18] (Table 1). A somewhat different value of the rate constant for this reaction in the temperature range 417 — 493°C was obtained by Kerr and Trotman-Dickenson[20] in the photolysis of isobutyraldehyde.

The β-rule breaks down similarly in the decomposition of butyl radicals. In a study of the photolysis of n-valeraldehyde at 300 — 416°C, the same workers[21] observed a rapid increase of the amount of methane and propene with retention of the ratio [methane]/[propene] ≃ 1. An anomalous decomposition reaction consisting of 1 — 3 migration of hydrogen and the dissociation of the C — C bond,

$$CH_3CH_2CH_2\dot{C}H_2 \rightarrow CH_3\dot{C}HCH_2CH_3 \rightarrow CH_3CH{=}CH_2 + \dot{C}H_3\,, \qquad (3)$$

was stated to be the cause of this behaviour.

Table 1. Kinetic parameters of the anomalous decomposition of alkyl radicals.

Reaction	T, °K	$\lg A$ (s^{-1})	E, kcal mole^{-1}	References
$CH_3\dot{C}DCH_3 \rightarrow CH_2CHD + \dot{C}H_3$	686—777	15.05	32.5±2.0	18
iso-$\dot{C}_3H_7 \rightarrow C_2H_4 + \dot{C}H_3$	690—770	10.6	29.5	20
	713—814	12.0±0.2	34.5±0.5	19
	690—814	11.28±0.68	31.88±2.36	25
n-$\dot{C}_4H_9 \rightarrow C_3H_6 + \dot{C}H_3$	523—650	11.0	23	22, 26, 27
	571—689	12.1	27.1	21, 26, 27
n-$\dot{C}_4H_9 \rightarrow$ s-$\dot{C}_4H_9 \rightarrow \dot{C}H_3 + C_3H_6$	913—933	14.71	41.0	23
t-$\dot{C}_4H_9 - C_3H_6 + \dot{C}H_3$	742—797	16.0	46.3	24, 27
	—	8.5	18.5	26

As in the work of Heller and Gordon[18], it remained obscure whether the rearrangement occurs before the decomposition or simultaneously with it. The authors believe that isomerisation precedes decomposition: the first reaction stage is exothermic and the s-butyl radical formed has a larger store of energy than is required for decomposition. If such a radical is not deactivated by a collision (the probability of which is small at low pressures), then it will of course decompose.

A reaction similar to reaction (3) was invoked still earlier by Bywater and Steacie[22] to explain the approximate equality of the rates of formation of methane and propene in the photolytic decomposition of n-butane (250 — 400°C, 200 mmHg) sensitised by mercury. A reaction of this kind should be accompanied by 1 — 2 or 1 — 3 migration of hydrogen.

The conclusion that the n-butyl radical isomerises to the s-butyl radical with subsequent decomposition into a methyl radical was also reached by Lin and Back[23] using results on the kinetics of the secondary formation of methane in the thermal decomposition of ethane (550 — 726°C, 10 — 600 mmHg). Probably the reaction does indeed occur in two stages, since for high degrees of conversion the presence of *cis*- and *trans*-but-2-enes in the system may be evidence of the existence of s-butyl radicals.

The isomerisation of t-butyl radicals was studied by Birrell and Trotman-Dickenson[24] in the photoinitiated decomposition of trimethylacetaldehyde. Above 470°C, they obtained considerable amounts of propene and methane. The authors explain this by isomerisation reactions followed by the decomposition of the t-butyl radical:

$$(CH_3)_2\dot{C}CH_3 \rightarrow (CH_3)_2CH\dot{C}H_2 \rightarrow CH_3CH{=}CH_2 + \dot{C}H_3\,. \qquad (4)$$

Thus it is evident that a number of studies appear to indicate the possibility of hydrogen shifts via a three-membered cyclic transition state under the usual experimental conditions of cracking and photolysis reactions. Table 1 lists the kinetic parameters of such reactions.

However, there exists no less convincing evidence that the decomposition of hydrocarbon radicals takes place always in accordance with the β-rule. Thus Jackson and McNesby[28] studied the thermal decomposition of [1,1,1-D_3]propane at 472 — 553°C and a pressure of about 50 mmHg. Under these conditions, the n-propyl radical decomposes rapidly into ethylene and a methyl radical, while for the isopropyl radical four possible decomposition pathways were suggested:

$$CD_3\dot{C}HCH_3 \rightarrow [\dot{C}D_2CHDCH_3] \rightarrow CD_2{=}CDH + \dot{C}H_3, \quad (5)$$

$$CD_3\dot{C}HCH_3 \rightarrow [CD_3CH_2\dot{C}H_2] \rightarrow \dot{C}D_3 + C_2H_4, \quad (6)$$

$$CD_3\dot{C}HCH_3 \rightarrow \dot{D} + CD_2{=}CH{-}CH_3, \quad (7)$$

$$CD_3\dot{C}HCH_3 \rightarrow \dot{H} + CD_3{-}CH{=}CH_2. \quad (8)$$

The authors detected 3% of C_2H_3D which they believe to have been formed via reaction (5). The ratio of the yield of ethylene formed as a result of isomerisation to the yield of propene is given by the ratio $(k_5 + k_6)/(k_7 + k_8)$ and corresponds to k_9/k_{10} for the reactions

$$CH_3\dot{C}HCH_3 \rightarrow [CH_3CH_2\dot{C}H_2] \rightarrow \dot{C}H_3 + C_2H_4, \quad (9)$$

$$CH_3\dot{C}HCH_3 \rightarrow \dot{H} + C_3H_6. \quad (10)$$

In the above temperature range, the ratio is on average 0.88. In general, this value increases with temperature, although some investigators[18,29] noted the opposite behaviour. Thus, despite the fact that the above investigation does not involve the rejection, in principle, of the possibility of the 3*ps* isomerisation of a small radical, under the usual cracking conditions this process takes place to only a small extent and can hardly compete with other reactions of the isopropyl radical.

The photolysis of di-isopropylmercury in a flow system at 150 — 300°C and a pressure of about 4 mmHg has been investigated[30]. Only one C_6 hydrocarbon (2,3-dimethylbutane, formed by the recombination if isopropyl radicals) was obtained. There is no isomerisation of iso-$\dot{C}_3H_7$ to n-$\dot{C}_3H_7$. However, the presence in the reaction products of isobutane and ethylene suggests the reaction

$$CH_3\dot{C}HCH_3 \rightarrow \dot{C}H_3 + CH_2{=}CH_2,$$

which is fully in agreement with the data of Heller and Gordon[18]. The results of a study by Billinge and Gowenlock[30] suggest that the decomposition and isomerisation stages take place simultaneously. This is indicated by the absence from the system of other isomeric hexanes following the addition of perfluorocyclohexane. Since even in the presence of the additive the pressure in the system did not exceed about 4.5 mmHg, deactivation due to perfluorocyclohexane is unlikely.

McNesby et al.[31] studied the pyrolysis of acetone in the presence of n-[2,2,3,3-D_4]butane at 365 — 506°C and 32 mmHg. Two decomposition pathways were suggested for each butyl radical:

$$\dot{C}H_2CD_2CD_2CH_3 \rightarrow \left[\begin{array}{c} D \\ \diagup \\ CH_2{-}CDCD_2CH_3 \end{array}\right] \rightarrow CH_2DCD{=}CD_2 + \dot{C}H_3, \quad (11)$$

$$\dot{C}H_2CD_2CD_2CH_3 \rightarrow CH_2{=}CD_2 + CD_2CH_3\dot{}, \quad (12)$$

$$CH_3\dot{C}DCD_2CH_3 \rightarrow \left[\begin{array}{c} CH_2{-}CDCD_2CH_3 \\ \diagdown \\ H \end{array}\right] \rightarrow CH_2{=}CDH + CD_2CH_3\dot{}, \quad (13)$$

$$CH_3\dot{C}DCD_2CH_3 \rightarrow CH_3CD{=}CD_2 + \dot{C}H_3. \quad (14)$$

The study of the mass spectra of the ethylene (mainly $CH_2 = CD_2$) and propene fractions led to the conclusion that reactions (12) and (14) predominate. Reaction (11), the 1 — 2 migration of deuterium, is not particularly important, since the amount of [D_4]-propene is not more than 1% of the main product—[D_3]propene. [D]ethylene is formed to a very slight extent or not at all. Thus isomerisations of the 3*sp* and 3*ps* types occur to an insignificant extent under the above experimental conditions.

Nevertheless the formation of [D_3]propene as the main product does not always imply a low degree of isomerisation of the butyl radical[21,24]. The formation of such propene can be accounted for also by the 1 — 3 migration of deuterium followed by decomposition via a reaction analogous to reaction (3):

$$\dot{C}H_2CD_2CD_2CH_3 \rightarrow CH_2DCD_2\dot{C}DCH_3 \rightarrow CH_3CD{=}CD_2 + \dot{C}H_2D.$$

In their study of the isotope composition of the methane fraction, Gordon and McNesby[32] did not detect dideuteriomethane, which should have been formed since under these conditions (400 — 450°) methyl radicals abstract deuterium more than twice as readily as hydrogen. However, the yields of methane and propene in the study by Kerr and Trotman-Dickenson[21] can be accounted for by the abstraction by free radicals of equivalent hydrogen atoms from n-valeraldehyde at the β- and γ-carbon atoms with subsequent decomposition of the large radicals:

$$\dot{R} + CH_3CH_2CH_2CH_2CHO \rightarrow RH + CH_3\dot{C}HCH_2CH_2CHO \rightarrow CH_3CHCH_2 + \dot{C}H_2CHO,$$
$$\dot{R} + CH_3CH_2CH_2CH_2CHO \rightarrow RH + CH_3CH_2\dot{C}HCH_2CHO \rightarrow \dot{C}H_3 + CH_2CHCH_2CHO.$$

Frey and Hepp[33], who studied the decomposition of di-n- and di-s-butylmercury at 490°C and 1 — 5 mmHg, also found that the decomposition of the n- and s-butyl radicals takes place in accordance with the β-rule and the isomerisation n-$C_4H_9 \rightleftharpoons$ s-C_4H_9 with subsequent decomposition takes place to only a very slight extent (about 0.1%) under these conditions if at all. It was also shown[34] that, at low pressures and at 350 — 525°C, the n-butyl radical decomposes only into ethylene and an ethyl radical and the s-butyl radical decomposes only into propene and a methyl radical. The decompositions of n-butyl and t-isobutyl radicals take place in accordance with the β-rule.

The isomerisations of isobutyl radicals were also studied by McNesby and Jackson in the thermal decomposition of [2-D]isobutane at 45 — 56 mmHg.[35] At 540°C the rate of the isomerisation reaction

$$(CH_3)_2CD\dot{C}H_2 \rightarrow (CH_3)_2\dot{C}CH_2D$$

is only one hundredth of the rate of the direct decomposition

$$(CH_3)_2CD\dot{C}H_2 \rightarrow \dot{C}H_3 + CH_3CD{=}CH_2.$$

Thus the results quoted show that the usual experimental technique and method do not allow a solution of the problem of the possible 1 — 2 or 1 — 3 migration of hydrogen in alkyl radicals and indicate only an unimportant role of these processes in the cracking and photolysis of many organic compounds. In particular, the β-rule holds with a high degree of precision for the decomposition of alkyl radicals.

The 3*sp* isomerisation of n-$\dot{C}_3H_7$ and iso-$\dot{C}_3H_7$ is also insignificant. In the study already discussed[30], the only hexane obtained in the photolysis of di-n-propylmercury at 380 — 460°C was n-hexane. Similarly in the photolysis of di-n-propyl ketone (55 — 357°C, 8 — 115 mmHg), 98% of the C_6 fraction consisted of n-hexane[36]. Lossing and de Sousa[34] also showed that the decomposition products of n-propyl radicals are ethylene and methyl radicals.

The most accurate results, whereby it is possible to infer the occurrence of 1 — 2 migration of hydrogen in radicals in both gaseous and liquid phases, were obtained in a tracer atom study employing hydrogen and carbon isotopes. Brown and Russell[37] chlorinated photochemically 2-methyl-[2-D]propane at −15°C. The products were t-butyl chloride, isobutyl chloride, hydrogen chloride, and deuterium hydride. This indicates the occurrence of two reactions:

$$(CH_3)_2CDCH_3 + Cl_2 \rightarrow (CH_3)_2CD\dot{C}H_2 + HCl, \quad (A)$$

$$(CH_3)_3CDCH_3 + Cl_2 \rightarrow (CH_3)_2\dot{C}CH_3 + DCl. \quad (B)$$

The occurrence of the rearrangement of radicals (A) and (B) was inferred from the DCl/HCl and t-butyl chloride/isobutyl chloride ratios respectively. The excellent agreement between these ratios clearly indicates the absence of any considerable degree of isomerisation with transfer of hydrogen according to the mechanisms

$$(CH_3)_2CD\dot{C}H_2 \rightarrow (CH_3)_2\dot{C}CH_2D \text{ and } (CH_3)_2\dot{C}CH_3 \rightarrow (CH_3)_2CH\dot{C}H_2,$$

$$(CH_3)_2CDCH_2 + (CH_3)_2CDCH_3 \rightarrow (CH_3)_2CDCH_2D + (CH_3)_2\dot{C}CH_3,$$

which constitutes essentially intermolecular isomerisation.

On the other hand, Bhardwaj and Lee[38] studied the isomerisation of [1-^{14}C]ethyl iodide and [2-^{14}C]ethyl iodide under the influence of γ-radiation and observed that at room temperature in a 2% aqueous solution of [1-^{14}C]ethyl iodide 0.28 of a molecule of [2-^{14}C]ethyl iodide is formed for each 100 eV of absorbed energy regardless of radiation dose†. However, the addition of 1% of iodine before irradiation lowers the degree of rearrangement to zero. The authors believe that the most probable process mechanism involves 1 — 2 migration of hydrogen:

$$CH_3-{}^{14}\dot{C}H_2 \rightarrow \dot{C}H_2{}^{14}CH_3. \quad (15)$$

The effect of iodine can be explained by a higher rate of its addition to the ethyl radical compared with reaction (15). The formation of [2-^{14}C]ethyl iodide via a different pathway, namely by the reaction between the main products (ethylene and hydrogen iodide),

$$CH_2={}^{14}CH_2 + HI \rightarrow CH_2I-{}^{14}CH_3,$$

is possible in principle but the marked inhibiting effect of iodine would then be unexplained. Similarly, when a 2% aqueous solution of [1-^{14}C]ethanol is irradiated with γ-rays, [2-^{14}C]ethanol with $G \simeq 0.04$ is formed[39], which is also evidence of a hydrogen shift. The higher value of G found by Bhardwaj and Lee[38] can be accounted for by the greater ease of formation of the ethyl radical from ethyl iodide than from ethanol.

There are also many experimental data of a different type, indicating the possibility of the migration of a hydrogen atom to an adjoining carbon atom with a free valence. Thus Callear and Cvetanović[40], who studied the mercury-photosensitised decomposition of C_2H_4, C_2D_4, and *cis*-$C_2D_2H_2$ at room temperature and 16 — 750 mmHg, found that the main products in this process (hydrogen and acetylene) are not obtained by a radical mechanism but in consequence of homogeneous intermolecular processes. In the photolysis of *cis*-$C_2D_2H_2$, the isotopic composition of the hydrogen formed corresponds to the ratios $H_2 : HD : D_2 = 2 : 5.7 : 1$. One explanation of this finding involves the recognition that hydrogen may migrate in excited species. The available data do not allow a rigorous proof of the process mechanism but the migration of hydrogen between carbon atoms is supported by the isomerisation of *cis*-$C_2H_2D_2$ to the *anti*-form, which can occur even on impact deactivation of the excited species (in the presence of a large amount of added carbon dioxide). On the other hand, if in the excited state of ethylene the hydrogen atoms exchange with one another, the hydrogen isotope composition should be identical regardless of whether *cis*- or *anti*-$C_2H_2D_2$ undergoes the mercury-sensitised decomposition. In the decomposition of *anti*-$C_2H_2D_2$, the hydrogen isotope composition corresponds to the ratios $H_2 : HD : D_2 = 1.8 : 4.6 : 1$.[41] This shows that intramolecular hydrogen exchange occurs in ethylene excited with $Hg(^3P_1)$. However, Okabe and McNesby[42] believe that this process is unlikely in direct photolysis *in vacuo* by ultraviolet radiation (1849 — 1236 Å).

Scala and Ausloos[43], who investigated the photolysis of $(CH_3)_2CDCH_2CH_3$ and $(CH_3)_2CHCH_2CH_3$ with light at a wavelength of 1048 — 1470 Å at a pressure of several mmHg, concluded that the rearrangements $CH_3\ddot{C}CH_3 \rightarrow CH_3CH = CH_2$ and $\ddot{C}HCD_3 \rightarrow CHD = CD_3$ take place in the propylidene and ethylidene biradicals respectively. Similarly studies of the photolysis of ethane (1048 — 1067 Å) showed[44-52] that for the above energies the most important process is splitting off of molecular hydrogen, which involves almost exclusively only one carbon atom. The vibrationally excited ethylidene formed on deactivation rearranges to ethylene: $\ddot{C}HCH_3^* \xrightarrow{M} CH_2 = CH_2$. Similar rearrangements with 1,2-shifts of hydrogen or deuterium were observed in the photolysis of other compounds. The 3*sp* migration of hydrogen in the trimethylene biradical occurs in the isomerisation of cyclopropane to propene (see the review by Lazár and Kysel[9]). It was found that[53] the activation energy for the transition

$$\dot{C}H_2CH_2\dot{C}H_2 \rightarrow CH_2{=}CHCH_3$$

is only 9.5 kcal mole^{-1}.

There are many experimental data indicating the occurrence of rearrangements of hydrocarbon radicals also in the solid phase. Ayscough et al.[54] observed a change in the hyperfine structure of the ESR spectrum of the n-propyl radical, reflecting the transformation of the latter into an isopropyl radical, and a spontaneous transformation of the spectrum of the isobutyl radical into that of the t-butyl radical. These transitions occur at the temperature of liquid nitrogen. A similar situation was observed by Iwasaki and Toryama[55] in an ESR study of the photoinduced radical transformation of isobutyl bromide at 77°K. γ-Irradiation of this compound leads to the formation of primary isobutyl radicals which during the period of storage (about 40 days) in the dark at 77°K are spontaneously converted into t-butyl radicals. Illumination of the latter with ultraviolet light at the same temperature for 90 min yields isobutyl radicals, i.e.

$$CH_3-\underset{|}{\overset{CH_2Br}{CH}}-CH_3 \xrightarrow[77°K]{\gamma} CH_3-\underset{|}{\overset{\dot{C}H_2}{CH}}-CH_3 \underset{h\nu}{\rightleftarrows} CH_3-\underset{\cdot}{\overset{CH_3}{C}}-CH_3.$$

Similar transitions occur on γ-irradiation of many polymers at 77°K. The process involving polypropylene[56] takes place as follows:

$$\text{polypropylene} \xrightarrow[77°K]{\gamma} \ldots CH_2-\underset{|}{\overset{\dot{C}H_2}{CH}}-CH_2 \ldots \underset{h\nu}{\rightleftarrows} \ldots CH_2-\underset{\cdot}{\overset{CH_3}{C}}-CH_2.$$

In general one may say that, under the influence of ultraviolet light, 3*pt* migration of hydrogen takes place at the temperature of liquid nitrogen with formation of an

† The number of molecules undergoing rearrangement following the absorption of 100 eV of energy is designated by the symbol *G*.

energetically more favourable radical. As was to be expected, the reverse process occurs spontaneously.

The isomerisation of radicals in the gas phase with 1 — 2 migration of hydrogen has not yet been investigated even qualitatively. The data examined suggest that the process can occur in principle. It is undoubtedly difficult under the usual conditions in the cracking of hydrocarbons (up to 600°C) but probably occurs in reactions of "hot" species and also in free-radical processes where subsequent reactions of the radical are "slow". Possibly intramolecular rearrangements of the simplest alkyl radicals might be observed in the study of processes at higher temperatures (about 1000 — 1500°C) and lower pressures.

III. 1 — 3 MIGRATION OF A HYDROGEN ATOM

Even fewer data have been obtained for the 4*ab* migration of hydrogen atoms in alkyl radicals in the gas phase. Apart from the studies by Trotman-Dickenson already mentioned[21,24], one may point to the work of Rabinovitch and coworkers[14], who studied the intramolecular isomerisation of many vibrationally excited alkyl radicals and concluded that rearrangements with $N < 5$ are insignificant and cannot occur as simple hydrogen transfers.

The possibility of 1 — 3 migration of hydrogen is indicated by a study of Reutov and Shatkina[57]. Using the carbon-14 isotope, they found that the free propyl radical formed on thermal decomposition in boiling carbon tetrachloride of n-butyryl peroxide labelled in the α-position,

$$(CH_3CH_2{}^{14}CH_2COO)_2 \rightarrow 2CH_3CH_2{}^{14}\dot{C}H_2 + 2\,CO_2,$$

isomerises with migration of a hydrogen atom from the β-position:

$$CH_2CH_2{}^{14}\dot{C}H_2 \rightleftarrows \dot{C}H_2CH_2{}^{14}CH_3. \qquad (16)$$

Analysis of the decomposition products showed that under these conditions such isomerisation occurs to the extent of 4.0 ± 0.5%. In their attempt to confirm reaction (16) by an independent method, Reutov et al.[58] studied the pyrolysis of [α-D_2]butyryl peroxide in boiling carbon tetrachloride. Together with the normal product, the formation (in an amount of 1.3 ± 0.1%) of the anomalous product $CD_2HCH_2CH_2Cl$ was observed, which also indicates the occurrence of the isomerisation reaction (16). The replacement of carbon tetrachloride by bromoform as a solvent leads to a decreased yield of the rearranged product (0.68 ± 0.1% at 140°C),[59] which can be explained by a decrease of the lifetime of the free radical. It was also shown that the structure of the rearrangement product cannot be accounted for by exchange reactions during analysis. One piece of evidence for the possibility of 1 — 3 migration of hydrogen, which is interesting rather than convincing, is provided by the experiments of Voevodskii and coworkers[60-63]. The authors showed by kinetic calculations[60] that the higher rate of exchange of hydrogen for deuterium in alkyl radicals observed in various studies at room temperature can be explained by the reactions $RH + D_2 \rightarrow RD + HD$, $RHD + D_2 \rightarrow RD_2 + HD$, etc., with only the hydrogen atoms linked to the carbon atom with a free valence being capable of undergoing exchange. However, further studies[61-63] showed that this limitation extends only to adjacent carbon atoms. If a free valence can migrate spontaneously to another carbon atom, further hydrogen exchange is probable. As a result, a radical with a higher deuterium content should be formed than in the absence of isomerisation. It has been shown for isobutyl radicals formed by the reaction $(CH_3)_2C = CH_2 + D \rightarrow (CH_3)_2CD\dot{C}H_2$ that the fraction of C_8 hydrocarbons, which are formed by the recombination of these radicals, is characterised by a degree of exchange of 40 — 50%, while without allowance for isomerisation the maximum degree of exchange should be 30%.[61] Consequently the following isomerisations are possible at room temperature:

$$CH_3(CH_3)\,CD\dot{C}H_2 \rightleftarrows CH_3(\dot{C}H_2)\,CDCH_3 \rightleftarrows \dot{C}H_2(CH_3)\,CDCH_3$$

in which 1 — 3 migration of hydrogen takes place. On the other hand, it has been shown for the isopropyl radical and radicals of the type $(CH_3)_2CD\dot{C}(CH_3)_2$ that the migration of the free valence to an adjacent carbon atom is impossible[63].

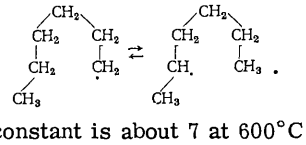
A weak feature of these experiments is the experimental technique. Atomic hydrogen was withdrawn from the discharge tube and was directed to the reactor mixed with the hydrocarbon and deuterium under a pressure of 0.2 — 0.4 mmHg at a rate up to 3 m s^{-1}. Although separate experiments showed that under these conditions the hydrocarbon hardly reached the discharge zone (the concentration of RH in the discharge zone was ≤0.25%[63]), the rate of diffusion of deuterium may be higher and the investigators might have dealt with atomic and not molecular deuterium. In this case the high degree of deuteriation cannot be accounted for by radical rearrangements.

Chesick[64], who investigated the photolysis of *cis*-but-2-ene by light at a wavelength of 2026 — 2062 Å at room temperature and 540 mmHg, concluded that 1 — 3 migration of hydrogen in the unsaturated radical $CH_3CH = \dot{C}H$ does occur:

$$CH_3CH{=}\dot{C}H \rightarrow \dot{C}H_2CH{=}CH_2.$$

IV. MIGRATION OF A HYDROGEN ATOM TO A MORE REMOTE CARBON ATOM WITH A FREE VALENCE

Rearrangements of this kind were first suggested in 1943 by Kossiakoff and Rice[65]. They believe that alkyl radicals containing five or more carbon atoms can isomerise under the usual cracking conditions. The activation energy for such isomerisation may be much lower than the decomposition energy of the radical. As a result, equilibrium should be established between two isomeric forms, for example in the isomerisation of primary n-hexyl radicals:



The equilibrium constant is about 7 at 600°C. The authors employed this hypothesis to calculate the thermal decomposition products of n-hexane and certain octanes. It was found that the calculation which includes the possibility of an intramolecular hydrogen transfer agrees better with experiment than calculation which neglects isomerisation. For radicals with longer chains, for example as obtained in the cracking of n-hexadecane[66], there is an even greater number of possibilities of isomerisation and the improvement of the agreement between the yield of reaction products and the calculation becomes even more marked when these possibilities are taken into account. Somewhat later Sefton and LeRoy[67] studied at 250 — 300°C the polymerisation of ethylene initiated by ethyl radicals labelled with carbon-14 in the methyl group.

2-Methylbut-1-ene was detected in the reaction products. If this product were formed by the addition of a labelled ethyl radical to propene with subsequent disproportionation of the 2-methylbutyl radical, its molar radioactivity should have been unity. Experiment however, yielded a value equal to only half that quantity. The authors explain the discrepancy by intramolecular radical isomerisation involving 1 — 4 and 1 — 5 migration of hydrogen.

No less convincing are the quantitative results of the experiments by Gordon and McNesby[68], who also investigated the reaction of methyl radicals with ethylene in the temperature range 300 — 500°C and at pressures in the range 109 — 360 mmHg. Under these conditions, the main product is propene. The authors suggest the following process mechanism:

$$\dot{C}H_3 + CH_2{=}CH_2 \rightarrow CH_3CH_2\dot{C}H_2 \xrightarrow{+CH_2=CH_2} CH_3CH_2CH_2CH_2\dot{C}H_2,$$

$$CH_3CH_2CH_2CH_2\dot{C}H_2 \rightarrow CH_3\dot{C}HCH_2CH_2CH_3 \rightarrow CH_3CH{=}CH_2 + \dot{C}_2H_5.$$

The reaction mixture contains also but-1-ene obtained as a result of a 1,5-rearrangement of heptyl radicals:

$$CH_3(CH_2)_3\dot{C}H_2 + CH_2{=}CH_2 \rightarrow CH_3(CH_2)_5\dot{C}H_2 \rightarrow CH_3CH_2\dot{C}H(CH_2)_3CH_3 \rightarrow$$
$$\rightarrow CH_3CH_2CH{=}CH_2 + \dot{C}H_2CH_2CH_3.$$

The validity of the above mechanism was demonstrated by the introduction of CD_3 radicals. At 300°C the propene fraction had the following isotope composition: 30% C_3H_6, 20% C_3H_5D, 30% $C_3H_4D_2$, and 20% $C_3H_3D_3$. This indicated the occurrence of exchange processes. One of the possible mechanisms, involving a number of rapid hydrogen exchanges between carbon atoms in the 1- and 4-positions and in the 1- and 5-positions, can be represented as follows:

$$CD_3(CH_2)_3\dot{C}H_2 \xrightarrow{1,5} \dot{C}D_2(CH_2)_3CH_2D \xrightarrow{1,5} CD_2H(CH_2)_3\dot{C}HD \rightarrow \text{etc.},$$
$$\downarrow 1,4 \qquad\qquad \downarrow 1,4 \qquad\qquad \downarrow 1,4$$
$$CD_3\dot{C}H(CH_2)_2CH_3 \rightarrow CD_3CH{=}CH_2 + \dot{C}_2H_5 \mid CD_2H\dot{C}H(CH_2)_2CH_2D \rightarrow CD_2HCH{=}CH_2 + \dot{C}_2H_4D,$$
$$\downarrow$$
$$CD_2H(CH_2)_2\dot{C}HCH_2D \rightarrow \dot{C}_2H_3D_2 = CH_2{=}CHCDH_2.$$

Wijnen[69], who photolysed heptan-2-one at 60 — 200°C, detected 2-methylpentane among the reaction products. This compound is produced by combinations of methyl and s-pentyl radicals. Consequently the reaction $\dot{C}H_2(CH_2)_3CH_3 \rightarrow CH_3(CH_2)_2\dot{C}HCH_3$ with 1 — 4 hydrogen migration plays a significant role not only at 250°C as, in the work of Gordon and McNesby[68], but also at a temperature as low as 150°C.

There are reliable data indicating the migration of hydrogen atoms in radicals in the liquid phase. For example, in a study of the telomerisation of ethylene by acetic acid at 140°C, Freidlina et al.[70] detected isoacids (α-ethylcaproic and α-n-butylcaproic acids) in the products. The formation of these acids can be readily explained by a rearrangement of $\dot{C}H_2CH_2CH_2CH_2CH_2COOH$ to $CH_3CH_2CH_2CH_2\dot{C}HCOOH$. On the other hand, the absence of isohexanoic acid from the reaction mixture indicates the impossibility of 1 — 3 migration of hydrogen in the $\dot{C}H_2CH_2CH_2COOH$ radical under these conditions. It has also been shown[71] that, as was to be expected, an increase of temperature favours the formation of a rearranged product, while a change in the concentration of the reactants does not have a significant influence on the yield.

Rearrangements similar to that indicated above occur also in the telomerisation of ethylene by methyl chloroacetate[72], methyl alcohol[72], propionic acid[73], methyl propionate[73], acetoacetic ester[73], etc. Probably, if the temperatures are sufficiently high and the telogens are comparatively ineffective, the rearrangement of radicals with 1 — 5 migration of hydrogen is a general phenomenon[72].

However, whereas radical isomerisation plays an appreciable role in solutions of relatively inactive telogens, in the telomerisation of ethylene in carbon tetrachloride solutions (at 140°C)[74-76] its importance is low. On passing to the gas phase (at a pressure of about 0.3 atm), 70 — 80% of the products are isomers of the normal telomers. Under these conditions, unimolecular rearrangements compete successfully with bimolecular reactions, for example:

$$Cl_3C(CH_2)_5CH_2- \begin{cases} \xrightarrow{+CCl_4} Cl_3C(CH_2)_5CH_2Cl & (38\%), \\ \xrightarrow{+C_2H_4} Cl_3C(CH_2)_7\dot{C}H_2 & (\sim 4\%), \\ \xrightarrow[\text{rearrangement}]{} Cl_3CCH_2\dot{C}H(CH_2)_3CH_3 & (\sim 58\%) \text{ etc.} \end{cases}$$

The contribution of such rearrangements diminishes very markedly with increase of pressure and ethylene and carbon tetrachloride concentrations.

Intramolecular rearrangements of radicals in the solid phase have also been mentioned[77,78]. A study of the hyperfine structure of the ESR spectra of alkyl radicals formed from n-hexadec-1-ene, n-dec-1-ene, n-oct-2-ene, n-hept-2-ene, etc. on irradiation with γ-rays (at 77°K) showed that they are spontaneously converted into energetically more favourable allylic radicals:

$$CH_2-\dot{C}H-(CH_2)_n-CH{=}CH-CH_2 \underset{h\nu}{\rightleftarrows} CH_2-(CH_2)_n-\dot{C}H-CH{=}CH-CH_2.$$

Under these conditions, the overall spin concentration remains constant. The reverse transition at liquid nitrogen temperature can be achieved on irradiation with ultraviolet light ($\lambda \leqslant 3400$ Å).

During recent years, the first quantitative data have been obtained for type 5*sp* and 6*sp* isomerisation rate constants. In a study of the photolysis of a mixture of acetone and ethylene (165 — 230°C, $P \simeq 104$ mmHg), Endrenyi and LeRoy[79] succeeded in estimating quantitatively the relative contributions of the reactions of n-propyl radicals. The radicals were obtained by the addition of $CH_3^{\cdot}$ to ethylene. The presence of isohexane among the reaction products was regarded by the authors as evidence that some of the n-pentyl radicals isomerise to s-pentyl radicals. The rate constant for the rearrangement

$$\text{n-}\dot{C}_5H_{11} \rightarrow \text{s-}\dot{C}_5H_{11} \qquad (17)$$

was found to be

$$k_{17} = 10^{7.148} \exp(-10800/RT)\ s^{-1}.$$

Watkins and Ostreko[80] studied the photolysis of a mixture of azobutane and ethylene at temperatures in the range 79 — 132°C and a pressure of about 55 mmHg. The presence of s-hexyl radicals in the system is indicated by the presence of 3-methylheptane in the products. Using the method of a previous investigation[79], the rate constant for the isomerisation

$$\text{n-}\dot{C}_6H_{13} \rightarrow \text{s-}\dot{C}_6H_{13}, \qquad (18)$$

was determined:

$$k_{18} = 10^{7.3 \pm 1.0} \exp[(-8300 \pm 1700/RT)]\ s^{-1}.$$

Rabinovitch and coworkers[14] studied the isomerisation of vibrationally excited alkyl radicals: heptyl-3· (Hp3·), octyl-4· (Oc4·), octyl-2· (Oc2·), 3-methylpentyl-2· (3MP2·), nonyl-2· (N2·), 3-methylhexyl-2· (3MH2·), and 3,3-dimethylhexyl-2· (33DMH2·). In all cases the radicals formed were chemically activated by the addition of a hydrogen atom to the corresponding alkene at room temperature. The results are compiled in Table 2, which also includes the rate constants for the competing isomerisation reactions expressed relative to the 5*ss* process, the rate of which was assumed to be unity.

Table 2 shows that the radicals the isomerisation of which is energetically feasible (i.e. for $N \geqslant 5$) rearrange almost completely and in most cases the isomerisation is the fastest process among those occurring in the given systems.

Table 2. Relative rates of isomerisation of radicals.

Radical	5sp	5 ss	5 pp	6 sp	6 ps	6 ss	7 ss	Products and absolute rates of dissociation of C-C bonds, 10^5 s^{-1}	
Hp3·	—	1(7.5)[a]	—	—	<1(<7.5)	—	—	B1+*n*-Pr·	1.2
Oc4·	—	1(2.1)	—	—	—	—	—	H1+Et	0.14

33DMH1·	—	—	—	(<200)	—	—	—	C_2H_4+2MP2·	4.0

[a] The numbers in round brackets denote the ratio of the rate of isomerisation to the rate of decomposition indicated in the last column.

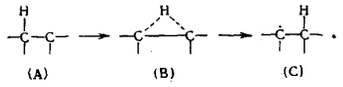
[b] The rates of decomposition have been estimated to within a factor or two.

Examination of the data leads to the conclusion that the isomerisation of alkyl radicals with hydrogen migration, proceeding via five-, six-, and seven-membered cyclic transition states, is possible. This process must undoubtedly be taken into account when specific free-radical reactions are considered.

V. THE MECHANISM OF THE MIGRATION OF HYDROGEN IN ALKYL RADICALS

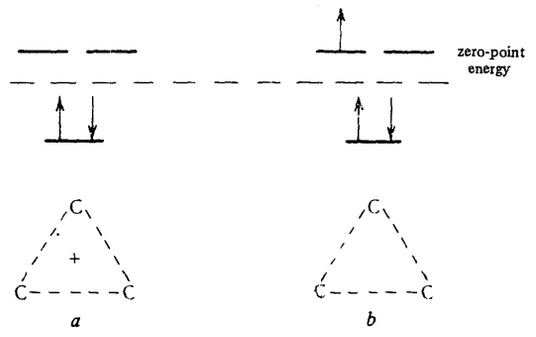
When examining the literature on the rearrangement of alkyl radicals, one cannot avoid the problem of the mechanism of hydrogen migration. Unfortunately the detailed mechanisms of the rearrangements have been little investigated and only hypothetical views have been expressed on this problem.

At the present time the hypothesis of Kossiakoff and Rice[65] that hydrogen migration in long-chain radicals proceed via a cyclic transition state is generally accepted. However, the possibility of forming a three-membered complex on transfer of hydrogen from a carbon atom to an adjacent carbon atom is nevertheless still open to some doubt[14]. Indeed approximate quantum-mechanical calculations show that a three-membered transition state should have a high activation energy, since "attack" on the bond takes place at an angle different from the most favourable angle, as a result of which the ring is strained[10,11]. In the rearrangement of a substance (A) to a substance (C), there is an intermediate with a configuration (B):



(A) (B) (C)

The activation energy for the rearrangement is determined by the energy difference between the compound (A) and the intermediate complex (B). The triatomic structure (B) has three orbitals, one of which is bonding and the other two are degenerate antibonding. In the case of the carbonium ion, the tendency of which to rearrange is well known, there are only two electrons and these can be assigned to the lowest bonding orbital (Fig. *a*).



Energy levels for a three-orbital three-carbon system[11].

The free electron of the radical must pass to one of the antibonding orbitals (Fig. *b*) which destabilises the system and increases its energy. The stabilisation and decrease of the energy of the transition state (B) are achieved by a redistribution of electron density which occurs during the shift of the migrating group, which in turn is determined by its nature (see for example data on the migration of aryl groups[81]). On the other hand, the 1 — 2 migration of halogen atoms, which take place fairly readily[13], cannot be understood on the basis of the foregoing considerations. Mayants[82] explains this contradiction by a difference between the vibration frequencies and modes of substituted and unsubstituted radicals. He believes that the rate of rearrangement is largely determined by the probability of the occurrence of the required transitional configuration as a result of intramolecular vibrations. On the other hand, the probability of the formation of such a transition state increases, other conditions being equal, with decrease of the vibration frequencies. One may expect[72] that, for radicals containing a halogen atom or an aryl group in the α-position relative to the free valence, the frequencies of the vibrations responsible for the formation of the transitional configuration will decrease in relation to unsubstituted radicals both as a result of the increase of the mass of the substituent and probably owing to a decrease of the deformation force constant. Therefore in substituted radicals one should expect an increase of the rearrangement rate constant (the 1 — 2 migration of the halogen and the aryl group) compared with the rearrangement of the unsubstituted radical (1 — 2 migration of hydrogen). If, on the other hand, the substituent is an alkyl group, then, according to Freidlina[72], isomerisation involving the migration of hydrogen atoms more remote from the radical centre and a more favourable angle of attack may compete with the 1 — 2 migration of the alkyl group.

On the other hand, if 1 — 2 and 1 — 3 migration of hydrogen is difficult on energetic grounds, the steric factors governing the rate constants for such processes should be fairly high. Indeed, within the framework of

absolute reaction rates, the pre-exponential factor for gas-phase reactions

$$A = \varkappa e \frac{kT}{h} e^{\frac{\Delta S^+}{R}}$$

is determined by the activation entropy ΔS^*, which is equal to the difference between the entropies of the activated and initial states of the system. For reactions proceeding via a three-membered cyclic activated complex, the entropies of the complex and the reactant differ mainly in terms corresponding to the loss of one hindered internal rotation and the change of the frequencies in the activated complex. This difference is of the order of −4 cal mole^{-1} deg^{-1}. On the other hand, rearrangements proceeding via five- and six-membered, etc. transition states lead to a loss of 4, 5, and more internal rotations in the complex. This greatly reduces the A factors for such rearrangements. Thus we observe the following situation: processes with 1 — 2 migration of hydrogen are characterised by a high activation energy and a high pre-exponential factor, while the kinetic parameters for many-centre processes are lower. Therefore in the series of 1 — 2, 1 — 3, 1 — 6, ... migrations of hydrogen one should expect the appearance of a compensation effect.

It is noteworthy that the anomalously low pre-exponential factors for reactions (17) and (18) cannot be accounted for within the framework of the theory of absolute reaction rates. This led Endrenyi and LeRoy to the conclusion[79] that reaction (17) has a transmission coefficient $\varkappa \ll 1$. However, experiments with added inert gases[80] did not show changes in the measured rate constant, which is evidence that the process is adiabatic. In order to account for the extremely low entropy of activation for these reactions, Watkins and Ostreko[80] proposed the model of a "rigid" cyclic transition state with very strong terminal interactions due to the fact that the hydrogen atom belongs to both "ends" of the radical. In this case the force constants of the low-frequency vibrations in the complex increase rapidly, which causes a decrease in entropy activation for the reaction in addition to a decrease owing to the loss of capacity for certain types of internal rotation.

Heterocycles Containing the Indole Residue

G.I.Zhungietu and G.N.Dorofeenko

The review describes the latest advances in the synthesis of heterocyclic compounds containing the indolyl residue, among which many physiologically active substances have been found. It is the first attempt at a general and systematic account of the extensive literature data on this subject.

I. INTRODUCTION

The pronounced physiological activity of many indole derivatives such as reserpine, serotonin, tryptamine, tryptophan, lysergic acid, etc. has aroused an unflagging interest among chemists and pharmacologists in the chemistry of indole over a period which now runs into several decades. Compounds in which the indole ring is condensed with heterocyclic compounds (numerous derivatives of carbolines, eserine, etc.) are of the greatest interest. However, during recent years there has been a considerable growth of interest in heterocyclic compounds containing the indole residue. Here one should include numerous indolyl derivatives of pyridine, piperidine, pyrrolidine, piperazine, etc. Many physiologically active compounds have been found among them. Such compounds have been isolated also from natural products—for example, the antiobiotics indolemycin and pimprinine.

Extensive data have accumulated in this field, however, they are widely scattered and hitherto have not been described systematically. Therefore we attempted to fill this gap bearing in mind that a review of this kind may prove useful in the choice of a further course of study on the preparation of new pharmacologically active indole derivatives.

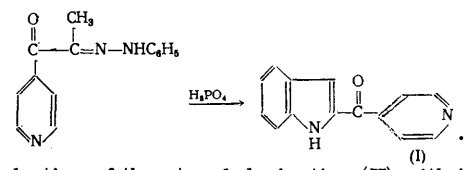
II. PYRIDINE DERIVATIVES OF INDOLE

Among indolyl derivatives of heterocycles, pyridine and piperidine derivatives probably play the most important role. The high interest in these compounds is partly due to the fact that among them many pharmacologically valuable preparations have been found and also because of their suitability as starting materials for studies on the synthesis and preparation of many indole alkaloids.

1. Indolylpyridines

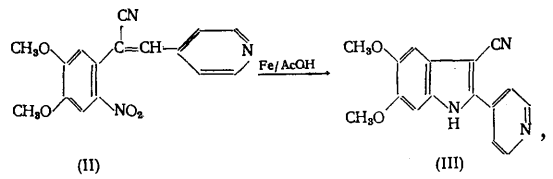
The Fischer indole synthesis is widely used for the preparation of indolylpyridines. For example, the cyclisation of the phenylhydrazones of 2-acetylpyridine in the presence of polyphosphoric acid leads to 2-(2-pyridyl)-indole [1,2]. 2-(3-Pyridyl)indole [1-4], 2-(4-pyridyl)indole [1,3], and 2-(5-ethyl-2-pyridyl)indole [1] were synthesised in the same way. Some of these compounds exhibit a diuretic activity and others may be used to reduce aldosterone concentration or in the treatment of cardiovascular diseases [5]. In addition, certain chemical reactions of the indolylpyridines synthesised have been investigated, such as, for example, their conversion into Mannich bases and cyanoethylation [1].

2-Isonicotinoylindole(I) was also synthesised by the Fischer reaction [6]:



(I)

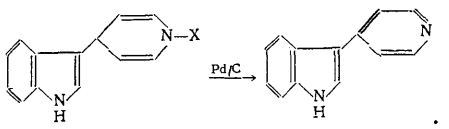
The reduction of the styryl derivative (II) with iron in acetic acid constitutes a very convenient synthesis of 5,6-dimethoxy-2-(4-pyridyl)indole-3-carbonitrile (III),



(II) (III)

and also of its thiophen and furan analogues [7].

3-(4-Pyridyl)indole (IV) is formed as a result of the debenzoylation and simultaneous dehydration of the *N*-benzoyl derivative (V) with atmospheric oxygen [8,9]. It can be obtained in large amounts by refluxing compound (V) in phenyl ether in the presence of palladised charcoal and one equivalent of dibenzylamine [10]:

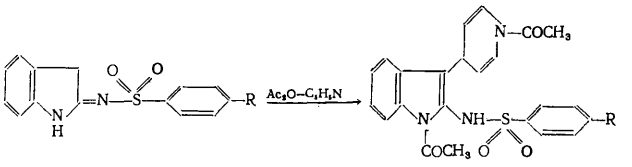


(V, X=C_6H_5CO)
(VI, X=CN)

(IV)

Compound (V) is readily formed from indole, pyridine, and benzoyl chloride [8]. Products with a similar structure are formed by quinoline, isoquinoline, phenanthroline, and scatole [9].

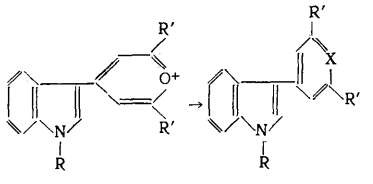
Another example of this kind of reaction is the formation of dihydropyridines of type (VII) from indole and tosyl azide or *N*-acetylsulphanilyl azide [11]:



(VII, R=CH_3, $NHCOCH_3$)

The benzoyl derivative (V) reacts with benzaldehyde to form diphenyltetrahydroindolocarbazole [12], while its analogue (VI) decomposes with formation of indole on treatment with 2% NaOH in aqueous alcohol [13].

The reaction, proposed by Dorofeenko et al. [14], of ammonia with indolylpyrylium salts (VIII), obtained by the interaction of (3-indolyl)-1,5-diketones with triphenylmethyl perchlorate, constitutes a very convenient method for the preparation of 4-(3-indolyl)pyridines (IX) containing various substituents in the pyridine ring. Treatment of compound (VIII) with tri(hydroxymethyl)phosphine in pyridine yields the phosphorus analogues (IX)—derivatives of indolylphosphabenzene (X): [15]

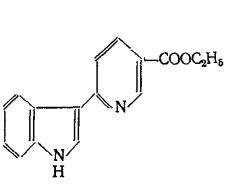


(VIII)

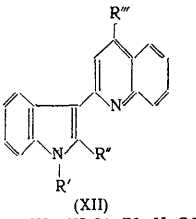
(IX, X=N)
(X, X=P)

This reaction may be of definite interest, since the salts (VIII) are readily formed in high yield also on treatment of *N*-substituted indoles with two moles of a 2,6-diarylpyrylium salt in dimethylformamide (DMF). [16]

Activated pyridine derivatives, such as the *N*-oxides, have been recommended as convenient starting materials for the synthesis of pyridine derivatives of indole. 2-(3-Indolyl)-5-ethoxycarbonylpyridine (XI) is formed from indole and the *N*-oxide of ethyl nicotinate in the presence of benzoyl chloride [17], while quinoline *N*-oxides yield a series of 2-(3-indolyl)quinoline derivatives of type (XII). [17] These reactions have been widely investigated in the interaction between indole, 2-phenylindole, and 1-methyl-2-phenylindole with *N*-acyloxyquinolinium, *N*-acyloxyisoquinolinium, and *N*-acyloxylepidinium derivatives [18]:



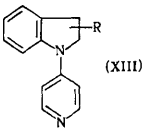
(XI)



(XII)

R'=H, CH_3, CH_3CO; R''=H, C_6H_5; R'''=H, Cl.

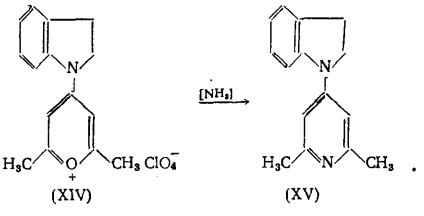
A series of pyridine derivatives of indoline have been described. For example, *N*-(4-pyridyl)indolines of type (XIII) can be readily obtained by fusing together the hydrochlorides of 2,3-dihydroindoles with *N*-(4-pyridyl)-pyridinium chloride [19,20]:



(XIII)

N-(5-Nitro-2-pyridyl)indolines, which have been recommended as polymer stabilisers, can be synthesised by the reaction of 2-chloro-5-nitropyridine with indolines at 80–110°C. [21]

1-(2,6-Dimethyl-4-pyridyl)indoline (XV) is formed in a high yield when 4-(1-indolinyl)-2,6-dimethylpyrylium perchlorate (XIV), obtained from indoline and 4-methoxy-2,6-dimethylpyrylium perchlorate, is treated with ammonium acetate or carbonate [22].



(XIV)

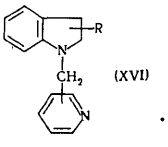
(XV)

The synthesis of indolines containing the isoquinoline residue by the interaction of benzoylisoquinolinium chloride with *N*-substituted indolines was described recently [23]. 1-Acylpyridinium salts are converted by the same reaction into 5-pyridylindolines [24] and 1-acylquinolinium salts give rise to 5-(2-quinolyl)indolines [25].

Many of the pyridine derivatives of indolines suppress the motor capacity of animals stimulated by amphetamine, suppress the orientation reflex, and sharply prolong the duration of Nembutal narcosis in mice, while exhibiting a moderate antiserotonin activity [19].

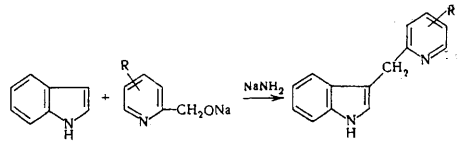
2. Indolylmethylpyridines

Pyridylmethylindolines (XVI) are obtained by the reaction of chloromethylpyridines with indoline [19]:



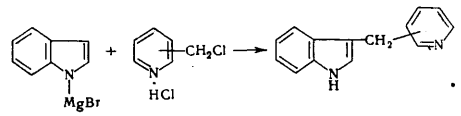
(XVI)

Other methods of synthesis are also known. One of these consists in the interaction of sodium salts of 2-hydroxymethylpyridines with indole [26]:



(R = 3-CH_3, 5-CH_3, 6-CH_3, 5-C_2H_5)

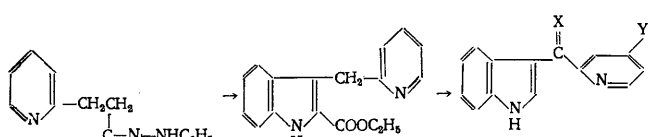
Another involves the interaction of indolylmagnesium bromide with chloromethylpyridine hydrochloride [27]:



Certain 2-scatylpyridines (and their iodides) exhibit anticholinergic and antihistamine activities [28].

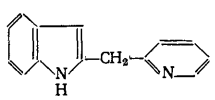
The interaction of indole-3-aldehyde with 2-pyridyllithium leads to the formation of (3-indolyl)(2-pyridyl)methanol (XVII). [29] The same compound is formed when indolylmagnesium halides react with 2-formylpyridine at −25°C, together with a small amount of di-indolylpyridylmethane [30]. The corresponding carbinols form 4-formylpyridine and 3-formylisoquinoline [30].

2-Scatylpyridine can be readily obtained by the Fischer reaction [31]:



(XVII, X=H,OH, Y= H)
(XVIII, X=H_2, Y=H)
(XX, X=O, Y=H)
(XXI, X=H_2, Y=CH_3)

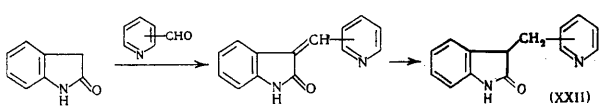
It has also been shown [31] that 2-scatylpyridine (XVIII) rearranges in the presence of $AlCl_3$ to 2-(2-indolylmethyl)pyridine (XIX) and on oxidation with selenium dioxide is converted into 3-indolyl-2-pyridyl ketone (XX).



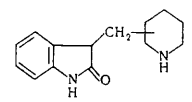
(XIX)

The hydrogenation of 4-methyl-2-scatylpyridine (XXI) methiodide and phenylethiodide, obtained by the Fischer method from the phenylhydrazone of (4-methyl-2-pyridyl)propionaldehyde, leads to tetrahydropyridine, which is cyclised under the influence of phosphoric acid to indolo-[2,3-*f*]morphan. [32] These compounds exhibit analgesic, expectorant, and anti-inflammatory activity.

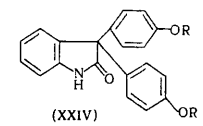
Oxindoles containing pyridylmethyl residues (XXII) are formed when oxindole is condensed with formylpyridines and the products are hydrogenated in ethyl acetate at 20°C in the presence of palladium on charcoal [33]. Further hydrogenation in ethyl acetate at 75°C or in acetic acid gives piperidine derivatives (XXIII). The latter exhibit a marked cholinergic effect [33].



(XXII)



(XXIII)



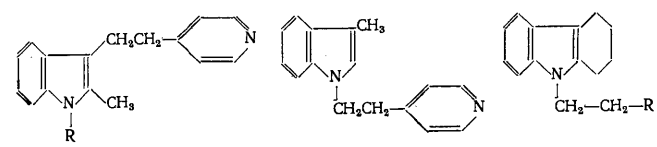
(XXIV)

[R = 3-pyridinoyl or (3-pyridyl)acryloyl]

Pyridine derivatives of oxindole of type (XXIV) were found to have a laxative effect [34].

3. Indolylethylpyridines

The pyridylethylation reaction has led to the wide employment of indole for the synthesis of pyridine derivatives [35]: in an acid medium it leads to 3-pyridylethylindole derivatives and in an alkaline medium it involves the indole nitrogen atom [36]. 4-Vinylpyridine reacts with 2-methylindole in boiling acetic acid to form 2-methyl-3-(4-pyridylethyl)indole (XXV) in 54% yield, while 1-ethylindole gives under the same conditions 1-ethyl-3-pyridylindole [37]. In the presence of sodium ethoxide, scatole reacts with 4-vinylpyridine to form 3-methyl-1-pyridylethylindole (XXVI) in 38% yield [37]. The same product is obtained albeit in an insignificant yield on prolonged refluxing of the reactants in acetic acid [37]. In the indole series, the same type of behaviour may be noted also for the Michael reaction, where, for example, acrylonitrile reacts with 2-phenylindole to form 1-cyanoethyl-2-phenylindole when catalysed by bases and 3-cyanoethyl-2-phenylindole when catalysed by acids [38]:



(XXV, R=H)
[XXIX, R = 2-(4-pyridyl)ethyl]

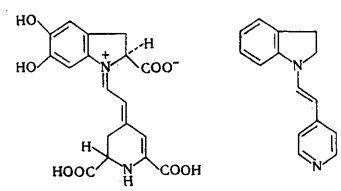
(XXVI)

(XXVII, R = 4-pyridyl)
(XXVIII, R = 2-pyridyl)

It was found that 3-(4-pyridylethyl)indole may increase the stimulation of motor activity by amphetamine [37]. 1-Pyridyl-2,3-tetramethyleneindoles (XXVII) and (XXVIII) and their salts stimulate the activity of the central nervous system [39].

Kost and coworkers [40] suggested that a higher-boiling alcohol be employed for the pyridylethylation reaction and obtained a greater number of pyridylethyl derivatives of indole when the reaction was carried out in hexyl alcohol.

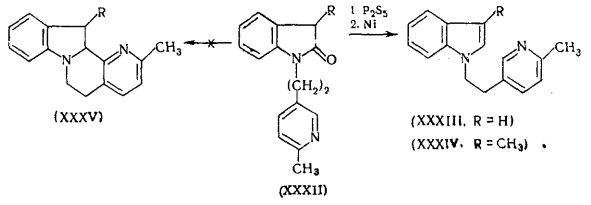
Pyridylethylation of indolines in acetic acid leads to *N*-pyridylethylindolines [19,41]. Analogues of these products have been detected in natural products, for example betanidine (XXX). [42] A simpler analogue (XXXI) was obtained by the condensation of *N*-formylindoline with γ-picoline. [43] Total synthesis of neobetanidine and neobetenamine-derivatives has been achieved [44]:



(XXX)

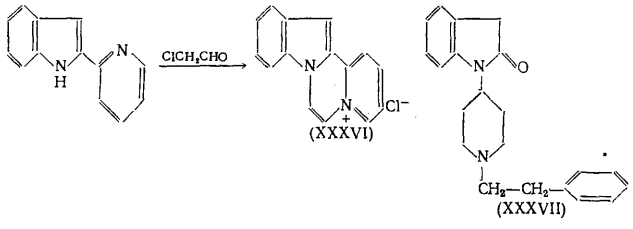
(XXXI)

The 1-(3-pyridyl)ethyl derivative (XXXIII) can be obtained via the corresponding oxindole derivative (XXXII, R = H):[45]



(XXXV) (XXXII) (XXXIII, R = H) (XXXIV, R = CH_3)

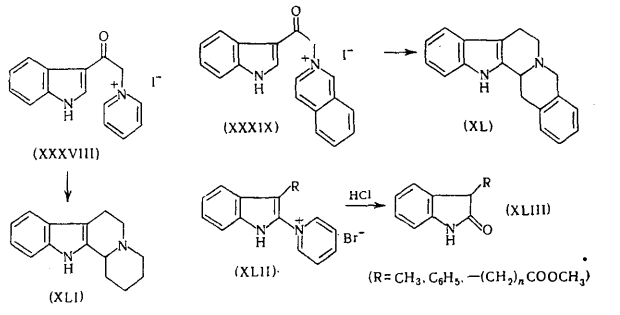
Compound (XXXIV) was synthesised according to the same scheme[46]. Certain reactions of compounds (XXXIII) and (XXXIV) have been investigated: bromination, nitration, the Mannich reaction, and formylation[41]. Compound (XXXII) could not be cyclised to the eburnamenine derivative (XXXV).[47] Its tetracyclic analogue (XXXVI) can be synthesised in a slightly different way[48]:



(XXXVI) (XXXVII)

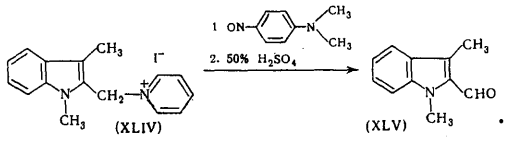
Biological tests showed that many bispyridylethyl derivatives of indole of type (XXIX) and also their piperidine analogues exhibit anticonvulsant activity[49]. The methiodide of compound (XXXII, R = CH_3) has a very pronounced curarelike activity at dilutions of the order of 1 : 10 000, the reactivity being extremely specific, since it disappears in the absence of the methyl group at the 3-carbon atom of the indole ring[45]. Oxindole derivatives of type (XXXVII) and their salts with non-toxic acids were found to have an analgesic activity and absorb ultraviolet light, which makes them valuable for protection from sunlight[50].

Certain indacylpyridium salts (XXXVIII), formed in the interaction between indolylmagnesium halides and iodoacetyl chloride followed by condensation with pyridine[51], should probably be also included in the section on pyridylethylindole compounds. They are obtained in better yields and in only one stage from 3-acetylindole, iodine, and a pyridine (or quinoline and isoquinoline) base via the King reaction[52,53]. These compounds are of interest also as starting materials for the synthesis of many indole alkaloids. In particular, the reduction of the salts (XXXIX) with lithium aluminium hydride and subsequent cyclisation constitute the simplest method for the formation of the yohimbine system (XL).[53] The reduction can also be carried out with sodium borohydride[54]. For example, compound (XLI) was synthesised in this way[55]:



(XXXVIII) (XXXIX) (XL) (XLI) (XLII) (XLIII) (R = CH_3, C_6H_5, $-(CH_2)_nCOOCH_3$)

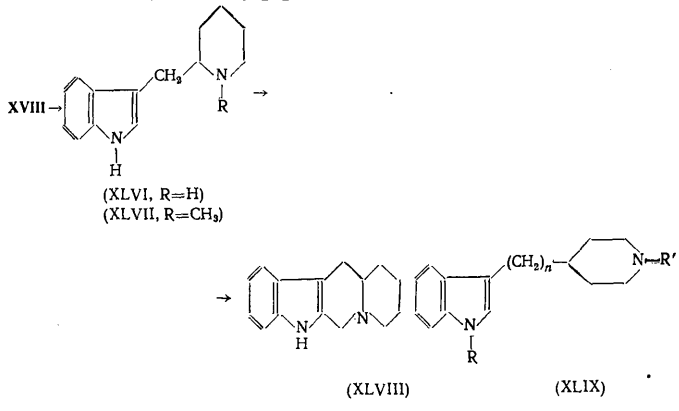
Many *N*-indolylpyridinium salts (XLII) are obtained by the bromination of indoles in the presence of pyridine bases and are then converted into oxindole derivatives (XLIII).[56-58] The salt (XLIV), formed when 1,2,3-trimethylindole is treated with iodine in pyridine, is subsequently converted into 2-formyl-1,3-dimethylindole (XLV):[59]



(XLIV) (XLV)

III. PIPERIDINE DERIVATIVES OF INDOLE

The principal method for the preparation of indolylpiperidines is reduction of the corresponding pyridines. When the pyridine derivative (XVIII) is hydrogenated in the presence of a palladium catalyst in an alcohol–acetic acid mixture, 2-scatylpiperidine (XLVI) is formed:



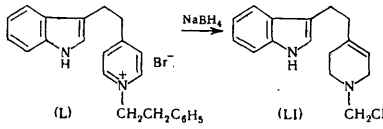
(XLVI, R=H) (XLVII, R=CH_3) (XLVIII) (XLIX)

It is methylated to compound (XLVII) and on treatment with formaldehyde and formic acid is converted into indolohexahydroquinolizine (XLVIII).[29] 1-Methyl-2-scatylpiperidine (XLVII) can also be obtained by the condensation of isatin with α-picoline and the reduction of the resulting dioxindole with sodium in butanol followed by *N*-methylation[60].

The hydrogenation of (3-indolyl)(4-pyridyl)methanol in the presence of Adams catalyst leads to 4-scatylpiperidine (XLIX, n = 1, R,R′ = H), which may be methylated with chloral[61] to the *N*-methyl derivative (XLIX, n = 1, R = H, R′ = CH_3).[30]

Catalytic hydrogenation of pyridylethylindoles in the presence of a platinum catalyst in glacial acetic acid or in aqueous alcoholic HCl leads to the formation of the corresponding piperidines (XLIX, n = 2, R = H or CH_3, R′ = H, CH_3, $C_6H_5CH_2$, etc.). In tests on mice these compounds were found to have an analgesic activity comparable with that of morphine[63]. An approximately similar activity is observed for compounds containing the phenylethyl, benzyl, and phenylacyl residues at the piperidine nitrogen atom; substitution of the indole nitrogen atom has an unfavourable effect on the activity[63].

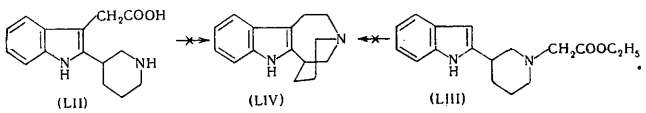
The reduction of salts of type (L) with sodium borohydride gives rise to piperidines (LI):[63]



(L) $CH_2CH_2C_6H_5$ (LI) $CH_2CH_2C_6H_5$

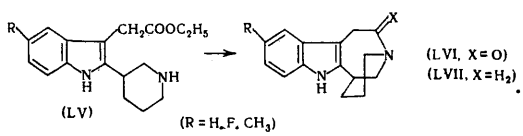
There are many other examples of the reduction of pyridinium salts with sodium borohydride. For example, this reaction has been used to prepare 2-(3-piperidinyl)-indole-3-acetic acid [62] (LII). In general, the reduction of salts of 3-substituted pyridinium with sodium borohydride to 1,3-disubstituted 1,2,5,6-tetrahydropyridines is a well known reaction [64].

Numerous attempts have been made to cyclise the aminoacid (LII) and also the piperidine derivatives (LIII) to the ibogamine structure (LIV), but were unsuccessful: [62]



(LII) (LIV) (LIII)

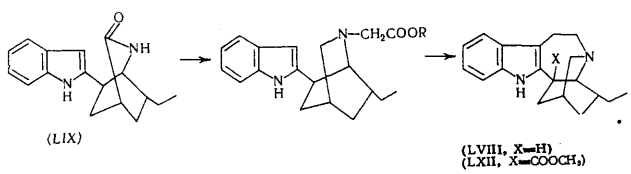
The search for methods of synthesis of systems similar to the ibogamine molecule is important for practical applications, since this alkaloid from *Tabernanthe iboga* (*Apocynaceae*) is well known to have a psychotomimetic activity. An extremely elegant solution has been recently found for the above problem [65]:



(LV) (R = H, F, CH_3) (LVI, X = O) (LVII, $X = H_2$)

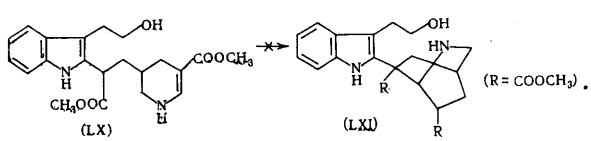
The piperidine derivatives (LV) were converted into ketones (LVI) at a reduced pressure and a temperature of 165–170°C and the ketones themselves were reduced further to compound (LVII) with lithium aluminium hydride in monoglyme.

Epi-ibogamine (LVIII) can be obtained from the piperidinone (LIX): [66]



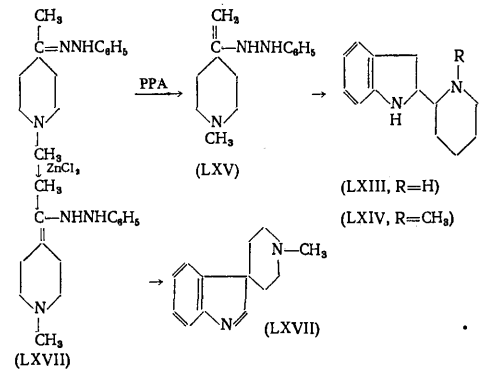
(LIX) (LVIII, X=H) (LXII, X=$COOCH_3$)

Wenkert et al. [67] were unable to cyclise the tetrahydronicotine derivative (LX) to the quinuclidine compound (LXI), which they intended to convert into coronaridine (LXII):



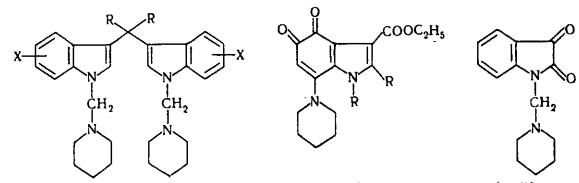
(LX) (LXI) (R = $COOCH_3$)

The piperidine derivative (LXIII) was obtained both on reduction of the corresponding pyridine derivative [62,68] and via the Schmidt reaction from 2-(2-indolyl)cyclopentanone [69]. Its *N*-methyl derivative (LXIV) is formed via the Fischer reaction on treatment of the phenylhydrazone of 4-acetyl-1-methylpiperidine with polyphosphoric acid, probably via the intermediate (LXV). It is interesting that, when zinc chloride is employed in this reaction, the cyclisation is completed by the formation of the 3*H*-indole derivative (LXVII), probably via the intermediate (LXVI): [70]



(LXV) (LXIII, R=H) (LXIV, R=CH_3) (LXVII)

The Mannich reaction has been used to synthesise piperidine derivatives of indole:



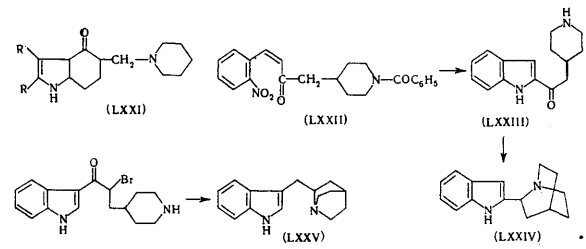
(LXVIII) (LXIX) (LXX)

(X = NO_2, halogen; R, R' = H, CH_3, C_3H_7)

Compounds of type (LXVIII) synthesised in this way and also their morpholine analogues act on the central nervous system [71].

Tests of the antimicrobial properties of indolequinones (LXIX) showed that they are not appreciably active [72]. A high antiviral activity was found in piperidine derivatives of isatin of type (LXX) [73] and the Mannich bases (LXXI) obtained from 6,7-dihydroindol-4(5*H*)-ones proved to be effective depressants of the central nervous system [74].

On heating with triethyl phosphite and subsequent debenzoylation, the *o*-nitrostyrene derivative (LXXII) gives 2-(4-piperidinyl)acetylindole (LXXIII), the reduction of which with sodium borohydride and subsequent refluxing in decalin lead to the quinuclidine derivative (LXXIV): [75]



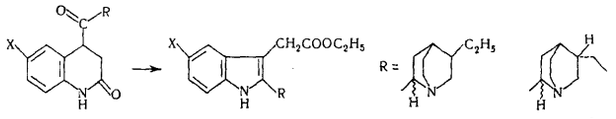
(LXXI) (LXXII) (LXXIII) (LXXV) (LXXIV)

Scatylquinuclidine (LXXV) can be obtained similarly via a stage involving the formation of the 3-indolylpiperidine derivative [76].

A mixture of epimers of quinuclidine derivatives (LXXVII) is formed when 2-oxohexahydrocinchoninones (LXXVI) are heated with hydrogen chloride in alcoholic solution [77,78].

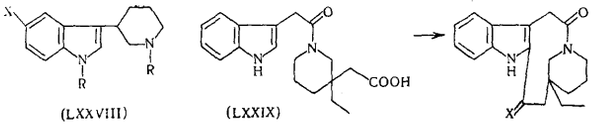
A series of 3-(3-indolyl)piperidines (LXXVIII) were obtained by heating salts of α-indolylglutaric acid with the corresponding amine without a solvent and by the reduction

of the resulting piperidinediones with lithium aluminium hydride[79]. 3-(1-Methyl-3-indolyl)piperidine (LXXVIII, R = CH_3, R′, X = H) and its *N*-methyl derivative (LXXVIII, X = H, R, R′ = CH_3) have a prolonged sedative effect, the second compound also showing some analgesic activity[79].



(LXXVI) (LXXVII) (X = H, CH_3O)

The synthesis of the alkaloid quebrachamine (LXXXI) by the cyclisation of an acylpiperidine (LXXXIX) in polyphosphoric acid and subsequent reduction of the diketone (LXXX) has been described[80]:



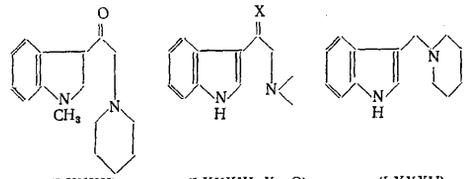
(LXXVIII) (LXXIX)

(LXXX, X = O)
(LXXXI, X = H_2)

1-[γ-(3-indolyl)propyl]piperidine can be conveniently synthesised from indole-3-propionic acid and piperidine[81].

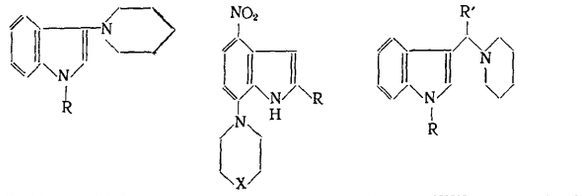
Prolonged refluxing of 3-chloroacetyl-1-methylindole with piperidine in alcohol leads to 1-methyl-3-(*N*-piperidinylacetyl)indole (LXXXII).[82]

When aminoketones of type (LXXXIII) are reduced with lithium aluminium hydride or by hydrogenation over nickel, the aminoalcohols (LXXXIV)[83]—the indole analogues of adrenaline—are formed[83]:



(LXXXII) (LXXXIII, X=O) (LXXXV)
(LXXXIV, X=H,OH)

When the molecules of these alcohols contain a secondary amino-group, they increase arterial blood pressure, but the presence of a tertiary amino-group (piperidine, morpholine, and other residues) leads to a lowering of arterial blood pressure and reduces the tone of the peripheral vessels[83]:



LXXXVI, R=H, CH_3, CH_3CO) (LXXXVII, X=CH_2; R=H,$COOC_2H_5$) (LXXXIX,R=H,R′=CN)
(LXXXVIII, X=NCH_3) (XC, R=CH_3,R′=CN)
(XCI, R=CH_3; R′=CH_2NH_2).

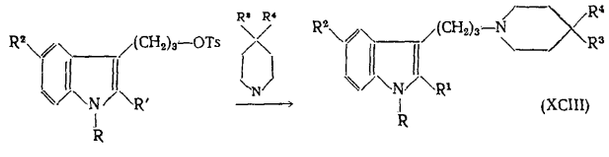
Piperidine can be *N*-alkylated with gramine[84], *N*-acetylindoxyl[85], and 7-chloro-4-nitro-derivatives of indole[86] with formation of the piperidine derivatives (LXXXV), (LXXXVI), and (LXXXVII) respectively.

When the lithio-derivative of piperidine reacts with 5-bromoindole, a mixture of 4-(1-piperidinyl)indole (60%) and 5-(1-piperidinyl)indole (40%) is formed in 59% yield.

The same substances can be isolated also as a result of the interaction of 4- and 5-aminoindoles with 1,5-dibromopentane[87].

The reduction of the nitrile (LXXXIX) and its *N*-methyl derivative (XC), obtained by the Strecker reaction, with lithium aluminium hydride has been investigated[88]. It was found that the reduction is somewhat unusual: the nitrile (LXXXIX) is converted into *N*-scatylpiperidine and compound (XC) gives rise to the tryptamine derivative (XCI).[88]

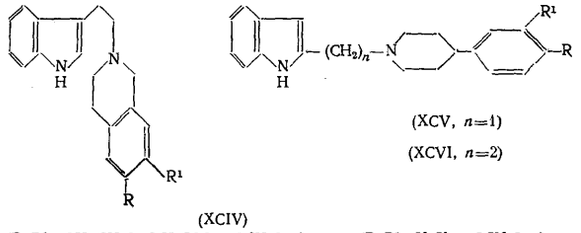
A pronounced sedative, analgesic, spasmolytic, anti-inflammatory, and hypocholesteremic activity was found in a number of piperidine derivatives of type (XCIII) formed when 1-(3-indolyl)-3-propyl *p*-toluene sulphonate (XCII) reacts with 4,4-disubstituted piperidines in alcohol in the presence of potassium carbonate[89-91]:



(XCII) (XCIII)

[R, R^1 = H, alkyl, or aryl; R^2, R^3 = H, alkyl, alkoxy, alkylthio, halogen, CN, etc.; R^4 = aryl, $N(Alk)_2$, or R^3; R^4 = alkylene or a heterocyclic residue].

In order to investigate the dependence of the physiological activity of reserpine on its structure, a series of 2-[β-(3-indolyl)ethyl]-1,2,3,4-tetrahydroquinolines (XCIV) were synthesised[92]:

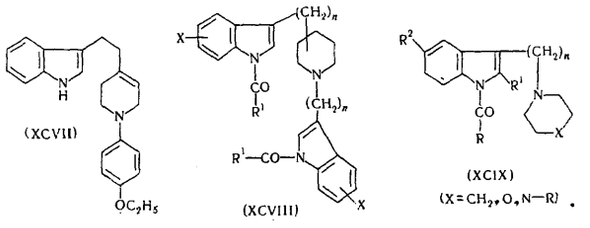


(XCV, *n*=1)
(XCVI, *n*=2)

(XCIV)
(R, R^1=OH, CH_3O, C_6H_5COO,—OCH_2O—) (R, R^1=H,Cl, —OCH_2O—).

The piperidine isomers (XCIII) containing the *N*-piperidinylalkyl group in the 2-position of the indole ring (XCI) are formed when isotryptamine is refluxed with ethyl β-aryl-δ-bromovalerate in xylene in the presence of potassium carbonate with subsequent reduction of the pyridones isolated under these conditions[93]. These compounds and also their salts were found to be effective analgesic and muscular relaxants[93]. The monomethyl derivative (XCV) can be obtained by the reaction of (2-indolyl)methylamine with the anhydrides of 3-aryl-substituted glutaric acids in benzene, the cyclisation of the products to piperidine-2,5-dione in acetic anhydride, and its reduction[93].

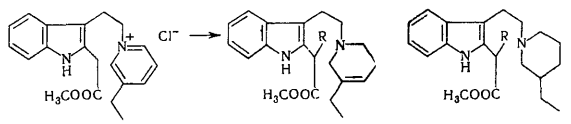
The tetrahydro-derivative (XCVII) was found to have an analgesic activity and also a vasodilating activity[94], while the piperidine derivatives (XCVIII) were found to have a sedative, hypotensive, depressant, anticonvulsive, and analgesic activity[95-97]:



(XCVII) (XCVIII) (XCIX)
(X=CH_2,O,N—R).

Anti-inflammatory, antipyretic, analgesic, antidepressant, and psychostimulating activity is shown by indolylpiperidines (XCIX) and also by their pyrrolidine, morpholine, and piperazine analogues[98]. Numerous *N*-[(1-piperidinyl)alkyl]-*N*-[(3,2,1-indolyl)alkyl)amines, which exhibit hypotensive, analgesic, psychomotor, depressant, anti-inflammatory, bacteriostatic, adrenolytic, antihelminthic, and antifungal activity, have been patented[99].

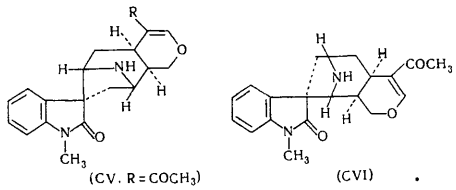
The structure of the alkaloid 16,17-dihydrosecodin-17-ol (CI), isolated from *Rhazya orientalis*, was demonstrated by synthesis from the pyridinium derivative (C):[100]



(C) (CI, R = CH_2OH) (CIII, R = CH_3) (CII, R = CH_2OH) (CIV, R = CH_3)

Tetrahydrosecodin-17-ol (CII) was isolated from the same plant and dihydrosecodine (CIII) and tetrahydrosecodine (CIV) were identified in *Rhazya stricta*[101].

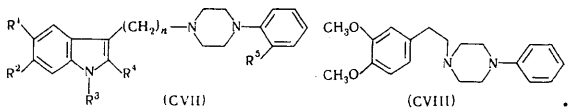
The alkaloids alstonerine (CV) and "alkaloid C" (CVI) were isolated from *Alstonia muelleriana*[102]:



(CV, R = $COCH_3$) (CVI)

IV. PYRAZINE AND PIPERAZINE DERIVATIVES OF INDOLE

A fairly considerable amount of attention is being devoted to piperazine derivatives of indole, mainly after the report in 1962 that the condensation of indolylalkanoic acids with 4-arylpiperazines followed by reduction of the resulting *N*-arylpiperazides yields 4-aryl-1-[(3-indolyl)-alkyl] piperazines (CVII) which are effective depressants of the central nervous system[103]. Among these, the highest activity was shown by compounds in which the methylene bridge consists of 2 or 3 methylene groups. Probably the activity is due to the presence of the indole moiety, because the phenyl analogue of this compound (CVIII) is inactive[103].

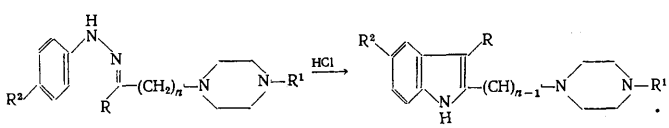


(CVII) (CVIII)

(R^1 R^2 R^3 R^4 = H, CH_3, OCH_3; R^5 = H, CH_3)

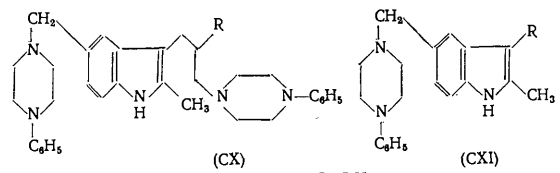
Sedatives, antipyretic agents, and muscle relaxants[104,105] and also compounds with adrenolytic, hypotensive, antipyretic, and sedative activity[106,108] were found among indolylalkylpiperazines.

A series of (2-indolyl)alkylpierazines (CIX) were synthesised by the Fischer reaction[106,107]:



(CIX)

Many compounds of type (CX) and(CXI) containing piperazine residues in the 5-position of the indole molecule were obtained[109,110]:

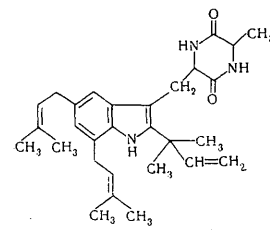


(CX) (CXI)

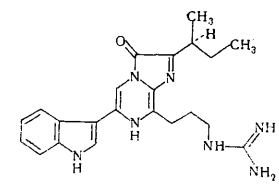
(R=H, CH_3, C_3H_7, C_4H_9, C_6H_5)

N-Scatylpiperazine is formed from (3-indolyl)methanol and piperazine[111]. Alkylation of piperazine with gramine in an aqueous medium leads to *NN*-discatylpiperazine[84]. The interaction of 6-chloro-4-nitroindole and its 2-ethoxycarbonyl derivative with 4-methylpiperazine is completed by formation of the corresponding 6-(4-methyl-1-piperazinyl)indole (LXXXVIII).[88]

Piperazine derivatives of indole have been found in natural products. Echinuline (CXII)[112,113] can be regarded as a piperazinedione in which the tryptophan residue has the configuration of a D-aminoacid and alanine has the L-configuration[114]:



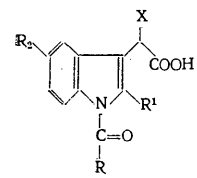
(CXII)



(CXIII)

Another natural pyrazine derivative of indole is luciferin (CXIII),[115-118] a negligible amount of which (5 mg) can produce sufficient light to read a newspaper for 30 min. It was synthesised recently[117].

Many α-halogenomethylindolylacetic acids (CXIV) containing a pyrazinecarboxylic acid residue at the nitrogen atom have been patented[119]. These acids and also their esters, amides, and salts exhibit antipyretic and anti-inflammatory activity and can be used to prevent and suppress the formation of tissue granuloma or to treat arthritis and dermatological affections[119]:



(R^1, R^2=H, Alk, Ar etc, X=CH_2Y, CHY_2, CY_3; Y=F, Cl, Br)

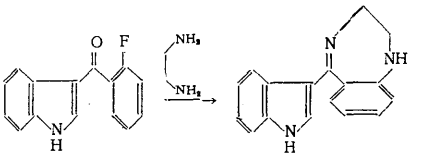
(CXIV, R=); (CXV, R=  ; R^1=CH_3; R^2=CH_3O; X=H)

Many analogues of compound (CXIV) containing aromatic and heterocyclic residues and exhibiting a considerable anti-inflammatory activity are known[120-127]. Among numerous compounds of this type, indomethacin, containing the *p*-chlorobenzoyl residue in the 1-position, may be recommended in practice. The *N*-isonicotinoyl derivative (CXV) is known to show a high anti-inflammatory activity and to be less toxic than indomethacin[129,130].

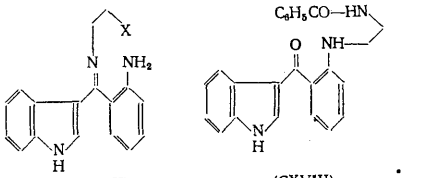
A number of analogues obtained on the basis of indole-3-carboxylic acids also show anti-inflammatory activity[128].

V. INDOLYLAZEPINES AND DIAZEPINES

5-(3-Indolyl)-2,3-dihydro-1*H*-1,4-benzodiazepines of type (CXVI), formed when 3-(*o*-halogenobenzoyl)indoles are treated with ethylenediamine in pyridine or on cyclisation of the imines (CXVII) or imides (CXVIII),[131] show antidepressant activity[132,133]:



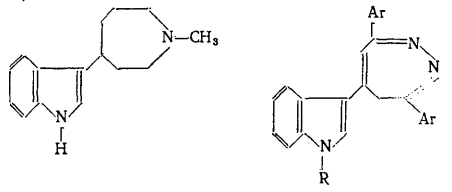
(CXVI)



(CXVII) (CXVIII)

A number of 4-indolylhexahydroazepines of type (CXIX) were found to possess an antiviral and antibacterial activity[134].

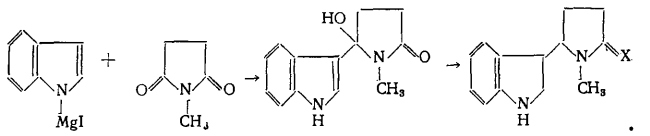
1,2-Diazepine derivatives of indole (CXX) can be simply and conveniently synthesised by the interaction of indolylpyrylium salts (VIII) with hydrazine hydrate[135]:



(CXIX) (CXX, R=CH$_3$, C$_6$H$_5$CH$_2$)

VI. INDOLYLPYRROLIDINES

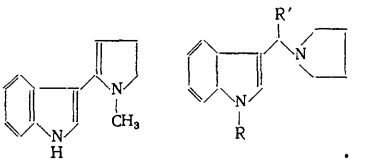
2-(3-Indolyl)-1-methylpyrrolidine-5-one (CXXI), formed by the reaction of indolylmagnesium iodide with *N*-methylpyrrolidine-2,5-dione, proved to be an effective tranquiliser[136]. It has also been reported that compound (CXXII), obtained by its reduction, inhibits the activity of pseudocholinesterase[137]:



(CXXI, X=O)
(CXXII, X=H$_2$)

N-Scatylpyrrolidine can be obtained both by the Mannich reaction[138] and by the alkylation of pyrrolidine with gramine[84].

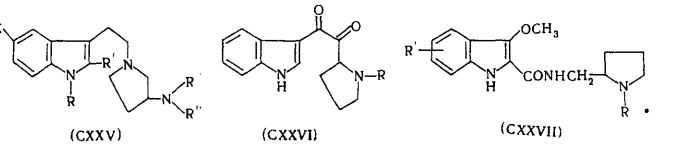
It is interesting to note that 3-(1-alkyl-2-pyrrolinyl)-indoles of type (CXXIII), which have been recommended as intermediates for the synthesis of pyrrolidinylindoles, exhibit anti-inflammatory activity and a capacity to reduce the appetite[139]:



(CXXIII) (CXXIV)

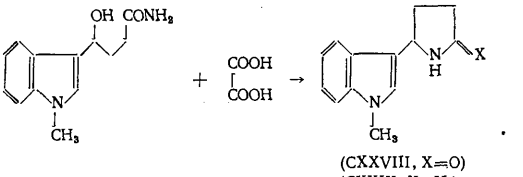
When the nitriles (CXXIV, R = H, R′ = CN) and (CXXIV, R = CH$_3$, R′ = CN) are reduced with lithium aluminium hydride, the latter compound gives rise to α-pyrrolidinyltryptamine (CXXIV, R = CH$_3$, R′ = CH$_2$, NH$_2$), while the former is converted into *N*-scatylpyrrolidine with elimination of the nitrile group[88].

3-Amino-substituted *N*-(β-indolylethyl)pyrrolidines (CXXV) were found to be capable of decreasing appreciably the tremor and muscular rigidity in Parkinson's disease[140] and the pyrrole derivative (CXXVI) was found to exhibit a depressive and an anticonvulsant activity[141]. The pyrrolidine derivatives (CXXVII) have an antipyretic effect, are capable of enhancing the effect of barbiturates, and are morphine antagonists[142]:



(CXXV) (CXXVI) (CXXVII)

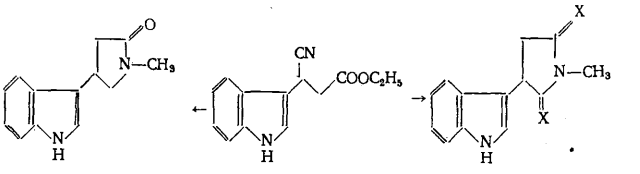
A patent was published recently for the preparation of 5-(3-indolyl)pyrrolidin-2-ones of type (CXXVIII) which exhibit antiviral and sedative activity in tests on birds and animals. Their reduction yielded the corresponding indolylpyrrolidines (CXXIX), which are used in the treatment of neuroses[143]:



(CXXVIII, X=O)
(CXXIX, X=H$_2$)

It has also been suggested that 3-(4-nitrobutyryl)indoles be used for the synthesis of derivatives of 3-(2-pyrrolidinyl)indoles, which show anti-inflammatory and anaphylactic activity and are capable of suppressing the appetite[144]. 2-(3-Indolylpyrrolidine) is obtained by the hydrogenation of 3-(β-cyanopropionyl)indole[145].

3-(3-Indolyl)-1-methylpyrrolidine (CXXX) has been synthesised by the reaction of indolylsuccinic acid[146] with 1,3-dimethylurea at 185–190°C and subsequent reduction of the resulting indolylsuccinimide (CXXXI):[146]

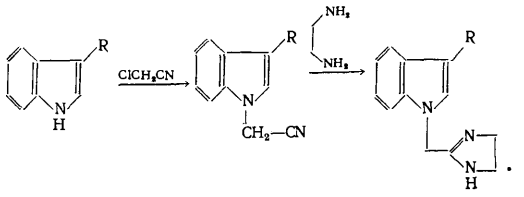


(CXXXIII) (CXXXII) (CXXX, X=H$_2$)
(CXXXI, X=O)

Hydrogenation of the nitrile (CXXXII) in the presence of a nickel catalyst at 80°C (100 atm) leads to 4-(3-indolyl)-pyrrolidin-2-one (CXXXIII) in 50% yield[147].

VII. INDOLYLIMIDAZOLES

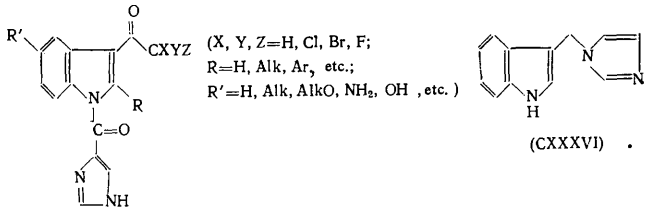
Certain 3-alkyl-1-(2-imidazolinylmethyl)indoles (CXXXIV) show vasoconstrictor activity [148]:



(CXXXIV)

A number of indole derivatives (CXXXV) containing the imidazolecarboxylic acid residue (and also carboxylic acid derivatives of pyrimidine, oxazole, thiazole, isoxazole, isothiazole, pyrazole, etc.), which may be used as intermediates in the synthesis of various derivatives of indolylacetic acids, have been patented [149,150].

1-Scatylimidazole (CXXVI) and its 2-methyl derivative are formed in the alkylation of imidazole with gramine [152]. 1-Scatylindazole, 1-scatylbenzimidazole, and 1-scatylpyrazole were obtained in the same way [153]:

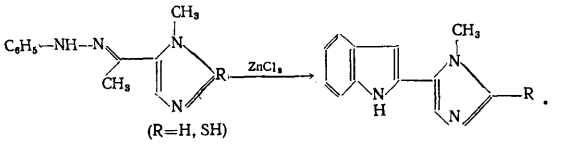


(X, Y, Z=H, Cl, Br, F; R=H, Alk, Ar, etc.; R′=H, Alk, AlkO, NH_2, OH, etc.)

(CXXXV)

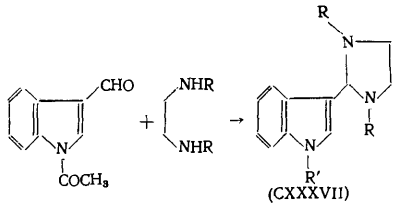
(CXXXVI)

Indole derivatives containing the imidazole residue in the 2-position in indole can be obtained by the Fischer reaction from 5-acetylimidazoles [151]:



(R=H, SH)

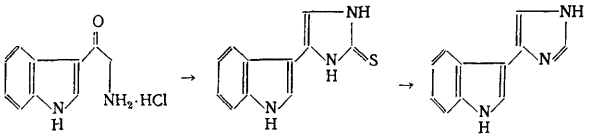
Suvorov and coworkers obtained 1,3-disubstituted 2-(3-indolyl)imidazolines (CXXXVII) from 1-acetylindole-3-aldehyde and *N*-substituted ethylenediamines [154]:



(CXXXVII)

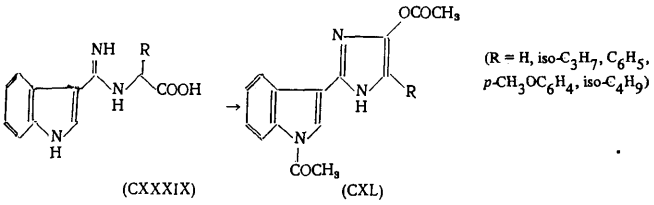
(R=C_6H_5, p-$CH_3OC_6H_4$, $C_6H_5CH_2$, p-BrC_6H_4; R′=H, $COCH_3$)

They also synthesised 4-(3-indolylimidazole (CXXXVIII) by the reaction of 3-chloroacetylindole with formamide or by treating 3-aminoacetylindole with potassium thiocyanate in the melt with subsequent elimination of sulphur from 2-mercapto-4-indolylimidazole formed [155]. The imidazole derivative (CXXXVIII) has a weak bacteriostatic effect in relation to *Mycobacterium tuberculosis* [155]:



(CXXXVIII)

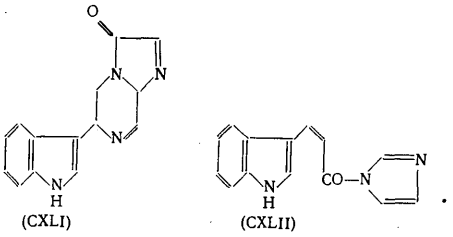
N-Acetyl derivatives of a number of 2-(3-indolylimidazoles (CXL) are formed when indole-3-carbamidicic acids (CXXXIX) are refluxed with acetic anhydride [156]:



(R = H, iso-C_3H_7, C_6H_5, p-$CH_3OC_6H_4$, iso-C_4H_9)

(CXXXIX) (CXL)

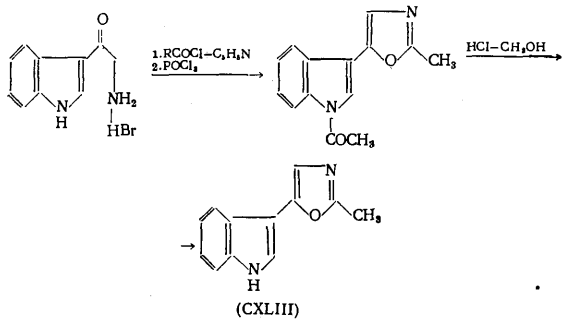
Imidazo[1,2-*a*]pyrazinone (CXLI) was obtained from 2-amino-5-(3-indolyl)pyrazine and methylglyoxal [158]. The synthesis of 1-[β-(3-indolyl)acryloyl]imidazole (CXLII) has also been described [157]:



(CXLI) (CXLII)

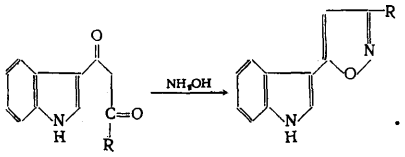
VIII. INDOLYLOXAZOLES AND INDOLYLISOXAZOLES

Compounds of this type have been isolated from natural sources. The antibiotic pimprinin, identified as 5-(3-indolyl)-2-methyloxazole (CXLIII), was obtained from *Streptomyces pimprina* [159]. The structure of pimprinin was subsequently confirmed by synthesis [160]:

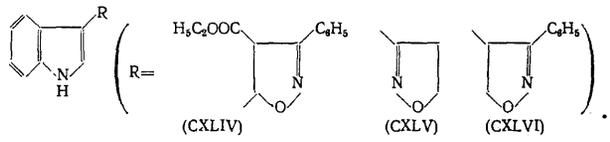


(CXLIII)

Sanna reported previously the synthesis of indolylisoxazoles from β-diketones of the indole series [161]:

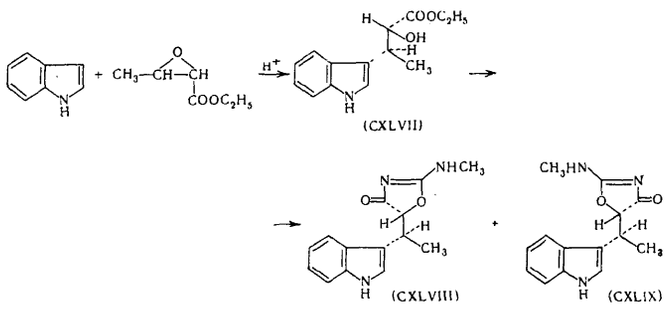


It is also known that the interaction of ethyl indolylacrylate in benzonitrile oxide leads to the formation of the isoxazoline (CXLIV) and that the isoxazoline (CXLV) and compound (CXLVI) may be obtained from 3-indolyl vinyl ketone and hydroxylamine by reaction with benzonitrile oxide [162]. Isoxazole derivatives could not be obtained by the reaction of benzylidene-3-acetylindole with hydroxylamine and benzonitrile oxide [162]:



(CXLIV) (CXLV) (CXLVI)

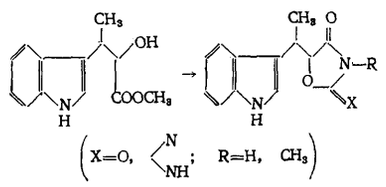
Strain BA-3972 of *Streptomyces albus* is known to suppress certain strains of staphylococci which are resistant to the usual commercially available antibiotics [163]. The active principle (an antibiotic), which was called indolmycin, was soon isolated [164], its structure (CXLVIII) was established, and it was synthesised according to the following scheme [165]:



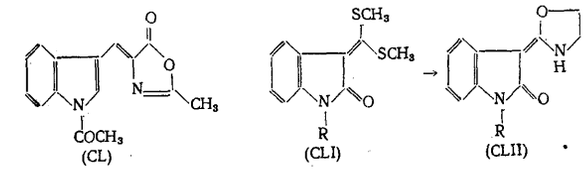
(CXLVII) (CXLVIII) (CXLIX).

The ethyl ester of α-indolmycenic acid (CXLVII), which can also be synthesised by the reaction of indolylmagnesium halides with ethyl *trans*-2,3-epoxybutyrate, is condensed with *NN*-dimethylguanidine. Apart from indolmycin itself, this results in the formation also of a certain amount of isoindolmycin (CXLIX) owing to the ready epimerisation of indolmycin under alkaline conditions [165].

In a stereospecific synthesis of indolmycin, Suvorov, Preobrazhenskaya, and coworkers also began with the ethyl esters of indolmycenic acids [166,167], the isomers of which they were able to resolve by crystallisation. In the last stage a mixture of approximately equal amounts of indolmycin and isoindolmycin was obtained with an overall yield of 40%. When *N*-methylthiourea, urea, and methyl isocyanate were introduced into this reaction, structural analogues of indolmycin were obtained [168]:

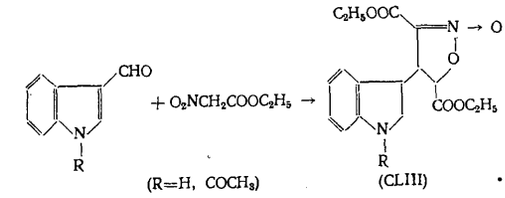


The interaction of indole-3-aldehyde with acetylglycine resulting in the formation of the azlactone (CL) has been described [169]. 3-(2-Oxazolidinylidene)oxindoles (CLII) are readily obtained when 3-bismethylthiomethyleneoxindoles (CLI) are refluxed with ethanolamine in alcohol [170]:



(CL) (CLI) (CLII)

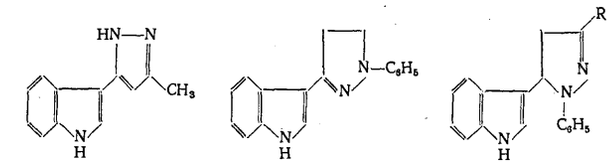
Isoxazoline *N*-oxides (CLIII) were obtained recently by treating indole-3-aldehyde and its *N*-acetyl derivative with nitroacetic ester [171]:



(R=H, $COCH_3$) (CLIII)

IX. INDOLYLPYRAZOLES, INDOLYLPYRAZOLINES, AND INDOLYLQUINOXALINES

The indolylpyrazole derivatives known at present are comparatively few although it would appear that these compounds might include preparations of pharmacological interest, since pyrazoles are in general interesting as biologically active substances [172]. Certain compounds of this type were obtained by the interaction of β-diketones of the indole series with hydrazine derivatives [161]. Thus the reaction of 3-acetoacetylindole with hydrazine hydrate led to the isolation of the pyrazole (CLIV). [173] The pyrazoline (CLV) is formed from 3-indolyl vinyl ketone and phenylhydrazine [162] and a series of Δ^2-pyrazolines (CLVI) were obtained from scatylideneketones and phenylhydrazine [174]:

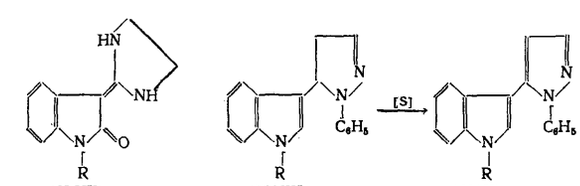


(CLIV) (CLV) (CLVI)

(R=C_6H_5, *p*-CH_3—, *p*-Cl—, *p*-Br—, *p*-$CH_3OC_6H_4$, etc.)

When 3-bismethylthiomethyleneoxindoles (CLI) are refluxed with ethylenediamine, 3-pyrazolidinylideneoxindoles (CLVII) are formed [170].

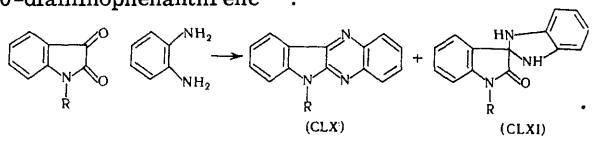
Suvorov and coworkers [175] showed recently that β-indolylacrylic aldehyde and its *N*-acetyl derivative are converted, on prolonged refluxing with phenylhydrazine (or with hydrazine) in acetic acid, into 5-indolylpyrazolines (CLVIII), which can be further dehydrogenated to the corresponding 5-(3-indolyl)pyrazoles (CLIX):



(CLVII) (CLVIII) (CLIX)

(R=H, $COCH_3$)

On reaction with *o*-phenylaminediamine in acetic acid, isatin is converted into 6*H*-indolo[2,3-*b*]quinoxaline (CLX, R = H).[176] When this reaction is carried out in alcohol, the spiro-derivative (CLXI, R = H) is also formed[177,178]. Its analogues have been synthesised also by the interaction of isatin with 4,5-diamino-1,3-dimethyluracil[174], 4,5-diaminopyrimidine[178], 1,2-diaminonaphthalene[177], and 9,10-diaminophenanthrene[178]:

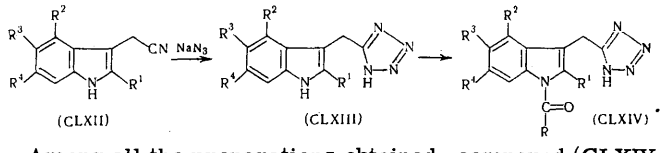


(CLX) (CLXI)

It is interesting that 2,3-diaminonaphthalene forms with isatin only quinoxaline[177], while its reaction with methylisatin gives a spiro-derivative[178] which on recrystallisation from acetic acid isomerises to the corresponding quinoxaline[178].

X. INDOLYLTETRAZOLES

1-(*p*-Chlorobenzoyl)-5-methoxy-2-methylindole-3-acetic acid ("indomethacin") is a powerful anti-inflammatory preparation[179]. In order to seek more effective preparations with similar activity, a number of compounds containing the tetrazole residue instead of the carboxy-group were synthesised from the nitriles (CLXII)[180] or from the tetrazoles (CLXIII) by acetylating the latter in DMF in the presence of sodium hydride[180-183]:



(CLXII) (CLXIII) (CLXIV)

Among all the preparations obtained, compound (CLXIV, R = *p*-ClC$_6$H$_4$, R^1, R^2, R^3, R^4 = H) proved to be the most active[180]. However its effectiveness is appreciably lower than that of "indomethacin". In addition, it is noteworthy that this compound has been found to have an antiserotonin and antihistamine activity[184].

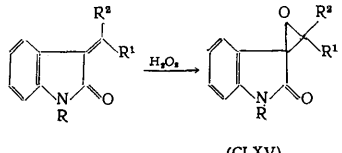
The tetrazole analogue of indole-3-acetic acid stimulates weakly the elongation of *Avena* cells[185].

XI. OTHER INDOLYL DERIVATIVES OF HETEROCYCLES

1. Derivatives of Oxygen-containing Heterocycles

A number of oxirans obtained from oxindole are of definite interest. When products of the condensation of oxindole with ketones are treated with 30% hydrogen peroxide in the presence of alkali in methanol, high yields of 3,1′-epoxides of 2-oxoindoline (CLXV) are obtained[186,187]. Among these compounds, preparations with sedative, diuretic, and anticonvulsant activity were discovered.

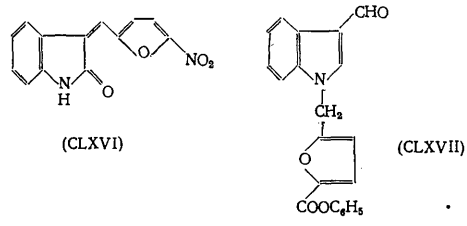
The 3,1′-epoxide of 3-cyclopentyl-2-oxoindoline exhibits a contraceptive effect[186]:



(CLXV)

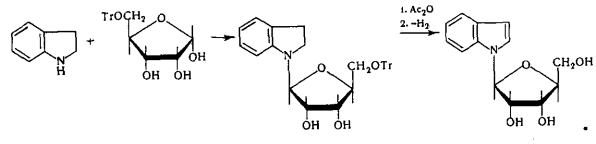
[R = H or CH$_3$; R^1, R^2 = (CH$_2$)$_n$, lower alkyls, aryls, arylalkyls, or pyridyl]

Among other oxygen-containing heterocycles with an indolyl residue, mention should be made of 3-(5-nitrofurfurylidene)oxindole (CLXVI), which shows antibacterial activity[188]. A compound containing a furan ring at the nitrogen atom of the indole molecule (CLXVII) has also been described[189]:



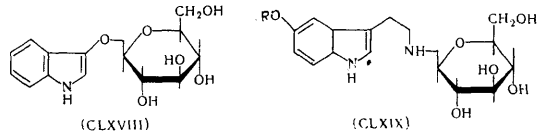
(CLXVI) (CLXVII)

N-Glycosylindoles may be obtained from indoline according to the following scheme[190]:

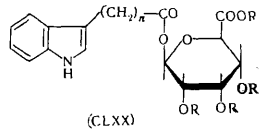


A number of indolyl-β-D-glycopyranosides (CLXVIII) have found application as agents for the histochemical location of individual β-glycosidases in mammalian tissues[191,192].

The synthesis of the *N*-glucosides of serotonin, 5-methoxytryptamine, and melatonin (CLIX) by brief refluxing of the corresponding indole derivatives with D-glucose in methanol has been described[193]:



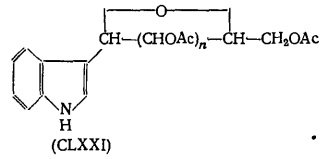
(CLXVIII) (R = H, CH$_3$, C$_6$H$_5$CH$_2$) (CLXIX)



(CLXX)

The glucuronides of 3-indolyl derivatives of aliphatic acids (CLXX) exhibit high anti-inflammatory activity and low toxicity[194].

The interaction of indolylmagnesium bromide with certain acetohalogenoses yielded tetra-acetyl-β-indolylglucose, tetra-acetyl-β-indolylgalactose, and tri-acetyl-β-indolylxylose—the indole series of *C*-glycosides of type (CLXXI), which had not been described hitherto[195]:

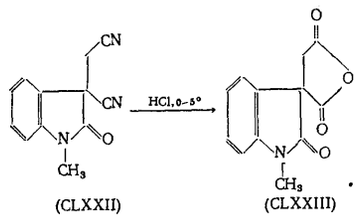


(CLXXI)

The application of mass spectrometry in the investigation of acetylated derivatives of glucopyranosylamine containing the indole residue was described in a review published recently[196].

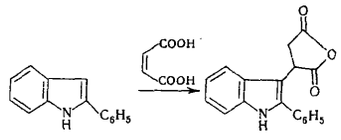
Certain additional information concerning the preparation of a series of carbohydrate derivatives of indoles may be found in a recent review[197].

Spiro[oxindole-3,3′-succinic]anhydride (CLXXIII) is formed in 79.5% yield on acid hydrolysis of the oxindole derivative (CLXXII) in a dioxan–methanol mixture [198]:



(CLXXII) (CLXXIII)

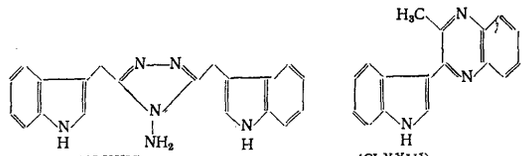
The interaction between 2-phenylindole and maleic acid with brief heating to 140°C leads to the formation of 3-(2-phenyl-3-indolyl)succinic anhydride (CLXXIV): [199]



(CLXXIV)

2. Derivatives of Nitrogen- and Sulphur-containing Heterocycles

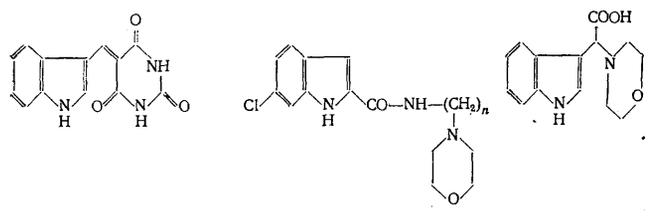
Prolonged refluxing (18 h) of indole-3-acetonitrile with anhydrous hydrazine leads to the formation of 4-amino-3,5-discatyl-*sym*-triazole (CLXXV). [200] As was to be expected, the product of the reaction of 1-(3-indolyl)propane-1,2-dione and *o*-phenylenediamine in alcohol is 2-(3-indolyl)-3-methylquinoxaline (CLXXVI): [201]



(CLXXV) (CLXXVI)

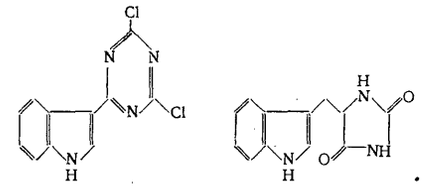
5-Scatylidenebarbituric acid (CLXXVII) is obtained in 84% yield by the condensation of indole-3-aldehyde with barbituric acid [202]. The attempts to reduce the product of this reaction to the 5-scatyl derivatives with triethylammonium formate were unsuccessful [203].

Morpholinylamides of type (CLXXVIII) were found to have antidepressant activity [204]. The morpholine derivative (CLXXIX) is formed by the Mannich reaction from indole, glyoxylic acid, and morpholine [205]:



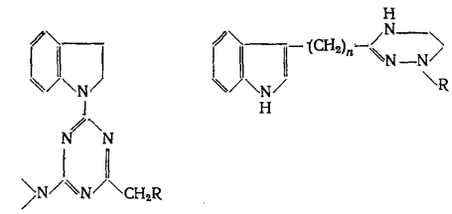
(CLXXVII) (CLXXVIII) (CLXXIX)

When indole reacts with cyanuryl chloride, the product is the derivative (CLXXX) [206] and cyclisation of the phenylhydrazone of β-(5-hydantoyl)propionaldehyde by an alcoholic solution of hydrogen chloride leads to 5-scatylhydantoin (CLXXXI): [207]



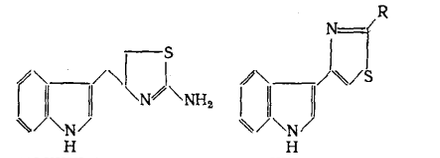
(CLXXX) (CLXXXI)

A number of 2-amino-4-(1-indolinyl)-*S*-triazines (CLXXXII) were found to have anti-inflammatory and analgesic activity [208], while indolylalkyltriazine derivatives (CLXXXIII) and their salts exhibit an antidepressant effect [209]:



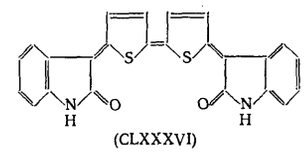
(CLXXXII, R=H, CH_3) (CLXXXIII, n=1, 2, 3; R=H, alkyl.)

In connection with their search for agents affording protection against radiation, Japanese chemists recently described the synthesis of 2-amino-4-scatylthiazoline (CLXXXIV) from α-chloromethyltryptamine and thiourea [210]. It is also known that the interaction of 3-chloroacetylindole with thioformamide, thiourea, and ammonium dithiocarbamate leads to the corresponding derivatives of 4-(3-indolyl)thiazole (CLXXXV): [211]



(CLXXXIV) (CLXXXV, R=H, NH_2, SH)

The indophenine pigment formed on interaction between isatin and thiophen may be included among compounds of this type; the structure (CLXXXVI) was recently finally demonstrated for this derivative [212]:



(CLXXXVI)

Polymerisation of Isocyanates

R.P.Tiger, L.I.Sarynina, and S.G.Entelis

The review deals with the present state of the problem of the ionisation of isocyanates: cyclic di- and trimerisation, homopolymerisation, and copolymerisation of isocyanates with other monomers. The mechanisms of the processes involving various catalytic systems are considered and the results of investigations of the polymerisation of isocyanates and their theoretical and practical importance are discussed.
The bibliography includes 125 references.

4. Copolymerisation of isocyanates with other monomers 782

I. INTRODUCTION

The chemical reactions of isocyanates are extremely varied, but so far only some of them have been used industrially, in particular in polymer chemistry. They include mainly the reactions of isocyanates with nucleophilic agents containing a so called active (mobile) hydrogen atom (alcohols, diols, water, amines, etc.). The formation of urethanes has been most thoroughly investigated. They were studied and are still being studied systematically both on model and polymeric systems and the advances achieved in the understanding of the mechanism of these reactions have been described in a number of reviews [1-3]. Other reactions of isocyanates have been less thoroughly investigated, which to some extent restricts the scope of their useful applications.

Of the numerous reactions in which isocyanates are involved, cyclic dimerisation and trimerisation and also homopolymerisation of isocyanates and their copolymerisation with other monomers with formation of high-molecular-weight products are of significant interest for polymer chemistry. Several tens of publications dealing with the polymerisation of isocyanates have now appeared. They have not been discussed so far from a single standpoint and the brief reviews of the literature in certain papers [4,5] and monographs [1,6] on the dimerisation and trimerisation reactions of isocyanates, discovered as early as the past century by Hoffmann, cannot claim to give a complete coverage of the data. The possibility of the homopolymerisation of isocyanates with formation of high-molecular-weight products was first established by Shashoua in 1959 [17] and since then many papers dealing with a quantitative treatment of the polymerisation of isocyanates in the presence of various catalytic systems and with the search for new polymerisation initiators have been published.

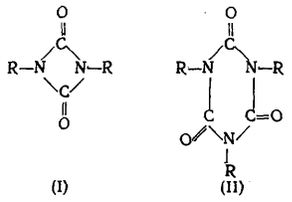
The fact that isocyanates are capable of entering into autocyclisation or polymerisation reactions with formation of linear high-molecular-weight products is not surprising if one bears in mind the electronic structure of the NCO group, which consists of a cumulative system of N=C and C=O double bonds. In this respect isocyanates are extremely similar to ketens $R_2C=C=O$, the capacity of which for cyclisation and homopolymerisation is well known [8].

The present review deals with almost all studies concerned in one way or another with the polymerisation reactions of isocyanates. We believe it reasonable to combine the discussion of the results of the study of the dimerisation and trimerisation of isocyanates, since in many cases they occur in the presence of the same or chemically similar catalysts, although there are a number of fundamental differences between these processes.

The problem of the homopolymerisation and of the copolymerisation of isocyanates with other monomers requires separate consideration. Together with its importance for polymer chemistry, the question of the possibility of the dissociation of the C=O bond in the NCO group in reactions involving the addition of nucleophilic agents to isocyanates, which has been frequently discussed (also by the authors of this review [2,3,9-11]) in connection with the mechanism of urethane formation, has a direct bearing on this problem.

2. CYCLIC DIMERISATION AND TRIMERISATION

The cyclic dimers (I) and trimers (II) of isocyanates are products of autocyclisation which takes place with dissociation of the N=C bonds:

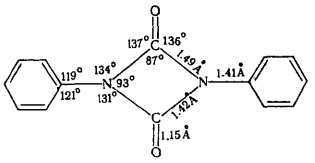


(I) (II)

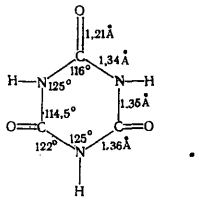
The dimers are a kind of symmetrical diketones (1,3-disubstituted uretidinediones); the trimers are derivatives of cyanuric acid (1,3,5-trisubstituted isocyanurates). The structures of isocyanate dimers and trimers have been demonstrated spectroscopically, by chemical analysis [4,12], and also by comparing the dimerisation and trimerisation products of isocyanates with products obtained by independent synthesis. For example, triphenyl isocyanurate was obtained from phenylcyanamide [13] and trimethyl isocyanurate was synthesised from cyanuric acid and diazomethane [14]. Compounds of type (II) were also

obtained by the condensation of cyanuric acid with oxiran, allyl chloride, ethyl chloroacetate, and acrylonitrile [15].

The structure of the phenyl isocyanate dimer was established by X-ray diffraction [16]:



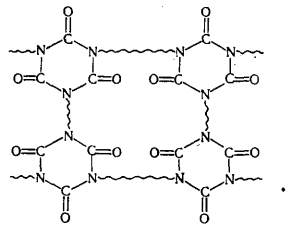
The central four-membered ring is planar. The length of the C–N bond corresponds approximately to its length in amides, for example in acetamide (1.426 Å), [17] and the length of the C–C bond in the aromatic ring differs only slightly from the usual length of this bond in benzene. There are no literature data on the structure of the trimers but some idea about it may be gained from an X-ray diffraction study of cyanuric acid [18]:



The six-membered ring of cyanuric acid is planar. One can hardly expect a significant change in the structure of the central six-membered ring on passing from cyanuric acid to isocyanurate. Before considering the dimerisation and trimerisation of isocyanates in the presence of various catalytic systems, we shall note why these reactions, which so far have been of purely academic interest (for the chemical properties of the NCO group), may be employed successfully in polymer chemistry for the synthesis of new materials.

The main procedure usually employed in the synthesis of structured (cross-linked) polyurethanes involves the introduction of various branching additives into the polymerising system. In the reactions of oligomeric polyesterdiols with di-isocyanates, triols are used for this purpose; polyesterpolyols or polyisocyanates containing more than two NCO groups per molecule can also serve as branching centres. The principal difficulty arising in the practical realisation of these processes reduces to the maintainance of an exact ratio of the concentrations of the NCO and OH groups and also involves the necessity to regulate with the aid of special catalytic additives or temperature conditions the ratio of the rates of all the reactions occurring in the system between NCO and OH groups, the reactivities of which are different depending on whether they are primary, secondary, or tertiary [1].

In the synthesis of structured polyurethanes by the trimerisation of isocyanates [19,20], a prepolymer containing terminal NCO groups, which are usually introduced by the reaction of a hydroxyl-containing polyol with di-isocyanates the NCO groups of which have fairly different reactivities (for example, 2,4-tolylene di-isocyanate), has been suggested as the starting material. In the presence of trimerisation catalysts, prepolymers with terminal NCO groups form a three-dimensional network:



In a system without hydroxy-groups, there is only one reaction—trimerisation of the isocyanate, the rate of which can be readily regulated by selecting an appropriate trimerisation catalyst.

Foams, varnishes, and polyaliphatic resins, which are hardened by the trimerisation of terminal NCO groups, are promising as regards technical applications. Polyisocyanurate resins formed, for example, by the cyclic polymerisation of aliphatic di-isocyanates, are distinguished by a high strength, thermal stability, and good optical properties and may be used to prepare plastics with improved optical transparency, which are used in aviation [20].

At the present time, the cyclic di- and trimerisation reactions of NCO groups in polymeric systems have been investigated inadequately, although some data concerning these reactions with participation of monomeric isocyanates are available. The catalytic systems used for this purpose and certain kinetic relations observed in the reactions are of main interest.

From the standpoint of the employment of the trimerisation reactions in polymer chemistry, it is significant that isocyanurates are much more thermostable than the usual polyurethanes. Thus the urethane chain breaks at a temperature as low as 150–200°C, while the thermal degradation of isocyanurates does not begin until 300°C. [21] Structured polymers, formed as a result of the trimerisation of NCO groups, are extremely rigid. In order to obtain fairly elastic materials, it is necessary to employ as the initial prepolymers oligomers the molecular weight of which is 3000–5000; plasticisers can also be employed.

The dimerisation of isocyanates is a reversible reaction, while the equilibrium in the trimerisation is almost completely displaced to the right. The equilibrium concentrations of the 2,4-tolylene di-isocyanate dimer are 8.5 and 7.1% respectively at 78° and 100°C. [22] When the temperature is reduced, there is a significant increase of the equilibrium concentration of the dimer and at 25° and 10° it amounts to as much as 71–74% and 90% respectively [4]. At 150–175°C the 2,4-tolylene di-isocyanate dimer is almost completely converted into the monomer.

Numerous catalytic systems for the dimerisation of isocyanates have been described [4–6]. The possibility of spontaneous non-catalytic dimerisation, which is extremely slow, has also been noted. Thus the equilibrium concentration of the 2,4-tolylene di-isocyanate dimer is reached at 78°C only after 1500 h. The activation energy for the spontaneous dimerisation of this isocyanate is 21 kcal mole^{-1}. [22] The best dimerisation catalysts are trialkylphosphines [23,24]; aryl- and alkylaryl-phosphines are less active.

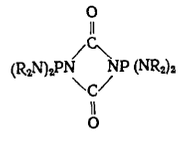
Isocyanates dimerise also in the presence of tertiary amines such as trialkylamines, pyridine, and its derivatives [4,5,25]. In recent years it was established that the

dimerisation of isocyanates also occurs in the presence of sodium benzoate [26], various organometallic compounds [6], and metal chelate complexes [6,27]. In most cases dimerisation is accompanied by trimerisation, but the above catalytic systems, particularly phosphines and tertiary amines, mainly promote the dimerisation reactions.

In the presence of iron acetylacetonate, the dimerisation of isocyanates is greatly accelerated compared with the non-catalytic process [27]. The reaction is then found to be of first order with respect to the catalyst and the activation energy is somewhat reduced, amounting to 19.5 kcal mole^{-1} for the dimerisation of 2,4-tolylene di-isocyanate.

The reasons for the catalytic activity of nucleophilic agents such as phosphines and amines should not be sought solely in their high basicity. For example, the basicities of dimethylphenylphosphine and dimethylaniline are similar, but the former is much more active as a dimerisation catalyst. Certain phosphines and their oxides catalyse the formation of carbodiimides R–N=C=N–R from isocyanates [28,29]. This reaction is a kind of dimerisation of RNCO with liberation of CO_2; $2RNCO \rightarrow R-N=C=N-R + CO_2$. The kinetics of the formation of carbodiimides in the presence of a number of catalytic systems have been investigated in fair detail [30,31].

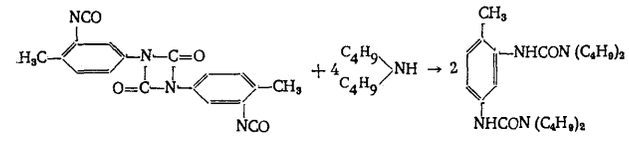
The capacity for dimerisation greatly depends on the structure of isocyanates. Aromatic isocyanates dimerise much more satisfactorily, owing to their lower electrophilicity. Teh dimerisation and trimerisation of acyl isocyanates RCONCO, in particular of benzoyl isocyanate and its methoxy-, chloro-, and nitro-derivatives in the presence of triethylamine, has also been described [32]. The formation of acyl isocyanate dimers and trimers is accompanied by side reactions involving the formation of cyclic products with breakdown of the C=O carbonyl bonds. Dimers of isocyanates derived from tervalent phosphorus acids with the general formula



were described recently [33]. Uretidinediones consisting of two different types of cyanates can be obtained [12].

The kinetics of the dimerisation reactions have been very little studied. One can only point to Davis's infrared spectroscopic investigations [22,27] of the solid-phase dimerisation of 2,4-tolylene di-isocyanate. The presence of an extremely intense band due to the stretching vibrations of the C=O group of the uretidinedione ring in the region of 1790 cm^{-1} makes it possible to identify the dimers readily and to investigate the kinetics of their formation from isocyanates. Downs and Haas [34,35] quote the infrared spectra of a number of dimers derived from phenyl isocyanate and the ^{19}F NMR spectra of isocyanate dimers with a fluorine substituent. Aryl isocyanate dimers melt in the range 160–200°C, depending on their structure [4].

The reactivity of the dimers is due to their capacity for dissociation with formation of the initial isocyanates and therefore their reactions with alcohols, water, and amines result in the formation of urethanes, ureas, and biurets respectively. Since the dimers may be formed spontaneously when isocyanates are stored, the problem of the correct chemical determination of the isocyanate number of monomers is important [36]. For example, it has been shown [37] that the reaction of the 2,4-tolylene di-isocyanate dimer with dibutylamine takes place according to the equation



and at a temperature as low as 50°C the conversion of NCO groups is in excess of 70%. The high reactivity of the dimer in the determination of the content of NCO groups in the monomer can lead to high isocyanate numbers. This factor has a direct bearing on the problem of finding the optimum NCO/OH ratio for the synthesis of polyurethanes from di-isocyanates and hydroxyl-containing polyester-polyols. The reactivity of the dimers in relation to the hydroxy-groups of alcohols and polyols is extremely low and a very long time is required for the urethane-formation reactions to occur even in pure alcohol. The reaction with acidic alcohols (for example with phenols) takes place to an appreciable degree only at 100–150°C.

There are no quantitative literature data on the reactivity of the dimers.

The trimerisation of isocyanates takes place in the presence of catalytic amounts of triethylphosphine [38], alkaline earth metal acetates, formates, and carbonates [13,39], metal naphthenates [40], aluminium chloride [41], oxalic acid [42], triethylamine [43], and iron, sodium, magnesium, mercury, nickel, copper, zinc, aluminium, tin, chromium, etc. salts soluble in organic solvents [44]. The brief review by Arnold et al. [4] of the early studies on the trimerisation contains a list of the catalytic systems for the trimerisation of isocyanates discovered up to 1957. In recent years there has been a considerable growth of interest in this reaction. New trimerisation catalysts have been discovered: sodium benzoate in dimethylformamide (DMF), [26,45] pyridine oxide [32], quaternary ammonium and phosphonium bases [46], metal alkoxides [47], tertiary amines [21], organic derivatives of quadrivalent tin [48], trialkylarsenic and arsenic oxides [49], metal acetylacetonates, and other complexes [27,50,51]. Trimers are also formed in the synthesis of urethanes in the presence of tertiary amines. Kogon showed [52] showed that, in the reaction of phenyl isocyanate with ethanol at 125°C in the presence of *N*-methylmorpholine, the phenyl isocyanate trimer is formed together with the urethane. It is interesting that the trimer appears only in systems containing an amine and an alcohol. In the presence of an amine and a urethane (ethyl carbamate) the trimerisation does not occur. In their attempt to prepare *N*-substituted oxazolidinones by the condensation of epoxides with isocyanates in the presence of pyridine, Jones and Savill [53] showed that the trimerisation reaction takes place vigorously under these conditions. Triphenyl isocyanurate was obtained in oxiran, propene, styrene, and epichlorohydrin solutions in the presence of traces of pyridine in a yield close to 100%. In the presence of oxides, quaternary ammonium bases also catalyse the trimerisation reaction, but much less effectively [53,54]. Subsequently these results served as a starting point in the search for new cocatalysts of the trimerisation in the presence of tertiary amines.

Isocyanate trimers are also formed in the high-temperature (230–250°C) condensation of bisurethanes of the type $RO-\overset{O}{\overset{\|}{C}}-\overset{H}{\overset{|}{N}}-(CH_2)_n-\overset{H}{\overset{|}{N}}-\overset{O}{\overset{\|}{C}}-OR$ in the presence of titanium butoxide [55]. Isocyanate dimers and higher-molecular-weight products of different compositions are also formed

under these conditions. In those cases where the trimerisation and dimerisation of isocyanates take place simultaneously, the yield and rate of accumulation of each product vary significantly as a function of the conditions and the structure of the monomer. For example, in a study of the cyclic polymerisation of phenyl isocyanate in DMF at temperatures in the range 0–70°C under the influence of sodium benzoate, it was shown [26] that at 70°C the yield of the trimer was 50% of theoretical after 3 h and that of the dimer was less than 5%. At 0°C the content of the trimer fell to 30% and that of the dimer rose to 10%. At 30°C the ratio of the rates of dimerisation and trimerisation was 0.05%. [26] In the cyclic polymerisation of benzoyl isocyanate and its derivatives in the presence of tertiary amines and pyridine oxide, a significant change in the mode of reaction as a function of the structure of the isocyanate was established: at 50–80°C benzoyl isocyanate forms mainly the dimer under these conditions, while the less reactive *p*-methoxybenzoyl isocyanate yields the trimer—tribenzoyl isocyanurate [32].

Herbstman [49] made a detailed study of the trimerisation of isocyanates of different structures in the presence of a number of organic derivatives of antimony and arsenic. In the presence of 2 mole % of tri-n-butylarsenic and triisobutylarsenic oxides, phenyl isocyanate, and *m*-chlorophenyl isocyanate trimerise with a yield of 94–100% at room temperature over a period less than 1 h. The less reactive isocyanates *p*-$CH_3OC_6H_4NCO$ and C_2H_5NCO form trimers only on heating to 80°C with a yield of 95–97%. Isocyanates are very readily trimerised at low temperatures in the presence of catalytic amounts of tri-n-butylantimony diethoxide and diacetate. In the presence of triphenylarsenic oxide, even an inert monomer such as CH_3NCO trimerises in 15 min and *m*-chlorophenyl isocyanate forms under these conditions 30% of the trimer and 70% of carbodiimide. Antimony derivatives of the type $(t\text{-}C_4H_9)_5Sb$ and $(t\text{-}C_4H_9)_3SbCl_2$ do not catalyse the trimerisation process. It was established that tributylantimony oxide forms a stable complex with phenyl isocyanate, which is probably responsible for the catalysis [49]. The infrared spectrum of the complex has an intense C=O absorption band (1725 cm^{-1}); the N–H, N=C=O, and C=O bands of triphenyl isocyanurate (1705 cm^{-1}) are absent. A complex of the catalyst and triphenyl isocyanurate is not formed.

Organotin compounds are much less active as trimerisation catalysts. Bloodworth and Davies [48] showed that tributylmethoxytin $[(C_4H_9)_3SnOCH_3]$ and bistributyltin oxide $[(C_4H_9)_3Sn-O-Sn(C_4H_9)_3]$ react with isocyanates in equimolecular proportions to form 1:1 adducts. Under these conditions, the conversion of RNCO into the trimer is extremely slow.

There are no accurate quantitative literature data on the rates of trimerisation under the influence of organometallic compounds, with the exception of the results of a study of the trimerisation of 2,4-tolylene di-isocyanate in the presence of iron acetylacetonate [27]. The trimerisation reaction is of first order with respect to the catalyst, the catalytic effect of iron acetylacetonate in the trimerisation being more pronounced than in the dimerisation. Thus, 0.51 wt.% of the catalyst accelerates the solid-phase dimerisation reaction at 78°C by a factor of 60 and the trimerisation process by a factor of 200. The activation energy for spontaneous trimerisation in the absence of a catalyst is 16 kcal $mole^{-1}$ [22] and in the presence of iron acetylacetonate, 10.5 kcal $mole^{-1}$. [27] It is noteworthy that the cyclopolymerisation of isocyanates in the presence of iron acetylacetonate leads to an additional consumption of NCO groups in urethane formation, where iron acetylacetonate is frequently employed as a catalyst [56,57]. In the general case this is important, but comparison of the rate of urethane formation in the reaction between 2,4-tolylene di-isocyanate and the hydroxy-groups of a polyesterpolyol and the rate of the di- and trimerisation of this isocyanate in the presence of 0.5 wt.% of iron acetylacetonate shows that, while the first reaction is accelerated by a factor of approximately 50, [57] the consumption of NCO groups in the di- and trimerisation side reaction is only 0.1%, [27] i.e. it may be disregarded.

In the presence of organometallic compounds, isocyanate trimers do not form complexes with the catalyst [48,49], although isocyanurates are known to form readily molecular complexes even with the usual organic solvents, which can be identified spectroscopically [58]. The 1:1 complexes of a number of aryl isocyanurates with benzene, acetone, and DMF can be readily isolated in the form of colourless crystals. The infrared spectra of the complexes contains virtually the same bands as the spectrum of the free isocyanurate, but the relative intensity and position of the C=O band are altered. Table 1 lists the vibration frequencies of the C=O group in a number of isocyanurates and their complexes with solvents. Methanol, ether, and benzophenone do not form complexes with isocyanurates, but ethylene carbonate forms at 130°C a stable 1:1 complex with triphenyl isocyanurate having a molecular weight of 230, which corresponds to the formula $(C_6H_5NCO)_3.C_3H_4O_3$. [59] It is noteworthy that in the presence of traces of *N*-methylmorpholine the trimerisation of isocyanates is much faster when ethylene carbonate is introduced into the system as a cocatalyst, the reactivity of the resulting trimer bound in a complex with ethylene carbonate being higher in the reaction with primary amines than that of the free trimer [59].

The complexes of aryl isocyanurates with organic solvents are fairly stable at room temperature. *In vacuo* at 100–200°C the complexes decompose into the initial components. Aliphatic isocyanurates form complexes much less readily.

The mechanism and kinetics of the trimerisation of NCO groups can be inferred at the present time only from studies on trimerisation in the presence of tertiary amines and tertiary amine–cocatalyst catalytic systems [21,60,61]. As already stated, alkylene oxides are usually employed as cocatalysts; aldehydes, lactones, alkylene carbonates, and imines also exhibit a high cocatalytic activity. The trimerisation of NCO groups probably involves an anionic mechanism. In particular, this is indicated by data on the reactivity of aryl isocyanates in trimerisation: electron-accepting substituents accelerate trimerisation, while electron-donating substituents retard it (Table 2). [21] Interpretation of data for the relative reactivities of *meta*- and *para*-substituted phenyl isocyanates on the basis of the Hammett equation yields $\rho = 3.5$, which confirms the nucleophilic nature of the trimerisation of isocyanates. Steric factors play a significant role. This is reflected in a markedly lower reactivity of *ortho*-substituted aryl isocyanates (Table 2).

The trimerisation reaction in the presence of amines is significantly faster in polar media than in solvents with a low dielectric constant. Thus the relative reactivities of phenyl isocyanate in benzene ($D = 2.3$), chlorobenzene ($D = 5.7$), acetonitrile ($D = 37.5$), and dimethyl sulphoxide (DMSO) ($D = 45.0$) are 1.5, 2.4, 8.4, and 12.3 respectively [21]. The acceleration of the reaction in media with a high dielectric constant indicates a significant polarity of the transition complex in the trimerisation process.

The principal data on the catalytic activities of tertiary amines combined with cocatalysts of different types are quoted by Beitchman[60], who investigated the catalytic activities of a large number of tertiary amine–catalyst compositions by calorimetric methods from the rate of attainment of the maximum temperature rise in the system. It is striking that in the presence of triethylenediamine–alkylene oxide systems the kinetic curve is S-shaped. At the end of the induction period, the duration of which depends significantly on the concentration of both components of the catalytic system and the isocyanate, the reaction is of first order with respect to the monomer and 100% conversion is reached. The S-shape of the kinetic trimerisation curve is not a result of the autocatalytic effect of the reaction product: the shape of the kinetic curves remains unaltered when the dimer or trimer is introduced into the system before the start of the reaction.

The rate of the reaction catalysed by tertiary amine–alkylene oxide systems increases sharply with the [oxide]/[amine] ratio (see Figure) and reaches an approximately constant value from a ratio of about 30 : 1. It was shown subsequently[61] that the rate of trimerisation is proportional to the product of the concentrations of the components of the catalytic system; the presence of the induction period observed in the catalysis by the triethylenediamine–propylene oxide system[60] is not a general characteristic of reactions catalysed by tertiary amine–alkylene oxide systems

Table 2. Effect of the ring substituent in phenyl isocyanate on the reactivity of the monomers in the trimerisation reaction.

Variation of the time of attainment of the maximum temperature rise in the system in the solid-phase trimerisation of tolylene di-isocyanate in the presence of the triethylenediamine–methyloxiran catalytic system with the [epoxide]/[amine] ratio (plotted on the basis of Beitchman's data[60]).

The catalytic activity of amines under the conditions of joint catalysis in the presence of oxides and other cocatalysts depends significantly on their structure but there is no direct relation with the basicity of the amines. Tertiary amines can be arranged in the following sequence in terms of their catalytic activity: triethylenediamine > triethylamine > *NNN'N'*-tetramethyl-1,3-butylenediamine > *N*-methylmorpholine > 2-methylimidazole[60].

It is also noteworthy that tertiary amines incorporating heterocycles with structures resembling that of the isocyanurate ring, for example the symmetrical *NN'N''*-tri-(dimethylaminopropyl)hexahydrotriazine or 2,4,6-tri-(dimethylaminomethyl)phenol, exhibit a high catalytic activity in the reaction [21]. One cannot rule out the possibility that, together with the basicity factor, the possibility of the coordination of the monomer to the catalyst plays a significant role in the mechanism of the catalysis by such amines. In order to elucidate this factor, detailed studies on the kinetics of the reaction and of the formation of a complex between the catalyst and the monomer are required.

Table 3. Reactivities of olefin oxides, aldehydes, and imines as cocatalysts of the trimerisation of isocyanates (trimerisation of 2,4-tolylene di-isocyanate) in the solid phase (26–27°C; catalyst—0.0022 M triethylenediamine).

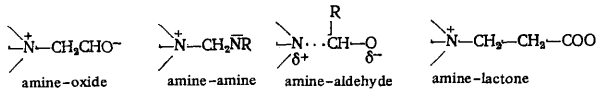
**The time of attainment of the maximum temperature rise in the reaction characterising the relative reactivity of the cocatalyst.
***The maximum temperature rise in the reaction mass.

Table 3 shows that in the series of cocatalysts of different chemical types, alkylene oxides are the most effective. Although the times required for the attainment of the maximum temperature rise in the system cannot be strictly speaking regarded as criteria of catalytic activity, they can nevertheless be used for qualitative estimates.

The question of the nature of the active centre in the catalysis of the trimerisation by tertiary amine–cocatalyst systems is controversial. Despite the fact that there exists a possibility, in principle, of the opening of the epoxide, lactone, or imine rings in the presence of tertiary amines [62,63] and despite the significant polarisation of the carbonyl group when amines interact with aldehydes, the experimental proof of the involvement of zwitterions such as



as active catalyst species in the reaction has not so far been found. One should also bear in mind the possibility of the formation in the amine–alkylene oxide systems of quaternary ammonium bases [64–66] as a result of the interaction with traces of water frequently present in solution in fairly large amounts (compared with the catalyst):

Definite information about the nature of the active centre in the reaction could be obtained from NMR data, but such experiments have not been performed. For catalytic systems of a similar chemical type (triethylphosphine–aldehyde and triethylphosphine–acrylonitrile) in the polymerisation of formaldehyde and acrylonitrile, it has been established by NMR [67,68] that the active species are zwitterions of the type $(C_2H_5)_3\overset{+}{P}-CH_2-\overline{O}$ and $(C_2H_5)_3\overset{+}{P}-CH_2-\overset{-}{C}H$, which interact with water or alcohol to form
|
CN

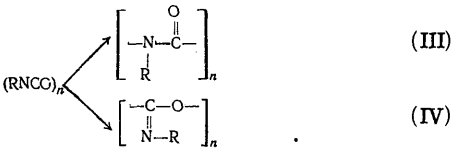
quaternary phosphonium compounds analogous to quaternary ammonium bases.

Petrov et al. [61] showed that, when dimethylbenzylamine and glycidyl phenyl ether are mixed together, the electrical conductivity of the mixture increases very rapidly, approximately by a factor of 200, and then remains unchanged for several hours. The opening of the epoxy-ring of glycidyl phenyl ether is much slower. The fact that in the trimerisation of NCO groups in the presence of this catalytic system an induction period is not observed, the electrical conductivity does not change after a sharp rise at the beginning of the reaction, and there is a linear relation between the rate of the process and the product of the concentrations of the components of the catalytic system enabled the authors to suggest the possibility of the formation of ion pairs at catalytically active species without the opening of the epoxy-ring:

The final determination of the nature of the active centre in the trimerisation reaction, the causes of ring closure in the trimer or dimer stage, and the relation between the yield of the trimer or dimer and the type of catalyst will be possible only as a result of a detailed investigation of the reaction kinetics under different conditions and a study of the processes occurring in the catalyst–cocatalyst interaction. These studies are directly related to the investigation of the polymerisation of isocyanates and the formation of high-molecular-weight products, since in both cases the process has an anionic mechanism consisting of a nucleophilic attack on the electrophilic carbon atom of the NCO group.

3. LINEAR HOMOPOLYMERISATION

In view of the structure of the isocyanate group, one must consider the possibility of the existence in a linear polyisocyanate or at least two types of homopolymers formed as a result of the dissociation of the N=C (III) or C=O bonds (IV) respectively:



In the first case the macromolecular chain has the structure of an *N*-substituted polyamide and in the second it has

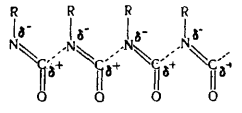
a polyacetal structure. A similar phenomenon is known in polymer chemistry. Thus, when ketens ($\begin{matrix}R\\R\end{matrix}\!\!>\!C=C=O$), which have a structure similar to that of isocyanates, are polymerised, both polyketones (polymerisation via the C=C bond) and polyacetals (polymerisation via the C=O bond) can be formed, depending on the conditions and the chemical nature of the catalyst. In a more general case, there is a possibility of the formation of polymers with alternating blocks or polymers having the ester structure [69,71]. In the homopolymerisation of isocyanates, it is very difficult to incorporate in the polymer chain structures (III) and (IV) simultaneously and can be achieved only in certain specific cases. Moreover, the isocyanate homopolymer with a purely polyacetal chain structure has not so far been obtained, although, as will be shown below, in certain copolymerisation reactions chain propagation takes place mainly as a result of the dissociation of the C=O bond.

Shashoua [7,72] and Natta [73] showed that in the presence of anionic catalysts the homopolymerisation of monoisocyanates involves the formation of high-molecular-weight ($M = 10^4-10^5$) polymers with a structure of type (III) in the main chain, i.e. substituted 1-nylons. The anionic polymerisation of about 30 different isocyanates has been studied [72]. The polymerisation takes place with a high yield in the presence of NaCN, sodionaphthalene, and sodiobenzophenone in DMF between $-20°$ and $-100°C$. The polymerisation of aliphatic and aromatic isocyanates has been investigated in the presence of ethyl-lithium, diethylberyllium, n-octylsodium, and lithium ethoxide in various solvents between $-60°$ and $-78°C$. [73]. It has been shown by X-ray diffraction that highly crystalline polymers are formed in all cases. Their infrared spectra have characteristic absorption bands in the region of 1700 cm^{-1} due to the presence of the C=O group. In the presence of cationic catalysts [$AlBr_3$ and $BF_3(C_2H_5)_2O$], amorphous polymers are formed in much lower yields [73]. In this case a mixed structure (III and IV) is probably formed in the main chain.

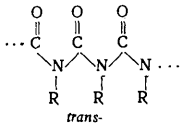
The yield and the molecular weight of the polymer obtained under the conditions of anionic polymerisation pass through a maximum as a function of catalyst and monomer concentrations in the mixture. When the temperature is reduced, the yield and molecular weight increase significantly [72].

The polymerisation of monoisocyanates under the influence of water-soluble initiators—alkalis and inorganic and organic acid salts in DMF at $-50°C$—has been described [50,74]. In the presence of alkalis the polymerisation is initiated by OH^- ions and in the presence of inorganic salts, by the acid anions. When alkali metal salts of carboxylic and dicarboxylic acids are used as the initiating system, the polymer yield is found to depend very markedly on the pK_a of the acid. In the presence of sodium salts of carboxylic acids with pK_a (in water) of the order of 1–3, there is hardly any polymerisation, while in the presence of salts formed by weaker acids (pK_a = 3–6) the yield of the polymer is 50–80%. With increase of the [H_2O]/[monomer] ratio, the yield and the molecular weight of the polymer fall.

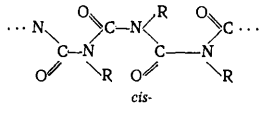
It has been established that the homopolymerisation of isocyanates occurs spontaneously on prolonged heating of the monomer [75] and also on radiation-chemical [76] and electrochemical initiation [77]. The pyrolysis of 2,4-tolylene di-isocyanate yielded linear dimers, trimers, heptamers, with the 1-nylon structure in the main chain [75]. It is interesting that radiation-induced polymerisation by γ-irradiation from cobalt-60 at temperatures between 20° and $-196°C$ can give high yields of isocyanate homopolymers, which, as in the presence of typical anionic catalysts, are formed by polyaddition with dissociation of the N=C double bond. Characteristic features of the radiation-induced polymerisation are the absence of an induction period, direct proportionality between the rate of polymerisation and the dose rate, and the acceleration of polymerisation at low temperatures when the polymer is in the solid state. It is also significant that in the presence of diphenylpicrylhydrazyl the yield of the polymer does not change, which shows that the radiation-induced polymerisation has a non-radical mechanism. The infrared spectra of polymers obtained in the liquid and solid phases are different and the stereoregularity of the "solid-phase" polymer is much higher. The structure of this polymer is identical with that of the polyisocyanates obtained by anionic polymerisation [72,73] and electrochemically [78]. It is suggested [77] that in the crystalline state the radiation-induced polymerisation takes place as a result of a cooperative interaction of the excited monomer molecule via the N=C bond:



Thus the available data show that in the anionic polymerisation of monoisocyanates the fundamental unit of the polymer chain is the amide group. Dielectric measurements [79] and also studies on the viscosity and sedimentation of poly(n-butyl isocyanate) [80] showed that the polyisocyanates obtained by polymerisation via the N=C bond are extremely rigid and probably have a helical conformation. X-ray diffraction data for poly(n-butyl isocyanate) obtained by the anionic polymerisation of n-butyl isocyanate confirmed the hypothesis of a helical configuration of the polymer chain [81]. The helix has a translation of 1.94 Å; the hexagonal unit cell parameters are a = 13.3 Å and c = 15.4 Å. It is suggested that the conformation of the elementary polyisocyanate unit is more consistent with the *cis*-structure than the *trans*-structure [81]:



trans-



cis-

The viscosity and light scattering data for solutions of poly(n-hexyl isocyanate) in tetrahydrofuran (THF) lead to an analogous conclusion [82].

Burchard [80] measured by sedimentation and diffusion methods the molecular weights of poly(n-butyl isocyanate) obtained by anionic polymerisation and established a relation between the viscosity of the polymer in benzene and tetrahydrofuran and the molecular weight:

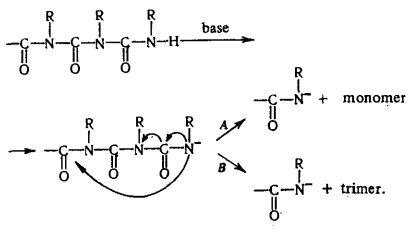
$$[\eta]_{THF} = 0{,}457 \cdot 10^{-3} \cdot M^{1{,}18}; \quad [\eta]_{benzene} = 1{,}10 \cdot 10^{-3} \cdot M^{1{,}11}.$$

A study of the dielectric properties of poly(n-butyl isocyanate) in benzene established a strong dependence of the relaxation time on the molecular weight [79]. Thus, when the molecular weight changes from 1.4×10^5 to 2.3×10^6, the change in τ_{obs} is from 1.6×10^{-6} to 5×10^{-3} s. Hence follows the conclusion of a broad

molecular weight distribution in the polymer. For example, it has been shown [79] by an independent determination of M_w and M_n for different polymer specimens obtained in toluene at −78°C in the presence of n-butyllithium that $M_w/M_n = 3.2-4.3$.

The amide structure of the polyisocyanates obtained on anionic polymerisation of monoisocyanates has been demonstrated by Iwakura et al. [83] by investigating the products and characteristics of the chemical degradation of the polymers in the presence of di-n-butylamine. The products of the reactions occurring at temperatures in the range 30−100°C over a period of several tens of hours are mainly cyclic trimers and the corresponding *NN*-di-n-butyl-*N'*-substituted ureas. The reaction is accelerated in the presence of bases and electron-donating solvents. In certain cases the formation of small amounts of free isocyanate (degradation of polymers formed from aryl isocyanates with electron-donating substituents in the ring) was observed.

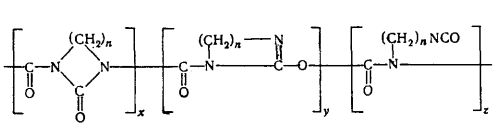
The mechanism of degradation in the presence of a base, the role of which reduces to the abstraction of a proton from the end of the polymer chain with formation of a macroanion, can be represented as follows:



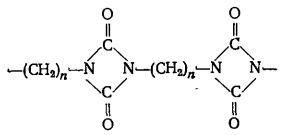
Depending on the chemical nature and conformation of the polymer chain, the reaction can proceed mainly via pathway *A* or *B* or via both simultaneously.

Interesting relations have been observed in the homopolymerisation of aliphatic isocyanates with different lengths of the methylene bridge between two NCO groups. Sections with a polyacetal chain structure were observed for the first time in the homopolymers formed from such monomers, which demonstrates the possibility of the homopolymerisation of isocyanates with dissocation of the C=O double bond. The polymerisation of aliphatic $\alpha\omega$-polymethylene di-isocyanates $OCN(CH_2)_nNCO$ with $n = 1-4$ in the presence of sodium cyanide in DMF at low temperatures was studied simultaneously by King [84] and Iwakura et al. [85] The polymers formed have an extremely high thermal stability and decompose as a rule above 350°C with the exception of the polymers formed from ethylene di-isocyanate. The polymers are soluble in hot sulphuric acid, *m*-cresol, DMSO, and ethylene carbonate.

It was shown that the infrared spectra of the polymers contain two types of absorption band due to the C=O group: at 1710−1770 and 1690 cm^{-1}. This demonstrates the simultaneous presence in the polymer of carbonyl groups in the ring (high frequencies) and in the main chain (low frequencies). On the basis of these data [84,85] and data obtained for the chemical degradation of the polymers [85], it was established that in the general case the polymer contains three types of structure:



The quantitative proportions of various structures in the chain depend on the nature of the monomer, in particular on the length of the polymethylene chain (Table 4). Studies of the infrared spectra of the polymers led to the rejection of the "polydimeric" chain structure:



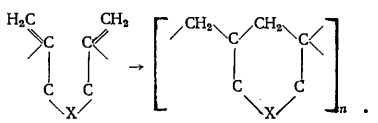
although the polymerisation of certain di-isocyanates did in fact occur in the presence of typical cyclic dimerisation catalysts, for example pyridine [85].

Linear cyclopolymerisation was also observed when cyclohexylene di-isocyanate, hydroxymethylene di-isocyanate, and 1,2,3-propylene tri-isocyanate were employed as monomers [84].

Table 4. The content of various structures in the chain of $\alpha\omega$-polymethylene di-isocyanate polymers (in %).

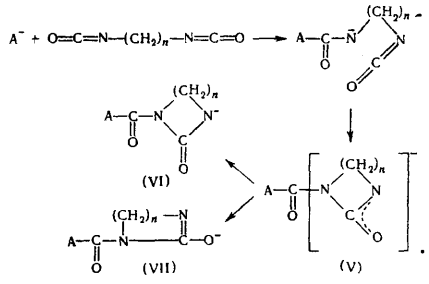
n in $OCN(CH_2)_nNCO$			
1	66	34	
2	0	100	0
3	76	24	0
4	40	60	0

Thus one may conclude that in the anionic polymerisation of $\alpha\omega$-polymethylene di-isocyanates the formation of linear polymers containing repeating cyclic units in the main chain takes place in accordance with alternating intermolecular and intramolecular chain propagation mechanisms. Ring formation of this kind in the growing main macromolecular chain is well known from studies on the polymerisation of dienes [86] and other bifunctional compounds containing ring double bonds [87]. The fundamental unit of such linear cyclopolymers can be readily represented if it is assumed that polymerisation requires the operation of alternating intramolecular and intermolecular chain propagation mechanisms:



In the linear cyclopolymerisation of di-isocyanates, initiation takes place as a result of the attack by the catalyst anion on the carbon atom in the isocyanate group located at one of the ends of the monomer. This results in the dissociation of the C=N bond, as in the anionic polymerisation of mono-isocyanates, with formation of 1-nylons. The second, intramolecular propagation stage may consist of the coordination of the nitrogen atom in the

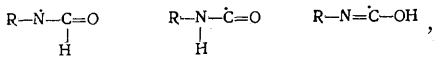
anion to the carbon atom of the second isocyanate group in the monomer with formation of a ring:



In the cyclic intermediate (V), the negative charge is in general delocalised between the nitrogen and oxygen atoms. Depending on the structure of the monomer, structure (VI) or (VII) is formed. Intermolecular chain propagation takes place via the attack by the macroanion on another monomer molecule at the N=C bond.

The question of the dissociation of the N=C or C=O bond in various reactions involving isocyanates is crucial to the chemistry of these compounds. Calculations on the distribution of electron density in the NCO group by the MO-LCAO method have shown that, depending on the structure of the isocyanate, electron density may be enhanced both at the nitrogen and at the oxygen atom [88]. The possibility of urethane formation and the hydrolysis of isocyanates via a stage involving the dissociation of the C=O bonds was recently demonstrated by oxygen isotope exchange [11]. There are no literature data permitting a comparison of the N=C and C=O bond energies in the N=C=O cumulative systems, but indirect information concerning a greater or lesser ease of dissociation of a particular bond may be obtained from the ESR spectra of the radicals formed on γ-irradiation of isocyanates and isothiocyanates and in their reactions with thermal hydrogen atoms [89].

Of the possible radicals formed in such reactions with various alkyl and aryl isocyanates involving the NCO group,

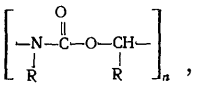


only the first two were detected in the system employed [89] and, depending on the structure of the isocyanate, a radical with an unpaired electron at the nitrogen or at the carbon atom was produced. However, these extremely useful data cannot be treated as proof of the impossibility of the dissociation of the C=O bond in nucleophilic reactions of isocyanates.

The relations in the polymerisation of isocyanates considered here and the data for this copolymerisation which are described below merely emphasise the earlier conclusion [10,11] that the reactions of isocyanates can involve the dissociation of both N=C and C=O bonds, which depends both on the structure of the monomer and hence on the distribution of electron density in the NCO group and on the mechanism of the process and reaction conditions.

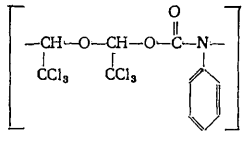
4. COPOLYMERISATION OF ISOCYANATES WITH OTHER MONOMERS

The majority of known copolymers of isocyanates have been obtained by their copolymerisation with aldehydes. Copolymers of formaldehyde with phenyl and alkyl isocyanates [90,91], of acetaldehyde with phenyl and ethyl isocyanates with tolylene di-isocyanate [92], and of butyraldehyde with phenyl isocyanate [92] have been described. Copolymers of phenyl isocyanate and *N*-sulphinyl isocyanate with chloral have also been obtained [93,94]. In most cases copolymerisation occurs in the presence of anionic initiators—sodium cyanide, sodionaphthalene, and fluorenylsodium, but in the copolymerisation of chloral the reaction occurs in the presence of tertiary amines [93] and organometallic complexes such as metal acetylacetonates [95,96]. It has been shown that the chemical nature of the monomers plays such a significant role in their capacity for copolymerisation that in some cases the reaction does not take place at all. Thus acetaldehyde, benzaldehyde, acrolein, and metacrolein do not copolymerise with phenyl isocyanate [92]; on the other hand, butyl isocyanate does not copolymerise with chloral [93]. The copolymers with aldehydes have a fundamental unit with a urethane structure:



(VIII)

i.e. in the copolymerisation the N=C bond of the isocyanate and the C=O bond of the aldehyde dissociate. The presence of the carbonyl group is evident from the infrared spectra (ν = 1725 cm^{-1}) of the copolymers. The molecular weight of the copolymers with chloral, obtained in the presence of triethylamine and triethylenediamine, is $(1-2) \times 10^4$. [93] The polymers have a high melting point (240–250°C) and are white powders readily soluble in benzene, chloroform, carbon tetrachloride, and other solvents. It has been shown by infrared spectroscopy and elemental analysis that the copolymers with chloral formed by anionic copolymerisation do not contain dimeric and n-meric isocyanate blocks, while two monomeric chloral units enter into the fundamental unit of the copolymer with phenyl isocyanate [92]:

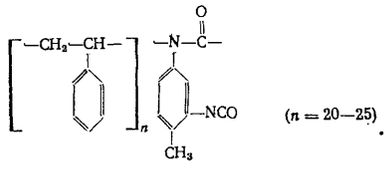


(IX)

In this copolymer the content of chloral corresponding to different monomer ratios (ranging from 3 : 1 to 1 : 3) varies from 62 to 75%. In the copolymer obtained in the presence of a tertiary amine, the content of chloral is 52–66%. The copolymerisation constants for the phenyl isocyanate–chloral system are respectively 0 and 0.4, [92] i.e. the phenyl isocyanate adds at a higher rate to the chloral than to the phenyl isocyanate molecule and conversely phenyl isocyanate is more reactive than chloral in relation to the anion of the latter. 1 : 1 copolymers of phenyl isocyanate and butyl isocyanate with chloral are formed in the presence of metal acetylacetonates, the catalytic activity of the latter depending on the nature of the metal and increasing in the sequence [96] Fe < Cu < Co < Ni. It has been shown by ultraviolet spectroscopy [96] that the formation of a complex by metal acetylacetonate with chloral is responsible for the initiation of polymerisation. The carbonyl group of chloral, inserted between the metal ion and the oxygen atom of acetylacetone, is polarised, which leads to an increase of the negative charge on the oxygen atom of chloral. Thus the copolymerisation has an anionic mechanism.

Isocyanates readily copolymerise with ketens; the mechanism of chain formation in this reaction does not show significant differences from the copolymerisation with aldehydes. At 0°C and room temperature in the presence of n-C_4H_9Li, LiOR, NaOR, and NaCN, diphenylketen and phenyl isocyanate form an alternating copolymer as a result of the dissociation of the C=O bonds of the keten and the C=N bonds of the isocyanate [97]. Block-copolymers containing several phenyl isocyanate units in succession are formed at lower temperature (−45°C).

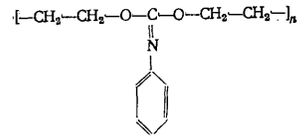
Copolymers of isocyanates with acrylonitrile and vinyl acetate [97], styrene, isoprene, methyl methacrylate, etc. [98-100] have been described. In the copolymerisation of tolylene di-isocyanate with styrene at 20−100°C in the presence of benzoyl peroxide and isopropylphenyl hydroperoxide initiators, the block copolymers (X) are formed:



(X)

The block-copolymerisation of vinyl monomers with butyl isocyanate and 2,4-tolylene di-isocyanate, which proceeds via a "live" polymerisation mechanism at low temperatures in the presence of n-C_4H_9Li in toluene–tetrahydrofuran mixtures has been studied in very great detail. The molecular weight distribution in the copolymers was investigated by gel chromatography: M_w/M_n is 1.14−1.17 in block-copolymers of styrene with butyl isocyanate and 1.5−1.6 in the copolymers of styrene, methyl methacrylate, and isoprene with tolylene di-isocyanate [99]. The di-isocyanate copolymers containing free NCO groups [copolymer (X)] are readily cross-linked by diols, water, and diamines and therefore are of significant practical interest. The trimerisation of the NCO groups can be used for the cross-linking of these copolymers.

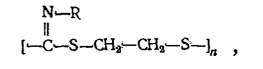
Studies on the copolymerisation of isocyanates with olefin oxides have a direct bearing on the possibility of the dissociation of the C=O bond in reactions involving isocyanates which we are considering. Furukawa and coworkers [101,102] were the first to establish that in the presence of triethylaluminium the monomers are copolymerised in the phenyl isocyanate–oxiran system together with the formation of polyoxiran. The copolymers contain acetal units in the main chain:



(XI)

The structure of the fundamental unit was demonstrated spectroscopically and by studying the hydrolysis products of the copolymers: one of the hydrolysis products of the copolymer (XI) is aniline. *N*-phenylmonoethanolamine should be formed in the hydrolysis of the copolymers formed by the addition of oxiran with dissociation of the N=C bond of the isocyanate.

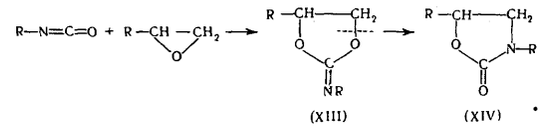
Subsequently a number of isothiocyanates were copolymerised with thi-iran in the presence of triethylamine [103], n-C_4H_9Li, and sodionaphthalene [104,105]. It was shown that the copolymerisation involves the formation of a polymer having the following structure:



(XII)

i.e. the addition of thi-iran to the isothiocyanate proceeds with dissociation of the C=S bond. The copolymerisation of thi-irans with isothiocyanates in the presence of typical anionic initiators involves the "live" polymerisation mechanism, which makes it possible to obtain block-copolymers of the required composition [105].

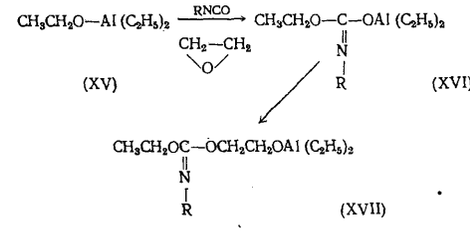
The very fact of polymerisation via the C=O and C=S bonds is not unexpected. Gulbins and Hamann [107] showed that the formation of the addition product (XIII) with dissociation of the C=O bond is an intermediate stage preceding the formation of 2-oxazolidinones (XIV) from epoxides and isocyanates:



(XIII) (XIV)

The conversion of compound (XIII) into 2-oxazolidinone (XIV) as a result of a rearrangement with opening of the dioxolan ring takes place at temperatures in the range 150−200°C and is catalysed by Lewis acids [108].

However, it has been shown [109,110] that compounds of type (XIII) and (XIV) are not intermediates in the copolymerisation of isocyanates with epoxy-compounds in the presence of triethylaluminium. The copolymerisation has a coordination-anionic mechanism with alternating insertion of the monomers in the Al−O bond of the diethylaluminium monoalkoxide (XV) and compound (XVI) being formed:



(XV) (XVI)

(XVII)

The structure of the intermediate (XVI) was established by infrared and NMR spectroscopy.

The data discussed above show that, despite the considerable number of studies concerned in some way with the problem of the polymerisation of isocyanates, the question of the mechanism of the processes involving various catalytic systems is still far from being finally elucidated. The limited number and in some cases the total absence of quantitative kinetic studies hinders greatly both the interpretation of the results and the possibility of a deliberate regulation of the rates of the processes and of the composition of the polymers formed. Much still remains to be done in the field of isocyanate polymerisation and one of the aims of the present review was to draw the attention of investigators to this interesting problem, which is important from the practical point of view.

After the manuscript had been sent to the editors, a number of studies with data on new catalytic systems and on the trimerisation [111-113], polymerisation [112,113], and copolymerisation of isocyanates with various monomers [114-121], as well as data on the thermal degradation of polymers with isocyanurate rings in the chain [122] and detailed studies on the properties and structures of polyisocyanates in solution [123-125] were published.

Chemical Dosimetry of Pulsed Electronic Radiation

A.K.Pikaev

Existing methods for chemical dosimetry of pulsed electronic radiation are reviewed. Sources of this type of radiation are described, and the special problems arising in the dosimetry of high dose rates (up to 10^{14} rad s^{-1}) are discussed. The effect of dose rate on the yield of radiolysis products is discussed in detail for a number of systems used in dosimetry (aqueous solutions, organic liquids, polymers, gases, etc.). Dosimetric systems particularly suitable for different ranges of dose rate are listed. 112 references.

1. INTRODUCTION

Pulsed electronic radiation, generated by electron accelerators, has become widely used in radiation chemistry during the last few decades. This development arose, in the first instance, as a result of the penetration of pulse radiolysis into radiation-chemical practice. A powerful, short pulse of high-energy electrons can generate short-lived particles (free radicals, ions, excited molecules) in quantities sufficient to allow their detection by existing physicochemical methods. This enables the particles to be identified and their reaction kinetics to be measured directly. The method has been discussed in monographs [1,2] and in review articles [3,4], and it has given results of fundamental significance in radiation chemistry and in many other fields of science (chemical kinetics, photochemistry, radio-biology, etc.).

A system subjected to a pulse of this type receives a fairly high dose (up to 10^6–10^7 rad). The pulse is of very short duration (usually 10^{-6}–10^{-9} s). Hence, radiolysis by pulsed radiation usually involves very high dose rates (up to 10^{13}–10^{14} rad s^{-1}), which give rise to a number of special features in the radiolytic reactions induced in the system. For example, competitive reactions of the radical–solute and radical–radical type become important in aqueous systems (see Ref. 1). This is an additional reason for the growing popularity of pulsed electron radiation among research workers.

Lastly, electron accelerators are already fairly widely used in radiation chemistry (see, for example, Ref. 5). Hence, accelerators capable of generating pulsed radiation are also likely to find applications.

Obviously, correct dosimetry of pulsed radiation is one of the main prerequisites to the successful application of this type of radiation in radiation-chemical experiments. The recent literature contains a large number of papers on the chemical dosimetry of pulsed radiation. The earlier work is discussed in recent books [1,2] and in a recent review [6]. The present review deals with results published up to the middle of 1971.

2. SOURCES OF PULSED ELECTRONIC RADIATION

Pulsed electronic radiation is usually generated with linear accelerators. These machines can produce either trains of pulses with a prescribed periodicity or single pulses. Pulses of electrons can be obtained also in accelerators of other types with special attachments. In recent years, pulse accelerators of the "Febetron" type, operating on the capacitor discharge principle, have become popular in radiation chemistry laboratories outside the Soviet Union. They are the most powerful accelerators yet developed, giving electron pulses corresponding to currents of thousands of amperes. Other accelerators capable of producing pulsed electron radiation include the dynamitrons and resonance transformers. The operating characteristics of typical sources of pulsed electron radiation are listed in Table 1.

The length of the pulses produced by linear electron accelerators is usually of the order of 10^{-6}–10^{-9} s. However, these pulses usually have a fine structure. For example, a single pulse from the Vickers accelerator at Toronto University, 3.5×10^{-8} s long, actually consists of approximately 100 pulses 2×10^{-11} s long separated by 3×10^{-10} s intervals [13]. The linear accelerator installed at the Argonne National Laboratory (USA) has very similar characteristics: the fine structure of the pulses generated by this accelerator [14] is shown in Fig. 1. Thus, modern electron accelerators offer pulses as short as $\sim 10^{-11}$ s to the research worker.

Pulsed electron accelerators can be used also to generate pulses of X-rays by focussing the electron beam from the accelerator on a heavy-metal target (tungsten, lead, gold, etc.). The method has been used to measure the radiation-induced electrical conductivity of various liquids [21-23].

Table 1. Characteristics of pulsed electron accelerators.

3. GENERAL COMMENTS

A knowledge of the following basic parameters is needed in radiation-chemical experiments with pulsed radiation: the dose per pulse absorbed by the system, the pulse length, and the pulse waveform. As an example, oscillograms of the electron pulses generated by various accelerators are shown in Fig. 2.

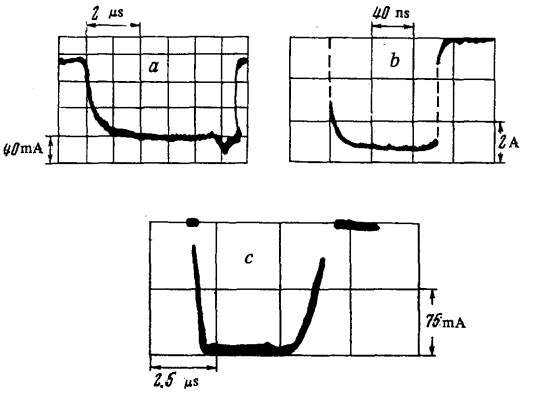

Figure 2. Oscillographic traces of electron pulses generated by (*a*) a linear accelerator [9], (*b*) a Van de Graaf accelerator [19], (*c*) a Cockroft–Walton accelerator [17].

If the duration of the pulse is $\leqslant 10^{-6}$ s the resulting, short-lived radiolysis products have half-lives greatly in excess of the pulse length. The reactions involving these products take place, effectively, after the pulse has subsided. Hence, in these reactions the dose per pulse (which determines the concentration of short-lived products) is more important than the dose rate (which determines the rate of formation of these products). The dose per pulse is measured by physical or by chemical methods. Among the former, calorimetric methods are the most important [19,24-26]. Willis and coworkers [19,26] used an aluminium disk as the calorimeter. With liquid samples, the calorimetric disk was identical in shape and size to the volume of the experimental liquid [26]. However, the method does not lend itself to studies of radiolysis in gaseous systems. In this case, thin disks covering a range of thickness are used, and the dose in an infinitely thin calorimeter is found by extrapolation to zero thickness [19]. Ionisation methods are not suitable for dose measurements in pulsed radiation experiments because the intensities are too high [27,28]. If the average energy of the electrons in the irradiated system is known, the dose can be found by measuring the charge in the system (if sufficiently conducting) [1,17]. The charge can be conveniently measured with an integrator based on capacitor discharge.

In the vast majority of radiation-chemical experiments, doses have been measured by chemical methods. The dose is calculated from the amount of chemical reaction induced by the radiation in some suitably chosen system. Chemical dosimetry has been discussed in recent monographs [29,30] and reviews [6].

Two types of dosimetric measurement are used in pulse radiolysis, depending on the aim of the experiment. If the experiment is designed to measure the radiation-chemical yield of a specific product, we need to know the mean dose over the whole sample volume. If, on the other

hand, we are monitoring short-lived particles by some optical method we need to know the optical density of the system as well as the dose. In this case, since the dose field is never uniform within the cell, one measures the dose absorbed along the path of the monitoring light beam rather than over the whole of the sample.

At the very high dose rates produced by pulsed electron radiation the radiation-chemical yields of many dosimetric systems differ from the values measured at less extreme dose rates. In aqueous dosimetric systems the effect is due to recombination of the primary radiolysis products of water (hydrated electrons $e^-_{aq.}$, hydrogen atoms, OH radicals). Evidently, we must allow for this effect when using aqueous systems for the dosimetry of pulsed radiation.

Many authors have reported a characteristic change in the yield of the radiation-chemical changes of practically all dosimeters based on aqueous solutions. The recombination of the primary radiolysis products of water can be inhibited by using relatively high concentrations of solutes.

The yields under pulsed radiation conditions can also be different (as compared, for example, with γ-radiolysis) in gaseous dosimeters. The effect has been reported, in particular, in mixtures of oxygen and nitrous oxide (see Section 9).

Electron accelerators are complex machines whose operation presents a number of special problems. Although the current does not usually vary by more than 10% from pulse to pulse, much larger variations are occassionally produced. A significant shift in the position of the beam is also possible. These effects can lead to large experimental errors: in order to ensure against these errors it is desirable to monitor the dose rate continuously throughout the experiment. Various methods have been used for this purpose. Keene [8,31] has monitored the electron beam with a secondary emission ionisation chamber, in which the electrons pass through a thin metal foil in a vacuum before reaching the sample cell. Slow secondary electrons appear at the surface of the foil, giving a charge which is proportional to the number of incident fast electrons [8,31-33]. The chamber can be calibrated, for example, against the ferrous sulphate dosimetric system. Schmidt and Buck [34] monitored the dose by bringing the beam to rest in a copper target situated behind the sample cell and measuring the charge acquired by the target. Other methods of monitoring the dose rate have also been described [1,35-37]. In linear accelerators a change in beam current usually gives rise to a significant change in electron energy. Gass and coworkers [38] have described a novel magnetic analyser for measuring electron energies, which can be located within the accelerator in front of the exit window.

4. THE FERROUS SULPHATE DOSIMETRIC SYSTEM

The ferrous sulphate system, usually called the Fricke dosimeter, is most commonly used in radiation chemistry to measure dose. The dosimeter consists of a 10^{-3} M solution of Fe^{2+} in 0.4 M H_2SO_4, saturated with air and containing 10^{-3} mole litre^{-1} of NaCl. Irradiation causes oxidation of bivalent to tervalent iron, with a $G(Fe^{3+})$ value of 15.6 ions/100 eV for solutions of this composition at low dose rates.

Many workers [17,18,24,39-50] find that $G(Fe^{3+})$ for the Fricke dosimeter begins to decrease at dose rates of $\sim 10^8$ rad s^{-1}. The decrease is found [40,44,47] to be even greater when the solution contains NaCl. However $G(Fe^{3+})$ can be made practically independent of dose rate up to $\sim 6 \times 10^9$ rad s^{-1} by increasing the concentration of Fe^{2+} ions to 10^{-2} M and saturating the solution with oxygen [42,44,47-49]. $G(Fe^{3+})$ is 16.07 ions/100 eV for the γ-radiolysis of a solution of this composition [48]. Table 2 lists the results of some recent measurements by Fricke and coworkers [48] of $G(Fe^{3+})$ for solutions of the above compositions. According to Thomas and Hart [44], $G(Fe^{3+})$ in an oxygen-saturated 10^{-2} M solution of Fe^{2+} in 0.4 M H_2SO_4 is 11.2 ions/100 eV at dose rates of $\sim 10^{11}$ rad s^{-1}.

Table 2. Values of $G(Fe^{3+})$ for the ferrous sulphate dosimetric system at high dose rates.

Dose rate, rad s^{-1}	$G(Fe^{3+})$, ions/100 eV	
	10^{-3} M soln. of Fe^{2+} in 0.4 M H_2SO_4 (saturated with air)	10^{-2} M soln. of Fe^{2+} in 0.4 M H_2SO_4 (saturated with O_2)
$\leqslant 10^8$	15.60	16.07
$7.14 \cdot 10^8$	15.33	16.07
$1.43 \cdot 10^9$	15.04	16.07
$2.86 \cdot 10^9$	14.55	16.02
$5.72 \cdot 10^9$	13.76	15.88
$1.14 \cdot 10^{10}$	12.68	15.65
$2.29 \cdot 10^{10}$	11.33	15.20
$5.58 \cdot 10^{10}$	9.64	14.61

Thus, an oxygen-saturated 10^{-2} M solution of Fe^{2+} in 0.4 M H_2SO_4 (often called the modified Fricke dosimeter) can be used to measure the dose of pulsed radiation at dose rates up to $\sim 6 \times 10^9$ rad s^{-1}.

The concentration of Fe^{3+} ions formed by irradiation is usually determined spectrophotometrically by measuring light absorption at 304 nm. The molar extinction coefficient of Fe^{3+} in 0.4 M H_2SO_4 is 2197 litre mole^{-1} cm^{-1} at 25°. Its temperature dependence [6] is 0.69% per degree.

5. OTHER AQUEOUS DOSIMETRIC SYSTEMS

The yield $G(Ce^{3+})$ in the cerium dosimetric system (10^{-4}–10^{-3} M solution of Ce^{4+} in 0.4 M H_2SO_4) has been found [41,42,44,46,51] to increase at dose rates above $\sim 10^8$ rad s^{-1}. For example, in a 2×10^{-4} M solution of Ce^{4+} in 0.4 M H_2SO_4 the yield $G(Ce^{3+})$ is ~ 3.3 ions/100 eV at a dose rate of $\sim 8 \times 10^9$ rad s^{-1}, [51] as compared with 2.3–2.5 ions/100 eV for the same solution exposed to γ-radiation from ^{60}Co. Hence, the cerium system is not very useful for the dosimetry of pulsed radiation at dose rates in excess of $\sim 10^8$ rad s^{-1}.

According to Hutchinson [52], the yield of the bleaching reaction of Methylene Blue in aqueous solutions is drastically lowered under pulsed electron radiation conditions. Thus, the dose required to lower the optical density of a 5×10^{-6} M solution of this dye by 37% at a dose rate of $\sim 10^{10}$ rad s^{-1} is greater by a factor of 2–4 than at lower dose rates.

Bjergbakke and Sehested [53] studied the effect of dose rate under pulsed electron radiation conditions on $G(Fe^{3+})$ in a 5×10^{-3} M solution of H_2SO_4 containing 10^{-3} mole litre^{-1} of Fe^{2+} and 10^{-2} mole litre^{-1} of Cu^{2+}. They found that $G(Fe^{3+})$ in a deaerated solution is practically independent of dose rate up to 5×10^8 rad s^{-1}, whereas in an oxygen-saturated

solution the yield ceases to be constant at 10^8 rad s^{-1}. In the former solution $G(Fe^{3+})$ is 0.65, in the latter 0.75 ion/100 eV. The yield is independent of dose between 5×10^4 and 8×10^6 rad. At higher doses $G(Fe^{3+})$ begins to increase. At normal dose rates the value of $G(Fe^{3+})$ in this system is ~0.7 ion/100 eV.[53-56]

Feng and coworkers[54] published a more detailed study of the radiolysis of aqueous $FeSO_4$–$CuSO_4$–H_2SO_4 solutions at high dose rates. They found that $G(Fe^{3+})$ increases with dose rate, acidity, and oxygen concentration to ~4 ions/100 eV. However, the dependence of $G(Fe^{3+})$ on dose rate is much less marked when the solution contains large concentrations of Cu^{2+} ions. In a solution containing Fe^{2+}, H^+, O_2, and Cu^{2+} at the concentrations 10^{-3}, 10^{-2}, 2.4×10^{-4}, and 5×10^{-2} mole $litre^{-1}$ respectively, $G(Fe^{3+})$ is independent of dose rate up to ~$(1.0-1.4) \times 10^{10}$ rad s^{-1}. (The yield of Fe^{3+} under these conditions is 0.58 ion/100 eV) At slightly higher (0.1 M) concentrations of Cu^{2+} the yield remains constant up to a dose rate of ~3×10^{10} rad s^{-1}.

The yield of Fe^{2+} in a 5×10^{-3} M solution of H_2SO_4 saturated with air and containing Fe^{3+}, Cu^{2+}, and formic acid decreases at high dose rates[45]. Even at dose rates of ~10^8 rad s^{-1} the value of $G(Fe^{2+})$ in solutions containing large amounts of Cu^{2+} or HCOOH is lower than the yield for γ-radiolysis.

Sehested and coworkers[57,58] have studied the behaviour of an aqueous oxalic acid dosimeter at high dose rates. They found that the yield for the decomposition of oxalic acid (at a dose corresponding to 25% decomposition) is independent of dose rate up to 2×10^8 rad s^{-1} when the concentration of oxalic acid is up to 2×10^8, 2×10^9, and 2×10^{10} rad s^{-1} when the concentration of oxalic acid is 0.05, 0.1, and 0.2 M respectively. The yield for the decomposition of $H_2C_2O_4$ was 4.9 molecules/100 eV.

Anderson and Hart[59] measured the yield of radiolysis products in an oxygen-saturated solution containing 10^{-2} mole $litre^{-1}$ of HCOOH and 5×10^{-4} or 5×10^{-3} mole $litre^{-1}$ of H_2SO_4 at dose rates of ~3×10^9 rad s^{-1}. The results (in molecules/100 eV) are: $G(H_2O_2) = 3.25$, $G(CO_2) = 2.75$, $G(-O_2) = 2.82$, and $G(H_2) = 0.43$. These values are practically identical to the yields observed with γ-radiation from ^{60}Co.

Pikaev and Glazunov[45] found that $G(Fe^{3+})$ in deaerated sulphuric acid solutions of Fe^{2+} under pulsed electron irradiation is considerably lower than under γ-radiolysis conditions. Thus, $G(Fe^{3+})$ for a 3×10^{-3} M solution of Fe^{2+} in 0.4 M H_2SO_4 is ~6.7 ions/100 eV even at a dose rate of 5×10^7 rad s^{-1}.

The yield of phenol in solutions of benzene saturated with air or oxygen is strongly dependent on the dose rate of the pulsed radiolysis[9,60,61]. For example, $G(C_6H_5OH)$ is found[60,61] to be 0.8 molecule/100 eV at a dose rate of 3.6×10^9 rad s^{-1}, as compared with 1.9–2.1 molecules/100 eV during γ-radiolysis.

Pikaev and coworkers[61-63] found that in sulphuric acid solutions of Fe^{2+} containing oxygen and benzene or ethanol the $G(Fe^{3+})$ value decreases very substantially at high dose rates. For example, in a 2.5×10^{-4} M solution of Fe^{2+} in 0.4 M H_2SO_4 saturated with benzene and air the $G(Fe^{3+})$ value is ~15 ions/100 eV at a dose rate of ~5×10^8 rad s^{-1}, as compared with 64 ions/100 eV for γ-radiation from ^{60}Co in the same solution.[61,62]

Many workers[44,59,64-66] have studied the pulse radiolysis of water at different pH values. Fricke and Hart[6] recommend the use of a deaerated solution of H_2SO_4 at pH 3–4 for the dosimetry of pulsed radiation. In this solution, $G(H_2O_2) = G(H_2) = 1.16$ molecule/100 eV at dose rates up to ~2×10^9 rad s^{-1}.[65] According to Willis and coworkers[66], $G(H_2)$ in deaerated, neutral water decreases from ~1 to ~0.8 molecule/100 eV as the dose rate is increased from ~1.6×10^{12} to ~1.6×10^{14} rad s^{-1}. At a dose rate of ~1.6×10^{14} rad s^{-1}, $G(H_2)$ increases from 0.8 to 1.1 molecule/100 eV as the pH decreases from 7 to 1.

6. USE OF HYDRATED ELECTRON FORMATION IN DOSIMETRY

Hart and coworkers[6,67-71] suggested the use of the hydrated electron formation reaction in 10^{-2} M NaOH solutions saturated with hydrogen (7×10^{-4} mole $litre^{-1}$ H_2) in pulsed radiation dosimetry†. In these solutions the $e^-_{aq.}$ species produced by doses between 1 and 100–150 rad per pulse decay mainly by recombination.

The hydrated electron is characterised by a strong optical absorption in the visible region of the spectrum, with a band maximum at 720 nm. According to some recent measurements[73], the molar extinction coefficient of $e^-_{aq.}$ is 1.85×10^4 litre $mole^{-1}$ cm^{-1} at 715 nm. Evidently, the concentration of hydrated electrons can easily be measured spectrophotometrically. However, $e^-_{aq.}$ is a short-lived particle, with a half-life of ~25 ms in a solution of the above composition[69]. Hence, fast spectrophotometric methods must be used to measure the concentration of $e^-_{aq.}$: these methods are discussed in Refs. 1 and 2.

The dosimetric method consists in measuring the kinetics of the decay of optical absorption associated with the $e^-_{aq.}$ species. To calculate the dose from these measurements we need to know the initial optical density E_0 of the hydrated electron and the product $G\cdot\epsilon$ (where ϵ is the extinction coefficient of $e^-_{aq.}$) at the chosen wavelength. The quantity E_0 is found by extrapolating the kinetic curve to $t = 0$ (where t is time). The value of $G\cdot\epsilon$ at 700 nm for a hydrogen-saturated solution (pH 12) is 1.21×10^5 (litre $mole^{-1}$ cm^{-1})·molecules/100 eV. The formula for the dose D in this case is

$$D = \frac{0.994 \cdot 10^9 E_0}{1.21 \cdot 10^5 l} = 7.8 \cdot 10^3 \frac{E_0}{l} \text{ rad/pulse} \qquad (1)$$

where l is the optical path length of the measuring beam in the cell (in cm).

This dosimetric method enables[69] doses between 1 and 100–150 rad/pulse to be measured. With doses below 1 rad/pulse accurate measurements are difficult. With doses in excess of 100–150 rad per pulse the product $G\cdot\epsilon$ begins to decrease because the transformation of OH into $e^-_{aq.}$ is incomplete. The upper limit of measurable dose can be raised by lowering the pH of the medium to 9 and by replacing H_2 by, for example, methanol (at a concentration to 10^{-3} M). In this solution H and OH are not converted into $e^-_{aq.}$, and therefore $G\cdot\epsilon$ at 700 nm remains equal to 5.0×10^4 (litre $mole^{-1}$ s^{-1})·molecules/100 eV. Using this solution, doses per pulse up to 10^4 rad can be measured[6].

This dosimetric method cannot be used with pulses longer than a few microseconds[69], because the duration of the pulse must be kept shorter than the half-life of the $e^-_{aq.}$ species so that the recombination of $e^-_{aq.}$ during the pulse can be ignored. However, at low doses per pulse (~1 rad) the half-life of $e^-_{aq.}$ is long enough for pulses of 10^{-3} s duration to be acceptable. Fielden and Hart[69] showed that the limitations can be defined as

†The formation of $e^-_{aq.}$ by the radiolysis of aqueous systems and the properties of these particles are discussed in recent monographs[67,72].

follows: for doses of ~100 rad per pulse the minimum dose rate must be 10^7 rad s^{-1}, while for doses of ~1 rad the dose rate must be at least 10^3 rad s^{-1}. The dosimeter gives the same results for electron pulses and for pulses of X-rays.

The dosimetric solution can be used repeatedly. Fielden and Hart [69] obtained reproducible results over a period of 2 years, during which the total dose was greater than 1 Mrad, with a solution sealed in a quartz cell. Traces of oxygen present in the original solution are removed by a preliminary irradiation. If the solution is accidentally exposed to an excessive dose rate, the resulting hydrogen peroxide can be destroyed by irradiating the cell at a low dose rate.

Hart and Anbar [67] recommend, for measurements at high dose rates (up to 10^{10} rad s^{-1} with microsecond pulses and up to 10^{12} rad s^{-1} with nanosecond pulses), a method based on the steady-state concentration of hydrated electrons. In a solution free from acceptors for the $e^-_{aq.}$ particle the maximum concentration of these particles is reached at the end of the pulse. However, if the solution contains a relatively high concentration of electron acceptors, a steady-state concentration of $e^-_{aq.}$ is set up during the application of the pulse. The dose rate can be found by measuring this concentration, using the formula

$$I = \frac{k[S][e^-_{aq}]_{st} \cdot 6{,}02 \cdot 10^{25}}{G(e^-_{aq})} \qquad (2)$$

where I is the dose rate (eV litre^{-1} s^{-1}), k is the rate constant of the reaction between the acceptor S and $e^-_{aq.}$ (litre mole^{-1} s^{-1}), [S] and $[e^-_{aq.}]$ are the molar concentration of S and the steady-state concentration of $e^-_{aq.}$ during the pulse, and $G(e^-_{aq.})$ is the yield of $e^-_{aq.}$ (2.7 electron/100 eV).

Perchloric acid at 10^{-3}–10^{-2} M concentration can be used as the acceptor for $e^-_{aq.}$. The value of k for H^+ ions is 2.2×10^{10} litre mole^{-1} s^{-1}. [74] The main weakness of this method is that $G(e^-_{aq.})$ may be a function of the acceptor concentration [75].

Evidently, the most serious drawback of these methods of dosimetry is the complicated equipment needed to measure the optical absorption of $e^-_{aq.}$. Hence, these methods are used only in laboratories already committed to pulse radiolysis studies with optical monitoring of short-lived particles.

7. DOSIMETERS BASED ON POLYMER SYSTEMS

Various polymers have bean suggested for the dosimetry of pulsed radiation. Boag [76] recommends the use of plates of poly(methyl methacrylate) between 1 and several millimeters thick. Irradiation of this polymer produces optical absorption with a maximum at 292 nm. The optical density at this wavelength is linearly related to the dose in the range from 5×10^4 to ~10^6 rad.

Harrah [77,78] used polystyrene and polyhalogenostyrene plates containing various additives. He showed [77] that polystyrene plates containing *trans*-stilbene are suitable for dose measurements in the range 2×10^5–10^8 rad at dose rates between 300 and 7.5×10^{13} rad s^{-1}. Under these conditions the effect is independent of the energy of the radiation over the range 1.25×10^{-3}–4.7 MeV. The plates were prepared from benzene solutions of polystyrene (10 wt.%) and *trans*-stilbene (0.025 wt.%). Irradiation induces the isomerisation of *trans*-stilbene into the *cis*-isomer. This transformation is conveniently monitored spectrophotometrically from the absorption of light at 324 nm: at this wave length the extinction coefficient of *trans*-stilbene is more than an order of magnitude greater than the extinction coefficient of *cis*-stilbene. The measurement consists in finding the ratio $R = (D_0 - Dt)/D_0$, where D_0 is the initial optical density of the plate at 324 nm and Dt is the optical density after absorption of the dose. The radiation-chemical yield of the disappearance of *trans*-stilbene is 0.73 molecule/100 eV. The precision of this method is ±5% at doses greater than 1.5×10^6 rad, and ±10% at lower doses.

In his next paper [78], Harrah showed that polyhalogenostyrene plates containing the methoxide of Malachite Green can be used to measure doses between 5×10^4 and 1.5×10^7 rad at dose rates up to 10^{14} rad s^{-1}. The plates were prepared from benzene or chloroform solutions containing 10 wt.% of the polymer and 0.1 wt.% of the dye. The dye was used in its leuco-form, obtained by slowly adding a methanol solution of Malachite Green to a 1 M solution of sodium methoxide with vigorous stirring, followed by recrystallisation from benzene after treatment with activated charcoal. Irradiation induces a colour in the plate. The intensity of the colour is measured spectrophotometrically from the light absorption at 630 nm (for doses up to ~3×10^6 rad) or at 430 nm (for doses of 10^6–1.5×10^7 rad). The extinction coefficient of the dye at 430 nm is ~20% of the extinction coefficient at 630 nm. The effect of dose rate was tested with poly(4-chlorostyrene) plates. The measured optical densities at dose rates up to ~10^{14} rad s^{-1}, produced by electron pulses 2×10^{-8} s long (electron energy 2 MeV), differed by no more than 2% from those obtained with dose rates of 300 rad s^{-1} of γ-radiation from ^{60}Co. For a dose rate of 10^{15} rad s^{-1} the difference increases to 8%. All measurements were done in vacuum. In the presence of air the sensitivity of the films to γ-radiation is 25% higher than for vacuum irradiation. With poly(4-bromostyrene) plates the effect of oxygen is less marked (only ~4%). The existence of an oxygen effect is one of the drawbacks of this method of dosimetry. Another drawback is the marked dependence of the results on the presence of impurities in the plates.

Willis and coworkers [26] examined the possibility of using blue Cellophane films marketed by the firm of Dupont (USA) for the dosimetry of pulsed radiation from an accelerator of the "Febetron" type. These films contain the dye dimethoxyphenyl-*bis*-azo-*bis*-8-amino-1-naphthol-5,7-disulphonic acid [79], which is bleached by irradiation. The extent of bleaching is measured in a spectrophotometer at 655 nm. Willis and coworkers found that these films can be used to measure doses between 5×10^5 and 1.4×10^7 rad.

The energy of the radiation is not fully absorbed in the films, which must therefore be calibrated and can be used only as relative dosimeters.

8. ORGANIC LIQUIDS AS DOSIMETRIC SYSTEMS

Willis and coworkers [26] found that $G(H_2)$ for the radiolysis of liquid benzene by pulsed electrons generated by a "Febetron 705" accelerator (dose rate 10^{14} rad s^{-1}) is 0.04 molecule/100 eV. Thus, the yield of hydrogen is almost the same as reported [80–82] for lower dose rates (0.036–0.040).

The same workers pointed out a special feature of dosimetric measurements at very high dose rates using benzene (and possibly also other liquids of low electrical conductivity). Each pulse injects a charge of a few hundredths of a microcoulomb into the liquid. The relaxation time of the conductivity in these liquids is of

the same order as (or greater than) the duration of the pulse ($\sim 3 \times 10^{-8}$ s). Hence, the strong electric charge induced in the liquid by the leading edge of the pulse will tend to repel the electrons arriving during the main period of the pulse, and the measured dose will be seriously in error. Obviously, the magnitude of this effect increases with the thickness of the sample. It is found[26] to be negligible with sample thicknesses of 0.2–1.0 cm (for which $G(H_2) = 0.04$ molecule/100 eV), but it becomes significant with benzene samples 1.5 cm thick, for which $G(H_2) = 0.02$–0.03 molecule/100 eV.

Boyd and coworkers[83] studied the radiolysis of cyclohexane by electron pulses at dose rates up to $\sim 10^{14}$ rad s^{-1}. Under these conditions $G(H_2)$, though smaller than in γ-radiolysis, remains constant (14 molecules/100 eV) for dose rates between 6×10^{12} and 1.3×10^{14} rad s^{-1}. $G(H_2)$ is also independent of dose over the range which was explored (4×10^5–2.4×10^7 rad).

Dvornik and coworkers[84] recommend the use of ethanolic solutions of chlorobenzene containing 4 vol.% of water for the dosimetry of pulsed electronic radiation. With this system, the dose is measured by the formation of H^+ or Cl^- ions. They found that if the solution contains more than 10 vol.% of C_6H_5Cl the value of $G(HCl)$ is practically the same for γ-rays from ^{60}Co and for pulsed electron radiation at a dose rate of 10^9 rad s^{-1} (pulse length 7×10^{-6} s, electron energy 10 MeV). The following values of $G(HCl)$ were obtained for different concentrations of C_6H_5Cl (shown in brackets as vol.%): 4.53(10), 4.95(15), 5.19(20), 5.34(30), and 5.47(40).

9. GASEOUS DOSIMETRIC SYSTEMS

The possibility of using ethylene, oxygen, and nitrous oxide as dosimetric systems for pulsed electronic radiation has been investigated[15,85–89]. $G(H_2)$ for the radiolysis of ethylene at dose rates of $\sim 10^{14}$ rad s^{-1} is found[15] to vary with pressure. The yield of hydrogen decreases from 1.9 to 1.04 molecule/100 eV as the pressure is increased from 0.5 to 10 atm. In the γ-radiolysis of ethylene (at 1 atm pressure) $G(H_2) = 1.31$ molecule/100 eV.[90]

The yield of ozone in the radiolysis of gaseous oxygen by electron pulses (dose rate 10^{12}–3×10^{13} rad s^{-1}) is much higher than in γ-radiolysis[87–89,91]. According to Willis and coworkers[88], $G(O_3) = 12.8 \pm 0.6$ molecules/100 eV at the above dose rates, whereas only 6.2 ± 0.6 molecules of O_3 are produced by 100 eV in γ-radiolysis. The dose rate at which $G(O_3)$ begins to vary has not been identified precisely. Hence, oxygen can be used as a dosimetric system only at dose rates in the range 10^{12} to 3×10^{13} rad s^{-1}, for which $G(O_3)$ is known[88] to have a constant value of 12.8 molecules/100 eV. Under these conditions $G(O_3)$ remains constant over the pressure range 0.04–1 atm and for total doses in the range 0.05 to 0.35 Mrad. The ozone produced by the electron pulses is conveniently detected spectrophotometrically by light absorption at 254 nm. Its extinction coefficient at this wavelength[92] is 132 cm^{-1}, or[93] 135 cm^{-1} (both values being reported for normal pressure and temperature). Alternatively, the ozone can be determined iodometrically when higher precision is required. Boyd and coworkers[94] have recently made a detailed study of the reaction between I^- and O_3: they find that at pH 7 one molecule of O_3 generates 1.53 molecules of I_2.

In the radiolysis of gaseous nitrous oxide, $G(N_2)$ increases by approximately 20% as the dose rate is raised from the $\sim 10^2$–10^3 rad s^{-1} level to $\sim 10^{12}$ rad s^{-1}. The yield for γ-radiolysis[95] is ~ 10 molecules/100 eV, rising to 12.4 molecules/100 eV for radiolysis by powerful electron pulses[15,85,86]. For N_2O at 1 atm pressure, the change in yield occurs[86] in the range of dose rates 1.6×10^8–1.6×10^{11} rad s^{-1}. In pulse radiolysis, $G(N_2)$ is independent of N_2O pressure between 0.5 and 5.0 atm.[15] At 1 atm pressure the yield does not vary[85] if the temperature is raised to 200°. The yield is insensitive to dose up to 6.4×10^6 rad. According to Willis and coworkers[96], $G(N_2)$ equals 12.4 molecules/100 eV even at dose rates as high as $\sim 3 \times 10^{14}$ rad s^{-1}.

Boyd and coworkers[97] discovered an interesting feature of the dosimetry of pulsed electron radiation by means of gaseous systems. They studied the effect of pressure on the radiolysis yields of gaseous HCl, HBr, and N_2O at a dose rate of 1.6×10^{13} rad s^{-1}, and they found that below 0.5 atm the yield of H_2 in HCl and HBr is much higher than above 1 atm. (The same is true of the yield of N_2 in N_2O.) The effect is ascribed to the acceleration of secondary electrons in the transient electric field generated by the powerful electron pulses. A similar phenomenon occurs[96] in the radiolysis of N_2O and H_2S by electrons at a dose rate of $\sim 3 \times 10^{14}$ rad s^{-1}.[96]

Gaseous dosimetry at dose rates above 10^{12} rad s^{-1} is carried out in cells made of stainless steel. Lampe and coworkers[98] noticed a catalytic effect of this material in the decomposition of nitrous oxide of γ-radiolysis. The increase in the nitrogen yield due to this effect, $\Delta G(N_2)$, is described by the empirical formula

$$\Delta G(N_2) = \frac{4.2}{PI}, \qquad (3)$$

where P is the pressure of N_2O (atm) and I is the dose rate (Mrad h^{-1}).

It follows from formula (3) that for $P = 1$ atm and $I >$ 10 Mrad h^{-1} the quantity $\Delta G(N_2)$ is small in comparison with $G(N_2)$, which is usually 10–13 molecules/100 eV. Evidently, the effect can be ignored in pulse radiolysis, for which $I \gg 10$ Mrad h^{-1}.

10. OTHER DOSIMETRIC SYSTEMS

The output of the LiF thermoluminescent dosimeter is reported[99–101] to be independent of dose rate up to 2×10^{11} rad s^{-1}. It is also independent of dose[101] up to 10^5 rad.

Fielden and Hart[69] made a detailed study of the suitability of LiF single crystals for the dosimetry of pulsed radiation. They found that the response of this dosimeter is independent of dose rate between 0.9 and 1.5×10^6 rad s^{-1}. The measurements were made with γ-radiation from ^{60}Co and with X-ray pulses of different duration (10^{-6}, 9.5×10^{-8}, and 1.1×10^{-8} s). These authors stress that LiF can be used to measure extremely small doses (down to 10^{-2} rad per pulse).

Lithium fluoride has also been examined by Alsop and coworkers[102] as a possible thermoluminescent dosimeter for electron pulses at dose rates up to 10^{12} rad s^{-1}. These workers also considered the possibility of using CaF_2, activated with Mn, for the dosimetry of this type of radiation.

Schmidt and Buck[103] proposed a calorimetric method for the dosimetry of pulsed electronic radiation in which thermal changes are monitored conductimetrically. Their quartz cell, fitted with two parallel platinum foil electrodes, is filled with electrolyte and placed behind the collimator which defines an electron beam 2.5 cm in diameter. When the electron pulse strikes the cell, the

Table 3. Dosimetric systems for pulsed radiation.

System	Indicator reaction	Radiation-chemical yield (ions or molecules/100 eV)	Dose rate (rad s^{-1}) for constant radiation-chemical yield
10^{-3} M aq. Fe^{2+}, 0.4 M H_2SO_4, saturated with air	Formation of Fe^{3+}	15.6	$<10^8$
10^{-2} M aq. Fe^{2+}, 0.4 M H_2SO_4, saturated with oxygen	ditto	16.07	$<6 \times 10^9$
10^{-4}–10^{-3} M aq. Ce^{4+}, 0.4 M H_2SO_4	Reduction of Ce^{4+}	2.3–2.5	$<10^8$
10^{-3} M aq. Fe^{2+}, 10^{-2} M Cu^{2+}, 5×10^{-3} M H_2SO_4, deaerated	Formation of Fe^{3+}	0.65	$< 5 \times 10^8$
10^{-3} M aq. Fe^{2+}, 10^{-2} M Cu^{2+}, 5×10^{-3} M H_2SO_4, saturated with oxygen	ditto	0.75	$<10^8$
10^{-3} M aq. Fe^{2+}, 5×10^{-2} M Cu^{2+}, 10^{-3} M H_2SO_4, saturated with air	"	0.58	$<10^{10}$
10^{-3} M aq. Fe^{2+}, 0.1 M Cu^{2+}, 10^{-2} M H_2SO_4, saturated with air	"	0.58	$<3 \times 10^{10}$
5×10^{-2} M aq. $H_2C_2O_4$	Decompn. of $H_2C_2O_4$	4.9	$<2 \times 10^8$
0.1 M aq. $H_2C_2O_4$	ditto	4.9	$<2 \times 10^9$
0.2 M aq. $H_2C_2O_4$	"	4.9	$<2 \times 10^{10}$
10^{-2} M solution of NaOH, saturated with hydrogen	Formation of e^-_{aq}	6.6	$<1.5 \times 10^8$
10^{-3} M solution of CH_3OH (pH 9)	ditto	2.7	$<10^{10}$
aq. H_2SO_4 (pH 3–4)	Formation of H_2O_2 or H_2	$G(H_2O_2) = G(H_2) = 1.16$	$<2 \times 10^9$
Benzene	Formation of H_2	0.04	6×10^{12}–$1.3 < 10^{14}$
Cyclohexane	ditto	4	
Chlorobenzene in ethanol, containing 4 vol.% H_2O	Formation of HCl	4.5–5.5 (depending on concn. of C_6H_5Cl)	up to 10^9
Gaseous oxygen	Formation of ozone	12.8	10^{12}–3×10^{13}
Gaseous nitrous oxide	Formation of N_2	12.4	1.6×10^{11} and above
Polystyrene plates containing *trans*-stilbene	Stilbene isomerisation	0.73	up to 7.5×10^{13}
Polychlorostyrene plates containing the methoxide of Malachite Green	Colouration of plate	—	up to $\sim 10^{14}$
LiF single crystals	Thermoluminescence	—	up to 2×10^{11}–10^{12}

emperature of the electrolyte rises due to the absorption of the dose, and the electrical conductivity also changes by ~ 2% per degree). Changes in electrical conductivity are measured by a sensitive bridge method. This calorimetric cell can be used for doses of $\sim 10^3$ rad. The best electrolyte is a phosphate buffer (pH ~ 7), in which changes of electrical conductivity due to radiation-chemical reactions are negligible. A correction for the energy absorbed by the platinum foil electrodes must be made.

1. DOSE MEASUREMENT ALONG THE LIGHT BEAM DURING PULSE RADIOLYSIS WITH OPTICAL MONITORING OF SHORT-LIVED PARTICLES

As was pointed out earlier in this review, when optical monitoring of the short-lived particles is used in pulse radiolysis it is necessary to know the dose along the path of the light beam used as a probe. This is because the distribution of the dose is not usually uniform in these experiments (for example, only part of the solution is exposed to the radiation, the cross-section of the light beam is smaller than the cross-section of the electron beam, etc.). In these systems the dose is measured from observations of the optical absorption of any reaction product whose optical characteristics are known.

Dorfman and coworkers [104,105] suggest, for dosimetry under these conditions, measurement of the optical absorption of the Fe^{3+} ions produced during the irradiation of a solution of ferrous sulphate in sulphuric acid. In this system the kinetic curve shows a stationary period lasting several seconds after the application of the pulse. Adams and coworkers [106] used an aqueous solution of ferrocyanide, in which the plateau of the kinetic curve is reached in a few milliseconds. Fletcher and coworkers [107] used a $\times 10^{-3}$ M solution of KCNS saturated with oxygen, in which $(CNS)_2^-$ ion-radicals are formed by the reaction between OH radicals and thiocyanate ions. The molar extinction coefficient of this particle is 7350 litre $mole^{-1}$ m^{-1} at 475 nm, and $G[(CNS)_2^-] = G(OH) = 2.9$. [108,109]

Other workers [110–112] also used a CNS^- solution for this purpose. The formation of hydrated electrons (see Section 6) is a possible alternative approach to this problem.

---o0o---

This review has highlighted a number of special features of chemical methods of dosimetry when applied to pulsed radiation as opposed to γ-radiolysis. The most important effect is a dependence of the yield of the radiolysis products upon the dose rate: hence, it is essential to choose a dosimetric system whose response is independent of dose rate within the expected range. Table 3 has been compiled to assist the reader in the choice of a suitable system.

The following conclusions can be made by inspection of Table 3. Liquid benzene is the most generally applicable dosimetric system. The yield of hydrogen during radiolysis of liquid benzene is constant over the entire range of dose rates likely to be available to present-day workers. With aqueous solutions, the range of dose rates over which the yield is constant usually increases with solute concentration. The most convenient gaseous system for the dosimetry of pulsed radiation is nitrous oxide, because the yield of N_2 varies only by 20% between γ-radiation and electronic radiation from an accelerator of the "Febetron" type. Lastly, chemical changes in some polymer systems can also be independent of dose rate between wide limits.

Mechanism of the Action of an Electron Beam on Organic Photoresists

S.A.Neustroev and E.B.Sokolov

The litereature dealing with the decomposition of positive and negative photoresists by actinic light and by electron bombardment is reviewed, and the action of a stream of electrons on other organic materials, metals, and inorganic dielectrics is discussed. A mechanism producing internal irradiation of the resist is considered: the incident electrons excite the resist molecules into fluorescence and phosphorescence.
The influence of the (metallic or dielectric) substrate on the achievement of the required line widths is discussed. It is shown that the cross-linking of a negative photoresist under the influence of an electron beam occurs by free-radical polymerisation.

I. INTRODUCTION

The basic components of integrated microcircuits (semiconductor diodes and transistors, capacitors, interconnections, and resistors) have simple geometric shapes of micron or sub-micron dimensions. The main requirement in the production of integrated circuits is the ability to reproduce a given pattern a large number of times and to register it very accurately on a pre-existing pattern. Even the production of discrete transistors requires the superposition of 4 or 5 patterns[1]. Photolithography is the only procedure by which this requirement can be met with acceptable yields.

The photolithographic process consists in coating the article with a layer of acid-resistant polymer, which protects the metal, dielectric, or semiconductor from the action of an etchant. The need for ever-greater miniaturisation of the components of microcircuits poses a number of difficult scientific and technological problems concerning the synthesis of improved photoresists and the development of new methods of exposure.

The resolving power of processes relying on exposure to light is, of course, limited by the wave length of the light. The smallest line widths so far reported[2] are of the order of 1 μm (0.65 μm windows and 0.35 μm stripes between windows). These dimensions coincide almost exactly with the theoretical limit of line width attainable by exposure to light of wave length 0.3–0.4 μm.

The use of an electron beam to produce lines and patterns of small dimensions is not subject to the same limitations. An electron beam can be focussed to a spot a few Ångstroms in diameter, and the effective wave length of the electrons can be decreased to one Ångstrom or less by using a sufficiently high accelerating voltage (see Table 1). This effect is of the utmost importance in minimising diffraction phenomena and increasing the resolving power.

The results achieved in practice by exposing photoresists with an electron beam fall very far short of theoretical predictions. Some data on the line widths obtained by irradiating photoresists with electrons are summarised in Table 2. Even the narrowest lines are wider than the electron beam by a large factor, whereas the most commonly reported results are orders of magnitude worse than the theoretical expectations.

Table 1. Relationship between electron wave λ and accelerating voltage U.[3]

U, V	1	10	100	1000	10000	30000	40000	50000

Note. KPR (Kodak Photo Resist, Eastman Kodak, USA) is the vinyl ester of cinnamic acid; KOR (Kodak Ortho Resist, Eastman Kodak, USA) is a type of KPR improved by the addition of a sensitiser; KMER (Kodak Metal Etch Resist, Eastman Kodak, USA) is a polymer of modified natural rubber, improved by a diazide sensitiser; KTFR (Kodak Thin Film Resist, Eastman Kodak, USA) is similar to KMER but needs to be decanted before use; AZ-1350 (Shipley, Azoplate, USA); SH-200 (Japan) is a polysiloxane containing methyl radicals.

This divergence between theory and practice is explained by various factors, including the lack of resists specially designed for electron beam exposure, complex interactions between the stream of electrons and the layer of resist (or the substrate), the lack of monochromaticity of the beam, etc. A working theory of the interaction between an electron beam and the resist is needed before any attempt can be made to formulate resists of the required composition and structure.

The most important parameters from the point of view of device fabrication are the line width and the unevenness of the edge. Hence, this review will deal specifically with the factors which influence the technologically accessible line widths.

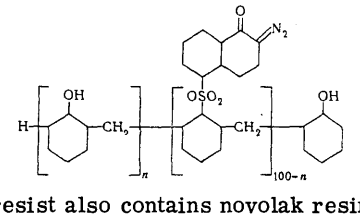
The interactions between high-energy electrons and polymers of various compositions have been discussed in detail by several workers (see, for example, Ref. 16, and the references quoted in the following Sections), particularly in the case of thin films [17,18].

Because of the complexity and multiplicity of the phenomena which accompany the passage of electrons through the photoresist and the substrate, a full discussion of the problem is not an easy matter. To facilitate the analysis, we shall deal first with the reactions accompanying the exposure of photoresists with light, the reactions induced by electron bambardment, and the interactions between a stream of electrons and the photoresist and substrate.

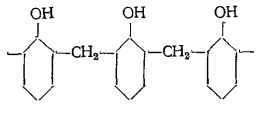
2. EXPOSURE OF RESIST BY A LIGHT BEAM

Positive resists are the most commonly used in the planar technology for the production of semiconductor devices [2]. Typical of this group of organic polymers are the compounds AZ-1350 (USA) and naphthoquinonediazide NKhDA (USSR). The two compounds have very similar compositions, differing only in some of the functional groups responsible for some specific properties.

The positive resist 1,2-naphthoquinonediazide(2)-5-sulphoester of novolak has the following structural formula [19]:

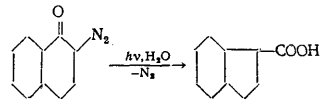


The photoresist also contains novolak resin as the film-forming component. Novolak consists of a complex mixture of products of different molecular weight, based on the polymer chain



When the resist is heated the photosensitive component decomposes with evolution of nitrogen. At first the thermoplastic film is converted into an insoluble compound which is very stable and adherent to the substrate. This reaction begins at 140–160°, i.e. below the temperature at which the novolak forms insoluble compounds. The reaction is assisted by the products of the decomposition of NKhDA. The most likely mechanism of this conversion is acylation of the hydroxy groups of the novolak by the ketens formed by thermal decomposition of the naphthoquinonediazido groups of the photoresist. Heating at temperatures above 250° is accompanied by heat evolution, characteristic of the condensation of the novolak units into a polymer of high molecular weight [20].

The application of NKhDA as a photoresist follows from the following change in the material under the influence of actinic light. Illumination with light of wave length shorter than 460–480 nm decomposes the NKhDA with evolution of nitrogen. The resulting indeneketen absorbs water present in the film, giving rise to indenecarboxylic acid which has hydrophilic properties and can dissolve in the aqueous developer. Addition of alkali to the developer helps to dissolve the exposed film. It should be noted that the novolak resin added to the resist is transparent to light of this wave length.



The quality and the sharpness of the image produced depend on a number of factors, including the completeness of the photochemical reaction and the avoidance of spurious polymerisation phenomena during the heating stage of the process.

One possible side reaction is acylation of the novolak by the ketens; other reactions include interaction of the ketens with the carbonium ions responsible for the photochemical reaction and decarboxylation of the decomposition products at high enough temperatures. The products of the side reactions are insoluble in organic solvents and in the alkaline developer. Tsirlin and coworkers [21] studied the effect of side reactions on the sharpness of the image obtained, and demonstrated the influence of resist composition and of the ratio of novolak to naphthoquinonediazide on the onset of negative resist behaviour.

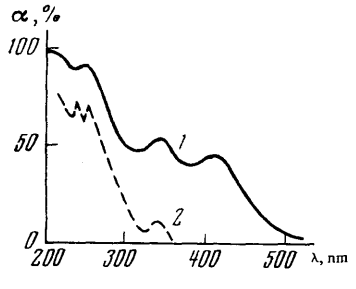


Figure 1. U.v. absorption spectra of (*1*) positive photoresist and (*2*) K-18 novolak resin [2].

Fig. 1 shows the absorption spectra of a layer of 1,2-naphthoquinonediazide(2)-5-sulphonate of novolak, and of the novolak resin K-18. The novolak resin absorbs at wave lengths below 370 nm.

The first and the second absorption band of phenol occur [22] at ~ 2780 Å and ~ 2380 Å respectively. The photolysis of phenol involves the series of reactions

$$ROH + h\nu \rightarrow ROH^* \overset{H_2O}{\rightleftarrows} RO^* + H_3O^* \rightarrow RO^- + h\nu' \overset{H_2O}{\rightleftarrows} ROH + OH^-.$$

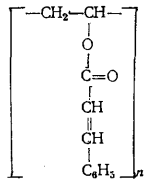
RO denotes a phenyl or a substituted aromatic system.

The most commonly used light source is a mercury lamp. The emission spectrum of the mercury lamp has a discrete line structure. The light of wave length 2537, 3650, 4050, and 4358 Å is active towards the photosensitive layers. The intensity distribution of these spectral lines in mercury lamps is 2:10:4:8. High-pressure lamps also emit a background radiation whose intensity amounts to 0.1–0.25 of the intensity of the main lines.

Negative photoresists, mostly based on poly(vinyl cinnamate), are known as PVTs in the USSR and KPR, KOR, etc. in the USA. These resists also are widely used in photolithographic processes for the production of electronic devices.

A very important feature of negative photoresists is their high stability—they are superior to positive resists in this respect.

PVTs is obtained by the etherification of poly(vinyl alcohol) and cinnamic acid, and has the following structural formula [2,23–25]:

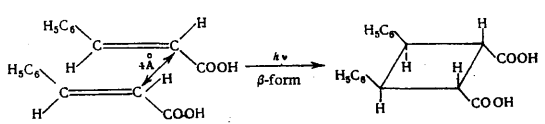


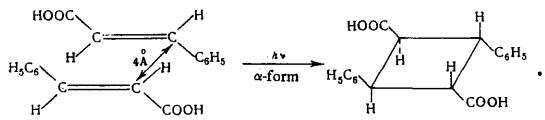
Irradiation of the resist with actinic light produces cross-linking of the molecules. Unsensitised PVTs has an absorption maximum at 270–320 nm and a long-wave absorption edge at 330 nm [26,27]. After irradiation, photoresist layers absorb more weakly in this region because of the decrease in the number of double bonds. Exposed resist contains up to 15% of three-dimensionally cross-linked groups [28]. The quantum yield of the cross-linking reaction can be as high as 50%.

The addition of a sensitiser shifts the absorption maximum to the region of 360–370 nm, and the absorption edge to 400–420 nm. Studies of absorption in the infrared region have shown [27] that the function of the sensitiser is to transmit to the double bonds of PVT's the energy of quanta of long-wave radiation. The quantum efficiency of the sensitiser (Michler's ketone) [29] does not exceed 0.76. This rather low efficiency is due to steric effects, which prevent intimate contact between the sensitiser and the PVTs molecules. The sensitiser is added in amounts of about 10% by weight. The loss of sensitiser is almost insignificant (0.04%): this is because the photon energy is insufficient to cause decomposition of the sensitiser.

According to Lyalikov and coworkers [27], the absorbed radiant energy is transmitted to the double bonds, which are converted into single bonds. The resulting biradicals interact to form cross-linkages, and the solubility of the photoresist in organic solvents decreases.

Robertson and coworkers [26] suggest that the cinnamoyl groups of PVTs form a four-membered ring. *Trans*-cinnamic acid is also believed [30] to form four-membered rings. It is known, from crystallographic studies, that effective photodimerisation is impossible unless the reacting centres are less than 4 Å apart. The dimer can be formed in two configurations, depending on the relative orientation of the constituent molecules:



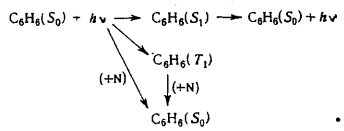


The probability of polymerisation increases when the molecules are excited to the triplet state. The sensitiser plays a special role in transmitting triplet–triplet energy to the PVTs molecules. Energy transfer is possible only when the triplet-state energy of the donor is greater than the triplet-state energy of the acceptor [31–33]. The height of the triplet level of the sensitiser affects the yield of the polymerisation products: for example, the efficiency of the dimerisation falls off steeply [30] when $E_T < 53$ kcal mole^{-1}. The triplet levels of some of the commonest sensitisers are listed below:

acetophenone	74 kcal mole^{-1}
benzophenone	69 kcal mole^{-1}
Michler's ketone	61 kcal mole^{-1}

Mention must also be made of the contribution of the benzene groups of the photoresist and of the sensitiser to the transfer of radiant energy.

High fluorescence yields are common [22] for aromatic hydrocarbons in solution at low concentration. Photodecomposition of aromatic molecules has a very low quantum efficiency in the first absorption band (0.01 to 0.0001 or less). In benzene, the primary processes induced by irradiation within the second or third absorption band (1849 Å) are very different from those induced by the first band (2537 Å). When benzene is excited to the S_2 and S_3 state, internal conversion to the S_1 state has a very low probability, but chemical reactions can occur very readily, including aromatic ring opening with formation of isomers and hydrogen:



The excitation of benzene groups is accompanied by the subsequent emission of light of greater wave length.

3. EXPOSURE OF RESIST BY AN ELECTRON BEAM

Thornley and Sun [4] exposed various kinds of photoresist to electron beams of 14 and 20 keV energy. In their view, electrons having these high energies must break all the chemical bonds in their path when they pass through a layer of resist: the resist molecules can then undergo a complete reorganisation. They found that 14 keV electrons are more effective than 20 keV electrons, and they ascribe this behaviour to the fact that the faster electrons can lose less energy than the slower electrons in collisions with resist molecules.

Matta [5] measured the dose needed for the exposure of negative and positive photoresists on a silicon substrate by electrons of various energies. The average current density required was found to be constant and independent of the thickness of the layer of resist. The optimum current densities are plotted in Fig. 2 as a function of accelerating voltage. A possible explanation of this phenomenon is that the exposure is due (at least partly) to the electrons reflected by the substrate). Matta also showed that the current density for optimum exposure with different depths of penetration of the primary electrons is

a function of the angular distribution of the electrons reflected by the silicon substrate. The positive resist required current densities 10 times greater than the negative resist.

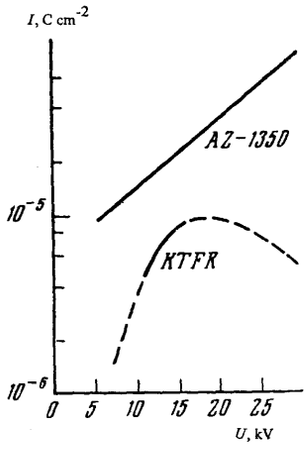


Figure 2. Variation of total charge needed with accelerating voltage.

Koichi and coworkers [6] studied the effect of an electron beam on negative resists. They concluded that the limitations on the obtainable line width are set by the reflection of electrons at the substrate interface and by the low sensitivity of photoresists to electrons. They considered the model for the interaction of the electron beam with the photoresist and the substrate shown in Fig. 3. The electrons, having passed through the resist, penetrate into the substrate material following a straight path up to a depth x_d equal to the mean free path of the electrons in that material. Beyond this point they suffer diffuse scattering in all directions. Formulae for x_r and x_d are given:

$$x_r = \frac{I^2 A}{8\pi q^4 N \rho Z} \bar{E}_i \left\{ 2 \ln \frac{2E_p}{I} \right\}; \quad (1)$$

$$r_0 = \sqrt{x_r (x_r - 2x_d)}; \quad (2)$$

$$x_d = \frac{C \cdot x_r}{Z + 8}; \quad (3)$$

where $\bar{E}i$ is an exponential integral, I is the mean excitation potential of the atom, A is the atomic weight, q is the electronic charge, ρ is the density of the substrate material, N is Avogadro's number, Z is the atomic number, E_p is the electron energy, and C is a constant depending on the atomic number of the material ($C = 8-12$).

When a beam of electrons having energies in excess of 20 keV interacts with a layer of resist most of the chemical bonds are broken, and a complete redistribution of the molecular bonds can take place. Analogous effects occur in positive resist. It can be shown that the line width is a sensitive function of the thickness of the resist: lines cannot be narrower than the sum of the resist thickness and the beam diameter. For example, with a beam diameter of 0.3 μm and a layer thickness of 0.1–0.2 μm we can produce lines 0.3–0.5 μm wide. Furthermore, the line width depends also on the radius of the back-reflection r_b, which is determined by the properties of the substrate material. Experiments using aluminium and copper substrates gave minimum line widths in the ratio of 2 to 5. The raggedness of the line edges was of the order of 0.05 μm.

Studies of the exposure of different polymers have also been described [34]. Ordinary resists are shown to be insensitive to electron bombardment, and the need to develop special electron resists is pointed out. When the polymer is bombarded with electrons, instantaneous cross-linking of neighbouring side-chains is induced, but some significant breaking of the main chains also takes place. These effects influence the size of the molecules and the solubility of the polymer. Depending on the predominance of one or other of these processes, polymers may be classified into cross-linking types and degrading types. The following materials were examined in detail: poly(vinyl cinnamate) (degree of polymerisation 500–1000), polydimethylsiloxane (degree of polymerisation ~7000), and polydimethylsiloxane containing vinyl radicals (degree of polymerisation 5000–10 000).

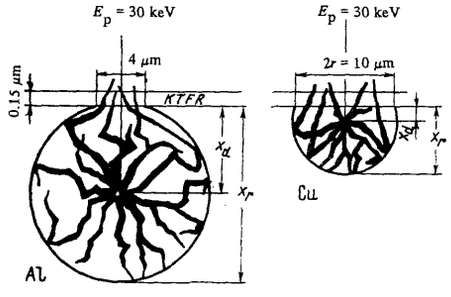

Figure 3. Schematic of the motion of electrons in a solid [6].

Miyauchi and coworkers [14,15] have published a study of the sensitivity to electron irradiation of several commercial grades of resist (KPR, KOR, AZ-1350, etc.). They obtained best exposures under the following beam conditions: beam voltage 10–30 kV, charge 5×10^{-6}–10^{-4} C cm^{-2}.

The sensitivity of the resist is constant within the stated limits of accelerating voltage. The optimum exposure time depends on the thickness of the layer of resist. The width of the resulting stripe is greater than the beam diameter: this effect is due to scattering of the electrons in the material and reflection at the substrate interface. The minimum width obtained after development is equal to the sum of the thickness of the layer and the diameter of the beam. Broyde has described some experiments on the exposure of negative [35] (KPR, KTFR) and positive [36] (AZ-1350) resists. He explained the cross-linking processes in negative resists by radiation-chemical considerations. The cross-linking energy of the resists was determined experimentally (2.5×10^{20} eV cm^{-3} for negative resists, 1.5×10^{20} eV cm^{-3} for positive resists). The cross-linking of KPR, in the presence of oxygen, is thought to be evidence for a free-radical polymerisation mechanism. The addition of sensitisers (benzotriazole, imidazole, indazole) to positive photoresist lowers the

threshold current of electrons by a large factor. Overexposure causes swelling in negative resists and loss of solubility in positive resists.

The main conclusions from this experimental study of the exposure of photoresists by an electron beam are: a) the exposure processes are influenced by the secondary electron emission characteristic of the substrate material; b) the use of terms such as "bond breaking" and "gel point" is quite inadequate as an explanation of the molecular restructuring produced by electron bombardment—Broyde's macroscopic explanation[35] in radiation-chemical terms is almost totally irrelevant to the mechanism of molecular conversion; c) there is no satisfactory explanation of the mechanism of the elementary polymerisation reactions in negative photoresist and of the degradation reactions in positive photoresists.

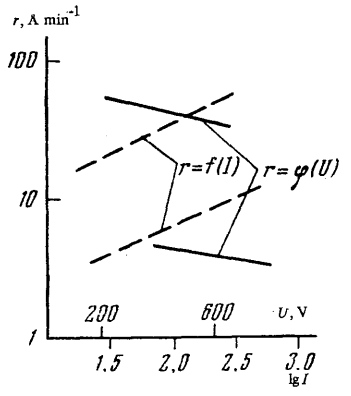

Figure 4. Rate of film growth against accelerating voltage and current density[39].

The molecular rearrangements induced by electron bombardment can be explained by using the results of work[17,18] on the deposition of polymer films from the gas phase. Workers are unanimous in their conclusion that film deposition occurs through the stages of adsorption of monomers by the solid surface, followed by electron-bombardment-induced polymerisation. Two mechanisms are considered: a) polymerisation by a radical mechanism[37], in which the radicals react with each other and with monomers; b) polymerisation by an ionic mechanism[38], in which the molecules dissociate into fragments which subsequently interact. The two polymerisation mechanisms lead to formally identical equations when detailed equilibrium [steady state condition (Ed. of Translation)] is assumed. The rate of growth of the film is

$$r = K_1 p \sqrt{I} \tag{4}$$

by the radical mechanism, and

$$r = K_2 p \sqrt{I}, \tag{5}$$

by the ionic mechanism, where K_1 and K_2 are constants, p is the monomer concentration (butadiene) in the gas phase, I is the current density. The form of the growth rate against current density relationship does not uniquely identify the polymerisation mechanism. Haller and White's experiments[38] with oxygen and hydrogen in the polymerisation vessel provide some evidence for an ionic mechanism of the polymerisation of butadiene.

Kolotyrkin and coworkers, after a critical assessment of a mass of published data, concluded that both polymerisation mechanisms may be operative in film formation, but one mechanism usually predominates, depending on the experimental conditions and on the nature of the starting material[17]. Tsapuk and coworkers[39] have described the deposition of polymers from the gas phase under the influence of electron bombardment. They find that the growth rate of the films decreases as the accelerating voltage increases, and increases with the power 0.5 of the current density. Plots of the growth rate of the polymer against accelerating voltage and current density are shown in Fig. 4. By solving simultaneously the equations $r = f(I)$ and $r = \varphi(U)$ we obtain a quadratic relationship between the current and the accelerating voltage:

$$I = -\alpha U^2 + \beta, \tag{6}$$

where α and β are constants, and I and U are the current density and the accelerating voltage respectively.

We note a qualitative agreement between this equation and the observed current density–accelerating voltage relation for the negative photoresist KTFR (see Fig. 2). On the other hand, the $I = f(U)$ relationship for positive resist is entirely different.

4. INTERACTION OF AN ELECTRON BEAM WITH SOLIDS

Many studies have been made[41,42] of the passage of electrons through solids, the energy loss of electrons per unit length of absorber, the magnitude of the secondary electron emission, etc. (A recent review of the literature[40] contains 1035 references.) In order to discuss the interaction of an electron beam with a photoresist and the substrate material we need to know the range of the electrons in the materials, the energy loss, the secondary electron emission coefficient (SE), and the inelastic scattering coefficient of the electrons (IS).

According to Bethe[42], the energy losses of moving electrons due to inelastic collisions are described by the equation

$$\frac{dE}{dx} = \frac{2\pi \cdot q^4 NZ}{E} \ln \frac{2E}{J} \tag{7}$$

whence we can derive, by integration, the range of the electrons in the material:

$$R = \frac{J^3}{8\pi q^4 NZ}\left[E_i\left(2\ln\frac{2E}{J}\right)\right] \tag{8}$$

where R is the electron range, T, q, and x are the energy, charge, and path length of the electron in the absorber, NZ is the number of electrons per cm^3 of the absorber (for a photoresist we can take $NZ = 3 \times 10^{23}$), $J = \frac{8}{e} I$ is the energy needed to produce an ion pair in the absorber, e is the base of natural logarithms, and $I = 26.4$ eV is assumed for gaseous ethylene irradiated with electrons. It is assumed that the value of I does not differ very much for other hydrocarbons ($I = 24.8$–27.1 eV), and is independent of the state of aggregation; $[E_i(2\ln\frac{2E}{J})$ is an exponential integral which can be expressed in the form

$$\left[\frac{e^{2\ln\frac{2E}{J}}}{2\ln\frac{2E}{J}}\right]\left(1+\frac{1}{2\ln\frac{2E}{J}}+\frac{2}{\left(2\ln\frac{2E}{J}\right)^2}\right)$$

Calculations by Eqn. (8) agree well with experimental data on the passage of electrons through the negative resists KPR and KTFR [35] (see Table 3).

Table 3. Experimental ranges and ranges calculated by Eqn. (8).

Electron energy, keV	Range, μm (exp.)	Range, μm (calc.)
5	0.65	0.66
10	2—2.5	2.3
15	—	4.8
20	—	8.3

Broyde also points out[35] that calculations by the Thomson–Widdington equations gives low results (by a factor of five). His expression for the energy transferred by collisions is

$$\Delta E_p = \frac{2\pi q^4 NZT}{2E}\left(\ln\frac{2\pi q^4 NZT}{I(1-\beta^2)} - \beta^2 - 0.34\right) \qquad (9)$$

where, in addition to the symbols defined above, T is the thickness of the layer of resist, and $\beta = v/c$ is the ratio of the electron velocity to the velocity of light.

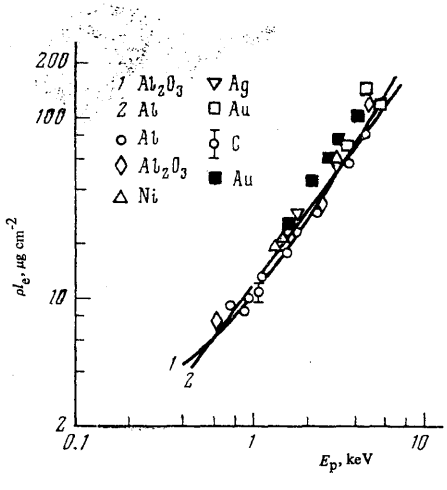

Figure 5. Depth of penetration against electron energy[43].

A great deal of experimental information on the transmission of electrons through matter is available in the literature. The most accurately measured quantity is usually the gravimetric depth of penetration (see Fig. 5), although the linear range is also quoted.

Plots of the secondary electron emission coefficient and the inelastic scattering coefficient for a number of materials are reproduced in Fig. 6.

The SE and the IS coefficient are related to the spectrum of secondary electrons (i.e. the relative proportions of fast and slow electrons). Fast electrons (energy > > 50 eV) include electrons emitted by the absorber and primary electrons reflected at 180°. The angular distribution of IS electrons for a massive metal target normal to the primary beam is closely approximated by the cosine law.

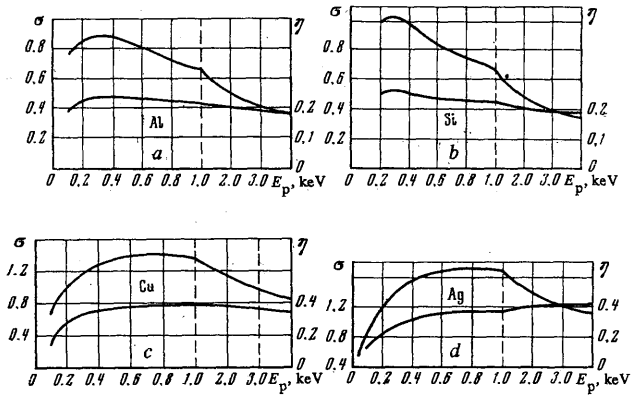

Figure 6. Secondary electron emission coefficients (σ) and inelastic scattering coefficients (η) for electrons in a number of materials[40].

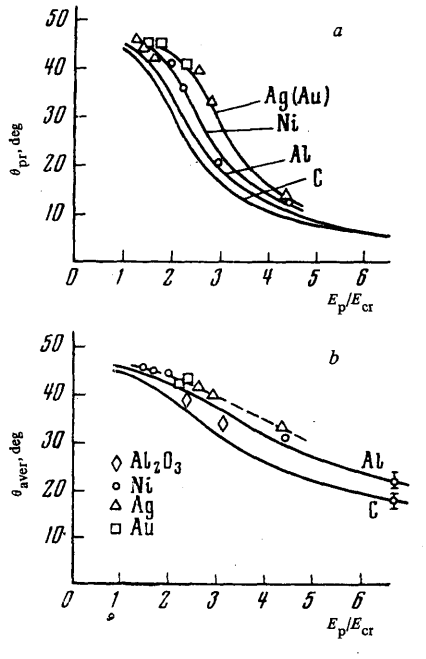

Figure 7. (*a*) Most probable and (*b*) average scattering angle of electrons[44].

Fig. 7 shows the most probable (*a*) and the mean (*b*) angle of scatter of electrons passing through films of various metals.

Irradiation of a solid by electrons is accompanied by a discrete energy absorption (called the characteristic

energy loss, CEL). Data on the CEL of various solids are summarised in Table 4.

The passage of electron beams through a carbon film and through films of various hydrocarbons [poly(vinyl formamide), poly(vinyl acetal), etc.] produces characteristic losses with very similar spectra[49]. The main difference noted[50] is that carbon has an additional absorption peak at 5.4 eV which is not found in poly(vinyl acetal).

Table 4. Characteristic energy losses of electrons in solids.

Material	CEL, eV					Reference	Remarks
	level I	level II	level III	level IV	level V

C	—	5.4	—	—	—	50	

The origin of the characteristic energy losses of the electrons can be explained by two mutually exclusive hypotheses: one-electron interactions and collective interactions.

According to Sternglas[51], the CEL are associated with electron transitions from the inner shells to the uppermost levels, ultimately leading to escape from the atom. This suggestion is confirmed by the good agreement between the magnitude of the characteristic losses and the fine structure of the X-ray absorption edge.

A CEL mechanism involving the excitation of plasma waves in the metal cannot be excluded. This hypothesis was put forward by Watanabe[47].

The secondary electron emission of metals and semiconductors varies between relatively narrow limits (from 0.5 to 1.8 eV). Narrow-gap semiconductors (Ge, Si, and others) have secondary emission properties similar to those of metals. The most probable energy of slow secondary electrons in these materials is ~1.5–3.5 eV, and is almost independent of the primary beam energy above ~200 eV.

In dielectrics, the secondary electron emission coefficient and the secondary electron energy are quite different from the corresponding values for metals. For example, the number of secondary electrons decreases as the energy of the incident electrons increases, and the escape depth of secondary electrons is greater in dielectrics. In metals the internal secondary electrons interact strongly with the conduction band electrons, and therefore their energy is insufficient to overcome the surface barrier after a few collisions. Conversely, the internal secondary electrons in dielectrics are located in the conduction band with an energy less than 10 eV, which they cannot transfer to electrons in the filled band.

The secondary electron emission from glass and fused quartz[40,41] has a value of 2–3; values reported for paraffin oil and for diffusion pump oil are 3–4.8 and 2.8–2 respectively.

The anomalous secondary emission given by metallic emitters covered with a layer of dielectric consists in a large secondary emission coefficient coupled with an unusually high emitted electron energy. It follows from the above arguments that electron bombardment of such an emitter must result in the appearance of positive charge in the dielectric, due to the large difference in secondary emission coefficient between the metal and the dielectric.

By exploiting the analogy with a maintained gas discharge, Jacob (quoted in Ref. 40) analysed experimental data on the emission from magnesium oxide and showed that the average electron energy was 10–20 eV, with a field strength of 10^6 V cm^{-1} in the dielectric.

According to Fridrikhov and coworkers[52], these parameters have the values 11 eV and 5×10^5 V cm^{-1} in sodium chloride. Goetze[53] finds that the energy of secondary electrons emitted from potassium chloride reaches 4 eV. The calculations assume that the enhanced secondary emission and secondary electron energy in dielectrics is due to the positive space charge in the dielectric, and also to the presence of pores. In dense dielectrics the anomalous secondary emission parameters are not observed[40].

Polymers (including photoresists) may also contain gas-filled pores: experimental evidence for this assumption is given by Karasev[54].

5. MECHANISM OF INTERNAL IRRADIATION OF A POSITIVE PHOTORESIST

The essential facts concerning positive photoresists can be summarised as follows:

1. The changes in positive photoresist due to irradiation with light occur by two competing reaction paths: a) decomposition of the light-sensitive component and conversion of the resist into a water-soluble component (this reaction occurs when the resist is exposed to light of wave length shorter than 4600–4800, i.e. to a photon energy of 2.6 to 2.7 eV); b) deacylation of the NKhDA by ketens with formation of insoluble compounds (this reaction is observed when the resist is heated). Because the commonly used lamps do not emit radiation of wave length shorter than 3700 Å, and the photoresist layers are usually cooled during exposure, we may assume that the role of the novolak resin is an entirely passive one (film-forming ingredient).

2. The reaction products are the same after irradiation with electrons and with light. The exponential relationship between accelerating voltage and current suggests that the molecular rearrangement following electron bombardment involves neither a free-radical nor an ionic mechanism.

3. The electrons passing through a layer of photoresist lose fairly substantial amounts of energy. Calculations by Eqns. (8) and (9) indicate the following losses:

Energy of incident electrons, keV	Thickness of resist, Å	Energy loss, keV
15	3600	1.2
15	6000	2.4
15	12000	5.1
20	6000	1.6

The energy take-up by secondary electrons is relatively small (a few per cent). The large characteristic energy losses of electrons passing through organic compounds suggest electronic excitation of the molecules.

4. The secondary electron emission from a solid includes two characteristic groups of electrons: a) slow electrons, having an energy of a few electron-volts, and b) fast electrons, with energies higher than 60 eV. The energy of the fast electrons is high enough to cause excitation and ionisation of hydrocarbon molecules. The passage of fast electrons through a dielectric causes the appearance of positive space charge. The dielectric–metal combination of materials offers an enhanced secondary electron emission coefficient and slow-electron energy (up to 4, 10, or 20 eV).

Inelastic collisions between electrons and atoms or molecules lead to excitation and ionisation of the latter. An electron can excite a molecule provided that its energy exceeds that of the excited level of the molecule.

Electrons can excite different groups in the NKhDA molecule during their passage through a layer of resist: a) excitation of naphthyl groups causes decomposition of the photosensitive component, followed by typical photolytic changes in the NKhDA molecule; b) excitation of the electrons in the novolak and in the phenolic groups of NKhDA is accompanied by fluorescence, inter-state transition to the triplet state, and partial phosphorescence.

The photon energy of the phosphorescence is probably close to the u.v. absorption edge of the novolak (typically, 3.3–4 eV).

Lastly, the recombination of ion-molecules produced by electron impact can produce similar effects (i.e. fluorescence and phosphorescence). A rough estimate of the number of resulting ions from the measured secondary emission suggests that their role in the balance of internal radiation is very limited (a few per cent).

We shall now consider in detail the conditions which obtain when a photoresist is irradiated by a stream of electrons, the effect of the substrate material on the width of the resulting line and the sharpness of its edges, and lastly the optimisation of the resist composition from the standpoint of further miniaturisation of electronic devices.

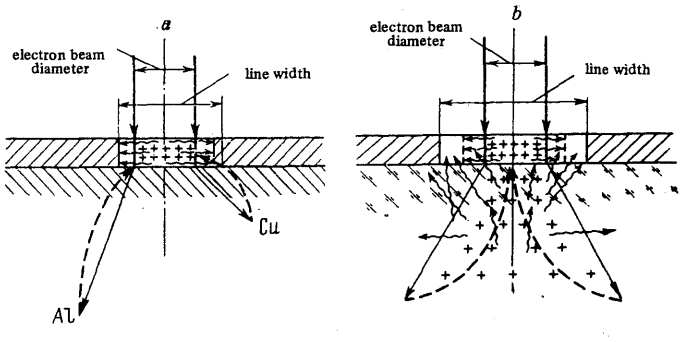

Figure 8. Passage of electrons through a layer of resist into a solid, and resulting diffuse irradiation: *a*) metallic substrate; *b*) dielectric substrate.

1. Irradiation of a positive photoresist on a metal substrate (Fig. 8*a*). We assume negligible divergence of the beam in the resist. The left-hand side of Fig. 8*a* depicts the penetration of the electrons into a light-metal substrate (Al), the right-hand side applies to a heavy-metal substrate (Cu). As a result of secondary electron emission, positive charges appear in the photoresist along the path of the primary electrons. The passage of the electron beam through the photoresist causes excitation and ionisation of the molecules. Both the NKhDA and the novolak resin molecules are excited.

The instability of electronically excited naphthyl groups in the NKhDA molecules results in decomposition by a reaction path indicative of excitation by photons of 2.7 to 2.8 eV energy.

The phosphorescence of the phenolic groups of the NKhDA molecule, of the novolak resin, and of the recombining ion-molecules gives rise to radiation in all directions (including the horizontal). This radiation is the main reason for the large difference between the line widths obtained in practice and the width of the electron beam.

The presence of positive space charge in the resist produces, on the one hand, an acceleration of the slow secondary electrons to energies at which they become able to excite molecules, and on the other hand it deflects the trajectories of inelastically scattered electrons, which therefore suffer a drift in the direction of the positive charge. Because of the shallower escape depth of the inelastically scattered electrons in heavy metals, and of their greater concentration, their interaction with the charge is less marked in heavy metals, and therefore the lines are broader (the comparison between copper and aluminium was given by Koichi and coworkers [6]).

The electrons which have passed through the resist are gradually slowed down, and they transfer their energy to the substrate. The temperature rise of the substrate favours competing reactions like the deacylation of the naphthyl groups by ketens and the condensation of the novolak resin. It is interesting to note that the roughness of the edges obtained in practice is of the same order as the grain size of thin metal films thermally evaporated in a vacuum. (The edge roughness is given [6] as 0.05 μm, the grain size [55–57] is 500–1000 Å.)

2. Irradiation of a positive photoresist on a dielectric substrate (Fig. 8*b*). The internal irradiation of the photoresist is similar to the case of a metal substrate, but there are some important differences. Because of the finite dielectric constant of the substrate material, the secondary and the inelastically scattered electrons suffer more marked interactions with the space charge (which now appears in the substrate as well as in the resist). Their trajectories will be drawn towards those of the primary electrons, and as a result the line width should be less dependent on the density of the substrate material.

However, if the substrate material is transparent to u.v. light (e.g., silicon dioxide) the radiation produced in the bulk of the substrate is propagated in all directions and can irradiate the resist from below. This effect also influences the line width which can be obtained, as compared with a metallic substrate (see Table 2). Many workers [4,6,14] have deposited metallic films on the transparent dielectric substrate in order to attenuate the u.v. light emerging from the substrate: the metal film acts as a screen to short-wave radiation. However, the use of a u.v. screen produces undesirable side effects, discussed above.

These variants include the whole range of experimental conditions quoted in the literature. It is evident from the above discussion that there are a number of reasons why the very narrowest lines cannot be obtained. The most important are: internal irradiation of the resist, bombardment of the resist by reflected and accelerated secondary electrons in the case of a metallic substrate, and irradiation from the substrate in the case of a dielectric substrate transparent to actinic light.

In spite of their different origin, all these effects lead to the same undesirable result: a broadening of the line. Procedures to localise phenomena conducive to line broadening have been suggested.

a) The use of photoresists containing ions and atoms which absorb light of 480 nm wave length and below (Cr^{6+}, V^{5+}, Cu, Au, etc.) minimises internal irradiation and prevents its lateral propagation from the exposed areas.

b) The use of thin screens of light metals protects the photoresist from the radiation emitted by the dielectric substrate.

c) The stream of short-wave radiation emerging from the dielectric substrate can be attenuated by providing a screen of glass containing heavy-metal ions and atoms (Cr^{6+}, V^{5+}, Cu, Au, etc.). The low thermal conductivity of glass and its high secondary electron emission coefficient should favour the production of narrow lines.

6. COURSE OF POLYMERISATION REACTIONS UNDER ELECTRON BOMBARDMENT

The internal irradiation phenomena observed in positive photoresists occur also in negative resists, for the following reasons: a) the presence of benzene rings, excited to the first singlet level by the beam of primary electrons, produces efficient fluorescence and phosphorescence effects—the excitation and deactivation of the sensitiser is accompanied by similar phenomena; b) inelastically scattered electrons are able to excite resist molecules; c) the generation of positive space charge in the bulk of the resist by the anomalous secondary electron emission results in the excitation of the resist molecules by secondary electrons which are accelerated to sufficiently high energies.

The deactivation of the resist molecules which are excited by primary electrons, by inelastically scattered electrons, and by accelerated secondary electrons is accompanied by radiation which is propagated into the bulk of the resist.

The procedures used to localise the radiation in positive resists (by adding absorbing ions) are applicable, in general, also to negative resists.

The excitation and the deactivation of the cinnamoyl groups in the photoresist molecules, and their subsequent polymerisation (both in the irradiated and in the adjacent areas), are the exact counterpart of the reactions which occur in the photoresist under the influence of light (i.e. biradical polymerisation). The energy of u.v. light is insufficient to extract electrons from the molecules.

The polymerisation mechanism involving excitation of the double bonds of the cinnamoyl groups is not the only one available to the resist. Electron irradiation produces, in addition to excitation, substantial ionisation of the molecules (up to 50% of the irradiated molecules): in other words, this form of irradiation gives rise to a greater number of primary processes than does irradiation with light. The subsequent deactivation and recombination of the molecules can take place by a great variety of possible reaction paths.

Thus, electron bombardment can activate other groups in the PVTs molecule, whilst also forming free radicals and ions. Hence, polymerisation reactions involving other groups of the PVTs molecule and of the sensitiser are possible, for example: a) bond formation between benzene ring, between a benzene ring and a linear chain, etc.; b) free-radical polymerisation; c) ion–molecule reactions.

Deactivation of the benzene rings, and also of radicals and ions, is accompanied by fluorescence and phosphorescence effects. The energy of transitions from the excited levels to the ground state is fairly high: in benzene, for example, it corresponds to the edge of the first absorption band, i.e. ~ 2537 Å. Light quanta of this energy can excite the cinnamoyl groups of the photoresist molecules, the sensitiser, etc. This stepwise utilisation of the energy of the electron beam partly explains the well known fact that the exposure of a negative photoresist with an electron beam requires less energy than exposure with light.

Several workers[27,35,58] have found that the energy needed to polymerise a poly(vinyl cinnamate) photoresist such as PVTs or KPR with an electron beam is smaller by a factor of 3 than the energy needed for exposure with light.

It must be stressed that electron irradiation can also lead to polymer degradation. According to Pshezhetskii, irradiation of poly(vinyl alcohol) causes evolution of hydrogen (95%), methane, carbon dioxide, and other radiolysis products[16]. The yield of gaseous products can be as high as 1.7 molecules per 100 eV of energy absorbed and increases with the dose of radiation. The optimum dose for the production of high-molecular products varies between 0.5 and 5 Mrad for different substances[59]. Negative photoresists have been irradiated with doses as high as 4.65 Mrad[35], 3.9 Mrad[11], 23 Mrad[6], 46 Mrad[12], etc.

As stated above, the irradiation of poly(vinyl alcohol) with high-energy electrons is accompanied by polymer degradation and gas evolution. Poly(vinyl esters) are also readily degraded by penetrating radiation[60]. PVTs is obviously an exception to this rule, at least within the range of electron energies and radiation doses of relevance to this review.

The polymerisation produced by electron bombardment is largely determined by the nature of the target molecules[61] and by the specific features of the reactions induced by the radiation.

Because of the difficulty of isolating individual products, and of defining conditions for the unambiguous identification of the polymerisation mechanism, contradictory results are often obtained. In spite of the generally adopted working hypothesis that radiation-induced polymerisation involves free radicals, the polymerisation is often accompanied by interactions between ions and molecules.

Irradiation with an electron beam can initiate a large number of reactions in a photoresist. None of the published papers deals specifically with the polymerisation mechanism of poly(vinyl cinnamate) resists: this is unfortunate, because a knowledge of the predominant reaction could be of great help in the choice of the best resist composition and of the best exposure energy. The cross-linking of separate molecules into blocks undoubtedly influences the resolution of the photolithographic process.

Press[2] has shown that the energy needed for exposure with light, assuming excitation of the double bonds in PVTs, obeys an exponential law. Even allowing for the stepwise, repeated utilisation of the energy of the primary electrons, transmitted through fluorescence and phosphorescence phenomena, this energy is insufficient to cause cross-linking of the resist. The ion–molecule reaction mechanism, or the free-radical mechanism, seems to be more economical in energy.

The system in which a film of resist on a metallic layer is irradiated by scanning a beam of accelerated

electrons in a vacuum behaves as a complex emitter. Electron bombardment of this two-layer structure (dielectric–metal) is accompanied by anomalous secondary electron emission. The appearance of positive space charge in the bulk of the resist can be treated as the addition of a large number of ions with a sufficiently long life time. These ions are not usually carbonium ions, though they may give rise to carbonium ions (possibly as intermediate products) during subsequent decomposition.

In the gas phase these ionic particles can be formed only at sufficiently low pressures, because the breaking of a covalent bond to give a carbonium ion requires a greater expenditure of energy than does the formation of radicals. It must also be remembered that the ions formed as a result of excitation have a life time of the order of 10^{-5} s, followed by decomposition. Ionisation with formation of carbonium ions is possible only when the required ionisation energy is compensated by solvation of the resulting ion in solution or by coulombic interaction in an ion pair (either in solution or in the gas phase) [62].

In the solid phase the course of the reaction is affected by heterogeneities, defects, etc., which enable the electrons to be captured and retained by the crystal lattice. This effect is responsible for the high stability of cations in solids.

Although the possibility of an ionic–molecular polymerisation mechanism is not entirely excluded, the most likely mechanism for the polymerisation of poly(vinyl cinnamate) photoresists under electron bombardment is a mechanism involving free radicals, for the following reasons:

1. Irradiation of PVTs with u.v. light gives rise to cross-linking even though the quantum energy of the light is insufficient to cause ionisation.

2. Addition of oxygen to the chamber in which KPR is irradiated with electrons does not affect the polymerisation [35]. Oxygen is the strongest known inhibitor of cationic polymerisation.

3. The fact that irradiation with a beam of 14 keV electrons is more effective than irradiation with 20 keV electrons [1] also suggests a free radical polymerisation mechanism. The beam of 14 keV electrons suffers considerably greater losses in the layer of resist, which is therefore heated to a higher temperature.

The cross-linking of negative photoresists by a free-radical polymerisation mechanism explains a number of previously surprising features of electron-beam exposure. The most important are: a) the energy needed for the cross-linking reaction becomes lower; b) the spatial resolution of the resist depends on the tendency of free-radical reactions to initiate chain growth, which can propagate sideways from the point of initiation; c) the roughness of the edge of the polymerised stripe depends both on the propagation of free-radical chains and on the properties of the substrate (thermal conductivity, thermal diffusivity, thickness, grain size, etc.).

7. DISCUSSION AND CONCLUSIONS

The many and complicated phenomena which accompany the passage of an electron beam through a photoresist have not yet been fully investigated. This is the main reason for the inconsistent results reported by different workers and for the contradictory explanations advanced to account for them.

Although some encouraging results have been obtained in attempts to decrease the size of the microcircuit elements, and in defining the optimum accelerating voltage, charge, and other technological parameters, many outstanding problems still stand in the way of a more general application of electron-beam exposure of photoresist. Some of these are: a) the inconstancy between theoretically expected and practically accessible dimensions of the microcircuit elements [6,11,13,63]; b) the low operating efficiency, due to the slow scanning speed of the beam—according to Thornley and coworkers [64], electron beam exposure can be profitable only if projection or multiple-beam apparatus is used; c) the difficulty of obtaining a spot of sufficiently small diameter.

Although the above problems have separate identities, they are by no means unconnected: a decrease in beam diameter is accompanied by a decrease in the flux of electrons, which makes the permissible scanning speed even slower and therefore lowers the operating efficiency of the process. The discrepancy between the calculated and the experimentally obtained line widths is explained by the lack of monochromaticity of the beam, by the lack of resists specially designed for exposure by electrons, and by the influence of the substrate material. The low productive capacity, and the difficulty of producing patterns of prescribed dimensions, stem from the use in electron lighography of materials which were designed as photoresists, although other materials could be used to better effect [13,64,65].

Detailed analysis of the problems is complicated by the large numer of commercial resists and by the wide variety of their properties [23].

The reactions considered in this review (changes in positive photoresist based on naphthoquinonediazide and changes in negative photoresist based on PVTs) are a convincing illustration of the problems underlying the use of an electron beam for exposure. We have deliberately chosen the most familiar and widely used resists, though many other types and grades are available. For the grades considered here, the following parameters of the layer of resist can be calculated with quite good accuracy: energy balance, resolving power of the beam, edge roughness of the resulting pattern, thickness of resist, and accelerating voltage. With other types of polymer (of both the cross-linking and the degrading type), based on different compounds, the phenomena and the rules discussed above should be applied with care, taking due notice of the structure and composition of the starting materials and of their reactions under electron irradiation.

The sequence of reactions in the polymers should be investigated in accordance with the nature of the chosen material: a) primary excitation and ionisation reactions; b) secondary reactions involving deactivation and recombination of the molecules.

It is important to consider first of all the physical processes associated with fluorescence, phosphorescence, triplet–triplet energy transfer, and secondary electron emission. The subsequent chemical reactions (intramolecular decomposition, degradation, or polymerisation) are critically dependent on the properties of the starting compound. In addition to the reactions of the main component of the resist, we must consider also the role of the various additives.

The main conclusion to be made from the present review is that the widespread penetration of electron-beam exposure into industrial practice must await the solution of the following problems:

1. The influence of the substrate material on the exposure and on the development of the film of resist (including the effect of secondary electron emission).

2. The effect of the radicals and ions formed by electron bombardment on the course of chemical reactions in photoresists.

3. Minimising the energy required for the exposure of the resists. Special interest attaches to the use of an electron beam for exposing negative photoresists, for the following important reasons: a) the energy required for exposure is lower by a factor of 6 as compared with positive photoresists; b) the energy required is lower by a factor of 3 as compared with exposure by light; c) negative resists are more stable towards etchants than positive resists.

The use of sensitisers to decrease the energy required for the exposure of positive photoresist has been convincingly demonstrated by Broyde[36].

4. The synthesis of new resists, more sensitive towards electron irradiation, and free from internal irradiation effects. The latter requirement is essential to the achievement of even smaller dimensions in microelectronic circuits.

Reaction Mechanisms of the Direct Epoxidation of Alkenes in the Liquid Phase

D.I.Metelitsa

Reaction mechanisms for the liquid-phase epoxidation of alkenes are reviewed critically: the classical Prilezhaev reaction, catalytic epoxidation with participation of hydrogen peroxide and of organic hydroperoxides, reactions for the production of alkene oxides in the oxidation of unsaturated hydrocarbons, reaction of a combined oxidation of alkenes with aldehydes. The mechanism and prospects of the catalysed oxidation with oxygen of alkenes to epoxides are discussed in detail. 150 references.

1. INTRODUCTION

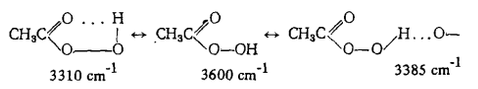
Alkene oxides are important intermediates in industrial organic synthesis. In addition to traditional uses—the production of antifreezes, solvents, and plasticisers for plastics and explosives—new ways of using them have appeared: the production of non-ionogenic surface-active substances, polyethers, polyurethanes, etc. In this connection the direct oxidation of alkenes now has a permanent place in the organic synthesis industry with an extremely promising future[1]. Processes for the oxidation of alkenic hydrocarbons are displacing such traditional and well-accepted processes as the synthesis of ethylene oxide through 2-chloroethanol. Almost all the ethylene oxide is obtained by the direct vapour-phase oxidation of ethylene on a silver catalyst. Monographs and reviews have dealt with this important process and the mechanism of the reactions on which it is based[2-5]. Although the direct vapour-phase oxidation of alkenes is used in all the works built in the last 10–15 years, there is a continuous search for new paths of liquid-phase oxidation of alkenes, since this allows the temperature at which the processes are conducted to be reduced and (especially important) their selectivity to be increased. For example, in addition to the classical method of epoxidising propene with peracids a new method of epoxidation with the hydroperoxides of such organic compounds which are readily oxidised by molecular oxygen has appeared. The combined oxidation of propene plus aldehydes lies at the basis of processes developed by the Institute of Chemical Physics of the

Academy of Sciences of the USSR and by the Institut francais du Pétrole. Very recently there have been extensive searches for catalytic systems activated by oxygen in the epoxidation of unsaturated compounds. Complexes of metals of variable valency (Mo, V, W, Ir, and Rh) with various ligands form such systems. An investigation of liquid-phase epoxidation processes is continuing and being extended. A special part is played by the study of the mechanisms of these reactions, which are of practical importance. The task of the present review is a critical examination of papers dealing with the reaction mechanisms of liquid-phase epoxidation—from the classical Prilezhaev reaction to the most recent investigations into the activation of molecular oxygen in the epoxidation of alkenes.

2. THE PRILEZHAEV REACTION

The Prilezhaev reaction[6,7] between a per-acid and an alkene is now reliable and has been studied in detail: methods of preparation of the per-acids and the reactions of many unsaturated compounds have been examined in detail[8,9]. However, the search for the most effective per-acids in particular reactions and for the most convenient paths for effecting epoxidations with a per-acid is still continuing[10-12]: for example, there is the use of *o*-sulphoperbenzoic acid as an epoxidating agent allows *trans*-1,2-cyclohexane-1,2-diol to be obtained at 25°C in yields of up to 88% from cyclohexene[12] via the oxide.

The per-acids exist in solutions in various forms depending upon the nature of the solvent[13-15]. When the solvent does not form hydrogen bonds the per-acid is a monomer with an intramolecular hydrogen bond[14]. The stretching frequency of the hydroxyl of the per-acid (3600–3750 cm^{-1}) is depressed to 3000–3500 cm^{-1} under the influence of a hydrogen bond. Below we show peracetic acid in various states with the corresponding vibration frequencies of the hydroxyl of the acid[15]:



The reactivity of the per-acids is quite different in solvents which form a hydrogen bond—nitromethane, acetone, etc. Thus it is well known that perbenzoic acid which is formed in the oxidation of benzaldehyde can be isolated solely in acetone, since in solvents which do not form hydrogen bonds the per-acid reacts rapidly with benzaldehyde by the Bayer–Villiger reaction[16].

The per-acids are weaker acids than their analogues which do not contain a peroxide group[17]:

Acid	p*K*
HCOOH	3.7
HCO_3H	7.1
CH_3COOH	4.8
CH_3CO_3H	8.2

Organic per-acids are readily polarised and they have a tendency to heterolytic breaking of a weak O–O bond:

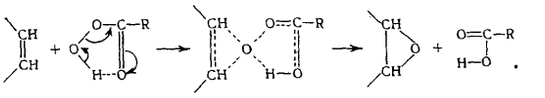
However, the hydroxy-cation HO^+ cannot exist in the free form, since it would be a species with a very high energy.

Even in the first kinetic investigations the Prilezhaev reaction[18,19] was found to be first order with respect to both components and it was shown that this reaction is bimolecular like other heterocyclic reactions of per-acids with amines, sulphides, phosphines, phosphites, azo-compounds, and aryl iodides[20]. In early studies it was suggested that the epoxidating species is the free hydroxy-cation HO^+, which attacks the alkene[21,22]:

But as stated above the cation HO^+ cannot be formed.

A study of the relative reaction rates of per-acids with various alkenes showed that per-acids are typical electrophilic agents[23]. The per-acids can be arranged in a series in order of decreasing electrophilic character in full agreement with the values of the Taft σ constant for the R groups: CF_3CO_3H (+2.6), $C_6H_5CO_3H$ (+0.6), HCO_3H (+0.49), CH_3CO_3H (0).

A systematic study of the rates of epoxidation of substituted alkenes by substituted perbenzoic acids[24] provided a basis for a molecular mechanism of the reaction of a per-acid with an alkene[25-28]:



This reaction mechanism, in which the π-bond of the alkene is attacked, is supported by experimental facts found in the epoxidation of *trans*-stilbene and its derivatives (4-OCH_3, 4-CH_3, 4-Cl, 4-NO_2, 3-Cl, 3-NO_2) with per-benzoic acid and its derivatives (4-NO_2, 4-Cl, 3-NO_2, 3-Cl, 4-CH_3, 4-OCH_3).[24]

1. As a result of a study of these reactions at 20–40°C in benzene the activation parameters ΔG^*, ΔH^*, and ΔS^* were determined and it was found that despite the small range, the variation in ΔH^* (14.0–16.0 kcal $mole^{-1}$) and ΔG^* (20.0–23.0 kcal $mole^{-1}$) by the effect of substituents on the electron density of the reaction centre.

Electron-donating substituents in *trans*-stilbene decrease ΔG^* and ΔH^*, but electron-withdrawing substituents increase ΔG^* and ΔH^*. On the other hand, electron-withdrawing substituents in perbenzoic acids decrease ΔG^* and ΔH^*, but electron-donating substituents in perbenzoic acid increase ΔG^* and ΔH^*. Hence the alkene behaves as a nucleophilic agent in the reaction, and the per-acid as an electrophilic one.

2. The addition of the salt $Mg(ClO_4)_2$ to the reaction has no effect whatsoever on the rate of the process, that is, it does not possess ionic limiting stages.

3. The reactivity of substituted ethylenes falls with decrease in the order of the double bond: styrene > *trans*-stilbene > triphenylethylene > tetraphenylethylene (Table 1).

4. The effect of solvent on the rate of epoxidation of the alkenes is completely connected with the formation of hydrogen bonds between the per-acids and molecules of the solvent (Table 2).

Hence all the above results show that the reaction of an alkene with a per-acid is bimolecular. The rate constant for the reaction of *trans*-stilbene with perbenzoic acid is, in the usual form[24]: $1.78 \times 10^8 \exp(-15\,850/RT)$ litre $mole^{-1}$ s^{-1}.

The intermediate formation of a π-complex has recently been demonstrated kinetically in the reaction of propene

with peracetic acid[29]. The reaction is effected in benzene solution at 20–60°C. The absence of radical stages in the reaction was shown by the introduction into the system of an inhibitor of radical processes—2,6-di-t-butyl-4-methylphenol; the inhibitor introduced had no effect on the reaction rate. A detailed kinetic investigation of the reaction of peracetic acid with propene allowed the following scheme to be suggested for the process:

$$CH_3CO_3H + n\,C_3H_6 \underset{k_2}{\overset{k_1}{\rightleftarrows}} [CH_3CO_3H \cdot n\,C_3H_6] \xrightarrow{k_3} C_3H_6O + CH_3COOH.$$

Table 1. Kinetic characteristics of the epoxidation of alkenes by perbenzoic acid in benzene at 20–40°C.[24]

Alkene	$10^4k^{20°}$, litre mole^{-1} s^{-1}	$\Delta H^{\neq}$, kcal mole^{-1}	$\Delta G^{\neq}$, kcal mole^{-1}	$-\Delta S^{\neq}$, cal mole^{-1} deg^{-1}
Styrene	6.12	14.2	21.7	24.8
cis-Stilbene	5.70	14.1	21.7	25.2
Triphenylethylene	—	15.7	22.6	22.7
Tetraphenylethylene	—	17.2	24.1	22.6
Cyclohexene	127	12.7	19.9	24.0
Cyclohexene*	3.72	15.3	22.0	22.0

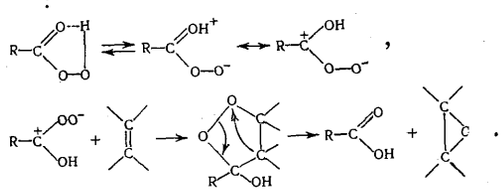
* Reaction in diethyl ether.

It was shown that one molecule of per-acid reacts with two molecules of propene ($n = 2$) and the equilibrium constant was determined: $K = k_1/k_2 = 3 \times 10^3 \exp(-5500/RT)$ litre^2 mole^{-2}. The rate constant of the decomposition of the π-complex is $k_3 = 6.7 \exp(-11\,600/RT)$ s^{-1}.

Table 2. Effect of the solvent on the epoxidation rate constant at 30°C.

trans-Stilbene + CF_3CO_3H (Ref.11)		Ethyl crotonate + *m*-chloroperbenzoate (Ref.24)	
solvent	10^4k, litre mole^{-1} s^{-1}	solvent	10^4k, litre mole^{-1} s^{-1}
CCl_4	14.6	CCl_4	0.115
$CHCl_3$	36.0	C_6H_6	0.173
CH_2Cl_2	36.1	$CH_3COOH+(CH_3CO)_2O$	0.0075
$ClCH_2CH_2Cl$	32.7		
$(CH_3)_3COH$	0.42	CH_3COOH (90%)+H_2O (10%)	0.053
C_6H_6	18.9		

A few papers have also suggested that per-acids react with alkenes by a bipolar 1,3-addition mechanism[30], which is well known[31] and is realised in the ozonation of alkenes[32–34]:



In support of the mechanism of bipolar 1,3-addition there is the low value of ρ in the Hammett equation (−0.8) for the reaction of per-acids with alkenes and the same effect of the solvent on this reaction as in the oxonation of alkenes[35]. However, there is no clear proof of the bipolar 1,3-addition mechanism in the reaction of alkenes and per-acids, whereas the reaction of an alkene and per-acid with the formation of a π-complex has been proved convincingly[24,29]. In the reaction of propene with peracetic acid the limiting stage is the decomposition of the π-complex[29]; in all the other instances studied the reaction is limited by the bimolecular reaction of the alkene with the per-acid. It is possible that the kinetic investigations of the reactions of alkenes and per-acids over wide ranges of concentration of the two components will give new examples of such reactions where the decomposition of an intermediately-formed complex of the per-acid with the alkene is limiting.

Table 3. Rate constants for the epoxidation of substituted cyclohexenes by perbenzoic acid at 5°C in benzene[38].

Compound	10^4k, litre mole^{-1} s^{-1}	Relative rate
Cyclohexene	63.3	1.0
3-Hydroxycyclohexene	34.5	0.55
3-Methoxycyclohexene	4.25	0.067
3-Ethoxycyclohexene	4.72	0.075
3-Acetoxycyclohexene	2.90	0.046
4-Hydroxycyclohexene	2.67	0.042

The reaction of per-acids with cycloalkenes is stereospecific[36–40]: when a cyclic alkene reacts, the oxygen atom of the epoxide that is formed occupies an axial position and the π-bond of sterically hindered molecules is attacked from the less hindered side. The formation of epoxides from cyclic allyl alcohols takes place in the *cis*-position to the OH group[38], which shows the strong accelerating action on epoxidation:

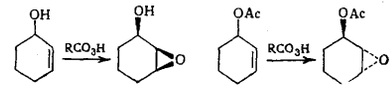


Table 4. Rate constants for the epoxidation of substituted cyclohexenes by *m*-chloroperbenzoic acid in ether at 25°C.[40]

Compound	10^3k, litre mole^{-1} s^{-1}	Relative rate
Cyclohexene	1.88	1.0
4-t-Butylcyclohexene	1.76	0.94
3-Methylcyclohexene	1.77	0.94
4-Methylcyclohexene	1.52	0.81
trans-4,5-Dimethylcyclohexene	1.49	0.79
cis-4,5-Dimethylcyclohexene	0.87	0.46
3,3-Dimethylcyclohexene	0.83	0.44
cis-4,5-(CH_2OCH_2)-Cyclohexene	0.94	0.50
trans-4,5-(CH_2OCH_2)-Cyclohexene	0.55	0.29

The epoxidation of 3-acetoxycyclohex-1-ene takes place much more slowly than reaction with cyclohexen-3-ol and is accompanied by the preferential formation of the *trans*-epoxide. Stereospecificity strongly affects the rates of epoxidation of cycloalkenes by per-acids (Table 3).

The introduction of alkyl groups into cyclohexene retards epoxidation, the action being purely steric, and not inductive, in nature[40] (Table 4).

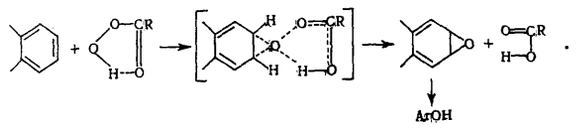
Stereoselectivity is pronounced in the epoxidation of substituted cyclohexenes:

Substituent in cyclohexene	% of *trans*-epoxide in reaction with *m*-chloroperbenzoic acid at 25°C
4-t-Butyl	39.5
4-Methyl	53.6
cis-4,5-Dimethyl	87.0

The electrophilic properties of per-acids were convincingly confirmed and used in the hydroxylation of aromatic compounds[41-50]. Use of such a strongly electrophilic agent as CF_3CO_3H with additions of BF_3 for the hydroxylation of mesitylene allowed mesitol to be obtained in 88% yield[48]. Hydroxylation of phenol with the system (H_2O_2 + HF) gives 54% hydroquinone and 42% pyrocatechol[49], and the use of performic and peracetic acids with additions of polyphosphoric acid and P_2O_5 gives 52.5% pyrocatechol and 16.6% hydroquinone[50]. There has been hardly any investigation of the kinetics and mechanism of hydroxylation of aromatic compounds by per-acids, although it has been clearly established that there are no radical steps in this reaction[46,47]. It has also been shown that the distribution of the isomers of substituted benzenes during hydroxylation with CF_3CO_3H is typical of electrophilic substitutions in the benzene nucleus[47]:

Compound	Phenols			Reactivity in relation to benzene
	ortho	*meta*	*para*	
Anisole	73.7	0	26.3	530
Toluene	78.2	2.3	19.7	11.7
Fluorobenzene	17.2	0	82.8	0.27

It was shown very recently that, in the combined oxidation of aromatic compound plus benzaldehyde, phenols are formed and the rate at which they accumulate does not alter when inhibitors of radical reactions are introduced into the system[51,52]. The formation of the phenols proceeds by the reaction of benzenes with perbenzoic acid formed in the oxidation of the benzaldehyde. The behaviour of an inhibitor confirms that the hydroxylation of aromatic compounds by perbenzoic acid does not proceed by a radical mechanism. We assume that the mechanism of the hydroxylation of aromatic compounds by per-acids is molecular by analogy with the epoxidation of alkenes:



The formation of epoxides of aromatic compounds, which rapidly isomerise into phenols is now not in doubt[53].

3. EPOXIDATION OF ALKENES WITH HYDROPEROXIDES AND WITH HYDROGEN PEROXIDE WITH PARTICIPATION OF CATALYSTS

Organic hydroperoxides possess the capability of heterolytic breaking of the O–O bonds to a lesser extent than per-acids. However, such breaking can be facilitated with the aid of catalysts—metals of variable valency, which can be divided into two groups according to their type of reaction with organic hydroperoxides. To the first group belong metals such as Fe, Co, and Cu, for which the lower and higher valence states differ by unity. These metals usually facilitate homolysis of the O–O bond in hydroperoxides and generate radicals in the reactions with them. The second group includes such metals as V, Mo, W, and Cr, which in their highest oxidation states can cause heterolysis of the O–O bond in organic hydroperoxides.

Investigation of epoxidation by t-butyl hydroperoxide (TBHP) with participation of the acetylacetonates of various metals showed that the epoxidation of 2,4,4-trimethylpent-1-ene, oct-1-ene, and 4-vinylcyclohexene is accelerated especially effectively by the acetylacetonates of Cr, V, VO, and MoO_2, whereas those of Co, Cu, and Fe are not effective[54]. Epoxidation of propene with ethylbenzene hydroperoxide lies at the basis of a method for obtaining propene oxide developed by the firm Halcon[55]. Salts and compounds (naphthenates, acetylacetonates, oxalates, nitrates, etc.) of molybdenum, tungsten, titanium, vanadium, niobium, tantalum, and rhenium that are readily soluble in the reaction medium are used as catalysts. Recently, not only various compounds of metals having variable valency but also various organic hydroperoxides have been widely used in the epoxidation of alkenes. TBHP and vanadium and vanadyl acetylacetonates are used for the epoxidation of cyclohexene[56], cumene hydroperoxide (CHP) and molybdenum naphthenate and also $MoCl_5$ are used for the epoxidation of cyclohexene[57] and of cyclohexen-3-ol[58]. The epoxidation of propene with molybdenum resinate and various hydroperoxides—TBHP, CHP, and ethylbenzene hydroperoxide (EBHP)—has been studied in special detail[59,60]. The epoxidation of 2-methylpent-2-ene[61] and various butenes[62] has been studied. The kinetics and mechanism of these reactions have been investigated[56,59,60,62,63].

Table 5. Epoxidation of oct-1-ene with t-butyl hydroperoxide in the presence of $Mo(CO)_6$.

Solvent	Conversion, %	Yield of epoxide, %
Benzene	75.0	92.0
Methylcyclohexane	72.0	84.0
Ethanol	40.0	37.0
t-Butyl alcohol	16.0	58.0
Acetone	39.0	5.0

The effect of the alkene structure, the hydroperoxide structure, the temperature, and the solvent on the epoxidation of alkenes and the kinetics of epoxidation of oct-1-ene and oct-2-ene with participation of TBHP and molybdenum hexacarbonyl $Mo(CO)_6$ have been investigated in detail[63]. It was found that out of a great number of various salts and coordination compounds of metals of various valency the greatest catalytic activity in epoxidations is exhibited by coordination compounds of molybdenum. The conversion of the alkene and the yields of the oxide are greater in non-polar solvents (benzene or cyclohexane) than in polar (Table 5).

We think that Sheng and Zajacek[63] were wrong in attributing the effect of the above solvents solely to their polarity, since the solvents, which in this instance are polar, can affect the reaction in various other ways; acetone and alcohols form hydrogen bonds with TBHP and reduce its activity, alcohols can enter the coordination

sphere of the catalyst and lower its effectiveness, as several investigations have confirmed[56,59].

For the epoxidation of oct-1-ene hydroperoxides (HP) can be arranged in the following sequence of decreasing activity: *p*-nitrocumene HP > cumene HP > t-butyl HP.[63]

Carrying out the reactions in an atmosphere of CO retards the epoxidation catalysed by $Mo(CO)_6$. The epoxidation of *cis*- and *trans*-but-2-enes shows the stereospecificity of the process, since the *cis*-epoxide is obtained exclusively from the *cis*-butene whereas *trans*-butene yields exclusively the *trans*-epoxide. In an investigation of the kinetics of the epoxidation of oct-1-ene with TBHP and $Mo(CO)_6$ it has been shown that the reaction is first order with respect to all three components. Oxygen does not affect the rate of epoxidation but influences the life of the catalyst.

The combination of such facts as the absence of an effect of O_2 on the epoxidation rate, the passivity of Co, Mn, and Fe complexes which react with the hydroperoxides with the formation of radicals, and the stereospecificity of epoxidation show that there are no radical steps in the epoxidation. The proposed mechanism of epoxidation is[63]:

$$ROOH + Mo^{n+} \rightarrow Mo^{n+}_{cat} , \quad (1)$$

$$ROOH + Mo^{n+}_{cat} \rightleftarrows \left[\begin{matrix} ROOH \\ \vdots \\ Mo^{n+}_{cat} \end{matrix}\right] \quad (2)$$

$$\left[\begin{matrix} ROOH \\ \vdots \\ Mo^{n+}_{cat} \end{matrix}\right] + >C=C< \rightarrow >C-C< + ROH + Mo^{n+}_{cat} .$$
$$\qquad\qquad\qquad\qquad\qquad\quad O$$

In the first reaction the catalyst is activated, in the second a complex of the catalyst and ROOH is formed, the reaction of which with the alkenes limits the rate of the whole process. The drawback of this scheme is the absence of specific indications of the activation and regeneration of the catalyst. In addition, according to the above scheme at high ROOH concentrations the rate of epoxidation should be independent of [ROOH], as has been noted in several instances[63], but this fact is interpreted as the consequence only of the decomposition of ROOH by a side-reaction. It was subsequently shown[56,59,60,64] that the kinetics of epoxidation are more complex and ways of regenerating the catalyst were also demonstrated.

As an example we will consider the mechanism of the epoxidation of cyclohexene with participation of TBHP and V and VO acetylacetonates[56].

t-Butyl hydroperoxide oxidises (activates) the catalyst:

$$VO(acac)_2 \xrightarrow{TBHP} -\overset{|}{\underset{|}{V^{V}}}- .$$

The activation is rapid and irreversible. The active form of the catalyst rapidly forms a complex with TBHP by the reverse reaction:

$$-\overset{|}{\underset{|}{V^{V}}}- + BuO_2H \overset{K_{equil}}{\rightleftarrows} -\overset{|}{\underset{|}{V^{V}}}-O-\overset{Bu}{\underset{OH}{}} .$$

The equilibrium constant is $K_{equil} = 10.3$ litre mole^{-1} at 50.6°C.

The complex reacts with cyclohexene; this determines the rate of the entire process:

$$-\overset{|}{\underset{|}{V^{V}}}-O-\overset{Bu}{\underset{OH}{}} + \bigcirc \xrightarrow{k} HO-\bigcirc + -\overset{|}{\underset{|}{V^{V}}}-O-\overset{Bu}{\underset{}{}} .$$

The following two reactions then occur rapidly:

$$HO-\bigcirc + -\overset{|}{\underset{|}{V^{V}}}-OBu \rightarrow O=\bigcirc + -\overset{|}{\underset{H}{V^{V}}}-OBu ,$$

$$-\overset{|}{\underset{|}{V^{V}}}-O-\overset{Bu}{\underset{H}{}} + BuO_2H \rightleftarrows -\overset{|}{\underset{|}{V^{V}}}-O-\overset{Bu}{\underset{OH}{}} + BuOH .$$

The last reaction is confirmed by the retarding action of alcohols on the epoxidation of cyclohexene[56]. The above scheme agrees with all the experimental results; an equation typical for such schemes is obtained for the initial rate of accumulation of epoxide:

$$W_0 = \frac{k \cdot K_{equil}[TBHP][V_0][ol]}{1 + K_{equil}[TBHP]}$$

where $[V_0]$, and [ol] are the concentrations of VO acetylacetonate and cyclohexene respectively, and k is the velocity constant of the rate-limiting step. The activation parameters of the rate-limiting process of the reaction are:

$$\Delta H^{\neq} = 12.7 \text{ kcal mole}^{-1}, \Delta S^{\neq} = -19.8 \text{ e.u.}$$

An analogous mechanism is proposed for the epoxidation of propene by various hydroperoxides with participation of a molybdenum-containing catalyst[59,60]. In the epoxidation of propene, alcohols can be arranged in the following order according to their inhibiting action[59]: MeOH > EtOH > Pr^nOH > n-octanol > 1-phenylethanol. The reactivity of hydroperoxides is determined by a combination of electronic and steric factors: in the epoxidation of propene the hydroperoxides can be arranged in the series: EBHP (2,4), TBHP (1,3), and CHP (1). CHP is the least effective in the reaction with propene. For the rate-limiting reaction between the complex of the hydroperoxide with the molybdenum catalyst and propene the rate constants in the temperature range 50–80°C and the activation energy of this reaction were determined:

Hydroperoxide	Activation energy, kcal mole^{-1}
EBHP	15.2
TBHP	15.0
CHP	15.6

In the technological realisation of the epoxidation of propene by ethylbenzene hydroperoxide with the participation of a molybdenum-containing catalyst it was shown that above 90°C the selectivity of the process is reduced significantly, since the hydroperoxide is destroyed by undesirable side-reactions[64]. A study of the reaction at 76–120°C aimed at obtaining equations for the optimisation of the process yielded the multistage mechanism:

$$R_1(R_2)(R_3)COOH + Mo \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} [R_1(R_2)(R_3)COOH \cdot Mo] , \quad (I)$$

$$X + C_3H_6 \xrightarrow{k_2} C_3H_6O + [R_1(R_2)(R_3)COH \cdot Mo] , \quad (II)$$

$$[R_1(R_2)(R_3)COH \cdot Mo] + R_1(R_2)(R_3)COOH \xrightarrow{k_3} R_1(R_2)(R_3)COH + X , \quad (III)$$

$$X + R_1(R_2)(R_3)COOH \xrightarrow{k_4} 2R_1(R_2)C{=}O + 2R_3OH + Mo , \quad (IV)$$

$$X + R_1(R_2)(R_3)COOH \xrightarrow{k_5} [R_1(R_2)(R_3)COH \cdot Mo] + R_1(R_2)(R_3)COH + O_2 . \quad (V)$$

The distinguishing features of this mechanism are the irreversibility of stage (III) and the side-reactions (IV) and (V) for decomposition of the hydroperoxide. On the basis of this scheme differential equations describing the consumption of the hydroperoxide and accumulation of propene oxide (PO) were written. Having used the experimental results on the rates of consumption of hydroperoxide w_{HP} and the rates of accumulation of the epoxide w_{PO} and having solved the equations by the Runge–Kutta method the investigators obtained a set of constants, the values of which were approximated to the Arrhenius equation. The coefficients of the Arrhenius equation were found by the least squares method.

The resulting equations for the rate of consumption of hydroperoxide and accumulation of the epoxide had the following form:

$$w_{HP} = K_I[Mo][HP](2K_{II}[HP] + k_2[propene])/(1 + K_{III}[HP]),$$

$$w_{PO} = K_1 \cdot k_2 \cdot [HP][Mo] \cdot [propene]/(1 + K_{III} \cdot [HP]),$$

where $K_I = \kappa_1/k_{-1}$, $K_{II} = k_4 + k_5$, $K_{III} = k_4/k_{-1}$.

The following values of the constants were obtained for the temperature range 76–120°C:

$$K_I = 49.6 \exp(-3480/RT) \text{ litre mole}^{-1};$$

$$K_{II} = 2.19 \cdot 10^5 \exp(-5960/RT) \text{ litre mole}^{-1} \text{ min}^{-1};$$

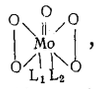
$$K_{III} = 113 \exp(-15800/RT) \text{ litre mole}^{-1};$$

$$k_2 = 5.7 \cdot 10^7 \exp(-10500/RT) \text{ litre mole}^{-1} \text{ min}^{-1}.$$

The results obtained can serve as the basis for the optimisation of the epoxidation of propene by ethylbenzene hydroperoxide in various types of reactor [64]. It is noteworthy that stage II, the rate-limiting step for the entire process has an activation energy of 10.5 kcal mole^{-1}, which differs significantly from the activation energy for this stage obtained in the epoxidation of propene by the same hydroperoxide with a molybdenum-containing catalyst at 50–80°C, 15.2 kcal mole^{-1}. [59,60] The various butenes can be arranged in the following series according to reactivity in their epoxidation by hydroperoxides in the presence of a molybdenum catalyst [62]: *cis*-but-2-ene : *trans*-but-2-ene : but-1-ene = 36.6 : 14.2 : 1.0. This ratio shows the effect of steric factors on the reaction rate in the epoxidation by hydroperoxides with participation of catalysts.

A characteristic feature of catalysed epoxidations with hydroperoxides is that the catalyst oxidised at the start of the process is not reduced at the end but is regenerated in an active form by exchanging an alcoholic ligand for hydroperoxide [56,59]. There remains a series of unexplained details in the mechanism of these reactions: the activation step of the catalyst, the chemistry of the limiting reaction, etc. Evidently these problems cannot be solved with the aid of kinetic investigations alone. An important part in the explaining of the details of the mechanism of these reactions should be played by the use of physicochemical methods of investigation of intermediate complexes formed during the course of the process and also a study of the reactions of the complexes themselves with alkenes. Such a type of investigation of the covalent peroxo-complexes of Mo^{VI} has been made [65].

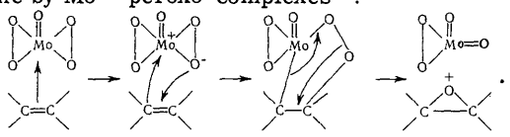
The epoxidation of alkenes by peroxo-complexes of Mo^{VI} of the following structure:



where L_1 and L_2 are aromatic amines, amides, phosphoramides, or phosphines, has been studied in various solvents at various temperatures.

The selectivity of the epoxidation with participation of such complexes reaches 50–95%, depending upon the conditions. The epoxidation of cyclohexene in dichloroethane at 10–30°C by the complex $[Mo(O_2)O]$–HMPTA (where HMPTA is hexamethylphosphorictriamide) proceeds through the intermediate formation of an associate of this complex with cyclohexene, the decomposition of which limits the rate of the process. The reaction was followed by the decrease in active oxygen (1 mole of the complex gives 2 atoms of active oxygen) and the process characterised by the effective first-order rate constant; the effective activation energy is 15.9 kcal mole^{-1}, very close to the values of E_{act} obtained for the epoxidation of propene by hydroperoxides in the presence of molybdenum-containing catalysts [60].

Solvents with various dielectric constants do not markedly affect the rate of epoxidation of a peroxo-complex although some of them can act on the reaction, by entering into the coordination shell of the complex. The coordination ability of some of the solvents used decrease in the order: HMPTA > DMF > tetramethylurea. The accumulated experimental results allowed a bipolar 1,3-addition mechanism to be proposed for the epoxidation of an alkene by Mo^{VI} peroxo-complexes [65]:



In addition to organic peroxides, hydrogen peroxide can be used in the epoxidation of alkenes [66–72]. The reaction of hydrogen peroxide with alkenes is catalytically accelerated by the addition of tungstic acid and tungstates [66–70], molybdenyl acetylacetonate [71], and isocyanate [72]. The mechanism of the catalytic action of tungstic acid and tungstates has now been well studied [68,70]. The epoxidation of allyl alcohol in an aqueous medium by hydrogen peroxide with addition of H_2WO_4 or Na_2WO_4 is characteristically zero order with respect to peroxide, and first order with respect to allyl alcohol and tungstate. The effective activation energy of this reaction is 14.6 kcal mole^{-1}. The following results have been obtained on the reactivity of alkenes in epoxidation by hydrogen peroxide (40°C) in the presence of tungstate:

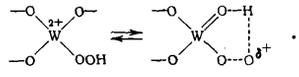
Hydrocarbon	$10^6 k$, s^{-1}
Cyclohexene	4.0
Allyltrimethylsilane	2.7
Allylmethylether	1.6
Allyl bromide	1.0
Allyl chloride	0.9

The logarithm of the constant is related linearly with the Taft σ constant, the coefficient ρ in the Taft equation being −0.44.

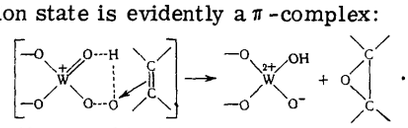
On the addition of tungstic acid or a tungstate to the peroxide the anion of pertungstic acid is formed rapidly:

$$HWO_4^- + H_2O_2 \rightleftarrows HWO_5^- + H_2O.$$

The actual anion HWO_5^- is the active species in the epoxidation of alkenes [70]; it exists in cyclic form owing to the formation of an intramolecular hydrogen bond and has an oxygen atom capable of electrophilic attack at the double bond:



The transition state is evidently a π-complex:



An interesting combination of epoxidation by hydrogen peroxide with the use of isocyanate has been described [72]. At 20°C cyclohexene, styrene, and hex-2-ene are epoxidised with 33–69% yield in reaction with hydrogen peroxide and phenyl isocyanate. The stoichiometry of the reaction is:

Two molecules of phenyl isocyanate and hydrogen peroxide form a complex (maximum absorption corresponds to a wavelength of 314 nm), which is also an epoxidising agent. It was found that under these conditions peroxocarbamic acid does not epoxidise alkenes.

Hence whereas in several instances the reaction mechanism is clear, for example, in the epoxidation of alkenes by hydrogen peroxide and tungstates, many problems of the reaction mechanism in the catalytic epoxidation by hydroperoxides have still not been settled. It is not clear whether the metal in the complex with hydroperoxide undergoes valency changes during the reaction or regeneration of the catalyst is effected solely by exchange of ligands[56,59]. The oxidation of a catalyst by hydroperoxides with the formation of active species has not yet been investigated, and the reaction between the complex of a metal with hydroperoxide and an alkene has not been studied at the level of the physical chemistry of the elementary act. Complexes of hydroperoxides with metals are not always capable of epoxidating an alkene, and in several instances such complexes generate radicals from the hydroperoxides and accelerate the autoxidation of the alkene, for example, in the autoxidation of oct-1-ene with participation of t-butyl hydroperoxide and Cr^{III} acetylacetonate[73]. In isolated instances an important part is played by the catalytic decomposition of the peroxides with participation of the metals, which becomes an undesirable side-process in epoxidation[60].

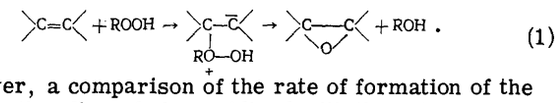
Despite a series of unsolved problems in the catalytic epoxidation of alkenes with hydroperoxides, requirements which are presented to the catalysts by this reaction can be formulated: (1) the central atom should be present in a high oxidation state; (2) the metal atom should have vacant *d*-orbitals capable of adding a pair of electrons; (3) one-electron redox reactions should be absent; (4) the metal should be employed in the form of a complex with labile ligands.

Clearly, all these requirements are not unique, are general in nature, and are typical for many catalytic reactions of coordination compounds.

4. NON-CATALYSED OXIDATION OF ALKENES WITH OXYGEN

The mechanism of non-catalysed oxidation of unsaturated hydrocarbons has been studied in detail and described in several monographs and papers[74-76]. There can now be no doubt as to the radical-chain nature of the oxidation of unsaturated hydrocarbons by oxygen. This is confirmed by the photochemical sequence in the oxidation of alkenes[77], by the initiating action of peroxides[78], by the accumulation during the reaction of hydroperoxides, aldehydes, ketones, and acids. However, in addition to the above products in the oxidation of alkenes by oxygen, epoxides are formed. The aim of the present section will be to consider the mechanisms by which the alkene oxides are formed. Comparison of the oxygen absorbed with the amount formed in the oxidation of alkenes by peroxides showed that the alkenes absorb oxygen more than is observed with peroxides[79]. It appeared that in addition to hydroperoxides alkene oxides are formed; they were observed in the oxidation by oxygen of di-isobutene[80], styrene[81], methylstyrene[82], methyl elaidate[83], 2,4,4-trimethylpentene[84], cyclohexene[84], but-1-ene and but-2-ene[85], propene[86-90], and 2-methylpent-2-ene[91]. In isolated instances[87-91] alkene oxides can be obtained with yields which are of practical value (40–50% on the alkene which has been oxidised).

By which reactions are the epoxides formed in the oxidation of the alkenes by oxygen? One of the first reactions was proposed by Farmer and coworkers[92]:



(1)

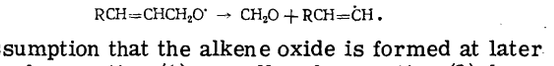
However, a comparison of the rate of formation of the epoxide in the alkene being oxidised with the rate of conversion of the hydroperoxide showed that in the initial period of reaction the epoxide is formed in parallel with the hydroperoxide and is one of the primary products of the oxidation of the alkene[81]. A mechanism by which the epoxide is accumulated in parallel with the hydroperoxide has therefore been proposed[93]:

(2)

This reaction has been studied by the example of styrene[81] and methylstyrene[82]. In addition to reaction (2) in the oxidation of styrene the intermediate radical is converted into a peroxide radical:

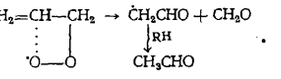
and a polymeric peroxide is formed[81]; in the oxidation of di-isobutene a polymeric peroxide is not formed: only the oxide and hydroperoxide accumulate. This allowed Mayo[80] to suggest that reaction (2) proceeds in a single step. Others have expressed similar opinions[94,95]. However, as further investigations showed, this reaction does not agree with several experimental facts[86].

The common oxidation of isopropylbenzene or ethylbenzene with propene at 80–90°C in the presence of an initiator is not accompanied by the formation of propene oxide, although a sufficiently high concentration of peroxide radicals was observed in the oxidation of cumene and ethylbenzene by EPR[96]. The formation of epoxide by reaction (2) should be accompanied by the accumulation of an equivalent amount of alcohol, but in the oxidation of cyclohexene, for example, alcohol is not observed in the early stages of reaction[94]. A second difficulty can be avoided by assuming that the RO· radical decomposes before the formation of alcohol, according to the scheme adopted for the oxidation of di-isobutene[80]:

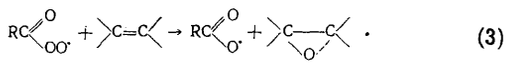


The assumption that the alkene oxide is formed at later stages than by reaction (1) as well as by reaction (2) does not agree with the experimental facts: the rate of formation of the alkene oxides by reaction (1) in an atmosphere of nitrogen is many times less than under oxidation conditions[94].

These difficulties can be avoided by postulating that in the oxidation of an alkene the epoxidising species is not the radical $RO_2^{\cdot}$ but the acyl peroxide radical RCOOO·, which is formed in the oxidation of aldehydes[86]. Actually, at 120–145°C during the oxidation of propene the accumulation of propene oxide precedes the formation of acetaldehyde[86]. The relation of the rates of accumulation of acetaldehyde and hydroperoxide tend towards a constant value at $t \to 0$ that is, the aldehyde accumulates in parallel with the hydroperoxide. Therefore the reaction proposed for the formation of the aldehyde is the unimolecular decomposition of the peroxide radical by analogy with the gas-phase oxidation of aldehydes[97]:



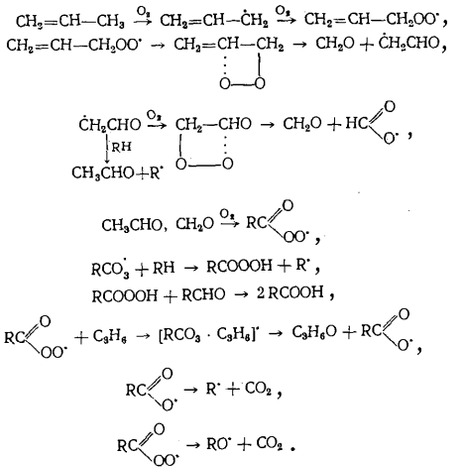
The oxidation of the aldehydes which are formed leads to acylperoxy-radicals, which are more reactive towards a double bond than the alkenylperoxy-radicals, and form oxides by the reaction:



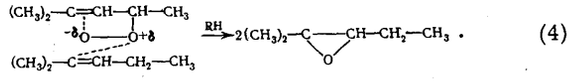
(3)

Reaction (3) can be one of the main paths for the formation of an alkene oxide, since aldehydes almost always accumulate in the oxidation of an alkene[85,86,90]. A detailed study of the liquid-phase oxidation of propene in non-metallic reactors (Teflon) showed that the intermediate products of the oxidation are formaldehyde and acetaldehyde, by way of which ~ 90 mole % of the propene reacts[87-90].

A scheme for the oxidation of propene in non-metallic reactors has been proposed[90]:



In the oxidation of 2-methylpent-2-ene at 120°C in a stainless steel reactor it was shown quite recently[91] that the rate of formation of the epoxide is much greater than the rate of accumulation of the conversion products of the acyl and alkenyl peroxide radicals, that is, reactions (2) and (3) cannot be explained by the accumulation of 2-methylpent-2-ene oxide in the quantities which are obtained experimentally (42% oxide in the conversion of methylpentene). A new reaction scheme for the epoxidation of alkenes was therefore proposed:



(4)

During the interaction of the unpaired electron of the radical with the π-bond the O–O bond in the radical is polarised, which facilitates the transfer of oxygen to the double bond and the detachment of a second oxygen atom by the neighbouring alkene molecule.

On making an overall examination of the epoxidations of alkenes during their oxidation it can be stated that hydroperoxides hardly participate at all in the epoxidation processes; during the epoxidation of the lower alkenes an important part is played by reaction with acylperoxy-radicals (3), but reaction of the double bond with alkenylperoxy-radicals (2) cannot be excluded completely. However, evidently there are also other paths of epoxidation, for example, reaction (4): the structure of the alkene plays a large part in the epoxidation.

5. MECHANISM OF COMBINED OXIDATION OF ALKENES AND ORGANIC COMPOUNDS OF OTHER CLASSES

It is well known that the combined oxidation of alkenes with aldehydes gives the possibility of increasing the yield of epoxide compounds to 50% or over[98-104]. This fact was used to create a new method of preparing alkene oxides[101,104]. Blyumberg and coworkers proposed to use the active oxygen of peroxide radicals formed during the oxidation of organic compounds for the epoxidation of alkenes. In one stage of the combined oxidation alcohols, ketones, acids, etc. are formed simultaneously with the alkene oxides. Substances which are carriers of active oxygen can be ketones or aliphatic and aromatic hydrocarbons in addition to aldehydes[105]. The best results are achieved by use of acetaldehyde and ethyl methyl ketone. The process is carried out in an inert solvent and air serves as oxidant. In the oxidation of propene plus acetaldehyde the optimal temperature is 55–60°C, the pressure 50 atm, the ratio acetaldehyde:propene = 1–2 : 8–9. 0.05 wt.% cobalt acetate is introduced as a catalyst. An excess of propene, benzene, ethyl acetate, acetone, dichloroethane, or acetic acid is used as solvent. Table 6 gives the results for the combined oxidation of alkenes with other organic compounds[105]. An analogous process was proposed by the Institut français de Pétrole[104]: the epoxidation of propene, but-1-ene, hex-1-ene, or 2-ethylhex-1-ene is effected at a partial pressure for the alkene of 22–30 atm in the presence of acetaldehyde, propionaldehyde, or butyraldehyde. Benzene, chlorobenzene, dichlorobenzene, toluene, or xylene is used as solvent. The temperature for the process is determined by the nature of the alkene being oxidised. Azo-compounds, organic peroxides, or salts of metals of variable valency are used as initiators of the epoxidation.

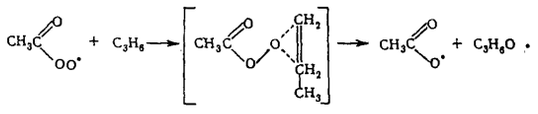
Table 6. Characteristics of the combined oxidation of alkenes and other compounds[105].

Conjugated pair	Temp., °C	Concn., wt.%	Yield of oxide, kg per 100 kg first component
Acetaldehyde + propene	55—80	34.0	70.0
Propionaldehyde + propene	70	12.0	50.0
Ethyl methyl ketone + propene	145	10.0	96.0
Butane + propene	145	3.0	11.0
Isopropylbenzene + propene	130	3.0	13.4
Ethylbenzene + propene	120—140	3.0	15.0
Acetaldehyde + 2-methylpropene	80	12.0	82.0
Acetaldehyde + ethylene	80	8.5	13.0

The problems of the combined oxidation of alkenes and aldehydes were investigated using the pair propene plus acetaldehyde[106-108]. A study of the kinetics and mechanism of oxidation of this pair of substances at 70–80°C and 50 atm in an inert solvent (benzene) showed that the main epoxidating species is the acylperoxy-radical formed in the oxidation of acetaldehyde by oxygen[106]. At the moment of reaching the maximum rate of accumulation of propene oxide in the reaction mixture an inhibitor of radical reactions was introduced—2,6-di-t-butyl-4-methylphenol. After the introduction of the inhibitor the propene oxide concentration rose very slightly, that is, the bulk of the oxide is accumulated from the reaction of propene with free radicals, and a smaller part by reaction with the per-acid.

A study of the epoxidation of propene with peracetic acid under the same conditions made it possible to estimate the contribution of this reaction to the total accumulation of

propene oxide[29]. It was found that at 70–80°C only ~ 15% of the propene oxide is formed by reaction with peracetic acid and the rest comes from the reaction with acylperoxy-radicals[106]:



In addition to the epoxide, methanol, methyl acetate, biacetyl, and methyl formate are formed in the combined oxidation of acetaldehyde and propene[106]. The composition of the oxidation products is greatly dependent upon the oxygen partial pressure[107].

The principal reactions which occur during the combined oxidation of acetaldehyde and propene are[107]:

$$CH_3CHO + O_2 \xrightarrow{k_1} CH_3\dot{C}O + HO_2^{\cdot},$$

$$CH_3\dot{C}O + O_2 \xrightarrow{k_2} CH_3COOO^{\cdot},$$

$$CH_3COOO^{\cdot} + CH_3CHO \xrightarrow{k_3} CH_3COOOH + CH_3\dot{C}O,$$

$$CH_3CHO + CH_3COOOH \xrightarrow{k_4} 2\,CH_3COOH,$$

$$\left.\begin{array}{l} 2\,CH_3CO^{\cdot} \xrightarrow{k_5} (CH_3CO)_2 \\ CH_3CO^{\cdot} + CH_3COOO^{\cdot} \xrightarrow{k_6} \\ 2\,CH_3COOO^{\cdot} \xrightarrow{k_6} \end{array}\right\} \text{chain breaking,}$$

$$CH_3COO\dot{O} + C_3H_6 \xrightarrow{k_7} CH_3COO^{\cdot} + C_3H_6O,$$

$$CH_3COO^{\cdot} + CH_3CHO \xrightarrow{k_{2'}} CH_3COOH + CH_3\dot{C}O\ .$$

The rate of oxidation of CH_3CHO (RH) in the absence of propene is described by the formula:

$$w_0 = \frac{k_2[RH]\sqrt{w_i}}{\sqrt{k_6}}\left\{1 + \frac{k_5 k_2[RH]}{k_6 \cdot k_1[O_2]} + \frac{k_4}{k_6}\left(\frac{k_2[RH]}{k_1[O_2]}\right)^2\right\}^{-1/2}.$$

When the rate of oxidation is independent of $[O_2]$:

$$w_\infty = \frac{k_2[RH]\sqrt{w_i}}{\sqrt{k_6}}.$$

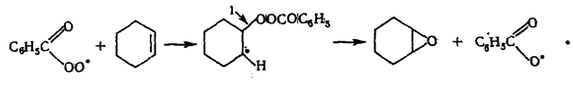
The validity of the above formulae is confirmed by the linear relation between $[(w_\infty/w_0)^2 - 1][O_2]$ and $[O_2]^{-1}$ obtained from experimental results[107].

From the above scheme, clearly a change in O_2 concentration will affect the composition of the radicals participating in recombination and also affect the composition of the reaction products. Actually when the O_2 concentration is reduced there is an increase in, for example, the quantity of biacetyl formed.

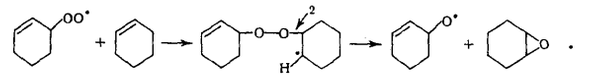
In an investigation of the common oxidation of propene and acetaldehyde in dimethyl phthalate solution (70–90°C, 55 atm air) the effective rate constants for the consumption of acetaldehyde and the effective activation energy (9.6 kcal mole^{-1}) were determined[109,110].

In some studies the combined oxidation of benzaldehyde and unsaturated compounds was investigated[111,112].

In studying the oxidation of cyclohexene and benzaldehyde with participation of cobalt acetate, which reacts rapidly with per-acids, it was noted that only ~ 3% of perbenzoic acid reacts with cyclohexene with the formation of epoxide; all the remaining epoxide is formed by the reaction of cyclohexene with peroxide radicals[111]:

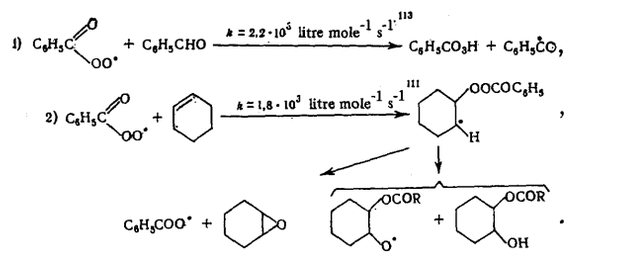


It is suggested[111] that cyclohexenylperoxy-radicals also participate in the epoxidation:



This reaction is quite possible, since the energy of bond 2 is greater than the energy of bond 1.

It is known[102,103] that alkenes retard the oxidation of aldehydes. This is easy to understand on considering that the rate constant for chain propagation in the oxidation of benzaldehyde at room temperature is close to the rate constant for the reaction of acylperoxy-radicals with a double bond:



Clearly, either stable products or radicals with little activity in chain propagation are obtained in the second reaction.

The kinetic results examined above obtained in the combined oxidation of propene with plus aldehydes[105–107] and of cyclohexene plus benzaldehyde[111] show that the principal reaction in epoxidation is the interaction of radicals with the double bond and the per-acids—oxidation products of the aldehydes—make a relatively small contribution to epoxidation. Only in isolated instances, for example, in the oxidation of α-methylstyrene and benzaldehyde does non-radical epoxidation of the double bond by reaction with a per-acid amount to more than 10–15%.[112]

6. CATALYSED OXIDATION OF ALKENES BY THE OXYGEN IN AN OXIDE

The use of catalysts in processes of liquid-phase oxidation of alkenes allows the temperature of the reaction to be significantly reduced and the selectivity of the processes to be increased. In the oxidation of propene suspensions in dibutyl phthalate of finely ground copper, silver, or their oxides are used as catalysts. The yield of propene oxide on these catalysts reaches 87%. It has also been proposed to use Co, Cu, Mn, V, or Cr promoted with Ba or Pb salts for these purposes[114,115]. Various catalysts based on Cu and Ag are used in the oxidation of butenes. A special copper catalyst containing alkali metal halides has been developed[116]. In addition, it is thought that in the oxidation of butenes to the epoxide it is not necessary to employ catalysts but it is quite sufficient to use initiators to shorten the induction period[117].

The catalysts used until now for the liquid-phase oxidation of alkenes to epoxide are usually heterogeneous and selected by analogy with the catalysts for the gas-phase oxidation of alkenes. The mechanism of action of the heterogeneous catalysts in the epoxidation will not be examined in the present review. We will concentrate attention on the use of homogeneous catalysts in the oxidation of alkenes to epoxides, since there have been many recent studies in this direction and in several instances

alkene oxides have been obtained in high yields under comparatively mild conditions. An investigation of the liquid-phase oxidation of propene with oxygen with participation of chelates of MoO_2^{2+}, WO_2^{2+}, Co^{2+}, Cr^{3+}, and Cu^{2+} (various azo-compounds obtained by diazotisation of substituted phenols and naphthols were used as chelating ligands) showed that the complexes of MoO_2^{2+} and WO_2^{2+} are the most selective in the oxidation of propene to its oxide, and allow the oxide to be obtained in up to 70% yield in the conversion of ~ 7% of the propene (temperature: 150°C; solvent: benzene; total pressure: 45 atm).[118,119] The remaining cations with the same ligands are less selective in this reaction and give a lower yield. A detailed investigation of the catalysis of the oxidation of propene with participation of chelates obtained from MoO_2^{2+}, $MoCl^{4+}$, and $OMo(OH)_2^{2+}$ and the study of the magnetic properties of these chelates suggested that the catalyst in this reaction takes up a molecule of oxygen and activates it[120-126].

In a study of the mechanism of activation of oxygen in the oxidation of propene to its oxide with participation of molybdenum chelates, the effect of a large number of chelating azo-compounds on the state of the central ion, on the magnetic properties of the chelate which adds to oxygen, and on the activity of the chelate in the epoxidation was investigated[120-126]. For each of the inorganic cations MoO_2^{2+}, $MoCl^{4+}$, and $OMo(OH)_2^{2+}$, chelates were obtained with compounds of the azonaphthoquinone type containing various substituents; for all the chelates their magnetic susceptibility was measured and their magnetic moments calculated[121]. For each of the three inorganic cations a linear relation was found between the magnetic moment and the Hammett σ constant for the ligand:

$$\mu - \mu_0 = R - S\sigma_{lig},$$

furthermore,

$$R = U + T\sigma_{cation},$$

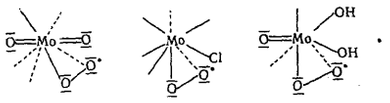
where σ_{cation} is the characteristic of the donor–acceptor capability of the cation with inorganic ligands. Hence:

$$\mu = \mu_0 + U + T\sigma_{cation} - S\sigma_{lig},$$
$$U = 1.83, \quad T = 1.15\ \mu_B.$$

The values of the other constants in these equations are:

Constants	MoO_2^{2+}	$MoCl^{4+}$	$OMo(OH)_2^{2+}$
σ_{cation}	1.00	0.23	−0.24
R, μ_B	3.00	1.47	2.20
S, μ_B	0.57	0.57	0.40

Hence the effect of the ligands and the state of the central atom were connected and characterised quantitatively. All three series of molybdenum chelates were used as catalysts for the epoxidation of propene and it was found that the selectivity of this reaction is linked with the state of the complex. For all three series of complexes the most selective were the chelates in which 0.7 of an unpaired electron is localised on the molybdenum. A departure from this optimal figure to one side or the other decreases the selectivity of the chelate in the epoxidation of propene. An investigation of the magnetic properties of the complexes and the parameters for the activation of oxygen by the complexes in relation to their selectivity in epoxidation suggested[122-126] that the epoxidating species are paramagnetic associates of the chelates with oxygen having the following structure:



In all three species the molybdenum is sexivalent.

In the homogeneous-catalytic reactions complexes of other metals which add an oxygen molecule in the coordination sphere were also employed: thus the complexes $IrX(CO)(PPh_3)_2$ and $RhX(CO)(PPh_3)_2$ (where X = Cl, Br, or I), first prepared by Vaska[127,128] were used in the oxidation of styrene[129,130], cyclohexene[131], and ethylbenzene[132]. Before turning to an examination of the mechanism of epoxidation of alkenes with participation of metal complexes which activate oxygen, we will consider the characteristic properties of these complexes. Complexes have recently been obtained that are capable of adding a molecule of oxygen and have as central atom iron, cobalt[133,134], iridium[127,128], rhodium[127,128], or ruthenium[135].

An oxygenated complex of a metal necessarily has a central atom which exhibits redox activity:

$$Co^{II} \rightarrow Co^{III};\quad Ir^{I} \rightarrow Ir^{III};\quad Fe^{II} \rightarrow Fe^{III},$$

and oxygen, which also exhibits redox activity as a ligand. Here the concept of valency loses significance and one can speak only of partial charges on the partners in the bond, when the total molecular orbital is predominantly localised at the metal or the ligand. The internuclear distance in the O–O group is a reliable measure of these partial charges. In the complex $[(Cl)Ir(CO)(PPh_3)_2]$ (I), which adds oxygen reversibly, both oxygen atoms are equivalent and at equal distances from the iridium. The distance between the oxygen atoms is 1.30 Å, which is greater than in molecular oxygen (1.21 Å) but significantly less than in O_2^{2-} (1.49 Å), and corresponds to the distance in $O_2^{\cdot-}$ (1.28 Å). Despite this it cannot be assumed that the oxygen in the iridium complex is the radical-anion $O_2^{\cdot-}$ since this complex is diamagnetic.

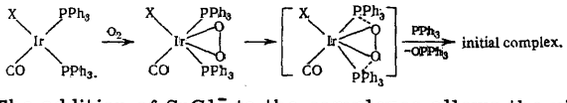
A characteristic feature of complex (I), extremely significant from the standpoint of the catalysis of the epoxidation of alkenes, is the capability of this complex to add ethylene reversibly[136]; an analogous complex is formed with tetrafluoroethylene[137]. A comparison of the bonding of oxygen with the bonding of the alkenes in these complexes is quite permissible, since the electronic structure of the oxygen molecule in the ligand field corresponds to the electronic structure of ethylene[138].

We will consider yet another property of the complexes which bond oxygen—the strength of the bonding of the oxygen with the central atom. If the Cl in complex (I) is replaced by iodine, the strength of the bonding of O_2 with the metal increases and the complex $[(O_2)Ir(CO)(I)(PPh_3)_2]$ (II) bonds oxygen irreversibly. An X-ray diffraction analysis of complex (II) gave an interesting result: the change from reversible (I) to irreversible (II) oxygen-containing complex is associated with an increase in the length of the O–O bond from 1.30 Å to 1.47 Å, but the equidistance of the oxygen atoms is retained. This distance corresponds to the anion O_2^{2-} (1.49 Å), hence the transfer of electrons from the metal to the O_2 ligand increases when chlorine is replaced by iodine[139]. Replacement of chlorine by phosphine also leads to the stabilisation of the compound of oxygen with $Ir[(PPh_2-[CH_2]_2-PPh_2)_2]^+$.[128,140] The addition of O_2 to the phosphine complexes of nickel, palladium, and platinum is irreversible[141]. In these complexes an intramolecular

redox reaction rapidly takes place, leading to the oxidation of the phosphine. In peroxo-complexes, such as the derivatives of Cr^{V}, Cr^{VI}, CrO_5, or $[CrO_8]^{3-}$, there should be preferential transfer of charge from O_2^{2-} to the central atom (a strong acceptor) and as a consequence of this the O–O bond length is 1.40 Å.[142]

Hence there is a continuous increase in the bond strength and the O–O internuclear distance in the series: labile compounds of oxygen → compounds with reversible addition of oxygen → peroxo-complexes.

Vaska complexes have been used as catalysts for the epoxidation of styrene with oxygen[129–130]:



The addition of $SnCl_3^-$ to the complexes allows the yield of epoxide to be increased 477% relative to the catalyst used. Iridium and palladium chlorides ($IrCl_3$ and $PdCl_2$) are also used as catalysts of the epoxidation of styrene. At 110°C they give 51 and 184% styrene oxide respectively[129]. The use of $RhCl_3$ as catalyst enables 1232% styrene oxide to be obtained after reaction for 8 h at 110°C.[130] It is noteworthy that Takao and coworkers[129,130] did not suggest any reaction mechanism for the epoxidation and oxidation of styrene. A great drawback of these Japanese studies is that the reaction was investigated in the most inappropriate solvent (toluene). Under the conditions employed (110°C, 1 atm oxygen, presence of the catalysts $IrCl_3$, $PdCl_2$, etc., there must be oxidation of the toluene with formation of benzaldehyde and other reaction products. Actually, the main product of the oxidation of styrene in toluene is almost always benzaldehyde[129]. The benzaldehyde which is formed, on being oxidised in combination with styrene can give styrene oxide, as was shown by the example of the oxidation of α-methylstyrene plus benzaldehyde[112]. Undoubtedly, toluene should be oxidised under the experimental conditions of the Japanese investigators, as was confirmed by the success in using Vaska complexes for the oxidation of ethylbenzene at 130°C and *p*-xylene at 120°C with the formation of acetophenone (90%) and *p*-tolylaldehyde respectively[132]. The unfortunate choice of solvent hinders the interpretation of the results of the Japanese investigators: possibly the catalytic epoxidation of styrene actually takes place but undoubtedly benzaldehyde—the oxidation product of toluene when any catalyst is used—plays an important part in the epoxidation.

Only kinetic investigations of the epoxidation of alkenes with participation of Vaska complexes in an inert solvent will make it possible to judge their true catalytic activity in this reaction and its mechanism. An investigation of the catalytic influence of Vaska complexes on the oxidation of cyclohexene in benzene and CH_2Cl_2 at 25–60°C showed that the main oxidation product is cyclohexen-3-one[131]. Hence the catalytic activity of Vaska complexes—transporters of the oxygen atom—is certain[131,132] but it is difficult to judge to what extent these complexes are selective in epoxidations on the basis of the results that have been published.

We will now return to the problems of the activation of oxygen in the epoxidation of propene with participation of molybdenum chelates. As already noted, the epoxidating species is a paramagnetic associate of the chelate with an oxygen molecule[122]. In this associate the molybdenum is in the highest oxidation state. After the act of epoxidation has occurred or during the course of this act the molybdenum should be reduced to the quinquevalent state.

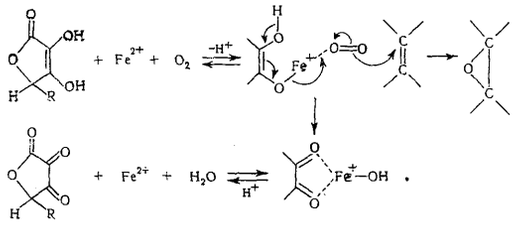
Various investigations[118–126] did not show any specific reduction paths for the molybdenum, that is, the regeneration of the catalyst during the course of the reaction. We can presume that in the reduction of molybdenum reaction products participate, for instance acetaldehyde formed in parallel with propene oxide by the non-catalysed oxidation of the latter:

$$CH_3CHO + Mo^{VI} \rightarrow CH_3\dot{C}O + Mo^{V} + H^+ .$$

We represent the epoxidation itself as follows:

Such a type of transfer of an oxygen atom from an O_2 molecule to a substrate is known to be effected by oxidases with mixed functions[143,144], which epoxidise alkenes, oxidise aliphatic compounds to alcohols, and hydroxylate aromatic compounds to phenols.

Several systems which can be regarded as models of oxidases with mixed functions have been studied recently[53,145]. The study of such models helps to answer the problem of how many electrons are transported on the O_2 molecule and how this transport is linked with the epoxidation of the substrate. A scheme of epoxidation of an alkene with participation of one of the oxidase models with mixed functions—the Fe^{2+} + O_2 + ascorbic acid system—is given below[53]:



As this scheme shows, the epoxidising agent is a complex, the function of the ferrous ion in which is to unite with the reducing agent and oxygen and to convey to the latter electrons to form the transition state. The iron ion allows a singlet oxygen atom to be transferred from the combined O_2 molecule to the substrate in such a manner that the intermediate biradical compound is unnecessary. If a triplet oxygen atom were transferred the process would be less favourable energetically owing to the formation of a triplet reaction product, which is less stable than the singlet. The transfer of a proton of ascorbic acid into the complex with O_2 is evidently simultaneous with the transfer of electrons through the ferrous ion leading to the reduction and stabilisation of the oxygen atom which is not passed on to the substrate. The other oxygen atom, which has 6 electrons (hence the analogy with carbenes and nitrenes, which also have 6 electrons around the carbon or nitrogen and are extremely reactive) is introduced into the substrate. In this way four-electron exchange is effected with minimal motion of the nuclei.

If it is assumed that the reduction of the molybdenum is brought about by the ligand (which is not excluded) then the scheme for the epoxidation of propene with participation of molybdenum chelates does not differ from that discussed above. If the reduction of molybdenum is effected in interactions with the oxidation products of propene—acetaldehyde, etc.—then we have a new example of models of oxidases with mixed functions, distinguished by the fact that the reducing agent does not enter the coordination sphere of the complex, but reacts with the oxidised complex after the act of epoxidation has been completed. Unfortunately,

the most interesting studies of epoxidation with participation of molybdenum chelates[118-126] do not provide results on the regeneration of the catalyst, and we cannot now choose between these two possibilities. It is very significant that it could be shown which of the forms of active oxygen:

$$[Mo^{5+} \ldots O_2] \leftrightarrow [Mo^{6+} \ldots \dot{O}_2^-] \leftrightarrow Mo^{6+} + \dot{O}_2^-$$
(I) (II) (III)

is the main one in the epoxidation of propene.

It is form (II). However, this does not signify that in all other instances this form of the reacting species will be predominant. As Hamilton thinks[53], the nature of the attack of the substrate in different model systems can vary from radical to electrophilic and even nucleophilic. It all depends upon which state of the attacking species predominates. And this state is in turn determined by the type of metal and especially the ligands which are around it. In general there can be several forms of attacking species and the determination of the valence state of the metal or oxygen in it has no significance in itself. It is necessary to know which of the resonance forms is the most important because this will determine the nature of the attack of the substrate. The difficulty in determining the nature of the bonding in oxygen complexes was descriptively characterised by Alfred Werner, founder of the chemistry of complexes, 70 years ago, but his words are still true today: "The labile bonding of oxygen .... is so peculiar, that it is very difficult to give a satisfactory answer to the question of whether there is a valence bond or simply addition of the oxygen as a molecule, if this question has meaning at all".[146]

---o0o---

Not all the epoxidations that we have considered can at present be characterised by rate constants of the limiting stages. However, for several epoxidising agents the energetic characteristics of the limiting reactions have been determined—the enthalpies of activation or the energies of activation. Table 7 gives the values of these energetic characteristics.

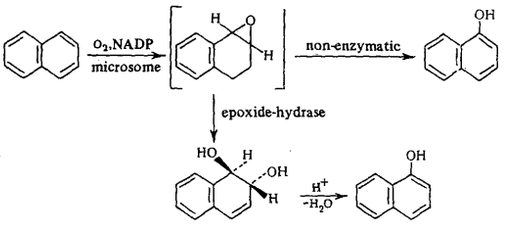
Table 7. Energetic characteristics of limiting reactions in the epoxidation of alkenes.

Epoxidising agent	Alkene	$\Delta H^{\times}$ or E_{act}, kcal mole^{-1}	Reference
Perbenzoic acid and its substituted derivatives	*trans*-stilbene and its substituted derivatives	$\Delta H^{\times}=14.0+16.0$	24
Perbenzoic acid	cyclohexene	$\Delta H^{\times}=12.7$	24
Peracetic acid	propene	$E=11.6$	29
HWO_5^-	allyl alcohol	$E=14.6$	70
TBHP + Mo-cat.	propene	$E=15.0$	60
CHP + Mo-cat.	propene	$E=15.6$	60
EBHP + Mo-cat.	propene	$E=15.2$	60
EBHP +Mo-cat.	propene	$E=10.5$	64
TBHP + $VO(acac)_2$	cyclohexene	$\Delta H^{\times}=12.7$	56
$[Mo(O_2)_2O]L_1L_2$	cyclohexene	$E=15.9$	65

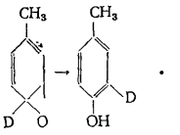
From Table 7, the activation energies or activation enthalpies for various epoxidising species are rather similar. This fact is not unexpected, since in almost all the reactions considered the epoxidating agent is an electrophilic species which attacks the π-bond of the alkene.

The nature of the alkene naturally affects the activation energy of the epoxidation: thus $\Delta H^{\times}$ in epoxidation with perbenzoic acid varies from 12.7 kcal mole^{-1} for cyclohexene to 17.2 kcal mole^{-1} for tetraphenylethylene (see Table 1). The epoxidation of a single alkene, for example, cyclohexene or propene by different agents leads to a change in the energetics within the limits of 2–4 kcal mole^{-1} (see Table 7), from which it seems that epoxidating agents are close to one another in their electrophilic properties. Unfortunately, there are no results on the energetics of the reactions in the epoxidation of alkenes by acylperoxy-radicals and molybdenum complexes which activate oxygen. In these two instances the epoxidating agents evidently exhibit a smaller electrophilic capacity than per-acids or complexes of hydroperoxides with ions of metals of variable valency.

A study of the mechanisms of epoxidation of alkenes helps a deeper understanding of the processes in the hydroxylation of aromatic compounds, since in several instances it has been reliably shown that arene oxides are intermediate products in the formation of phenols[53,147,148]. In the oxonation of benzene, for example, benzene epoxide is isolated but rapidly isomerises at room temperature into phenol[53]. Microsomal oxidation of aromatic compounds showed that arene oxides can play a part in the metabolism of aromatic substrates[147,148]:



3,4-Epoxy[4-^{2}H]toluene has been synthesised[148] and is converted into 4-hydroxy[3-^{2}H]toluene, with displacement of the deuterium:



Without the intermediate formation of the epoxide this fact cannot be explained. The unity of the mechanisms of epoxidation of alkenes and hydroxylation of aromatic compounds is confirmed by the fact that most of the epoxidating agents are simultaneously hydroxylating agents for aromatic substrates. Per-acids effectively epoxidate alkenes and hydroxylate aromatic compounds to phenols[41-50], oxidases with mixed functions and their models are also active in these two reactions[53,145]. It is quite possible that acylperoxy-radicals are not only epoxidating agents but can also hydroxylate aromatic compounds[51,52].

The practical significance of epoxidation is particularly great: new technological processes have now been developed on the basis of epoxidations with hydroperoxides with participation of catalysts[149,150]. An investigation of catalysts which activate oxygen and the study of their mechanism of action will undoubtedly open new prospects of direct epoxidation of alkenes with molecular oxygen under mild conditions. This direction of investigation of epoxidation seems to us to be the most important now.

Methods of Chemical Synthesis of Aminoacid and Peptide Esters of Nucleosides, Nucleotides, and Oligonucleotides†

T.L.Tsilevich, A.A.Kraevskii, and B.P.Gottikh

The review gives a systematic account of the literature data for and the methods of synthesis of aminoacid esters of nucleosides, nucleotides, and oligonucleotides. The principle of the selection of protecting groups, the methods of activation of aminoacids, and the reaction conditions necessary for the synthesis of specific compounds are discussed.
A separate section is devoted to the discussion of methods for the preparation of peptide derivatives, in particular peptidyl-tRNA on the basis of natural aminoacyl-tRNA derivatives.
The bibliography includes 93 references.

CONTENTS

I. Introduction 822

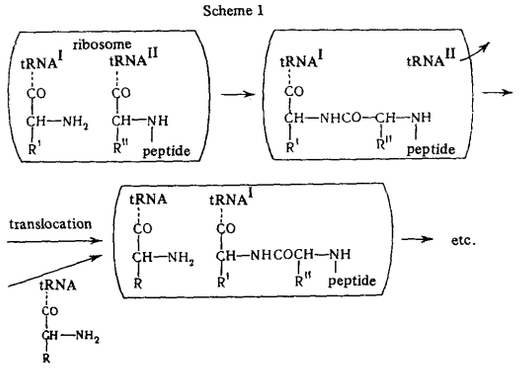
IV. Synthesis of acylaminoacyl and peptidyl derivatives of nucleosides, nucleotides, oligonucleotides, and tRNA 829

I. INTRODUCTION

Aminoacyl-tRNA and peptidyl-tRNA are always involved in the synthesis of each peptide bond during the matrix biosynthesis of protein on ribosomes. The peptide bond is formed as a result of electrophilic attack by the C-end of the peptide residue of peptidyl-tRNA on the amino-group of aminoacyl-tRNA (Scheme 1). At the present time this process can be achieved *in vitro* both in the form of a continuous cycle in which ribosomes act upon an endogenic or synthetic RNA-matrix, with formation of a polypeptide chain containing at least several peptide bonds [1,2], or stepwise with control of each succeeding stage in ribosomal activity [3].

Apart from the natural participants in the biosynthesis of a polypeptide on a ribosome (aminoacyl-tRNA and peptidyl-tRNA), aminoacid esters of nucleosides [4], nucleotides [5], and oligonucleotides [6] (as acceptors of the peptide, i.e. as analogues of aminoacyl-tRNA) and peptidyl-(or acylaminoacyl)oligonucleotides [7] (as donors of the peptides, i.e. analogues of peptidyl-tRNA) are employed successfully in single model steps involved in the formation of the peptide bond.

Scheme 1



The use of such compounds helped demonstrate the location of the peptidyl transferase centre of the bacterial ribosome on the 50 S-subunit [7] and also yielded some information about the substrate specificity of this centre [5-7,8].

Bearing in mind that the ribosomal synthesis of peptides and individual proteins in *in vitro* systems is widely used to investigate the functioning of the ribosome, it is of interest to develop methods for the chemical synthesis of aminoacyl- and peptidyl-tRNA.

Such methods would enable investigators to acquire all kinds of "Hybrid" variants in which the aminoacid of peptide [9] would be joined to tRNA which is non-specific in relation to them.

Despite the considerable advances achieved in the chemistry of natural products in the synthesis of amino-acid nucleotide derivatives and related compounds, the search for new methods of synthesis remains an urgent task. Derivatives of this kind will find application in the study of ribosomes and possibly of many enzymes involved in nucleotide synthesis. We believe that development of new methods of synthesis is a [necessary] stage on the path to non-enzymatic synthesis of aminoacyl-tRNA.

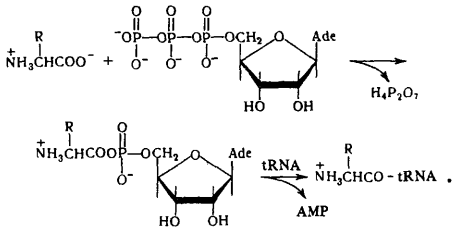
†List of abbreviations employed: tRNA = transfer ribonucleic acid, ATP = adenosine 5′-triphosphate, AMP or pA = adenosine 5′-monophosphate, pG = guanosine 5′-monophosphate, pC = cytidine 5′-monophosphate, pU = uridine 5′-monophosphate, pI = inosine 5′-monophosphate, A = adenosine, G = guanosine, C = cytidine, U = uridine, Ade = adenine, Gua = guanine, Cyt = cytosine; Ura = uracil, DMF = dimethylformamide, DMSO = dimethyl sulphoxide, THF = tetrahydrofuran, DCC = *NN′*-dicyclohexylcarbodi-imide, Z = benzyloxycarbonyl, BOC = t-butyloxycarbonyl, NPS = *o*-nitrophenylsulphenyl, Trit = trityl (triphenylmethyl), Mtrit = monomethoxytrityl, Ac = acetyl, F = formyl, and Im = imidazolyl. Residues of activating esters: OSu = hydroxysuccinimide, ONp = *p*-nitrophenyl.

The aminoacids and nucleic acid components have been named in accordance with the nomenclature adopted by IUPAC.

II. SYNTHESIS OF 3′(2′)-*O*-AMINOACYLNUCLEOSIDES

In protein-synthesising systems, aminoacyl-tRNA is formed from the aminoacid, tRNA, and ATP (Scheme 2) on special enzymes: aminoacyl-tRNA synthetases[2]. In the first stage of this enzymatic reaction, ATP is hydrolysed to AMP and inorganic pyrophosphate with coupled formation of aminoacyladenylate in which the aminoacid residue exhibits electrophilic properties. Next, this aminoacid residue is transferred to the 3′-hydroxyl of tRNA, which results in the synthesis of aminoacyl-tRNA with an ester linkage between the aminoacid residue and tRNA. The chemical nature of this linkage was established[10] in 1960 and it was shown to be a high-energy bond.

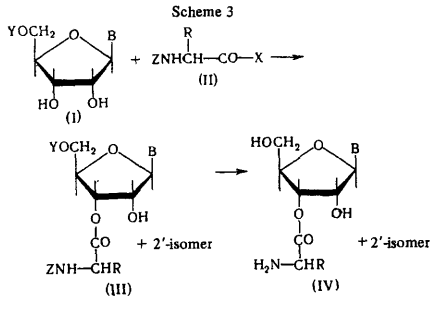
Scheme 2



In the development of approaches to the synthesis of aminoacylnucleosides and their more complex analogues, investigators have employed the principle of the biological process. In all cases the aminoacid residue was activated initially and then allowed to interact with the nucleoside component. Various methods of activation available in the chemistry of peptide synthesis were employed for this purpose. In terms of types of compounds and intermediate activated aminoacids, they can be classified as based on anhydrides, amides, and esters. The reactivities of the aminoacids or peptides activated in this way are different and moreover depend on reaction conditions to different extents. One must also bear in mind the possibility of the acylation of the amino-groups of the bases.

Numerous studies have been made on the synthesis of 3′(2′)-*O*-aminoacylnucleosides(IV).[11-18] The principle of the synthesis, which is common to all these investigations, consists in the reaction of 5′-*O*-protected nucleosides (I) and aminoacids (II) protected at the amino-groups and activated at the carboxyl (Scheme 3).

Scheme 3



where Y = triphenylmethyl or monomethoxytriphenylmethyl and Z = benzyloxycarbonyl, t-butyloxycarbonyl, or *O*-nitrophenylsulphenyl.

Since 5′-*O*-trityl or 5′-*O*-monomethoxytrityl-nucleosides(I) are insoluble in water, all the syntheses were performed in organic solvents such as pyridine, DMF, dioxan, and THF. It was shown that selective synthesis of aminoacid esters of nucleosides under these conditions without side reactions involving *N*-acylation of the bases is possible for adenosine, uridine, and guanosine. In the case of cytidine, the first step is the aminoacylation of the amino-group of the heterocyclic base, which necessitates a preliminary protection of this group.

Among the known methods for the activation of carboxy-groups of aminoacids for the synthesis of 3′(2′)-*O*-aminoacylnucleosides (IV), condensation with the aid of DCC,[4-7] symmetrical anhydrides of *N*-protected amino-acids[11,12], and imidazolides of *N*-protected[17] and *N*-protonated amino-acids[18] have been successfully employed. In the most fundamental study on the preparation of esters of all four main nucleosides (adenosine, guanosine, cytidine, and uridine) the synthesis was carried out by the method of symmetrical anhydrides[12]. As a result of all the stages in the synthesis, the yields of the phenylalanine esters of these nucleosides were respectively 36, 5.3, 19.3, and 33.6%.

3′-*O*-Aminoacid esters of 2′-deoxynucleosides (deoxyadenosine[12] and deoxythymidine[15]) were synthesised by a procedure similar to that used for the aminoacid esters of nucleosides, involving condensation with the aid of DCC or symmetrical anhydrides. The yields of these esters were close to those of ribonucleoside esters.

Among the *N*-protecting groups for aminoacids employed in the syntheses of 3′(2′)-aminoacylnucleosides, the benzyloxycarbonyl (Z),[11-16] t-butyloxycarbonyl (BOC),[4,19] and *o*-nitrophenylsulphenyl (NPS)[17,19] protecting groups have been used. It is not always a simple matter to make rigorous recommendations concerning the choice of a particular group when a new synthesis is planned. Each laboratory where aminoacylnucleosides were synthesised used a new set of protecting groups. However, we believe that the Z-protecting group, which can be eliminated by catalytic reduction without loss of purines, is most suitable for the preparative synthesis of aminoacyladenosine and aminoacylguanosine. Moreover, the comparatively low solubility of 5′-*O*-trityladenosine in the majority of the usual solvents, apart from pyridine and DMF, hinders the employment of the NCS group. For the aminoacid esters of uridine and cytosine, a wide-scale employment of BOC and NPS protecting groups is possible, their elimination being achieved by mild acid treatment—either with anhydrous trifluoroacetic acid or with ethereal hydrogen chloride—and does not lead to the cleavage of the ester linkage[19]. In one of the proposed methods of synthesis of 3′(2′)-*O*-aminoacyladenosines, the imidazolides of *N*-protonated aminoacids were employed[18]. This method does not require a preliminary introduction and subsequent elimination of a protecting group and is therefore suitable for microsyntheses, for example of radioactive esters. However, owing to the difficulty of dissolving the imidazolides of aminoacid trifluoroacetates, this procedure is fairly inconvenient for preparative syntheses.

Having described various methods for the synthesis of *O*-aminoacyl derivatives of nucleosides, a further important question must be discussed, namely their structures.

When nucleosides and nucleotides are aminoacylated, one may expect the formation of a mixture of the 2′- and 3′-isomers. The questions of the preferential aminoacylation of one of the hydroxy-groups of ribose and the migration of the aminoacyl residue between the 2′- and 3′-hydroxyls are not only of independent chemical interest but are also closely related to the determination of

the true position of the aminoacyl residue in aminoacyl-tRNA. It is important to know this in order to understand the mechanism of the formation of aminoacyl-tRNA on aminoacyl-tRNA synthetases [11] and the mechanism of the synthesis of the peptide bond on ribosomes [20].

In order to establish the location of the aminoacyl residue, a number of studies have been made both on synthetic aminoacyl derivatives of nucleosides and nucleotides [4,11,12,21-28] and on aminoacyladenosine isolated from aminoacyl-tRNA. [29,30] The conclusions arrived at proved to be extremely contradictory but considered together they demonstrate that, even if the synthetic methods for the preparation of *O*-aminoacyl-nucleosides and -nucleotides lead to a mixture of isomers, the 3′-isomer greatly predominates as the final product, although in some cases the aminoacylation reaction yielded both the pure 3′-isomer (Z-phenylalanyladenosine) [12] and the almost pure 2′-isomer (*O*-BOC-L-leucyladenosine) [4].

Apart from positive data on the aminoacylation of nucleosides under specified conditions (organic solvents, room temperature, several hours), negative results are also important. For example, it has been shown that the *p*-nitrophenyl, *N*-hydroxysuccinimide and 5-chloro-8-hydroxyquinolinyl esters of *N*-protected aminoacids do not react with the nucleoside hydroxyls, while *p*-nitrophenyl and *N*-hydroxysuccinimide esters react slowly with the amino-group of cytosine [31,32].

Concluding the discussion of the methods of aminoacylation of nucleosides, the following two conclusions may be reached:

1. For reaction with the hydroxyls of the riboside residue, the activation of the *N*-protected aminoacid must be fairly powerful; the imidazolides and anhydrides of aminoacids are capable of reacting with the hydroxyls (the synthesis using DCC probably also involves intermediate anhydrides).

2. Apart from the ribose hydroxyls, in anhydrous solvents only the NH_2 group of the cytosine residue reacts with the anhydrides, amides, (imidazolides), and esters of *N*-protected aminoacids. (Here and henceforth only the four main heterocyclic bases—adenine, guanine, uracil, and cytosine—are considered as part of the composition of nucleosides or nucleotides).

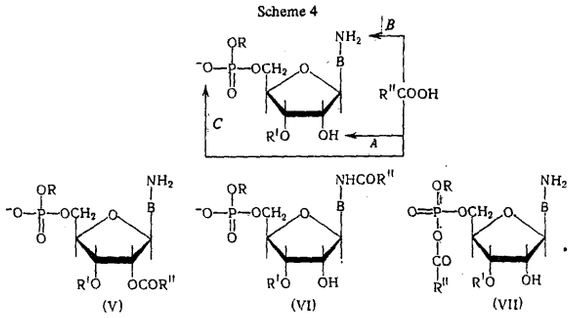
Like the synthesis of 3′(2′)-*O*-aminoacylnucleosides, the method using DCC makes it possible to introduce *N*-protected peptides into 5′-*O*-tritylnucleosides with formation of 3′(2′)-*O*-peptidylnucleosides [15]. Unfortunately, in this case, owing to the intrinsic features of the chosen scheme, appreciable racemisation of the *C*-terminal aminoacid of the peptide is bound to occur, and its extent remains unknown.

III. SYNTHESIS OF 3′(2′)-*O*-AMINOACID ESTERS, NUCLEOTIDES, NUCLEOSIDE 5′-DIPHOSPHATES AND 5′-TRIPHOSPHATES, AND OLIGONUCLEOTIDES

The difficulty of selective aminoacylation of ribose hydroxyls greatly increases on passing from nucleosides to nucleotides. Here the hydroxyls of the phosphate residue are added to the existing groups with nucleophilic properties—the ribose hydroxyls and the amino-groups as the bases. As a result, there is a possibility of the formation of three types of compounds on aminoacylation—esters (V), amides (VI), and mixed anhydrides (VII) (Scheme 4).

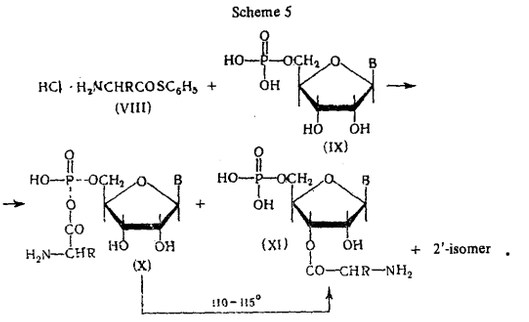
Indeed, the first attempts to extend the method of symmetrical or mixed anhydrides in anhydrous solvents or to carry out a condensation with the aid of DCC under the same conditions led exclusively to mixed anhydrides of type (VII). This showed that it is necessary to find conditions suitable for the aminoacylation of nucleotides in which the reactivity of the phosphate group is negligible.

Scheme 4



In 1958–1960 the first method was developed for the aminoacylation of nucleotides, consisting of the reaction of the thiophenol esters of aminoacid hydrochlorides (or hydrobromides) (VIII) with the nucleotides (IX) at 110 to 115°C in DMSO (Scheme 5). [33,34]

Scheme 5



The authors of the method showed that, when the reaction is carried out at 40°C, a mixture of the anhydride (X) and the ester (XI) is formed; when the temperature is raised to 110–115°C, the anhydride (X) rearranges to the ester (XI).

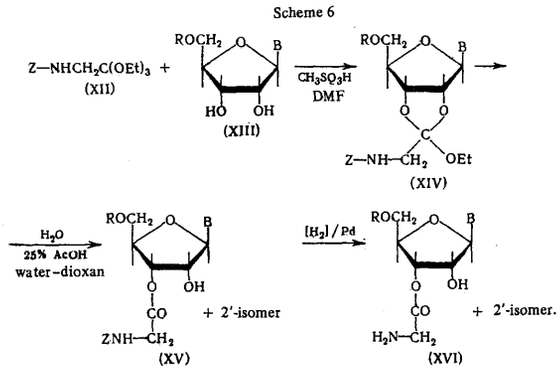
Aminoacid derivatives of (XI) were obtained by the thiophenol ester method in yields of 12–18% for pA esters, 9–10% for pU and pG esters, and 2–3% for 3′(2′)-*O*-aminoacyl-pC. In terms of aminoacids, the synthesis has been extended to valine, leucine, alanine, and methionine. It has been claimed that 3′(2′)-*O*-leucyladenosine 5′-triphosphate has also been obtained by this procedure [35], but the yield of this ester did not exceed 2% and convincing evidence for the structure of the compound obtained was not adduced.

The syntheses of 3′(2′)-*O*-aminoacylnucleotides by the thiophenol ester method, which are the first examples of the synthesis of such compounds, were in addition very important as models for the determination of the type of linkage between the aminoacids and tRNA. [10] It was found that the properties of the ester linkage between the aminoacid and the nucleotide in these compounds are very similar to the properties of the bond between the aminoacid and tRNA, which proves that the latter is also an ester linkage.

However, for preparative purposes the thiophenol ester method suffers from one major disadvantage in addition to low yields. Under the condensation conditions, the nucleotide is appreciably broken down, as a result of which at the end of the reaction the reaction medium contains a mixture of compounds from which the required substance is difficult to isolate. For example, when one of the syntheses by the thiophenol ester method was repeated in our laboratory, at least eight side products in appreciable amounts and several minor admixtures were obtained in addition to the 3′(2′)-*O*-aminoacyl nucleotides, but its yield was the same as that quoted in the literature.

From 1965, a series of studies were published in which a general method was proposed for the synthesis of glycine esters of nucleosides[22], nucleotides[36], and dinucleoside phosphates[37,38]. It is based on a selective reaction of the Z-glycine orthoester (XII) with the *cis*-hydroxy-groups of the nucleoside, nucleotide, or oligonucleotide (XIII). The resulting cyclic orthoester (XIV) hydrolyses to the corresponding Z-glycylnucleoside or its derivative (XV), from which the Z-protecting group is then removed, yielding 3′(2′)-*O*-glycylnucleoside (XVI) or its derivative (Scheme 6).

Scheme 6



(R = H, PO_3H_2, $P_3H_4O_9$, or nucleoside 3′-phosphate)

In the method described the transesterification involves exclusively the *cis*-glycol group: single hydroxyls do not react with the orthoester (XII). The yields of products are fairly high at all stages (60–80%). However, the method has two significant limitations. Firstly, hitherto it has been applicable exclusively to the synthesis of nucleoside or nucleotide esters of glycine, since the orthoesters of other L-α-aminoacids have not been described. Secondly, the conditions governing the interaction of the orthoester (XII) with the nucleoside (or the nucleotide) (XIII) and also the subsequent hydrolysis of the orthoester (XIV) are fairly severe (transesterification in DMF for 1–3 days in the presence of large amounts of methanesulphonic acid, hydrolysis in 25% acetic acid in aqueous dioxan over a period of several hours). Probably these disadvantages precluded the employment of the method for the synthesis of glycyl-tRNA.

Here mention should be made of yet another application of this method, in which the orthoester of benzyloxycarbonylglycine and $N_{(6)}$-dimethylaminomethyleneadenosine 5′-phosphate was used for condensation with $N_{(4)}$-dimethylaminomethylene-5′-*O*-tritylcytidine with the aid of DCC, which resulted in the formation of the corresponding orthoester of the nucleoside diphosphate; after hydrolysis and hydrogenolysis, it yielded CpA-Gly.[39] CpI-Gly was obtained by a similar procedure. This synthesis shows that the orthoester of the aminoacid can be used successfully to protect the *cis*-glycol group in the synthesis of oligonucleotides and thus gives rise to the possibility, in principle, of synthesising the glycine esters of oligonucleotides.

The first report of a series of studies in which a general method was proposed for the synthesis of aminoacid esters of pA, pU, pG, and pC using aminoacid imidazolides, was published in 1967. In the development of this method, the authors began with the following two conditions. Firstly, either water or a water–organic solvent mixture with water predominating was chosen as the condensation medium. The use of water made it possible to reduce sharply the nucleophilicity of the phosphate hydroxyls owing to their dissociation: $pK_a^I = 0.7–1$ and $pK_a^{II} = 5.9$ to 6.0 for pA, pU, pG, and pC. Moreover, it was found that, under these conditions, the reactivity of the amino-group of cytidylic acid, which does not react at all with activated aminoacids, is significantly reduced.

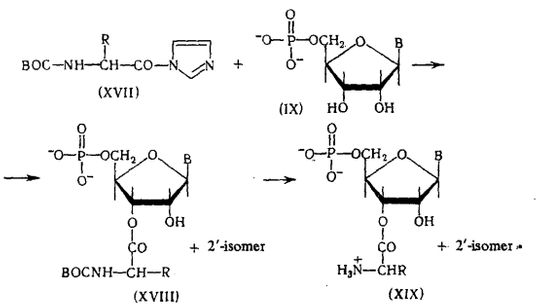
These characteristics of the behaviour of phosphates and amino-groups were known earlier. For example, whereas in acetylation with acetic anhydride in anhydrous solvents the *N*-acetyl derivative of cytidylic acid is always synthesised and the mixed anhydride of the nucleotide and acetic acid is formed[40,41], in an aqueous medium nucleotides or oligonucleotides are acetylated by acetic anhydride[42,43] exclusively at the ribose hydroxyls.

However, the hydroxyls of the riboside residues in nucleotides are also less nucleophilic in an aqueous medium than in anhydrous organic solvents. For example, in organic solvents the symmetrical anhydrides of *N*-protected aminoacids react vigorously with the hydroxyls of the riboside residues of nucleosides[11,12], while in an aqueous medium the same anhydrides altogether fail to react with nucleotides[19,44]. Furthermore, DCC has been widely used as the condensing agent for the synthesis of the ester linkages between *N*-protected aminoacids and nucleosides[45], while a water-soluble carbodi-imide {*N*′-cyclohexyl-*N*″-[β-(*N*-methylmorphilinium)ethyl]-carbodi-imide} is incapable of forming an ester linkage with the similar hydroxyls of tRNA.[46] Therefore successful condensation in water requires the choice of a powerful activating agent, which would make possible reaction with weak nucleophilic groups.

Imidazole was chosen as such activating agent. The imidazolides of *N*-protected aminoacids were used earlier to form the amide linkage in the synthesis of peptides[47,48] and also the ester linkage in depsipeptides[48]. The imidazolides of *N*-protected aminoacids were obtained by the reaction of *N*-protected aminoacids with *NN*′-carbonyldiimidazole by a standard method[47,48]. The condensation of BOC-alanylimidazolide with all the principal components of ribonucleic acids in a 5:1 water–DMF mixture at 20°C over a period of 3.5 h yielded 3′(2′)-*O*-BOC-alanylnucleotides in acceptable yields, ranging from 25 to 60% with respect to the initial nucleotide[19,49] (Scheme 7). In all cases the amides or anhydrides of type (VI) and (VII) (see p. 824) were completely absent from the reaction products. Virtually the only products were 3′(2′)-*O*-BOC-alanylnucleotides (XVIII, R = CH_3). Apart from them, the initial nucleotides (IX) and aminoacids were isolated from the reaction mixture. The yields of the esters with respect to the nucleotide which had reacted were 80–98%.

The BOC protecting group in (XVIII) was then removed by treatment with anhydrous trifluoroacetic acid (15 min at 0°C), which gave high yields of 3′(2′)-*O*-alanylnucleosides (XIX, R = CH_3). In the case of 3′(2′)-*O*-alanyladenosine 5′-phosphate, partial loss of the purine (sometimes to the extent of 15%) was observed.

Scheme 7

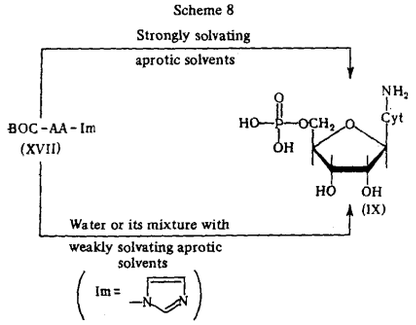


However, it was found that in this version the method is satisfactory only for alanine and glycine. The imidazolides of other BOC-aminoacids cannot be dissolved to a sufficient extent in a medium with 80% of water. Other readily removed *N*-protecting groups (for example Z, Trit, Mtrit, and NPS) only reduce further the solubility of aminoacid imidazolides. Therefore subsequently a large number of various solvents in 1 : 1 mixtures with water were investigated and it was found that the *O*-acylation of all nucleosides can be achieved in 1 : 1 mixtures of water with weakly solvating solvents such as acetonitrile, THF, and acetone. If the amount of strongly solvating aprotic solvent (DMF, DMSO, formamide, and pyridine) reached 30% of the total volume of the reaction medium, the reaction also involved the amino-group of pC (Scheme 8). [50] Thus esters involving the 3′(2′)-hydroxy groups of nucleotides with phenylalanine, lysine, aspartic acid, valine, proline, asparagine, etc. were obtained in such mixtures (the water–acetonitrile mixture was best) [19, 50, 51, 52].

One should note that 3′(2′)-*O*-aminoacylnucleotides of adenylic and uridylic acids are formed in high yields in anhydrous solvents, for example in a 5 : 1 DMSO–DMF mixture. However, this involves also the formation of a certain amount of impurities by side reactions, including 2′,3′-di-*O*-aminoacylnucleotides [19].

The imidazolide method also makes it possible to introduce into nucleotides fragments larger than aminoacids. The applicability of the method to all four nucleotides has been demonstrated for two peptides—BOC-Leu-Gly-Trp-OH and BOC-Ala-Ala-OH. [53] The BOC-protecting groups were removed by treatment with trifluoroacetic acid.

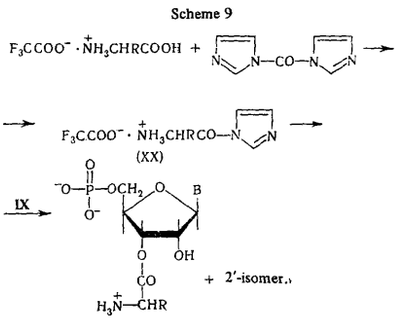
Scheme 8



It is noteworthy that the racemisation of the *C*-terminal aminoacid is not ruled out in this procedure.

The next version of the imidazolide method [19, 54, 55] involved the use of the imidazolides of *N*-protonated aminoacids (XX) in which the amino-group was protected by protonation. Aminoacid trifluoroacetates (or hydrochlorides) were converted into aminoacid trifluoroacetate imidazolides, which were then condensed with nucleotides in an aqueous medium at pH 7. Here the synthesis of 3′(2′)-*O*-aminoacylnucleotides (XIX) takes place virtually in only one stage (Scheme 9).

Scheme 9



It was found that the nucleotide (IX) reacts in different ways with the imidazolides of the *N*-protonated aminoacids (XX). Under the same conditions (for example with the same molar ratio of the reactants, dilution, time, and temperature), the imidazolides of valine and alanine trifluoroacetates reacted best with pA (yields 15–20%), less satisfactorily with pU and pG (yield 4–5%), and altogether failed to react with pC. In the last case all the pC was recovered unchanged from the reaction. (It is noteworthy that in the reaction with pA, pU, and pG the substances isolated contained, apart from the reaction products, mainly the initial nucleotides and only small amounts of side products.)

If the differences between the reactivities of nucleotides are represented by an inequality, the following formulation is possible:

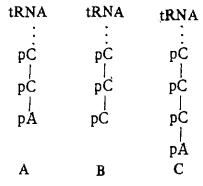
$$pA \gg pU = pG \qquad pC = 0.$$

A similar sequence was observed in the synthesis with thiophenol esters, where *N*-protonated aminoacids were also employed [33, 34]:

$$pA > pU = pG > pC.$$

These data are of interest from the standpoint of the aminoacylation of tRNA *in vivo*. Regardless of the type of tRNA or its origin [2], the end of tRNA carrying the aminoacid (the acceptor end) is known to contain always the same polynucleotide fragment —pCpCpA (A). Among cellular enzymes, there is a special enzyme which builds this fragment into tRNA, namely ATP(CTP)-tRNA nucleotidyltransferase [56]. In its usual form (A), tRNA is capable of being aminoacylated on the corresponding type of aminoacyl-tRNA-synthetase, forming aminoacyl-tRNA. However, if the terminal pA nucleotide is removed with the aid of ATP(CTP)-tRNA nucleotidyltransferase and pC is introduced instead, then the resulting molecule (B) is no longer capable of being aminoacylated. On the other hand, if one obtains with the aid of the same enzyme under

anomalous conditions a type of molecule, modified in relation to natural tRNA, in which one superfluous pC residue is present



(C), then the latter are capable of being aminoacylated on aminoacyl-tRNA synthetase [57] although they are larger than (A). This emphasises the role of the pA residue in enzymatic aminoacylation.

One must stress that the preferential chemical aminoacylation of pA has been demonstrated in both methods where the aminoacid is introduced into the synthesis with the amino-group protected by protonation, i.e. as under the natural conditions on the enzyme. On the basis of these data, one may suppose that the structure of pA makes it most reactive in relation to aminoacylation when two pC residues before the terminal pA in tRNA rule out the erroneous aminoacylation of the incomplete tRNA molecule.

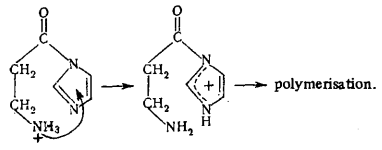
A study of the scope and limits of the applicability of the imidazolides of *N*-protonated aminoacids showed that anhydrous solvents may be used to synthesise *O*-aminoacyl-pA and *O*-aminoacyl-pU. In this case the yield increased to 30–35% for aminoacyl-pA and to 10% for aminoacyl-pU. However, in anhydrous solvents (DMSO, DMF, hexamethylphosphoramide), a number of impurities are formed together with aminoacylnucleotides; when pC is aminoacylated under these conditions, a mixture of side products is formed exclusively in a high yield [19].

Since it was not known from the available literature data whether the optical purity is retained in the synthesis of activated forms of *N*-protonated aminoacids and in their subsequent reaction, the stereospecificity of the synthesis of 3′(2′)-*O*-aminoacylnucleotides obtained with the aid of the imidazolides of *N*-protonated aminoacids was investigated. pA-Phe and pA-Val, obtained from pA, L-Phe, and L-Val, were hydrolysed with hydrochloric acid; next the aminoacids were purified and converted by reaction with salicylaldehyde into *N*-salicylidene derivatives. In the form of their copper complexes, such Schiff bases were investigated by circular dichroism (CD). The CD spectra of the copper complexes of the Schiff bases of salicylaldehyde and α-aminoacids show an anomalous rotation at 360–370 nm, the molecular ellipticity depending on the structure of the aminoacids and its sign on the configuration of the asymmetric carbon atom [58]. It was shown by this method that, within the limits of its sensitivity (up to 3%), the aminoacid is not racemised.

Further development of the aminoacylation method with the aid of the imidazolides of *N*-protonated aminoacids showed that the protection of the amino-groups by protonation is possible solely for α-aminoacids. If the amino-group is separated from the carboxy-groups by more than one carbon atom [for example in $NH_3(CH_2)_n$ COOH, $n > 1$ (2–10)], the formation of imidazolides involves a very rapid polymerisation:

$$\overset{+}{N}H_3(CH_2)_n\text{—CO—Im} \rightarrow \text{H—[NH}(CH_2)_n\text{CO]}_m\text{—OH}.$$

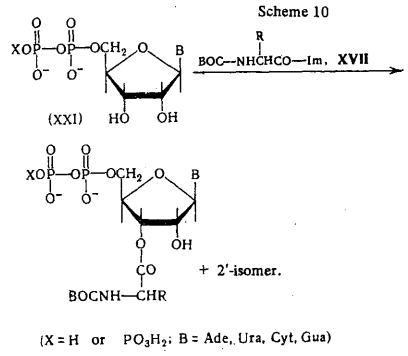
From the standpoint of the formal p*K* values for amino-groups, such a process appears unlikely. Thus, whereas the p*K* for the NH_2 group of glycine (the imidazolide of which is comparatively stable) is 9.6, for $n = 2$ and above the p*K* for the NH_2 group increases to 10 and above; therefore in this case the protection of the amino-group should be unreliable. A tentative explanation of this phenomenon involves a probable intramolecular proton transfer from the $\overset{+}{N}H_3$ group of the aminoacid imidazolide to N(3) of the imidazole ring. For α-aminoacids, such transfer is impossible due to steric hindrance, while for aminoacids with $n > 1$ it is theoretically (according to Stuart models) quite feasible. For example,



With α-aminoacids, the polymerisation reaction also occurs but its rate is very low. Probably here it involves an intermolecular mechanism, the dipeptide imidazolides formed undergoing a rapid further polymerisation, since their α-amino group is separated from the imidazole ring by more than four atoms. In an aqueous medium, the formation of oligopeptidylnucleotides takes place to a very small degree. In absolute solvents, dipeptidylnucleotides are formed in amounts up to 10%, their yield depending on the nature of the initial carbonyldi-imidazole.

A report of the use of the imidazolides of *N*-protected aminoacids for the synthesis of 3′(2′)-*O*-aminoacylnucleoside 5′-diphosphates and 5′-triphosphates (XXI) [59] under conditions resembling those in the aminoacylation of nucleotides (Scheme 10) was published in 1968.

Scheme 10

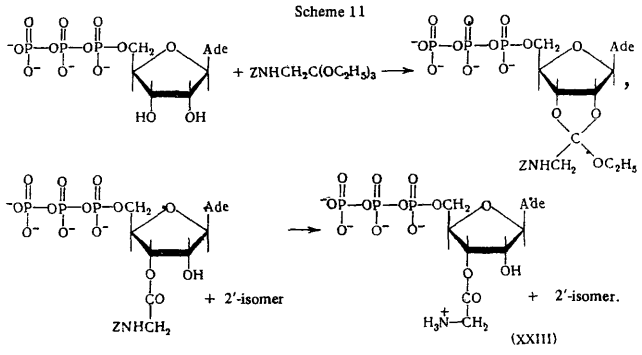


(X = H or PO_3H_2; B = Ade, Ura, Cyt, Gua)

3′(2′)-*O*-Peptidylnucleoside 5′-triphosphates were obtained similarly [60].

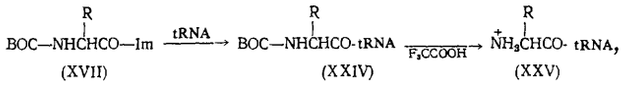
The applicability of the orthoester method in the synthesis of 3′(2′)-*O*-glycyl ATP (XXIII) was demonstrated in the same year [61] (Scheme 11).

Scheme 11



Investigators encountered the greatest difficulty in attempts to carry out a chemical aminoacylation of tRNA. tRNA is known to comprise 70–80 nucleoside units bound by (3′-5′)-phosphodiesters linkages. In such polymeric molecules (molecular weight about 25 000) there are on average 80 intermediate 2′-hydroxyls of the riboside residues, one 2′,3′-*cis*-diol group (to which the amino-acid in fact adds in enzymatic aminoacylation), a phosphomonoester group at the 5′- end of tRNA, and about 60 amino-groups of the bases. Under certain conditions, all these groups are capable of reacting with the activated aminoacid. Therefore it is not fortuitous that none of the methods, which are not distinguished by a high selectivity of the reaction with respect to the hydroxyls or by the mildness of the conditions of synthesis, yielded aminoacylated tRNA. The first and so far the only hope of developing a method for chemical aminoacylation arose in connection with the imidazolide method. A report concerning the interaction of the imidazolide of formylphenylalanine and BOC-glycine with a preparation of total tRNA from bakers' yeast was published in 1967.[62] The possibility, in principle, of the aminoacylation of tRNA in a mainly aqueous medium at 20°C over a period of several hours was demonstrated. Under the reaction conditions, compounds with ester type linkages and not anhydride or amide linkages are formed. Stable and high yields of aminoacyl-tRNA were achieved when the reaction was carried out in 1 M imidazole buffer. The BOC protecting group was removed from compound (XXIV) by treatment with anhydrous trifluoroacetic acid (Scheme 12).[63]

Scheme 12



(XVII) (XXIV) (XXV)

where R = H (glycine) or $C_6H_5CH_2$ (phenylalanine).

In the process of elimination of the protecting group from the molecule, the aminoacyl-tRNA lost their adaptor function, i.e. the capacity to combine specifically with information RNA on ribosomes and thus participate in the biosynthesis of protein. Therefore it was necessary to eliminate this severe stage of the synthesis. This was achieved by employing the imidazolides of *N*-protonated aminoacids, which react with tRNA forming aminoacyl-tRNA in one stage (Scheme 13).[64]

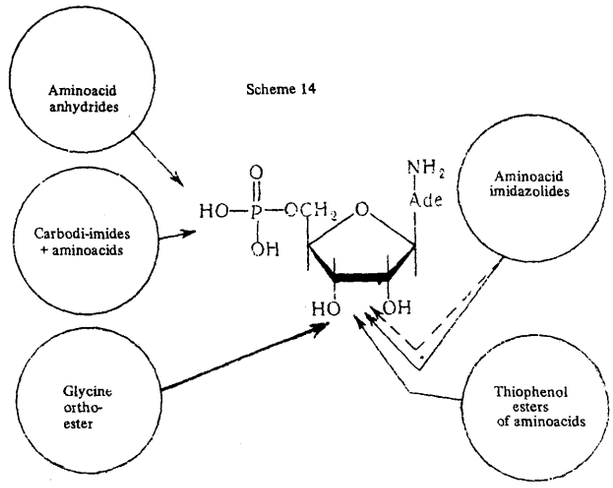
Scheme 13

(XXV)

This reaction took place under very mild conditions—in 1 M imidazole buffer in water at pH 7 and 4°C over a period of several hours. The aminoacyl-tRNA separations obtained in this way are being studied at present.

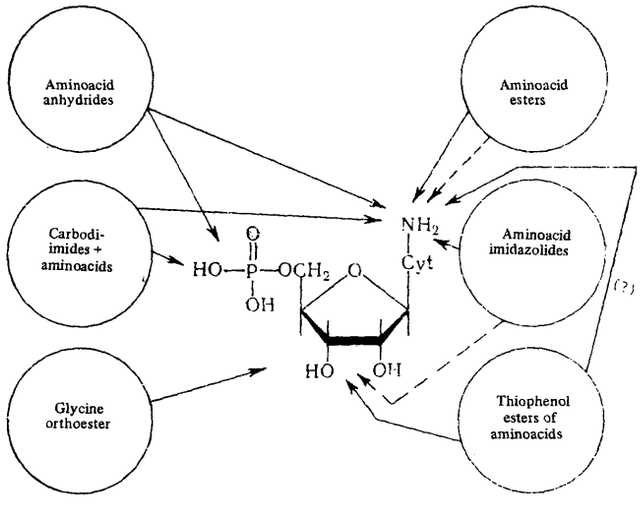
In conclusion, we shall attempt to summarise the data on the mode of the aminoacylation reaction as a function of the conditions and the reactivity of the activated aminoacid (Schemes 14 and 15). The nucleotides in the examples are adenylic acid (pA), the esters of which are widely employed in biochemistry, and cytidylic acid (pC) which has the most reactive amino-group. The properties of *p*-nitrophenyl and *N*-hydroxysuccinimide esters of *N*-protected aminoacids, which do not react either with the phosphate groups or with the ribose hydroxyls, should be considered separately. As regards their interaction with the amino-group of pC, the available data are contradictory: on the one hand, it is asserted that in water–organic solvent media such a reaction does not occur[65]; on the other hand, other investigators[32] did observe the reaction. Whatever the actual state of affairs, the unreacted nucleotides are isolated from the reaction mixture when the nucleotides are treated in a water–organic solvent medium at 20°C. These data served as a foundation for a large series of investigations which led to the discovery of methods for the selective acylation of the amino-group in aminoacylnucleotides and also aminoacyloligonucleotides (including aminoacyl-tRNA) (Section IV).

Scheme 14



The reactions designated by continuous arrows are carried out in organic solvents and those designated by broken arrows are carried out in solvents where water predominates.

Scheme 15



The reaction designated by continuous arrows are carried out in organic solvents and those designated by broken arrows are carried out in a medium where water predominates.

IV. SYNTHESIS OF ACYLAMINOACYL AND PEPTIDYL DERIVATIVES OF NUCLEOSIDES, NUCLEOTIDES, OLIGONUCLEOTIDES, AND tRNA

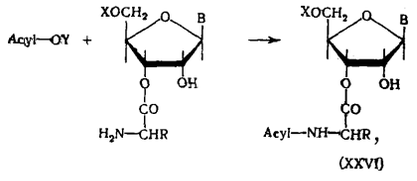
The last section of the review deals with the selective aminoacylation of aminoacyl derivatives of nucleosides, nucleotides, oligonucleotides, and tRNA. Above it was already stated that a rational approach to the search for aminoacylating agents of this type consists of the following steps: (a) the choice of activated forms of aminoacids the reactivity of which is insufficient for the interaction with ribose hydroxyls but permits condensation via the amino-group of the aminoacid residue of the aminoacylnucleoside and (b) the choice of conditions ruling out the reaction via the amino groups of the heterocyclic bases and via the phosphate groups.

Among the activated forms of carboxylic acids (including *N*-protected aminoacids), attention has been concentrated on activated esters. Activated esters such as the *p*-nitrophenyl and *N*-hydroxysuccinimide esters are most widely employed in peptide synthesis. These esters were in fact investigated in the first place as possible activating agents for aminoacylnucleosides and aminoacyl-tRNA.

Activated carboxylic acid esters (acetates, benzoates, etc.) were first allowed to interact with pC in anhydrous solvents, which gave high yields of $N_{(4)}$-acetyl-[66] or $N_{(4)}$-benzoyl-cytidine[67]. (As mentioned above, the amino-groups of adenine and guanine resist acylation by more reactive acylating agents such as anhydrides). However, it was shown in 1967[65] that in a mixture of water and an organic solvent the *N*-hydroxysuccinimide esters of acetic, formic, and other acids do not react with pC. On the basis of these data, a rational synthesis of acylaminoacyl-tRNA and peptidyl-tRNA was developed and is described below.

In 1967–1970 two reports were published[31,32] where it was shown that acyloxysuccinimides and acyl-*p*-nitrophenols can react in a water-organic solvent medium with the amino-group of pC at 24°C, and the yields of *N*-acylcytidylic acid can reach more than 35–45% in 24 h. In order to avoid this process, the authors suggested milder acylating agents, namely 5-chloro-8-hydroxyquinoline esters[32], which do not react with pC in a water–organic acid medium but do acylate the amino-group of the aminoacid residue. The acylation (aminoacylation) of the aminoacid esters of tRNA components or tRNA itself is shown in a general form in Scheme 16.

Scheme 16



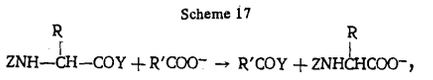
(XXVI)

where Y is the alcoholic component of the activated ester and X = H (nucleosides) or H_2O_3P (nucleotides or oligonucleotides).

A-(AcGly), A-(Val-Gly), A-(Lys-Gly), CpA-(AcGly), and CpA-(Lys-Gly) have been synthesised by activation with N-hydroxysuccinimide according to Scheme 16.[68,69]

Aminoacylation of aminoacylnucleosides and their analogues should not be carried out in acetate or formate buffer solutions. On the basis of the final results, one may suppose that in the presence of acetates of formates in organic solvents or in water there is an exchange of the activating group between the acylamino-acid and acetate or formate (Scheme 17).[70,71]

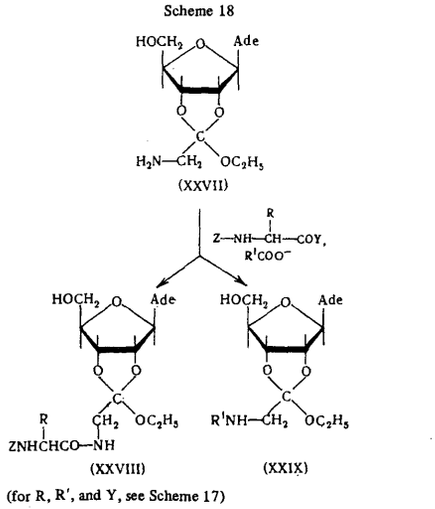
Scheme 17



where R = $CH(CH_3)_2$ or $(CH_2)_4NHZ$, Y = OSu or ONp, and R′ = H or CH_3.

The overall reaction, between the glycyladenosine orthoester (2′,3′-*O*-aminomethylethoxymethyleneadenosine) (XXVII) (Scheme 18) and the *p*-nitrophenyl or *N*-hydroxysuccinimide esters of benzyloxycarbonylvaline or $N_{(\alpha)}N_{(\epsilon)}$-dibenzyloxycarbonyl-lysine in the presence of acetate or formate in both anhydrous DMF or DMSO and in their mixtures with water results in the formation of a mixture of 2′,3′-*O*-(*N*-acyl)aminomethylethoxymethylene-adenosines. Apart from the main products, 2′,3′-*O*-(*N*-benzyloxycarbonylvalyl)- and 2′,3′-*O*-(*N*-dibenzyloxy-carbonyl-lysyl)-aminomethylethoxymethyleneadenosines (XXVIII), 2′,3′-*O*-(*N*-acetyl)- and 2′,3′-*O*-(*N*-formyl)-aminomethylethoxymethyleneadenosines (XXIX) were isolated from the reaction mixtures, their yield in a mixture of DMF and 2 M aqueous acetate buffers amounting to 39–42%.

Scheme 18



(for R, R′, and Y, see Scheme 17)

However, few examples of the synthesis of peptidyl-nucleosides or oligonucleotides have been described so far. The acylation of aminoacyl-tRNA has been investigated to an incomparably greater degree. Acylaminoacyl-tRNA is of particular interest for the investigation of the mechanism of the biosynthesis of protein on ribosomes. Acylaminoacyl-tRNA initiates the formation of the polypeptide chain in ribosomes (for example, FMet-tRNA in the protein synthesising system of *Escherichia coli*[72], AcPhe-tRNA in a model system with ribosomes and polyuridylic acid as the matrix[73], and in other cases).

FMet-tRNA was synthesised for the first time in 1964 by the reaction of *p*-nitrophenyl formate with Met-tRNA.[74] Acetic anhydride has been employed similarly[73] for the acylation of aminoacyl-tRNA, but this reaction does not

follow a single pathway: there is partial acylation of certain other parts of tRNA.[75,76] A convenient general method was developed in 1967–1970 using *N*-hydroxysuccinimide esters[75,76]. The condensation of *N*-hydroxysuccinimide esters of carboxylic acids with aminoacyl-tRNA is carried out in a mixture of water and organic solvents at 20°C and pH 5–6.

Among the numerous organic solvents employed, DMSO proved to be the most convenient. The yields of a number of acylaminoacyl-tRNA (FPhe-tRNA, AcPhe-tRNA, capryloyl-Phe-tRNA, lauroyl-Phe-tRNA, palmitoyl-Phe-tRNA, AcVal-tRNA, and AcMet-tRNA) were nearly qualitative and the yield of $N_{(\alpha)}N_{(\epsilon)}$-diAcLys-tRNA was about 90%. The acylaminoacyl-tRNA obtained did not lose their adaptor properties, i.e. in the presence of the corresponding codons they are capable of binding to ribosomes[76] and of initiating polypeptide synthesis[77,78].

The synthesis of oligopeptidyl-tRNA was first achieved using a water-soluble carbodi-imide[43,73]. Above it was already stated that this condensing agent in an aqueous medium is incapable of forming ester linkages between aminoacids and the hydroxyls of the ribose residues of tRNA; the amino-groups of the heterocyclic bases and the phosphate residues also fail to react under these conditions. This made it possible to develop with the aid of *N'*-cyclohexyl-*N''*-[β-(*N*-methylmorpholinium)ethyl] carbodi-imide (CME-carbodi-imide) the first method for the synthesis of formylpeptidyl-tRNA. Gly-Val-tRNA[46] and FGly-Gly-Val-tRNA[79] were obtained in this way. However, this method has not found wide application, possibly partly owing to the difficulty of removing the formyl protecting group without disrupting the structure of formylpeptidyl-tRNA.

A method employing *N*-hydroxysuccinimide esters, which nowadays makes it possible to synthesise derivatives up to deca- and trideca-peptidyl-tRNA, was developed more thoroughly. The synthesis of Gly-Phe-tRNA was achieved for the first time by the condensation of the *N*-hydroxysuccinimide ester of Mtrit-glycine (XXX) with Phe-tRNA to form Mtrit-Gly-Phe-tRNA (XXXI) followed by elimination of the protecting group (Scheme 19).

Scheme 19

$$\underset{\text{(XXX)}}{\text{MtritGlyOSu}} + \text{Phe-tRNA} \rightarrow \underset{\text{(XXXI)}}{\text{MtritGly-Phe-tRNA}} \rightarrow \underset{\text{(XXXII)}}{\text{Gly-Phe-tRNA}} .$$

The choice of the protecting group in (XXX) and of the conditions for the condensation of (XXX) with tRNA is not trivial, since the protecting group must be removed subsequently from compound (XXXI) under very mild conditions. Otherwise the labile peptidyl-tRNA bond might be easily broken. t-Butyloxycarbonyl (BOC), trityl (Trit), and monomethoxytrityl (Mtrit) *N*-protecting groups were tested for this purpose, but the attempts to eliminate the BOC and Trit protecting groups under mild conditions were unsuccessful. The Mtrit group was removed from (XXXI) with 5% dichloroacetic acid at 4°C in 5 min; the Gly-Phe-tRNA (XXXII) obtained as a result of such treatment possessed the adaptor function and was capable of functioning as a peptide donor on ribosomes[78].

Tests of this method of synthesis on a large group of dipeptidyl-tRNA showed[80] that the condensation of *N*-hydroxysuccinimide esters of Mtrit-aminoacids with aminoacyl-tRNA takes place just as satisfactorily at pH 5–8 in a 4 : 1 DMSO–aqueous buffer mixture. Among the organic solvents tested (DMSO, DMF, ethanol, THF, and ethyl acetate), DMSO was found to be most convenient. In this solvent the reaction takes place under the most homogeneous conditions and as a result has the highest yield.

The structure of the aminoacid in compound (XXX) (Scheme 19) also affected the yield of (XXXI). Whereas for the *N*-hydroxysuccinimide esters of Mtrit-glycine and Mtrit-alanine the yields were nearly quantitative[80–84], for the *N*-hydroxysuccinimide esters of Mtrit-phenylalanine and Mtrit-valine the yields did not exceed 55–85%.[80] This decrease of the yield can be accounted for by the steric hindrance of the aminoacid component to the synthesis of compound (XXX), since both the *N*-protecting group and the side group of the aminoacid are in this case fairly bulky. In order to overcome this difficulty, the NPS *N*-protecting group, which is readily removed from NPS-peptidyl-tRNA with a 0.4 M solution of sodium thiosulphate in water at 30°C in 2 h, was employed. Val-Gly-Phe-tRNA[85] and many other derivatives[86,87] were obtained in this way in nearly quantitative yields.

Peptidyl-tRNA with larger peptide residues were synthesised according to a scheme which is similar in principle but involves both stepwise and block procedures in the formation of the peptide chain[82]. The synthesis of penta-alanyl-tRNA (XXXV, Scheme 20) may be quoted as an example.

Scheme 20

$$\underset{\text{(XXXIII)}}{\text{Ala-tRNA}} \xrightarrow{\text{MtritAla-AlaOSu}} \text{Mtrit-(Ala)}_2\text{-tRNA} \rightarrow$$

$$\underset{\text{(XXXIV)}}{\text{(Ala)}_2\text{-tRNA}} \xrightarrow{\text{MtritAla-AlaOSu}} \text{Mtrit-(Ala)}_5\text{-tRNA} \rightarrow \underset{\text{(XXXV)}}{\text{(Ala)}_5\text{-tRNA}} .$$

According to this scheme, the pentapeptide (XXXV) is formed from 1 + 2 + 2 aminoacid units. The yield of (XXXIV) relative to (XXXIII) employed in the reaction was 93% and the yield of (XXXV) relative to (XXXIV) was 80%. Several tri- and tetra-peptides containing valine, phenylalanine, alanine, leucine, and methionine as aminoacids introduced by an enzymatic procedure and glycine or alanine introduced synthetically were obtained by a similar method[83]. $(Gly)_n$-Phe-tRNA, $(Gly)_n$-Val-tRNA, $(Ala)_n$-Phe-tRNA and $(Ala)_n$-Ala-tRNA, where $n = 4–12$, were also synthesised in 4–5 stages[84]. In the synthesis of such relatively large peptidyl-tRNA, the condensations were carried out at 30°C over a period of 12 h.

The use of the NPS-protecting group permitted the extension of this method to hydroxyl-containing aminoacids (serine, tyrosine, threonine[86], and phenylalanine[87]). In the case of these aminoacids, the condensation of NPS-peptidyl-OSu with aminoacyl-tRNA was carried out at 30°C in 2 h in a mixture of an aqueous buffer at pH 8.1 and DMSO in proportions of 1 : (1–4) by volume; there was then no need to protect the hydroxyls of serine, tyrosine, and threonine. The yields of the peptidyl-tRNA were nearly quantitative.

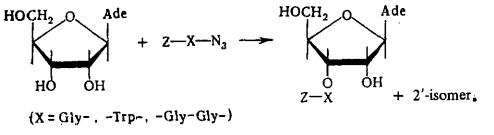
Activation of the formation of *N*-hydroxysuccinimide esters is now beginning to find application in the synthesis of special variants of acylaminoacyl-tRNA and peptidyl-tRNA for the solution of specific biochemical problems. For example, phenoxyacetyl-Phe-tRNA (forming part of the overall tRNA) was synthesised from the *N*-hydroxysuccinimide ester of phenoxyacetic acid and Phe-tRNA (forming part of the overall tRNA). This made it possible to develop a method for the isolation of the individual phenylalanyl-tRNA[88]. A similar method has been

developed also for Val-tRNA[89]. A series of acylamino-acyl-tRNA ($tRNA^{Phe}$, $tRNA^{Val}$), with a stable radical attached to the amino-group of the aminoacyl-tRNA, were obtained by the formation of the *N*-hydroxysuccinimido-ester of 2,2,5,5-tetramethylpyrroline-3-carboxylic acid N-oxide containing the stable radical[90,91]. The tertiary structures of the above compounds were investigated with the aid of ESR spectra.

A number of peptidyl-tRNA have been employed as substrates for the enzyme peptidyl-tRNA hydrolase[92], which hydrolyses selectively aminoacyl-tRNA.

In conclusion we must point out that the possibilities of the synthesis of the aminoacid esters of nucleosides, nucleotides, and polynucleotides have still been comparatively little investigated. This is illustrated by a recent study in which 3′(2′)-*O*-benzyloxycarbonylglycyl-, 3′(2′)-*O*-benzyloxycarbonyltryptophanyl- and 3′(2′)-*O*-benzyloxycarbonyldiglycyl-adenosines were obtained[93] (Scheme 21).

Scheme 21



(X = Gly-, -Trp-, -Gly-Gly-)

The synthesis was achieved by the condensation of benzyloxycarbonylaminoacid and benzyloxycarbonyldipeptide azides with adenosine in 3 : 1 aqueous dioxan at pH 9 and 8°C. This method is interesting from several points of view. Firstly, it does not require the protection of the 5′-hydroxyl. Secondly, it will probably make it possible to prevent the racemisation of the *C*-terminal aminoacid in peptides, provided that it can be extended to optically active peptides. Thirdly, the unusual behaviour of the azides of *N*-protected aminoacids and peptides in a medium containing mainly water at a high pH has been demonstrated in this case. It is known from experimental peptide chemistry that the use of aminoacid and peptide azides is possible solely for reactions involving the amino-group, since the hydroxyls of serine, threonine, and tyrosine do not react with azides under these conditions.

Recyclisation Reactions of Heterocyclic Compounds Involving Hydrazine and Its Substituted Derivatives

O.P.Shvaika and V.N.Artemov

In the review an attempt is made for the first time to give a systematic account of the available literature data for the recyclisation reactions of heterocyclic compounds under the influence of two-centre nucleophilic agents-hydrazine and its derivatives. The recyclisation reactions are classified taking into account the capacity of heterocycles to undergo such reactions as a function of the structure and the distribution in the heterocyclic compounds of reaction centres determining the mode of recyclisation. Particular attention has been devoted to heterocyclic rearrangements involving the hydrazine moiety of the molecule. The mechanisms of the recyclisation processes are discussed. The importance of these reactions in organic synthesis has been demonstrated.
The bibliography includes 255 references.

I. INTRODUCTION

The recyclisation reactions of heterocyclic compounds involve a rearrangement of the heterocyclic skeleton in which the ring heteroatom is replaced and the heterocyclic nucleus is contracted or expanded or undergoes isomerisation. From the theoretical point of view, these reactions are complex transformations involving ring opening and ring closure. Nevertheless for preparative purposes they are single-stage processes. In practice, recyclisation reactions can yield compounds which are frequently difficult to obtain in other ways and allow the transformation of one ring into another in complex molecules, giving rise thereby to a powerful and discriminating synthetic procedure. In their analytical aspect, as a method for the identification of heterocycles, such reactions have been used in biological chemistry.

Recyclisation reactions are a result of the interaction between heterocyclic compounds and other chemical agents or are a consequence of a rearrangement under the influence of temperature, light, or catalysis by acids or bases. Nucleophilic, electrophilic, and dipolar substances can serve as the chemical agents. A number of reviews have been devoted to the transformations of rings under the influence of dipolar agents[1]. The recyclisation reactions under the influence of electrophilic agents are characteristic only of specific heterocyclic systems. However, one frequently encounters ring rearrangements under the influence of nucleophilic agents. The latter must always be binucleophilic. This is because the ring rearrangement—its opening and reclosure—always requires the participation of two reaction centres in the heterocyclic molecule with which the binucleophilic agent interacts. The binucleophilic nature of the substance involved in recyclisation reactions can concern only one or two of its atoms. In the first case we are dealing with one-centre nucleophilic agents such as ammonia, 1,1-disubstituted hydrazines, primary amines, and sulphide and hydroxide ions. In the second case we have two-centre nucleophilic agents—hydrazine, hydroxylamine, and their derivatives. Ring rearrangements under the influence of one-centre nucleophilic agents usually reduce the replacement of the ring heteroatom via an intermediate ring opening step. The recyclisation reactions under the influence of two-centre nucleophilic agents, which involve nucleophilic additions and eliminations and obey the relations for the nucleophilic reactions of polar double bonds, are more complicated. For example, the two-centre nucleophilic agents involved in reactions with heterocycles containing polar double bonds (C=X, X=O, S, N, or P) have a higher reactivity than one-centre agents, due to the so-called α-effect[2,3]. Therefore they are also referred to as supernucleophilic agents[3]. This factor may affect significantly the rate-determining stages in the recyclisation reactions and can influence the mode of rearrangement. Moreover, two-centre nucleophilic agents can be involved in the ring rearrangement via one or both heteroatoms. Among supernucleophilic agents, the effect of hydrazine and its derivatives on heterocyclic systems has been particularly widely investigated, primarily in connection with the search for medicinal substances among heterocyclic derivatives of hydrazine.

Recyclisation reactions with hydrazines take place in both polar and non-polar solvents or in an excess of hydrazine in the temperature range 0 – 250°C.

One should bear in mind that the interaction of heterocycles with hydrazines can stop at the stage involving the substitution of labile groups in the heterocycle and the formation of ring-opening products or can be completed by a recyclisation the mode of which may be varied depending on structural factors and the reaction conditions. The expected reaction products may be isomeric. Hence one can understand the difficulties which frequently arise in the interpretation of the addition of hydrazines to heterocycles when a rearrangement of the latter is possible. This is reflected by frequent revisions of the mechanisms of such reactions initially suggested in the literature.

Despite this considerable number of published studies concerning the rearrangement of heterocycles, attempts to give a systematic account of the available data have not so

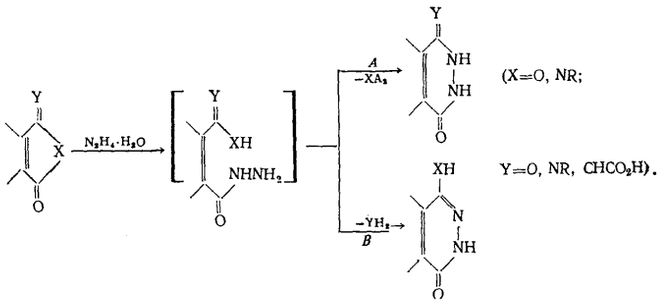
far been made. Although studies on the quantitative interpretation of recyclisation reactions have not been carried out, the available literature data based on synthetic investigations nevertheless permit definite generalisations and allow a systematic arrangement of the results. The present review includes the literature published in 1970 and partly in 1971.

II. RECYCLISATION REACTIONS OF HETEROCYCLES WITH TWO CENTRES IN THE RING SUSCEPTIBLE TO NUCLEOPHILIC ATTACK

1. FIVE-MEMBERED HETEROCYCLES

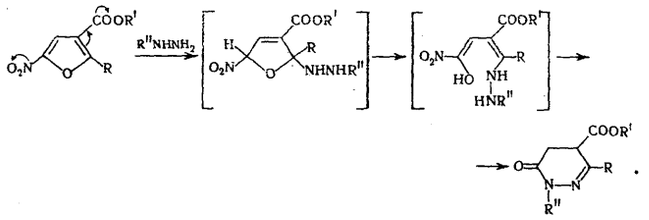
Five-Heterocycles with a Single Heteroatom

Recyclisation reactions with hydrazines are not typical for unsubstituted five-membered heterocycles with a single heteroatom in the ring. The presence of electron-accepting substituents in the ring renders both saturated and unsaturated and aromatic heterocyclic systems susceptible to nucleophilic attack. The rate of recyclisation is influenced by the electronic nature of the ring heteroatom (S > O ≫ NH), the presence of double bonds (cf. Feuer et al.[4]), and the position of activating substituents relative to the centres susceptible to attack. The outcome of the recyclisation reaction depends significantly on the positions of the centres susceptible to nucleophilic attack in the heterocycle. If they are in the α-positions relative to the ring heteroatom, then rearrangement to the pyridazine system usually takes place under the influence of hydrazines. Unsaturated five-membered heterocycles, including condensed heterocycles, containing exocyclic polar multiple bonds in both α-positions, react in this way:



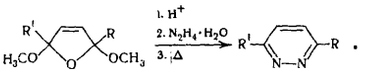
The mode of ring rearrangement—with elimination of the ring heteroatom (pathway *A*) or the α-substituent (pathway *B*)—depends on the nature of the substituent in the α-position. The occurrence of the reaction via both pathways has been noted only in the series of imino-oxoisoindolines [X = NH and Y = NR].[5] In other cases, where X = O or NR and Y = O or CHCOOH, the ring heteroatom is split off and a type *A* pyridazine structure is formed. The method of synthesis of type *A* cyclic hydrazides by the recyclisation of the corresponding cyclic anhydrides, which occurs when the reactants are simply mixed, is well known[6]. The anhydrides of 5,6-dihydro-*p*-dithi-in-2,3-dicarboxylic acids readily undergo a similar reaction, in particular with methyl- and *syn*-dimethyl-hydrazines[7,8]. Among reactions of this type, that of phthalidylideneacetic acid (X = O and Y = CHCOOH) with methylhydrazine to form oxophthalazineacetic acid has been used in the synthesis of physiologically active compounds[9].

Substituted furans, in which the $\alpha\alpha'$-centres susceptible to nucleophilic attack are activated by electron-accepting groups in the 2,4-positions of the ring, are recyclised under the influence of hydrazines into pyridazines[10], which resembles the ring rearrangement via pathway *B*:

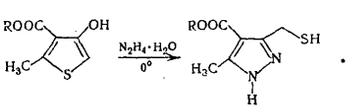


When R = H, the reaction takes place even at room temperature, but with R = alkyl it becomes strongly inhibited, which the authors believe is due to steric hindrance.

Recyclisation reactions with hydrazines in the furan series, where the $\alpha\alpha'$-centres of nucleophilic attack are activated saturated carbon atoms, have been described; they yield 3,6-substituted pyridazines which are otherwise difficult to obtain[11,12]:



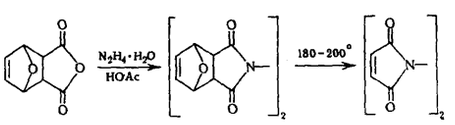
The thiophen ring with polar substituents in the $\beta\beta'$-positions is readily transformed into the pyrazole system[13]:



Nitrogen-containing heterocycles undergo recyclisation with somewhat greater difficulty than their oxa- and thia-analogues. Nevertheless a modification of the Gabriel synthesis (the Ing – Manske reaction)[14,16], based on the addition of hydrazines to cyclic dicarboxylic acid imides (X = NR and Y = O), is known.

The rearrangements into pyridazine systems of a number of pyrrole derivatives (X = NH), in which the $\alpha\alpha'$-centres of nucleophilic attack are activated by substituents in the β-position of the ring, are also known[17,18]. 3-Benzoyl-4-isonitrosopyrrole undergoes recyclisation into the bicyclic isoxazolopyridazine system under these conditions[19].

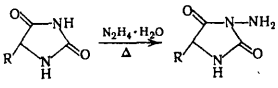
In the above reactions, the hydrazine molecule enters the ring via both nitrogen atoms, which results in the expansion of the initial ring. However, hydrazine can also enter the ring via only one nitrogen atom, which apparently depends to a considerable degree on the nature of the substituent in the hydrazine and on the medium. In acetic acid, cyclic dicarboxylic acid anhydrides give rise to the corresponding cyclic *N*-aminoimides on heating with hydrazine, phenylhydrazine, and acid hydrazides[20,21]:



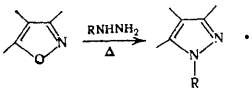
There are also literature data on the interconversion of cyclic hydrazides and imides[22–24]. Their formation depends sometimes on very slight changes in the structure of the anhydride[21,25]. Probably some of these reactions require further investigation.

Five-Membered Heterocycles with Two Heteroatoms

Five-membered heterocycles containing two nitrogen atoms in the ring (pyrazoles, imidazoles, and their hydrogenated analogues) do not undergo recyclisation reactions with hydrazines under the usual conditions. The presence of exocyclic heteroatoms appreciably activates such heterocycles. A simple preparative synthesis of aminohydantoins from hydantoins is known[26]:

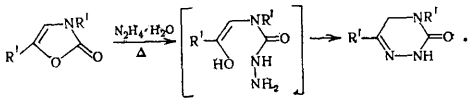


The capacity of five-membered heterocycles with two different heteroatoms to undergo recyclisation reactions depends on the relative positions of the heteroatoms in the ring. On heating with hydrazines, isoxazoles are converted into pyrazoles[27-30], but together with the latter other ring-transformation products were also detected:

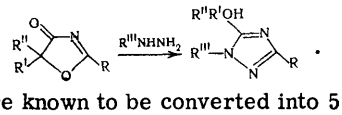


When the β-position of the isoxazole ring contains a powerful electron-accepting group (for example R″ = NO_2),[31-33] recyclisation with hydrazines, including even arylhydrazines, takes place particularly readily.

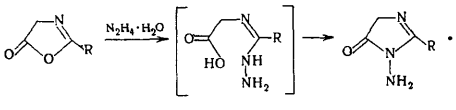
1,3-Oxazoles without activating substitutents are sensitive to hydrazinolysis but subsequent ring closure does not occur[34,35]. However, isomeric oxazolones and their derivatives containing an oxo group in addition to the multiple bond in the ring are capable of recyclisation when acted upon by hydrazines. Under these conditions, the outcome of the reaction depends significantly on the relative positions of the oxo-group and the ring multiple bond, which determine the mode of nucleophilic attack in the heterocyclic nucleus. On refluxing with hydrazine hydrate, 2-oxazolones yield triazinones[36]:



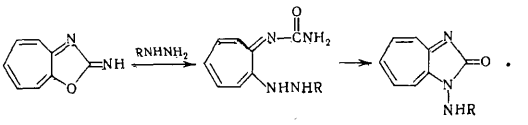
4-Oxazolones react vigorously with hydrazine forming triazoles[37]:



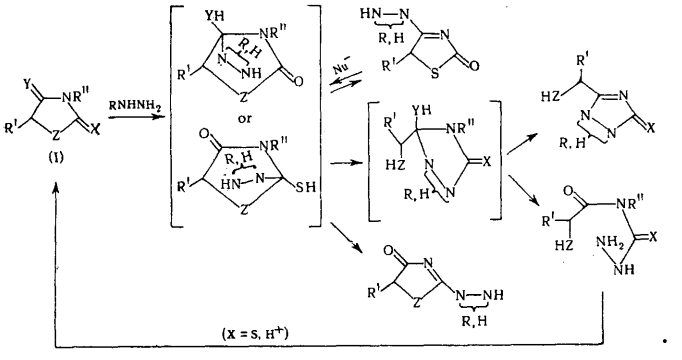
5-Oxazolones are known to be converted into 5-imidazolones when acted upon by hydrazine hydrate[38,39]. In contrast to both previous transformations, in this case hydrazine enters into the ring via only one heteroatom:



This difference in the behaviour of oxazolones probably depends on the activity of the nitrogen atoms of the hydrazine group in relation to the secondary electrophilic centre. If the latter is a carbonyl group, as in the first two cases, the interaction with the more basic β-nitrogen atom is preferable. On the other hand, the more strongly polarised α-atom interacts with the carboxy-group. The possibility of an interachange of the sites of attack in the heterocycle by the hydrazine molecule cannot be ruled out; this has been observed in the recyclisation of 2-imino-2*H*-cycloheptoxazole derivatives[40], in which *N*-amino-heterocycles are formed:



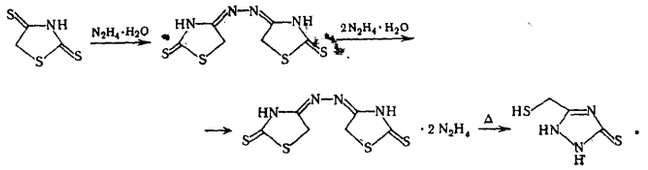
The oxa- and thia-zolidine rings activated by exocyclic heteroatoms in the 2- and 4-positions readily react with hydrazines with recyclisation into triazolones or triazolethiones[41]. Alkyl substituents in azolidinones (I, Z = S) inactivate them with respect to the addition of hydrazines, while *N*-arylated azolidinones are readily degraded[41,42]. The mode of reaction depends on the nature of the exocyclic heteroatoms in (I)[43,44] and also on the substituents in the hydrazine molecule, which determines the site of primary attack in the heterocycle by the hydrazine[45]. Depending on the reactivity of electrophilic centres in the azolidinone and the rate of removal of the XH_2 or YH_2 fragment, a hydrazonoazolidinone or triazolone (triazolethione) is formed. In isorhodanine (I, X = O, Y = Z = S), for example, the rate of elimination of hydrogen sulphide is much higher than the rate of reaction involving the 2-position in the ring and the rate of dissociation of the C — Z bond, which results in the formation of 4-hydrazinoazolidinone as the primary product. If conditions favouring such interaction are created (in the presence of nucleophilic agents), recyclisation into triazolone takes place. In rhodanines (I, X = Z = S, Y = O), the outcome of the reaction depends on the medium to an even greater extent[43,46]. 2-Hydrazinoazolidinones are formed only in an alcoholic medium, while in aqueous and alkaline media recyclisation into triazolethiones takes place:



When hydrazine acts upon rhodanines, it is possible to isolate an acyclic hydrazinolysis product, which is converted, depending on the conditions determining the competitive cyclisation reaction[47,48], into 2-hydrazinoazolidinone (in neutral solvents, on heating) or into a triazolethione (in alkaline media) or is reconverted into the initial rhodanine (in acid media). Recyclisation of substituted rhodanines into benzylidenehydrazonoazolidinones[49] and thiadiazine structures[46,50] has also been described.

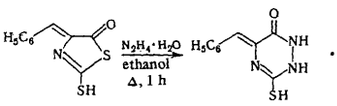
The recyclisation in the series of thiorhodanines has an unusual feature[43]. The presence of the reactive 4-thione group in the ring leads to the initial formation of an azine which reacts further with hydrazine in the presence of an

excess of the latter to form a saltlike adduct, which is converted on heating into a triazolethione:

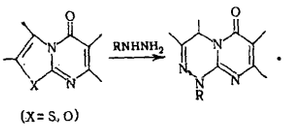


The recyclisation reaction of azolidine systems with hydrazine constitutes a convenient method for synthesising triazolones and triazolethiones with a mercapto-substituent in the side chain[51], which are difficult to obtain in other ways and which are of interest for pharmaceutical chemistry[52].

The conversion of benzylidenemercaptothiazolidine into mercaptobenzylidenetriazilone on refluxing with hydrazine, accompanied by ring expansion, has been described[53]:

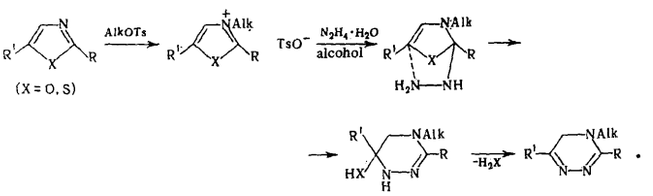


Condensed oxa- and thia-zole rings with a bridging nitrogen atom are converted in high yields into condensed cyclazine systems[54]. The reaction has a wide scope and in the pyrimidine series is of interest for the preparation of biologically active compounds:



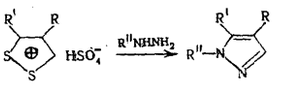
(X = S, O)

An effective method of increasing the reactivity of nitrogen-containing heterocycles in recyclisation reactions involves their conversion into a cationic state by the quaternisation of the ring nitrogen atom, as a result of which the electrophilic properties of the ring carbon atoms become much more pronounced. Even systems as stable as diaryloxazoles and diarylthiazoles are readily converted in this way into triazines[55,56]. Apart from this mechanism, which postulates a preliminary ring opening, yet another possibility of the rearrangement of cyclic cations via a quasi-1,2-addition of hydrazine to the ring has been considered[56]. In this case, after the initial attack by hydrazine on the azolium cation, the β-nitrogen atom interacts very rapidly with another electrophilic centre, which entails the dissociation of the C—X bridge bond:



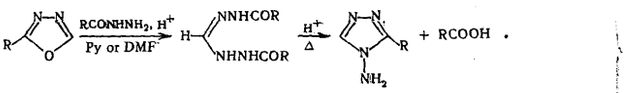
(X = O, S)

Dithiolium salts are very readily recyclised with replacement of the disulphide fragment in the ring by the hydrazine fragment[57,58]:

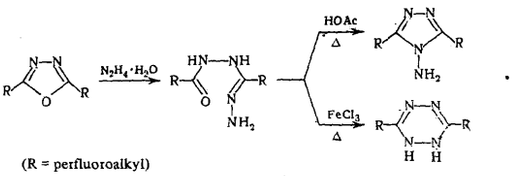


Five-Membered Heterocycles with Three Heteroatoms

Triazoles, particularly symmetrical triazoles such as pyrazoles, are extremely resistant to the action of hydrazine. Among five-membered heterocyclic compounds with three heteroatoms in the ring, derivatives of 1,3,4-oxadiazole have been most thoroughly investigated in recyclisation reactions under the influence of hydrazine. Despite their formal aromaticity, they are capable of exhibiting iminoether properties[59,60]. Alkyl- and monoaryl-substituted oxadiazoles are very sensitive to nucleophilic attack[61]. According to Eggert et al.,[62] they can be converted into aminotriazoles when acted upon by hydrazines:



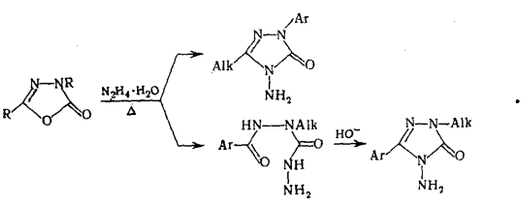
The recyclisation of perfluoroalkyl derivatives of oxadiazole under the influence of hydrazine hydrate has been described[63]. It takes place in two stages: ring hydrazinolysis (under mild conditions) and recyclisation into tetrazine or aminotriazole derivatives:



(R = perfluoroalkyl)

The substitution of both hydrogen atoms by aryl residues in the oxadiazole ring lowers its reactivity in recyclisation reactions with nucleophilic agents[61], probably in consequence of an increase of the overall aromaticity of the system[60]. Such oxadiazole derivatives do not react with hydrazines under the usual conditions. However, in the cationic state they are capable of recyclisation into *N*-aminotriazoles or tetrazines depending on the conditions[56]. In contrast to other azolium salts, the reaction is very sensitive to the nature of the anion.

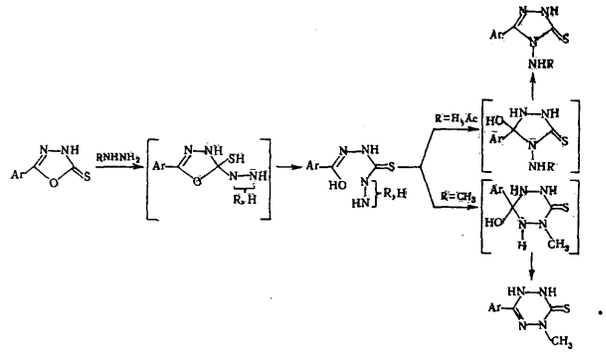
The presence in oxadiazoles of exocyclic oxo-, thio-, or amino-groups promotes the recyclisation reaction with hydrazine. On heating with stoichiometric amounts of hydrazine hydrate, oxadiazolones are converted into aminotriazolones[64]:



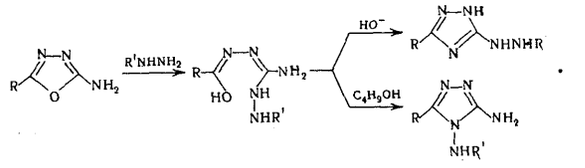
The reaction is very sensitive to the nature of the substituents and to the reactant ratio. On heating in an excess of hydrazine, oxadiazalones merely decompose into hydrazides[64-66].

On heating with hydrazines, oxadiazolethiones are capable of rearrangement via two pathways: into *N*-aminotriazolethiones (with unsubstituted hydrazines and acid

hydrazides) or into tetrazinethiones (with methylhydrazine)[67,68]. The reaction mechanism can be interpreted as follows:



The interaction of amino-oxadiazole derivatives with hydrazines has been widely investigated. It has been shown that, on heating with hydrazine, amino-oxadiazoles are capable of recyclising into *N*-aminotriazoles or hydrazinotriazoles[69]:



It has been stated[70,71] that the hydrazinolysis of the oxadiazole ring can involve both the $C_{(2)}-O$ and the $C_{(5)}-O$ bonds, depending on the nature of the substituent in the ring and in the amino-group. The reaction can lead directly to the triazole system[72-74] or, as usually happens when substituted hydrazines are employed, stops at the stage of the acyclic ring hydrazinolysis product. The subsequent mode of ring closure depends on the medium and the substituent[75-78].

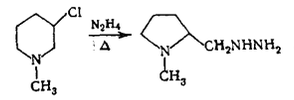
In the series of thiadiazoles, conversions into tetrazines under the influence of hydrazine are known[56]. Diarylthiadiazoles are inactive in relation to nucleophilic agents, but, like other azole systems, in a cationic state they are very vigorously recyclised into tetrazines under the influence of hydrazine.

2. SIX-MEMBERED HETEROCYCLES

The recyclisation reactions of six-membered heterocyclic compounds with two-centre nucleophilic agents take place not only with expansion or retention of the size of the initial ring, as in five-membered heterocycles, but can also involve ring contraction, although in the latter case hydrazine is involved via both its nitrogen atoms in the ring rearrangement. The outcome of the recyclisation is not determined solely by the positions of the centres of nucleophilic attack and the reactivity of the nitrogen atoms in the hydrazines. Energy factors can assume significant importance, for example in recyclisation reactions in the series of aromatic six-membered heterocycles with a single heteroatom, when there is a choice between the formation of a non-aromatic strained diazepine structure and an aromatic azole or pyridine system.

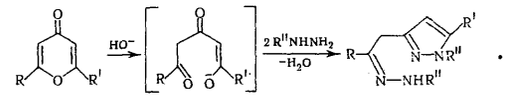
Six-Membered Heterocycles with a Single Heteroatom

Hydrogenated heterocycles—tetrahydro-γ-pyrone and tetrahydro-γ-thiapyrone and its sulphone as well as the thione analogues of both types of compound—do not react with amines but readily react with hydrazine, apparently owing to the α-effect[2], via the exocyclic heteroatom to form the corresponding hydrazones or azines[79], but there is no recyclisation. β-Chloro-*N*-methylpiperidine is known to undergo ring contraction when the halogen is replaced by hydrazine[80]:



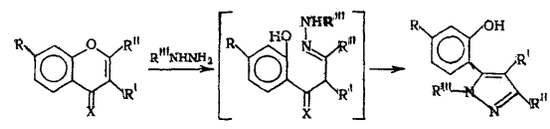
Unsaturated systems—pyrones, thiapyrones, and pyridones as well as their condensed analogues (chromones and coumarins)—readily enter into recyclisation reactions with two-centre nucleophilic agents. Although these compounds are represented in a non-ionic form, according to Schweizer[8] they can also assume the betaine-like structure of pyrylium, thiapyrylium, and pyridinium cations respectively, which show a very high tendency towards ring rearrangement, particularly on reaction with hydrazine. Although, depending on the nature of the heteroatom in the six-membered ring, the recyclisation reactions exhibit certain characteristic features, their outcome in the above series of compounds depends mainly on the position of the exocyclic heteroatoms, which determine the sites of nucleophilic attack in the ring. Therefore, fairly significant differences are observed between the recyclisation reactions of γ- and α-pyrones and their thio-analogues.

γ-Pyrone and its derivatives are readily converted under the influence of hydrazine or its substituted derivatives (on heating with the latter) into pyrazole derivatives[82-84]:



It is appropriate to mention here that the rearrangement of γ-pyrones under the influence of another two-centre nucleophilic agent (hydroxylamine) does not lead to isoxazoles, as might have been expected by analogy with the reaction quoted above, but to pyridone *N*-oxides[85]. Probably in this case the energy factors prevail over kinetic factors, since the isoxazole ring is less aromatic than the pyridine ring, while the pyrazole ring shows a high degree of aromaticity[81].

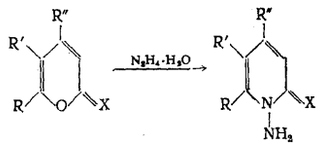
The condensed system—chromones and thiochromones—behave in recyclisation reactions with hydrazine analogously to γ-pyrones, being readily converted in the presence of catalytic amounts of alkali into *o*-hydroxyphenyl derivatives of pyrazoles in high yields[86-89]:



The authors believe[86,87] that the hydrazine molecule attacks primarily the C — O bond of chromone, since under analogous conditions the reactivity of both the carbonyl

and the thione group in these compounds in relation to nucleophilic agents is very low. When chromones and thiochromones react with arylhydrazines in a neutral or acid medium, only the corresponding hydrazones are formed; the latter are no longer capable of rearrangement under the influence of alkali[87].

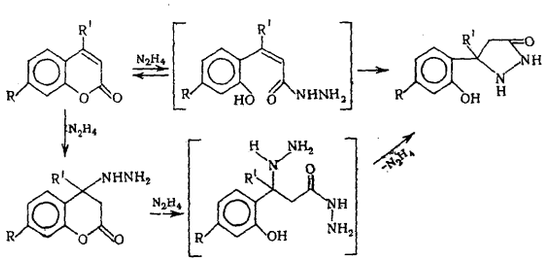
In contrast to γ-pyrones, α-pyrones and α-thiopyrones react with nucleophilic agents with much more difficulty. With hydrazine, they are converted fairly slowly into aminopyridones or aminopyridinethiones[90-92]:



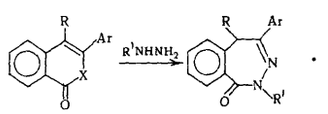
The rate of recyclisation of pyrones is appreciably influenced by the ring substituents. Aryl substituents in the hydrazine molecule hinder recyclisation. When α-thiopyrones react with phenylhydrazine, there is only a replacement of the sulphur atom by the hydrazine group[91,93]. It is noteworthy that the analogous reactions involving amines takes place with difficulty.

As stated above, condensed systems of the γ-pyrone type (chromones) are recyclised similarly to non-condensed analogues on reaction with hydrazine. In the series of α-pyrones, two condensed isomers are known—coumarins and isocoumarins—which differ very appreciably in the recyclisation reactions both from one another and from their monocyclic analogues. This is due to a different distribution of centres of nucleophilic attack which is greatly altered on condensation.

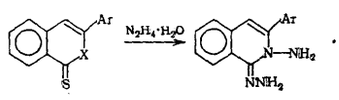
On heating with hydrazine hydrate, coumarins give low yields of pyrazoline derivatives[94]. The authors consider two alternative pathways for this reaction:



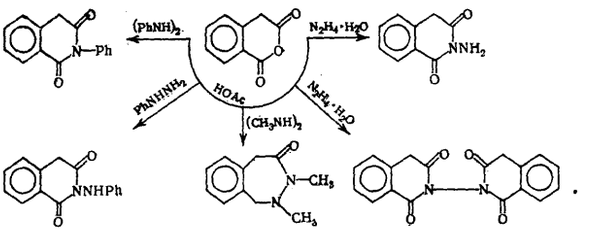
Under the influence of hydrazines, isocoumarins and isothiacoumarins recyclise into diazepinones[95-98], which are obtained in high yields:



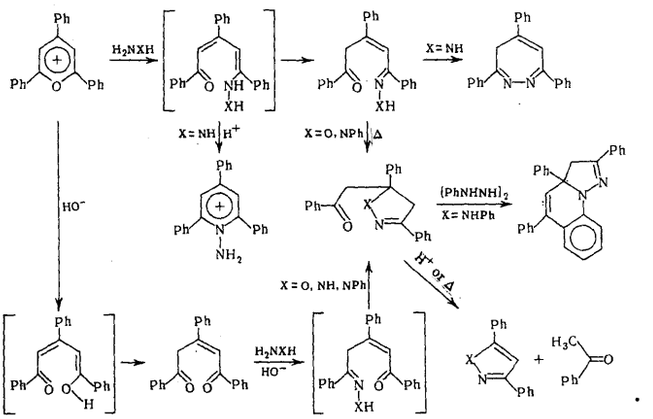
On the other hand, in the presence of an excess of hydrazine, thioisocoumarins and thioisothiacoumarins yield *N*-amino-1-hydrazonoisoquinolinones. In the case where equimolar amounts of the reactants are employed, there is merely a replacement of the thione sulphur atoms by the hydrazine group[99,100]:



In certain studies[101,102] the diazepine structure was attributed to the products of the recyclisation of homophthalic anhydride and its derivatives in the reaction with hydrazine. Subsequently these views were revised[103] and it was shown that, depending on the substituents in the hydrazine molecule, the reaction yields products with an imide structure and not azepines, which could not be detected either when the reaction was carried out in neutral solvents or in acetic acid. However, the formation of diazepine was noted when homophthalic anhydride reacted with *sym*-dimethylhydrazine:



The recyclisation reactions of pyrylium and pyridinium salts with hydrazines take place with exceptional ease. Their outcome is influenced significantly by the nature of the ring heteroatom and the substituents in both components, the nature of the anion, and also the medium. Depending on these factors, the cyclic cation can be transformed via three pathways: with ring expansion to the diazepine system, with ring contraction to the pyrazoline system and subsequent aromatisation by conversion into the pyrazole ring, and with replacement of the terminal heteroatom by the nitrogen atom and formation of *N*-aminopyridinium salts. The different types of recyclisation reactions in the series of pyrylium salts with two-centre nucleophilic agents (hydrazines and hydroxylamine) are most completely accounted for by Balaban's scheme[104-106] illustrated here for triphenylpyrylium perchlorate as an example:



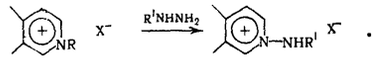
Triarylpyrylium salts are very readily converted into diazepines when acted upon by an excess of hydrazine hydrate[107]. However, pyrylium cations containing even only one methyl group in the α-position, for example 2-methyl-4,6-diphenyl- and 2,4,6-trimethyl-pyrylium perchlorates, are rapidly converted into pyrazoles in an excess of hydrazine hydrate in alcohol even at room temperature[108]. It has been shown[105,109,110] that the conversion into pyrazoles is more characteristic of pyrylium pseudobases. It is the main recyclisation pathway for pyrylium salts reacting with methylhydrazine[109] and benzenesulphonylhydrazine[110] and also for condensed pyrylium systems containing an activated γ-position and reacting with hydrazine hydrate (even in acetic acid)[111], but such

rearrangement takes place more slowly, usually on heating.

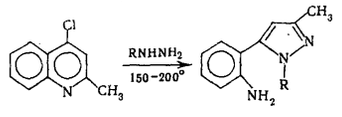
The interaction of hydrazine and its derivatives (phenylhydrazine and acid hydrazides) with pyrylium salts on heating in acetic acid leads to their recyclisation into *N*-aminopyridinium salts[105,112-116]. It has been shown[108,114] that 2,4,6-trimethylpyrylium perchlorate reacts with equimolar amounts of hydrazine hydrate even in an alcoholic medium with conversion into *N*-aminocollidinium perchlorate at a temperature as low as 0 – 5°C. Various substituted derivatives[117-119], including condensed pyrylium salts[108], were investigated in this reaction. The formation of two aromatic systems, pyrazole or pyridine, is probably due to competing processes which depend not only on the reactant ratio and the medium but also on the nature of the anion in the pyrylium salt[109], which affects the distribution of the electron density in the cyclic cation[120].

Balaban's scheme illustrated above includes also an interesting variant of the "pyrazole" recyclisation of arylpyrylium salts on heating in alcohol with an excess of phenylhydrazine, which involves a catalytic effect of the latter on the formation of the condensed pyrazoloquinoline system[121]. Under these conditions, neither hydrazine itself, nor hydroxylamine, nor various amines catalyse this reaction.

Recyclisation with hydrazines into *N*-aminopyridinium salts is characteristic of pyridinium salts[122-125]. It is also typical for their condensed analogues (isoquinolinium salts) and takes place under mild conditions in an alcohol – dioxan medium both with hydrazine and with its derivatives—phenylhydrazine, acid hydrazides, and thiosemicarbazide[125]:

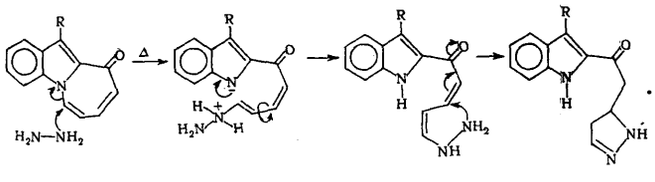


If the pyridinium ring contains an electronegative substituent in the 4-position, as in 4-chloroquinaldine, it is capable of recyclising into the pyrazole ring under the influence of hydrazine or phenylhydrazine[89]:



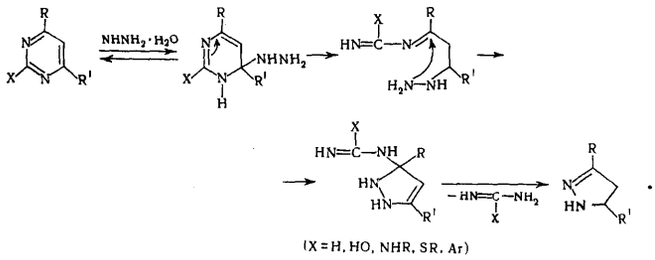
(R = H, Ph)

With increase of ring size, geometrical factors can assume a significant importance in recyclisation. For example, when indolinoazepinones react with hydrazine, the azepine ring is not converted into a six-membered derivative but into a five-membered derivative (pyrazoline)[126]:



Six-Membered Heterocycles with Two Heteroatoms in the Ring

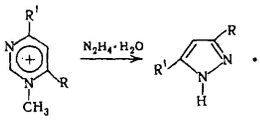
With increase of the number of heteroatoms in the ring, its electrophilic reactivity becomes enhanced and recyclisation reactions with hydrazine take place even without additional activating factors in the molecule. While unsubstituted or alkyl(aryl)-substituted pyridine bases do not undergo recyclisation under the usual conditions when acted upon by nucleophilic agents, pyrimidines are converted into the corresponding azole systems depending on the positions of the centres of nucleophilic attack. With sodium hydrazide[127], pyrimidines give high yields of pyrazole even at room temperature. With hydrazine hydrate and methylhydrazine, the conversion of pyrimidines into pyrazoles takes place under more severe conditions (130 – 200°C, 5 h).[128] It has been suggested that this process involves attack by the hydrazine molecule on the 4- or 6-position in the pyrimidine ring with its subsequent recyclisation, which is completed by aromatisation as a result of the elimination of a urea moiety[129]:



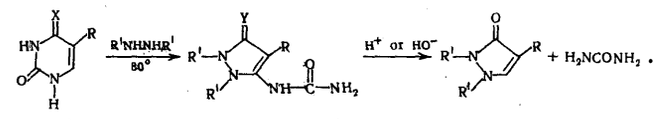
(X = H, HO, NHR, SR, Ar)

The recyclisation reactions of pyrimidines are extremely sensitive to the nature and position of the ring substituents. Electron-donating substituents (alkyl, aryl, OH, NH_2, SCH_3) in the 2- and 4-positions of the pyrimidine ring do not alter the above mode of reaction but polar groups appreciably accelerate it[130-134]. The electron-donating properties and the steric effect of the methyl group in the 4- or 6-position inhibit the reaction, which requires higher temperatures[129]. Depending on the substituents in the heterocyclic nucleus[131], in certain cases the interaction can lead only to hydrazinolysis products.

The quartenisation of one of the nitrogen atoms in the pyrimidine ring greatly facilitates the above recyclisation reaction without altering its outcome[129]:



In the series of certain biologically important pyrimidine derivatives, the following sequence of their reactivities in relation to hydrazine has been noted[133,134]: uracil, cytosine, thymine. In the reaction with methylhydrazines it is possible to isolate intermediates containing the ureide group, which is subsequently split off under the influence of alkali or acid[133]:

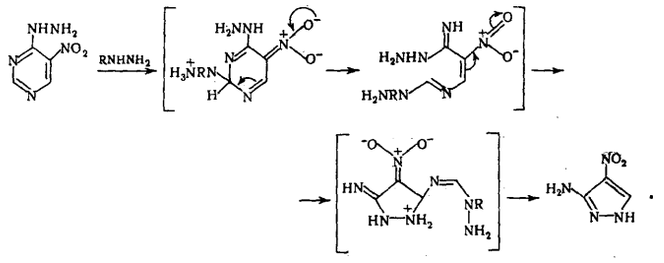


(R' = H, CH_3; X = O, NH; Y = O, NH, NNHR')

The hydrazinolysis of purines, pyrimidines, and the related nucleosides and nucleotides, which is completed by the formation of pyrazole systems, has been widely investigated in order to identify the pyrimidine bases[135-140].

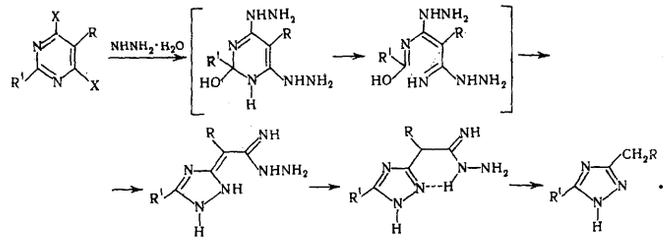
The introduction of powerful electron-accepting substituents into the pyrimidine ring has a significant influence on the distribution of electron density in the latter[130], with a corresponding alteration of the centres of nucleophilic attack, which influences the mode of the

recyclisation reaction. The effect of the nitro-group is particularly pronounced; when it is present in the 5-position, the recyclisation mechanism is significantly modified[141,142]. The reaction occurs even at room temperature in the presence of an excess of hydrazine (or methylhydrazine) and leads to aminopyrazoles. In contrast to the mechanism quoted above[129], nucleophilic attack by the hydrazine molecule on the 2- or 6-position in the heterocycle, its opening at the 2 — 3 bond, and recyclisation are suggested[142]. Under these conditions, the $N_{(3)}$ atom is converted into an exocyclic amino-group and the residue comprising the $N_{(1)} - C_{(2)}$ fragment of the pyrimidine ring is split off:



The above mechanism is confirmed by the reaction of methylhydrazine with 6-hydrazino-5-nitropyrimidine[142] which resulted in the isolation of the same pyrazole and not its methyl analogue.

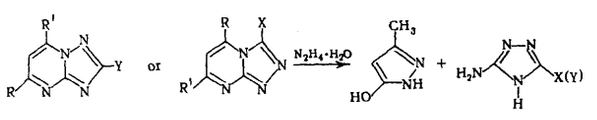
Pyrimidines containing polar substituents (OCH_3, $NHNH_2$) in the 4- and 6-positions are capable of transformation via a different pathway (with rearrangement of the ring to triazole)[128,143]. The reaction takes place with a 30 — 90% yield but under fairly severe conditions (210°C, 5 h):



According to van der Plas and Jongejan[143], the elimination of the carbazide residue is promoted by the formation of a hydrogen bond.

Special cases of the recyclisation of pyrimidines, occurring under severe conditions probably by ring fragmentation, are also known. Thus, on refluxing with hydrazine for 24 h, 4-hydroxy-6-methyl-2-phenylpyrimidine gives a 75% yield of 4-amino-3,5-diphenyl-1,2,4-triazole together with 3-methyl-5-pyrazolone.

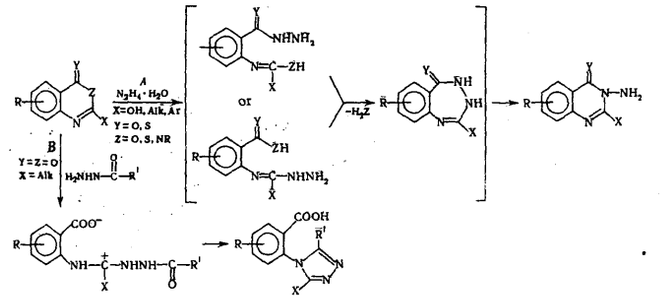
The recyclisation of condensed derivatives of pyrimidine containing the triazole ring, which is very resistant to the action of hydrazine, involves only the pyrimidine ring. It results in the formation of the corresponding pyrazoles and triazoles[144]:



(R = CH_3; R' = OH; X = SH, SAlk; Y = SAlk, NH_2, H)

The mode of reaction is not altered as the substituents (X, Y) in triazaindolizine are varied, but it is sensitive to substituents in the hydrazine molecule and the reaction does not occur when phenylhydrazine is employed.

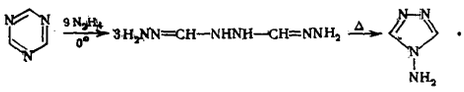
The recyclisation of the heterocyclic nucleus when hydrazine adds to quinazolones[145,146], benzoxazolones[147], and their thioanalogues[148], where a six-membered heterocyclic nucleus containing two different heteroatoms is condensed with the benzene ring, yields either *N*-aminoquinazolones (pathway *A*) or pyrazole derivatives (pathway *B*):



The rearrangement of benzoxazinones on reaction with benzoyl hydrazide, semicarbazide, and carbohydrazide leads to the formation of quinazolones. In the reaction with dicarboxylic acid dihydrazides, quinazolones are formed together with triazoles. In the reaction with formyl-, acetyl-, cyano-, nitro-, phenoxy-, and diaminoacetyl-hydrazines, triazoles are the main reaction products[147,149]. Owing to the higher nucleophilicity of the unsubstituted β-nitrogen atom compared with the α-nitrogen atom in the hydrazine fragment, the transformation of such systems via pathway *A* should occur, as suggested for benzothiazinethiones[148], via a diazepine structure with its subsequent rearrangement (of the type described below) to quinazoline, which is favoured by energy factors. If there is an acyl substituent at the β-nitrogen atom, the α-nitrogen atom, which has a steric advantage in this case, is probably involved directly in ring closure. However, such recyclisation is much slower. On the other hand, in the formation of triazoles by pathway *B*, the reactivity of the second competing carbonyl centre in the substituted hydrazine is decisive.

Six-Membered Heterocycles with Three and More Heteroatoms

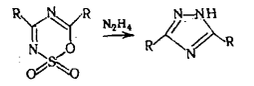
In the series of triazines, the mode of reaction with hydrazines is determined to a considerable degree by the nature of the substituents in both the ring and in the hydrazine derivatives employed. Unsubstituted *sym*-triazine in anhydrous hydrazine undergoes complex hydrazinolysis at a temperature as low as 0°C with subsequent recyclisation into *N*-aminotriazole:



Sym-disubstituted hydrazines do not react under these conditions, but semi- and thiosemi-carbazides and aminoguanidine yield respectively 3-hydroxy-, 3-mercapto-, and 3-amino-1,2,4-triazoles[150-153].

Among the recyclisation reactions of heterocycles containing several different heteroatoms in the ring, the

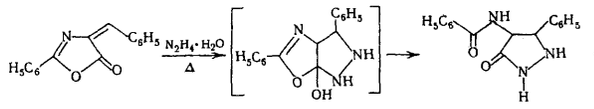
conversion of 4,6-diaryl-1,2,3,5-oxathiadiazine-2,2-dioxides into 3,5-diaryl-1,2,4-triazoles is known[154,155]:



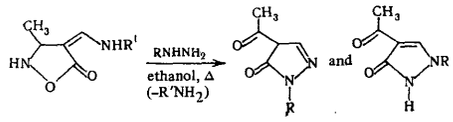
III. RECYCLISATION REACTIONS OF HETEROCYCLES WITH ONE CENTRE IN THE RING SUSCEPTIBLE TO NUCLEOPHILIC ATTACK

The recyclisation reactions of heterocyclic compounds containing one centre of nucleophilic attack in the ring and another in the side chain are nucleophilic addition or addition — elimination reactions involving polar multiple bonds. They can take place via two main mechanisms: with the intermediate formation of a bicyclic system and subsequent rupture of the initial ring or with preliminary ring opening after the initial addition of hydrazine and subsequent ring closure. The recyclisation pathway should be influenced mainly by steric factors and by the reactivity of the reaction centres. If the reaction centre in the ring adjoins the side chain but its reactivity is lower (or almost the same) than that of the electrophilic centre in the side chain, one may expect the reaction to proceed via an intermediate bicyclic compound. If, however, owing to the higher reactivity of the centre of nucleophilic attack, the primary addition of hydrazine begins at the heterocyclic nucleus, ring opening can take place initially†.

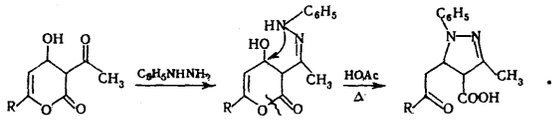
In the series of five-membered heterocyclic compounds, azlactones are probably recyclised[156] via the first pathway into the corresponding pyrazolidinones on heating with hydrazine:



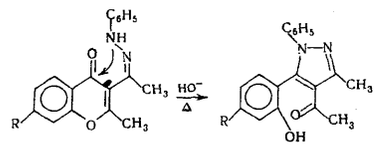
A similar reaction has been described also for isomeric isoxazolidinones[157]:



In the series of six-membered heterocycles such reactions are known for pyrone derivatives[158] on heating with substituted hydrazines in acetic acid:

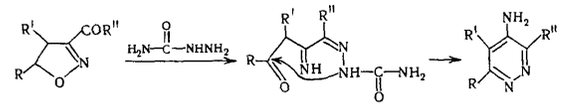


With condensed pyrone analogues (chromones), a similar conversion into pyrazole derivatives takes place under the influence of alkali[86]:



† See also Wamhoff and Korte[255].

The recyclisation of diacylfuroxans into dihydroxyiminopyrazolines[159] and of *N*-chloroethyl-2-oxazolidinone into N-aminoimidazolinone[160] under the influence of hydrazines has been described in the literature; the authors believe that it proceeds via the intermediate opening of the initial ring, which is a general characteristic of such systems[161]. The conversion of heterocycles in which the reaction centre in the ring does not adjoin the side chain with another electrophilic atom may proceed similarly and therefore the formation of a bicyclic system is hindered by steric factors. Under the influence of semicarbazide, acyl derivatives of isoxozole are converted into pyrazines[19,162]:



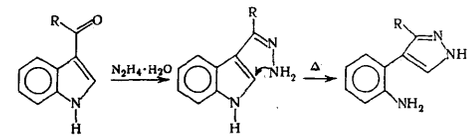
IV. RECYCLISATION REACTIONS DUE TO HETEROCYCLIC REARRANGEMENTS INVOLVING THE HYDRAZINE MOIETY IN THE MOLECULE

1. THE ALBERTI — BOULTON — KATRITZKY REARRANGEMENT OF HETERYLHYDRAZINES

The Alberti — Boulton — Katritzky rearrangement is a special case of recyclisation reactions involving one centre of nucleophilic attach in the ring. Heterocycles containing an electrophilic centre adjoining the ring heteroatom with a substituent containing the hydrazine group in the α-position relative to the electrophilic centre are capable of undergoing such rearrangement. The rearrangement consists in the formation of a new ring via an intramolecular interaction of the hydrazine nitrogen atom in the side chain with the electrophilic centre of the initial heterocycle.

Both a carbon atom and heteroatoms such as nitrogen (usually in the sp^2-hybridised state) can behave as an electrophilic centre in the heterocycle. The rearrangement takes place under the action of heat or bases.

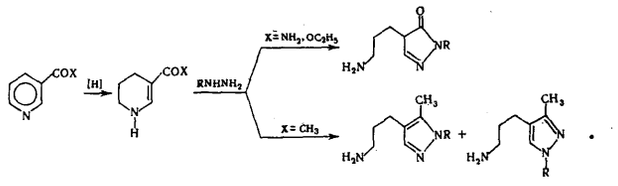
The rearrangement of heterocycles with a carbon atom as the electrophilic centre was discovered by the Italian chemist Alberti[163], who showed that, when 3-acetylindoles are heated in an alcoholic medium with hydrazine hydrate, a hydrazone is formed initially and then isomerises further to a pyrazole derivative[163,164]:



Alberti suggested that heterocyclic compounds containing the group $-X-C=C-CO-R$, where X is the heteroatom, undergo a similar recyclisation when acted upon by hydrazine[165]. The reaction was extended to other classes of heterocycles containing an acyl substituent in the β-position relative to the ring heteroatom—the thionaphthene, pyrrole, quinoline, and γ-pyrone series, from which pyrazole derivatives were obtained. However, whereas in the indole, γ-pyrone, and γ-chromone series the rearrangement takes place when the initial components are refluxed in alcohol, in the pyrrole and quinoline series heating to 160 — 165°C in an autoclave is required[166-168].

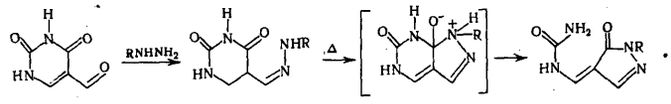
The conditions governing the rearrangement were examined in a series of studies by Alberti[169-174].

Recyclisation reactions of various heterocycles with an electrophilic centre in the α-position relative to the acyl group were described later. These reactions evidently proceed via the same rearrangement. They usually occur when the heterocycle is heated briefly with hydrazine but the intermediate hydrazone was not always identified. Thus pyrazole derivatives were obtained in high yields from acyltetrahydropyridines[175,176]:

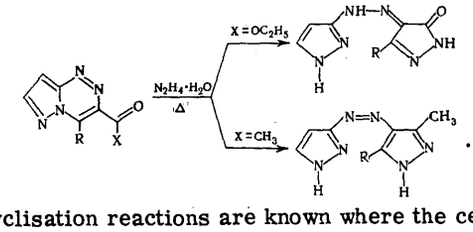


The reaction can serve as a convenient method of synthesising aminoalkylpyrazolones or pyrazoles from acylpyridines, which are readily reduced to tetrahydroderivatives.

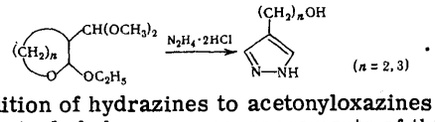
In the above examples, an olefinic carbon atom served as a centre of nucleophilic attack in the ring. In pyrimidine derivatives [177] the carbon atom of a carbonyl group functions as a centre of this type:



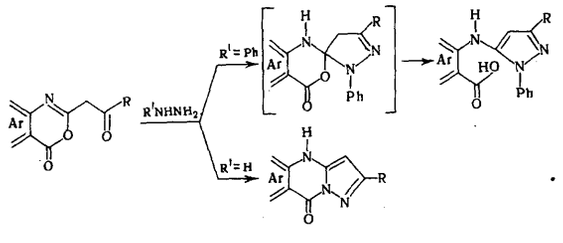
The rearrangement can occur also in systems such as pyrazolotriazines[178], where the electrophilic centre adjoins a bridging heteroatom:



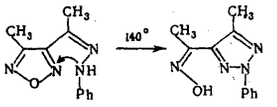
Recyclisation reactions are known where the centre of nucleophilic attack in the ring is a saturated carbon atom subjected to the influence of two electronegative heteroatoms—endocyclic and exocyclic. Here the rearrangement is based on a substitution reaction. Such rearrangements occur readily in both five-membered and six-membered heterocycles[82]:



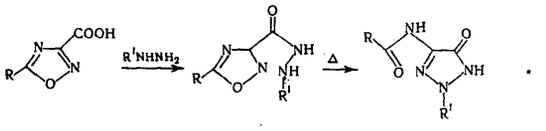
The addition of hydrazines to acetonyloxazines can probably be included among rearrangements of this kind [179,180]; the outcome of the reaction depends in this case on the presence of substituents in the hydrazine. Here isomerisation proceeds via an intermediate spirocompound:



Boulton and Katritsky[181-183], who studied heterocyclic isomerisations, greatly extended the scope of this rearrangement and established that a nitrogen atom can also serve as a centre of nucleophilic attack in the ring. For example, acetylfurazan phenylhydrazone can be converted into a 1,2,3-triazole system on heating in dimethyl sulphoxide in the presence of alkali[181]:



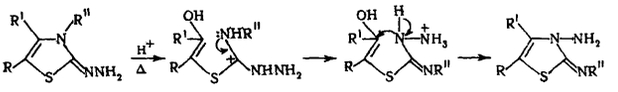
Hydrazine derivatives of 1,2,4-oxadiazoles[184] and isoxazoles[185,186] isomerise similarly into triazole. The rearrangement can proceed not only with participation of a base but also under the influence of heat. 1,2,4-Oxadiazole-3-carboxylic acid hydrazides isomerise almost quantitatively into a triazole system[187] not only under the influence of a base but also on heating above the melting point:



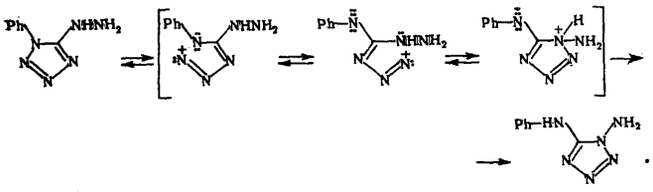
It is noteworthy that in almost all the cases considered a similar rearrangement occurs also in the presence of another two-centre nucleophilic agent—hydroxylamine.

2. THE DIMROTH REARRANGEMENT OF HYDRAZINE CONTAINING HETEROCYCLES

The Dimroth rearrangement consists in the interchange of endocyclic and exocyclic heteroatoms (together with their substituents) adjoining the same carbon atom in the ring and proceeds via ring opening in the presence of acids and bases or under the influence of heat. For example[188,189]:



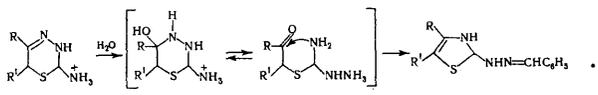
Dimroth observed the rearrangement in the series of 5-amino-1,2,3,4-tetrazoles[190,191]. Nirenburg and Postovskii described a similar thermal isomerisation and its mechanism for 5-hydrazino-1,2,3,4-tetrazoles[192]:



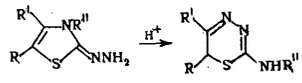
Hydroxylic solvents are the most suitable media for such isomerisations.

A number of general relations noted by Wahren[193] for the Dimroth rearrangement are also typical for heterocyclic hydrazines, although the latter have their own characteristic features. Here the rate of isomerisation should depend on the electron density at the α-carbon atom[194-197]. An important characteristic of the rearrangements of hydrazine-containing heterocycles is that the hydrazine group can participate in the isomerisation via the α- or β-nitrogen atom. Frequently the α-nitrogen atom is more reactive regardless of whether the β-atom is substituted or free. This may be due to the marked

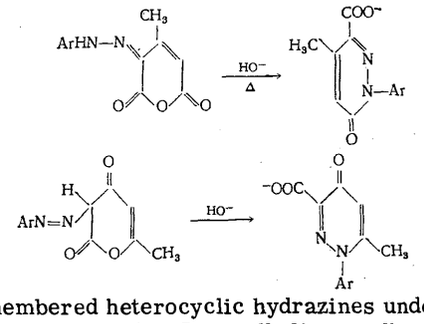
polarisation of the α-nitrogen atom of the hydrazine group in the acyclic intermediate owing to the influence of electronegative substituents. As a result, it can give up a proton to the polar medium, becoming more nucleophilic in the ring closure reaction. This variant corresponds to the Dimroth rearrangement where the ring sizes before and after isomerisation remain unchanged[193]. From the standpoint of the process mechanism, this limitation is hardly obligatory for hydrazine-containing compounds. When 3-amino-5,6-dimethyl-1,3,4-thiadiazine hydrochloride is heated with benzaldehyde in alcohol, ring contraction takes place with formation of the corresponding thiazolehydrazone[198]. Such recyclisation fits quite satisfactorily within the framework of the Dimroth rearrangement, which follows from the following mechanism:



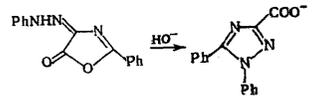
The example considered constitutes, as it were, a retrorearrangement in relation to the isomerisation of heterocyclic hydrazines accompanied by ring expansion where the hydrazine residue is involved via the β-nitrogen atom. Thus the conversion of thiazolehydrazones into thiadiazines is known[199]:



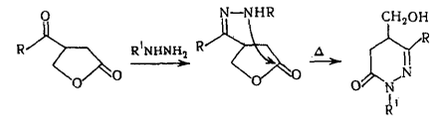
The isomerisation reactions of hydrazine-containing heterocycles accompanied by the exchange of complete fragments of the ring are probably related to the Dimroth rearrangement. For example, the isomerisation of hydrazinopyrones to pyridazones, which occurs on heating in an alkaline medium[200-202], constitutes an exchange of the exocyclic hydrazine group in the β-position in the ring with the endocyclic —CO—O fragment. Here the hydrazine group does not adjoin the ring heteroatom and it enters the ring via the β-nitrogen atom and not the α-atom:



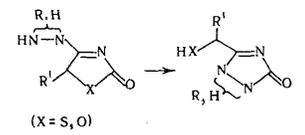
Five-membered heterocyclic hydrazines undergo a similar rearrangement. In an alkaline medium, 4-phenylhydrazono-2-phenyloxazolin-5-one undergoes a very rapid quantitative conversion even at room temperature into 3-carboxy-1,5-diphenyl-1*H*-1,2,4-triazole[203]:



Rearrangements involving the β-nitrogen atom of the hydrazine group are regarded in the literature also as transannular addition of hydrazine[126] which does not proceed via a preliminary hydrazinolysis of the initial ring. An attack on the ring electrophilic centre by the hydrazine β-nitrogen atom has been suggested; it takes place via a transannular mechanism and leads to an intermediate bicyclic system in a manner similar to the formation of bicyclic acetals and lactones in the pyran series. For this purpose, the hydrazine group or the substituents containing it should be located at a tetrahedral carbon atom in a ring in which there is a sterically accessible electrophilic centre. According to Wamhoff and Korte[204], the hydrazones of β-acyl-γ-lactones isomerise on heating to pyridazines via a transannular mechanism:



In heterocyclic compounds where the hydrazine group is attached to an unsaturated carbon atom, transannular rotation is difficult owing to the rigidity of the bond. However, it becomes possible under the influence of alkalis or other nucleophilic agents, which results in a tetrahedral configuration of the carbon atom linked to the hydrazine group. The isomerisation of hydrazinoazolidinones[41,205-207], occurring in alkaline media or on heating, has been interpreted in this way. Here a second molecule of the hydrazinoazolidinone behaves as the nucleophilic agent:



(X = S, O)

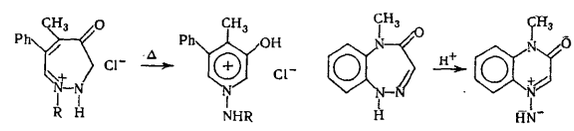
Various substituted hydrazinoazolidinones (derivatives acylated at the hydrazine group, hydrazones, and azines) undergo similar rearrangements.

The Dimroth rearrangement can occur in complex reactions and is accompanied by the cleavage of unstable components of the molecule. For example, the recyclisation of uloses into pyrazole derivatives in an acid medium, via the corresponding hydrazone, is known[208,209]. Alkaline cleavage of imidazophthalazine[5], the recyclisation of 2-hydrazino-4-hydrazono-3-phenylquinazoline into 2-anilino-4-hydrazinoquinazoline[210], etc.[113,211] also involve the Dimroth rearrangement.

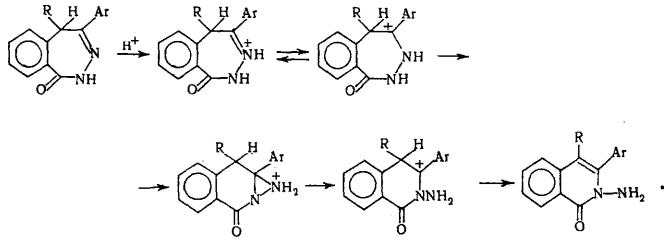
3. REARRANGEMENT OF CYCLAZINES

Heterocyclic compounds containing an endocyclic hydrazine group and multiple bonds are capable of a rearrangement involving the contraction of the ring by one nitrogen atom, which passes to an exocyclic *N*-imino- or *N*-amino-group. The rearrangement, which takes place under the influence of heat or an acid, is characteristic of various six-membered and seven-membered azine systems: diazines, triazines, tetrazines, and diazepines.

Depending on the structure of the initial cyclazine, the final isomerisation products may be betaines or cyclic *N*-amines. 4-Oxo-2,3-dihydro-1,2-diazepines[212] or 4-oxo-1*H*-4,5-dihydro-1,2,5-benzotriazepines rearrange to betaines:

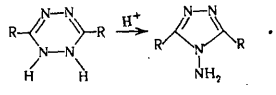


If there is a possibility that the charge in the betaine structure may be compensated by the β-elimination of a proton, the final product is a cyclic *N*-amine[98]:

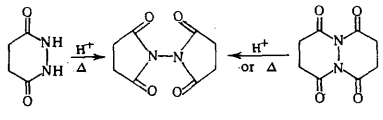


The isomerisation of cyclazines may be regarded as an endocyclic sextet rearrangement. The above scheme shows that its mechanism involves[98-100,141,212,213] an endocyclic interaction between the nitrogen atom of the hydrazine moiety and an activated unsaturated carbon atom or a carbonium centre with formation of an intermediate three-membered condensed ring, the opening of which results in the liberation of the amino group. The role of the acid as a catalyst reduces to the protonation of the heteroatom adjoining the sp^2-hybridised carbon atom. However, one should note that, under certain conditions, one cannot rule out the possibility that such a rearrangement can also proceed via a preliminary hydrolytic ring opening at the azomethine linkage with subsequent ring closure under acid conditions, as rule via the α-nitrogen atom of the hydrazine group.

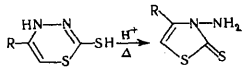
The cyclic *N*-amine rearrangement is very characteristic of tetrazines, which are readily converted in an acid medium into *N*-aminotriazoles[214,215]:



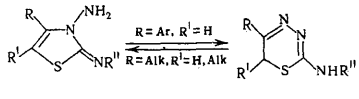
The isomerisation of cyclic hydrazides[216,217], including hydrazides condensed with ring systems[216,218] and their thioanalogues[219], allows a ready synthesis of *NN'*-bis-succinimides, *N*-aminothiazolethiones, and *N*-aminohydantoins:



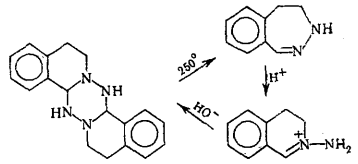
Cyclic thiohydrazides and thiadiazinethiols[219], for which a Dimroth rearrangement might have been expected in an acid medium, undergo preferentially the cyclic *N*-amine isomerisation:



Depending on the structure of the compound, it is possible to achieve the reverse transition from cyclic *N*-amines to cyclazines. Such interconversion has been described for the thiadiazine — *N*-aminothiazole series[199] and others[22,23]:

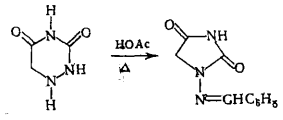


The cyclic *N*-amine rearrangement and its retrovariant were observed by Schmitz and Ohme[220].

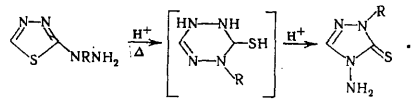


One may suppose that the retrorearrangement also proceeds via the intermediate formation of a three-membered condensed ring.

The cyclic *N*-amine rearrangement can occur in combination with other reactions. On heating with aldehydes, usually in the presence of acetic acid, cyclic hydrazides are converted directly into the corresponding cyclic *N*-arylideneamines[217]:



Complex recyclisation reactions may be also accompanied by the above type of isomerisation, as happens, for example, in the conversion of hydrazinothiadiazoles into *N*-aminotriazolethiones[221]:

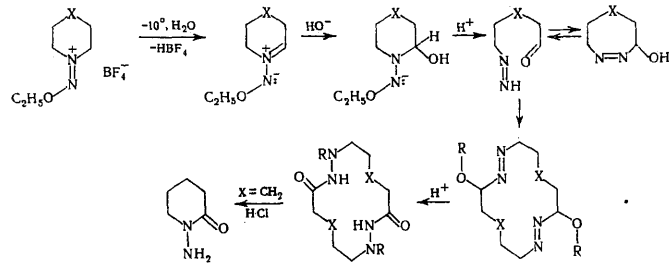


On reaction with hydrazines, certain isochromones recyclise directly into isoquinolinones[98].

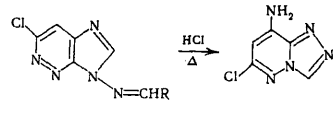
V. OTHER REARRANGEMENTS AND RECYCLISATIONS OF HYDRAZINE-CONTAINING HETEROCYCLES

The reactions of heterocycles involving hydrazines which are described in the literature can be usefully examined separately owing to their characteristic features. Here we shall be concerned also with the recyclisation reactions of small rings under the influence of hydrazines.

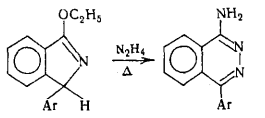
In an alkaline medium under very mild conditions, substituted iminopiperidinium and iminomorpholinium salts undergo a dimerisation recyclisation with formation of a macroring, which in the case of piperidinium recontracts under the influence of acids into the aminopiperidine system[222,223]:



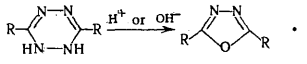
The recyclisation of imidazopyridazine derivatives into triazolopyridazines, which occurs on heating in an acid medium, was described recently[224]:



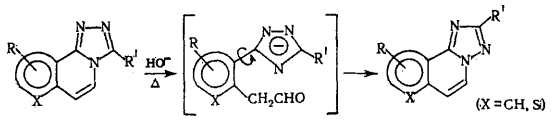
The reaction of 1*H*,1-aryl-3-ethoxyisoindolinenes with hydrazine, with recyclisation into benzopyridazines, is somewhat unusual:



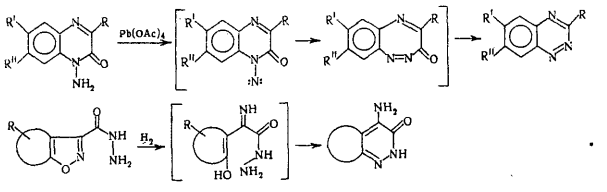
Certain substituted tetrazines are converted in acid or alcoholic alkaline media into oxadiazoles and not into *N*-aminotriazoles. The reaction is greatly influenced by the nature of the ring substituent[56,226-228]:



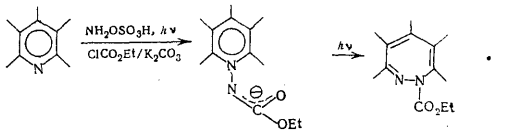
Thermal recyclisation of tetrazines into pyrazoles is also known[229]. On heating in alkaline media, triazoloisoquinolines and triazolothienopyridines undergo an isomerisation involving the hydrazine moiety of the triazole ring[230]:



In many cases recyclisation reactions involving the hydrazine group in the molecule can occur as a result of oxidation — reduction processes[231-233]:

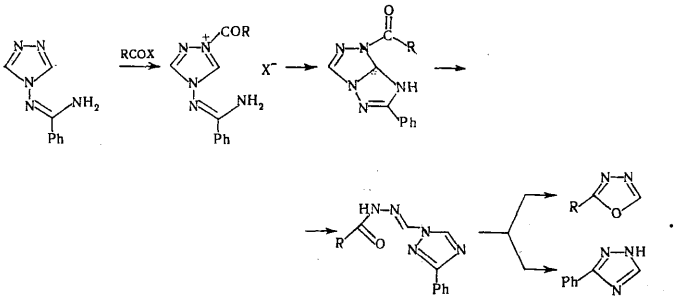


Photochemical recyclisation reactions of heterocycles involving the hydrazine moiety are known for a series of five-membered[234] and six-membered heterocycles, in particular the conversion of *N*-aminopyridines into diazepines[235,236]:

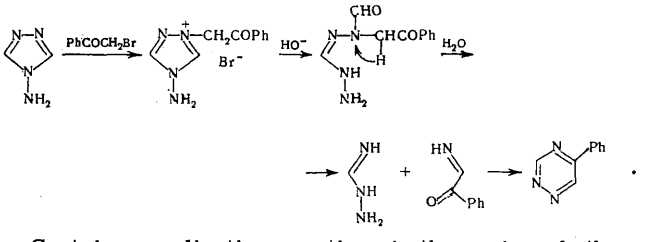


Relay Syntheses

In a series of studies by Becker and coworkers[237-244], recyclisation reactions of hydrazine-containing heterocycles, called relay syntheses, are described. They consist of ring opening and closure, for example the formation of triazole rings, accompanied by fragmentation. Despite their complex mechanism, these syntheses usually take place smoothly and they are of preparative value. As an example, one may quote the coupled recyclisation reaction of triazole derivatives[239]. It can be divided into stages or can be carried out successfully in one stage:



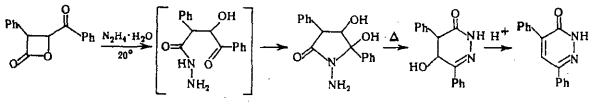
The authors believe[240] that relay syntheses can be achieved via complete fragmentation of the ring with its subsequent reassembly into a new ring, as shown in the following scheme:



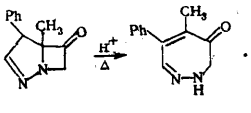
Certain recyclisation reactions in the series of other heterocycles (oxadiazolopyrimidines[245] and amino-oxadiazolium salts[246]), which permit a conversion into triazole and imidazole derivatives, can also be included among the relay syntheses.

Recyclisation Reactions of Small Rings

The recyclisation reactions of small rings under the influence of hydrazines are accompanied by ring expansion. Cyclic β-ketoesters form bicyclic pyrazole derivatives. According to Jacobs[247], the synthesis of 3-methyl-1-phenylpyrazol-5-one from diketen and phenylhydrazine is of industrial interest. In the series of β-lactones, the rearrangement of a four-membered ring to a six-membered ring takes place by successive recyclisation; under certain conditions, the intermediate heterocycles were isolated and identified[248]:



The bicyclic pyrazoline system condensed with a four-membered ring via a C — N bond isomerises to a diazepine structure on heating in a weakly acid medium[249,250]:



Three-membered rings usually rearrange to five-membered rings and more rarely to six-membered rings, mainly depending on the nature and positions of the substituents in the small ring. Reaction involving the recyclisation of aziridines into pyrazoles[247], pyrrolines[251], and imidazoles[252], of azirines into a six-membered triazine system[253], and of oxirans into pyrazoles[247,254], are known.

Non-standard Phosphorus-containing Derivatives of Carbohydrates

E.E.Nifant'ev and I.P.Gudkova

The review deals with the analogues of natural carbohydrate phosphates modified in the phosphorus-containing fragment. Synthetic pathways leading to compounds which are of greatest interest owing to their chemical properties and their behaviour in certain enzymatic reactions have been examined.
The bibliography includes 110 references.

I. Introduction 850
II. Derivatives of phosphorus(V) acids and carbohydrates 850
III. Derivatives of phosphorus(III) acids and carbohydrates 856

I. INTRODUCTION

Numerous studies on the synthesis and chemical properties of phosphorus-containing carbohydrate derivatives and their applications in biochemical studies have been published. As a rule sugar mono-, di-, and tri-phosphates or phosphoramidates were investigated. Such substances are either natural products or their close analogues, differing in detailed features of the ester groups.

However, there exists another group of phosphorus-containing carbohydrate derivatives consisting of derivatives of phosphorus-containing acids which have not been detected hitherto in animal and plant organism. The importance of these substances (we shall call them "non-standard phosphorus-containing derivatives of carbohydrates")† is evident, since they can be widely used to investigate many questions of sugar metabolism at a molecular level and to elucidate the structure of the active centres in the corresponding enzymes. Moreover, some of the above types of compounds are of interest for the synthetic chemistry of carbohydrates.

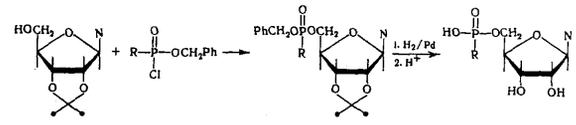
The non-standard phosphorus-containing carbohydrate derivatives were begun to be investigated mainly recently and in the literature there are no reviews dealing with their chemistry. Bearing this in mind, we undertook the writing of the present review, which covers the literature mainly up to the end of 1970: the first section deals with problems of the chemistry of phosphorus(V) acid derivatives and the second with phosphorus(III) acid derivatives. Each section begins with a description of phosphorylated pentoses.

II. DERIVATIVES OF PHOSPHORUS(V) ACIDS AND CARBOHYDRATES

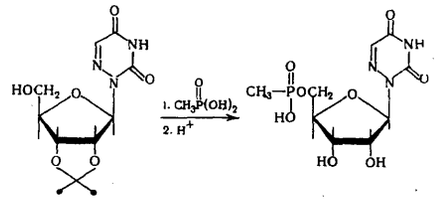
Among other non-standard phosphorus-containing carbohydrate derivatives, the phosphonic analogues of natural phosphates have been most widely investigated both chemically and biochemically and therefore the first subsection of the first section will be devoted to them. Alkylphosphoric, phosphoramidic, and phosphorothioic acid esters of carbohydrates and some of their derivatives containing quinquevalent phosphorus will be considered next.

1. Carbohydrate Phosphonates‡

The phosphonates of natural sugars were obtained for the first time in 1951 by Todd[3], who described analogues of adenosine 5'-phosphate, and uridine 5'-phosphate containing phenyl- and ethyl-phosphonic acid residues instead of the orthophosphoric acid residue. These esters were synthesised by phosphorylating 2',3'-*O*-isopropylidene-adenosine and 2',3'-*O*-isopropylideneuridine by the corresponding phosphonochloridic acid with subsequent elimination of the protecting groups:



Subsequently the synthesis of nucleoside phosphonates was investigated by Holý[4]. By allowing 2',3'-*O*-isopropylidene-6-azauridine to react with pyridinium methylphosphonate in the presence of dicyclohexylcarbodi-imide, he obtained 6-aza-uridine 5'-methylphosphonate:

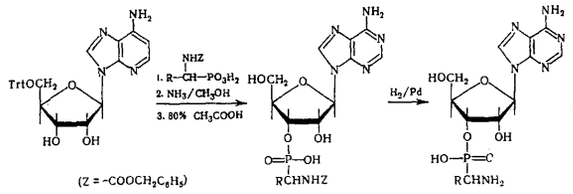


When 5'-*O*-acetylazauridine is used as the starting material, 6-azauridine 2'(3')-methyl-phosphonates are formed.

† One should bear in mind that the term "non-standard phosphorus-containing carbohydrate derivatives" is to some extent arbitrary. Recently phospholipids[1] and an antibiotic[2] belonging to the class of phosphonic acids have been found in natural products and therefore it now appears quite likely that phosphonates and other unusual sugar derivatives will be detected among products of plant and animal origins.

‡ This subsection will also deal with the esters of other acids with C–P bonds containing two or three phosphorus atoms. Such acids, which do not have generally accepted names as yet, will be combined under the term "phosphonic" just as orthophosphoric, pyrophosphoric, and triphosphoric acids are frequently referred to as "phosphoric" acids.

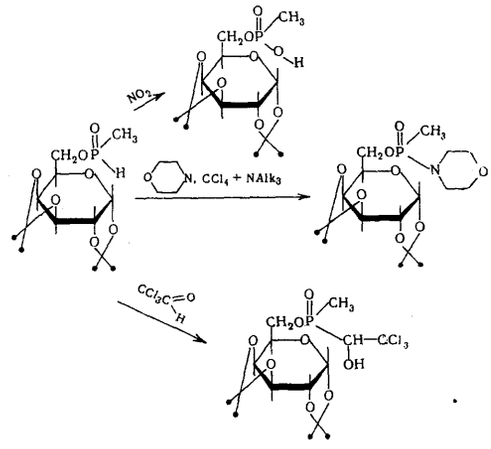
Žemlička and Chladek[5] obtained by this procedure the phosphonic analogues of 2′(3′)-*O*-alanyl- and 2′(3′)-*O*-phenylalanyl-adenosines in which the carboxy-group of the aminoacyl residue was replaced by the H–O–P=O group:



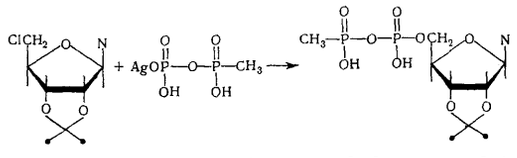
According to preliminary data, α-aminophosphonates of nucleosides inhibit the biosynthesis of certain peptides; in this respect they behave similarly to the antiobiotic chloramphenicol.

Comparison of the above two methods of synthesis of nucleoside phosphonates shows that the latter is preferable, since it is simpler, gives better yields of the desired compounds, and requires much more readily available phosphorylating compounds.

Carbohydrate phosphonates may be also obtained from the corresponding phosphonites. Thus 1,2;3,4-di-*O*-isopropylidenegalactose-6-methylphosphonite was oxidised to the corresponding methylphosphonate[6]. The same phosphonite was made to react successfully with morpholine and carbon tetrachloride to form a phosphonamidate, and with chloral to form 1,2;3,4-di-*O*-isopropylidenegalactose-6-ββ-trichloro-α-hydroxyethylmethylphosphinate:

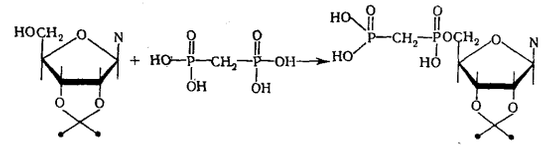


In the first half of the 1960's, the analogues of nucleoside pyrophosphates, in which one of the acid hydroxy-groups was replaced by a carbohydrate substituent, were investigated. Two methods were proposed for the synthesis of these compounds. The first consists of the interaction of a 5′-deoxy-5′-halogenonucleoside, the hydroxy-groups of which are protected, with a metal salt of the corresponding acid[7], for example:

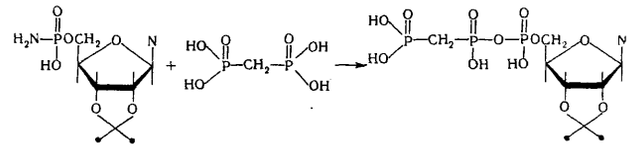


This investigation cannot be regarded as complete. The point is that the structures of the compounds obtained have not been proved. Indeed one can imagine the formation of two pyrophosphonate isomers in one of which the sugar is linked to the phosphate fragment of the acid residue and in the other to the phosphonate fragment. On the basis of general concepts concerning the electronic effects in the series of phosphorus-containing acids, one can postulate a greater probability of the formation of the second structure, while the authors chose the alternative structure without any explanation. The second method, which was investigated in greater detail, is based on the reaction of nucleotides with alkylphosphonic acids in the presence of dicyclohexylcarbodi-imide[8] or another condensing agent[9,10].

Analogues of nucleoside di- and tri-phosphates in which one of the oxygen bridges between the phosphorus atoms has been replaced by a methylene unit have also been described in the literature. It has been suggested that these nucleoside diphosphonates be obtained by the condensation of partly protected nucleosides with methylenediphosphonic acid in the presence of condensing agents[10], for example:



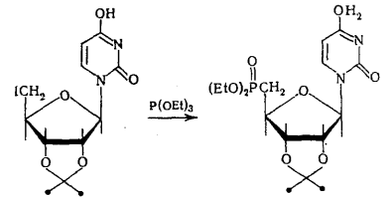
Myers et al. proposed two methods for the preparation of phosphonic analogues of adenosine triphosphate[10]. In the first, adenosine 5′-phosphoramidic acid is allowed to interact with methylenediphosphonic acid:



In the second method adenosine 5′-monophosphate is condensed with methylenediphosphonic acid under the influence of dicyclohexylcarbodi-imide. The first method gives a higher yield of the final product, while the second is simpler.

The compounds described above are of definite interest from the standpoint of biochemical studies of those reactions in which the dissociation of phosphoanhydride linkages is postulated[11,12].

Compounds in which there is a direct covalent bond between the phosphorus atom and the carbon atom of the main sugar chain are extremely interesting phosphonic analogues of natural phosphates. Such structures were obtained for the first time by the Arbuzov reaction. Bannister and Kagan synthesised in this way diethyl 5′-deoxyuridine 5′-phosphonate[13]:

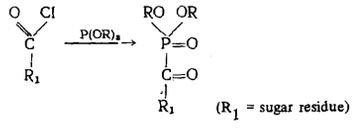


In the hydrolysis of the diethyl phosphonate under severe conditions, undertaken to eliminate the *O*-ethyl groups, the sugar molecule decomposed and the free phosphonic acid could not be isolated. Griffin and Burger reported[14] that this difficulty may be overcome by using specially

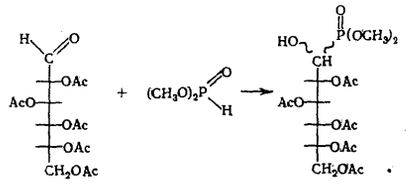
selected esters with a high chemical lability, for example benzyl phosphonates. However, it is difficult to achieve this reaction, since the required phosphonates are obtained from phosphites which enter into the Arbuzov reaction with difficulty. Thus, according to Holy's data, phosphites with 2-cyanoethyl, 2-chloroethyl, 2,2,2-trichloroethyl, and benzyl groups are not alkylated satisfactorily by halogenodeoxynucleosides. Therefore Holy suggests the use of tri-(2-benzoyloxyethyl) phosphite which gives a satisfactory result; however, in this case one has to employ a multistage procedure for the removal of protecting groups[15]. On the basis of the results of Maruszewska-Wieczorkowska et al.[17], Rammler et al.[16] suggest that the phosphite group be protected with allyl groups, which can be subsequently removed by catalytic hydrogenolysis.

Apart from riboside derivatives, derivatives of 6-halogeno-6-deoxyhexoses have been introduced into the Arbuzov reaction: 6-bromo-6-deoxytetra-acetylglucopyranose[14], 7-(2,3,4-tri-*O*-acetyl-6-bromo-6-deoxy-β-D-glucopyranosyl)theophylline[18], and 6-benzamido-9-(2,3,4-tri-*O*-acetyl-6-bromo-6-deoxy-β-D-glupyranosyl)purine[19]. In all these cases, substances differing sharply in hydrolytic stability from the corresponding phosphates were synthesised. It is significant that the phosphonic acids obtained are structurally very similar to the related hexose-ω-phosphates, but they possess a skeletal system of covalently linked atoms which is shorter by one unit.

Recently Zhdanov and coworkers[20] extended the Arbuzov reaction to aldonic acid chlorides and obtained a new type of sugar derivative in which the phosphorus atom is linked directly to the first carbon atom of the carbohydrate chain:

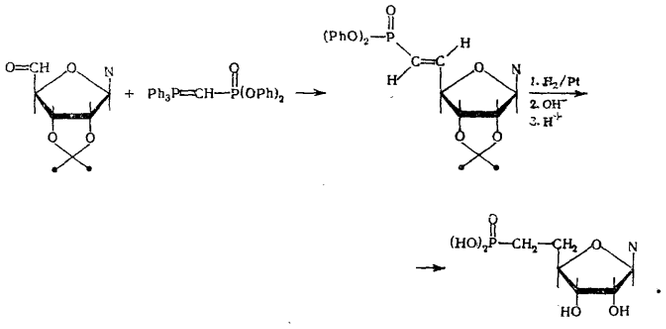


Apart from the Arbuzov reaction, other fundamental methods of the chemistry of organophosphorus compounds, in particular the Abramov and Wittig reactions, may be employed for the synthesis of the phosphonic analogues of sugar phosphates under discussion. Certain esters of phosphonic acids containing a hydroxy-group at the α-carbon atom (in relation to phosphorus) have been obtained by the Abramov reaction[21,22], for example:



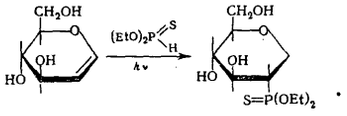
The authors suggest that the products be employed as insecticides.

The Wittig reaction makes available compounds in which the phosphorus atom is joined to the polyol fragment of the carbohydrate residue by an ethylene link. Thus, when modified adenine- or uridine-nucleosides with an aldehyde group at the 5′-carbon atom react with the corresponding Wittig reagent, the following products are obtained after hydrogenation[23]:

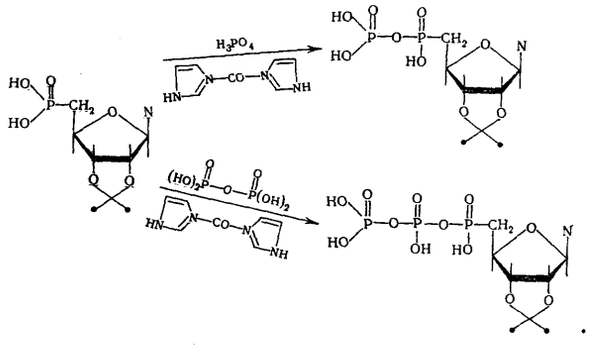


Phosphonic acid derivatives of carbohydrates containing a direct linkage between the phosphorus atom and a carbon atom in the sugar residue can also be synthesised by oxidising the corresponding phosphonous acids which have become available recently (see p. 858–859).[24]

There are literature data on the synthesis of a number of esters of the thioanalogues of the phosphonic acids under consideration. For this purpose, diethyl phosphorothioite was linked to unsaturated sugars[25], for example:



A method based on phosphonic acid derivatives of carbohydrates has been developed for the synthesis of phosphonate analogues of sugar diphosphates and triphosphates differing structurally from the esters with two and three phosphorus atoms already mentioned. The synthesis is carried out according to the following simple scheme[16] using inorganic phosphates and pyrophosphates in the presence of the usual condensing agents:



2. Carbohydrate Alkyl Phosphates

This subsection deals with compounds having the general formula nucl–O–P(=O)(OR)–OR and nucl–O–P(=O)(OH)–OR which are of direct interest for biochemical research. We shall not

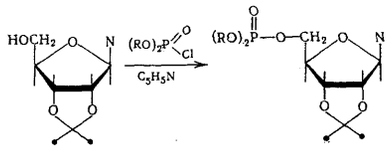
consider the numerous esters of this type which are used solely as intermediates in syntheses, for example, of benzyl, phenyl, and 2-cyanoethyl phosphate derivatives of sugars. The literature data on this problem have already been discussed[26].

Nucleoside dialkyl phosphates were obtained by the usual methods developed in the chemistry of organophosphorus compounds. The main problem, always arising in the extension of the phosphorylation procedures to carbohydrates, was the choice of suitable protecting groups.

Todd and coworkers[27] described the synthesis of the dimethyl ester of uridine 3′-phosphate by treating the corresponding acid with diazomethane. Szer and Shugar[28] extended their method to the synthesis of the dimethyl esters of uridine 5′-phosphate and cytidine 5′-phosphate. Later the reaction with diazomethane was investigated in detail for several mononucleotides[29] and *N*-aminoacid derivatives of nucleotides[30]. It was shown that not only the phosphate fragment but also the heterocyclic ring is methylated, the latter pathway being preferred.

Probably this side reaction also occurred in the earlier investigations[27,28].

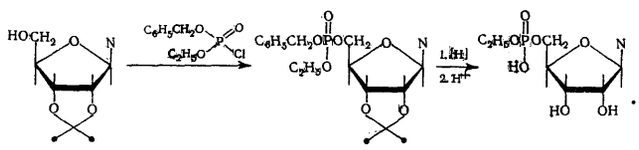
Montgomery et al.,[31] Libman and Heidelberger[32], and later Šorm[33] investigated another method of synthesising alkyl nucleoside 5′-phosphates. It consists of the interaction of 2′,3′-isopropylidenenucleosides with dialkyl phosphorochloridates in the presence of pyridine:



We shall now consider the monoalkyl esters of nucleotides. In a number of studies it has been stated that the desired compounds are formed on partial hydrolysis of the corresponding neutral esters[27,28,31-33]. Probably this procedure is of no preparative value, since under the conditions of such treatment the bond linking the phosphorus atom to the sugar residue is the first to dissociate.

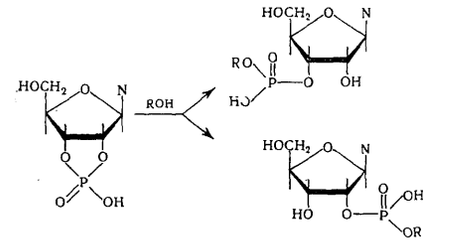
An unsuccessful attempt to obtain the methyl ester of uridine 5′-phosphate by treating the nucleoside with methyl phosphorodichloridate in the presence of pyridine has been described. In this case the main reaction product was the nucleotide. When ethyl phosphorodichloridate is employed, a mixture of products is obtained[34].

The monoethyl esters of adenosine and uridine 5′-phosphates were obtained by the reaction of 2′,3′-*O*-isopropylidenenucleosides with benzyl ethyl phosphorochloridate and subsequent elimination of the isopropylidene and benzyl protecting groups[35]:

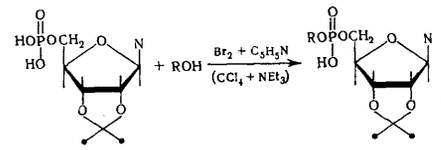


Another method of synthesising alkyl nucleoside 5′-phosphates consists of the treatment of a mixture of the alcohol and the nucleotide with carbodi-imide[33,36]. Despite the weak nucleophilic properties of alcohols compared with those of the phosphate anion, a large excess of the alcohol ensures that the reaction takes place in the required direction.

Alcoholysis of nucleoside 2′:3′-cyclicphosphates by primary alcohols, catalysed by both bases[37] and acids[38] (the latter is preferable), leads to a mixture of alkylnucleoside 2′- and 3′-phosphates:



An interesting method for the preparation of nucleoside esters with monoalkylphosphoric acids is the oxidative phosphorylation proposed by Todd[39]. The synthesis is carried out according to one of two variants—using bromine in pyridine as the oxidising system or carbon tetrachloride and triethylamine:

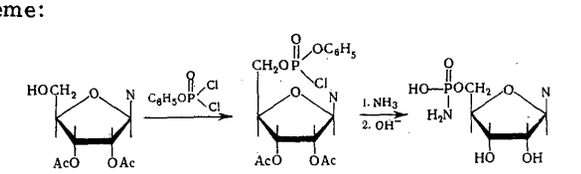


The alkyl esters of nucleotides are of interest in the study of certain problems in molecular biology. Thus it has been shown that they increase the permeability of cell membranes to nucleotide analogues[32]. Moreover alkyl esters of nucleotides have been used in the synthesis of highly specific chemical modifying agents for nucleic acids[40].

3. Carbohydrate Phosphoramidates

Numerous studies have been devoted to the phosphoramidates of various sugars. In the present review we have excluded from consideration those compounds with a P–N bond which are of purely synthetic importance. Data concerning the very interesting aminoacid derivatives of nucleotides have also been omitted, since the latter were considered recently in detail in a review by Shabarova and Prokof'eva[41].

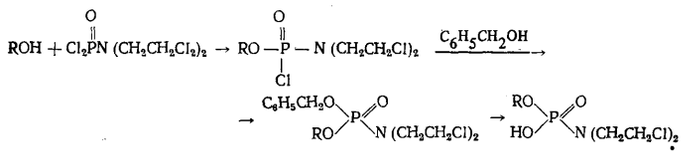
The first study on the synthesis of the relevant compounds[42] was carried out according to the following scheme:



A more effective single-stage method of synthesis of the required amides, based on the condensation of nucleotides with ammonia in the presence of dicyclohexylcarbodiimide, was developed somewhat later[43]. Adenosine, uridine, cytidine, and guanidine phosphoramidates were obtained in high yields by this general method[43,44]. The piperidide and morpholide derivatives of nucleotides were synthesised similarly[45].

Several examples of the synthesis of phosphoramidate derivatives of monoses[46] with the general formula sugar–O$\overset{\displaystyle O}{\overset{\|}{P}}$(OH)–N$(CH_2CH_2Cl)_2$ are also known. The following

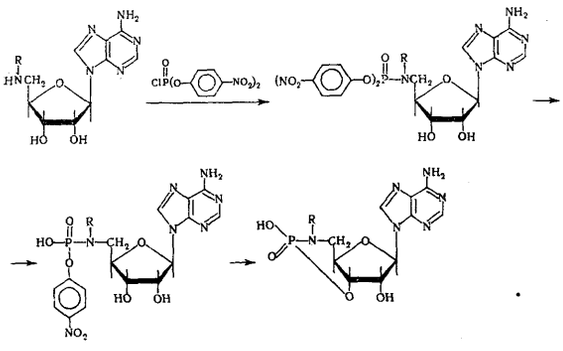
scheme is employed. Partly protected sugars are phosphorylated with an excess of an acid dichloride—*NN*-bis-(dichloroethyl)phosphoramidic dichloride; next the phosphoramidochloridate, which is the primary product, is converted by treatment with benzyl alcohol into an asymmetric diesteramide which yields the required compound after the removal of the protecting groups:



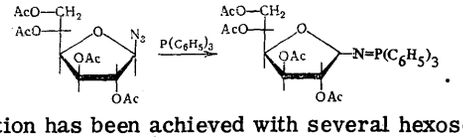
Derivatives of ribose, fructose, and glucose were used as the carbohydrate components. It is suggested that, owing to the presence of the carbohydrate residue, these compounds can readily penetrate the cell, where, under the influence of phosphatase and phosphoamidase, they split off bis-β-chloroethylamine, which suppresses the growth of malignant cells.

In addition to the methods for the preparation of sugar phosphoramidates described above, yet another procedure for their synthesis, based on the corresponding amides of acids containing phosphorus(III), may be mentioned. Thus 1,2;3,5-di-*O*-isopropylidineglucofuranose-6-(*NNN'N'*-tetramethyl)phosphorodiamidite is readily oxidised by oxygen, nitric oxide, and nitrogen dioxide[47]. 2,3,4,6-Tetra-*O*-acetylglucopyranose 1-(*NNNN'*-tetramethyl)phosphorodiamidite was oxidised under similar conditions[48].

Several compounds in which the nitrogen of the amide group in the phosphoramidates is linked directly to a carbon atom in the sugar ring have been described. Starting with 5'-amino-5'-deoxynucleosides and di-*p*-nitrophenyl phosphorochloridate, Jastorff and Hettler[49] obtained 50–85% yields of nucleoside phosphoramidate diesters[49]. Later the 5'-amide analogue of adenosine, converted subsequently into 3':5'-cyclicphosphoramidate, was obtained by a similar procedure[50]:



In conclusion of this subsection, mention should be made of compounds which are only indirectly related to the phosphoramidates discussed above as regards their structures. These are sugar derivatives of phosphine imide, for which a synthesis involving the treatment of the sugar azide with triphenylphosphine has been proposed[51]:

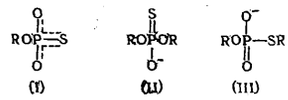


The reaction has been achieved with several hexoses. The final products are obtained in high yields.

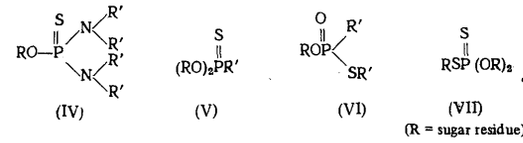
4. Sugar Phosphorothioates

In studies of enzymatic reactions at a molecular level using analogues of natural sugar phosphates, the phosphorothioates should be investigated first, since they involve minimal structural changes but differ significantly in one feature. Unfortunately, certain difficulties arise in their synthesis and this is why they have been comparatively little investigated hitherto.

The nucleoside phosphorothioates described in the literature can be represented by three types of general formulae:

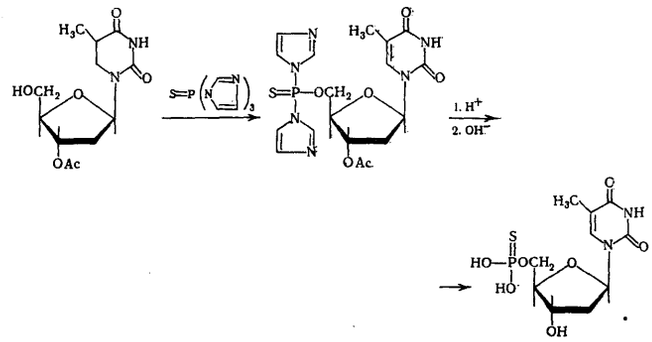


In addition, compounds with the following structures have been obtained from hexoses:



The methods of synthesising sugar phosphotothioates in the sequence (I)–(VII) specified above will be discussed below.

Nucleoside phosphorothioates were first obtained by Eckstein in 1966.[52] He phosphorylated 3'-*O*-acetyl-2'-deoxythymidine with tri-imidazolylphosphine sulphide:



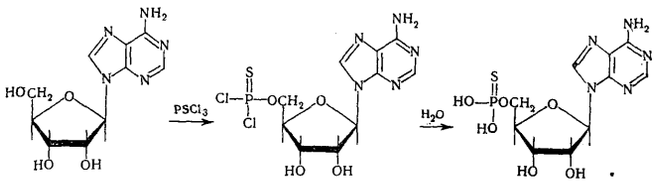
Somewhat later other investigators synthesised a series of nucleoside 5'-phosphorothioates using the same phosphorylating agent[53].

Eckstein employed tri-imidazolylphosphine sulphide to synthesise 2':3'-cyclic phosphorothioates from 5'-*O*-acetyluridine[54]. However, the desired product was isolated in a yield of 12% only. Moreover, the reaction was complicated by a side process involving the formation of 5'-*O*-acetyluridine 2':3'-cyclicphosphate.

Uridine 2':3'-cyclicphosphorothioate is interesting as a substrate for pancreatic ribonuclease[55].

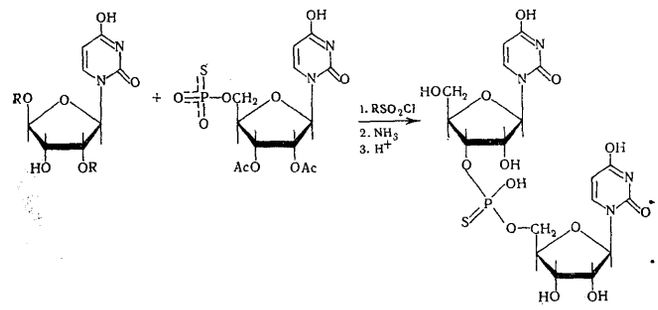
It is stated in the literature that tri-imidazolylphosphine sulphide employed as a phosphorylating agent gives satisfactory results only in the synthesis of the 5'-analogues of nucleotides. The attempts to synthesise the 3'-isomers were unsuccessful[56].

Phosphorus thiochloride was also used for the synthesis of nucleoside phosphorothioates. Thus adenosine 6′-phosphorothioate was obtained in a high yield by this procedure[57]:



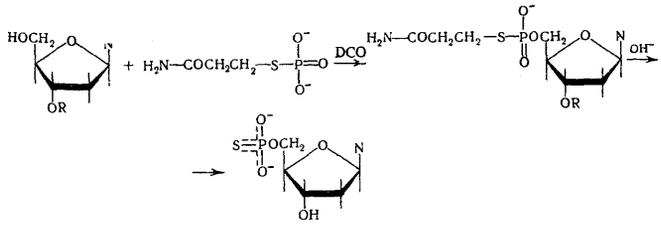
However, when phosphorus thiochloride was used in the phosphorylation of 2′,3′-*O*-isopropylideneinosine, the desired product was isolated in a relatively low yield after the removal of the isopropylidine protecting group[58].

It has been reported that nucleoside 5′-phosphorothioates are themselves effective phosphorylating agents. By treating 2′,5′-di-*O*-ethoxyethyluridine with 2′,3′-di-*O*-acetyluridine 5′-phosphorothioate, Eckstein achieved the synthesis of diuridine-3′,5′-phosphorothioate[59]:



In this reaction tri-isopropylbenzenesulphonyl chloride was employed as an activator.

Unfortunately the carbodi-imide method, which has been developed satisfactorily in the chemistry of nucleotides, could not be extended for a long time to the synthesis of phosphorothioates because the intermediate complex of the phosphorothioate and dicyclohexylcarbodi-imide decomposes with formation of dicyclohexylthiourea[60]. Cook et al. found a way of obviating this difficulty by employing in the carbodi-imide synthesis an inorganic phosphorothioate with a protected thio-group. Initially ethyl phosphorothioate was employed in the synthesis of sugar phosphorothioates[61]. However, subsequently it was suggested that the 2-carbamoylethyl protecting group, which is labile in an alkaline medium and can be readily removed at the end of the synthesis, be employed[62].

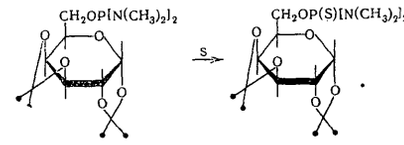


Nucleoside 3′ as well as 5′-phosphorothioates were obtained in this way in high yields.

The use of the 2-carbamoylethyl protecting group in this synthesis is analogous to the employment of the commoner 2-cyanoethyl protecting group in nucleotide synthesis. The reason for the above modification is that the authors were unable to synthesise 2-cyanoethyl phosphorothioates.

Carbohydrate phosphorothioates as well as phosphoramidates can be synthesised from the corresponding phosphorus(III) compounds.

Compounds with trico-ordinate phosphorus are known to combine readily with sulphur. This reaction has been carried out with 2,3;5,6-di-isopropylidinemannofuranose 1-(*NNN′N′*-tetramethyl)phosphorodiamidite[48], 1,2;3,5-di-isopropylideneglucofuranose 6-(*NNN′N′*-tetramethyl)phosphorodiamidite, and 1,2;3,4-di-isopropylidenegalactopyranose 6-(*NNN′N′*-tetramethyl)phosphoramidite[47], for example:

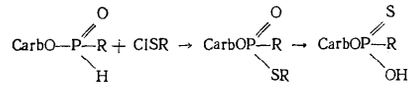


Glycosyl phosphoramidites react with sulphur on fusion of the starting materials and non-glycosidic sugar phosphoramidites react with spontaneous heating simply on mixing the components. In both cases the reaction gives high yields. Thus it is easy to obtain from readily available phosphorodiamidites the closest analogues of natural products—phosphoramidothioates. The biochemical properties of glucose 6-(*NNN′N′*-tetramethyl)phosphorodiamidothioate were investigated in a number of enzymatic reactions and it was shown that the compounds behave like the natural glucose-6-phosphate when acted upon by a number of glycolytic enzymes. However, the rates of its reactions are lower[63].

The addition of sulphur to disugar methylphosphonites has also been achieved[64]:

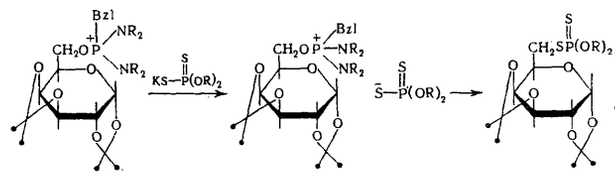
It has been shown that on heating the phosphonothioates [phosphonothionates?] thus synthesised partly isomerise to phosphonothiolates.

It has been suggested that phosphonothiolates, in which sulphur is present as a thiol group, be synthesised by treating partial sugar phosphonite esters with sulphenyl chlorides; the esters can be converted also into the corresponding phosphonothionates[6]:



The synthesis of acid phosphonamidothioates from phosphonamidites has also been described[65]. In this case the thione–thiol isomerisation does not take place.

Dialkyl sugar phosphorodithioates were obtained very recently by replacing the halogen anion by a phosphorodithioate anion in quasiamidophosphonium compounds with subsequent decomposition via the mechanism of the Arbuzov reaction[66]:



A characteristic feature of these compounds is the position of the sulphur atom between the phosphorus atom and the carbohydrate skeleton of the molecule.

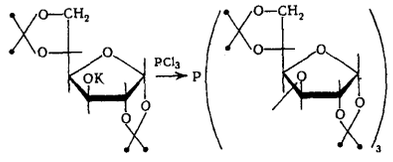
III. DERIVATIVES OF PHOSPHORUS(III) ACIDS AND CARBOHYDRATES

In recent years studies were begun in a number of laboratories on the synthesis and chemical properties of derivatives of phosphorus(III) acids and carbohydrates. These substances appear to be very promising as intermediates for the preparation of a wide variety of non-standard phosphorus-containing derivatives of carbohydrates, natural phosphates, and numerous dephosphorylation products. This assessment is due primarily to the high chemical reactivity of derivatives of tervalent phosphorus acids and sugars and also the fact that they are obtained under milder conditions and usually in higher yield than the corresponding phosphorus(V) acids. There is no doubt that the analogues of natural carbohydrate phosphates containing phosphorus(III) acid residues are of independent interest for biochemical research. Studies on those lines have already begun [63,67-69]. Certain facts now suggest that phosphites and other phosphorus(III) acid derivatives are formed in organisms as metabolic intermediates from a number of sugar phosphates and phosphoramidates.

In this review we shall consider the derivatives of phosphorus(III) acids and carbohydrates in the following order: neutral and acid phosphites and phosphoramidites and neutral and acid phosphonites, phosphonamidites, and phosphinites.

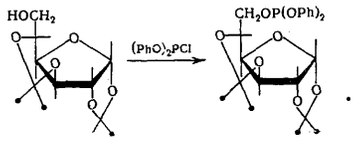
1. Neutral Phosphites

In the first studies on the synthesis of neutral sugar phosphites, acid chlorides were employed as phosphorylating agents. The phosphorylation of the potassium alkoxide derivatives of diacetoneglucose with phosphorus trichloride was reported in 1934. For a 3:1 reactant ratio, the formation of a neutral phosphite was postulated [70]:

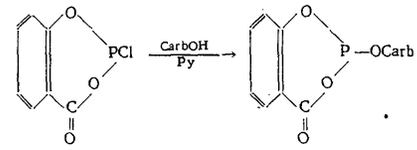


Unfortunately the yield of the reaction product, the methods of its purification, and necessary evidence for the individuality and structure of the trisugar phosphites are not included in the above report.

Later attempts were made to employ phosphorochloridite esters for the phosphorylation of carbohydrates. Thus the reaction between 1,2;3,5-di-isopropylideneglucofuranose and diphenyl phosphorochloridite has been described [71]:

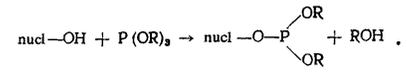


Later Tanaka published data on the preparation of diacetoneglucose-6-phosphite and diacetone galactose-6-phosphite using bis-(2,4-dichlorophenyl)phosphorochloridite as a phosphorylating agent [72]. The same investigator drew attention to the desirability of choosing cyclic phosphorochloridites, for example salicyl phosphorochloridite [73]:



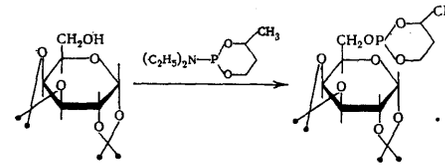
One may suppose that the phosphorochloridite method described has not found wide application because it suffers from disadvantages such as the instability of the initial reactants and the occurrence of side reactions. It is significant that phosphorochloridites cannot be used in the synthesis of glycosyl phosphites. Like other glycoside esters, they should be decomposed by amine hydrochlorides, which are formed as side products in the phosphorylation reactions [74], with formation of glycosyl halides.

Neutral phosphite esters have been proposed as phosphorylating agents for carbohydrates. In a series of studies by Czech chemists, a transesterification reaction for the synthesis of nucleoside phosphites has been described [75-81]. They employed triethyl and triphenyl phosphites as the transesterifying components:

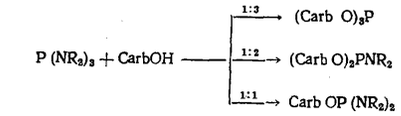


On treatment with triphenyl and triethyl phosphites, ribonucleosides yield nucleoside mono-, di-, and triphosphites and possibly also cyclicphosphites and dinucleoside phosphites. On subsequent hydrolysis, all these substances decompose to dihydrogen phosphite esters. Ribonucleosides with protected 2′- and 3′-hydroxy groups yield 5′-phosphites on transesterification with neutral phosphites [75-79].

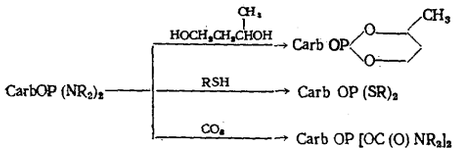
The transesterification method appears to be promising for the chemistry of sugars and nucleosides. However, recently the range of its applications has been restricted owing to the appearance of a new method—the alcoholysis of phosphoramidites [82,83]. This reaction has important advantages in syntheses: it is achieved under mild conditions, it does not involve the liberation of corrosive side products, and the starting materials are readily available. The method can be illustrated by the following example [84]:



An interesting variant of this reaction is phosphorylation of sugar derivatives with phosphorous hexa-alkyltriamides. In this case, depending on the reactant ratio, it is possible to obtain one of three types of compounds [65,84]:



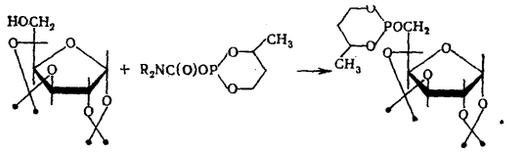
Phosphorodiamidites are valuable intermediates for the preparation of new phosphite derivatives. Thus, they readily react with alcohols[85], aminoalcohols[86], mercaptans[87], and carbon dioxide[88] and are converted into new phosphoramidite esters, phosphorothioite esters, phosphite esters, and carbamoyl phosphites. In particular, the following reactions have been achieved:



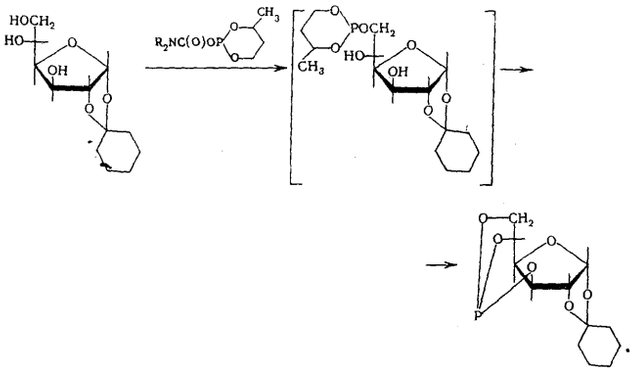
The phosphoramidites can be converted into monosugar phosphites by hydrolysis and acidolysis[89].

The synthesis of phosphites and phosphoramidites involving the alcoholic sugar hydroxyls was described above. The synthesis of glycosyl phosphites was achieved using phosphoramidous acids and their esters[48].

Sugar acyl phosphites[90], particularly carbamoyl phosphites[90], react under even milder conditions than the phosphoramidites, for example:

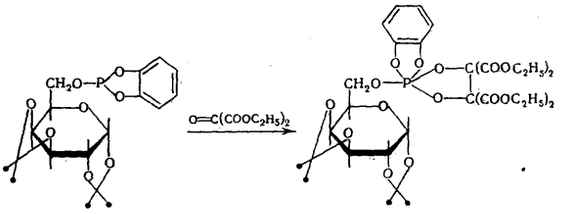


1,3-Butylene *NN*-dimethylphosphoramidite and 1,3-butylene dimethylcarbamoyl phosphite were investigated in a reaction with 1,2-cyclohexylideneglucofuranose[92]. In the phosphorylation with the carbamoyl phosphite, the reaction takes place at room temperature with formation of a bicyclic phosphite. Probably the first stage involves the formation of the sugar 1,3-butylene phosphite, which undergoes spontaneous transesterification to 1,2-cyclohexylideneglucofuranose 2,5,6-phosphite as a result of the specific properties of the carbohydrate phosphite system:



The structure of the bicyclic phosphite was demonstrated by synthesis involving the phosphorylation of 1,2-cyclohexylideneglucose with phosphorous hexaethyltriamide[92].

In the preview section of the review it was already mentioned that neutral sugar phosphites and phosphoramidites serve as starting materials for the synthesis of the corresponding phosphorus(V) derivatives. In addition, other reactions involving them have been achieved. Thus, alkylation, leading to a wide variety of deoxysugar derivatives[66,93], and the reaction with mesoxalic esters[94] deserve mention:

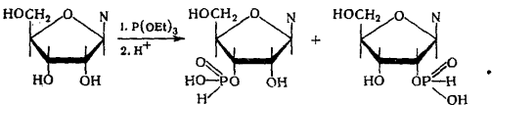


2. Acid Phosphites

It has been suggested that sugar dihydrogen phosphite esters be synthesised by the reaction of the sugar with phosphorous acid in the presence of dicyclohexylcarbodiimide as the condensing agent. This method was employed for the first time in 1961 by Todd[95]. Subsequently Holý et al.[96] developed on this basis a preparative synthesis for certain nucleoside phosphites.

A second method for the preparation of mononucleoside phosphites involves the hydrolysis of Menshutkin acid chlorides of the type $ROPCl_2$, formed when specially protected nucleosides are treated with phosphorus trichloride[97,98]. The problem of whether the phosphorodichloridite esters enter into various side reactions before treatment with water still remains uninvestigated. Therefore it is difficult to assess the preparative value of the method.

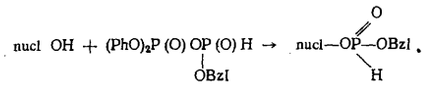
It has been suggested that mononucleoside phosphites be obtained by the hydrolysis of the corresponding neutral phosphites[76-78]. Initially 2′(3′)-phosphites were obtained from nucleosides with a protected 5′-hydroxy-group[76]. However, subsequently it was reported that nucleoside 2′(3′)-phosphites can be synthesised by the reaction of unprotected ribonucleosides with triethyl phosphite[78]:



The authors suggest that such selectivity of the secondary hydroxyl in the presence of a free primary hydroxyl is due to the formation of the thermodynamically more favourable 2′:3′-cyclic phosphite structure the hydrolysis of which leads to the acid phosphite. However, the formation of such cyclic esters is possible only when *cis*-hydroxy-groups are present. Thus all the acid phosphites which may be expected on hydrolysis of the cyclic phosphites, presumed to be formed via the transesterification of the alkyl phosphites with the *cis*-hydroxy-groups of the sugar, were obtained from lyxose, xylose, and arabinose[79]. Moreover, it is asserted that ribonucleosides with protected 2′,3′-hydroxy-groups as well as 2′-deoxyribonucleosides altogether fail to be phosphorylated by triethyl phosphite under the chosen conditions.

A synthesis of monosugar phosphites by the acidolysis and hydrolysis of the corresponding phosphorodiamidites has been proposed[85,89].

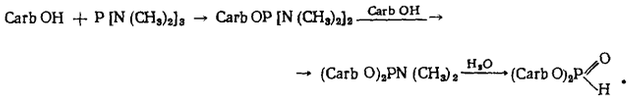
For the synthesis of monohydrogen phosphite esters, Todd proposed the method of mixed anhydrides requiring the use of the *O*-benzylphosphorous-*OO*-diphenylphosphoric anhydride:



Ribonucleosides containing blocking groups at the 2',3'- and 3',5'-hydroxyls and also 5'-protected 2'-deoxyribonucleosides are usually introduced into this reaction.

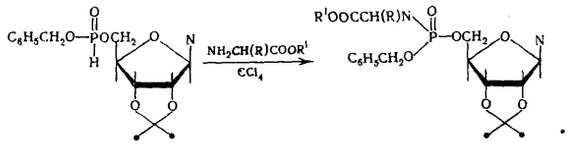
Nucleoside benzyl phosphites are synthesised in connection with the solution of a wide variety of chemical problems and such synthesis has become fairly common[26]. However, its further applications are restricted by the low availability of phosphorylating agents which can only be obtained by a fairly complex procedure.

Monohydrogen phosphite esters containing one or two sugar residues are formed on hydrolysis or acidolysis of the corresponding phosphoramidites, which are in turn obtained via a two-stage phosphorylation procedure[85], for example:



Acid phosphites of carbohydrates are very interesting synthetically. Dihydrogen phosphite esters have been suggested as intermediates in the synthesis of phosphates. Nitrogen dioxide[85], hexachloroacetone[76], and mercury(II) chloride[98] have been used as oxidising agents. Monohydrogen esters are readily converted into the corresponding phosphorochloridates by treatment with *N*-chlorosuccinimide and similar reagents[100]. Such phosphorochloridates are highly reactive and are readily converted into a wide variety of carbohydrate derivatives.

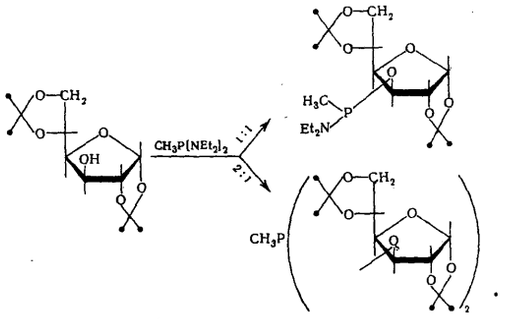
Benzyl nucleoside phosphites react with amines in the presence of carbon tetrachloride to form phosphoramidates[101]. This reaction was employed by Prokof'ev, Shabarova, and coworkers to synthesise compounds containing the phosphoramidate linkage between a nucleotide and an aminoacid[102-104], for example:



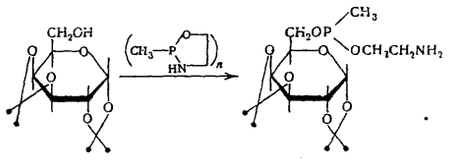
3. Neutral Phosphonites and Phosphonamidites

The alcoholysis of methylphosphonite esters and methylphosphonamidous acids has been suggested as a method of phosphorylating carbohydrates. Thus isopropylidineadenosine can be converted into an asymmetric phosphonite by treating it with diphenyl methylphosphonite[105] and diacetonehexoses can be converted into the corresponding methylphosphonamidites by reaction with methylphosphonous tetraethyldiamide[65].

With a 2 : 1 reactant ratio, disugar methyl phosphonites are formed[65], for example:



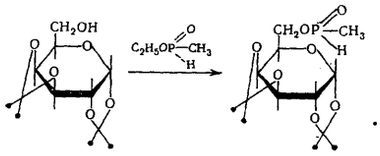
The following synthesis has been suggested for asymmetric phosphonites containing the ethanolamine residue:



Carbohydrate phosphonites and phosphonamidites are highly reactive. They are readily oxidised, combine with sulphur to form the corresponding phosphorus(V) derivatives[65,85], and enter into the Arbuzov reaction with formation of deoxysugars[93]. Phosphonamidites also react with a wide variety of reagents containing a mobile hydrogen, becoming converted into other sugar phosphonites[6,65].

4. Acid Phosphonites

Acid phosphonites of protected monoses have been obtained by the transesterification of phosphonites and by the alcoholysis of amides. The transesterification method has been used to prepare 1,2;3,4-di-isopropylidenegalactose 6-methylphosphonite by treating the sugar with ethyl methylphosphonite[6]:

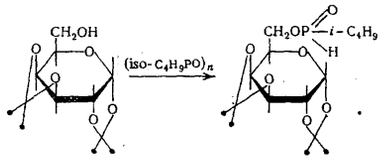


The reaction takes place under severe conditions (170°C, 7h). In the alcoholysis of amides, the phosphorylation takes place under milder conditions. The reaction temperature is reduced (110°C) and the yield of the final product increases.

Acid phosphonites can also be obtained by the acidolysis and hydrolysis of the corresponding phosphonamidite esters[89].

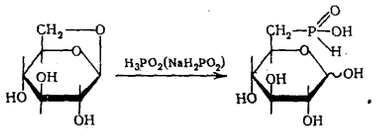
Acid carbohydrate phosphonites can be obtained under the mildest conditions by the interaction of protected sugars with anhydrides of the type $(R-PO)_n$.[106] The

reaction is not accompanied by the formation of side products and takes place at room temperature on simple mixing of the reactants:



Both alcoholic and glycosidic hydroxyls can be phosphorylated in this way. However, the anhydrides themselves are extremely labile. They polymerise rapidly with formation of unreactive products.

Among phosphorus(III) acid derivatives, analogues of natural phosphates with a direct covalent bond between the phosphorus atom and the carbon atom of the main sugar chain have also been obtained. Such phosphonous acids have been synthesised by the opening of the ring in 1,6-anhydrohexoses with hypophosphorous acid or its mixture with sodium hypophosphite[24]:



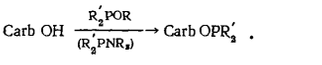
This reaction has been achieved with 1,6-anhydroglucose and 1,6-anhydrogalactose.

The above method of synthesis of phosphonous acids is particularly valuable because it makes it possible to avoid the laborious procedures involving the introduction and removal of protecting groups.

Phosphorous acid has also been investigated in the reaction with laevoglucosan, but in this case a product with a phosphorus-carbon bond was not isolated.

5. Carbohydrate Phosphinites

Two methods have been proposed for the synthesis of carbohydrate phosphinites: using phosphinite esters[107] and phosphinous amides[84,107] as phosphorylating agents:



These substances have been less thoroughly investigated than the phosphites and phosphonites owing to the experimental difficulties in their synthesis. Nevertheless, it has been shown that sugar phosphinites enter into a wide variety of substitutive phosphorylations leading to halogenodeoxy-[84,107-109] and mercaptodeoxy-derivatives[110] of sugars.

Some Applications of the Optical Activity of Coordination Compounds

V.V.Dunina, E.G.Rukhadze, and A.P.Terent'ev (deceased)

The review covers the principal directions in which electronic absorption spectra, rotational dispersion curves, and circular dichroism are at present used in determining the absolute configurations of complex compounds and their structure. A list of 225 references is included.

I. INTRODUCTION

During recent years the study of the dispersion of optical rotation and the circular dichroism of dissymmetric coordination compounds has become widely recognised as a method for solving spectroscopic and stereochemical problems. The discovery of definite relations between optical activity and various structural features of complex compounds, a more discriminating approach to the observed spectral characteristics (optical rotatory curves and circular dichroism spectra [1,2]), the enhanced sensitivity and extended spectral range of modern spectropolarimeters and dichrographs—all this has created a basis for the successful application of the optical rotatory dispersion and the circular dichroism of coordination compounds in solving various problems both in the chemistry of complex compounds and in organic chemistry.

The present review surveys some of the main directions in which the use of optical rotatory dispersion and circular dichroism has proved especially fruitful—the interpretation of electronic absorption spectra because of the better resolution of bands into individual transitions and further opportunities for their assignment, the determination of the absolute configurations of complex compounds from configurational effects (information which can be obtained by no other method except X-ray diffraction), determination of the absolute configurations of organic compounds from the sign of the rotatory power of $d-d$ transitions of metals in their complexes with the test substances, and the study of complicated natural macromolecules containing a coordinated metal ion.

The abbreviated symbols for ligands, often used in the text, are listed here for the convenience of the reader.

aaH	amino-acid
aba	*o*-aminobenzaldehyde
acacH	pentane-2,4-dione (acetylacetone)
ala	alanine
ala_2en	*NN'*-dialanylethylenediamine
alaglygly	alanylglycylglycine
allothr	allothreonine
asp	aspartic acid
atcH	acetylcamphor
big	biguanidine
bipy	2,2'-bipyridyl
bn	butane-2,3-diamine
2,3-bnpic	*NN'*-bis-(2-methylpyridyl)butane-2,3-diamine
chxn	cyclohexane-*trans*-1,2-diamine
cptn	cyclopentane-1,2-diamine
diam	diamine
dien	diethylenetriamine
1,10-diMetrien	2,5,8,11-tetra-azadodecane
2,9-diMetrien	2,9-dimethyl-1,4,7,10-tetra-azadecane
3,8-diMetrien	3,8-dimethyl-1,4,7,10-tetra-azadecane
5,6-diMetrien	5,6-dimethyl-1,4,7,10-tetra-azadecane
ece	*trans-NN'*-bis-(2-aminoethyl)butane-2,3-diamine [see 5,6-diMetrien]
edda	ethylenediaminediacetic acid
edta	ethylenediaminetetra-acetic acid
edts	ethylenediaminedisuccinic acid
eee	3,6-dithiaoctane-1,8-diamine
$ee(salH)_2$	1,8-bis-salicylideneamino-3,6-dithiaoctane
en	ethylenediamine
epe	4-methyl-3,6-dithiaoctane-1,8-diamine
$epe(salH)_2$	4-methyl-1,8-bis-salicylideneamino-3,6-dithiaoctane
glut	glutamic acid
gly	glycine
glyalagly	glycylalanylglycine
gly_2chxn	*NN'*-diglycylcyclohexane-*trans*-1,2-diamine
glyglyala	glycylglycylalanine
gly_2pn	*NN'*-diglycylpropylenediamine
hmcar	hydroxymethylenecarvone
hmch	hydroxymethylenecamphor
ibn	isobutane-1,2-diamine
leu	leucine
$\alpha\alpha$-Me_2gly	$\alpha\alpha$-dimethylglycine
N-Mepn	*N*-methylpropylenediamine
7-MesalH	*o*-hydroxyacetophenone
meth	methionine
5-Metrien	5-methyl-1,4,7,10-tetra-azadecane
mpkH	2-acetylpyrrole
ox	oxalic acid
pcaH	pyrrole-2-carboxaldehyde
pdta	propylenediaminetetra-acetic acid
penten	pentaethylenehexamine
pep	1,8-dimethyl-3,6-dithiaoctane-1,8-diamine
$pep(salH)_2$	1,8-dimethyl-1,8-bis-salicylideneamino-3,6-dithiaoctane
o-phen	1,10-phenanthroline
phenen	phenylethylenediamine
pn	propylenediamine
prol	proline
ptnta	pentane-2,4-diaminetetra-acetic acid
sal_2pn	*NN'*-disalicylidenepropylenediamine
ser	serine
stien	stilbenediamine
tart	tartaric acid
tdta	trimethylenediaminetetra-acetic acid
2,3,2-tet	1,4,8,11-tetra-azaundecane
$tet(salH)_2$	[1,11-disalicylidene-1,4,8,11-tetra-azaundecane (?)]
threo	threonine
tn	trimethylenediamine
trien	triethylenetetramine
val	valine

II. ELECTRONIC SPECTROSCOPY AND SPECTROPOLARIMETRY

Spectropolarimetry and ordinary electronic spectroscopy are complementary and undoubtedly mutually useful methods of solving structural and spectroscopic problems. Both consist essentially in recording electron transitions occurring in a symmetrical or an unsymmetrical environment. Their main advantage is the appearance of a new parameter—the sign of the optical rotation—in addition to the usual characteristics of an absorption band (extinction coefficient ϵ, frequency ν of maximum, and band half-width $\delta_{1/2}$). The complicated sigmoid character of individual inverse curves of optical rotatory dispersion corresponding to an individual transition often complicates interpretation of the curves observed when several such inverse curves are superposed.

Two bands of opposite sign can be distinguished in the circular dichroism spectra even if their separation does not exceed 100 cm^{-1}. In such a situation the absorption spectrum will give only a single overall band, which the usual methods—graphical and mathematical—are generally almost completely unable to resolve [3]. The use of circular dichroism spectra should be especially helpful in such cases, since the sum of the rotatory powers of bands obtained from almost degenerate transitions in related complexes of higher symmetry is zero [4].

Furthermore, certain differences in the selection rules for optically active and inactive absorption bands provide extremely valuable information for the assignment of bands in the absorption spectrum on the basis of an analysis of the intensities of the corresponding dichroic components. The rotatory power of an electronic transition is defined as the real part of the pseudoscalar product of the electrical and magnetic moments of the transition. The presence of the former is due to the transfer of charge (dipole moment), and of the latter to its rotation (magnetic dipole moment). And since by definition the transition is optically active only when the two moments act collinearly, this corresponds to a helical displacement of charge. Movement along a right-hand helix is associated with positive circular dichroism, and along a left-hand helix with negative circular dichroism [5].

As a consequence of this, transitions whose electrical and magnetic moments are mutually perpendicular cannot be optically active. Transitions that are magnetic-dipole-forbidden give a Cotton effect of insignificant amplitude [6]. On the other hand, d–d transitions of slight or moderate intensity (in the absorption spectrum) in dissymmetric metal complexes show strong dichroism, provided that these electronic transitions are magnetic-dipole-allowed in the given microsymmetry group [7]. Hence the character of the transition in an optically active molecule can be deduced from the value of the g-factor†, which usually exceeds 0.01 for magnetic-dipole-allowed transitions, and is smaller than this value for electric-dipole-allowed transitions [8]. For example, the anisotropy factors for the two transitions of Cr^{3+} in O_h symmetry, $^4T_{2g} \leftarrow {}^4A_{2g}$ and $^4T_{1g} \leftarrow {}^4A_{2g}$, are respectively 0.013 and 0.0008, in conformity with their magnetic-dipole-allowed and -forbidden character [9].

Another criterion which may be useful for assigning bands in the absorption spectrum to definite electron transitions is the specific effect of polarisable anions (phosphate, selenite, and certain others) on the circular dichroism spectra of complex cations. In the case of trisdiamine complexes (symmetry D_3), for example, the effect is evident in an increase in intensity of the A_2 dichroic component at the expense of a decrease in the E_g component, while the absorption spectrum in the region of the $^1T_{1g}$ band remains almost unchanged [10].

Thus important information on the number and nature of the components of an absorption band covering several closely located transitions can be obtained by determining and analysing the optical rotatory dispersion curves and especially the circular dichroism spectra.

On the other hand, progress in the electronic spectroscopy of certain metals, especially those free from d^3 spin (Cr^{3+}) and those with d^6 spin pairing (Co^{3+}, Rh^{3+}, Pt^{4+}), has enabled several empirical relations to be derived between the type of a transition and the sign of its rotatory power. These have subsequently been widely used for investigating the configuration of complexes, the conformation of the chelate ring in them, the configuration of asymmetric carbon atoms in a ligand, and several other stereochemical features of coordination compounds.

It has been established, for example, that all trichelate complexes of Co^{3+} having the absolute configuration $S(C_3)R(C_2)$ are characterised by a $^1E_a \leftarrow {}^1A_1$ transition of positive rotatory power [11]. This relation has since proved useful both for determining the absolute configuration of related complexes from the sign of the circular dichroism of this transition and for assigning a band to a definite transition on the basis of the sign of its circular dichroism with a known absolute configuration [12]. Qualitative similarity of the circular dichroism spectra in a certain spectral region for two complexes having the same absolute configuration can often be a basis for accepting that the energy levels of the d-orbitals of the complexing metals are arranged in the same sequence. Such comparison has been made [13] for the tri-α-alaninates of Co^{3+} and Rh^{3+}.

This type of interrelationship between electronic spectroscopy and spectropolarimetry makes a parallel study of all three types of spectra—absorption spectra, rotatory dispersion, and circular dichroism—especially fruitful. We shall examine several examples of spectroscopic results obtained by the use of optical rotatory dispersion and circular dichroism for various types of complexes of several transition metals.

1. Metals with d^3 and d^6 Electronic Configurations

Trisbidentate complexes $[M(AA)_3]^{n+}$

When six ammonia molecules in the coordination sphere of Co^{3+} are replaced by three ethylenediamine molecules, the d-levels of the metal are split in D_3 symmetry with the appearance of two dichroic components of opposite signs in the region of absorption band I of Co^{3+} ($^1A_{1g} \rightarrow {}^1T_{1g}$, a magnetic-dipole-allowed transition), corresponding to ^1E and $^1A_2$ transitions. Of the two components into which band II is split ($^1A_{1g} \rightarrow {}^1T_{2g}$), corresponding to ^1E and $^1A_1$ states, only the first transition is optically active. This resolution is insufficiently large to affect the absorption spectrum, which consists of two bands as before [14].

† The g-factor—or anisotropy factor—is defined as follows:

$$g = \frac{\epsilon_l - \epsilon_r}{\varepsilon},$$

where ϵ_l and ϵ_r represent absorption of the left-hand and the right-hand circularly polarised rays.

The corresponding trichelate complexes of Co^{3+} and Cr^{3+} with biguanidine (an optically inactive ligand, which on coordination forms planar rings containing the metal) are distinguished from the diamine chelates by a considerably greater intensity of the $d-d$ bands in the absorption and circular dichroism spectra, but the qualitative pattern of splitting is preserved in the latter spectrum. The chromium(III) complexes exhibit ^4E and $^4A_2$ components in the long-wavelength range, and only a ^4E component in the short-wavelength range [15].

The unsymmetrical character of amino-acids leads, on their coordination with metals, to the formation of two geometrical isomers of complexes of type $[M(AB)_3]$—1,2,3 (β) and 1,2,6 (α)—which differ in symmetry and can be identified spectroscopically. In fact the β-isomer is characterised by one Cotton effect in the region of absorption band II of Co^{3+}, whereas the less symmetrical α-isomer has three Cotton effects in the same region [11].

trans-Bisbidentate complexes $[MX_2(AA)_2]$

In these complexes the octahedral triplet states $^1T_{1g}$ and $^1T_{2g}$ are split into $^1A_{2g} + {}^1E_a$ and $^1B_2 + {}^1E_b$ components respectively [16]. The fact that band I is magnetic-dipole-allowed is responsible for the high rotatory power (of opposite signs) of the first two transitions in the complexes with diamines, in contrast to band II, where smaller circular dichroism is observed only for the E_b component [8]. Splitting of this type is exhibited also by the spectra of such complexes in polarised light [17].

The circular dichroism spectra of optically active bis- and tris-β-diketone complexes also consist of two components of opposite sign [18] in the region of band I (the dominant peak at a higher energy) and a broad maximum within the octahedral absorption band II of Co^{3+}.

Splitting of band I of Co^{3+} in the circular dichroism spectrum into two components is observed, also with *trans*-(*N*)-bis-amino-acid complexes having a *trans*-$[MO_4N_2]$ chelate unit, in conformity with the same microsymmetry (D_{4h}). However, splitting of this band into three components, corresponding to the true C_{2v} symmetry of such complexes, could be observed only in the circular dichroism curves of the vicinal effect for the ions $[MX_2(AB)_2]$, e.g. with AB = *L*-ala. [19]

cis-Bisbidentate complexes *cis*-$[MX_2(AA)_2]$

When AA = diam, four dichroic components are now observed in the region of the two $d-d$ bands in the absorption spectrum. Each absorption band corresponds to two dichroic maxima if X_2 represents unidentate ligands; when the latter are replaced by a single bidentate [and conjugated] ligand, one and three maxima in the circular dichroism spectrum are associated respectively with the long-wavelength and with the short-wavelength unpolarised absorption bands [20].

Similar complexes having configurational asymmetry with AA = acac [$X_2 = (NH_3)_2$ or en] exhibit a smaller separation in the circular dichroism spectrum—two components of opposite sign $A_1 \rightarrow B_1$ and $A_1 \rightarrow B_2 + A_2$ (dominant at higher energies) near absorption band I of CO^{3+} and a third component in the region of absorption band II. We note for comparison that $d-d$ transitions are represented in the absorption spectrum by one maximum in band I, while band II is represented by a shoulder on a neighbouring, more intense charge-transfer band [18].

Monobidentate complexes

The microsymmetry of these complexes, e.g. $[Co(L\text{-aa})(NH_3)_4]$, is D_{4h}. Resolution of the experimental optical rotatory dispersion curves into inverse curves corresponding to individual optically active transitions [8] showed the presence of two Cotton effects for band I and one in the region of band II. The g-factor of 0.002 for this last transition is consistent with an electric-dipole-forbidden transition [21]. Splitting of the octahedral $^1T_{1g}$ level into three singlet ^1A levels, corresponding to the actual symmetry C_1, could be observed in the circular dichroism spectrum of the monochelate complex with aa = leu (all components magnetic-dipole-allowed and therefore optically active). [22]

[Complexes with unidentate amino-acids]

In conformity with theory the circular dichroism spectra of such complexes as $[Co(L\text{-aaH})_2en_2]^{3+}$ and $[Co(L\text{-aa})(NH_3)_5]^{2+}$, which have D_{4h} and C_{2v} symmetry, show the resolution of Co^{3+} absorption band I into two components of opposite sign [22]. Under certain conditions the degeneracy of the E_g transition is also removed when the circular dichroism spectra of complexes of the latter type are determined, the two resolved components having opposite signs [23].

[Multidentate complexes]

It has never proved possible to observe splitting of the octahedral $^1T_{1g}$ level in the absorption spectra of the Co^{3+} complex with the multidentate ligand propylenediaminetetra-acetic acid, although theory predicts three components in the region of band I for the symmetry C_{2v} characteristic of this complex. The circular dichroism spectra exhibit two resolved components in conformity with the formal symmetry D_{4h} of this chelate unit $[MX_4Y_2]$. [3]

2. Metals with a d^7 Electronic Configuration

Interesting results have been obtained in the study of the absorption spectra and circular dichroism in the visible and near infrared of several square planar complexes of cobalt(II) with quadridentate Schiff bases of general formula (7-X-sal)$_2$(−)-pn, having the chelate unit $[MN_2O_2]$ and symmetry C_{2v}. Three of the ten spin-allowed $d-d$ bands of the metal should occur in the infrared, but they are represented by a single band in the absorption spectrum owing to the nearness of the $d_{xz,yz}$ and d_{z^2} orbitals. Determination of the circular dichroism spectra in the near infrared enabled all three components associated with the $(d_{xz} \pm d_{yz}), d_{z^2} \rightarrow d_{xy}$ transition to be observed [24]. In the visible range $d_{xy} \rightarrow d_{x^2-y^2}$ and $d_{z^2} \rightarrow d_{x^2-y^2}$ transitions could be identified only from the circular dichroism spectra, since interpretation of the absorption spectrum in this range is greatly impeded by the superposition of intense charge-transfer bands. The assignment of the bands led to the following proposed [24] scheme for the arrangement of d-orbitals in the cobalt(II) complexes investigated

$$d_{z^2} < \frac{1}{\sqrt{2}}(d_{xz} - d_{yz}) < \frac{1}{\sqrt{2}}(d_{xz} + d_{yz}) < d_{xy} < d_{x^2-y^2}.$$

3. Metals with a d^8 Electronic Configuration

(*a*) Octahedral coordination

In an octahedral field Ni^{2+} has three spin-allowed $d-d$ transitions. Measurement of the circular dichroism spectrum of the $[Ni(l\text{-chxn})_3]^{2+}$ ion in the range 300–1200 nm showed optical activity in all three bands, which, in view of their strong, moderate, and weak rotatory power, were assigned to $^3A_{2g} \rightarrow {}^3T_{2g}$, $^3A_{2g} \rightarrow {}^3T_{1g}(F)$, and $^3A_{2g} \rightarrow {}^3T_{1g}(P)$ transitions [25]. The first transition in the similar complex ion $[Ni(l\text{-pn})_3]^{2+}$ has $g = 0.23$, whereas for the other two transitions $g < 0.01$.[26] The complete absence of optical activity in the $d-d$ transitions in the nickel(II) complex of tribenzo[*bfj*]-1,5,9-triazacycloduodecine—a macrocyclic Schiff base—with appreciable rotatory power of the charge-transfer bands is rather unexpected [27].

(*b*) Square planar coordination

The nearness of the three possible $d-d$ transitions of square planar complexes of d^8 metals and their strong overlapping with charge-transfer bands create considerable difficulties in the interpretation of their absorption spectra. A further complication is the dependence of the energy levels of the d-orbital on the degree of tetragonal distortion of the chelate unit and on the strength of π-bonding of the metal with the ligand. This has resulted in several different arrangements of d-levels for square planar complexes of D_{4h} symmetry (Fig. 1).[28] Of the four possible $d-d$ transitions in scheme (III) (Fig. 1)—$d_{xy} \rightarrow d_{x^2-y^2}(A_{2g})$, $d_{xz}, d_{yz} \rightarrow d_{x^2-y^2}(Eg)$, and $d_{z^2} \rightarrow d_{x^2-y^2}(B_{1g})$—only the first two have magnetic moments, and in the A_{2g} transition the electrical and magnetic moments are mutually perpendicular. Hence only the transition to the Eg state should be optically active.

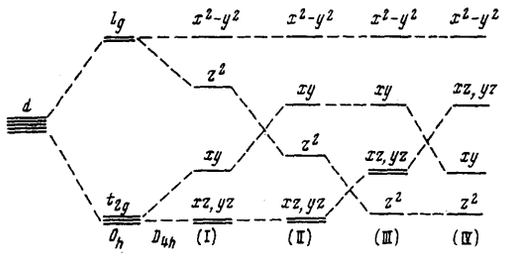

Figure 1. Possible types of splitting of the α-levels in square planar complexes of symmetry D_{4h}.

Scheme (III) is evidently supported [6,28] by the presence of two positive dichroic components in the $d-d$ region with several complexes of types $[M(diam)_2]^{2+}$ and $[MCl_2diam]$, where diam = *l*-pn, *l*-chxn and M = Pd^{2+}, Pt^{2+}, Au^{3+}. However, a study of the circular dichroism of the $[Ni(l\text{-pn})_3]^{2+}$ ion, which exists in certain solvents as a yellow (planar, diamagnetic) form, showed the existence of three dichroic $d-d$ bands, two of which had $g \geqslant 0.01$, which was interpreted as supporting scheme (IV).[26] A similar result was obtained from a study of the optical rotatory dispersion and the circular dichroism of dichelate complexes of Ni^{2+} and Pd^{2+} with amides of amino-acids, which also exhibited considerably greater splitting of the band in the circular dichroism spectra than in the absorption spectra [29]. The 1 : 1 and 1 : 2 complexes of Ni^{2+} with the amino-acids themselves have also been examined spectropolarimetrically [30].

The circular dichroism spectra of square planar complexes of Ni^{2+} and Pd^{2+} [31,32] with deprotonated tri- and tetra-peptides each contain two maxima in the $d-d$ range, which have been assigned, on the basis of their position and intensity, to $A_{1g} \rightarrow A_{2g}$ and $A_{1g} \rightarrow Eg$ transitions, in conformity with scheme (II) (Fig.1).

The pattern changes substantially on passing to complexes of nickel(II) with cysteine and its ester. The latter complex has three components in the absorption and circular dichroism spectra, the middle one of which is split into peaks of opposite sign in the complex of the cysteinate ion. Since only Eg among the three possible $d-d$ transitions is degenerate, this type of splitting of the bands indicates the sequence $A_{2g} < Eg < B_{1g}$ for the three transitions: i.e. the order of the a levels in complexes having the chelate unit $[MN_2S_2]$ differs significantly from their sequence in systems with an $[MN_4]$ chelate unit [31].

Complexes of nickel(II) with quadridentate Schiff bases [33,34], such as $(sal)_2(-)$-pn and its analogues produced by varying both the diamine component [RR(−)-chxn] and the aldehyde component (7-Mesal, acac, aba, pca, mpk), [35] exhibit an especially marked contrast between the circular dichroism and absorption spectra. The former displays up to three components in a range where the absorption spectrum contains only a shoulder on an intense charge-transfer band. As was to be expected, the increase in symmetry on passing to complexes with an $[MN_4]$ chelate unit, e.g. with $(aba)_2(-)$-pn as ligand, leaves only one transition in the circular dichroism spectrum, which does not appear at all in the absorption spectrum [35].

A new method of interpreting the absorption spectra of optically inactive complex compounds, based on a study of the circular dichroism induced in the $d-d$ transitions of the metal by optically active solvents, should prove extremely useful. Thus measurement of the circular dichroism spectra of the ions $[PtCl_4]^{2-}$ and $[Ni(CN)_4]^{2-}$ in $d(-)$-butane-2,3-diol and $d(-)$-propane-1,2-diol respectively has confirmed scheme (I) for the arrangement of the d-levels of these metals [7,36].

4. Metals with d^1 and d^9 Electronic Configurations

Depending on the symmetry of the environment, Cu^{2+} ions may give up to four transitions in the $d-d$ range, whereas the absorption spectrum usually contains one or at best two individual bands. Even in the spectra of single crystals of $[Cu(L\text{-aa})_2]$ in polarised light only two transitions could be observed—$^2A \rightarrow {}^2A$ and $^2A \rightarrow {}^2B$.[37]

The circular dichroism spectra of 1 : 2 complexes of Cu^{2+} with amino-acids revealed all four components of magnetic-dipole-allowed $d-d$ transitions, in conformity with the predictions of theory for C_{2h} symmetry (*trans*-$[MN_2O_2]$ chelate unit). The signs of these dichroic bands for amino-acids of the *L*-configuration are +, +, −, − in the hypsochromic direction [38]. Complexes with *D*- and *L*-alanine, *L*-serine, *L*-valine, *L*-threonine, *L*-allothreonine, *L*-proline, etc. have been investigated [39]. The circular dichroism spectra of 1 : 2 complexes of Cu^{2+} with

(+)-pseudoephedrine and (+)-2-aminopropanol each contain two dichroic components of opposite sign in each of the two bands in the absorption spectrum [40].

The circular dichroism spectra of complexes containing a *cis*-$[MN_2O_2]$ chelate unit—including chelates of Cu^{2+} with quadridentate Schiff bases from optically active diamines, e.g. R(−)-pn and RR(−)-chxn—contain three bands (symmetry of complexes C_2) all representing electric and magnetic-dipole-allowed transitions, and hence quite intense. These bands were assigned to $d_{z^2} \rightarrow d_{xy}$, $d_{x^2-y^2} \rightarrow d_{xy}$, and $d_{xz} \rightarrow d_{xy}$ transitions on the basis of a study of the effect of solvents coordinated along the z-axis of the complex on the circular dichroism spectra (the effect is largest with the $d_{z^2} \rightarrow d_{xy}$ transition) and an analysis of the relative sensitivity of these bands to the increasing degree of tetragonal distortion of the chelate unit when the azomethine hydrogen of the ligand is replaced by alkyl (the effect is greatest for the $d_{x^2-y^2} \rightarrow d_{xy}$ transition owing to the breakdown of π-bonding). The assignment of the bands led to the following proposed [41] sequence of the Cu^{2+} orbitals

$$d_{xy} \gg d_{x^2-y^2} > d_{z^2} > d_{xz}.$$

Observation of the individual components in the $d-d$ region has also permitted a more definite arrangement of all the ligands investigated [Schiff bases of various aldehydes with (−)-pn] with increase in the field that they produce [41].

Thus in these cases the circular dichroism spectra have proved extraordinarily useful not only as a method of observing individual $d-d$ transitions but also for studying the slightest distortions of planar complexes, information on which cannot be obtained in any other way [41].

The molecular orbital model predicts for oxovanadium-(IV) complexes the scheme of levels $^2B_2 < {}^2E < {}^2B_1 < {}^2A_1$, where the ^2E state may be resolved if the symmetry diminishes. The circular dichroism spectra of vanadyl-(IV) *d*-tartrato- and *l*-lactato-complexes show that this splitting into two components of opposite sign is sufficiently large only in the 1 : 2 complexes. In the region of one broad band in the absorption spectrum the circular dichroism spectrum reveals three electronic transitions, two of which ($^2B_2 \rightarrow {}^2E$ and $^2B_2 \rightarrow {}^2B_1$) are magnetic-dipole-allowed, while $^2B_2 \rightarrow {}^2A_1$ is not so allowed [42].

5. Metals with d^0 and d^{10} Electronic Configurations

The optical activity of complexes of zinc and isoelectronic metals is concentrated in the ultraviolet and is due only to internal transitions in the ligand and perhaps to a charge-transfer band. In zinc complexes of amino-acids, for example, an $n \rightarrow \pi^*$ transition of the acyl portion of the ligand is the first at long wavelengths [43]. However, valuable information on the structure of a complex can be extracted from the optical activity even of intraligand transitions. Thus the splitting of the $\pi \rightarrow \pi^*$ transition of the azomethine chromophore in the complex $[Zn(sal)_2(-)$-pn] into two components of opposite sign in the circular dichroism spectrum has been attributed, in conformity with the postulates of exciton theory, to a tetrahedral structure of the complex compound [33,34].

6. Metals with an f^n Electronic Configuration

The spectral behaviour of rare-earth metal complexes is especially complicated. The absorption spectra of lanthanide(III) ions in the visible and ultraviolet ranges are due to transitions of electrons from the ground j-level to the following j-levels in the f^n configuration ($n = 2-12$). Splitting of the j-levels of the free ion into the Stark components, which is usually too small to appear in the absorption spectra, is observed excellently in the circular dichroism spectra. The contrast between the resolving power of these two types of spectra is especially marked here. For example, the absorption spectrum of the 1 : 1 praseodymium(III)–tartrate complex contains three bands in the range 430–510 nm, whereas 21 components are observed in the same wavelength range of the circular dichroism spectrum [45]. Spectra of the latter type contain several sharp extrema near each band in the former with all the spectropolarimetrically investigated complexes of amino-acids with neodymium(III) [46] and praseodymium-(III), [47] hydroxy-acids with praseodymium(III), [45] and *l*-propylenediaminetetra-acetic acid with praseodymium-(III), neodymium(III), samarium(III), dysprosium(III), and erbium(III). [4]

The absorption spectra of rare-earth metal ions usually vary little with the chemical environment, in comparison with 3*d*-transition metal complexes. The only exceptions are a few transitions, which have been termed hypersensitive [48]. Study of the circular dichroism spectra of optically active rare-earth metal complexes has significantly expanded the number of such hypersensitive bands, which have been called c.d.-sensitive, in contrast to most other components of the circular dichroism spectrum, whose intensity is proportional to that of the corresponding band in the absorption spectrum. These latter dichroic maxima usually have g-factors of $10^{-5}-10^{-6}$, whereas this quantity increases tenfold for the c.d.-hypersensitive bands, to the order of $10^{-4}-10^{-3}$. [49]

The increase in the number of bands responsive to a change in the structure of the complex, on passing from the absorption to the circular dichroism spectrum, undoubtedly enhances the value of applying spectropolarimetry to structural investigations. For example, the conversion of unidentate ligands (amino-acids, gluconic and galactonic acids) in the coordination sphere of the europium(III) ion into chelated ligands, with increase in the pH, produces a considerable increase in intensity and reversal of sign in the dichroic band corresponding to the $^5D_1$ transition, while the absorption spectrum remains almost unchanged. The substantial differences both in intensity and in the character of the splitting of circular dichroism spectra may be due to finer structural differences in related ligands, such as e.g. alanine and serine, gluconic and galactonic acids [48].

The above values for anisotropy factors demonstrate the far smaller rotatory power of $f-f$ than of $d-d$ transitions. The weakening of the asymmetrising effect is probably due to the effective screening of f-electrons in the deeper atomic orbitals. The superposition of such weak Cotton effects due to $f-f$ transitions on the more intense Cotton effects centred in the short-wavelength region leads merely to a smooth resultant curve when the dispersion of optical rotation is measured, as has been observed e.g. with the lanthanide complexes of (−)-propylenediaminetetra-acetic acid. Because of such sharply diminished resolution of individual bands in the dispersion of optical rotation, this method is evidently far less useful for spectroscopic purposes. An interesting regularity in this case is the smooth increase in the molecular rotation at any point on such smoothed curves as a function of the ionic radius of the metal—from −275° to +210° for $[M]_D^{20}$ on passing from Yb^{3+} to La^{3+}. [50]

Thus the application of circular dichroism spectra to the investigation of rare-earth metal complexes is especially useful because of their higher resolving power compared with the absorption spectra and the presence of c.d.-hypersensitive (to fine structural features) bands.

III. DETERMINATION OF THE ABSOLUTE CONFIGURATION OF COORDINATION COMPOUNDS

It is important to determine the absolute configuration of optically active complex compounds not only for the sake of pure knowledge but also for spectroscopic purposes. As already remarked, bands observed in the absorption spectrum can be assigned to definite transitions on the basis of the sign and magnitude of the rotatory power of the latter, provided that the chirality of the environment of the metal ion is known.

Existing indirect methods for determining the absolute configuration of dissymmetric metal complexes usually involve measuring the circular dichroism and the optical rotatory dispersion and are of three types—(*a*) non-empirical methods based on the postulates of exciton theory, (*b*) semi-empirical methods, which include all kinds of octant rules, and (*c*) empirical methods, in which certain properties of the test substance (mostly the character of the dispersion of optical rotation or the circular dichroism in a certain range) are compared with those of a standard compound whose absolute configuration is known from X-ray examination.

As in organic chemistry, X-ray examination is undoubtedly the most direct and convincing. The sharp increase in the number of X-ray structural studies on optically active coordination compounds during recent years provides a firm foundation for further correlations among related compounds by means of the dispersion of optical rotation and circular dichroism [51].

1. Nomenclature

A quite varied notation has been used for absolute configurations in the literature. Opposite (left and right) chiralities in tri- and *cis*-di-chelate compounds are denoted as *D* and *L*, *M* and *P*,[52] Λ and Δ, $S(C_3)R(C_2)$ and $R(C_3)S(C_2)$, and are represented by the stereochemistry respectively of a left-handed and right-handed three-bladed propeller on clockwise rotation about the C_3 axis, and of right-handed and left-handed on rotation about the C_2 axis. The symbols Δ and Λ are used also to denote the absolute configurations of tetrahedral complexes of bivalent metals [34].

Preliminary proposals have recently been published for the nomenclature of conformations and configurations of octahedral six-coordinate complexes of various types, based on the representation of helical systems by two non-orthogonal skew lines [53].

2. Non-empirical Methods

The absolute configuration of a complex compound can be determined by quantum-mechanical calculation of the signs of the circular dichroism to be expected in the region of internal transitions of the ligands [54], especially those having their own system of π-bonds, such as 1,10-phenanthroline and 2,2′-bipyridyl [54]. This line of attack is especially important for complexes of metals having a d^0- or d^{10}-electron shell, to which the usual correlations based on the signs of the rotatory powers of *d*–*d* transitions are inapplicable [55].

The first successes in this field [56,57] have since been greatly extended by Bosnich [58,59] and several other workers [60–62]. The use of the exciton theory of optical activity to determine the absolute configuration of a complex ultimately requires knowledge merely of the direction of polarisation of a certain electron transition in the ligand and the approximate geometry of the complex. The method is based on analysis of the type of exciton splitting of one of the ligand transitions (most frequently $\pi \rightarrow \pi^*$) in the circular dichroism spectrum into two equal and opposite components. With a Λ absolute configuration about the central metal atom in tetragonal complexes, for example, the negative component of such a doublet should occur at a higher energy, but conversely with the Δ configuration [33]. In fact, with copper(II) complexes of quadridentate Schiff bases from RR(−)-chxn, which preserves stereospecifically the Δ configuration at the central metal ion, positive and negative resolved components of the azomethine $\pi \rightarrow \pi^*$ transition are observed at higher and lower energies respectively [41].

There are certain indispensable conditions for the exciton splitting of a transition: firstly, two or more chelate rings having π-electron systems must be present; secondly, the two chromophores of two ligand molecules in the complex must be non-coplanar (thus analysis of the optical activity of complex compounds in the ultraviolet yields the most valuable information on the smallest departures from planarity in the chelate unit); and thirdly, the transition should have approximately the same energy and intensity whether the ligand is free or coordinated [18]. A further condition for the successful application of this method is absence of overlapping between the components of the exciton splitting and adjacent bands, e.g. a charge-transfer band.

The predictions of the exciton theory have been confirmed by chemical methods [63] in a series of complexes related to $[Co\,phen_3]^{3+}$ and $[Co\,bipy_3]^{3+}$. Determination of the absolute configurations of complexes by means of the criteria of the exciton theory is undoubtedly a promising method [64,65].

3. Octant Rules

Various octant rules are widely applied in organic chemistry to determine the absolute configurations of cyclic carbonyl compounds from the sign of the Cotton effect for the $n \rightarrow \pi^*$ transition in the carbonyl group [66].

In coordination chemistry the situation is greatly complicated by the practical impossibility of finding any isolated non-degenerate transition common to all complexes of various metals with different types of ligands. Nevertheless, such regular relations between the signs of the Cotton effect and of the octant (and hence the configuration) have been established for *d*–*d* transitions chosen in a certain fashion.

The sign of each octant is given by the product of its coordinates; the octant sign of the complex is obtained by adding those of its component chelate rings, where the sign of each atom should correspond to that of the octant in which it is situated. The main rules for arranging complexes in a right-hand coordinate system were worked out by Hawkins and Larsen [67], who showed their applicability not only to diamine chelates but also to other complexes containing bi- and multi-dentate ligands [68,69]. This

last is especially important, because establishing the absolute configurations of complexes containing multidentate ligands by comparing their circular dichroism and optical rotatory dispersion with those of complexes of bidentate ligands does not always yield the correct results[70].

The following general empirical octant rule has been suggested for cobalt(III) complexes from an analysis of well known published data: if a cobalt(III) complex of symmetry D_3, D_2, C_2^a, and C_2^b‡ has a ^1E, $^1B_1$, ^1A, or ^1B transition respectively with a negative Cotton effect, it possesses an absolute configuration corresponding to a negative octant sign[71]. Similar rules can probably be deduced for complexes of other metals.

This general octant rule was found to apply also to several square planar complexes of copper(II) with such ligands as gly$_2$(−)-pn, gly$_2$(−)-chxn, and (+)-ala$_2$en.[72] On passing to complexes of copper(II), nickel(II), and palladium(II) with deprotonated tri- and tetra-peptides, however, their optical activity can no longer be explained in terms of a simple octant rule, since substituents attached to an α-carbon atom are situated in octants of opposite sign with the same absolute configurations of the amino-acid residues. A so called double octant or hexadecadic rule was therefore suggested, according to which the complex is placed in a coordinate system with sixteen sectors alternating in sign. The example in Fig. 2 shows that all methyl groups of the three L-alanine fragments are located in negative octants, which correlates well with the negative total Cotton effect of the $d-d$ transitions of this complex[73].

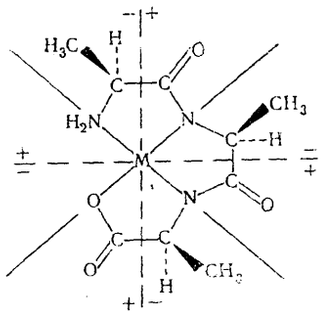

Figure 2. Distribution of charges in square planar complexes according to the octant rule.

Both the identity of sign of the dichroic bands for a series of tripeptides in which the position of an optically active amino-acid residue varies (e.g. alaglygly, glyalagly, glyglyala) and the additivity of the contributions made by asymmetric carbon atoms in different positions in an oligopeptide ligand in its 1 : 1 complex with nickel(II)[31] and palladium(II)[32] are excellently explained on the basis of the hexadecadic rule. Certain departures from additivity in the presence of an amino-acid residue with a bulky side-chain in the N-terminal position are explained by the appearance of a conformational contribution, opposite in sign to the vicinal contribution[31].

The octant rules for the $n \rightarrow \pi^*$ transition of the carbonyl chromophore, worked out by Moffitt for organic compounds, have been used equally successfully in coordination chemistry[74]. Thus a study of copper(II) complexes with L-cysteine and L-histidine showed that the Cotton effect of the $n \rightarrow \pi^*$ transition (~220 nm), which is positive in the copper(II) complex with the methyl ester of cysteine, becomes strongly negative in the complex with the free amino-acid. The opposite octant signs of the two complexes result from a change in conformation: chelation involving the carboxyl stabilises a conformation which is impossible for the ester[75,76].

Thus the employment of octant rules in interpreting optical rotatory dispersion and circular dichroism yields valuable information both on the absolute configuration of a complex and on its conformational features.

4. Empirical Methods

Several empirical methods can be distinguished depending on the way in which the relatedness of configurations of two complexes is established.

(*a*) Spectroscopic methods

The absolute configurations of two related dissymmetric molecules can be said to be identical if the Cotton effects have the same sign in the same spectral range. Thus the occurrence of a positive Cotton effect at 470 nm in the series of complexes—D(+)-[Co en$_3$]$^{3+}$, (+)-[Co(+)-pn$_3$]$^{3+}$, (−)-[Co(+)-chxn$_3$]$^{3+}$, (+)-[Co(−)-tn$_3$]$^{3+}$, (+)-[Co.(*meso*-2,3-bn)$_3$]$^{3+}$, (+)-[Co(−)-cptn$_3$]$^{3+}$, and (+)-[Co en$_2$.ibn]$^{3+}$—enabled the same, D-configuration to be assigned to all of them on the basis of the L-configuration established for the first member by X-ray diffraction[77].

However, such configurational correlations without preliminary assignment of the bands give sufficiently correct results only with closely related compounds. The possibilities of the method are considerably extended by using the rotatory powers of individual transitions to relate the configurations. An empirical rule for trigonal metal complexes (symmetry D_3) connects their configuration with the sign of the rotatory power of the E_a transition ($^4E \leftarrow {}^4A$ for Cr^{3+} and $^1E \leftarrow {}^1A$ for Co^{3+}): the rotatory power (R) of the E_a transition is positive for complexes having the $M(C_3)(D,\Lambda)$ configuration and negative for complexes having the enantiomeric $P(C_3)(L,\Delta)$ configuration[78]. The second component A_2 of band I has negative and positive Cotton effects for the $M(C_3)$ and $P(C_3)$ configurations respectively[79]. The range of application of this rule is probably quite wide: it covers the most diverse cationic, anionic, and inner-complex compounds with bi- and multi-dentate ligands, e.g. [Co diam$_3$]$^{3+}$,[9] [Co aa en$_2$]$^{2+}$,[80,81] [Co edda(L)] (where [(L) =] L-gly, L-ala, en, l-pn),[82] [Co ox$_n$acac$_{3-n}$]$^{m-}$ (where n = 1, 2, 3),[83] [Co(+)-pdta]$^{3-}$, and [Co aa$_3$].[52]

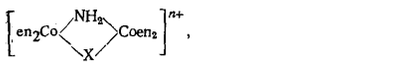
In the trisamino-acid complexes the $^1A \rightarrow {}^1E$ transition in the β-isomers and the dominant peak in the region of band I of Co^{3+} for the α-isomers have positive rotatory power if the complex has the D-configuration;[13,52,84] the latter has been confirmed by the determination by X-ray diffraction of the absolute configuration of α(+)-[CoL-ala$_3$].[85] This rule was used in assigning the D-configuration to the 1,2,3-isomer of (+)-[Co(+)-hmch$_3$], having a

‡ The notation C_2^a and C_2^b denotes complexes of symmetry C_2 with (*a*) configurational and (*b*) conformational asymmetry.

related geometry, on the basis of the positive rotatory power of the E-transition [34].

Similar regularities constituted the grounds on which the $\Lambda(C_3)$ configuration was ascribed to a series of rhodium(III) complexes, such as $(+)_D$-[Rh aa$_3$] [86] and the mixed $(-)_D$-[RhL-aa en$_2$]$^{2+}$, where aa = ala, val, leu, ser, threo, meth [87].

The absolute configurations of dinuclear complexes, e.g.



are established on the basis of the analogy of their circular dichroism spectra and optical rotatory dispersion curves with those of corresponding mononuclear complexes [88,89].

An exception to the general rule is $(-)_D$-[Cr big$_3$] with a $\Lambda(C_3)$ configuration according to X-ray diffraction [90] and a negative E_a component in the circular dichroism spectrum [15]. On the other hand, further investigations have shown that the above relations are entirely correct only when sufficiently analogous complexes are compared. Thus the absolute configuration $(-)_D$-[Co tn$_3$]$^{3+}$ determined by X-ray examination [91] was enantiomeric to that previously assigned on the basis of rules for complexes containing five-membered chelate rings [77]. Moreover, the two cations $(-)_D$-[Co tn$_3$]$^{3+}$ and $(-)_D$-*cis*-[Co(NCS)$_2$tn$_2$]$^+$, which have the same absolute configuration (Λ) according to X-ray results [91,92], have enantiomeric circular dichroism spectra, probably owing to a change in the sequence of the E_a and A_2 components into which the absorption band I of Co^{3+} is resolved [93].

Considerable risk is entailed [95] in the spectroscopic assignment of absolute configurations to complexes of multidentate ligands on the basis of the analogy of their optical rotatory dispersion and circular dichroism with those of analogous complexes of bidentate ligands of known configuration [94]. Thus X-ray determination showed the absolute configuration of the ion $(+)_D$-[Co penten]$^{3+}$ to be enantiomeric to that predicted earlier from the circular dichroism spectra [97].

Here we have the additional difficulties of bringing the chirality of the arrangement of the rings in a multidentate ligand into unambiguous correspondence with the simple Δ and Λ configurations. Thus even in the coordination of a terdentate ligand (2,3-diaminopropionic acid) into a 1 : 2 complex, for example, the helicity of the arrangement of the ethylenediamine chelate rings corresponds to a Λ configuration, while the α- and β-amino-acid chelate rings are arranged about the metal in a Δ-configuration [98].

In such cases the most unequivocal results are undoubtedly obtained by X-ray examination of typical representatives of the classes of complexes. Determination of the absolute configuration of the cobalt(III) complex of L-3,8-diMetrien suggested [69] the following empirical relation between the sign of the circular dichroism and the chirality of the complex for linear quadridentate ligands: a complex having a negative Cotton effect in the region of the band corresponding to the $^1A_{1g} \rightarrow {}^1T_{1g}$ transition in Co^{3+} has a Δ-configuration [69].

However, errors can be avoided even within the limits of spectral methods by "ring pairing", which consists essentially in constructing every possible combination of two non-bonded chelate rings, and determining for every pair the chirality with respect to the C_2 axis. The dominant chirality determines the designation of the configuration [99].

In some cases it is useful, in determining the absolute configuration of the complex, to examine the effect of outer-sphere coordination of readily polarisable anions—such as selenite, sulphate, phosphate—on the dispersion of optical rotation and the circular dichroism. If the complex has a D-configuration, the effect is to increase the intensity of the A_2 component in the circular dichroism spectrum with a parallel decrease in the height of the E peak, probably owing to formation of an ion-pair [97,100].

It is evidently possible to use not only spin-allowed but also certain spin-forbidden $d-d$ transitions to determine the absolute configuration of a complex. The absolute configurations of trichelate complexes of chromium(III) with the most diverse ligands—en, tn, *o*-phen, ox, tart, etc.—correlate well with the sign of the rotatory power of the low-frequency component in the circular dichroism spectrum that corresponds to a ^2E_a transition: if its rotatory power is positive, the absolute configuration of the complex ion is $\Delta(C_2)$. [101]

Nuclear magnetic resonance spectroscopy has recently found increasing use for confirming results obtained by analysing the dispersion of optical rotation and the circular dichroism of complexes of diastereomeric type, i.e. with two sources of asymmetry [102-104]. For example, comparison of the n.m.r. spectra of the two isomers (+)- and (−)-[Co ox$_2$(−)-pn]$^-$ revealed that the chemical shifts of methyl protons in (−)-pn were larger in the Δ- than in the Λ-configuration [105].

Study of the stereochemistry of substituted metallocenes [106-112] is also based on comparing the signs of the circular dichroism of certain $d-d$ transitions, but this class of sandwich compound constitutes too specialised a field of coordination chemistry to be discussed in greater detail here.

(*b*) Non-spectral methods

Chemical conversion of a complex compound into another of known absolute configuration is a quite rigorous method for correlating configurations provided that the reaction does not involve rupture of any M−L bond. Until recently the use of chemical correlations in coordination chemistry was only incidental, since in most reactions of complex compounds this condition—and hence the preservation of the configuration during the changes—cannot be guaranteed [113].

The oxidation of (+)-[Ru phen$_3$]$^{2+}$ with potassium permanganate followed by reduction of the resulting 3,3′-dicarboxy-2,2′-bipyridyl in the coordination sphere to (+)-[Ru bipy$_3$]$^{2+}$ served as basis for assigning optical configurations to a long series of complexes of general type [M bipy$_n$phen$_{3-n}$]$^{m+}$, where $n = 1-3$, and M = Ru^{2+}, Fe^{2+}, Ru^{3+}, Os^{2+}, Os^{3+}, Co^{3+}, and Ni^{2+}. [114] A similar attempt to convert [Co phen$_3$]$^{3+}$ into the bipyridyl complex halted at the stage of complexes of cobalt(III) with 5-nitro-1,10-phenanthroline and 1,10-phenanthroline-5,6-quinone, which is also of some value [63].

Reduction of the [Ru en$_3$]$^{3+}$ ion to [Ru en$_3$]$^{2+}$, during which the optical activity was maintained, enabled the rules for the assignment of configurations obtained with d^6 metals to be extended to dissymmetric trigonal complexes of d^5 metals [115].

Two further reactions in which the asymmetric centre is unaffected are the oxidation of the cysteine complex of cobalt(III) to the cysteinesulphinate complex [116] and the conversion of L-[Co gly en$_2$]$^{2+}$ into L-[Co ser en$_2$]$^{2+}$ by Knoevenagel's reaction [117].

The chemical assignment of configurations by oxidising a dinuclear tartrato-complex to a monomeric oxalato-complex is not only of intrinsic interest but also a basis for further correlations in a series of bridged dinuclear complexes by their spectroscopic comparison with mononuclear complexes [118,119].

The general configurations of a series of complexes of general type $[CoXYen_2]^{n+}$ [where XY = $(CN^-)_2$, $(NCS^-)_2$, $(NCS^-)(NH_3)$, and $(NH_3)_2$] has been established, on the basis of the known absolute configuration of the first member, from their interconversions under conditions that exclude racemisation [120].

The change from [Co edta]$^-$ to $[Co\,en_3]^{3+}$ involves the rupture of M–L bonds. Nevertheless, it occurs with partial retention of optical activity, the sign of which can be used in a certain range to establish the configuration of complexes of multidentate ligands [121].

Another useful criterion in determining absolute configurations is provided by the stereospecific requirements of an optically active ligand. In many cases only one isomer can be formed without special strain, and its configuration can be determined by constructing models based on the known absolute configuration of the ligand [5,122,123]. Sometimes the absolute configuration can be deduced from the preferential formation of one isomer rather than another [124]. The configuration of a complex with an optically inactive ligand can be established by comparing its optical rotatory dispersion and circular dichroism with those of an analogous complex of an optically active ligand, provided that the latter is formed stereoselectively. This is based on the insignificance of the vicinal contribution compared with the configurational contribution. An example is the establishment of identical configurations for the ions $(+)_D$-*trans*-$[CoCl_2trien]^+$ and $(+)_D$-*trans*-$[Co(SS)Cl_2(3,8\text{-diMetrien})]^+$, which have similar circular dichroism spectra [125]. However, such correlations, based on stereoselectivity, should evidently be confined to $d-d$ transitions, since in the region of a charge-transfer band the vicinal contribution becomes sufficient to affect not only the magnitude but also the sign of the rotatory power [124].

A solubility rule may also be useful in establishing the configuration of an optically active complex. It states that complexes of similar configurations have similar solubilities [126].

However, X-ray structural analysis undoubtedly provides the last word in solving the problem of the absolute configuration of a complex compound, as well as the soundest foundation for further correlations in a series of closely related compounds. The number of publications in this field has grown rapidly during recent years, the classic papers on trisethylenediamine [127–129] and tris-*l*-propylenediamine [130,131] complexes of cobalt(III) and of ethylenediamine with chromium(III) [132,133] having been supplemented by investigations on complexes of other metals, e.g. $[Cu\,l\text{-}pn_3]^{2+}$ [134] and $[PtCl_2en_2]^{2+}$, [135] and complexes with new ligands, e.g. *trans*-$[Cr\,atc_3]$. [136] Several reviews on this subject give a more detailed account of the state of the problem [51,85,137].

IV. NATURALLY OCCURRING OPTICALLY ACTIVE COMPLEX COMPOUNDS AND THEIR MODELS

This Section reviews the application of the optical rotatory dispersion and the circular dichroism of coordination compounds to structural studies on certain optically active natural macromolecular complexes and also complexes of metals with optically active natural macromolecules (polypeptides, nucleic acids).

Study of the optical rotatory dispersion of natural materials must take into account, besides the contributions from the asymmetric centres of amino-acids and from the helical secondary structure (where present), the role of the metal atom, which, on becoming an asymmetric centre, may make a large contribution to the total optical rotatory dispersion of the molecule. Establishment of the structure and the optical rotatory power of natural complexes of this type is made more important by the fact that metal atoms are usually biologically active portions of the molecule.

Complexes of metals with di- and tri-peptides can be regarded as model compounds. They are also of intrinsic interest as chelates with multidentate ligands.

Complexes of Di- and Tri-peptides

The optical rotatory dispersion curves for copper(II) complexes with dipeptides are in general similar to those of the corresponding amino-acid complexes, the shape of the curve being determined by several factors [138]. As was to be expected, the absolute configuration of the amino-acid residue contained in the dipeptide is the decisive factor in complexes without configurational asymmetry: the curves for mixtures of the Cu^{2+} ion with gly-*L*-ala and gly-*L*-ala are mirror images one of the other. Replacement of one amino-acid residue by another of the same configuration and without additional donor groups leads merely to an unimportant quantitative change in the optical rotatory dispersion. These two properties are undoubtedly of use for determining the configuration of an amino-acid involved in coordination.

Further, the form of the optical rotatory dispersion curve is strongly dependent on the type of complex present at a given pH. Addition of one, two, and three equivalents of alkali to a solution of a 1 : 1 mixture of the Cu^{2+} ion and a dipeptide (L)yields the complexes CuL^+, CuL, and $Cu(OH)L^-$, corresponding to successive stages of proton elimination from terminal amino-nitrogen, amide nitrogen, and a coordinated water molecule. The most marked changes in optical rotatory dispersion are observed on passing from the free ligand to the CuL^+ and CuL complexes, obviously owing to formation of the first and second chelate rings [138].

Similar titration with alkali with simultaneous determination of the circular dichroism spectra showed for amides of dipeptides the existence of two main types of complexes—CuL (protons dissociated from amide and peptide groups) and $CuOHL^-$ (third proton dissociates from coordinated water molecule). [139]

The position of the optically active amino-acid residue in the dipeptide molecule has a significant influence on the dispersion of optical rotatory dispersion. On passing from the Cu^{2+} complex with *L*-alagly to the complex with gly-*L*-ala, for example, the rotation increases sharply in absolute magnitude, and the curve passes into the negative region. Together with the close similarity in the dispersion of the gly-*L*-ala and *L*-ala-*L*-ala complexes, this presupposes that the carboxy-terminal amino-acid residue plays the dominant part, probably as a consequence of different degrees of non-planarity of the two types of chelate rings [138,140].

Investigations of the octahedral complexes of dipeptides with Co^{3+} are interesting because this ion activates certain

enzymes in reactions involving hydrolysis. Stereoselectivity in such systems is probably due to easier coordination of the metal with one of the enantiomorphs of the substrate, whose configuration is determined by the stereochemical requirements of the enzyme. Indeed it has been shown that, when dipeptides made up of amino-acids of *L*-configuration are coordinated with Co^{3+}, the preferred isomer of the complex also has always the *L*-configuration [141].

The optical rotation depends significantly on the position of the optically active amino-acid residue in the peptide chain also in complexes of copper(II) and nickel(II) with tripeptides. Thus we have the sequence

L-ala-*L*-ala-*L*-ala > gly-*L*-ala gly > gly gly-*L*-ala > *L*-ala gly gly

for the amplitude of the Cotton effect induced in $d-d$ transitions of the ions Cu^{2+} and Ni^{2+} (at 550 and 475 nm respectively) depending on the structure of the ligand in complexes of the type ML^-. Maximum rotatory power is thus obtained by introducing the optically active fragment into the middle chelate ring of the three. This is probably due to maximum departures from planarity in this metal ring, which contains two trigonal nitrogen atoms of deprotonated amide groups.

It is interesting that the contributions to the rotatory power of transitions made by asymmetric centres in each of the three chelate rings in tripeptide complexes are not only additive in magnitude but also identical in sign, which is readily explicable only within the framework of the hexadecadic (or double octant) rule [142]. Thus in a comparison of the integral circular dichroism areas in a definite region for the series of complexes of type NiL^- with the above four tripeptides containing the *L*-ala residue in different positions, for example, it was shown that the rotatory power of the complex with the first tripeptide constitutes 103% of the sum of those of the complexes with the other three tripeptides [141].

Tripeptides containing an *L*-histidine residue are already potentially quinquedentate ligands, and their complexes have considerably greater optical activity than those of simple tripeptides. This complicated ligand coordinates with metals through four nitrogen atoms—an imidazole, an amine, and two amide atoms. The circular dichroism data indicate that the optical rotatory dispersion curves represent the superposition of two Cotton effects (at 590 and 490 nm), the signs of which depend on the relative position of the histidine residue in the tripeptide molecule [143].

Detailed investigations of the coordination of model compounds—di- and tri-peptides—have permitted the study of more complicated systems. Thus the interaction of the polypeptide of apomyoglobin with Cu^{2+} and Ni^{2+} shows that it coordinates four metal ions—one at the terminal amino-portion and the other three at histidine portions inside the polypeptide chain [144]. Examination by means of circular dichroism of two copper-containing proteins—one of which acts as an electron-transmitting fragment in the cytochrome chain, while the other catalyses the oxidation of various aromatic structures by molecular oxygen—revealed a sharp increase in the rotatory power of $d-d$ transitions in these natural complexes compared with the models, perhaps as a consequence of a charge-transfer band between Cu^{2+} and Cu^+ located side by side [145].

Determination of the sites of coordination with a metal (Cu^{2+} and Ni^{2+}) in a series of proteins, such as lysin, vasopressin, conalbumin, α-chymotrypsin, etc., became possible as a result of preliminary investigation of the circular dichroism spectra characteristic of complexes of these metals with terminal amino-groups, histidine, and thiol-containing groups in model oligopeptides [146].

The circular dichroism spectra of rubredoxin (an iron-containing protein) have yielded evidence of the quasi-tetrahedral geometry of the environment of the metal (the chelate unit $[FeS_4]$, with the sulphur atoms from four cysteine residues) in this protein [147].

An interesting problem is the effect of metal ions on the secondary structure of polypeptides. Some metals stabilise a helical conformation of the macromolecules; others, on the other hand, break it down [148]. A model process—the interaction of copper ions with polyglutamic acid—has been examined by means of optical rotatory dispersion. Calculation of the spiral content from the rotation at 233 nm showed that the spiral structure is apparently preserved even at relatively high pH-values if a sufficient quantity of Cu^{2+} ions is added. The latter probably act as bridges stabilising the spirals [149]. A similar stabilising effect of metals on the structure of nucleic acids was suggested [150] from the dependence of the melting point and certain other properties of deoxyribonucleic acid on the content of metal ions. On the assumption that the sugars of DNA were involved in metal fixation, an investigation was made of equimolecular complexes of manganese, cobalt, nickel, and copper with adenosine triphosphate; their optical rotatory dispersion indicated that 2′,3′-hydroxy-groups of ribose were involved in coordinating the metal with the ATP molecule [151].

A further use of the optical activity of complex compounds is to establish the identity of natural and synthetic macromolecules from the optical rotatory dispersion of their metal complexes. For example, the optical rotatory dispersion curves of the natural antibiotic polymyxin B and its synthetic analogue, which are smooth up to 260 nm, carry too little information, in contrast to the complexes of these cyclic decapeptides, which exhibit clearly defined Cotton effects in the vicinal region. Analysis of the form of the curves for the complexes of the two substances showed their general qualitative similarity, with slight quantitative differences that disappear completely with time owing to denaturation of the natural macromolecule; this enabled the decapeptides to be regarded as identical [152].

Hitherto the discussion has been concerned mainly with complexes of metals with natural macromolecules. Such complexes are probably responsible for certain aspects of the functioning of enzymes containing a "labile metal". Another group of natural metal complexes contain various porphyrin systems, where the metal is firmly bound in a square planar complex with an $[MN_4]$ chelate unit, examples of which are haemoglobin, myoglobin [153], plastocyanin [154], cytochrome c [155,156], and other natural products, which have also been investigated by optical rotatory dispersion. The Fe^{2+} ion present in haem becomes asymmetric on coordination at the apical position with two different ligands (e.g. with two polypeptide chains, as in cytochrome c [155]). As a consequence both forms—oxidised and reduced—of this important respiratory pigment of blood have a sharp Cotton effect of great amplitude in the region of 530 nm. The optical rotatory dispersion results from the superposition of three effects—due to the asymmetric carbon atoms of the amino-acid residues, to the helical portions of the polypeptide chain, and to the asymmetric metal atom—and is quite complicated to interpret exhaustively. Nevertheless it was concluded, in view of the reversibility of the changes occurring in the dispersion on passing from the oxidised to the reduced

form of cytochrome c, that this process involved a change only in the electronic state of the metal, while the structure of the natural ligand remained unchanged [156]. Study of the concentration and temperature dependence of the circular dichroism spectra of ferrihaem octapeptide (a fragment of cytochrome c) has yielded information on the relative orientation of the haems; the results obtained on model systems are used to interpret certain structural features of haemoglobin and of cytochrome-c oxidase [157].

Several chlorophylls and protochlorophyll pigments have also been investigated by means of circular dichroism and magnetic circular dichroism [158]. A quite detailed study has been made of the effect of complex formation with several bivalent metals (zinc, copper, nickel) on the optical activity of bile pigments, which can also be included structurally among porphyrin ligands [159].

V. DETERMINATION OF THE ABSOLUTE CONFIGURATION OF ORGANIC COMPOUNDS

For many classes of organic compounds the transitions responsible for optical activity are at too high an energy level for direct observation of the Cotton effect to be possible without appropriate apparatus for the vacuum ultraviolet. This applies to alcohols, amines, carboxylic acids, hydroxy-acids, and most amino-acids [160]. The problem can be solved also by introducing into the molecule a chromophoric group, which absorbs in a spectral range convenient for measurement. Thus Djerassi and his coworkers achieved considerable success in using $n \rightarrow \pi^*$ transitions of C=S groups in so called "chromophoric derivatives" of hydroxy-acids, amino-acids, and steroids to establish their absolute configurations [66]. Yet complexes of transition metals are especially convenient as such "chromophoric derivatives", both spectroscopically (because of the position of their $d-d$ transitions in the visible range) and practically (thanks to the simplicity of preparation of the complexes and the possibility of working in solution without isolating them).

Since the first attempts at using the Cotton effects of metal complexes to study dissymmetric organic molecules [161-163] several papers have appeared on the use for these purposes of the vicinal effect in various types of complex compounds. The rational basis for such configurational comparisons is the hypothesis that similar ligands having the same configurations in related complexes should induce rotatory forces of the same sign in corresponding transitions of the metal ion. As the same ligand may form part of several types of complexes, e.g. trisbidentate and bisbidentate, this provides an opportunity for checking the accuracy of the assignment of a configuration. The absolute configuration can be postulated by comparison with complexes of a ligand of known absolute configuration. The identity of the configurations of a series of diamines—(−)-pn, (−)-bn, (−)-chxn, (−)-phenen, (+)-stien—has been established in this way [164].

Configurations have been assigned to a series of hydroxy-acids related to mandelic acid by use of the sign of the Cotton effect of the copper(II) complexes of the amidines of these acids, which is positive for complexes obtained from amidines of the $L(R)$ series and negative for those of the $L(S)$ series [165]. Since the amidines themselves also have a Cotton effect at 270 nm, it is recommended that the two optical rotatory dispersion curves of the ligand should be subtracted from the curve observed for the complex [166].

The absolute configurations of different asymmetric carbon atoms in polyhydroxy-carboxylic acids can probably be determined from the optical activity of complexes formed at definite pH-values. Thus the signs of the circular dichroism of praseodymium(III) complexes with hydroxy-acids obtained in acid and neutral medium correlate with the configurations of the α- and γ-carbon atoms respectively [45]. Europium(III) complexes of hydroxy-acids differing only in the configuration of the α-carbon atom have circular dichroism spectra of mirror-image type [48]. When hydroxy-acids coordinate with nickel(III) at low pH, the sign of the circular dichroism correlates with the absolute configuration of the α-carbon atom, whereas at higher pH the deprotonation of the β-hydroxyl and ring formation with the metal enable the sign for the neutral complex to be related to the configuration of the β-carbon of the ligand (aldonic acid) [167].

The sign of the Cotton effect in the visible range for biscomplexes of copper(II) and nickel(II) [30,168] with amino-acids also depends on the configuration of the ligand, rotatory powers of opposite sign being induced in transitions of these two metals [168]. Probably here too, on coordination of the metal with ter- and multi-dentate amino-acids under certain conditions, individual types of complex compounds can be distinguished by differences in the optical rotatory dispersion and circular dichroism. Thus L-asparagine on coordination with copper(II) induces in the region of 600 nm Cotton effects of opposite sign depending on the pH. [169] The circular dichroism spectra of 1 : 1 complexes of praseodymium(III) with potentially terdentate amino-acids have been used to study aspects of the chelation of these ligands in various media [47].

Torchinskii and Koreneva [170,171] proposed a method for determining the absolute configuration of α-amino-acids and their derivatives (including N-terminal amino-acid residues in peptides) by measuring the optical rotatory dispersion of chelate compounds of several metals—copper(II), nickel(II), zinc(II), cobalt(III), aluminium(III)—with Schiff bases of the amino-acids with certain aromatic o-hydroxy-aldehydes. The sign of the Cotton effect was shown to be determined by the absolute configuration of the α-amino-acid and to be independent of the sign of rotation of the free ligand: a negative Cotton effect corresponded to compounds of the L-series, and a positive effect to those of the L-series. The complexes do not need to be isolated in the free state.

We have been discussing the use for configurational correlations of the sign of the rotatory power of definite $a-a$ transitions in metal complexes. The use of charge-transfer bands has been proposed for the same purposes. In copper complexes of amino-acids this band is located at ~250–270 nm and is of the L→M type. The coordination of amino-acids of the L-configuration with copper(II) at pH 8–10 gives a charge-transfer band of negative rotatory power. It is supposed that correlations based on the rotatory power of these bands may be more generally applicable, since both possible conformations of five-membered chelate rings induce Cotton effects of the same sign in the charge-transfer bands for biscomplexes with copper [169].

A second possible way of eliminating additional effects due to conformational contributions is to use for the determination of configurations complexes in which the compound occurs as a unidentate ligand L, e.g. of the type $[CoL(NH_3)_5]^{2+}$, where L represents an amino-acid [160] or a hydroxy-acid [172]. Cobalt(III) complexes have the advantages of kinetic inertness and the fact that the spectroscopy of Co^{3+} has been well studied. There is no difficulty

in obtaining the above complexes under controlled conditions (pH ≃ 5, below 40°C), although in the case of potentially bidentate ligands raising the temperature may lead to loss of ammonia and chelation. The optical activity of complexes with unidentate ligands is due solely to the vicinal contribution by an asymmetric carbon atom: if the dominant Cotton effect of the long-wavelength spin-allowed transition in it is negative, the acid has the *L*-configuration, related to *L*(+)-lactic acid[160]. This method is obviously applicable only to carboxylic acids with an asymmetric centre in the α-position with respect to the carboxyl, since the increase in distance between this centre and the chromophore (here the metal) in β- and γ-substituted carboxylic acids produces a sharp decrease in the relatively small vicinal effect. Complexes of the same type $[CoLX_5]^{n+}$ but with more bulky optically inactive ligands X may be more useful in these cases. Even in a series of complexes $[CoLX(NH_3)_4]^{n+}$ increase in the volume of the optically inactive ligand X is accompanied by a significant increase in the vicinal effect of the *O*-coordinated unidentate α-amino-acid L, caused by the diminution in the conformational mobility of the optically active ligand L with growth in the steric requirements of the neighbouring group X.[173]

A further important advantage of using the non-chelate type of complexes consists in the possibility of making configurational comparisons between different classes of substituted carboxylic acids of general type R.CHX.COOH (X = Alk, OH, NH_2, etc.), since all $[CoL(NH_3)_5]^{n+}$ complexes have the same microsymmetry C_{4V} when the acids are coordinated through the carboxyl, so that the way in which the *d*-levels are split and the energetic sequence of the transitions should be the same independently of R and X. Such comparison of the configurations of amino- and hydroxy-acids cannot be based on the optical activity of chelate complexes of the type $[Co(R.CHX.COO)(NH_3)_4]^{2+}$, since their microsymmetry changes from C_{4V} when X = NH_2 to C_{2V} when X = OH. In conformity with this the splitting of the triply degenerate octahedral $^1T_{1g}$ level is different in the two cases: $^1T_{1g} \rightarrow {}^1A + {}^1E$ with C_{4V} microsymmetry, but $^1T_{1g} \rightarrow {}^1A + {}^1B + {}^1B$ with C_{2V}.

Nevertheless, monochelate complexes can be quite useful for comparing the configurations of a series of ligands of the same type. For example, an intense circular dichroism band in the region of the absorption band II of Co^{3+} at 342–335 nm may be useful for comparing amino-acids, its Cotton effect being negative for compounds of the *L*-configuration and positive for *D*-amino-acids in the complexes $[Co\,aa(NH_3)_4]^{2+}$.[8,22]

Complexes of other metals can also be employed for configurational comparisons. Thus the absolute configuration of the β-carbon atom of (+)-pseudoephedrine has been established[40] from the analogy of the circular dichroism and absorption spectra in the region of *d*–*a* transitions of copper biscomplexes of this ligand and of the related *L*-(+)-2-aminopropanol of known absolute configuration.

The effect of complex formation with copper (in the form of cuprammonium solutions) on optical rotatory dispersion is used widely for the stereochemical analysis of amino-sugars[174], cyclic diols and amino-alcohols[175], and their acyclic analogues[174]. The molecular rotation of sugars is significantly increased by complex formation with molybdate ions, and the anomaly in the dispersion at 345 nm has been proposed for the analysis of sugar isomers[176]. The conformation of the first three hydroxyls of the pyranose ring is significant for complex formation. Molybdate solutions of sugars show three or four Cotton effects in the range 220–350 nm if the hydroxyls are arranged in a *cis*–*cis* configuration, and two Cotton effects in the same wavelength range if they are in the *trans*–*trans* positions[177].

The configurations of alcohols and amines can be determined from the sign of the rotatory power of the bands at 480 and 420 nm due to dichelates of nickel with xanthate or dithiocarbamate ions obtained from these alcohols and amines respectively. Both the Cotton effects are negative when the alcohol or amine has the *l*-configuration, as has been shown for *l*-menthol, *l*-2-methylbutanol[178], and secondary amines obtained from *l*-phenylethylamine[179,180].

Another interesting application of the circular dichroism of metal complexes is to determine the configuration of alkenes, whose own π–π^* and n–σ^* absorption occurs in the fairly remote ultraviolet (190–200 nm). Existing methods for obtaining chromophoric derivatives—osmates and episulphides—disturb the geometry of the ethylenic bond and therefore are not always acceptable. The formation of π-complexes of platinum(II) with alkenes is free from this defect, so that chromophoric *d*–*a* transitions of Pt^{2+} have been successfully used for configurational comparisons.

When ethylenic compounds undergo π-type coordination with a metal, the substituted carbon atom of the double bond becomes asymmetric. Monosubstituted ethylenes acquire one asymmetric centre, and *trans*-disubstituted ethylenes acquire two such centres having the same configuration; *cis*-disubstituted ethylenes yield a *meso*-form on coordination, since the two asymmetric centres have opposite configurations[181]. In complexes of mixed type $[PtCl_2LL']$, containing an optically active amine L and an alkene L', the sign of the low-energy transition of Pt^{2+} is independent of the relative positions (*cis* or *trans*) of amine and alkene, and indicates only the configuration of the coordinated alkene. This conclusion is confirmed by applying the quadrant rule[182–189].

VI. DETERMINATION OF THE COMPOSITION AND THE STABILITY OF COMPLEX COMPOUNDS

As a consequence of the presence of an additional parameter—the sign of the optical rotation—optical rotatory dispersion and circular dichroism should be far more effective than ordinary spectrophotometry for determining the composition and the stability of complexes. Nevertheless, very little work has been done on these lines, and most investigators, even when working with optically active ligands, use only potentiometry or absorption spectra[190–192]. However, a few examples of the application of spectropolarimetry can be mentioned. A group of French workers have developed methods for determining the composition and the stability of complex compounds, in particular of copper(II), zinc(II), cobalt(II), nickel(II), and cobalt(III) with optically active amino-acids[193–196], and of iron(III) with tartaric acid[197]. The formation of complexes by molybdate, tungstate, and uranyl ions with hydroxy-acids[198], by zinc(II), cobalt(II), and nickel(II) with *L*-mandelic acid[199–201], and by arsenic acid with *d*(−)-mannitol[202] has been investigated by means of the optical rotatory dispersion or even simply by measuring the specific rotations at a single wavelength[203]. Similar results were obtained when the stability constants were determined by other methods, e.g. potentiometric pH measurement[200].

Circular dichroism can also be used to investigate complex formation [204], although the apparatus is less accurate [205]. However, determination of the stability constants of complexes of oxovanadium with lactic acid showed not only good agreement with those obtained by the independent method of absorption spectra over a wide range of values of $\bar{n}$ (the formation function) but also that circular dichroism is even more sensitive at low values of $\bar{n} \simeq 0.2$. [206]

The spectropolarimetry of complex compounds can be useful in determining not only their composition [207-209] and their stability [207,210] but also for the quantitative determination both of metals [211-214] and of organic compounds [212,215,216].

Measurement of the optical rotatory dispersion and the circular dichroism of coordination compounds will yield the most valuable information on the finest structural features of the environment of the metal. Thus a diminution in the rotatory power of $d-d$ transitions may indicate flattening of the chelate unit, e.g. by interaction with a donor solvent [217] or as a consequence of fewer steric interactions within the molecule of the complex [218-220].

Many other applications of spectropolarimetry—such as e.g. study of the reactions of coordination compounds by means of optical rotatory dispersion and circular dichroism [221-224], analysis of conformational equilibria in complex compounds [225], investigation of geometrical and optical stereoselectivity in the coordination of metals with optically active ligands, and certain other aspects—are not dealt with here, since they may form the subject of separate reviews.

---o0o---

In conclusion it may be stated that the wide application of spectropolarimetry in the field of inorganic chemistry during recent years has in effect provided a new method for studying the structure of coordination compounds, the possibilities of which have been by no means fully revealed so far.

Macromolecular and Oligomeric Compounds as Stabilisers for Polymers

L.M.Terman and L.S.Kochneva

The preparation is described of various types of macromolecular and oligomeric compounds, together with their use as stabilisers for polymers (to heat and light as well as to oxidation). Possible mechanisms of their action are discussed. Carbon-chain polymers, macromolecular and oligomeric compounds containing elements in Groups IV–VI of the Periodic System (silicon, tin, nitrogen, phosphorus, oxygen, and sulphur), and polymers having a system of conjugated double bonds are considered as stabilisers. These products have the advantages over the usual stabilisers of being polyfunctional, non-volatile, long lived in the polymers, and in individual cases considerably more effective. A list of 221 references is included.

I. INTRODUCTION

Polymeric materials, though possessing valuable physical and mechanical properties, have the important defect of undergoing various types of aging under the influence of heat, light, atmospheric oxygen, etc. One method for improving the operational durability of these materials is to introduce stabilisers into them. Various oligomeric and polymeric compounds have been proposed comparatively recently for this purpose, in addition to the usual stabilisers. As early as 1964 Kargin suggested that macromolecular additives to polymers were most effective for regulating almost any processes in them [1]. The chief advantages of macromolecular and oligomeric stabilisers can be summarised as follows.

1. By interacting with the polymer during its degradation such stabilisers may prevent a decrease in the molecular weight of the material [1] associated both with depolymerisation and with the chance rupture of macromolecular chains.

2. Macromolecular and oligomeric stabilisers possess valuable technical properties—non-volatility, prolonged retention in the polymer, and, when of similar chemical structure, good compatibility with the latter.

3. In several cases these stabilisers are more effective than analogous compounds of low molecular weight.

The chief obstacle to the widespread application of polymeric and oligomeric stabilisers is probably the difficulty of blending them with the stabilised polymer, and also the possible adverse influence of degradation products of these stabilisers.

Polymeric and oligomeric derivatives of elements in Groups IV–VI of the Periodic System—carbon, silicon, tin(IV), nitrogen, phosphorus(V), and oxygen, sulphur, selenium, tellurium(VI)—have now been suggested as stabilisers for plastics. A large number of novel heteroatomic polymers have been synthesised during recent years [2–4], many of which have still been little studied and have not found practical application. It must be expected that in the near future macromolecular derivatives of such elements as boron, germanium, lead, and antimony will considerably supplement the list of practically useful polymers in general and effective polymeric stabilisers in particular.

Mainly factual data on polymeric and oligomeric stabilisers have been published; very few investigations have been made on the mechanism of their action. The aim of the present Reviewers has been not only to assemble and systematise the available information but also to direct the attention of research workers to this new and interesting branch of the chemistry and technology of high polymers.

II. HETEROATOMIC MACROMOLECULAR AND OLIGOMERIC COMPOUNDS

1. Polyorganosiloxanes

Polyorganosiloxanes have been suggested comparatively recently for protecting polymeric materials from thermal and thermo-oxidative degradation and from the action of ultraviolet radiation. They possess great resistance to oxidation and high temperatures. Their own thermal stability is strongly influenced by the nature and number of the organic radicals attached to the silicon atom: methyl and ethyl groups lower the thermal stability of polyorganosiloxanes, whereas phenyl groups enhance it [5,6]. Chemical modification of polyalkenes by liquid polyorganosiloxanes [7–9] leads to an improvement in their stability towards aging by heat and light. Modification was effected by heat-treating either the crude polyalkene or manufactured articles in the liquid polyorganosiloxane. The first stage in the modification of (low-density) polyethylene is regarded as the production of free radicals by the oxidation of carbon–hydrogen bonds at tertiary carbon atoms. The resulting hydroperoxy-groups in turn oxidise the organic portion of the (stabiliser) molecules with the rupture of silicon–carbon bonds. Subsequent reactions yield Si–O–C groups, as is confirmed by the infrared spectra of the modified polyethylene (absorption in the region of 1077, 1044, and 936 cm^{-1}). Furthermore, polysiloxane units are grafted on also at double bonds, as evidenced by the diminished number of unsaturated groups in the modified polyethylene (disappearance of absorption in the region of 886 cm^{-1}). Thus the great stability of modified polyalkenes to all forms of aging is explained

by a decrease in the number of mobile hydrogen atoms at tertiary carbon atoms and by the formation of energetically stable siloxane bonds in the macrochains. Similar mechanisms are probably responsible for the action of liquid polyorganosiloxanes containing the units

$$[(CH_3)(OSnR_3)SiO]_n \qquad (I)$$

(where R is a C_1–C_{12} alkyl), [10,11] and also for those of polyphenyl(hydroxyphenylpropylphenoxy)silcane and polyphenylaluminosiloxane [12]. These compounds exert a strong stabilising effect at high temperatures and surpass industrial organotin stabilisers in effectiveness.

Poly(vinylidene chloride) preserves its colour well at 130°C in the presence of

$$R[-O-Si(CH_3)(C_6H_5)]_nOR \qquad (II)$$

where R = t-butyl or pentyl and $n = 1$–5. [13] Improving the stability of the liquid polyorganosiloxanes themselves to thermal oxidation may enhance their stabilising effect. Thus additions of 8-hydroxyquinoline–titanopolydimethylsiloxane increase the thermal stability of liquid polyorganosiloxanes by factors of 15–18. [14]

2. Tin-containing Polymers and Oligomers

Organotin compounds have become widely used for stabilising plastics based on poly(vinyl chloride). They improve the stability towards heat and light, and are antioxidants. An advantage of organotin stabilisers is that their decomposition products strengthen the stabilising effect; whereas the decomposition products of stabilisers not containing tin often accelerate the degradation of poly(vinyl chloride). [1,15] In fact, because of the presence of organic residues attached to the tin atom through an oxygen atom, a sulphur atom, or a carboxy-group, the double decomposition of organotin compounds with hydrogen chloride yields, depending on the nature of these residues, thiols, dienophilic reagents, epoxy-compounds, phenols, ethers, esters, and other products which themselves have a stabilising action. Effective organotin stabilisers of poly(vinyl chloride) combine the functions of an inhibitor of dehydrochlorination of the polymer, an acceptor of hydrogen chloride, and a dienophile [16,17]. Organotin stabilisers probably coordinate with segments of conjugated double bonds in the polymers, thereby ensuring that the polymer retains its original colour for a long time [18]. However, no convincing evidence has yet been found for this.

Increasing interest has recently been taken in polymeric organotin stabilisers, since they are usually more effective than the corresponding stabilisers of low molecular weight. They have the considerable advantages of almost complete non-toxicity and of insolubility in water. The mechanism of the stabilising action of polymeric organotin compounds has not been studied. It can only be assumed that their action is closely analogous to that of the corresponding simple compounds [1].

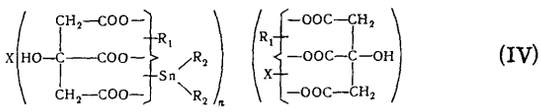
Poly(vinyl chloride) and copolymers of vinyl chloride are stabilised by polymeric alkyl(cycloalkyl)aryl-stannonic and -thiostannonic acids or their condensation products [19–22].

Polymeric organotin carboxylates and alkyl sulphides [23–26] are more effective than those of low molecular weight. Poly(vinyl chloride) resins are stabilised by the introduction of 0.1 -- 5.0 wt. % of the reaction product of a poly(alkyl(ene)tin oxide or dihalide) with an alkali-metal salt of lauric, thiobenzoic, β-mercaptopropionic, or octylthioglycollic acid or dodecanethiol [27,28]. Organotin compounds of formula [29]

$$R_1R_2R_3Sn[XSnR_4R_5]_mR_6 \qquad (III)$$

(where R_1–R_6 are hydrocarbon radicals (C_{1-30}) or OH groups, X = O or S, and $m = 0$–15) have also been used mixed with other stabilisers.

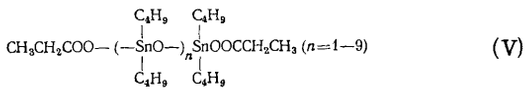
A polymeric organotin stabiliser, which improves the heat resistance of poly(vinyl chloride) and poly(vinylidene chloride), has been obtained by heating dibutyltin oxide with a polyester based on bicyclo[2,2,1]heptene-2,3-dicarboxylic acid (or its anhydride) and a glycol (ethylene, propylene, butylene, etc.). [30,31] The compounds



(IV)

(where X = H or an alkali metal, R_1 = Alk (C_{1-10}) or alkylene (C_{3-10}), R_2 = Alk (C_{1-20}), and $n = 1$–20), obtained from alkali-metal salts of citric monoesters and dialkyltin oxides or hydroxides, have been proposed as stabilisers against heat and light [32]. Poly(vinyl chloride) films stabilised with these compounds remain colourless after exposure to ultraviolet radiation for 500 h, whereas control films darkened after exposure for 20 h.

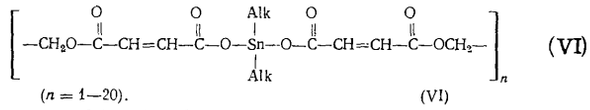
Polymeric dibutyltin dipropionate



(V)

was considerably more effective than its simple analogue ($n = 0$). [33–35]

Polymeric dialkyltin dicarboxylates



(VI)

have been used to stabilise halogen-containing polymers (0.5–5.0 wt. %). They possess diminished toxicity and blend well with the stabilised polymers [36,37]. Sulphur-containing organotin oligomers, e.g. polymeric tin dibutyl dithiodimaleate, have also been proposed as stabilisers [38,39].

3. Macromolecular and Oligomeric Compounds Containing Nitrogen

Among compounds containing nitrogen, aromatic amines have been most widely used as practical antioxidants. There is no generally accepted view on the mechanism of their action: formation of a charge-transfer complex between the aromatic ring of the inhibitor and the peroxy-radical responsible for the development of oxidative processes has been postulated [40]. Inactive products are formed when such a complex decomposes. A more soundly based hypothesis is that inhibition is accompanied by abstraction of hydrogen atoms from the amino-group [1,40,41]. This forms radicals stabilised by conjugation with the aromatic ring; their existence has been proved by means of electron spin resonance. The subsequent fate of these radicals depends both on their structure and on the reaction conditions. Several years' practical application of amines as antioxidants has shown that diamines in which the functional groups are close together are the most effective. The probable explanation [40] is that diamines are able to deactivate both active radicals

formed by the breakdown of a hydroperoxide, which prevents the development of degenerate branching processes. When a monofunctional inhibitor is used, only one of the radicals is deactivated, while the second escapes from the "cage" and continues the oxidation chain.

Products of the reaction of an epoxidised butadiene with *p*-aminodiphenylamine, 2-naphthylamine, aniline, *p*-aminophenol, and *p*-anisidine have been used to stabilise various classes of rubbers[42]. Considerably smaller quantities of the amine component are required when these compounds are employed than with the usual antioxidants. This is probably due to better compatibility of polymeric stabilisers with rubber. Low-temperature interfacial polycondensation of the bischloromethyl ether of ethylene glycol with hexamethylenediamine yields polyamine-ethers, whose use has been proposed[43,44] for stabilising synthetic rubber.

Polyalkenes have been stabilised by introducing polycarbodi-imides of molecular weight exceeding 500.[45,46]

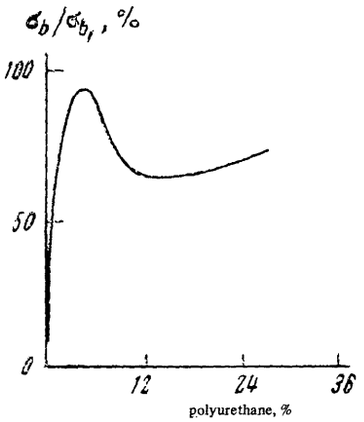


Figure 1. Dependence of tensile strength of acetylcellulose on content of added polyurethane[55], where σ_b is the tensile strength of the initial specimens and σ_{b_1} the tensile strength after exposure to ultraviolet radiation for 20 h.

Condensates of formaldehyde with respectively melamine, dicyanodiamide, urea, and thiourea have been suggested as stabilisers for polyacetals[47]. The molar ratio of the components in the condensation may vary within wide limits. The first two resins with a slight molar excess of formaldehyde (1.5–3.5 : 1) are acceptors of the formaldehyde liberated when the polymers are processed, and are thermally more stable. It is particularly noteworthy that polyacetals stabilised by the condensates do not discolour during processing. It is advisable to use these condensates mixed with known antioxidants and photostabilisers[47–50]. The thermal stability of polyformaldehyde is enhanced by the addition of polyacetalamides (M = 1000–10 000).[51]

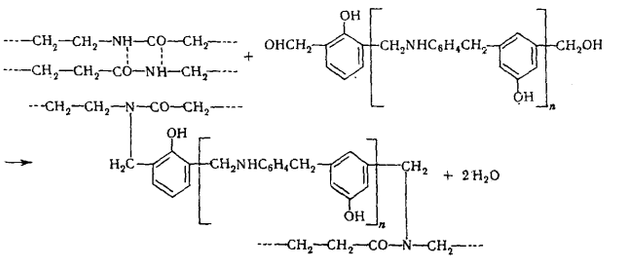
The use of copolymers of acrylamide (5–80 mole %) with styrene, alkyl acrylates, vinyl ketone, vinylnaphthalene, etc. has been proposed[52,53] for the thermal stabilisation of polyoxymethylene. The stabilised polyoxymethylene remained homogeneous and transparent.

The heat-resistance of polyurethane foams can be increased considerably by means of cyclic polyisocyanates obtained from aniline and formaldehyde or their derivatives[54].

The presence of polyurethanes—products of the condensation of tolylene di-isocyanate with ethylene glycol and of naphthylene di-isocyanate with triethylene glycol—diminishes appreciably the evolution of gas when acetylcellulose is exposed to ultraviolet radiation[55,56]. The variation in the tensile strength of exposed specimens indicates that the stabilising effect is considerably greater than could have been expected solely from the light-filtering action of the polyurethanes (Fig. 1). These products were more effective stabilisers for acetylcellulose than the phenyl salicylate usually employed industrially.

On ultraviolet exposure the polyurethane molecules are easily excited to a biradical triplet state (presence of phosphorescence in the luminescence spectra), and therefore become traps for free radicals formed by photolysis of the acetylcellulose. At low polyurethane contents this mechanism of stabilisation is decisive. In addition, the photodegradation of polyurethanes yields products having a system of conjugated bonds which exert a light-filtering effect. This latter mechanism of the stabilisation of acetylcellulose becomes dominant at high polyurethane contents. During exposure to ultraviolet the efficiency of polyurethanes as stabilisers does not diminish but, on the contrary, increases as degradation products accumulate. In principle any polyurethanes based on di- and polyisocyanates and polyhydroxy-compounds (glycols, polyethers) have a stabilising action. However, the energy of excitation of polyurethane molecules to the triplet state and the compatibility of a polyurethane with the polymer to be stabilised depend on the chemical structure of the polyurethane.

An aniline–phenol–formaldehyde resin has been suggested[57,58] for stabilising polyamide films. The stabilising effect is obviously due to the ability of the resin to react chemically with polyamides[59,60]:



which probably explains its efficiency as a photostabiliser. One cause of the aging of a polyamide film is the increase in the crystallinity of the polyamide with keeping. It may be supposed that the number of hydrogen bonds and the degree of crystallinity of the polyamide decrease in the presence of the ternary resin (1–2 wt.%).[61] Furthermore, the presence of phenolic and amine groups favours the appearance of inhibiting properties in the aniline–phenol–formaldehyde resin under certain conditions. This ternary resin, unlike other stabilisers (especially aromatic amines), does not increase the light absorption of polyamide films.

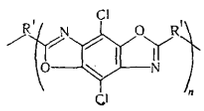
Polymeric antioxidants, whose efficiency has been tested in unfilled mixtures based on natural rubber, have been obtained by the reaction of a butadiene–methacrylaldehyde copolymer containing active aldehyde groups with

aniline and di-t-butylphenol[40]. A kinetic study of vulcanisation of the mixtures revealed that these products increase the degree of structuring of the mixtures. The explanation is that, in reacting with the peroxy-macroradicals of the rubber and forming complicated intermediate compounds, the polymeric antioxidants cross-link the molecular network of the vulcanised rubber, as it were, thereby stabilising it during oxidative degradation. Investigation of thermal aging showed polymeric antioxidants to be more effective than the usual stabilisers. They were found also to lengthen the induction period in the oxidation of pure and vulcanised rubber, as a consequence of their action on hydroperoxides. The similar chemical structure of polymeric antioxidants makes them readily compatible with vulcanised rubbers, with the absence of surface "blooming".

A few other examples of the use of oligomeric nitrogen-containing compounds as stabilisers should be mentioned. The elasticity and the heat-resistance of poly(vinyl chloride), poly(vinyl acetate), and their copolymers are improved by introducing a polyglutamate (M = 500–10 000)

$$[-NH-CH_2-(CH_2CH_2COOCH_2R)\,CO-] \qquad \text{(VII)}$$

where R = C_6H_5 or Alk (C_{5-21}).[62] Polymeric and simpler benzobisoxazole derivatives of the type



(VIII)

where R′ represents an alkylene or a phenylene radical, have been prepared[63,64]; they can be used as heat-stabilisers for halogenated polyalkenes.

4. Phosphorus-containing Polymers and Oligomers

Organophosphorus compounds have recently been proposed as thermal stabilisers and antioxidants. Phosphorous esters have become widely used. The stabilising effect of tervalent phosphorus compounds is due to their great reactivity. These stabilisers can take part in various processes underlying the stabilisation of polymers —in inhibiting oxidative processes, suppressing the degenerate branching of an oxidation chain, breaking down chromophoric groups, and also suppressing the harmful action of derivatives of metals of variable valency, which are often present as impurities in polymers[65–68].

The stabilising action of phosphites in poly(vinyl chloride) at high temperatures (80–200°C) consists mainly in combining with the hydrogen chloride catalysing breakdown of the polymer

$$(RO)_3P + HCl \rightarrow (RO)_2POH + RCl,$$

and in reacting with polymeric peroxides to prevent degradation of the main chain of the polymer

$$R'OOR' + (ROP)_3 \rightarrow (RO)_3P\begin{matrix}OR'\\OR'\end{matrix} \rightarrow R'OR' + (RO)_3P{=}O.$$

Furthermore, chemically combined phosphorus is detected in the polymer on the thermal decomposition of poly(vinyl chloride). This is explained by the reaction

$$\cdots\underset{\displaystyle Cl}{\overset{|}{CH}}\cdots + (RO)_3P \rightarrow RCl + (RO)_2\overset{\cdots CH\cdots}{\overset{/}{P}}\!\!=\!\!O$$

(the Arbuzov rearrangement), which may be catalysed by the alkyl chloride formed from the phosphite and hydrogen chloride. The rearrangement results in the replacement of labile chlorine atoms in the α-position to a double bond by groups more firmly bound to the polymer[69–73]. The efficiency of stabilisation increases with increase in the chain length of R.

Polymeric phosphites possess still more efficient inhibiting properties[74–78]. Polyphosphites of formula

$$[-O-\underset{\displaystyle OR_1}{\overset{|}{P}}-O-R-O-]_n \qquad \text{(IX)}$$

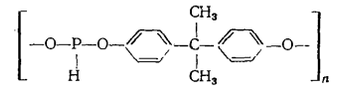
where

$$R{=}CH_2{-}CH_2,\ CH_2{-}CH_2{-}OCH_2{-}CH_2,\ C_6H_4,\ -C_6H_4-\overset{\displaystyle CH_3}{\overset{|}{C}}(CH_3)-C_6H_4-;$$

$$R_1{=}C_2H_5,\ C_4H_9,\ C_6H_5,\ ClC_6H_4;\quad n{=}2{-}10,$$

blend well with many polymers (polyalkenes, poly(ethylene terephthalate), rubbers) and are firmly retained in them[79]. This confers on polyphosphites valuable properties not possessed by the usual antioxidants (alkyl aryl phosphites). Polyphosphites have been obtained by transesterification of such esters with dihydroxy-compounds[76,79], but the products hydrolyse in air, which makes their use difficult in practice. Polyphosphites obtained by transesterifying complete and mixed esters of phosphorous acid with alkylated bishydroxyphenyl sulphides are free from this defect. The inhibiting action of sulphur-containing polyphosphites has been assessed from the change in the rate constants for the chemical relaxation of tension, which is an unambiguous measure of the resistance of vulcanised butadiene–styrene rubbers to thermo-oxidative degradation. The polyphosphite obtained by transesterifying triphenyl phosphite with bis-4-hydroxy-2-methyl-5-t-butylphenyl sulphide, in which the oxygen-phosphorus bonds are shielded by t-butyl groups and are stable to hydrolysis, was especially effective[80].

Not only complete polyphosphites but also intermediate structures, e.g.



(X)

have been proposed for the stabilisation of poly(ethylene terephthalate). Addition of 1 wt.% to about one-quarter reduces the thermo-oxidative degradation of the polymer at ~ 260°C. The effectiveness of this stabiliser is probably due to the presence of oxidisable P–H bonds[81].

The colour of solutions of a copolymer of vinyl chloride with acrylonitrile is preserved in the presence of mixtures of alkylene oxides with polymeric organic phosphites of general formula

$$(RO)_2PO\,[-R'-O-\underset{\displaystyle OR}{\overset{|}{P}}-O-]_n-R'-OP\,(OR)_2 \qquad \text{(XI)}$$

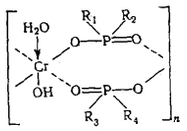
or with organic polyphosphonites of the type

$$RO-PO\,[-R'-O-\underset{\displaystyle C_6H_5}{\overset{|}{P}}-O-]_n R'-O\underset{\displaystyle C_6H_5}{\overset{|}{P}}-OR \qquad \text{(XII)}$$

where R = Alk (C_{1-10}) or C_6H_5, R′ is a residue of a saturated aliphatic diol, and n = 1–8. The use of lower alkylene oxides combined with polymeric organic phosphites and phosphonites improves the stability of resin solutions[82,83].

Halogenated resins have been stabilised by salts (cadmium, barium, lead, calcium, magnesium, zinc,

aluminium, tin, etc.) of organic or inorganic polyphosphoric acids[84]. Polymeric chromium phosphinate



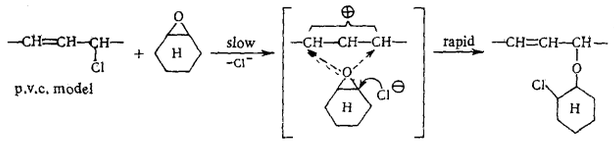
$(R_1-R_4 = Ph, Me; n > 1)$ (XIII)

provides good protection for vinyl chloride polymers from ultraviolet radiation[85].

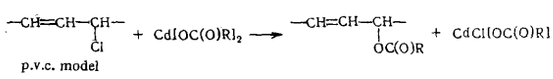
5. Polymers and Oligomers containing Epoxy-groups

The main types of epoxide stabilisers are glycidyl ethers—condensates of epichlorohydrin with phenols and aliphatic alcohols—and epoxidised esters of higher fatty acids.

The stabilising effect of epoxy-compounds and of their mixtures with the salts of aliphatic acids with Group II elements has been studied on model compounds—mixtures of 4-chlorohex-2-ene and 2-chlorohex-3-ene—that simulate a degraded poly(vinyl chloride) unit[86]. At 150°C the model compounds decomposed with the evolution of hydrogen chloride. Degradation was greatly retarded by the introduction of stabilising additives (cyclohexene oxides with cadmium–barium or calcium–zinc carboxylates). The labile chlorine atom in the allyl position was thus detached without formation of a new double bond, so that autocatalytic decomposition reactions did not develop:



p.v.c. model

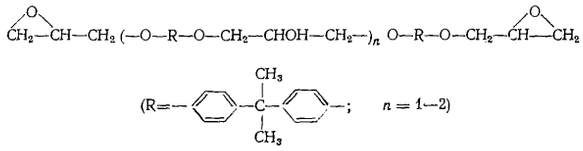


p.v.c. model

$(R = CH_3, C_7H_{15})$

Furthermore, epoxy-compounds evidently retard chain oxidations by inhibiting breakdown of the intermediate hydroperoxides. The model reaction of t-butyl hydroperoxide with cobalt octanoate shows that a mixture of an epoxide resin and a cadmium soap is more efficient than its components in inhibiting the decomposition of a hydroperoxide. The mixture approaches dibutyltin dilaurate in the efficiency of its action[87,88].

The lower glycidyl ethers have the disadvantages of being volatile and causing dermatitis, so that the non-volatile and less toxic epoxide resins are preferred for stabilising polymers. The glycidyl polyether



(XIV)

obtained by condensing a bisphenol with epichlorohydrin, has been suggested[89] for stabilising vinyl halide polymers.

Polyalkylene glycol ethers RO.[AO]n.R′, where R′ = 2,3-epoxypropyl, A = alkylene (C_6), and n = 2–4, also have a stabilising effect[90]. Dialkyltin epoxysuccinates (n = 1–20) blend well with vinyl halide polymers, do not decompose with the liberation of toxic products when processed, and ensure that compositions should have prolonged thermal stability and good light stability[91].

Products obtained by the reaction of epichlorohydrin with sulphones of formula HO.R.SO_2.R′.OH (R and R′ = C_6H_5 or $C_6H_5CH_2$) have been recommended for stabilising vinyl polymers[92,93]. Epoxidised esters of higher aliphatic acids present in compositions based on poly(vinyl chloride) have not only a stabilising effect but also a plasticising action[94–98]. They are generally used as a secondary stabiliser with magnesium, calcium, and zinc stearates, organotin stabilisers, and phosphites[99–111]. Extremely stable compositions have been obtained by introducing into polyalkenes products of the reaction of polymers containing epoxy-groups with various organic hydroxy- and thio-acids and hydroxyl-containing compounds[112–118].

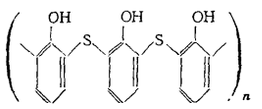
Rubbers modified by furan resins possess enhanced thermal and chemical stability[119].

6. Macromolecular and Oligomeric Sulphur-containing Compounds

Compounds containing sulphur effectively inhibit the thermo-oxidative breakdown of many polymers.

Products obtained by the action of sulphur on atactic polypropylene have been used to stabilise isotactic polypropylene[120–122]. The sulphurised atactic polymer blended well with isotactic polypropylene, was retained in it for a long time, and was not washed out by water. Products of the action of dibenzothiazolyl disulphide (Altax) on atactic polypropylene surpass the sulphurised atactic polymer in their stabilising action[123]. The inhibiting activity of products of the reaction of atactic polypropylene with sulphur or with Altax depends on the period of contact between them. The initial products contain mainly thiol and polysulphide groups, which are converted during the reaction into monosulphide and thioketone groups[124–126]. The greatest stabilising activity is possessed by the initial products, which are as good as certain industrial antioxidants, e.g. isobornylmethylphenol. The high activity of low concentrations of the initial products is due to the rapid conversion of polysulphides into sulphoxides and the involvement of mercapto-groups in chain-terminating reactions. However, thiyl radicals are highly reactive, and are able to initiate oxidation; for this reason the inhibiting activity of the initial products decreases as their concentration increases[127]. If ionol is also added, the thiyl radicals are stabilised, hence secondary initiation is absent, and the efficiency increases[121]. The final products of the interaction of atactic polypropylene with sulphur contain predominantly monosulphide and thioketone groups, which are oxidised to sulphoxides with greater difficulty than is explained by their insignificant stabilising activity[128]. The inhibiting power of the reaction product of polystyrene with sulphur exceeds many times that of sulphurised atactic polypropylene: addition of the former protects polypropylene at 200°C for 110–150 min, whereas the latter guarantees protection for only 7–12 min[129].

Other suggestions for the stabilisation of polyalkenes are a polydisulphide based on decane-1,10-dithiol combined with carbon blacks[130], oligomers obtained by the reaction of phenols with sulphur monochloride or dichloride[131]



$(n = 1-4)$ (XV)

and polyesters based on aliphatic thiodicarboxylic acids mixed with antioxidants of phenolic type [132,133]. Sulphur-containing stabilisers for poly(vinyl chloride) resins are generally used mixed with stabilisers that are acceptors of hydrogen chloride, an example being a mixture of an organic derivative of tin or zinc with a liquid polythiopolythiol

$$HS(CH_2CH_2OCH_2OCH_2CH_2SS)_nCH_2CH_2OCH_2OCH_2CH_2SH \quad (n = 3-6)^{134-136}. \quad \text{(XVI)}$$

The thermo-oxidative degradation of poly(vinyl chloride) resins is presented by polyester condensates of mercapto-alcohols and dicarboxylic acids mixed with lead silicate [137-139].

III. POLYMERS WITH A SYSTEM OF CONJUGATED DOUBLE BONDS

Polymers having systems of conjugated double bonds have recently been proposed as stabilisers for macromolecular compounds. These polymers are able to form relatively inactive biradicals on excitation to a triplet state, and thereby prevent the development of chain decomposition processes in the degradable polymer. The activation energy for the addition of radicals to conjugated polymers is less the lower the energy of excitation of the latter to the triplet state.

Polymers with systems of conjugated double bonds comprise a set of homologous polymers differing in conjugation energy in the transition state, in activation energy, and in energy of excitation. Therefore the use of these conjugated polymers as stabilisers of macromolecular compounds makes it possible in principle to inhibit chain breakdown processes over a wide range of temperatures or energies of exposure. In this connection the use of conjugated polymers is especially promising for raising the limiting operating temperature of known organic and heteroatomic polymers.

Polymers having an acyclic chain of conjugation—polyphenylacetylene, an equimolecular *p*-diethynylbenzene-phenylacetylene copolymer, and dehydrochlorinated poly(vinyl chloride)—inhibit the dehydrochlorination of poly(vinyl chloride) at 175–180°C and retard its breakdown under the influence of ultraviolet radiation. They can be used either independently or mixed with other stabilisers. When polyphenylacetylene is used alone (1 wt.%), the rate of evolution of hydrogen chloride from poly(vinyl chloride) at 175°C diminishes to one-third; the action of polyphenylacetylene is far more effective when mixed with lead silicate [140-142].

Polymers with aromatic rings in the conjugated chain—polyphenylene, polyazophenylene, polyphenyleneaminoquinone—have also been examined as stabilisers for poly(vinyl chloride). Their stabilising action is different from that of polymers having an acyclic conjugated chain. Aromatic conjugated polymers become more effective with rise in temperature, but acyclic conjugated polymers become less effective. The reason for this is that the energy of excitation to the triplet state is higher for polyphenylene than for polyvinylenes; therefore the inhibiting action of the former develops at higher temperatures. The effectiveness of the stabilising action of conjugated polymers is strongly dependent on the conditions of the thermal degradation of poly(vinyl chloride). Comparison of the rates of dehydrochlorination of the latter in nitrogen and in the presence of oxygen shows that aromatic conjugated polymers suppress only the thermo-oxidative degradation of poly(vinyl chloride). This is explained by the greater activity of biradicals of conjugated polymers in reactions with *O*-radicals than in reactions with atomic chlorine and *C*-radicals [143,144].

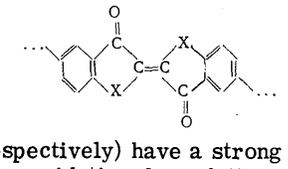
Conjugated polymers—polyphenylene, polyazophenylene, polyphenylacetylene, polydiphenylacetylene—have solved the problem of the thermal stabilisation of three-dimensional polymers based on polyether–acrylates. Addition of a conjugated polymer (5 wt.%) almost completely suppresses the thermo-oxidative degradation of hardened polyether–acrylates at 200°C, without impairing their physicomechanical properties. In the absence of stabilisers 30–35% of the initial polyether–acrylate is degraded under the same conditions [145-148].

Conjugated polymers retard the high-temperature oxidation of polyarylates [149], phenol–formaldehyde resins [150], and polycarbonates [151].

Examination of a large number of conjugated polymer inhibitors reveals that the most active contain in the main conjugation chain heteroatoms with a lone pair of *p*-electrons, such as polyquinonedioxins [152] (Table 1). Polymers having a ladderlike structure—(XX)–(XXIII), (XXV), (XXVI)—as well as polymer (XIX) possess the characteristic properties of conjugated systems: i.e. the *p*-electrons of their heteroatoms are conjugated with the π-electrons of the quinone and aromatic rings. In polymers (XVII), (XVIII), and (XXIV) conjugation is weakly developed, being least in (XVII), for which a tautomeric transition is impossible.

The thermo-oxidative degradation of polycarbonates was conducted at 300°C and an oxygen pressure of 500 mmHg. The efficiency of stabilisers against degradation was determined from the kinetics of the absorption of oxygen and from viscometric measurements in dichloromethane. An industrial polycarbonate may be contaminated with sodium chloride, which accelerates considerably the high-temperature degradation of the polymer (it reacts with terminal phenolic hydroxyls to evolve hydrogen chloride, which catalyses hydrolysis of the ester bonds in the polymer). Polyquinones inhibit degradation of an unpurified polycarbonate. Polymers of ladderlike structure containing two heteroatoms per monomer unit are especially effective; the inhibiting power of linear polymers is considerably lower (Fig. 2). The stabilising effect is strengthened by increasing the addition of polymeric quinones to 2 wt.%. [153-158]

Polymeric colorants such as polyindigo and polythioindigo



(XXVII)

(X = NH and S respectively) have a strong stabilising effect against the thermo-oxidative degradation of polyamide fibres [159]. When a fibre has been treated with such a dye or an analogue of low molecular weight, not only does its strength not diminish during degradation, but may even increase in some cases. The stabilising effect is most clearly evident in Kapron [6-polyamide] fibre, when the effectiveness diminishes in the sequence

polymeric dyes > lower analogues > Indanthren dyes

This can be attributed to completion of the supermolecular structure of the fibres under the influence of polar compounds deposited on their surface. Furthermore, a polymeric dye containing systems of conjugated bonds acts as an inhibitor of chain oxidation [159].

Table 1. Polyquinones investigated as stabilisers of polycarbonates[152].

Polymer	Monomer unit	Mol. wt.	Terminal groups	E.s.r. signal
(XVII)		1600	Br*	very weak

(XXVI)		2000–2200	—	signal

*Branched chain.

Berlin considers that paramagnetic centres of polyconjugated systems play an activating part in the thermooxidative degradation of polymers (local activation effect).

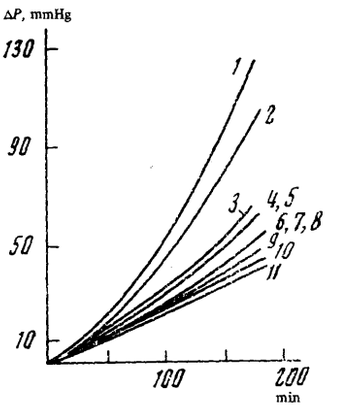

Figure 2. Rate of fall of pressure in the thermooxidative degradation of an unpurified polycarbonate in the presence of polymeric stabilisers (1 wt.%)[152]: 1) no addition; 2) (XIX); 3) (XXI); 4) (XXIII); 5) (XVIII); 6) (XVII); 7) (XX); 8) (XXIV); 9) (XXV); 10) (XXII); 11) (XXVI).

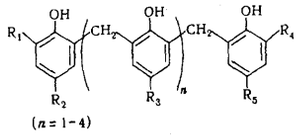
At high temperatures the diamagnetic conjugated polymer molecules undergo oxidative dehydropolycondensation, with an increase in their degree of conjugation and denser packing of the molecules in aggregates. This favours excitation of the diamagnetic molecules to the biradical state under the influence of the paramagnetic centres of the conjugated polymer, with the subsequent formation of charge-transfer complexes with peroxy-radicals. Further reactions of the complexes lead to the appearance of inactive products[160–166].

IV. MACROMOLECULAR AND OLIGOMERIC ANALOGUES OF STERICALLY HINDERED PHENOLS

Antioxidants of phenolic type have been widely used in industry because of their great effectiveness and the absence of toxicity[167]. They have the advantage of not discolouring the stabilised polymer. The mechanism of their action has now been studied quite thoroughly. Various sterically hindered phenols have been prepared and examined. Their effectiveness depends on several factors —including the nature of nuclear substituents and their bulk, the ease of free-radical detachment of hydrogen from the phenolic hydroxyl and the stability of the resulting phenoxyl radicals, as well as certain other factors—an aspect which has been reviewed in some detail[1,168–170]. The oxidation products of phenolic antioxidants also possess inhibiting properties, though less pronounced than those of the original phenols[171,172].

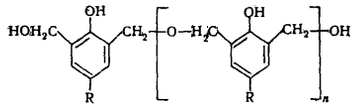
While exhibiting all the valuable features of phenolic stabilisers of low molecular weight, the polymeric analogues of sterically hindered phenols are considerably less volatile and soluble. Polyphenols of formula



(XXVIII)

($n = 1-4$)

(R^1–R^5 = alkyls and $n = 1-4$) have been prepared and found to be effective antioxidants for polyalkenes [173]. The phenolic polycondensate may consist of various aromatic monomer units—isopropylidene-*pp'*-diphenolic, s-butylidene-*pp'*-diphenolic, bisphenol sulphone, bisphenol sulphoxide, etc.—joined together by methylene, ethylene, ethylidene, di-isopropenylbenzene, and other groups [174–180]. A synergetic effect is observed when polyphenols are used mixed with bisdodecyl or bisoctadecyl thiodipropionate [181]. Polyhydroxyphenylalkanes also are effective antioxidants. Polypropylene has been stabilised with a mixture of a polyhydroxyphenylalkane (2,2,5,5-tetrakis-*p*-hydroxyphenylhexane) and bisoctadecyl thiodipropionate: the time at 140°C before darkening occurred was 180 h, but in the absence of a stabiliser 24 h. [182] Phenol–formaldehyde oligomers have been used to stabilise polyether-urethanes [183] and poly(vinyl chloride). [184] A method of stabilising poly(vinyl chloride) towards light and heat uses mixtures of a polyoxybenzyl ether



(XXIX)

($n > 1$; R = CH_3, $C(CH_3)_3$, C_6H_5, etc.) or a polyoxybenzyl alcohol with lead stearate or silicate as acceptor of hydrogen chloride. These inhibitors blend well with poly(vinyl chloride). The thermal stability of the latter is trebled by adding the polyoxybenzyl ether (1 wt.%). [185,186]

V. MACROMOLECULAR AND OLIGOMERIC ANALOGUES OF BENZOPHENONE

Derivatives of hydroxybenzophenone are widely used for the photostabilisation of polymers. Apart from the light-filtering effect, the decisive process with benzophenone derivatives is the resonance dipole–dipole interaction, leading to a radiationless transfer of the electronic excitation energy from the polymer to the photostabiliser [187–190].

Polymeric and oligomeric analogues of benzophenone have been proposed for protecting polymers from ultraviolet radiation. Polyalkenes and poly(vinyl chloride) resins have been stabilised with homopolymers of 2-hydroxy-4-methacryloylbenzophenone and 2-hydroxy-4-(meth)acryloylacetophenone. Poly(vinyl chloride) film yellowed and cracked after exposure to ultraviolet radiation for 200 h, but a film stabilised with poly-4-acryloyl-2-hydroxybenzophenone remained for 600 h without change. The photostability of poly(butyl acrylate) improved in the presence of poly-2-hydroxy-4-methacryloyl-5-t-butylbenzophenone [191]. Polymers of 2-hydroxy-4-(2-hydroxy-3-methacryloylpropoxy)benzophenone (XXX), 4-(3-acryloyl-2-hydroxypropoxy)-2,2'-dihydroxybenzophenone, etc. [192] and also the copolymer of (XXX) with phenyl 2-hydroxy-5-methacryloylmethoxybenzoate [193] have been recommended for the photostabilisation of a copolymer of vinylidene chloride with ethyl acrylate.

The homopolymers of acrylic and methacrylic derivatives of 4-alkoxy-2-hydroxybenzophenones have been used for the photostabilisation of polystyrene, poly(vinyl chloride), poly(methyl methacrylate), etc. Fig. 3 shows that poly(benzophenone acrylate) is more effective than the corresponding methacrylate as a photostabiliser for polystyrene, which is explained by the better compatibility of the former with the polymer. A copolymer of styrene with benzophenone methacrylate and a mixture of polystyrene with poly(benzophenone acrylate) have roughly the same stability towards light. Poly(benzophenone methacrylate) is an effective photostabiliser of poly(vinyl chloride) (Fig. 4). [194]

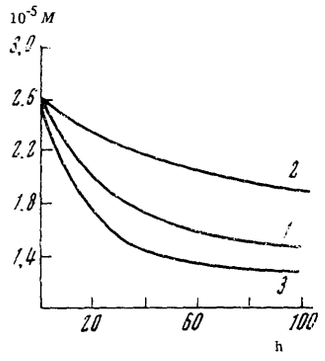


Figure 3. Dependence of molecular weight of polystyrene on time of illumination in the presence of polymeric stabilisers [194]: 1) poly(benzophenone methacrylate); 2) poly(benzophenone acrylate); 3) control specimen.

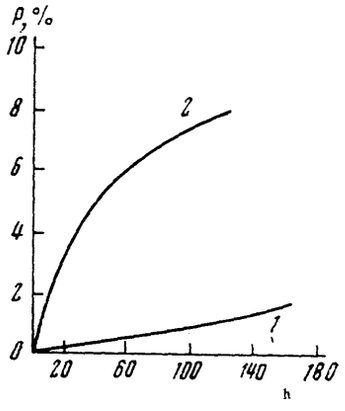

Figure 4. Dependence of content of gel fraction on time of irradiation of poly(vinyl chloride) [194]: 1) with added poly(benzophenone methacrylate); 2) no addition.

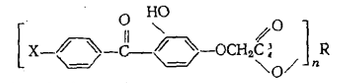
Oligomeric hydroxylated polyesters

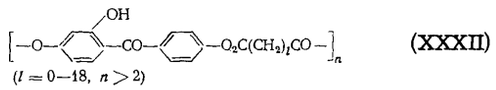


(XXXI)

(where X = H, AlkO (C_{1-4}), R = residue of aliphatic (C_{2-10}) polyhydric alcohol with $n = 2-6$ OH) have been

recommended as light-protective additives, which are well preserved in the polymer. They were obtained by reaction between 4-benzoyl-3-hydroxyphenoxyacetic acid and a polyhydric alcohol (ethane-1,2-diol, n-decane-1,10-diol, etc.). Tests in air for 10 weeks showed that the polymeric stabiliser was completely preserved in films, whereas the concentration of hydroxybenzophenones diminished considerably [195].

Products of the condensation of 2,4,4′-trihydroxybenzophenone with dicarboxylic acids (succinic, glutaric, adipic) or with their acid halides



(XXXII)

($l = 0$—18, $n > 2$)

have been proposed as photostabilisers which are well preserved in polyalkenes [196].

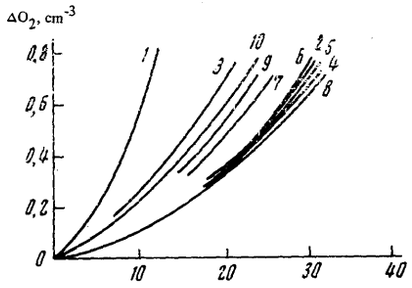


Figure 5. Photo-oxidation of stabilised polypropylene films at 60°C (distance from lamp to film 7 mm, with 2—mm Pyrex filter) with different stabilisers (0.0184 mole kg^{-1}): [197] 1) no additive; 2) 2-hydroxy-4-octyloxybenzophenone; 3) as (2) after extraction; 4) condensate (XXXIV); 5) as (4) after extraction; 6) condensate (XXXIII); 7) as (6) after extraction; 8) condensate (XXXV) before and after extraction; 9) condensate (XXXVI); 10) as (9) after extraction.

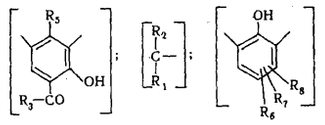
Polypropylene stabilised with various polycondensates—of 2-hydroxy-4,4′-bis-β-hydroxyethoxybenzophenone with thio-ββ′-dipropionic acid (XXXIII), 2,4,4′-trihydroxybenzophenone with a mixture of thio-ββ′-dipropionic (0.7 mole) and isophthalic (0.3 mole) acids (XXXIV), 2,2′-dihydroxy-4,4′-β-hydroxyethoxybenzophenone with thio-ββ′-dipropionic acid (XXXV), and 2,2′,4,4′-tetrahydroxybenzophenone with a mixture of isophthalic (0.7 mole) and adipic (0.3 mole) acids (XXXVI)—has been subjected to photodegradation before and after extraction with chlorinated hydrocarbons [197]. Fig. 5 shows that photo-oxidation is appreciably affected by extraction only with the relatively simple stabiliser 2-hydroxy-4-octyloxybenzophenone (curves *2* and *3*). The polycondensation product (XXXIII) is also partly extracted from polypropylene (curves *6* and *7*). The remaining stabilisers are almost unaffected by extraction. The most effective are polycondensates containing thio-ββ′-dipropionic acid—(XXXIV) and (XXXV)—probably because sulphur-containing groups are involved in the breakdown of hydroperoxides [198] formed during irradiation in air.

Halogenated polyalkenes have been stabilised by introducing an oligomeric product (M = 500) of the reaction of formaldehyde (or benzaldehyde) with *o*-hydroxybenzophenone (or acetophenone). The product absorbed intensely in the ultraviolet (340 nm) and exhibited high stabilising activity [199,200].

Polycondensates [201–203] with $M \geqslant 400$ and consisting of the units



(A) (B) (C)

(XXXVII)

(where R^1 and R^2 = H, Alk (C_{1-6}), chloroalkyl, furyl, vinyl, propenyl, phenyl; R^3 = Alk (C_{1-6}), Ar; R^4 and R^5 = H, OH, Hal, AlkO, Alk; and R^6, R^7, R^8 = H, OH, Hal, Ar, ArO, cycloalkyl) stabilise vinyl polymers towards heat and light. The molar proportions of the components are 1 : 2 : 1. Table 2 gives the test results.

Table 2. Stability of vinyl polymers containing added polycondensates towards heat and light [201].

Initial components of polymeric stabiliser			Polymer	Thermal stability*	Ultraviolet stability**
I	II	III			
o-Hydroxyacetophenone	formaldehyde	dodecylphenol	polypropylene	not discoloured	5
2-Hydroxy-4,6-dimethylbenzophenone	acetone	*m*-butylphenol	polyethylene	not discoloured	3
2,4-Dihydroxybenzophenone	furaldehyde	octadecylphenol	polyethylene	not discoloured	4
4-Chloro-2-hydroxybenzophenone	butyraldehyde	3,5-dichloro-4-methylphenol	poly(vinyl chloride)	discoloured	3
2-Hydroxy-4-methoxybenzophenone	benzaldehyde	octylphenol	ethylene–ethyl acrylate copolymer	not discoloured	3
o-Hydroxybenzophenone	formaldehyde	phenol	poly(vinyl fluoride)	not discoloured	4

*Under the test conditions (210°C for 30 min) the control specimen—the polymer without a stabiliser—is discoloured.

**The ratio of the time for the stabilised film to disintegrate to the corresponding time for the control film.

Macromolecular analogues of *o*-hydroxybenzophenone, obtained by the Fries rearrangement of polyarylates, have been proposed for the photostabilisation of various vinyl polymers [204]. The polymeric stabilisers possess low volatility, blend well with many polymers, and are as good as *o*-hydroxybenzophenone in effectiveness. Comparison of the infrared spectra of samples of poly(vinyl fluoride) film containing 1–2 wt.% of such a polyketone before and after being heated in a vacuum (0.1 mmHg) at 100°C for 3 h showed hardly any change in the content of polymeric stabilisers in the film, whereas the content of *o*-hydroxybenzophenone in a control specimen had decreased significantly. The effectiveness of the polymeric stabilisers was maintained even after exposure of the film at 60°C to ultraviolet radiation for 2 months.

VI. OTHER MACROMOLECULAR AND OLIGOMERIC COMPOUNDS

Various macromolecular compounds containing an open chain of carbon atoms have been suggested for stabilising polymers. Macromolecular hydrocarbons, alcohols, acids and their salts, esters, ethers, etc. have found application.

Thermal stabilisation of poly(vinyl halide) resins has been effected by additions of polyethylene (0.5–2.0 wt.%),[205,206] which eliminated charring or any decomposition of the material during processing. The stabilising effect of polyethylene is explained, in the Reviewers' opinion, by two factors. Polyethylene is able to combine with atomic chlorine formed in the thermal degradation of poly(vinyl chloride), thus preventing development of free-radical degradation processes in the polymer and in the corresponding segments of vinyl chloride copolymers[1]. Such explanation seems probable, since polyalkenes are easily chlorinated at ~150°C even in the dark[207]. On the other hand, hydrogen chloride catalyses the thermal breakdown of poly(vinyl chloride).[208–211] It has been shown recently that the thickness of the specimen has a great influence on the rate of breakdown of this polymer. There exists a critical size, beyond which the elimination of hydrogen chloride becomes autocatalytic[212]. This indicates that polyethylene acts as a stabiliser also by diminishing the contact between hydrogen chloride and the polymer macromolecules, diminishing the relative importance of autocatalytic processes in the polymer degradation, and hence decreasing the overall rate of breakdown. Polyalkenes also stabilise polyoxymethylene. Its thermal stability is improved by polybutene and by an ethylene–vinyl acetate copolymer[213,214]; polyethylene and polypropylene are less efficient in stabilising polyoxymethylene. Oligomeric polyphenylenes—derivatives of toluene, *o*-, *m*-, and *p*-xylene, etc.—show promise for the thermal stabilisation of isotactic polypropylene. The effectiveness of these stabilisers is greatly increased by the addition of bisdodecyl thiodipropionate[215].

A polyol (a polyethylene glycol) has been used[216] in combination with sodium tellurite or selenite to improve the thermal stability and the transparency of poly(vinyl chloride). Polymers containing nitrile groups are stabilised by the addition of a polyhydric alcohol based on polyoxypropylene having a hydroxyl number of 60–700 and molecular weight 400–3000.[217]

A linear acrylic ternary polymer (M = 150 000 to 2 000 000), comprising monomer units of methyl methacrylate, ethyl acrylate, and an ester of an alkoxy-acid of formula

(XXXVIII)

(where R = Alk (C_{1-4}) and R′ = H, CH_3) stabilises poly(vinyl chloride) of intermediate or high molecular weight[218]. Pure poly(methyl methacrylate) has no effect on the rate of breakdown of poly(vinyl chloride).[219]

The introduction of oligoether–acrylate segments into the poly(methyl methacrylate) chain improves its physico-mechanical properties and enhances the thermal stability[220].

The polymeric salt obtained by the reaction of a copolymer of styrene and maleic anhydride with ammonium hydroxide protects poly(vinylidene chloride) from the action of ultraviolet rays[221].

Affinity Chromatography of Enzymes

I.A.Cherkasov

The main principles and fields of application of a new method of enzyme chromatography, the so called "affinity" chromatography, are discussed. The method is based on the employment of an insoluble ligand of the enzyme (substrate, inhibitor, cofactor, etc.), that is sorption takes place owing to specific forces associated with affinities which constitute the basis of the biological function of the enzyme. The use of sorbents based on such ligands permits a more selective and effective isolation of pure enzymes from various sources compared with the usual types of sorbents, for example ion-exchange resins. In addition the review considers certain other techniques employing the specific affinity of the enzyme for the ligand in enzyme chromatography. Affinity chromatography can also be used to fractionate the products of chemical modification of enzymes and to investigate the physicochemical properties of enzyme-ligand complexes.
The bibliography includes 144 references.

I. INTRODUCTION

Numerous studies based on the selective binding of enzymes to ligands (substrates, inhibitors, coenzymes, etc.) for the purification of enzymes by adsorption (mainly chromatographic) methods have been published recently in scientific periodicals. Since the enzyme forms a complex with the ligand due to the so called affinity forces, the method has been given the name of "affinity" chromatography (from the Latin root "affinis"—related to, bearing a relation to), i.e. chromatographic separation of enzymes in accordance with their affinity for the substrate.

The tendency to seek selective sorbents for enzymes is itself quite understandable, since the usual types of chromatography, for example ion-exchange or gel chromatography, are not specific to the nature of enzymes; the purification of enzymes with the aid of these methods constitutes a multistage procedure and usually gives a low yield of the pure product. On the other hand, affinity chromatography normally makes it possible to extract enzymes from complex mixtures in a single stage with a high degree of purity and with a nearly quantitative yield.

Moreover, affinity chromatography is one of the most direct and at the same time simplest methods for the investigation of the formation of enzyme–ligand complexes, so that it can be used for a detailed elucidation of the physicochemical aspect of enzymatic catalysis.

The present review attempts to summarise and give a systematic account of studies in this field and to assess the potentialities of the method.

II. GENERAL PROBLEMS OF AFFINITY SORPTION

According to modern ideas, an enzymatic reaction can be represented by the following general equation

$$E + S \rightleftarrows ES \rightleftarrows EP \rightleftarrows E + P,$$

where E, S, and P are enzyme, substrate, and reaction product respectively. The equation shows that the elementary step in the simplest enzymatic reaction involves the formation of two complexes, namely the enzyme–substrate and enzyme–product complexes.

The first stage of the enzymatic reaction—the formation of the enzyme—substrate complex—take place as a result of specific interaction forces between the enzyme and substrate molecules, called the enzyme–substrate affinity. The few data obtained so far on the structures of enzymes and enzyme–substrate complexes[1-4] show that, in the binding of the enzyme to the substrate a number of non-covalent bonds of various types (hydrogen bonds, polar and non-polar interactions, etc.) are formed between them. Such multi-site contact between the enzyme and substrate molecules, leading to a high selectivity of interaction, is ensured by a specific spatial distribution of the functional groups of the enzyme, which is determined by its unique structure. In this case one usually speaks of the complementarity of the molecular structures of the enzyme and the substrate.

The enzyme–product complex is formed as a result of a chemical transformation of the substrate. Since in the course of this transformation the substrate remains bound to the surface of the enzyme molecule, evidently the enzyme–product complex is in general stabilised by the same forces (or involves the same interactions) as those involved in the stabilisation of the enzyme–substrate complex.

Apart from the complexes with the substrate and the reaction product, many enzymes form, by virtue of their functional specificity, extremely stable complexes with other types of ligands. These include coenzymes, allosteric activators, inhibitors, etc.

When the ligand is in a solid insoluble phase, it can be used as a specific sorbent for the corresponding enzyme. Like any sorbent used in chromatography, the affinity sorbent must have a fairly large surface area, a relatively high mechanical strength, and should not show a tendency to form either dense aggregates or conversely colloidal solutions. In a chromatographic column, the sorbent must allow an eluent flow rate acceptable in practice.

If the natural ligand satisfies these requirements, it can be used directly as the sorbent. However, the number of such sorbents is small and they are restricted to certain

biopolymers, mainly the substrates of digestive enzymes (starch, elastin, cellulose, etc.). In most cases ligands are soluble substances and are converted into an insoluble state by an artificial method. Here the following procedures are possible: (a) the ligand is modified chemically by the introduction of hydrophobic groups which make it insoluble; (b) the ligand is converted into an insoluble state by incorporation in an insoluble polymer which is polymerised for this purpose in a solution containing the ligand; (c) the ligand is attached (covalently or non-covalently) to an insoluble carrier. The procedure involving covalent attachment of the ligand is most frequently employed.

The main requirement which must be met by the affinity sorbent is sorption specificity. In principle, the affinity sorbent should contain only functional groups which ensure the selective binding of one specific enzyme in the absence of sorption of other substances. When the natural ligand is employed, the problem reduces to a test of its homogeneity and native properties, i.e. the absence from it of functional groups non-specific to the given ligand which may appear as a result of chemical side reactions, for example in purification or on storage.

The preparation of a synthetic sorbent requires a correct choice of the ligand, the carrier, and the method of joining the ligand to the carrier. The specificity and strength of the binding of the ligand to the enzyme may be estimated by preliminary tests using various methods, for example kinetic methods.

In order that the ligand which is bound effectively in solution should retain this capacity when attached to the carrier, it is necessary that the attachment should involve groups not participating in the interaction with the enzyme. Exact information about this may be obtained by the X-ray diffraction analysis of the corresponding enzyme – ligand complexes. These data are important for practical affinity sorption, since they constitute the basis for the most complete utilisation of the affinity forces and help to avoid an empirical search in the preparation of the sorbent. However one should note that information of this kind is still extremely limited [1-4].

When the ligand is attached to the carrier, one should also make sure that the functional groups responsible for complex formation are not only free but also accessible for binding to the enzyme in solution. Here we are concerned with possible steric hindrance in the approach of the enzyme molecule to the active surface of the sorbent. In particular, such hindrance may arise if the site of attachment of the ligand to the carrier is in the immediate vicinity of its functional groups involved in binding to the enzyme. In such cases it is desirable to attach the ligand to the carrier via intermediate reagents with a suitable length of molecular chains which function as a kind of "arm" which separates the active groups of the ligand from the surface of the sorbent.

In choosing the carrier one should bear in mind that it must not have a significant influence on sorbent specificity, i.e. that it must not contain functional groups which might give rise to the sorption of extraneous substances. The fact that the ligand is bound to the enzyme as a rule via several non-covalent linkages itself guarantees to some extent a minimal binding of impurities by such a sorbent, in which the ligand is attached to a fairly neutral carrier. Carriers of this type may include, for example, molecular sieves (Sephadex, Biogel, etc.) the very principle of whose action is designed to ensure the absence of non-specific sorption of proteins. Moreover, the choice of the neutal carrier makes it possible not only to eliminate the sorption of impurities but also to avoid a possible non-specific binding of the enzyme itself. In practice the specificity and efficiency of synthetic and natural sorbents must be tested experimentally in each case.

The next problem concerns the conditions governing the sorption and desorption of the enzyme. As stated above, the formation of an enzyme–ligand complex is due to the specific steric structure (conformation) of the enzyme protein molecule, which may change when the conditions in the medium are altered. Therefore it is extremely difficult to assess beforehand the optimal sorption and desorption conditions. On the basis of general considerations, one may expect that the optimal sorption of the enzyme on an affinity sorbent will occur close to the conditions governing its optimal catalytic activity and any departure from these conditions will lead to a weakening of the stability of the enzyme–ligand complex and to desorption of the enzyme.

If electrostatic interactions between the ionogenic groups of the enzyme and the ligand are important for their mutual binding, the stability of such a complex will vary with the pH of the medium and will decrease with increasing ionic strength. The stability of hydrogen-bonded complexes is probably an inverse function of temperature. Moreover, the stability of such complexes decreases in the presence of agents capable of forming hydrogen bonds (for example urea, guanidine, etc.). A similar approach is evidently applicable also to complexes stabilised by "hydrophobic" contact. Thus one of the desorption procedures consists of the weakening of individual types of bonds between the enzyme and the ligand in the complex. In the presence of bonds of different types, the decomposition of the complex requires a combined action of a variety of factors; one must bear in mind that the desorption conditions can then be very severe and can lead to denaturation of the enzyme.

Another desorption procedure, which is more appropriate to enzyme–ligand complexes, involves a weakening of the overall affinity of the enzyme for the ligand by altering the conditions in the medium (pH, ionic strength, temperature, etc.); for example, the conformation of the enzyme can be altered reversibly from complementary to non-complementary. Since the conformation of the protein molecule is as a rule senstive to the medium and the changes in it are of a cooperative type, these reversible conformational changes can occur under extremely mild conditions where the native structure of the enzyme is preserved. In addition, the sorbed enzyme may be desorbed competitively under the influence of the free ligands present in solution.

It is noteworthy that the study of the effect of each individual factor in the medium on the binding of the enzyme to the ligand can result in certain cases in definite deviations from the above general sorption and desorption rules. In principle, the attainment of optimal results in experiments on the isolation and purification of enzymes requires such preliminary study for each individual enzyme. In this case the optimisation of the conditions in the medium can not only ensure an efficient absorption and desorption of the enzyme itself but can also promote the elimination of possible impurities.

Yet another problem concerning the stability of the sorbent must be examined. This includes, first, the stability in relation to the conditions in the medium and, secondly, the resistance to the action of the enzyme. The first factor can be as a rule neglected since the choice of the conditions in the medium is determined in the first place by the stability of the enzymes themselves; it can be

taken into account only in the stage where the sorbent is prepared for the experiment or during its regeneration, which, when necessary, can be carried out under more severe conditions than sorption and desorption†.

As regards the stability of the sorbent to the enzyme, one should consider that it can be chemically transformed under the influence of the enzyme in those cases where a sorbent based on the substrate is employed. Evidently increased contact time between the sorbent and the enzyme can significantly decrease the capacity and specificity of the former although this factor is not common to all enzyme–substrate systems. In particular, one cannot rule out the possibility that under certain conditions in the medium the enzyme retains fully its affinity for the substrate but does not exhibit catalytic activity. In general preference should be given to sorbents where the ligand employed is not the substrate but a competitive inhibitor, which forms with the enzyme a so called "non-productive" complex (i.e. a complex which does not undergo a chemical transformation).

Resistance to enzyme action is important not only for the preservation of the sorption properties of the sorbent but also for the choice of the sorption procedure. The procedure can be static ("in a reservoir") or dynamic (chromatography). If a sorbent based on the substrate is employed, the sorption of the enzyme may be accompanied by a chemical transformation of the substrate with liberation of the reaction products to the surrounding solution. Since the reaction products also show affinity towards the enzyme and form fairly stable complexes with it, the result may be a competitive inhibition of the binding of the enzyme to the sorbent and the retention of part of the enzyme in solution. In those cases where the substrate reacts fairly rapidly and a static sorption procedure is employed, the inhibiting effect of soluble reaction products on the sorption of the enzyme can be very considerable. On the other hand, under dynamic conditions the products formed are continually removed by the stream of eluent flowing through the sorbent bed and have much less effect on the sorption of the enzyme. Therefore the static procedure can be used only with sorbents resistant to enzyme action or the sorption must be carried out under conditions where the enzyme is catalytically inactive; in other cases, the dynamic method is preferable.

The conditions governing the preparation and application of sorbents based on ligands discussed above apply in general also to sorbents based on enzymes. These are sometimes referred to as "enzymatic resins". Sorbents based on enzymes can be used to isolate and purify the corresponding ligands and also to investigate the binding of the ligand to the enzyme (although sorbents based on ligands are more suitable in this case). In view of the relative structural lability of enzymes, one must maintain conditions in the preparation and use of these sorbents which rule out irreversible denaturation of the enzyme.

The next section deals with studies based on using the affinity of the enzyme for the ligand, mainly for preparative purposes, and also data on the preparation of sorbents. A systematic account of the data described below may be based on the differences in the choice of the "sorbent–sorbate" system, which appears to be the most useful classification according to the general postulates concerning affinity sorption.

†In the operating cycle of the sorbent the author distinguishes its preparation for the experiment, the sorption and desorption of the enzyme, and sorbent regeneration (Editor).

III. THE USE OF ENZYME–LIGAND AFFINITY FOR PREPARATIVE PURPOSES

1. Natural Sorbents for Enzymes

The sorption of an enzyme on an insoluble substrate was first observed in 1910 by Starkenstein [5]—this was the sorption of liver amylase on potato starch. Later similar data were published by Ambard [6] for saliva amylase, by Chodat and Philia [7] for malt "diastase", and by Boekestein [8] for pancreatic amylase; in the last study, potato, rice, and wheat starches were tested as the sorbents.

Subsequently sorption on starch was widely used to isolate and purify amylases from various sources [9–20]. It was found that starch is a selective sorbent for α-amylase and does not sorb β-amylase. Thus Holmberg [9,10] discovered that malt α-amylase can be separated from β-amylase by sorption on starch from 50% ethanol solution in the presence of maltose; according to Holmberg's data, the sorbability of α-amylase increased as the concentration of alcohol was raised and the pH and temperature reduced. α-Amylase is an endoglycosidase, i.e. it cleaves the glycosidic linkages within the starch chain, in contrast to β-amylase, which splits off maltose residues from the non-reducing end of the carbohydrate chain. Therefore maltose, being a product of the activity of β-amylase, might have inhibited its binding to starch.

In a study of the sorbability of malt α-amylase on various starch and glycogen ("animal starch") specimens, Schwimmer and Balls [14] established that starch freshly precipitated with alcohol is the most effective sorbent; however, the sorbability of α-amylase on glycogen was highest. Bearing this in mind, Schwimmer and Balls [14] concluded that the efficiency of the sorption of α-amylase is determined by the area of the sorbent formed by maltoside chains with a length equivalent to 8 — 10 units and accessible to the enzyme in solution.

Schwimmer and Balls [15] purified malt α-amylase by chromatography on a column with wheat starch. The sorption was carried out at 5°C in the presence of 40% ethanol and calcium salts; the enzyme was desorbed with water saturated with calcium sulphate at room temperature. α-Amylase was isolated from the eluate in a crystalline state.

Thayer [17] separated the α- and β-amylases from *Pseudomonas saccharophila* by chromatography on a column with a mixture of potato starch and Celite. When the culture liquid was passed at 4°C through a column washed with water, only α-amylase was sorbed. Buffer solutions at different pH and with different calcium salt and maltose contents did not elute the sorbed enzyme. Elution was achieved using a concentration gradient of soluble starch and was very effective: the enzyme emerged in a sharp peak (3 ml of the eluate contained 75% of the total amount of the sorbed enzyme) and was concentrated by a factor of 100 compared with the initial solution. It is interesting to note that both amylases had the same pH activity optimum but differed sharply in their capacity for sorption on starch [17].

Markowitz et al. [18] reproduced Thayer's method [17] and obtained a highly purified crystalline preparation of α-amylase from *P. saccharophila*. A variant of this technique was employed by Neumann et al. [20] to isolate amylase from dog liver; the enzyme was purified by a factor of 23–147 with a yield of 45–75%.

Comparatively recently Vainer and Shul'man [21] published a report on the possibility of using starch to isolate amylase for practical purposes.

Leloir et al.[22] observed that insoluble starch can also be used as a sorbent for the purification of bean starch synthetase. Akazawa and Murata[23] and Tanaka and Akazawa[24] showed that starch synthetase is bound preferentially to amylose (a linear polysaccharide) rather than to the branched chain of amylopectin; the maximum sorption of starch synthetase on amylose occurred at a neutral pH and a low temperature but decreased sharply as the pH was reduced (to pH 5.0) and the temperature raised (above 25°C).

De la Haba[25] used sorption on starch for the purification of glycogen phosphorylase from rabbit muscle. When the whole muscle extract was passed through a column with potato starch at 3°C, the enzyme was completely bound to the sorbent; desorption was achieved by eluting the column with the soluble substrate (0.4% glycogen solution) and by raising the temperature simultaneously to 14°C. The enzyme was purified in this way by a factor of 33 with a yield of 100%; the specific activity of the resulting preparation corresponded to the activity of the doubly recrystallised enzyme. De la Haba[25] notes that the behaviour of glycogen phosphorylases *a* and *b* was identical under the conditions tested.

Hanabusa and Kohno[26] described a variant of the de la Haba method[25] in which the enzyme was desorbed solely by increasing the column temperature; they found this procedure more convenient, since it yields the enzyme without an admixture of glycogen and further purification is not needed.

Selinger and Schramm[27] studied the binding of glycogen phosphorylase to glycogen. They found that at pH 6.8 and a temperature of about 0°C phosphorylase *a* forms an insoluble enzyme–substrate complex with glycogen (up to 62% of the enzyme was precipitated). A similar complex was not formed with dextran, mannan, and levan, which indicated the specificity of the binding of phosphorylase *a* to glycogen. When the pH was changed to 5.0 or 9.0, the complex remained stable but at pH 4.0 it decomposed with loss of enzyme activity. An increase of temperature promoted the dissociation of the complex. It is interesting that the addition of α-amylase to the insoluble complex even at 0°C resulted in its complete decomposition in several minutes. According to the authors[27], this implies that phosphorylase *a* forms an insoluble complex only with native glycogen but not with its amylase-catalysed hydrolysis products, among which there are high-molecular macrodextrins resistant to the action of amylase[28]. Under comparable conditions, phosphorylase *b* was precipitated only in the presence of magnesium salts[27]. (This finding can probably be used for the separation of phosphorylases *a* and *b*.)

Leloir and Goldemberg[29,30] used the selective coprecipitation of glycogen synthetase with glycogen for the purification of specimens of this enzyme obtained from different sources. Rat liver glycogen synthetase was purified in this way by a factor of 300 and contained as impurities only small amounts of glycogen phosphorylase and amylase; however, the yield of the enzyme was low (only 12%).[29]

Loyter and Schramm[31] found that glycogen is able to bind α-amylase and used this property to isolate and purify the enzyme. The maximum coprecipitation of α-amylase with glycogen occurred at pH 8.0, a temperature of 0–3°C, and after the addition of ethanol up to a concentration of 40%. Subsequently Schramm et al.[32] found that not only glycogen but also macrodextrins, which are produced by the amylase-catalysed hydrolysis of glycogen and are resistant to the further action of amylase[28], are also capable of forming an insoluble complex with amylase. It is interesting that calcium ions, required for the enzymatic activity of α-amylase, were also necessary for its binding to glycogen and macrodextrin. Thus, when calcium ions were removed from solution by ethylenediaminetetra-acetate, an insoluble complex was not formed. Strontium and barium ions showed a similar activating effect, but cadmium and magnesium ions lacked this capacity. Schramm et al.[32] suggested that calcium ions are required either to maintain the active conformation of the enzyme or are involved directly in the binding of the substrate.

The above data on the binding of enzymes active towards the α-(1 → 4)-glucosidic linkage (i.e. capable of cleaving or synthesising this linkage) to various α-(1 → 4)-polyglucosides show that such binding is extremely selective. For example, starch effectively sorbs α-amylase but not β-amylase; starch synthetase, which is bound to amylose but not to amylopectin, exhibits a definite selectivity towards the polysaccharide. On the other hand, the selectivity is not absolute. Thus, apart from α-amylase, starch sorbs effectively starch synthetase and glycogen phosphorylase; similarly, glycogen ("animal starch") binds glycogen synthetase and α-amylase in addition to glycogen phosphorylase.

One might have expected that all the enzymes acting on α-(1 → 4)-polyglucosides would exhibit similar functional properties in relation to binding of the substrates in view of the similarity of the chemical properties of the latter. Apparently this happens to some extent although the selectivity characteristic of enzymes, depending on the steric structure of the substrate molecules and possibly on supermolecular structural factors, is shown in many cases. Moreover, the conditions in the medium where optimal binding takes place are different for different enzymes, which is evidently due to the individual characteristics of the structure of their protein molecules. This factor probably makes it possible to isolate in a pure form any enzyme without admixtures (or with minimal amounts of admixtures) of other related enzymes.

Natural sorbents have been used to isolate and purify a number of other enzymes. Jeuniaux[33–35] isolated a chitinase from soil streptomycetes by selective sorption on chitin from whole culture liquid. After the chitinase had been bound, the chitin with the sorbed enzyme was extracted and washed. The enzyme was not desorbed; instead the chitin was subjected to total hydrolysis by the chitinase and the soluble hydrolysis products were removed by dialysis. The chitinase was purified in this way by a factor of 70 with a yield of 27%. The resulting preparation contained no proteases, cellulases, pigments, and reducing sugars and the amount of protein impurities without chitinolytic activity was less than 5%.

The study by Grant and Robins[36] on the purification of elastase from pig pancreas showed that not only the active enzyme but also zymogen (proelastase) are bound with equal efficiency to elastin; this observation enabled the authors to reach the very important conclusion that the substrate binding centre, specifically the catalytic centre in the elastase molecule, is structurally autonomous. Gertler and Birk[37] purified proelastase using its adsorption on elastin.

Orekhovich et al.[38] investigated the binding of certain proteases (pepsin, trypsin, chymotrypsin, and papain) to comminuted sheep wool and silk fibroin. The experiments were performed at two pH values (3.9 and 7.9). Under these conditions, pepsin and papain were not bound either to wool or to silk. Trypsin and chymotrypsin were

bound fairly satisfactorily to both sorbents and at both pH values (the amounts of bound trypsin and chymotrypsin reached 83 and 75% respectively). Trypsin was desorbed using a solution of cysteine in the presence of urea and chymotrypsin using a solution of histidine in the presence of sodium chloride. Probably the differences in the behaviour of the proteases investigated reflect differences in their specificity.

Ogawa and Toyama [39] used chromatography on a column with powdered cellulose to separate a commercial preparation of cellulase from *Trichoderma viride* into three active components, which differ in their affinities for the substrate.

Reese and Avigad [40] described a method for the purification of levansucrase based on a selective coprecipitation of the enzyme with levan. The enzyme was purified by a factor of more than 2000 with a yield of 31%. Other enzymes (cellulose, β-galactosidase, α-amylase, galactose oxidase, and ribonuclease) were not coprecipitated under these conditions, which confirms the specificity of the binding of levansucrase to levan. A similar procedure was employed by Bauer and Avigad [41] for the purification of fructan hydrolase.

Cherkasov and coworkers [42-44] investigated the conditions governing the formation and decomposition of the enzyme–substrate complex of lysozyme with chitin using the chromatography of the enzyme on a column with the substrate. Two types of complexes, depending on the pH of the medium, were observed. One of the complexes predominates in a weakly acidic medium and is stable only in the presence of salts in solution, decomposing in a salt-free medium. The other complex predominates in a weakly alkaline medium, is stable also in the absence of salts, but decomposes when the solution is acidified. On this basis, two procedures were proposed for the isolation of lysozyme from various natural sources: (a) by sorption at pH ~ 5 in a salt solution followed by desorption with water and (b) sorption at pH 8–9 followed by washing the column with water and desorption with dilute acetic acid. Chitin obtained by standard methods usually contains free amino-groups owing to its partial deacetylation during purification. The presence of amino-groups imparts to such chitin the properties of an anion exchanger and leads to non-specific sorption of acid proteins (such as albumins), which are desorbed with acetic acid. Therefore, when ordinary chitin is employed, only the first procedure is applicable [45,46]. Treatment of ordinary chitin with dilute nitrous acid, which results in the replacement of the amino-groups by neutral hydroxy-groups, eliminates the non-specific sorption and permits the employment of the second procedure, which has the advantage that at pH 8–9 lysozyme does not exhibit a hydrolytic effect on chitin and the complex formed is more stable [47,48]. Lysozyme was isolated by this procedure from hen egg white and from aqueous extracts of horseradish and turnip in almost quantitative yields [45-48]. Chromatography on chitin was also successfully employed by Jensen and coworkers [49,50] for the purification of phage lysozyme. The authors note that the method made it possible to concentrate vanishingly small amounts of the enzyme and at the same time to free it from inhibitors which interfere with the determination of activity in the unpurified solution obtained by the lysis of phages. Thus the yield of lysozyme when isolated by this method was 300%, judging from the activity balance, which can only be explained by the liberation of the enzyme from inhibitors [50].

Among the studies discussed above, a typical adsorption technique was not always employed. For example, in the binding of enzymes to glycogen, the initial components were present in solution and yielded a precipitate only on interaction: this applies also to levansucrase and levan. However, the discussion of these investigations was useful not only because the method is similar to a variant of static adsorption but also because it is possible, in principle, to employ the data on the conditions governing the binding of the enzyme and substrate in experiments with synthetic adsorbents.

2. Synthetic Adsorbents for Enzymes

Erlanger [51] investigated the possibility of isolating and purifying chymotrypsin by binding it to a dipeptide inhibitor converted into a water-insoluble state: the benzyl ester of *N*-benzyloxycarbonyl-L-leucyl-D-phenylalanine (BECLP). It was rendered insoluble by introducing hydrophobic groups into the dipeptide molecule: the benzyl group (in the carboxy-group of phenylalanine) and the benzyloxycarbonyl group (in the amino-group of leucine). Bearing in mind the substrate specificity of chymotrypsin (chymotrypsin hydrolyses peptide bonds formed by the carboxy-groups of aromatic aminoacids), it might have been expected that BECLP would adsorb chymotrypsin. from solution. Indeed, Erlanger observed that chymotrypsin and chymotrypsinogen and pepsin were bound qualitatively to BECLP; trypsin and trypsinogen were also bound but less effectively. Other proteins tested (ribonuclease, human and bovine serum albumins, and β-lactoglobulin) were bound only in insignificant amounts. Erlanger believed that the approximately identical capacities of chymotrypsin and pepsin for binding to BECLP should have been expected in view of the similarity of their substrate specificities. However, the adsorption of trypsin (and trypsinogen) can hardly be due to a specific interaction, since this enzyme hydrolyses peptide bonds formed by the carboxy-groups of diamino-carboxylic acids (arginine and lysine). "Hydrophobic" ligands of the type employed by Erlanger have not found a wide application as sorbents.

Sorbents in which the ligand is linked covalently to an insoluble carrier acquired a greater practical importance for the sorption and chromatography of enzymes. Such sorbents were obtained for the first time by Lerman, who used them to isolate fungal tyrosinase [52]. Certain azophenols, known to inhibit tyrosinase, were chosen as ligands. They were linked to cellulose via an ether bond. Only sorbents whose ligands contain a *p*-hydroxyphenyl group at the free end, i.e. the group which is also present in tyrosine (the substrate of tyrosinase), showed a capacity for the selective sorption of tyrosinase:

1) cellulose —O—C_6H_3(OH)—N=N—C_6H_4—C_6H_4—N=N—C_6H_4—OH,
2) cellulose —O—C_6H_3(OH)—N=N—C_6H_4—N=N—C_6H_4—OH,
3) cellulose —O—CH_2—C_6H_4—N=N—C_6H_4—OH.

Sorbent (3), which was used for the chromatographic isolation of tyrosinase, proved to be the most effective. The enzyme could be purified by a factor of 61 with a yield of 56%.

Arsenis and McCormick [53] purified rat liver flavokinase by chromatography on flavin-substituted cellulose. 6-Amino-9-(1-D-ribityl)isoalloxazine, which is a substrate of flavokinase, and 7-amino-6,9-dimethylisoalloxazine, its

competitive inhibitor, were tested as ligands. In the reaction of these amines with chlorocarbonylmethylcellulose (the acid chloride of carboxymethylcellulose), the corresponding acetamide derivatives were obtained. Both adsorbents were found to be effective for the preparation of highly purified flavokinase.

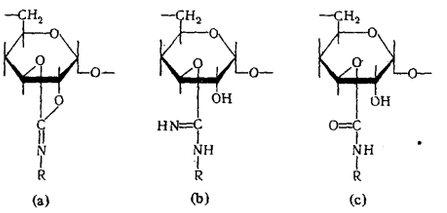
In another study, Arsenis and McCormick [54] investigated the possibility of purifying the apoenzymes of certain oxidoreductases containing flavin mononucleotide (riboflavin phosphate) as the coenzyme. The study was based on the observation that not only flavin mononucleotide but also its monomethyl ester can function effectively as the coenzyme of NADPH-cytochrome *C* reductase, pyridoxin (or pyridoxamine) phosphate oxidase, and glycolate oxidase. Bearing this in mind, the authors obtained esters of flavin mononucleotide with cellulose, phosphocellulose, and diethylaminoethylcellulose and tested them as adsorbents. It was found that, in column chromatography of the above apoenzymes on flavin-substituted cellulose, the enzymes are more firmly retained than on control specimens of celluloses, apparently due to the additional interaction between the apoenzyme and the coenzyme. Almost complete separation of the apoenzyme from impurities was achieved for apoglycollate oxidase; it was purified by a factor of more than 400 in a quantitative yield [54].

Lowe and Dean [55] purified oxidoreductases using adsorbents based on other coenzymes—nicotinamide-adenine dinucleotide (NAD) and nicotinamide-adenine dinucleotide phosphate (NADP) attached to cellulose. These adsorbents were found to be suitable for the isolation of glucose-6-phosphate dehydrogenase, lactate dehydrogenase, and threonine dehydratase, one chromatographic stage being sufficient for the separation of the enzymes.

Mosolov and Lushnikova [56] described a method for the purification of certain peptidohydrolases based on their selective binding to natural inhibitors of protein origin fixed on cellulose. The adsorbents were prepared by introducing the inhibitors into the azo-coupling reaction with *p*-diazobenzoylcellulose (this method presupposes that the protein inhibitors contain aromatic groups which are not essential for their functioning). Adsorbents based on the soya-bean trypsin inhibitor and the inhibitor of potato tuber proteases were obtained in this way. The adsorbent based on the trypsin inhibitor bound selectively and completely trypsin from solution at 0–3°C at pH 7.7 (1/15 M phosphate buffer); the enzyme was desorbed with dilute hydrochloric acid at pH 2.3; under these conditions, the enzyme–inhibitor complex is fully dissociated and the enzyme itself shows the maximum stability and does not undergo autolysis. Other proteins tested (bovine serum albumin, egg albumin, and ribonuclease) were bound to an insignificant degree, which indicated the specificity of the adsorbent. The efficiency of this adsorbent for the purification of trypsin is indicated by the finding that the specific activity of the crystalline trypsin preparation increased by a factor of 1.5–2 after adsorption and desorption, the preparation being completely free from autolysis products. The sorbent based on the inhibitor of potato tuber proteases was used [56] to purify the total protease preparation from *Actinomices fradiae*. After sorption and desorption, the proteolytic activity of the preparation also increased by a factor of 1.5–2; however, the solution retained an appreciable percentage of the activity, since not all the fractions of the preparation showed a sufficiently high affinity for the inhibitor.

The method of preparation of sorbents proposed by Porath and coworkers [57–60] has recently become most widely used. It consists of covalent binding of the ligand‡ to an insoluble polysaccharide carrier with the aid of cyanogen halides, for example bromocyanogen, and consists of two stages: (a) treatment of the polysaccharide with an aqueous alkaline solution of the cyanogen halide with formation of an intermediate reactive compound and (b) the coupling of the intermediate to the ligand in a neutral or weakly alkaline medium. The carriers can be starch, cellulose, and commercial products–Sephadex (cross-linked dextrin) and Sepharose (cross-linked agarose)—usually employed as molecular sieves. According to Porath and coworkers, the best carrier is Sepharose, which in aqueous solutions forms grains of an extremely porous gel so that not only its surface but also the inner space within the grains is accessible to enzyme molecules. As a result, adsorbents with a high capacity may be obtained on the basis of Sepharose.

An essential condition in the method of Porath and coworkers is the presence in the ligand of a free primary (aliphatic or aromatic) amino-group not required for binding to the enzyme, whereby the ligand can be attached to the carrier; if this group is absent, it must be specially introduced. The mechanisms of the reaction of cyanogen halide with the polysaccharide and of the subsequent stage where the primary amine is attached to the activated polysaccharide have not been finally elucidated. It has only been shown that, when a cyanogen halide reacts with the polysaccharide, a product containing additional nitrogen but not the halogen is formed; on the other hand, when this intermediate interacts with the amine, ammonia is liberated. Porath [59] suggests that this may involve the formation of the following structures:



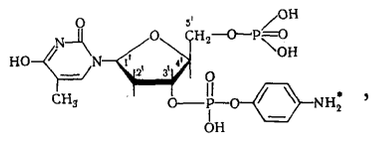
The adsorbents obtained by the method of Porath and coworkers are quite stable in the pH range between 2 and 12, which includes the region of stability of almost all enzymes. In 0.1 *N* hydrochloric acid, only 1.81% of the attached ligand groups are split off from the carrier in 4 days, while in 0.1 *N* sodium hydroxide 42.7% of these groups are removed during the same period; in the latter case the losses probably occur owing to the decomposition of the carrier itself [60].

Despite certain limitations, the method of Porath and coworkers generally makes it possible to obtain a fairly wide and varied selection of starting materials for the coupling of the ligand to the carrier and in this sense it can be regarded as one of the most general methods for preparing affinity sorbents. The preparation and applications of sorbents by this method are discussed below [57–60].

---

‡The method is used to attach to the sorbent not only the ligand but also the enzyme. In particular, it is used for the affinity chromatography of inhibitors, transfer RNA, and others—see the fourth International Fermentation Symposium, March, 1972, Kyoto, Japan, Abstracts, pp. 64–65 (Editor).

Cuatrecasas et al. [61] were the first to use this procedure to prepare sorbents for enzymes: the nuclease from *Staphylococcus aureus*, α-chymotrypsin, and carboxypeptidase A. The substrate of the nuclease is di-(*p*-nitrophenyl)thymidine 3′,5′-diphosphate. The nuclease readily splits off *p*-nitrophenyl phosphate from the 5′-position but has only a slight effect on the same group in the 3′-position. On the other hand, compounds with a free (not esterified) phosphate group in the 5′-position are powerful inhibitors of the nuclease. Bearing in mind these findings 3′-(*p*-aminophenylphosphoryl)deoxythymidine 5′-phosphate,

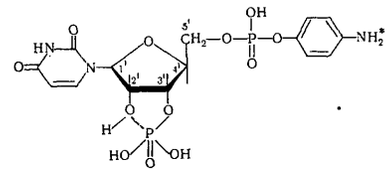


was chosen as the ligand for coupling with Sepharose. The inhibition constant for this substance, determined from kinetic data, is extremely low (10^{-6} M), which ensured a stable binding of the nuclease; the substance itself is stable in the pH range from 5 to 10; the p*K* of the amino-group is sufficiently low for effective interaction with Sepharose activated by bromocyanogen and the amino-group is sufficiently remote from the part of the ligand bound to the enzyme§. Nuclease from the whole culture liquid was isolated in quantitative yields in one stage by column chromatography using the sorbent obtained. The sorption was carried out at pH 8.0 (0.05 M borate buffer with added 0.01 M calcium chloride) and, after washing the column with the same buffer solution, the enzyme was desorbed with 0.01 M acetic acid.

In the preparation of a sorbent specific to chymotrypsin [61], an enantiomeric analogue of the substrate—the methyl ester of D-tryptophan—was chosen as the ligand. However, the resulting sorbent was not altogether satisfactory, probably because the small dimensions of the ligand produced steric hindrance to the approach of the enzyme to the active surface of the sorbent. In view of this, another ligand—the methyl ester of ε-aminocaproyltryptophan—was tested. In this ligand the tryptophan residue bound to chymotrypsin is much more remote from the site of attachment to Sepharose, so that it is much more accessible to the enzyme in solution. The resulting sorbent proved to be extremely effective both for the purification of chymotrypsin itself and for the elimination of admixtures of this enzyme from preparations of other enzymes, in particular ribonuclease. The sorption was carried out in 0.5 M tris hydrochloride buffer at pH 8.0 and the enzyme was desorbed with 0.1 M acetic acid. The yield of the pure enzyme was more than 90%. The dissociation constant of the chymotrypsin complex with this ligand is about 10^{-4} M, i.e. higher by 2 powers of 10 than the value for the enzyme—inhibitor complex of nuclease. Nevertheless, in this case too the adsorbability of the enzyme was sufficiently complete and stable. Thus the requirement for a very high stability of the enzyme—ligand complex is not strictly obligatory.

In the preparation of the sorbent for carboxypeptidase A, the dipeptide L-tyrosyl-D-tryptophan was employed as a ligand [61]. The sorption was carried out in 0.005 M tris-HCl buffer at pH 8.0 with sodium chloride added up to a concentration of 0.3 M (evidently in order to prevent the non-specific sorption of impurities by the free carboxy-groups of tryptophan residues). The enzyme was desorbed with 0.1 M acetic acid. The sorption of carboxypeptidase A (within the limits of the working capacity of the sorbent) and its desorption were quantitative. The specificity of the sorbent was demonstrated by the absence of binding of carboxypeptidase B under the same conditions.

Wilchek and Gorecki [62] described the preparation and application of a sorbent for ribonuclease. The ribonuclease substrates are ribonucleic acid and pyrimidine 2′ : 3′-cyclic phosphates; compounds such as cytidine 2′-monophosphate, cytidine 3′-monophosphate, and uridine 2′-monophosphate are known to be competitive inhibitors of the enzyme. However, the attempt to attach cytidine 2′-monophosphate to Sepharose by the method of Porath and coworkers was unsuccessful, probably owing to the low nucleophilicity of the amino-group in the 4-position. Therefore another class of inhibitors, namely 2′(3′),5′-diphosphates, was tested: firstly, only the 2′(3′)-phosphate group is important for their inhibiting activity and the group in the 5′-position can be modified; secondly, inhibitors of this type are the most powerful known (the inhibition constant determined from kinetic data is approximately 10^{-5} M). Therefore 5′-(*p*-aminophenylphosphoryl)uridine 2′(3′)-phosphate was chosen as the ligand:



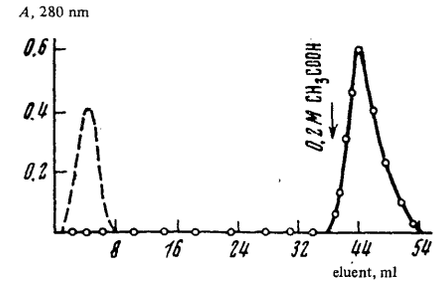


Figure 1. Affinity chromatography of ribonuclease A (after Wilchek and Gorecki [62]). The dashed line indicates the peak of ribonuclease inactivated by oxidation and reduction and also of enzymes with a different substrate specificity (trypsin and chymotrypsin). The arrow indicates the point where the eluent was changed. For details, see text.

The sorbent obtained firmly retained ribonuclease in 0.02 M acetate buffer at pH 5.2; the enzyme was desorbed with 0.2 M acetic acid (Fig. 1). With the aid of this sorbent, it was possible to free ribonuclease from various impurities, including phosphates of different types and also to eliminate selectively admixtures of ribonuclease from other preparations. The authors emphasise the importance of their method for the fractionation and purification of synthetic ribonuclease preparations [62].

§Here and henceforth the superscript* denotes the group attached to the carrier.

Porath and coworkers [63] synthesised a sorbent for asparaginase. The substrate of asparaginase is L-asparagine, while its enantiomeric form D-asparagine inhibits the enzyme. Therefore the ligand chosen was a product of the condensation of L(+)-β-chlorosuccinamic with hexamethylenediamine:

$$*H_2N-(CH_2)_6-NH-\underset{\displaystyle COOH}{\underset{|}{CH}}-CH_2-CO-NH_2\ .$$

The latter played the role of an "insert" between the functional groups of the ligand and Sepharose in order to eliminate the steric hindrance in the sorption of the enzyme. Optimum sorption occurred in 0.05 M borate buffer at pH 8.6 with sodium chloride added to a concentration of 0.3 M; at a higher ionic strength the enzyme was more weakly bound to the sorbent, while reduction of the ionic strength resulted in an increase of the sorption of impurities. The enzyme was desorbed with 0.001 M solution of D-asparagine in the same buffer. The specific activity of the asparaginase preparation obtained exceeded the activity of the preparations produced by other methods. The resistance of the sorbent to the action of the enzyme was entirely satisfactory.

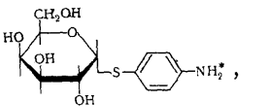
The sorbents obtained by the method of Porath and coworkers [57-60] have been used successfully for the isolation and purification of a number of other enzymes: chymotryptin-like enzymes [64], plasminogen [65], wheat proteases [66], papain [67,68], β-galactosidase [69], β-xylosidase [70], DNA polymerase [71], 3-deoxy-D-arabino-heptulosonate-7-phosphate synthetase [72], lecithin : chloesterol acyltransferase [73], acetylcholinesterase [74,75], and chorismate mutase [76]. Kasche [77] and Feinstein [78] obtained by this method a sorbent based on an inhibitor of soya-bean trypsin and showed that it binds not only trypsin but also chymotrypsin (cf. Mosolov and Lushnikova [56]).

Inman and Dintzis [79] described a method for the preparation of affinity sorbents based on Biogel (cross-linked polyacrylamide), used, like Sepharose, as a molecular sieve. In this procedure the carboxamide group of Biogel is converted by treatment with hydrazine hydrate into the hydrazide group, which in turn is converted subsequently into an acyl azide group by treatment with nitrous acid; the acyl azide group readily reacts with primary aliphatic and aromatic amines to form amides:

$$B-CO-NH_2 \xrightarrow{N_2H_4} A-CO-NH-NH_2 \xrightarrow{HNO_2} B-CO-N_3 \xrightarrow{R-NH_2} B-CO-NH-R.$$

Thus the method of Inman and Dintzis, like that of Porath and coworkers, requires the presence in the ligand of a free amino-group not required for binding to the enzyme; the difference is that polycrylamide has a carbon skeleton and in this respect is more stable than Sepharose or Sephadex.

Continuing the development of the methods of Porath and coworkers and Inman and Dintzis, Cuatrecasas [80-82] described the syntheses of various derivatives of Sepharose and Biogel, such that ligands can be attached to these carriers not only via the amino-group but also via the carboxylic, thiol, phenolic, and imidazole groups; also it is possible to vary the distance between the ligand and the carrier by interposing between them aliphatic chains with different numbers of atoms ("arms"). As mentioned above, the length of the "arms" is in some cases of decisive importance, for example in the synthesis of the adsorbent for chymotrypsin [61]. Another example described by Cuatrecasas [69,80] refers to bacterial β-galactosidase. *p*-Aminophenyl-β-D-thiogalactopyranoside



was employed as the initial ligand. When it was linked directly to Sepharose, the enzyme was not sorbed. When it was combined with the bromoacetamidoethyl derivative of Sepharose, a sorbent was obtained which only weakly retained the galactosidase:

$$\text{Sepharose}\ -NH-CH_2-CH_2-NH-CO-CH_2-NH-\ \text{ligand}\ .$$

On a sorbent with a longer "insert",

$$\text{Sepharose}\ -NH-(CH_2)_3-NH-(CH_2)_3-NH-CO-CH_2-CH_2-CO-NH-\ \text{ligand},$$

the enzyme was sorbed very strongly.

By comparing sorbents based on the same ligand but with different carriers, Cuatrecasas showed (using as an example the sorbents for nuclease [80] and β-galactosidase [80]), that the adsorbents based on Biogel have a lower capacity than those based on Sepharose, which is probably due to the lower porosity of Biogel.

3. Other Methods of Utilising the Affinity of the Enzyme for the Ligand in the Chromatography of Enzymes

Cavalieri and Caroll [83] showed that, by polymerising acrylamide in a solution containing DNA, it is possible to obtain a gel in which DNA is firmly incorporated and which is suitable for the isolation and purification of DNA polymerase.

In another method of employing ligands, a non-specific sorbent is saturated with a soluble ligand; for example, ligands containing basic or acid groups are attached to suitable ion exchangers. Such a procedure was described by Beers [84], who used it to purify polynucleotide phosphorylase on a column with polyadenylic acid attached to DEAE-cellulose. The properties of such sorbents have been hardly investigated and it is not clear whether the ligand molecules sorbed on the carrier retain the capacity for the selective binding of the enzyme. Bearing in mind the data of Cuatrecasas [61,69,80] concerning the role of the hydrocarbon "arm" between the ligand and the carrier, one must suppose that this capacity would be considerably weakened. In addition, it is evident that sorbents of this type are less stable than those with covalently bound ligands.

Yet another application of the affinity of the enzyme for the ligand in the chromatography of enzymes consists in a selective elution of the enzyme sorbed on a non-specific sorbent with a soluble ligand. Heppel [85] first showed that pyrophosphorylase sorbed on alumina gel is selectively and effectively eluted with a pyrophosphate solution. Subsequently this principle was used to purify fructose-1,6-diphosphatase [86-88], aldolase [87,89], malate dehydrogenase [90], nuclease [91], and pyruvate kinase [92]. Yoshida [93] isolated by this method glucose-6-phosphate dehydrogenase, pseudocholinesterase, lactate dehydrogenase, and alanine dehydrogenase. The chromatography of carboxypeptidase A on a DEAE-cellulose column in the presence of a competitive inhibitor (β-phenyl propionate) resulted in its resolution into five fractions differing in aminoacid composition and thermal stability [94].

IV. ANALYTICAL APPLICATIONS OF AFFINITY CHROMATOGRAPHY

An interesting analytical aspect of the application of affinity chromatography, described by Wilchek and coworkers [95], refers to the study of the active centres of enzymes by specific chemical modification. The specificity of the reaction in the region of the active centre (more precisely in the region of ligand binding) is achieved by employing in the reaction a ligand with a chemically reactive group. As a result, the ligand reacts with other groups of the enzyme in the region of ligand binding. Peptides obtained by the successive cleavage of the modified enzyme have been fractionated on a column with the native enzyme attached to an insoluble carrier¶. The column retains only the peptides which contain the modified amino acid residues—owing to the presence in them of the ligand group. By analysing these peptides, it is possible to locate the region of the active centre in the aminoacid sequence of the enzyme molecule. In the above study by Wilchek and coworkers [95], ribonuclease was azo-coupled with a diazotised inhibitor—5′-(*p*-aminophenylphosphoryl)uridine 2′(3′)-phosphate. This compound reacted with ribonuclease in molar proportions of 1 : 1. After the cleavage of the modified enzyme with trypsin, the mixture of peptides was fractionated on a column with native ribonuclease attached to Sepharose by the method of Porath and coworkers [57-60]. The chromatography was carried out at pH 5.0, which is optimal for the binding of the enzyme to the ligand [62]. The coloured product was firmly retained on the column and, after washing off the impurities, was desorbed with 0.8 M ammonium hydroxide solution. Analysis showed that the product is a single peptide incorporating aminoacid residues between 67 and 85 and containing the modified tyrosin residue. The authors note the rapidity and convenience of the method compared with ion-exchange chromatography and electrophoresis.

The same method, which has been called the method of "affinity labelling", was used by Wilchek [97] and Cuatrecasas [98] for the isolation of a modified peptide from staphylococcal nuclease. An affinity label was applied also to acetylcholinesterase [99], aspartate aminotransferase [100], lysozyme [101], and *β*-galactosidase [102].

Kravchenko and coworkers [103,104] used affinity chromatography to separate the products of the photochemical oxidation of lysozyme in the presence of Methylene Blue under the conditions of preferential oxidation of tryptophan residues. Chromatography on Amberlite CG-50 ion-exchange resin made possible only the separation of the overall photochemical oxidation products from the unchanged native enzyme (Fig. 2). Bearing in mind that the modification of tryptophan residues in lysozyme might affect its affinity for the substrate [1-4], the lysozyme was chromatographed on chitin [42,43]. The results of such chromatography are presented in Fig. 3. [103] The chromatogram shows clearly three peaks (*X*, *Y*, and *Z*), the *Z* peak emerging almost simultaneously with the front of the eluent. Since the peaks emerging with the front can have a complex composition, the *Z* peak was subjected to further analysis. When it was rechromatographed under conditions increasing the affinity of lysozyme for chitin (a higher ionic strength of the medium [43]), it was possible to separate it into several further fractions [104]. Kravchenko and Lapuk [105] showed that the main fraction of the *Z* peak consists of an individual modification product in which the tryptophan residue 28 was oxidised. It is interesting to note that the tryptophan residue 28 is remote from the active region of the enzyme and is not directly involved in the binding of the substrate [1-4]. Nevertheless, experiments showed that its oxidation leads to a significant decrease of affinity. Hence it follows that this aspect of affinity chromatography is not restricted to cases where the active region of the enzyme is modified.

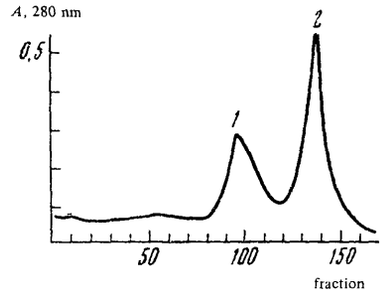


Figure 2. Chromatography of photochemically oxidised lysozyme on Amberlite CG-50 cation-exchange resin columns (after Kravchenko et al. [103]); 2.7 × 28.8 cm column; 0.2 M sodium phosphate buffer, pH 6.72; rate of elution 35 ml h^{-1}: 1) mixture of photochemical oxidation products; 2) native lysozyme. 10 ml fractions.

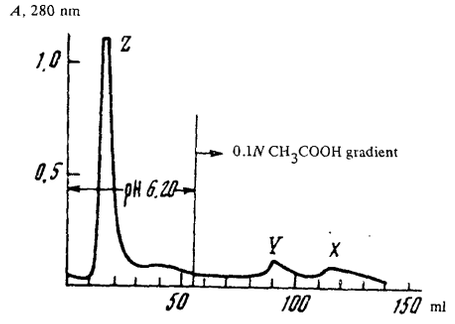

Figure 3. Chromatography of a mixture of products of the photochemical oxidation of lysozyme (peak *1* in Fig. 2) on chitin (after Kravchenko et al. [103]); 0.9 × 22.5 cm column with chitin dispersed to a 50 μm grain size; initial conditions: 1/15 M phosphate buffer, pH 6.20; volume of mixer for gradient elution 200 ml; rate of elution 15 ml h^{-1}.

¶There is an extensive literature on sorbents containing enzymes attached to insoluble carriers. The methods of their preparation and various aspects of their applications have been described in the reviews by Silman and Katchalski [96], Gryszkiewicz [141], and Goldman et al. [142].

A similar approach was employed by Kasche [77] to fractionate and characterise the functional properties of the products of the modification of heat-treated and γ-irradiated chymotrypsin on a column containing an inhibitor of soyabean trypsin attached to Sepharose by the method of

Porath and coworkers (Feinstein also reported [78] that, apart from trypsin, this type of sorbent is capable of specific binding of chymotrypsin). Native chymotrypsin showed an appreciable affinity for the inhibitor and lagged appreciably behind the eluent front. After heat treatment in solution, the enzyme was resolved into two fractions one of which emerged with the front and was completely inactive and the other corresponded to native chymotrypsin. After γ-irradiation, both in solution and in a dry state, two fractions were also obtained, one of which emerged with the front and was inactive. However, the second peak occupied an intermediate position on the chromatogram between the inactive and native enzymes. Measurements on the fractions showed that, as the enzyme emerges from the column, its enzymatic activity increases smoothly from 0 to 100%.

The use of affinity chromatography for analytical purposes is not as yet very common although this section has shown that there is a fairly broad base for such investigation and the few examples quoted demonstrate great possibilities of this method.

V. CHROMATOGRAPHIC CHARACTERISTICS OF THE PHYSICOCHEMICAL PROPERTIES OF THE ENZYME–LIGAND COMPLEX

Chromatography is one of the most direct and simplest methods for the investigation of the thermodynamics of sorption and complex formation [106–108].

Cherkasov and Kravchenko [109,110] were the first to employ this method for the investigation of the thermodynamic properties of the enzyme–substrate complex of lysozyme and chitin. Preliminary studies [42,43] showed that, depending on the pH of the medium, lysozyme forms two types of complex with chitin, with different conditions for their stability, as mentioned above (p. 895). Since the existence of two types of complex was not revealed by other methods, the chromatographic approach was employed for this purpose [109,110]. The equilibrium constant was found from the relation between the retention volume and the molar concentration of lysozyme at its peak on the output curve and the heat of complex formation was estimated from the relation between the retention volume and column temperature [106–108]. The determinations were made at pH 4.7 and 8.4, which correspond to the most favourable conditions for the two types of complex (at intermediate pH values lysozyme is distributed between the two complexes). The results obtained are listed in the Table which includes for comparison also data obtained by other methods at pH ~ 5 (there are no published quantitative data referring to pH 8–9; only graphical relations between the stability of the complex and pH, obtained by differential ultraviolet spectrophotometry [113] and fluorescence measurements [114,115], are available.

The Table shows that the results obtained by the chromatographic method at pH 4.7 agree very satisfactorily with those obtained at pH ~ 5 by other methods. Hence it follows that affinity chromatography is a fully valid method for the study of the thermodynamics of the binding between enzyme and substrate.

The data for the properties of the complex at pH 8–9 are contradictory. It follows from the work of Rupley et al. [113], Chipman et al. [114], and Lehrer and Fasman [115] that, on increase of pH from 5 to 8–9, the stability of the complex falls (the variation of other thermodynamic quantities with pH is not quoted in these reports). On the other hand, the results of the chromatographic determination show that the stability of the complex at pH 8.4 is higher almost by a factor of 10 than at pH 4.7 (cf. the values of ΔG° in the Table). The discrepancies are probably due to the inadequacy of the spectroscopic methods for the investigation of the complexes. Indeed these methods are indirect and are based on the detection of effects associated with changes in the conformation of lysozyme on formation of the enzyme–substrate complex.

Thermodynamic parameters of the formation of a lysozyme–substrate complex.

pH	$-\Delta F^\circ$, kcal mole^{-1}	$-\Delta H^\circ$, kcal mole^{-1}	$-\Delta S^\circ$, e.u.	Method	References
4.7	6.9	14.0	23.8	Chromatography	109, 110
5.0	7.0	12.8	19.7	Calorimetry	111
5.3	7.0	16.6	32.2	Kinetics	112
5.3	7.2	14.3	23.0	u.v. photometric	113
8.4	8.1	9.6	5.0	Chromatography	109, 110

On the other hand, analysis of the differences between the enthalpies and particularly the entropies of complex formation at pH 4.7 and 8.4 (see Table) shows that the conformation of lysozyme changes appreciably only when the complex is formed in an acid medium, but there is little alteration or none at all in an alkaline medium [110]. Thus, by virtue of the conformational properties of lysozyme, indirect methods evidently detect only the complex formed at pH ~ 5 and lead to the incorrect conclusion that the stability of the complex decreases as pH rises to 8–9. Similar situations can arise also in many other enzyme–substrate systems.

The applicability of kinetic methods for such purposes is limited to conditions where the enzyme exhibits its activity; for example, in the case of lysozyme and chitin these methods are applicable at ~pH 5 but not above pH 8.

Thus the direct method of affinity chromatography is more informative than the kinetic and spectroscopic methods now widely employed in this field.

The developments of recent years in the field of affinity chromatography show that the method can be fruitfully employed in a wide variety of different types of enzyme studies. On the whole, the present state of affinity chromatography shows it to be a promising analytical and preparative method in enzyme chemistry.

---o0o---

During the preparation of the review for the press, reports appeared on the use of affinity chromatography for the purification of tyrosine hydroxylase [116], neuraminidase [117], dihydrofolate dehydrogenase [118–120], plasminogen [121–124], thrombin [125], pepsin [126], carboxypeptidase A [127,128], carboxypeptidase B [128,129], transaminases [130], trypsin-like enzymes [131], and certain proteases [132]. Figs. 4 and 5 present examples of the isolation and separation of carboxypeptidases A and B.

The method of "affinity labelling" of the active centre of the enzyme has been described for carboxypeptidase A [133,134] and aldolase [135].

Akanuma et al. [136] used affinity chromatography to investigate the properties of carboxypeptidase B complexes with various analogues of basic and aromatic amino-acids.

Wilchek et al. [137] reported certain changes in the functional properties of protein kinase in its chromatography on Sepharose to which cyclic adenosine monophosphate had been attached.

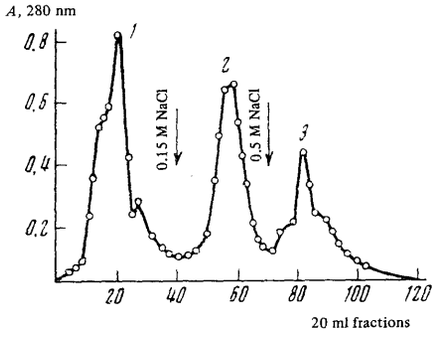

Figure 4. Separation of carboxypeptidases A and B by chromatography on Sepharose 4B with bound ε-aminocaproyl-D-tryptophan (after Reeck et al. [128]); initial eluent; 0.02 M tris-HCl buffer, pH 7.5, with added 0.05 M NaCl, followed by NaCl concentration gradient elution; the change of eluent is indicated by arrows: 1) impurities; 2) carboxypeptidase B; 3) carboxypeptidase A.

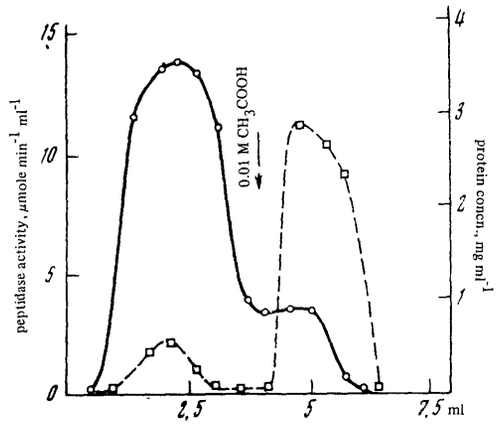

Figure 5. Isolation of carboxypeptidase A from a mixture of proteins by chromatography on porous glass with bound glycyl-D-phenylalanine (after Robinson et al. [127]). A column with granulated (200 mesh) porous glass (pore diameter 200 nm) was charged with a mixture of carboxypeptidase A, lysozyme, rubonuclease A, and bovine serum albumin. Initial eluent: 0.02 M tris-HCl buffer, pH 7.5, with added 0.2 M NaCl; the arrow indicates the change of eluent; continuous line—protein; dashed line—peptidase activity.

Mosbach et al. [138] and Weibel et al. [139] described the preparation of adsorbents for dehydrogenases with nicotinamide-adenine dinucleotide as the coenzyme.

The introduction of a new type of insoluble carrier—porous granulated glass—is noteworthy [127,139]. The porous glass is activated by treatment with aminosilanes, the amino-group introduced thereby being employed for the covalent binding of ligands.

Several reviews have been published on the affinity chromatography of enzymes and certain other bioorganic compounds [140,143,144].

State of Water in Inorganic Crystal Hydrates and the Characteristic Features of Their Dehydration

V.N.Makatun and L.N.Shchegrov

The state of water in inorganic crystal hydrates has been discussed, and the various distortions of the water molecule, as far as its dissociation, under the influence of the environment have been analysed. The reactions involved in the extensive dehydration of crystal hydrates have been examined from the viewpoint of the relationship between the state of water in the hydrate and the characteristic features of the dehydration processes leading to irreversible changes in the substance undergoing dehydration and to the decomposition of a complex oxo-anion. The bibliography contains 221 references.

I. INTRODUCTION

The nature and state of water in hydrated compounds has recently been attracting increasing attention from research workers. This is due to the part played by hydrates in the solution of general problems of solid structure and also to the considerable practical importance of these compounds, since many substances can be obtained most readily and in purest form as the crystal hydrates. In technology and preparative chemistry, in addition to the original hydrates, extensive use is also made of their dehydration products. For example, one possibility being discussed is the provision of water for cosmonauts by the dehydration of water-containing non-terrestrial minerals.

The variety of substances capable of combining with and firmly retaining water to some extent predetermines the variety of ways in which water can be bound. Moreover, the way in which the experimental results from the study of hydrates are presented often depends on the methods used and the aims of the work. This has apparently been responsible for the extreme variety of terms characterising the nature and the state of water in inorganic hydrates, which has led almost to a state of crisis in the present nomenclature for the types of water in hydrates. The chief among these are: 1) sorbed or hygroscopic (adsorption and capillary) water [1-3]; 2) water of crystallisation [1,4,5]; 3) water of constitution [1,6-8]; 4) structural water [9-11]; 5) hydrolysis water [12]; 6) lattice and non-lattice [13]; 7) layer and inter-layer [14]; 8) combined [15] and chemically combined [16]; 9) constructional [17]; 10) zeolite [18]; 11) peripheral [19]; 12) high-temperature [20]; 13) hydrate [21]; 14) oxonium [22-24]; 15) intercrystal-polyamorphionic [12]; 16) coordination [25]; 17) clathrate hydrate water [26], etc. To these should apparently be added the various forms of "anomalous water" [27-29], which are apparently stable only in the layer next to the wall in

capillaries, so that they can also be regarded as a special type of combined water [30]. If allowance is made for the fact that the varied forms of water in hydrates differ significantly from one another only in the limit, the indefinite nature of each of the above terms becomes clear. This indefinite character leads to the temptation to create "one's own" new terms, characterising "most fully" the state of water in specific materials.

As far as dehydration reactions are concerned, a considerable amount of work, particularly early work, has been carried out without an analysis of the real state of water in the substance, and the "anomalies" frequently observed in experiments, for example the removal of fractional quantities of water, have been regarded as "contrary to common sense" and have therefore been ignored [31]. The discussion of the kinetics and thermodynamics of dehydration processes often does not make allowance for the structural and even chemical changes in the solid phase on dehydration. If however these changes are too obvious, attempts are made to create attractive thermodynamic models without allowance for the actual processes taking place in the solid substances on heating. At the same time, a fairly large amount of experimental material has now accumulated, showing that the water molecule is not always present in a hydrate as an individual structural unit, that dehydration is often accompanied by the partial or even complete decomposition of the salt, and that in many instances this process is the primary process and not, for example, the hydrolysis of the salt by water vapour. This leads to the conclusion that the water in a solid substance has a unique reactivity, and the behaviour of water in the dehydration of a hydrate is evidently determined to a considerable extent by its spatial and energetic structure in the original hydrate. Information of this type has become available chiefly in the last ten years, as a consequence of the fruitful application of modern physical methods of study to the examination of hydrates.

The present review attempts to summarise the available data and to establish the relationship between the state of water in an inorganic hydrate and the characteristic features of its dehydration. Recognising that it is not appropriate to include in the present review a large number of sharply differing classes of water-containing substance, we shall restrict ourselves to an examination of so called crystal hydrates, that is phases with definite compositions, exhibiting physical and chemical individuality, with molecular compositions usually represented in the form $X.H_2O$. Particular attention will be paid to hydrates containing an oxo-anion, to an analysis of the various distortions of water in a hydrate lattice under the influence of the crystal field and intermolecular interactions, as far as its dissociation, and also to the decomposition of the complex oxo-anion of a salt on the dehydration of its hydrate.

2. METHODS OF STUDYING THE STATE OF WATER IN CRYSTAL HYDRATES

The most important methods for studying the structure of crystal hydrates are X-ray diffraction and neutron diffraction, for which the achievements in the determination of the symmetry and molecular parameters of compounds are familiar. With reference to the problems being discussed, it may be noted that despite the fact that the position of the hydrogen atom in a hydrate is determined from X-ray diffraction data with a low accuracy or is derived from general geometric considerations, the results obtained in this way by careful work in most instances show good agreement with the results obtained by neutron diffraction. When comparing the numerical data obtained by these methods, however, it must be borne in mind that O–H distances determined by X-ray diffraction are always shorter than those determined by neutron diffraction [32]; this is due not to the error in the measurements but to the difference in the nature of the quantities measured. Moreover, the shortened O...O distance found by X-ray diffraction in water-containing substances (less than the sum of the van der Waals' radii) does not always provide a sufficient criterion for concluding that there is hydrogen bonding in the substance [33,34].

The state of water in a crystal becomes more definite when the results of a structural analysis are compared with the results obtained by measuring quantities directly related to the strength characteristics of the chemical bond; in this field, a leading position is rightly occupied by the vibrational-rotational spectra of molecules—the infrared absorption and reflectance spectra and the Raman spectra (RS)—since these reveal the characteristic frequencies of the molecular vibrations, which depend in definite fashion on the geometry of the molecules and the strength characteristics of the chemical bond. When the molecule is perturbed by some external influence, the force constants of the chemical bond are altered, and this brings about a regular displacement of the bands in the vibrational spectra. These methods have been found to be particularly useful in the study of water-containing compounds, because of the comparative ease of isotopic replacement of hydrogen and the large (~1.4) coefficient of isotopic displacement of the frequencies of the vibrations of the groups of atoms containing hydrogen.

The vibrational spectra of water in various states have been the subject of a fairly large number of reviews and monographs on the infrared spectra of water in inorganic substances in adsorbed, zeolite, crystallisation, constitutional, and free forms [35,36], the librational vibrations of water in solid hydrated compounds [37], the spectroscopy of hydrogen bonds involving water [38–42], and the spectroscopic manifestation of coordinated water [36,43–45]. For the purposes of further discussion, we shall deal briefly with the most characteristic manifestations of water in vibrational spectra in relation to its state.

The stretching vibrations of the O–H groups in the monomeric gaseous water molecule have frequencies of 3650 cm^{-1} (ν_1) and 3750 cm^{-1} (ν_3). Polymerisation by H-bonds in the gaseous phase or conversion into the condensed state leads to a displacement of the absorption bands towards longer wavelengths, accompanied by broadening of the bands until they merge. There are a large number of empirical and semi-empirical correlations between the values of the νOH frequency and the length of the H-bond, [38,46–49] between the length of the H-bond, the potential curves, and the hydroxyl frequencies [50]; between the magnitude of the displacement $\Delta\nu$OH and the energy of the H-bond; [39,51–53] and between the frequency νOH and the electronegativity of the hydrate-forming element [54]. In the calculation of the displacement of the bands, the origin is usually taken as the ν_3 frequency of the non-perturbed water molecule or the averaged value 3700 cm^{-1}, since even when there are two bands in the νOH region, a reliable assignment to ν_1 or ν_3 is difficult. Calculations by means of empirical equations relating the length and energy of the H-bond to the displacement $\Delta\nu$OH often give satisfactory results even in the study of substances of different types, differing in chemical character

and crystal structure, as a consequence of the marked sensitivity of νOH to the configuration of the H-bond. These relationships are usually linear, if the length of the H-bond lies in the range 2.5–2.8 Å. There is as yet no sufficiently convincing criterion for selecting the limiting O...O distance in a H-bridge, at which interaction of the H-bond type can be neglected, since $\Delta\nu_{OH}$ approaches zero asymptotically in the range 2.9–3.4 Å. The value 2.84 Å in the frequently used expression:

$$\Delta\nu_{OH} = 4.43 \cdot 10^3 \cdot (2.84 - R) \quad (1)$$

where R is the O...O distance, in our opinion, is too low, since a distinct displacement of the absorption bands is observed even for much larger distances. Bellamy[48] proposed the more appropriate value 3.35 Å, beyond which, according to various theoretical considerations, the energy of the interaction should not exceed 0.2–0.3 kcal mole^{-1}. This quantity appears in the semi-empirical expression

$$\Delta\nu(\text{cm}^{-1}) = 50\left[\left(\frac{d}{R}\right)^{12} - \left(\frac{d}{R}\right)^{6}\right] \quad (2)$$

used in calculations covering a wide range of H-bond lengths. The energy of the H-bond can be estimated with sufficient accuracy by means of a relationship established from a large number of results, according to which one unit of energy in kcal mole^{-1} is equivalent to a change in frequency of 50 cm^{-1}. More accurate values can be obtained only for groups of substances of the same type, and always require verification by some independent method.

In view of the highly characteristic nature of the stretching vibrations of the OH groups, this range of the spectrum does not make it possible to obtain unambiguous information on the nature of the oxygen–hydrogen group in a solid substance, since the ranges corresponding to the νOH bands of hydroxide ions OH^-, molecular water H_2O, and the hydrated proton $H_{n+2}O_m^+$ overlap. This problem can be resolved by analysing the bending vibrations of the hydrates, for which the frequencies lie below 1500 cm^{-1} for OH^-, in the range 1590–1680 cm^{-1} for H_2O, and in the range 1680–1800 cm^{-1} for the hydroxonium ion H_3O^+.[55,56] The frequency of the bending vibration of an isolated water molecule is 1595 cm^{-1}. On association, including that due to H-bonding, the absorption band corresponding to this vibration is displaced towards higher frequencies[57], but the displacement is much smaller than that for the stretching vibrations, and for the same perturbation amounts to 10–50 cm^{-1}. The number of components of the bending band coincides with the number of forms of water molecule in the original hydrate, but unfortunately this criterion can be used only when the degrees of binding of the molecules differ considerably, since in most instances, because of the small displacement of δ_{H_2O}, the bands due to different kinds of water are not resolved.

The above regular features apply qualitatively for all substances, irrespective of their nature and state of aggregation. In the analysis of the bonding of water in inorganic hydrates from their infrared spectra, however, it is necessary to make allowance for the fact that coordination of the water molecules to a metal ion influences the vibrations of the molecules in the same way as H-bonding. The displacement of the bands due to the stretching vibrations of water towards longer wavelengths for strong electrostatic complexes as a consequence of the coordination of water to a metal, according to calculations, may reach 600 cm^{-1}, and is determined by the polarising and electron-accepting properties of the cations[58]. A rigorous separation of the perturbing influence of each of these two factors on the vibrations of water molecules is hardly possible, since on the one hand, hydrates in which the existence of H-bonding might be excluded are as yet unknown, and on the other hand, the effects of coordination and H-bonding are closely related, since the polarisation of the O–H bond in the field of the cation, by increasing the proton-donating properties of water, leads to a decrease in the force constant of the bond, and this is equivalent to an increase in the strength of the H-bond and a correspondingly greater displacement of ν_{OH}. Definite progress in this direction has been made in a study of the infrared spectra of series of isomorphous perchlorates[59–61], since the perchlorate ion is one of the weakest proton acceptors. These results show that in this class of compound, the value of $\Delta\nu$OH resulting from the coordination of water, even for *d* elements, is not more than 150 cm^{-1}.

The introduction of water into the first coordination sphere of a metal leads to the production, in the vibrational spectra of the hydrates, of bands characterising the vibrations of $M(H_2O)n$ complexes, at comparatively high frequencies. The M–O stretching vibrations in these groups are observed in the range 300–500 cm^{-1} for a number of aquo-complexes[62], and at higher frequencies for small ions with high charges; for example, the bands for $[Be(OH_2)_4]^{2+}$ and $[Al(OH_2)_6]^{3+}$ lie at 860 cm^{-1} and 600 cm^{-1} respectively[63,64].

Promising possibilities for the theory of the energy of H-bonding are provided by the analysis of the vibrational spectra of the H-bond itself; these spectra are produced as a result of the loss of rotational or translational degrees of freedom by the molecules of groups of atoms on formation of the H-bond. The vibrations of the hydrogen bond are observed in the frequency ranges 100–200 cm^{-1} for the stretching vibrations, and 50–80 cm^{-1} for the bending vibrations. Unfortunately, since the use of long-wave infrared spectrometers is not yet widespread, work in this field has been carried out chiefly by Raman spectroscopy, and this has restricted the range of substances studied to solutions and single crystals. Attempts have been made[65–71] to compare the frequencies with the lengths of H-bonds, but the state of water of crystallisation in this range of the spectrum has as yet been insufficiently studied, and no definite generalisations can be reached.

Difficulties in the Interpretation of the Infrared Spectra of Water in Crystal Hydrates

A clear distribution of the vibrations of water in different states in different regions of the spectrum is characteristic only of limiting ideal situations. As already noted, the nature of the spectrum in the range of the stretching vibrations of the OH groups does not make it possible to determine the nature of the oxygen–hydrogen group in the substance. The production of several bands in this frequency range can be related not only to the existence of several kinds and states of water but also to the formation of H-bonds with different energies by the same molecule, and also to the production of overtone, combination, and resonance frequencies. In this instance, partial deuteration of the substance, which makes it possible to determine the nature of the splitting of the OH bands, is extremely useful. At the same time, the absence of appreciable structure in a band does not indicate uniformity of the binding of water in a substance, since the vibrations of groups of different character may not be resolved, as a

consequence of the large width of the band due to a hydroxyl group forming an H-bond. Moreover, it must be borne in mind that the band frequently observed at 3450 cm^{-1} may be due not to the substance being studied but to the absorption of water adsorbed by the substance, particularly for substances with a highly developed surface. Fortunately, the low sensitivity of the position of this band to the nature of the sorbing substance facilitates its assignment [72].

In our opinion, considerable care must be exercised in the use of the repeatedly recommended method for the quantitative determination of different types of water in a substance by partial dehydration until a particular component of the spectrum disappears [55,73]. This method can be adopted without significant reservations only for substances of the zeolite type, since, as will be shown below, the state of water changes during the dehydration of a salt. This is particularly true of aquo-complexes.

The bending vibrations of water in a number of hydrates may be observed at frequencies of ~1670 cm^{-1}, and their assignment to molecular water or the hydroxonium ion becomes difficult. In this instance an unambiguous interpretation can also be carried out by studying partly deuterated materials. Allowance must be made, however, for the fact that in a number of substances the degree of hydration of the proton may be greater than unity, and this is also reflected specifically in the nature of the spectrum and must be taken into account in its interpretation [74]. Situations more difficult to explain are those in which the frequency of the bending vibration of water in a hydrate is displaced towards longer wavelengths relative to its position for monomeric water, and the structural data exclude the possibility of formation of hydroxo-compounds [75-78]. This may be due to a significant change in the angular characteristics of the water molecules. Thus in magnesium sulphate monohydrate the distance between the protons is 1.65 Å compared with the usually observed 1.50–1.58 Å, [76,79] and for $CuCl_2.2H_2O$ the HOH angle increases to 111.36°. [80]†

Although the analysis of the spectra in the stretching and bending ranges has shown that the water molecule retains its vibrational individuality, this does not exclude the possibility that bending vibrations of M–OH groups are produced when water is present in the first coordination sphere of an electron-accepting metal and its position is determined by the nature of the complex-forming metal.

The interpretation of the characteristic vibrations of an aquo-complex is most complicated, since this range corresponds to the stretching and bending vibrations of a large number of oxo-anions, and more particularly since deuteration has little influence on the positions of the bands of an aquo-polyhedron.

NMR and other methods. Considerable progress in the study of the state of water in hydrates has been made in recent years by proton magnetic resonance (PMR) and ^{17}O nuclear magnetic resonance (NMR) spectroscopy [42,44,81-83].

† It may be that the vibrational spectrum of water in aquo-complexes with H-bonding does not correspond to the triatomic model usually employed, and that the production of several bands in the range 1400–1600 cm^{-1} is due to the production of additional degrees of freedom in the vibration of, for example, a penta-atomic fragment of the type $M-O\begin{matrix}H\ldots O^- \\ H\end{matrix}$.

The PMR method has given important information on the lifetime of the H-bond and, most important, it has confirmed directly that in systems with H-bonding there is proton exchange in the O–H...O group, with a comparatively low activation energy (2–7 kcal $mole^{-1}$) [84,85] and has shown that reorientation and rotation of a molecule of water of crystallisation as a whole are possible [86-89]. An important feature for the understanding of the mechanism of the dehydration of a number of compounds is that the mobility and free path of a delocalised proton along the chain of H-bonds in ice have been found to be much greater than those in liquid water [90]. These quantities are even greater in clathrate hydrates [91], that is the stabilisation of the bonds by the lattice facilitates proton transfer.

Since the PMR method gives information primarily on protons, its use for the study of the state of water as a whole is somewhat limited. In the determination of the coordination of water to a metal ion it is preferable to study ^{17}O NMR, and this method has been used, in particular, to study the hydrate numbers of a number of metal ions. Unfortunately, this information has been obtained chiefly for the liquid state. For solid hydrates, for which low-resolution resonance is chiefly employed, its achievements have been much more modest. For a restricted range of substances, various empirical correlations have been found between the inter-proton distance and the length of the H-bond [83], but these relationships require verification for a wider range of substances and by other independent methods (vibrational spectra, structural analysis, etc.).

Other methods for studying the state of water in a solid, for example measurement of the dielectric properties, spectroscopy in the visible and ultra-violet ranges, magnetochemical methods, and EPR spectroscopy, are much less specific, and their application to the problem being considered is limited to several individual instances. If water is coordinated to a cation, however, these methods may give extremely useful additional information, particularly for the hydrates of salts of the transition metals.

3. STRUCTURE OF CRYSTAL HYDRATES

The mechanical, physical, and chemical properties of crystal hydrates are determined to a considerable extent by the position and state of the water molecules in their structure. At this stage, therefore, a general classification of hydrates, taking account of all the properties of the water-containing substance, is hardly possible. Any attempt to generalise the properties of large groups of hydrates must be based primarily on the final aims of the generalisation. From this viewpoint, for a description of the geometric arrangement of the water molecules relative to the other components of the crystal, it is quite satisfactory to use the classification adopted in crystal chemistry [92], based chiefly on Bernal's theories [93]; in this classification, all hydrates are divided into the following groups: a) hydrates in which the water molecules are isolated from one another; b) hydrates with isolated unit structures, in which water forms independent groups; c) chain hydrates; d) layer hydrates; e) hydrates with three-dimensional frameworks formed by water molecules. In the examination of dehydration reactions, however, this classification can be taken only as a first approximation, since it does not reflect the variety of forms of water and the influence which this has on the chemical properties of a

real hydrate, in which the water molecules interact strongly with the cation and anion of the salt and with one another, undergoing much greater distortion not only relative to their configuration in the gaseous phase, but also relative to water in the solid and liquid states; for example, in aquo-complexes the M–OH_2 distance is extremely close to or equal to the M–O distance in the corresponding oxide [94].

Since in most instances the analytical data do not give information on the forms in which water is present in a substance, it is necessary first of all to have criteria for distinguishing water of crystallisation from water of constitution, that is water present in ionised form, for example as hydroxide or hydroxonium ions. Since neutron diffraction techniques are not widely available, and X-ray diffraction does not give unambiguous results when applied to water, a suitable criterion for an extremely wide range of substances is provided by the presence of the band due to the bending vibration of molecular water in the vibrational spectrum of a hydrate, since the position of this band is highly sensitive to the conversion of water into the ionised state. Thus crystal hydrates can be regarded as substances in which the water molecule retains its vibrational individuality.

For the discussion of the state of water in crystal hydrates in relation to their dehydration, it is convenient to divide them into the following groups: 1) substances for which the hydrate number (n) is greater than the coordination number (CN) of the metal in the given compound; 2) hydrates with n equal to the coordination number; 3) hydrates with n less than the coordination number. As proposed by Shishkin [95], hydrates with variable composition, of the zeolite type, form an independent group of hydrates containing molecular water.

Many hydrates with a large quantity of water of crystallisation can be represented as solid solutions of water and the corresponding anhydrous salt, since their structure, with some assumptions, can be interpreted as corresponding to the structure of ice in which the positions of some of the water molecules and the cavities are occupied by ions of the salt. The nature and position of the bands in the infrared spectra of these hydrates in the range of the water vibrations are close to those in the spectrum of ice, and their heats of dehydration are also close to the heat of sublimation of ice.

When n is greater than the coordination number by one or two units, two structurally non-equivalent types of water can be clearly distinguished: part of the water, in quantities corresponding to the coordination number of the metal, is present in its first coordination sphere, and the rest of the water is present at a considerable distance from the cation (~4 Å). This situation is observed in many metal heptahydrates and in copper salt pentahydrates, and has been confirmed by direct structure determinations, from the bands due to water in the infrared spectra, and by NMR. [96–100] The water not combined with the metal forms H-bonds with a coordinated water molecule, or, if the steric conditions are favourable, with the anion; the energy (~4.5 kcal $mole^{-1}$) and length of these bonds are often independent of the nature of the anion, as shown by the presence, in the infrared spectra of these hydrates, of a band at ~3400 cm^{-1}, close to ν_{OH} for molecules bound by H-bonds in liquid water. This molecule has a much greater mobility than coordinated water [101].

The properties of water from the immediate environment of a metal are determined chiefly by its interaction with the cation and anion, and to a smaller extent by the interaction with water outside the coordination sphere, so that they are of the same type as those of hydrates of the second group. Hydrates in which the hydrates numbers are equal to the coordination number and in which all the water is in the inner coordination sphere of the metal (aquo-complexes) make up a large group among known inorganic crystal hydrates. The energy of the H-bond formed by coordinated water can vary over a fairly wide range (the value of $\Delta\nu_{OH}$ sometimes reaches 1000 cm^{-1} [102,103]), depending on the nature of the cation and anion. Ionic aquo-complexes in a solid substance undergo various distortions under the influence of the crystal field and the H-bonds, so that the water molecules among themselves and the OH groups of an individual molecule can become non-equivalent; this is often accompanied by the production of different M–OH distances, the difference amounting to 0.02–0.2 Å for neighbouring water molecules [94,104]. If the symmetry of the crystal is sufficiently high or a large number of states of water molecules with similar energies are produced, this non-equivalence may not lead to splitting of the bands in the infrared spectra, and more or less broadened single bands are observed in the range of absorption of water. With marked distortion of the coordination polyhedron, however, for example as a consequence of the Jahn–Teller effect or on formation of H-bonds of different energies by the same water molecule, the bands due to the stretching and sometimes also the bending vibrations of water may be split, and the water becomes spectroscopically non-uniform.

The most complicated sets of possible energy states of water molecules and positions in the structure are shown by the hydrates of the third group, containing a small quantity of water of crystallisation. At the same time, this class of hydrate is of greatest interest for the solution of the problems of preparing anhydrous substances, since as a consequence of the stepwise nature of the reactions, the dehydration of higher hydrates in the final stages gives products with small and sometimes fractional hydrate numbers.

If the water in these hydrates is present in the first coordination sphere of the metal, the coordination polyhedron also contains some oxygen atoms of the anion, so that in addition to the M–OH interaction there may also be interactions of the H-bond type between water and the anion of another polyhedron, leading to marked distortion of the water molecule itself and of its environment. Thus for nickel nitrate tetrahydrate [105], eight different O–H...O distances have been found, and each of these bonds produces its own absorption band in the infrared spectra in the range 3525–3130 cm^{-1}, the dependence on RO...O being given by the empirical function (1). For a definite mutual spatial orientation of the water molecule and the anion, both hydrogen atoms of water may be joined to the same oxygen atom of an anion, and this leads to a decrease, relative to liquid water and ice, in the inter-proton distance and hence in the HOH angle [97,106,107]. On the other hand, one of the hydrogen atoms may remain almost free, whereas the other takes part in the formation of a strong H-bond [108]. The angular characteristics of the water then undergo distortions which are the opposite of those in the first example, and the vibrations of the two OH groups can be regarded as almost independent. Thus the above correlation between the length of the H-bond and the inter-proton distance may have only a limited application for systems of this kind.

Lower hydrates sometimes show anomalous values for the frequencies of the water vibrations [109], unusual coordination [110,111], and fractional hydrate numbers. All these facts indicate that many lower hydrates, particularly

those obtained by the dehydration of higher hydrates, are in a stressed state; this may be attributed to some lack of correspondence between the small size of the cation and its extensive coordination possibilities and the large radii of the complex oxo-anions. This lack of correspondence is removed to a considerable extent for aquo-complexes, as a consequence of the increase in the effective radius of the complex aquo-cation. On this basis it should be expected that the decrease in the hydrate number as far as the formation of the anhydrous salt should be accompanied not only by the distortions of the water molecule noted above but also by an increase in the extent of the perturbing influence of the lattice on the anion.

The distortion of the symmetry of an anion can be followed by direct structure determinations, and also from the splitting of degenerate absorption bands and the appearance of forbidden bands in the vibrational spectra. For example, on going from copper sulphate pentahydrate to the monohydrate, the symmetry of the anion decreases [112] from T_d to C_{3v}, or to C_{2v} in the dehydration of the double sulphates of various transition metals [113] and even to C_s for the selenate anion, with the same symmetry, on going from the hexahydrate to the dihydrate in double copper selenates [114]. This situation is typical, and has also been noted for rare earth metal bromates [115], phosphates [116], and many other salts. An increase in the complexity of the spectra in the range of the vibrations of the anion may naturally be due not only to a decrease in the symmetry of the anion but also to a decrease in the site symmetry of the crystal, but in a number of instances these effects can be distinguished fairly simply [117]. Moreover, for systems in which the influence of the symmetry of the lattice can in practice be excluded, for example for ion exchange films, decrease in the degree of hydration is accompanied by a sharp increase in the magnitude of the splitting of the bands due to the degenerate vibrations of sulphate and selenite anions [118]. A number of authors have not noted any significant differences in the infrared spectra of higher and lower hydrates [119] or have observed a decrease in the complexity of the spectrum in the range of the vibrations of the anion on going from hydrates to the anhydrous salts [120,121], and this has led to the suggestion that H-bonds have a decisive influence on the decrease in the symmetry of the anion. Calculation of the stability of solid systems with H-bonds [122] has shown, however, that the rupture of the O–H...O bond is energetically more favourable than distortion of the valency angles of the anion, despite the fact that the linear H-bond is the most stable [123]. In the limit, this leads to a situation in which some hydrogen atoms in crystals may not take part in the formation of a H-bond. It appears that H-bonding in a hydrate under favourable conditions intensifies the decrease in the symmetry of the anion brought about by more powerful interactions. This is confirmed by the fact that when an anion is coordinated to a metal ion, the splitting of the bands due to the degenerate vibrations is accompanied by their displacement towards longer wavelengths [113,124,125]. Thus those instances where the symmetry of an anion increases with decrease in the hydrate number are to be regarded as exceptions, particularly since the decrease in the complexity of the spectrum is often only apparent, as a consequence of the conversion of the substance to the amorphous state on dehydration.

On the basis of the nature of the interaction of water with a metal ion, it should be expected that the strength of the $M-OH_2$ bond should be determined primarily by the polarising and electron-accepting properties of the cation, that is by its size, charge, and outer electronic structure. In a series of elements of the same type, ν_{OH} for water decreases regularly with decrease in the radius of the ion or with increase in its charge [126,127]. When several factors change simultaneously, however, it becomes difficult to predict the relative strength of the interaction of water with the cation. Thus $\Delta\nu_{OH}$ is much greater for hydrated salts of aluminium and beryllium than for zirconium and hafnium compounds. For transition metals, the degree of binding of water is greater than might have been expected for a purely electrostatic interaction. Within the first transition series, $\Delta\nu_{OH}$ and hence the degree of perturbation of the water molecules in the salts of the doubly-charged ions decrease in the order: $Mn < Co < Ni < Cu > Zn$, which corresponds closely to the familiar Irving–Williams series for the stability of complex compounds. The magnitude of the splitting of the degenerate vibration of the anion changes in the same order, indicating that the mechanisms of the interaction of the cation with water and the oxo-anion are similar.

The extent of the distortion of water under the influence of the anion is characterised by the proton-acceptor properties of the latter. Study of the hydration of anions introduced into an ion-exchange film based on polystyrene (R) has shown that these properties change in the opposite order to the abilities of the corresponding acids to undergo protolytic dissociation [128], increasing in the order RSO_3^-, $RSeO_3^-$, RPO_3^{2-}, $RSeO_2^-$, RPO_2H^-. In accordance with this, ν_{OH} in the spectrum of their hydrates decreases from 3465 cm^{-1} to 3335 cm^{-1}, indicating that the strength of the H-bond increases in the same order. Unfortunately, an unambiguous interpretation of the influence of various cations and anions on the state of water is possible only for strictly isomorphous series, which is not always possible, or in the study of ion-exchange films, although in the last instance it is not always possible to achieve reliable control of the degree of hydration. Despite this, the order of change in the energy of the H-bond with change in the nature of the anion, observed by Karyakin and Muradova [103] for substances of different types, where the energy increases from 1.7 kcal $mole^{-1}$ to 8.5 kcal $mole^{-1}$ in the series ClO_4^-, NO_3^-, Cl^-, CO_3^{2-}, SO_4^{2-}, and PO_4^{3-}, shows satisfactory qualitative agreement with the above order for the polystyrene acids.

Thus if we take as a measure of the influence of the cation the change in ν_{OH} relative to ν_{OH} for a similar hydrate of an alkali metal salt, and as a measure of the influence of the anion the magnitude of $\Delta\nu_{OH}$ relative to the perchlorate of the same element (assuming that the effects of the two factors on water are additive), we find that for a series of hydrates the frequency of the stretching vibrations of water should be displaced to 3000 cm^{-1}, which corresponds to a H-bond energy of about 15 kcal $mole^{-1}$, that is a value close to the energy of a chemical bond. The state and reactivity of water combined in this way must naturally differ significantly from those for the free state.

This should lead primarily to a marked increase in the degree of protolytic dissociation of water. Hydrated metal ions in solution exhibit acidic properties to a greater or lesser extent, as a result of dissociation to form hydrogen ions and a complex hydroxoaquo-ion. According to Schwarzenbach [129], water in the inner coordination sphere of metal complexonates can be titrated with alkali. Water of crystallisation can react with metals with which liquid water does not react [130]; a remarkable feature is that compounds with small hydrate numbers are much more active than the higher hydrates.

Modern theories of the energetics of H-bonding and the structure of substances containing hydrogen bonds make it

possible in many instances to explain the state of water in a hydrate and to predict its possible chemical properties. For substances with strong intermolecular interactions we can expect in the limit the production of a symmetrical O...H...O band, so that the proton belongs with equal probability to the water molecule and the anion, and this formation should acquire the properties of an acid salt. From the general course of the relationship between O–H and O...O distances, it follows that this situation should arise for an H-bond length of about 2.3 Å. This value is assumed in the discussion of various models of "anomalous" water or poly-water [131,132] and appears to have been confirmed experimentally [133]. In a number of solid substances a symmetrical hydrogen bond has been assumed at much larger distances [134–137] (of the order of 2.4–2.5 Å). In systems with longer H-bonds there is also a definite probability of transfer of a proton from water to the anion, since the potential curve for an unsymmetrical bond has two minima for which the height of the potential barrier may be reached on thermal excitation, and the efficiency of this process can be increased by an appreciable factor by tunnelling of the proton along the H-bond. According to calculations [138], this process is probable for a distance between the minima reaching 0.8 Å.

If a system of H-bonds is formed by several water molecules, the energy barriers to the removal of a proton may be decreased by the positive heat of formation of oxonium ions. In accordance with this, the state of water in iron phosphate and arsenate dihydrates is more accurately represented by the formula $MXO_4.(OH)^-H_3O^+$ than by the classical formula with isolated water molecules [139,140]. Oxonium ions have been found in the solid state in a number of hydrates of inorganic acids and salts [103,141–145]. According to Zundel and Metzger [146], a proton is completely removed from polystyrene sulphonic acid at a degree of hydration equal to two, that is when the ion $H_5O_2^+$ is formed. This ion has also been detected in hydrogen chloroaurate tetrahydrate [147], where the distance between the potential wells is 0.62 Å, and in perchloric acid dihydrate [148], where it is assumed that there is only one minimum on the potential curve. It is suggested [149] that the oxonium ion is most stable in the form of the trisolvate and that its hydrate should have the structure $H_9O_4^+$. According to Lundgren and Olovsson [150], this ion is present in hydrobromic acid tetrahydrate. Hydrated hydroxonium ions with the composition $H_3O^+.(H_2O)_n$, where n reaches 10, have been detected by mass spectrometry in the gaseous phase. Despite the fact that the $H_9O_4^+$ ion has been assigned [154] the planar symmetrical structure $H_3O^+.3H_2O$ (H-bond energy 46.3 kcal mole^{-1}), the heats of hydration of the hydroxonium ion found from the mass-spectrometric data do not show an inflection at n = 3, but show a smooth change, and at n = 7 they approach the heat of evaporation of water from a flat surface [155]. The structure $H^+(H_2O)_n$ is therefore to be preferred. A remarkable feature is that the geometric structure and energetics of the hydrated proton and hydroxide ion almost coincide for equal degrees of hydration [156].

In these complex formations, despite the fact that molecules of water of crystallisation often retain their individuality as vibrational units, the proton is completely delocalised over the entire ion. In the limit, as shown by Shakhparonov [157,158], many properties of aqueous systems can be described by assuming that a conductivity zone exists for protons. Although the concepts of a proton gas have been applied chiefly to liquid systems [159], it will be shown below that they have proved useful for the explanation of various characteristic features of the dehydration of solid inorganic hydrates.

Finally, for the salts of multiply-charged readily hydrolysed metals, the water may be completely dissociated, and these compounds should be regarded as complex acids, and not crystal hydrates. Nevertheless, many substances of this type are still classified as crystal hydrates, apparently because of the difficulty of determining the true state of water in the materials. A number of properties of solid hydrates of various zirconium and hafnium salts, however, make it impossible to regard these compounds as crystal hydrates or as the corresponding acids, which exist in solution. For zirconyl chloride hydrates, structures with oxo-bridges or hydroxo-bridges, or structures with complex polynuclear ions of the type $[Zr_4(OH)_8.(H_2O)_{16}]^{8+}$, [160,161] have been proposed. A tendency for hydrated compounds of this type to form bridging groups and to acquire more strongly acidic properties is shown by tin phosphates [162], aquopolytungstates [163], metal borates, etc. In these limiting situations, the water is present as water of constitution, and the suggested criterion for estimating the state of water does not apply.

In most hydrates, however, the state of water is characterised by a greater or lesser displacement of hydrogen ions towards the anion, and the magnitude of this displacement is determined by the properties of the cation and anion, and also by steric factors. In this connection, the corrections to the formulae of hydrates proposed by a number of authors on the basis of the vibrational spectra [for example for magnesium carbonate trihydrate [164,165] $Mg(OH)^+(HCO_3)^-.2H_2O$] must evidently be understood not as corresponding to complete dissociation of the water molecule but as an illustration of the fact that the water molecule reacts so strongly with the anion that a change in its vibrational characteristics becomes possible. To the same extent this is also true of Lendormy's conclusions [166] that many transition metal sulphate monohydrates should be regarded as acid salts of the type MH_2SO_5.

The tendencies, noted above, for the state of water in crystal hydrates to change with change in the hydration numbers and the nature of the environment relate primarily to systems in which all or part of the water is in the coordination polyhedron of the metal. There are therefore some exceptions, where the water in lower hydrates is less firmly bound than that in higher hydrates. This situation is observed in calcium sulphate hemihydrate [167], in which the water must be regarded as zeolite water, since the structure remains unchanged on dehydration. The interpretation of the spectra of hydrates of this kind in the far infrared range has been based on a crystal structure model [168] in which water forms a molecular lattice which is quasi-independent of the ionic lattice of the salt.

4. DEHYDRATION OF CRYSTAL HYDRATES

The extensive range of dehydration reactions has produced a large number of papers on the study of these reactions, but up to the present there has been no sufficiently well-founded approach to the interpretation of many experimentally established features of these reactions in relation to their kinetics or to the problems of the thermal stability of the intermediate hydrate forms produced in the decomposition of the original hydrate. To some extent this can be attributed to the variety of forms in which water is combined in solid inorganic hydrates, and also to the specific nature of the problems studied and hence of the conditions under which the experiments have been

carried out, and this has made it difficult to compare the results of different studies, even of the same substance.

In their monographs, Young [169] and Garner [170] have discussed a large number of studies of the kinetic features of dehydration. In many of these, sufficient attention has not been paid to the possible influence of the formation of various intermediate hydrates on the kinetic characteristics. On the other hand, the operations involved in the isolation of individual hydrated phases and the determination of their thermodynamic functions make it necessary to take account of kinetic factors, because of the ease with which false equilibria are established in hydrates. Only in a few papers have the macro-kinetic characteristics of a reaction been related to the energetic and geometric structure of water in the hydrate lattice.

In most instances, dehydration takes place in stages, and the number of intermediate phases may be extremely large. Thus in the dehydration of magnesium sulphate heptahydrate, seven intermediate hydrates are formed [171,172]. It is only in a few instances, chiefly when water is not combined with the metal, that it can be removed from water-rich hydrates in a single stage. Most of the intermediate forms are generally produced in the final stages of the process, often with the formation of compounds with fractional hydrate numbers which sometimes are not submultiples of the original number. Fractional hydrate numbers are sometimes also encountered in hydrates precipitated from solution under normal conditions [173], for example $CdSO_4.\frac{8}{3}H_2O$, so that there are insufficient grounds for assuming that these compounds should be regarded as solid solutions of the anhydrous salt and the corresponding hydrate. The number and composition of the intermediate hydrates depends to a marked extent on the nature of the substance and the conditions under which the reaction is carried out. They may be different even for isomorphous substances, for example aluminium sulphates [174] and selenates [175], or rubidium and caesium tellurites [176]. Measurement of the vapour pressure over hydrated strontium oxalate showed that in the range of hydrate numbers from 2.5 to 2 there exists a series of non-stoichiometric hydrates, for which the heat of dehydration [177] increases from 12.7 kcal mole^{-1} for $n = 2.5$ to 17.7 kcal mole^{-1} for $n = 2$. An increase in the heat of dehydration with decrease in the hydrate number is a common feature of most hydrates. The effective activation energy of the reaction changes in the same order, and in many instances it is close to the heat of the reaction. The differences sometimes observed in these quantities, or their anomalously high values (particularly for ΔH calculated from the vapour pressure) are often related to the possibility of formation of unstable intermediate compounds or to the increased energy of the final dehydration product. The values of these quantities also depend to a marked extent on the particle size of the original crystals. Thus the dehydration of goethite [178] is endothermic for the coarsely-crystalline material, athermic when the particle size is about 100 Å, and exothermic for specimens with a smaller particle size. Engberg [179] has shown that if the activation energy and heat of dehydration are determined for monodisperse particles with the same dimensions, the values are almost equal.

The conditions of the process, particularly the pressure and composition of the gaseous phase, have a marked influence on the chemistry of dehydration. For example, with change in the external water vapour pressure from 10 mmHg to 80 mmHg, the number of stages and the composition of the intermediate phases in the dehydration of strontium oxalate changes three times [177]. Examples are known where processes become more complicated [174] or simpler [180,181] (with reference to the number of stages) in a vacuum and at atmospheric pressure. The temperature dependence of the equilibrium vapour pressure above all possible intermediate hydrates in a given system does not always make it possible to predict the sequence of stages for given specific conditions, since the influence of kinetic factors may lead to the production of thermodynamically unstable compounds as the chief product.

To some extent, the state of the dehydrated product also depends on the external pressure. It has been shown by a complex thermal and X-ray diffraction study [182] that in the dissociation of copper sulphate pentahydrate at pressures above 15 mmHg the loss of water is synchronous with the change in crystal structure; with decrease in pressure, the rate of crystallisation differs to an increasing extent from the rate of decomposition, and the product obtained in a vacuum is amorphous towards X-rays, but crystallises with the liberation of heat on subsequent heating. The formation of a product amorphous towards X-rays on dehydration under severe conditions is fairly common, and is not observed only in substances for which the lattice remains unchanged on the removal of water, for example zeolites, or when rearrangement of the structure takes place very rapidly. In our view, this is one of the chief factors preventing the fruitful application of thermodynamic and kinetic methods to the study of dehydration, since it leads to the production of such anomalous effects as the Smith–Topley effect in macrokinetics [170] or the departure of the temperature dependence of the vapour pressure from the logarithmic law for static measurements [183]. The excess of energy of the disordered phase for various substances varies in the range 3–7 kcal mole^{-1}. It is suggested that increase in the vapour pressure of water in the gas decreases the surface energy of the amorphous phase as a consequence of adsorption, and facilitates the formation of crystallisation nuclei. The residual water of intermediate hydrates or the "anhydrous" final products stabilises the disordered state, however. This is indicated, in particular, by the fact that in a number of instances [184-186] the temperature of removal of the last traces of water coincides with the temperature of the start of crystallisation of the reaction product. In condensed phosphates, the last few tenths of a percent of terminal hydroxyl groups are held extremely firmly [187] and are not removed completely in one month at 800°, preventing further polymerisation of the phosphates or their conversion into products with a ring structure.

Moreover, the kinetic characteristics of dehydration are influenced to a considerable extent by the degree of perfection of the crystals and the presence of macro- and micro-defects on their surface. Thus the rate of propagation of the reaction zone is different for the external surface and for a freshly exposed surface of a single crystal [188].

The above brief list of the most important characteristic features of dehydration demonstrates the sensitivity of these reactions to a great variety of factors, which makes it difficult to compare the thermal stabilities even for hydrates of the same type. For the same reasons, the discussion of the problems of predicting the direction of dehydration reactions on the basis of an analysis of the state of water in the original hydrate may lead to pessimistic conclusions, particularly in relation to the kinetic parameters of the process. A large number of results show that the number of stages in the reaction very seldom coincides with the number of kinds of water in the original hydrate. The chemistry of dehydration can be predicted

fairly unambiguously for hydrated zeolites and to a lesser extent for hydrates in which the water is not present in the coordination sphere of the cation. In the decomposition of aquo-complexes, however, the direction of the change in the structure of the coordination polyhedron of the metal is almost always unknown, so that the possible composition of the dehydration product also remains indefinite. The rearrangement of the structure on the formation of an intermediate hydrate also leads to a change in the initial state of the water and this evidently casts doubt on the method sometimes used to estimate the number of forms of water in a hydrate from the number of stages in its dehydration. In these instances, water fractions which are physically completely identical are removed in stages; this is also observed in systems with low hydrate numbers [189]. This provides evidence that the disordered phases formed in the dehydration have a microcrystalline structure, since otherwise we should not expect the formation of stable intermediate hydrates with a definite composition during dehydration.

An all-round approach to the analysis of the state of water in hydrates, however, makes it possible to explain most of the observed characteristic features of dehydration, and in a number of instances to predict their development. This applies particularly to the dehydration of hydrates in which the types of water differ sharply, for example many heptahydrates, for which the water molecule which is not present in the coordination sphere of the metal is removed first [180,190]. In the complex diphosphatoaluminate anion [191], four of the ten water molecules are coordinated to the metal and six are joined to phosphate groups, and in accordance with this, six water molecules are removed in the first stage of the dehydration.

From a large number of observations, albeit often only qualitative, it follows that dehydration is reversible only in its initial stages; the removal of the last water molecules is generally difficult and is most frequently irreversible. This irreversibility is usually attributed to kinetic factors, but some results indicate that in many instances it is due to irreversible changes in the salt, undergone in the dehydration of the original hydrate. Processes involving hydrolysis by water of crystallisation are familiar for various halogen systems and some nitrates [192-195]. A characteristic feature of these reactions is that the reactivity of the water of crystallisation does not show any clearly defined specific features, since hydrolytic decomposition of the anhydrous salts under the influence of water vapour is possible at the same temperatures. In accordance with this, the extent to which these reactions take place depends on the vapour pressure of water and the corresponding hydrogen halide over the substance undergoing dehydration.

In many instances, however, extensive dehydration is accompanied by changes in the substance which do not take place or which are even thermodynamically unlikely under the given conditions in the reaction of the anhydrous compound with water. It is not always possible to obtain an anhydrous salt with stoichiometric composition by dehydrating its hydrate. Qualitative information is available on the decomposition of the complex oxo-anion in the dehydration of carbonates [196], selenites [197,198], various sulphates [199-201], oxalates [202,203], and acetates [204]. These results were obtained for substances in which decomposition of the anion leads to the formation of volatile products, so that the simplest thermogravimetric methods can be used to establish that the process takes place. The study of the state of the solid dehydration product indicates that this phenomenon is much more widespread.

Our ideas on the dehydration of phosphates have altered radically in literally the last five years. The use of infrared spectroscopy [116,205,206], chromatography [207,208], and NMR [209] for the analysis of the solid phase has established that the extensive dehydration of both acidic and normal phosphates leads to extensive changes in the anion with the production of a mixture of condensed phosphates in the solid phase while the overall composition of the product remains constant. The final formation of crystalline ortho-, pyro-, or metaphosphates with increase in temperature results from secondary processes involving the reaction of oxides with higher phosphates.

The extent to which the anion decomposes may be different, but a large number of results indicate it is constant for a given substance and is almost independent of the conditions of the reaction, particularly the external water vapour pressure. Thus as in the case of metal halides, the theories of ordinary hydrolysis are evidently not applicable to these systems.

Mechanism of Dehydration of Crystal Hydrates

The widely encountered theories of the development of the reaction zone and the mechanism of thermal dissociation do not explain the above characteristic features of the extensive dehydration of solid inorganic crystal hydrates. They can be discussed from the viewpoint of the theories, examined in the previous section, of a unique "pre-dissociation" state of water in many lower hydrates. According to this, the first stage of this intracrystalline hydrolysis should be the transfer of the hydrogen of the water to the anion and the formation and possibly the stabilisation of acidic and basic groups in the substance on heating. In fact, these groups have been detected at definite stages of the dehydration in, for example, the dehydration of magnesium sulphate [200] or thorium oxalate [203]. Experimental data on the possibility of reorientation and rotation of water molecules, the high mobility of protons in solids, and the low height of the potential barrier for the migration of a proton along an H-bond makes this conversion extremely probable. When an acid salt is dehydrated, this process may lead to the formation of appreciable quantities of free acid in the substance [208]. Thus up to 15% of free phosphoric acid has been detected in the dehydration products in separate stages of the dehydration of calcium [206] and strontium [208] hydrogen phosphates. These results indicate that the formation of linear and cyclic polyphosphates is a secondary process in the dehydration of orthophosphates.

Theories of the energetics of hydrated compounds were used by Dombrovskii [210-213] to provide a qualitative explanation for various kinetic features of dehydration. The increase in the reaction rate on the addition of proton-donating substances and its decrease by proton acceptors indicate that dehydration involves proton transfer and not electron transfer, and results from the migration of protons in the lattice and on the surface of the crystal. The reversible decrease in the intensity of ν_{OH} with increase in temperature for a number of hydrates is also related to proton delocalisation, and the activation energy for the transfer of the proton to the conductivity zone has been estimated [214] as 2 kcal mole^{-1}. Increase in temperature leads to an increase in the mobility of the water molecule [215,216] and in the concentration of free protons in the lattice; this is accompanied by an increase in the proton conductivity when the substance is heated below its decomposition temperature [217].

The subsequent stages of the dehydration lead to the separation of metal oxides and the decomposition products of the corresponding ion in the gaseous or solid states; the temperatures of this decomposition of the anion may in a number of instances be lower by hundreds of degrees than the decomposition temperature of the anhydrous substance. The concentration of metal oxide in excess may reach several percent, so that care must be taken in the use of dehydration for preparative purposes, for example to obtain anhydrous substances and to determine their thermodynamic functions, particularly if allowance is made for the fact that on further heating, the oxides may react with the normal salt to form basic compounds.

If the anhydrous salt is not sufficiently stable to heat, it is impossible to distinguish processes of extensive dehydration and dissociation. This is due primarily to the lability of the disordered dehydration products. The water-containing formations, amorphous towards X-rays, are characterised by high proton mobility even at room temperature [209]. Thus on heating, partial dehydration is accompanied by fairly rapid rearrangement of the solid phase into a new quasi-stable state with a higher thermal stability than the original state. If allowance is made for the fact that the residual water stabilises the state amorphous towards X-rays, this continuous series of changes leads to the production of a dehydration temperature range which can extend to extremely high temperatures (700 to 800°) for compounds stable to heat. This scheme is confirmed by the extremely rapid decrease in the rate of dehydration in the final stages and by the temperature dependence of the degree of dehydration [218]. As expected, the temperature coefficient of the reaction rate corresponds to the temperature coefficient of diffusion in the solid, and this casts doubt on the commonly encountered suggestion that this course of the process is due to diffusion restriction of the removal of the gaseous product. The temperature dependence of the vapour pressure is not logarithmic, however, but is close to linear; this also is not contradictory to the scheme discussed.

The estimation of the relative probability of this "intracrystalline" hydrolysis of a salt can be based on a comparison of the extents of the influence of the cation and anion on the water. In actual fact, almost all known examples of the partial decomposition or rearrangement of a complex oxo-anion on dehydration involve substances containing an anion with clearly defined proton-acceptor properties and a strongly polarising electron-accepting cation. The substances for which the temperature ranges of dehydration and subsequent dissociation of the anhydrous salt are fairly clearly distinguished are chiefly the phosphates, selenites, and tellurites of transition and light metals forming multiply-charged cations. The relative extent of this decomposition of the anion changes qualitatively in the same order as the degree of distortion of the water molecule in the hydrate. For example, in the dehydration of normal zinc phosphate [206], almost no production of poly-forms is observed, whereas they are observed in appreciable quantities for the analogous compounds of cobalt, nickel, and copper.

The possibility that reactions of this kind also take place with substances which bind water less strongly cannot be neglected, however. For example, the rate of dehydration of beryllium sulphate tetrahydrate is influenced considerably by the presence of sulphuric acid on the surface of the crystal, although the decomposition takes place according to the stoichiometric equation [219].

The introduction of theories of the change in the state of water under the influence of only the cation and anion provides a qualitative explanation for the nature of the experimentally observed effects. For quantitative conclusions this approximation in a number of instances is insufficient, and it becomes necessary to make allowance for the influence of energetically weaker interactions on the water. For transition metal salts these may be interactions of the ferromagnetic or antiferromagnetic type between the cations, leading to some rearrangement of the electronic structure of the aquo-polyhedron. Thus in the dehydration of $CuSeO_3.\frac{2}{3}H_2O$, every sixth SeO_3^{2-} anion is decomposed, with the liberation of selenium dioxide into the gaseous phase [197]. The EPR spectra show that every sixth copper ion remains relatively isolated in this hydrate [220], and the rest take part in exchange interactions of the antiferromagnetic type, as confirmed by measurement of the temperature dependence of the magnetic susceptibility. The participation of the copper ions in exchange interactions leads to a redistribution of the electron density with a decrease in the strength of the M—O bond and a corresponding decrease in the energy of the H-bond formed by the water molecules coordinated to these ions. A water molecule joined to an isolated copper ion is therefore deformed to a greater extent, and this leads to decomposition of the anion on dehydration, by the mechanism examined above. The difference in the energies of the hydrogen bonds formed by the two types of water, determined by infrared spectroscopy, is ~1.2 kcal $mole^{-1}$, in good agreement with the energy of the magnetic interactions in di- and polynuclear complexes of copper with anomalous magnetic properties. The relationship between the effective magnetic moment and the frequency of the νCuO vibrations [221] confirms that weak interactions have a significant influence on the thermal dissociation of the substances.

The material examined leads to the conclusion that many characteristic features of thermal dehydration are determined by the state of the water in the lattice of the inorganic hydrate. The relative probability of decomposition of a complex oxo-anion can be estimated from data on the degree of distortion of the water molecules under the influence of the environment. The extent of this distortion is determined by the strength of the interaction of the water molecules with the cation and anion, and depends on the polarising and electron-acceptor properties of the cation and the proton-acceptor power of the anion.

The mechanism of these processes can be explained on the basis of theories of the dynamic nature of hydrogen bonding and the partial delocalisation of the protons when the hydrate is heated.

Kinetics and Mechanism of the Dehydration of Crystal Hydrates

N.Z.Lyakhov and V.V.Boldyrev

The present review considers experimental data and the results of theoretical studies of the dehydration of crystal hydrates. The data have been systematised according to the stages of the reaction in the light of modern theories of the kinetics and mechanism of chemical reactions in solids. Attention has been drawn to a number of unsolved problems. It has been shown that the dehydration of crystal hydrates may prove a convenient model system in topochemistry for the solution of these problems. The bibliography contains 102 references.

1. INTRODUCTION

Modern theories of the mechanism and kinetics of topochemical reactions are based to a large extent on experimental studies of the dehydration of crystal hydrates, since these processes provide a convenient model system which can be used to study the regular features of an important class of topochemical thermal decomposition reactions of the type:

$$A_{(solid)} \rightarrow B_{(solid)} + C_{(gas)}.$$

Moreover, the study of these processes is of independent interest, since many dehydration reactions (for example the dehydration of gypsum, alum, and metal sulphate penta- and heptahydrates) have important applications and are used in chemical technology, the technology of building materials, the metallurgical industry, etc.

Initially, the attention of many research workers was drawn to crystal hydrates by the apparent simplicity of their decomposition. As experimental data accumulated, however, it became clear that dehydration is in fact much more complex than previously supposed, and many facts relating to its mechanism have still not been explained. For example, it is not known why in many instances dehydration, having started at some point on the surface of a crystal, continues to develop at the same point (autocatalysis of the reaction); the factors responsible for the catalysis of dehydration by various additives, including the solid product, have not been determined; the relationship between the original structure and the structure of the product has been little studied, etc. Thus new studies of the mechanism and kinetics of the thermal decomposition of crystal hydrates are urgently required.

The aim of the present review is to systematise available data on the nature of dehydration and to draw attention to some problems which are not yet fully resolved.

Modern theories of the kinetics and mechanism of chemical reactions in the solid phase[1,2] show that the processes occurring in the dehydration of crystal hydrates can be divided into three groups: 1) the production of nuclei of the reaction product (prenucleation period); 2) the formation and growth of reactive nuclei; and 3) the overall kinetics of the process and the overall mechanism of the reaction.

It is obvious that this division is to some extent arbitrary, and that in real situations these three stages are mutually related. Nevertheless, we shall use it in the present review, chiefly for convenience in the presentation of the material.

2. PERIOD PRECEDING THE FORMATION OF NUCLEI OF THE REACTION PRODUCT

The study of the processes preceding the production of observable growing nuclei of the reaction product has been the subject of a comparatively small number of papers; this is due not to lack of interest in the study of this phenomenon, but to the complexity of the investigations. Most of the published papers, therefore, are concerned with the verification of theories regarding which imperfections in the crystal are responsible for the production of nuclei.

Existing theories of nucleation[3-5] relate chiefly to the thermodynamic conditions for their production and show little relation to the physicochemical features of the crystal. Almost no experimental studies of the factors responsible for the production of nuclei have been carried out, although they are of considerable interest.

In 1954, Garner and Jennings[6] suggested that as the water is removed, the defects formed on the surface of the crystal diffuse into its volume and accumulate at dislocations. In their opinion, the aggregates of defects formed in this way might act as centres for nucleus formation. The experimental test of this theory carried out by these authors using the dehydration of chrome alum showed, however, that the rate of diffusion of defects through the crystal is too low to have any significant influence on the rate of movement of the boundary between the starting material and its solid dehydration product.

Macdonald[7] pointed out that for reversible reactions, such as dehydration, it is difficult to imagine that the reaction can begin in the interior of a crystal. Even if such an act took place, the marked hindrance of diffusion at the point of development of the reaction would finally establish an equilibrium pressure, and the reaction would stop. Thus water molecules evaporating from the surface

at the points where they are least firmly bound to the crystal (point defects, impurities, dislocations, etc.) will form vacancies. The formation of nuclei in this instance will take place as a result of the migration of water molecules over the surface and their volatilisation at the points where vacancies were formed in the earlier stages.

The influence of dislocations on dehydration has been studied by many workers. As a result of such studies, Thomas and coworkers[8-10] concluded that if dislocations do have an influence on the dehydration of $NiSO_4.7H_2O$, they do so only in the earliest stages of the reaction. These early stages are naturally of particular interest in investigating the factors responsible for the production of nuclei, but it has not been possible to detect any significant correspondence between the points of emergence of the dislocations on the surface of a crystal and the points at which decomposition nuclei appear[8-11]. Moreover, it should also be noted that even if such a correlation were established, it would not provide an unambiguous answer to the question of whether the dislocations are themselves responsible for the production of nuclei, since dislocation pits in most instances consist of other point defects, impurity centres, etc.

Nevertheless, a relationship between the nuclei and the various imperfections in a crystal apparently does exist. This is indicated by experiments on the dehydration of $NiSO_4.7H_2O$,[12] in which a marked scatter was observed in the times at which the first nucleus appeared. Under the given conditions, in one of the experiments, the first nucleus (which usually appeared during the first hour) appeared only 495 min after the start of dehydration in a high vacuum. In another experiment, no nuclei appeared even 32 h after the start of the observations. On the other hand, if the surface of carefully prepared copper sulphate pentahydrate crystals is rubbed with a crystal of the monohydrate of the same salt, nuclei appear immediately in large quantities over the whole of the treated surface[13].

These few papers apparently contain all the available information which might provide an answer to the problem of the factors responsible for the production of nuclei. There is as yet insufficient experimental material to make it possible to relate the production of nuclei unambiguously to specific properties of a crystal and to predict the law governing the time dependence of the formation of nuclei.

3. KINETICS OF THE FORMATION AND GROWTH OF NUCLEI

The regular kinetic features of the appearance and growth of nuclei of the reaction product have been studied to a greater extent than the factors responsible for their formation. After the existence of nuclei had been clearly established, it was suggested that the induction period which is always observed in the dehydration of freshly prepared crystal hydrates is due chiefly to the anomalously slow rate of growth of the nuclei in the initial stages of the reactions[14,15].

To verify this theory, the rate of increase in the linear dimensions of the nuclei on $CuSO_4.5H_2O$ and $NiSO_4.7H_2O$ was measured[12,16]. It was found to be constant and approximately equal to the rate of propagation of the surface of separation, calculated from kinetic measurements of the loss in weight using the equations for a compressed parallelepiped (see below, section 5). The nuclei grew at a constant rate, however, only when the dimensions reached values of $(2-5) \times 10^{-3}$ cm. An analogous picture was observed in the study of chrome alum. In this instance, two kinds of nucleus were observed, each of which had its own constant rate of growth[17]. An induction period was also observed in this instance[18]. Table 1, taken from the paper of Cooper and Garner[17], gives data on the rates of growth of nuclei at different temperatures.

Table 1.

Temperature, °C	Rate of growth of nuclei $\times 10^6$, cm s^{-1}
35	8.64—8.89
30	6.04—5.85
25	4.03—3.84
20	2.22
15	1.20—1.11

It would be of interest to determine whether the nuclei grow into the interior of the crystal at the same rate or whether they have a planar shape and grow only over the surface of the crystal. From the kinetic viewpoint these two situations should differ fundamentally[2]. To resolve this problem for the dehydration of chrome alum, the extent of the development of nuclei was observed in a direction perpendicular to the surface, by cleaving the crystal and measuring directly the depth of penetration of the nuclei in partly dehydrated crystals. Two of these experiments on the dehydration of chrome alum at 30° gave rates equal to 7.8×10^{-6} cm s^{-1} and 5.9×10^{-6} cm s^{-1}, which agree with the values obtained by following their development over the surface (compare the data in Table 1). These results indicate that in some systems the rates of growth of the nuclei in directions normal to and parallel to the surface are equal.

In a study of the dehydration of potassium hydrogen oxalate hemihydrate, Hume and Colvin[19] observed the interesting phenomenon of an arrest in the movement of the surface of separation; this could not be explained at the time. In their experiments, the nuclei of the product grew at a constant rate until they reached a certain size, after which growth stopped. After 5–10 min, growth of the nuclei began again, and the rate of growth was equal to that before the arrest.

A constant rate of growth of the nuclei has been observed in almost all studies of the decomposition of crystals. The kinetics of the growth of nuclei is thus described by a linear function of time, beginning from dimensions of $\sim 10^{-3}$ cm.

It was noted above[12] that a marked scatter is observed in the times at which the first nucleus appears on different single crystals of the same substance. Despite this feature, however, the curves obtained by plotting the number of nuclei against time are smooth (Fig. 1). These curves are described to a high degree of accuracy by the equation

$$\lg N = k \lg (t - t_i),$$

where t_i is the time at which the first nucleus appears. The existence of this relationship suggests that although the appearance of the first nucleus is apparently a random process, depending on a large number of factors, the crystal apparently subsequently undergoes irreversible changes which predetermine the times at which the second, third, etc. nuclei appear. In other words, the

time at which the $(n + 1)$th nucleus appears is determined unambiguously by the presence of the n nuclei previously formed on the surface of the crystal.

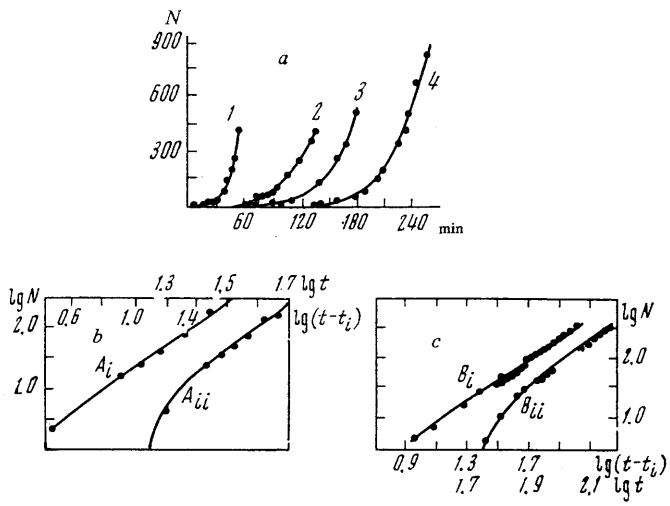

Figure 1. Time dependence of the number of nuclei at different temperatures: 1) 22°; 2) 15°; 3) 8°; 4) 1° (a), and the same curves on logarithmic coordinates: A_i, B_i—plots of $\lg N$ against $\lg(t - t_i)$ (b); A_{ii}, B_{ii}—plots of $\lg N$ against $\lg t$ (c).

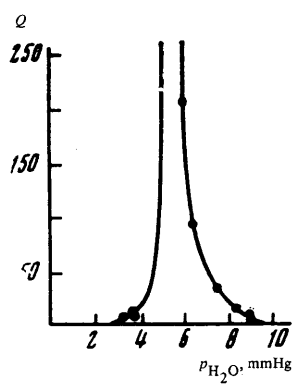

Figure 2. Dependence of the ratio of the maximal rate of formation of nuclei at a given water vapour pressure to the rate of nucleus formation in a vacuum (Q) on the water vapour pressure.

The presence of water vapour alters the rate of formation of nuclei on different crystal hydrates in different ways. If a crystal is treated with water vapour after it has been kept for some time in a vacuum, the rate of nucleus formation at first increases, and then decreases, passing through a maximum. This has been observed for $KCr(SO_4)_2.24H_2O$, $NH_4Cr(SO_4)_2.24H_2O$, and $CuSO_4.5H_2O$.[6] All these hydrates showed a sharp increase in the number of nuclei when the vessel was evacuated again. This effect has not been explained, although it is of undoubted interest. It is difficult to relate it to the blocking action of water vapour on the crystal surface, if we consider the nature of the relationship between the water vapour pressure and the ratio of the maximal rate at a given water vapour pressure to the rate of nucleus formation in a vacuum, given in Fig. 2 for the example of chrome alum. In contrast to the situation for chrome alum, the rate of nucleus formation in the dehydration of, for example, potassium aluminium alum is almost independent of the water vapour pressure in the space surrounding the crystal.

The influence of water vapour on the rate of movement of the surface of separation or, which is the same thing, on the rate of increase in the linear dimensions of the nuclei will be discussed below.

4. INFLUENCE OF VARIOUS FACTORS ON THE OVERALL KINETICS OF DEHYDRATION

In the kinetic approach to the study of solid-phase reactions, the degree of transformation of the substance (from the loss in weight or liberation of gas) during decomposition is usually measured. The curves obtained in this way are integral with respect to all parameters except time. More complete studies of reactions of this type have shown that the rate of dehydration depends markedly on a large number of factors. Some of these factors are structural (the dependence of the rate on the crystal habit, the degree of dispersion, the defect character of the lattice, etc.), and their influence on the decomposition has been described[20,21]. Another group of factors which must be taken into account in the study of the kinetics of the decomposition of solids is directly related to the general regular features of solid-phase reactions. In the present section, we shall examine these features as they apply to the dehydration of crystal hydrates.

Self-cooling. All crystal hydrates which have been studied lose water in a markedly endothermic process. As a consequence, on dehydration in a vacuum, when heat exchange between the specimen and the thermostat takes place chiefly by radiation, the temperature at which the removal of water takes place may generally speaking not be equal to the temperature of the thermostat. This feature has been pointed out by many workers. The effect has been described as self-cooling, and calculations based on the theory of black-body radiation have been proposed to take account of it. For example, in the dehydration of $CuSO_4.5H_2O$, Smith and Topley[22] suggested that the temperature of the crystal be calculated by means of the expression:

$$\lambda\left(-\frac{dm}{dt}\right) = S \cdot 1.38 \cdot 10^{-12}[T^4 - T'^4]$$

which allows for the physical characteristics of the crystals. Here λ is the heat of the reaction, $(-dm/dt)$ the mass rate of the reaction, S the external surface area of the specimen, and T and T' the temperatures of the thermostat and the specimen respectively.

An analogous equation was used by Cooper and Garner[17] in a study of the dehydration of alum:

$$\lambda\delta\Delta = k\Delta_0[T^4 - T'^4]$$

where k is Planck's constant, Δ_0 the initial surface area from which radiation takes place, Δ the surface of separation at a given moment of time, and δ the reaction rate

in g $cm^{-2}s^{-1}$. The self-cooling effect is not small enough to be neglected without distorting the true decomposition picture. The magnitude of this effect, calculated from the equation for chrome alum[17], is given in Table 2.

Table 2.

Cooling Δt, deg	Temperature of thermostat, °C
11.8	35
8.8	30
6.2	25
4.1	20
2.3	15

The results show that even at 15°, the extent of the self-cooling is much greater than the generally accepted limits of temperature stability in an isothermal process. Neglect of this effect may lead to significant errors in the determination of the kinetic parameters of a reaction.

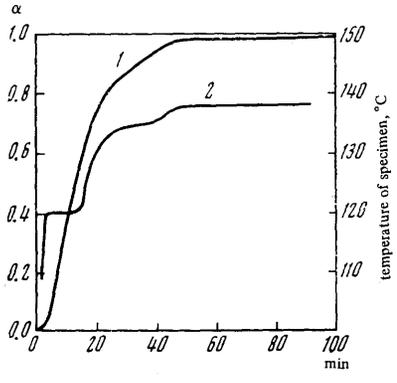

Figure 3. Simultaneous change in the loss in weight (1) and temperature (2) on the dehydration of $CaSO_4.2H_2O$ (temperature of thermostat 138°).

The question of the true conditions under which a reaction takes place naturally requires the most thorough analysis. For this purpose, experiments have been carried out in which the temperature of a specimen and its degree of transformation were recorded simultaneously[23,24]. An example of the results is given in Fig. 3. The simultaneous recording of the temperature and the degree of decomposition was carried out for the dehydration of $CaSO_4.2H_2O$. A noteworthy feature is that the temperature of the thermostat (138°) was not attained even as $\alpha \to 1$. Most of the specimen (see Figure) decomposed at an almost constant rate at ~ 120°. In this instance, equalisation of the thermal fluxes—the rate of supply of heat from outside and the rate of absorption of heat in the reaction—apparently took place. This conclusion appears the more correct since the reaction takes place at the surface of separation between the original hydrate and its decomposition product, so that heat exchange takes place through a surface which is also the reaction zone.

In this example, the dehydration of gypsum was carried out at a water vapour pressure equal to 200 mmHg. Despite the presence of a gaseous atmosphere facilitating heat exchange between the specimen and the thermostat, however, the effects of self-cooling were significant in this instance also. There thus appears to be little justification for the assertion[22] that in a gaseous environment the effect of self-cooling can be neglected.

In most instances, the curves for the topochemical decomposition of solids are S-shaped[1]. The latest studies[25,26] apparently prove that for reactions with marked endothermicity, such as the dehydration of crystal hydrates, the magnitude of the induction period on the $\alpha(t)$ curves depends to a large extent on the conditions of heating of the crystals.

Special mention must be made of the determination of the rate of dehydration from the rate of movement of the boundary of separation between the phases. In most instances this has been determined from some kinetic equation for a fixed value of α and has been related to a temperature calculated for the given value of α with allowance for the effect of self-cooling. This determination is correct, however, only if quasi-steady-state conditions obtain for the process. In other words, the change ΔT in the temperature of the specimen within a certain small time interval should be sufficiently small compared with the corresponding change $\Delta\alpha$ in the degree of transformation of the specimen during the same time interval:

$$\frac{\Delta T}{T} \ll \frac{\Delta\alpha}{\alpha}$$

where T and α relate to the middle of the time interval. If this condition is not observed, thermographic conditions will be established, so that the values of the kinetic parameters will differ from those obtained under isothermal conditions[26,27].

Influence of the gaseous atmosphere. The gaseous atmosphere in which the dehydration of crystals takes place may be inert or contain water vapour. Direct experiments have established that an inert atmosphere, up to pressures of 3–4 mmHg, has no significant influence on the rate of dehydration[28]. Above this pressure, diffusion control begins to have an effect, and perturbations associated with the presence of the inert atmosphere in the system become significant. It is very difficult to establish the nature of this influence, since it is superimposed on other effects and cannot be isolated in pure form.

Under dynamic conditions, the extent of the influence of an inert atmosphere depends on the rate of gas flow in the reaction zone. This problem has not been studied systematically, although there are indications that the rate of dehydration increases with increase in the rate of gas flow[29-31].

The presence of water vapour in the reaction zone influences the observed rate of dehydration. This is observed first because the rate of dehydration represents the difference between the actual rates of the forward dissociation and back reactions, and secondly because these opposed rates are themselves functions of the concentration of molecules in the reaction zone. They are determined by adsorption equilibrium. The relationship between the reaction rate constant (or constants) and the partial pressure of water vapour may therefore be very complicated, and it is complicated even further by the fact that water vapour may have a direct catalytic effect on the dehydration and also on the subsequent crystallisation of the product.

Topley and Smith[32], and Volmer and Seydel[33], in studies of the dehydration kinetics of manganese oxalate dihydrate, observed a complex relationship between the rate constant and the partial pressure of water in the reaction system, characterised by the presence of a maximum and a minimum on the plot of rate against H_2O pressure. Other crystal hydrates usually showed only a smooth decrease in rate with increase in pressure[34].

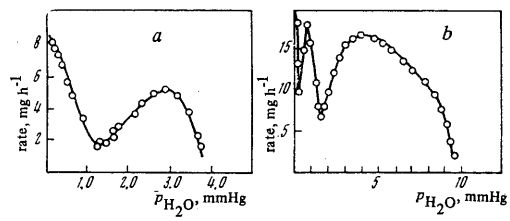

Figure 4. Dependence of the rate of dehydration on the water vapour pressure for $MnSO_4.4H_2O$ (a) and $ZnSO_4.7H_2O$ (b).

For a long time, manganese oxalate was regarded as unique in this respect. A systematic study of the phenomenon showed, however, that with increase in the water vapour pressure, most crystal hydrates behave in approximately the same way as manganese oxalate, and in some instances in even more complex fashion[35-37]. The relationships for the crystal hydrates $MgSO_4.4H_2O$ and $ZnSO_4.7H_2O$ are given in Fig. 4. For zinc sulphate, the rate of dehydration passes through two minima and two maxima with increase in the water vapour pressure, whereas magnesium sulphate tetrahydrate shows approximately the same behaviour as manganese oxalate.

A study[37] of the dehydration of various crystal hydrates at a fixed water vapour pressure in the surrounding atmosphere showed that at a certain pressure after the initial act of nucleus formation the reaction stopped completely (Fig. 5).

It is difficult to find an unambiguous interpretation of this complex behaviour of crystal hydrates on dehydration in the presence of water vapour. The shape of the curves obtained by plotting rate against pressure is usually attributed to competition between the accelerating action of water on the crystallisation of the product and the retarding action on the movement of water through the layer of product into the surrounding space[34,35]. In some instances the phenomena associated with the presence of water in the reaction zone are attributed to the formation of porous structures in the decomposition zone[38]. The difficulty of finding an explanation is due chiefly to the lack of experimental data on the adsorption equilibrium of water during the decomposition.

The existence of gaseous catalysis has been verified experimentally[39] for $CuSO_4.5H_2O$. Study of the dehydration in a stream of hydrogen in the presence of small quantities of water and HCl showed that the reaction rate is increased considerably (by a factor of 5–7). Analysis of the partly decomposed crystals showed that HCl is adsorbed by the surface of the crystals. These experiments demonstrate again the need for a study of the phenomena of adsorption and desorption of water by the surface of crystal hydrates during their decomposition.

The "impedance" of the layer of product. As the reaction develops into the interior of a crystal, the layer of product may finally become so thick that diffusion controls the removal of water molecules into the surrounding space from the surface of separation of the phases, which is also the place where the reaction is proceeding. This effect has been detected by many authors[22,28,39,40] in the study of dehydration, and has been called "impedance".

The magnitude of the impedance effect is measured as the difference between the observed rate of movement of the surface of separation into the interior of the crystal for a given layer thickness and the corresponding rate for zero thickness. Since the rate of movement of the surface of separation at zero layer thickness cannot be measured directly, it is found by extrapolation to zero layer thickness[41]. Strictly speaking, this extrapolation should be not to zero thickness but to the thickness corresponding to the maximal rate of movement of the surface of separation, since in the initial period after their production, the nuclei grow at an anomalously slow rate. This applies equally to the development of the reaction zone into the interior of the crystal in the initial stages of the reaction.

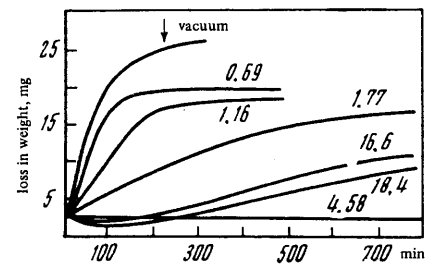

Figure 5. Dehydration curves for $MgSO_4.7H_2O$ at various water vapour pressures (given by the figures next to the curves). Decomposition does not take place at p_{H_2O} = 4.58 mmHg.

Despite the importance of an understanding of the phenomenon of impedance in the study of the kinetics and mechanism of dehydration, there is still lack of agreement on this subject. Taylor and Taylor[42] found that the product obtained in a comparatively thin layer has a high porosity, so that it could hardly have had a significant influence on the reaction rate. Nevertheless, they do not reject the possibility that water molecules adsorbed on the surface of the product may hinder considerably the removal of water from the reaction zone into the free volume. This may in turn be responsible for an increase in the water vapour pressure in the reaction zone and hence a decrease in the reaction rate.

Generally speaking, all explanations put forward for the origin of the impedance reduce in one way or another to a displacement of the equilibrium at the surface of separation between the starting material and the product. From the kinetic viewpoint, this question is probably closely related to the range—kinetic or diffusion—in which the reaction takes place.

We noted above that theories of the competition between the catalytic action of water on the crystallisation of the product and the retarding influence (as a consequence of diffusion) of the layer of product have been used to explain the "strange" dependence of the rate of dehydration on the water vapour pressure. From this it may be concluded that the diffusion and adsorption properties of the product cannot be neglected, but the extent to which they are significant is not yet known.

The phenomenon of impedance has also been used many times to explain the familiar so-called autocatalytic course of the curves for solid-phase decomposition (see Vorontsov's review[43]). The impedance effect possibly does not always apply, as far as can be judged from experiments on the measurement of the rate of growth of nuclei into the interior of a crystal[18]. Finally, it should be noted that for strongly endothermic dehydration, a decrease in the rate of propagation may also be due to a change (decrease) in the flow of heat supplied to the reaction zone as a consequence of differences in the thermal conductivity of the starting material and the product. An amorphous product in this instance may even act as a heat insulator.

The above examination shows that impedance is a complex phenomenon. Despite its small magnitude, neglect of the effect in the study of the dehydration of crystal hydrates may lead to significant errors in kinetic determination and to incorrect interpretation of reaction mechanisms.

Formation of Labile Phases and Intermediate Liquid Hydrates

Partington in 1911 suggested[44], and a large number of subsequent studies subsequently proved[33,39,45,46], that the dehydration of crystal hydrates, particularly at low partial water vapour pressures, gives an intermediate product amorphous towards X-rays. The absence of lines on the X-ray diffraction patterns for specimens dehydrated in a vacuum can be due entirely to the true amorphous character of this product. On the other hand, as pointed out by Roginskii[47], the product formed on dehydration in a vacuum may consist of a disordered assembly of very fine crystals (up to 10^{-7} cm in cross-section), and this would also lead to the absence of lines on the X-ray diffraction patterns, because of the insufficient sensitivity of the apparatus. Subsequent electron-microscope studies by Roginskii and coworkers[48] showed, however, that despite marked dehydration of $Na_2SO_4.10H_2O$ and $MgSO_4.7H_2O$ crystals at a pressure of 10^{-4} mmHg, the external form of the crystal and its ultramicroscopic structure initially remain unchanged.

It was only on prolonged irradiation that cavities were produced on the surface and a tendency for new cavities to be produced close to those previously formed (localisation) was observed. Some time after the start of the appearance of the cavities, the crystal consisted of a fine network of solid material surrounding the cavities produced, that is a skeletal structure appeared, indicating an amorphous intermediate product, rather than a submicrocrystalline product.

The problem of the formation of intermediate unstable phases has been most fully studied by Khomyakov[49] and Frost and coworkers[50]. Thus Khomyakov observed that partly dehydrated crystals of $CuSO_4.5H_2O$, immediately after the experiment was stopped, liberated a quantity of heat (4824 cal $mole^{-1}$) approximately equal to the difference between the heats of the dehydration of the freshly prepared and partly decomposed $CuSO_4.5H_2O$ crystals. According to Thomsen[51], these heats are −17334 cal $mole^{-1}$ and −12519 cal $mole^{-1}$ respectively, and their difference does indeed differ little from the heat determined by Khomyakov. This effect was not observed on repeated dehydration.

Frost carried out analogous experiments and followed the quantitative change in the amorphous product during the reaction at different water vapour pressures. He found that after the removal of water, the product remaining liberated heat for a definite time interval. This thermal effect was attributed to rearrangement of the structure from an amorphous state to a crystalline state corresponding to the structure of the product. Thus it was found that the intermediate amorphous products are rich in energy, and are metastable phases. The values of the heats of the transformation from the intermediate state to the final state, taken from a paper by Frost and coworkers[38], are given below:

$ZnSO_4.H_2O$(amorphous) → $ZnSO_4.H_2O$(crystalline); ΔH = −7600 cal $mole^{-1}$
$CuSO_4.H_2O$(amorphous) → $CuSO_4.H_2O$(crystalline); ΔH = −7170 cal $mole^{-1}$
$MgSO_4.H_2O$(amorphous) → $MgSO_4.H_2O$(crystalline); ΔH = −6550 cal $mole^{-1}$
$NiSO_4.H_2O$(amorphous) → $NiSO_4.H_2O$(crystalline); ΔH = −4720 cal $mole^{-1}$
$CoCl_2.H_2O$(amorphous) → $CoCl_2.H_2O$(crystalline); ΔH = −1390 cal $mole^{-1}$

(it is indicated in parentheses whether the compound is in the amorphous or crystalline state).

It was found that from a certain pressure, almost no amorphous product is produced on dehydration in water vapour. The values of these critical pressures are very close to those corresponding to the minimal rate on the plots of the rate of dehydration against H_2O pressure. Not all of the crystal hydrates form an amorphous intermediate product even on dehydration in a vacuum. For example, salts such as $NiNO_3.6H_2O$, $Mg(NO_3)_2.6H_2O$, and chrome alum, on dehydration in a vacuum, form a crystalline lower hydrate with an extensive internal surface due to formation of capillaries, whereas dehydration in the presence of water vapour at ordinary pressures, as with the other crystal hydrates, gives normal crystalline aggregates. An attempt to classify hydrates according to this characteristic was made in a review by Dell and Wheeler[52].

All the phenomena described above can be explained as follows: within a certain temperature range, the lattice framework is preserved even after the crystal (for example $CuSO_4.5H_2O$) has lost four water molecules. This also favours the flow of the water diffusing through the layer of product. The lattice framework is preserved until nuclei of the new stable phase appear. The production of these nuclei depends on the decrease in the flow of water through the layer of monohydrate and also on the temperature and surrounding pressure of water vapour.

Studies of the nature of the amorphous product and its role in the decomposition of crystal hydrates are of particular interest in relation to theories of the localisation of the reaction in a narrow zone at the surface of separation between the starting material and the product. Since the specific volumes of the original hydrate and final product are not always the same, the layer of amorphous product then will always compensate the structural stresses and ensure the structural change from the starting material to the reaction product.

The existence of intermediate lower hydrates has been established from vapour pressure isotherms[53,54], and their formation on thermal dehydration has been detected

in a large number of thermographic [55,56] and X-ray diffraction [57-70] studies.

The importance of thermographic investigations in the study of the kinetics of dehydration should not be overemphasised. Reisman and Karlak [58] showed that small changes in the conditions under which thermographic experiments are carried out produce a marked scatter in the experimental results obtained. This is in fact the reason for the frequently encountered lack of agreement in the thermographic results obtained by different authors. Thermographic studies are of greatest value in the discussion of the mechanisms of the dehydration of crystal hydrates, when, as we shall subsequently see, it is absolutely essential to allow for the formation of intermediate lower hydrates during the decomposition.

The intermediate hydrates are extremely unstable, and this explains the almost complete lack of information on the kinetics of their dehydration in pure form. Nevertheless, Cooper and coworkers [71] were able to study the kinetics of the dehydration of copper sulphate trihydrate. The kinetic curve which they obtained differs little from the usual curve for solid-phase decomposition.

Influence of the addition of the solid product. Since dehydration takes place at the surface of separation between the original hydrate and its product (usually a lower hydrate), the possibility of direct contact between the starting material and the amorphous or crystalline lower hydrate cannot be excluded. In this connection, the possible catalysis of the dehydration by solid decomposition products is of undoubted interest. Studies of this kind have been made by Rae [14], Skramovsky [55,72], and Vallet [30], and later by Sakovich [73] in an examination of the decomposition of hydrated salts of copper, cobalt, and magnesium.

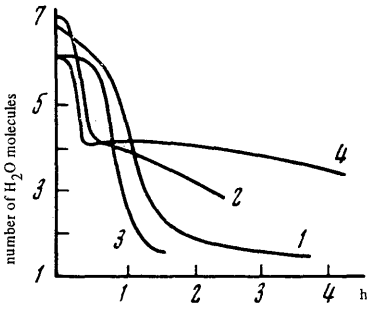

Figure 6. Dehydration curves for $CoSO_4.7H_2O$ and $CoSO_4.6H_2O$ in the pure state and with the addition of anhydrous salt: 1) $CoSO_4.7H_2O$; 2) $CoSO_4.7H_2O$ + 5% $CoSO_4$; 3) $CoSO_4.6H_2O$; 4) $CoSO_4.6H_2O$ + 5% $CoSO_4$.

These studies showed that the addition of a lower hydrate increases the stability of that intermediate hydrate and at the same time increases the rate of the stage leading to the formation of the salt added. This is illustrated by the curves, taken from Feitknecht's paper [69], for the dehydration of cobalt sulphate hexa- and heptahydrates containing 5% of the anhydrous salt (Fig. 6). According to Sakovich [73], the observed accelerating action of the added product on the dehydration of crystal hydrates is due to their interaction at the points of contact with the surface layer of the starting material. This interaction is due to the affinity of the reaction product for water vapour, the pressure of which is always greater above the original hydrates than above their dehydration products. Introduction of the additive produces regions of the reaction zone are produced even at room temperature, and this apparently leads to an increase in the rate of the process. This explanation is supported by a comparison of these experiments with Garner's observations of the formation of nuclei on the surface of copper sulphate pentahydrate treated with the monohydrate of the same salt, when nuclei appeared almost instantaneously.

The partial stabilisation of the intermediate hydrates added to the starting material, observed by Vallet [30], can be attributed rather to a simple increase in the quantity of intermediate phase.

The problem of the mechanism of the accelerating action of the added product is closely related to a more general problem in the chemistry of solids—the mechanism of the influence of various heterogeneous additives on solid-phase reactions. This problem is at present far from being solved, despite its obvious importance for topochemistry.

5. THEORETICAL DESCRIPTION OF THE KINETICS OF DEHYDRATION

The problem of the satisfactory description of the kinetics of dehydration has faced research workers since the earliest studies of these processes, and cannot be regarded as fully resolved. The first attempts to provide a quantitative description of dehydration were based, strangely enough, on the idea of autocatalysis [74,75]—an idea which has in fact been revived recently [76]. Historically, however, the development of modern topokinetics originated in the successful application of Langmuir's idea [77] that the surface of separation between the phases is the point at which reaction takes place to the description of the kinetics of decomposition of various hydrates [41].

In fact, the possibility of describing the kinetics on the basis of simple geometric representations of the form of nuclei and their number appeared very attractive. This simplicity proved to be deceptive, however. Hume and coworkers [78] examined three examples of topochemistry, differing radically in their mode of description. In the first, nuclei are formed immediately and cover the surface of the particle almost completely. The process is then described by the equation of a "contracting" sphere, parallelepiped, etc., depending on the shape of the crystal. In the other extreme case, when the frequency of formation of the nuclei is low compared with the rate of movement of the surface between the phases, the reaction obeys a unimolecular law, as for example in the conversion of monoclinic into orthorhombic sulphur. The example of greatest interest for topochemistry is the intermediate situation, where the ratio of the rate of production of nuclei to the rate of movement of the surface between the phases is such that at sufficiently small degrees of conversion, each particle will contain at least one nucleus. In this instance the reaction rate will pass through a maximum and an S-shaped curve will result. It is this third possibility which is usually realised in the decomposition of crystal hydrates.

One of the first equations used for the description of the kinetics of dehydration was an equation in which the

mass rate, divided by the original surface area of the crystal[22], was taken as the rate constant. Subsequently transformed into the equation of a compressed parallelepiped, it was used successfully by Hume and Colvin[28] to describe the kinetics of the dehydration of copper sulphate pentahydrate. A number of other equations[29,40,78], some simpler, some more complex, including the Polanyi–Wigner equation, have been applied to various reactions, with varying success.

With the development of the formal kinetics of reactions in the solid phase, more complex equations based on various physical models of the reactions have appeared. Thus a more important problem, in our view, is the applicability of the kinetic method of analysis to the determination of the mechanism of a reaction, or in other words the problem of the correspondence between the model used in the derivation of the kinetic equation and the real physical picture of the decomposition. Molony and Ridge[80], in a study of the kinetics of the dehydration of calcium sulphate dihydrate, found that the experimental results are described equally effectively by the equations

$$A - B(1-\alpha)^{1/3} = kt$$

and

$$A - B(1-\alpha)^{1/2} = kt$$

(naturally, with different constants). The correlation coefficients calculated for the two equations were −0.969 and −0.983 respectively, that is they almost coincided. In the opinion of these authors[80], this result provides an example of a situation in which applying the equations of formal topokinetics in itself cannot provide as a criterion for the unambiguous selection of one of two or more proposed reaction mechanisms. This conclusion applies not only to dehydration, but to topochemical reactions in general, and forms the basis of a contradiction between a real process and the method used to describe it. The efforts of many research workers have been directed towards the elimination of this contradiction. Some have adopted the approach of increasing the accuracy of familiar equations by including the distribution of particle sizes[81,82], by making allowance for mass and heat transfer in the crystal[83], by using the activated-complex theory[84], etc. Others consider that there is no point in trying to describe the entire decomposition curve by means of a single equation, since different stages of the process correspond to different mechanisms[85]. Despite all efforts in the field of the kinetics of dehydration, however, two of the anomalies noted by Garner[86] as early as 1938 have not yet been explained satisfactorily.

a. The reaction rate in a large number of examples of the decomposition of solids, including the decomposition of crystal hydrates, increases as a very high power of time. The exponent is much greater than might have been expected from simple theoretical considerations based on the theories of the boundary of separation.

b. The reaction rate in the initial stage is proportional to the mass of sample decomposed, and not its area.

It may therefore be definitely stated that the problem of an adequate description of dehydration is generally speaking a part of topokinetics, which is at present largely unsolved.

6. MECHANISM OF DEHYDRATION

We noted above that the dehydration of crystal hydrates involves the formation of intermediate amorphous or crystalline lower hydrates. This feature determines the possible decomposition schemes.

The transitions between the different stages of the reaction have been studied most fully for $CuSO_4.5H_2O$ and $CaSO_4.2H_2O$. When the reaction takes place in a single stage, for example from copper sulphate pentahydrate to the monohydrate, the reaction scheme can be represented in the form shown in Fig. 7.[17,40,87]

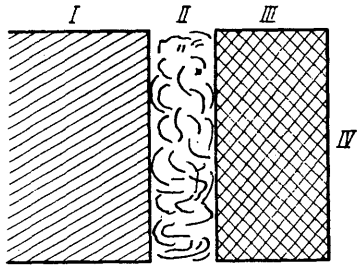

Figure 7. Dehydration of crystal hydrates: I) reagent; II) intermediate layer; III) product, undergoing slight recrystallisation; IV) open space (vacuum or water vapour).

Garner and Pike[88], referring to data on the structure of $CuSO_4.5H_2O$,[89] point out that dehydration in a vacuum, which always gives the monohydrate, corresponds to the loss of four water molecules coordinated to the copper atom. The fifth water molecule is not coordinated, and the strength of its bonding is apparently different. Their non-equivalence in the $CuSO_4.5H_2O$ lattice is also indicated by experiments on isotopic exchange[90].

In the presence of water vapour, the decomposition is complicated considerably, chiefly because of the production of the trihydrate as an intermediate compound. According to Colvin and Hume[34], the overall scheme for the dehydration of copper sulphate pentahydrate can be represented in the form:

$$CuSO_4 \cdot 5H_2O \rightarrow \underset{\text{amorphous}}{CuSO_4 \cdot 3H_2O} \begin{cases} \xrightarrow{I} CuSO_4 \cdot H_2O + 2H_2O \\ \xrightarrow{II} \underset{\text{crystalline}}{CuSO_4 \cdot 3H_2O} \xrightarrow{III} CuSO_4 \cdot H_2O + 2H_2O \end{cases}$$

The amorphous trihydrate formed in the decomposition, when treated in a vacuum, immediately loses two more water molecules (route I) and is converted into the monohydrate. The presence of water vapour may direct the reaction along route II → III, since water facilitates the crystallisation of the amorphous trihydrate.

The activation energy for the dehydration of $CuSO_4.5H_2O$ and $CuSO_4.3H_2O$ has the values E_1 = 16–18 kcal mole^{-1} [17] and E_2 = 15.6 kcal mole^{-1} [71] respectively, that is the difference is not large.

The various stages in the dehydration of $CaSO_4.2H_2O$ are given in the following scheme[91]:

$CaSO_4 \cdot 2H_2O$ (monoclinic)

Dehydration, possibly including topotaxy ↓ ↑ Recrystallisation without topotaxy

$CaSO_4 \cdot \frac{1}{2}H_2O$ + water (rhombohedral)

Quasi-zeolite dehydration of the lattice without recrystallisation ↓ ↑ Adsorption of water from vapour, quasi-zeolite reaction

$CaSO_4$ Soluble anhydrite.

↓

$CaSO_4$ Orthorhombic anhydrite

This compound is also of interest since the mechanism of its complete dehydration is complicated by an additional transformation between the two crystalline forms of the anhydrous salt[92].

It is impossible to give here all the crystal hydrate decomposition schemes which have been proposed: the number is greater than the number of hydrates. The examples given show sufficiently clearly the importance of making allowance for the stepwise character of the overall process and the formation of various intermediate compounds in the description of dehydration.

7. NEED FOR A STUDY OF THE LOCALISATION OF THE DEHYDRATION OF CRYSTAL HYDRATES

We have already mentioned various unsolved problems in the chemistry of crystal hydrates. In the present section we would like to consider particularly the problem of the localisation and auto-localisation of the process. As already mentioned in the introduction, we are referring to the interesting property of crystal hydrates and other topochemical systems of decomposition with the formation and growth of nuclei. It is extremely important to answer the question of why this takes place and to find methods of controlling this process. The importance stems primarily from the large number of practical applications of crystal hydrates on the one hand, and also from the considerable theoretical importance of the problems of localisation in topochemistry on the other hand, since the concept of nuclei forms the chief distinguishing feature of topochemical reactions.

An example of the practical utilisation of the results of these studies is provided by the production of catalysts by the dehydration of crystal hydrates. Partly dehydrated crystal hydrates are at present used as catalysts for a large number of industrial reactions[93,94]. In this connection, the control of the formation and growth of nuclei would open up the possibility of controlling the properties of the catalysts obtained, through the directed production of the catalytically active materials. This of course is not the only field in which it is important to find ways of controlling localised processes. They are equally important in photography, metallurgy, etc.

The problem of localisation naturally is not specific for dehydration alone. It can be applied equally successfully to any solid-phase reactions involving the formation and growth of nuclei of the product. It is convenient, however, to distinguish crystal hydrates from most other similar systems since it is at present difficult to find a class of substances which have been studied in such detail. In addition to a very large number of studies of the kinetics and mechanism of the dehydration of crystal hydrates, detailed structural studies have been made[70], the infrared spectra have been studied[95,96], dehydration has been studied by NMR[97] and dielectric spectroscopy[98], and data have been obtained by isotopic substitution[99] and from proton conductivity in crystal hydrates[100] and from the influence of ultrasonic radiation on the dehydration[101]; the absolute velocities of water molecules leaving a crystal surface on dehydration have also been measured[102]. These studies have been so extensive and varied because crystal hydrates provide one of the best model systems in topochemistry, by means of which it may be possible to come close to a solution of the problem of localisation; the importance of this problem in theory and practice has already been emphasised.

Oxygen Compounds of Iron(VI, V, IV)

I.G.Kokarovtseva, I.N.Belyaev, and L.V.Semenyakova

Published information on the chemistry of oxygen compounds of iron—the ferrates(VI, V, IV)—has been reviewed briefly. The methods of preparation, chemical properties, thermal decomposition in air and in O_2, the kinetics and mechanism of decomposition in solution, methods of analysis, structural, spectroscopic, and magnetic studies, the nature of the covalent bonding, and the uses of the ferrates(VI, V, IV) have been described. The bibliography contains 108 references.

I. FERRATES(VI)

Compounds of sexavalent iron in the form of salts of ferric acid ($MFeO_4$) have been known for a long time [1,2]. About twenty to thirty of these compounds have now been prepared; only the ferrates(VI) of potassium, rubidium, caesium, strontium, and barium have been obtained in the pure crystalline state, and the others are known in solution or have been isolated from solution in the solid state but with a considerable amount of impurity. The difficulties associated with the preparation of pure crystalline ferrates(VI) are due chiefly to their instability.

Preparation. The alkali metal ferrates(VI) can be prepared by the following methods: 1) by heating to red heat a mixture of iron filings and potassium nitrate or a mixture of iron oxide, alkali, and potassium nitrate [1-3]; 2) by oxidising, by heating in a stream of O_2, solid phases consisting of an alkali metal oxide, peroxide, or hydroxide with iron (or its oxide) in the ratio $M_{alk}:Fe = 2:1$; [4-8] 3) by the electrochemical dissolution of an iron anode in alkali solutions [9-12]; 4) by oxidising iron salts or the freshly prepared hydroxide with various oxidising agents (Cl_2, Br_2, NaOCl etc.) in a strongly alkaline medium [13-19]; and 5) by double decomposition [20].

Methods (1) and (2) are the simplest, but the ferrates(VI) obtained by these methods are usually contaminated by traces of the starting materials and side products of the reactions, and these cannot be removed without decomposition of the chief product. Method (3) gives only solutions of the alkali metal ferrates(VI), the concentration of which increases with increase in temperature to 50°, or with increase in the alkalinity of the solution and the current density.

Method (4), which has been used to prepare the pure crystalline ferrates(VI) of K, Rb, and Cs, is of particular interest. These ferrates have a limited solubility in saturated solutions of the corresponding alkalis. This property is used to precipitate them from solution. A product with a purity of 98–100% is obtained by recrystallising the precipitated ferrates(VI) and washing with alcohols [21]. The high solubility of Li_2FeO_4 and Na_2FeO_4 in concentrated alkalis makes it impossible to isolate them from solution in the crystalline state [22]. Solid Li and Na ferrates(VI) can be obtained by method (5), by the double decomposition of $LiClO_4$ or $NaClO_4$ with K_2FeO_4 with subsequent vacuum-drying of the filtrate [20]. The products, however, have a purity of only 15–69%. The ferrates(VI) of Na and more particularly Li decompose much more rapidly than the ferrates(VI) of the other alkali metals during preparation and purification.

As far as the alkaline earth metal ferrates(VI) are concerned, it should be noted that unlike the ferrates(VI) of Ca and Mg, the ferrates(VI) of Sr and Ba are sparingly soluble in water and are precipitated when K_2FeO_4 solution is treated with Sr or Ba nitrates, chlorides, or acetates [10, 16,23,24]. It has been possible to obtain pure crystalline $SrFeO_4$ and $BaFeO_4$† only at 0° in the complete absence of CO_2. In the moist state they decompose fairly rapidly by reacting with CO_2. [17] Solutions of Ca and Mg ferrates(VI) have been obtained by the double decomposition of Ca and Mg sulphates, carbonates, or oxalates with $SrFeO_4$. [23]

The ferrates(VI) of other metals have been obtained by double decomposition from solutions of the metal nitrates and a suspension of $BaFeO_4$ in water [25]. Solid ferrates(VI) of Pb, Cu, Ag, Hg, Al, Zn, Th, Co, Ni, Fe^{II}, and Fe^{III} have been isolated in this way. Most of these compounds decompose on drying or with a slight increase in temperature (30–40°).

Attempts to replace oxygen in ferrate(VI) by fluorine by fluorinating K_2FeO_4 [26] or a $4KO_2 + Fe_2O_3$ mixture [27] were unsuccessful.

Physicochemical properties. The dry crystalline ferrates(VI) of K, Rb, Cs, and Sr are stable in air and can be kept in closed vessels. Barium ferrate(VI) in the moist state with a water content of 4–5% is spontaneously converted into $BaFeO_3$ at room temperature [17,28]. The decomposition corresponds exactly to the equation

$$BaFeO_4 \cdot aq = BaFeO_3 \cdot aq + \frac{1}{2} O_2$$

At a moisture content of 1–2%, $BaFeO_4$ has an almost unlimited stability.

When heated, all ferrates(VI) decompose with the liberation of O_2 and the final formation of tervalent iron compounds. The decomposition of ferrates(VI) in air takes place at different temperatures: 150–400° for K_2FeO_4, 80–600° for $SrFeO_4$, and 105–800° for $BaFeO_4$. [29] The liberation of active oxygen in the thermal decomposition is not accompanied by the immediate reduction of Fe^{VI} to Fe^{III}, but involves the conversion of the ferrates(VI) through intermediate reduction states to

†$SrFeO_4$ is less stable than $BaFeO_4$. The maximal purity of Sr ferrate(VI) obtained did not exceed 95–97%.

ferrates(III).[17,30,31] For example, the decomposition of K_2FeO_4 in a stream of O_2 from 200° to 700° involves the formation of potassium ferrate(V) and ferrate(III) by the reaction:

$$2K_2FeO_4 = K_3FeO_4 + KFeO_2 + O_2$$

Above 700°, after the complete disappearance of K_2FeO_4, decomposition of K_3FeO_4 begins:

$$K_3FeO_4 = KFeO_2 + K_2O + \frac{1}{2}O_2$$

Pure $KFeO_2$ is obtained at 1000°, after the volatilisation of K_2O.

Sr and Ba ferrates(VI) decompose in a stream of O_2 as follows: at low temperatures (~200°) vigorous liberation of active oxygen takes place with the formation of ferrates(III); oxidation of Fe^{III} to Fe^{IV} begins at about 400°, reaching a maximum (~90% Fe^{IV}) at 700–900° with the formation of $SrFeO_3$ and $BaFeO_3$.[32]

The red-violet aqueous solutions of ferrates(VI) are unstable and gradually decompose according to the scheme:

$$2FeO_4^{2-} + 3H_2O = 2FeO(OH) + \frac{3}{2}O_2 + 4OH^-$$

Study of the rate of decomposition by measurement of the change in pH with time in solutions with different K_2FeO_4 concentrations[33] has shown that dilute solutions of ferrates(VI) are more stable than concentrated solutions. For example, after standing for 1 h, 0.02–0.025 M solutions still contained 89% of the FeO_4^{2-} taken initially, whereas 0.05–0.086 M solutions decomposed completely.

The decisive factors influencing the stability of ferrate(VI) solutions are temperature and alkalinity[34]. The rate of decomposition of ferrates(VI) decreases considerably at low temperatures. Thus the rate of decomposition of 0.01 M K_2FeO_4 solution at 25° is five times that at 0°. The influence of alkalinity on the decomposition of ferrate(VI) solutions is complex and depends on the magnitude of the surface area of the $Fe(OH)_3$ formed in the decomposition[35]. The properties of the latter are determined by the concentration of alkali. Thus in 10% and 40% alkali solutions the $Fe(OH)_3$ precipitate is bulky and settles very slowly. In this instance the ferrate(VI) solutions decompose rapidly. In 20% alkali solutions, in which $Fe(OH)_3$ is precipitated in a compact form and rapidly produces a binding film on the walls of the vessel, ferrate(VI) solutions decompose much more slowly.

The addition of salts to ferrate(VI) solutions influences their stabilities in different ways. Potassium periodate[37], metaphosphates, pyrophosphates, and borates[36] produce a sharp increase in their stability. The addition of alkali metal cations to a ferrate(VI) solution, on the other hand, increases the rate of decomposition in the order Li^+, Na^+, K^+, Rb^+, and Cs^+, the increase being greater, the greater the concentration of the added cation[38].

The decomposition may take place in different ways, depending on the initial ferrate(VI) concentration[39]. In dilute solutions the decomposition is homogeneous and corresponds to the kinetic equation $dx/dt = k(a-x)^2/x$. When the active form of iron hydroxide appears, the reaction rate increases and corresponds to fractional-order kinetics. In concentrated solutions (greater than 0.01 M) iron hydroxide is formed immediately on decomposition, and the reaction is heterogeneous almost from the start.

The decomposition of ferrates(VI) in highly concentrated alkali solutions is monomolecular and gives $Fe(OH)_3$ with the intermediate formation of ferrates(IV).[35,40,41] The first stage of the decomposition is characterised by the complete decolorisation of the violet ferrate(VI) solutions and the precipitation of dark-blue or black Na and K ferrates(IV) respectively. The composition of the latter has not been determined. In the second stage the unstable ferrates(IV) decompose, the decomposition being slow in concentrated alkali solutions and immediate on dilution with water.

Recent studies[42] have established that the decomposition of ferrates(VI) in alkali solutions (like the decomposition of permanganates and perrhenates) is catalysed by traces of nickel and cobalt always present in the reagents. It has been proved experimentally that the rate of decomposition of alkali ferrate solutions prepared from highly pure reagents is extremely low. On the addition of nickel or cobalt salts (10^{-6} M) the stability of these solutions decreased sharply. The influence of other salts, or of $Fe(OH)_3$, was slight, however. This specific influence of nickel and cobalt salts proves that the course of the decomposition of ferrates(VI) (like that of permanganates and perrhenates) cannot be explained by any of the mechanisms previously put forward. The reaction mechanism probably involves reduction on the surface of nickel or cobalt micelles and the reduction of their hydroxo-complexes. It is suggested[41] that the use of very pure chemical reagents in the study of oxidation may give qualitatively new results even for simple and familiar reactions.

Ferrates(VI) are powerful oxidising agents, more powerful than permanganates. Even in weakly acidic medium they decompose with the formation of Fe^{III} salts and the liberation of O_2. Mg, Al, P, and S powders react violently with solid K_2FeO_4 on heating. Ammonia is oxidised to nitrite by the action of small quantities of K_2FeO_4, and to nitrate by a large excess. Nitrites are oxidised to nitrates, bivalent manganese to quadrivalent[43], iodates to periodates[44], chromite to chromate[45], arsenite to arsenate[46], etc. Hydrogen peroxide in strongly alkaline medium reduces FeO_4^{2-} to $Fe(OH)_3$. The addition of H_2O_2 in the presence of Trilon B to a suspension of $Fe(OH)_3$ in alkali solution, however, gives ferrate(VI) solution[47,48]. The addition of Trilon B to a prepared alkaline solution of ferrate(VI) increases its rate of decomposition. The reason for the accelerating action of Trilon B on the formation of FeO_4^{2-} by the reaction with H_2O_2 has not been determined.

Organic substances, for example paper, wood, etc., are slowly oxidised by dilute ferrate(VI) solutions; sugar and egg albumin decolorise ferrate(VI) solutions rapidly[30]. Ferrates(VI) are insoluble in alcohols (except Li_2FeO_4 and Na_2FeO_4) and gradually oxidise them to aldehydes.

Ferrates(VI) are isomorphous with chromates and sulphates, and form solid solutions with them[16,49,50]. The infrared (IR) spectra of the isomorphous compounds K_2XO_4 and $BaXO_4$ (X^{VI} = S, Se, Cr, or Fe) are similar, particularly in the high-frequency range. The spectra of the solid solutions of these compounds are also similar[51].

Spectroscopic studies of ferrates(VI) have been shown that the following vibrational frequencies are characteristic of the FeO_4^{2-} ion. The infrared range (220–2000 cm^{-1}) shows an absorption band at about 800 cm^{-1}, with triplet splitting which is distinct for K_2FeO_4 and $BaFeO_4$ but much less distinct for $SrFeO_4$.[29] The visible spectra show a sharp maximum at 505 μm and two minima at 390 μm and 675 μm.[52,53] The high-frequency visible and ultra-violet spectra show a large absorption peak at 19 600 cm^{-1}, asymmetric with a shoulder at 17 800 cm^{-1}, and a small

peak at 12700 cm^{-1}. [54,55] This spectrum is similar to the spectrum of the isoelectronic ion MnO_4^{3-}. The interpretation of the electronic spectra of FeO_4^{2-} and MnO_4^{3-} on the basis of the MO method previously developed for the CrO_4^{2-} and MnO_4^{2-} ions [56] led to the conclusion that the unpaired electrons must occupy a triply degenerate orbital. The earliest measurements of the electron paramagnetic resonance (EPR) of FeO_4^{2-} and MnO_4^{3-} in alkali solutions confirmed this suggestion [57], but later measurements with single crystals of these salts led to the conclusion that the unpaired electrons occupy a doubly degenerate orbital [58].

K and Cs ferrates(VI) are paramagnetic [8]; the effective magnetic moments amount to 2.8–2.9 μ_B, corresponding to two unpaired electrons. The formation of regular tetrahedra is possible only for sp^3- or d^3s-hybridisation. According to Klemm [8], ferrates(VI) show sp^3- and not d^3s-hybridisation. This conclusion was reached by analogy with the FeO_4^{3-} ion, for which magnetic studies showed three unpaired electrons, so that d^3s-hybridisation is impossible. The interpretation of the isomeric shift in the Mössbauer spectrum of K_2FeO_4 shows, however, that the covalent contribution from the oxygen ligands is made to hybridised d^3s-orbitals of the iron [59,60].

Analyses. The familiar methods for the analysis of ferrates(VI) are based on their oxidising properties (arsenite and chromite methods) or on the instability of ferric acid H_2FeO_4 (gas-volumetric method).

The arsenite method is based on the reduction of the ferrate(VI) ion in strongly alkaline arsenite solution [46]:

$$2FeO_4^{2-} + 3AsO_3^{3-} + 11H_2O \rightarrow 2Fe(OH)_3(H_2O)_3 + 3AsO_4^{3-} + 4OH^-$$

The back titration of the excess of arsenite can be carried out with standard solutions of bromate (Methyl Orange indicator, 70–80°), cerate (phenanthroline indicator, in the cold), or permanganate (with the addition of KI). The arsenite method is recommended for the analysis of pure ferrate(VI) specimens which have not undergone decomposition and which do not contain impurities capable of oxidising arsenite.

The chromite method [45] is based on the oxidation of chromite by the ferrate(VI) ion in strongly alkaline solution according to the equation:

$$Cr(OH)_4^- + FeO_4^{2-} + 3H_2O \rightarrow Fe(OH)_3(H_2O)_3 + CrO_4^{2-} + OH^-$$

The chromate ion is titrated with a standard solution of Fe^{2+} and Na diphenylaminesulphonate indicator. The chromate method is particularly suitable for the analysis of dilute ferrate solutions. It can also be modified for insoluble ferrates(VI), with which reaction takes place only on prolonged heating (95–100°, 1 h). [24]

The gas-volumetric method [17,61] is recommended for ferrates(VI) with different degrees of purity; this method involves the decomposition of the ferrates by dilute acids, for example

$$2K_2FeO_4 + 5H_2SO_4 \rightarrow 5H_2O + 2K_2SO_4 + Fe_2(SO_4)_3 + \frac{3}{2}O_2$$

CO_2 impurity in the oxygen liberated in the analysis of specimens contaminated with carbonates is removed by absorption in KOH solution.

The reduction of ferrates(VI) by iodide ions in acid medium according to the equation $FeO_4^{2-} + 4I^- + 8H^+ \rightarrow Fe^{2+} + 4H_2O + 2I_2$ cannot give quantitative results, because of the expected reduction of Fe^{III} impurities usually present in the specimens. The iodometric method is sometimes used, however, for the determination of active oxygen (equivalent to the iodine liberated) together with the determination of the total iron in the specimen [16,17]. The degree of oxidation of the iron is readily calculated from the observed molar ratio Fe : O_{act}. The reaction of KI with ferrate(VI) solutions takes place smoothly, without spontaneous decomposition, but in the reaction of the insoluble $BaFeO_4$ and $SrFeO_4$ with KI in acid solution, which requires longer treatment and increased temperature, a small quantity of O_2 is volatilised, so that the analysis gives low results [17]. Thus for insoluble ferrates(VI), accurate values for O_{act} are obtained only by the gas-volumetric determination.

Uses of ferrates(VI) and their role in various industrial processes. In recent years there has been an increase in interest not only in the theoretical aspects of ferrates(VI) but also in their applied chemistry, chiefly in relation to their oxidising function.

Vil'nyanskii and Pudovkin [62] concluded that the production of sodium chromate from a mixture of natural chrome ironstone, sodium carbonate, and other additives involves the formation of sodium ferrate(VI), which is soluble in the liquid melt formed by the reaction mass at high temperatures (1150°). The ferrate(VI) acts as a carrier of oxygen from the furnace gas to the surface of the chromite granules. It is suggested that the existence of Na_2FeO_4 at such high temperatures is due to an increase in its thermal stability on dissolution in the molten chromate.

Studies of the passivation of iron in concentrated nitric acid have given interesting results [63]. It has been shown that the passivity of iron is due to the formation of a film of ferric acid H_2FeO_4 or a related compound of iron, and not a layer of iron oxide, as assumed by other workers. The sexavalent iron compound is formed in the anodic region as a consequence of the intense local action of galvanic currents when iron reacts with concentrated HNO_3. The formation of this compound is accompanied by its chemisorption on the iron surface, and it has a higher chemical stability in this state than in the free state (analogous to the stability of the passive chromate films chemisorbed on iron). It is unaffected by a large number of reagents with which it reacts, with rapid decomposition, in the free state. On reaction with solutions of ferrates(VI) (or chromates) iron was covered with a passive film which was the same as that formed in the reaction of the acid with iron. When the passivated iron was immersed in NaOH solution, the red-violet colour typical of the ferrate ion was produced, by the replacement of this ion on the iron surface by the preferentially adsorbed OH^- ion. This solution exhibited oxidising properties typical of ferrate(VI). The metastable ferrate film is decomposed by cathodic reduction, mechanical shock, and heating, and in the presence of halide ions.

The production of a corrosion-resistant layer on metallic surfaces by ferrate(VI) solutions has been used to develop a method for protecting iron and steel castings from corrosion [64]. The method is based on the rapid formation of Fe_2O_3 by the decomposition of the thin film of ferrate(VI) on the metal and ferrate(VI) solution. It involves bringing the metal successively into contact with an alkali solution containing a reducing agent (12.5% NaOH + 0.4% 8-quinolinol) and a solution containing an alkali metal ferrate (1%).

Alkali metal ferrates(VI) have found application for decolorising coloured impurities in the caustic solutions obtained in electrolyte baths [65]. The addition of a small quantity of ferrate(VI) (for example 0.5 g Na_2FeO_4) to a very large quantity of a solution containing coloured

impurities (for example 100 g of blue NaOH solution) leads to decolorisation on gentle heating. The resulting solution, purified from chlorine and iron, satisfies industrial standards.

Na_2FeO_4 has proved useful for the purification of hemicellulose by precipitation from alkali solutions [66]. Compared with other methods for precipitating hemicellulose by means of $CuSO_4$, $Pb(CH_3COO)_2$, or Na_3AlO_3, the new method not only gives better purification of the alkali solution and an improvement in the quality of the viscose, but also gives a hemicellulose precipitate which can be filtered off rapidly and used for the production of other materials. It is recommended that Na_2FeO_4 be produced in the plant by direct electrolysis in the baths in which the precipitation is carried out.

Solid K_2FeO_4 is used as an activator in the production of catalysts used in the Fischer–Tropsch process [67,68]. The catalyst is prepared by mixing Fe_2O_3 (α- or γ-modification) with potassium ferrate(VI) powder (0.2–20 wt.%) in a small quantity of alcohol. Tablets with this composition are heated for 4 h at 540° in an oxidising atmosphere and then for approximately 24 h in a reducing atmosphere at 370–870°.

II. FERRATES(IV)

The first papers on the preparation and study of properties of compounds of quadrivalent iron were published in the nineteen-forties [69], although the possibility of existence of these compounds was noted as early as 1909, by Moeser and Borck [70]. They were the first to prepare Sr and Ba ferrates(IV), for which they used the formulae $SrO.FeO_2$ and $BaO.FeO_2$, by heating dry $Fe(NO_3)_3 + Sr(NO_3)_2$ and $Fe(OH)_3 + Ba(OH)_2$ mixtures in a stream of O_2 at 600° and 400° respectively. As shown later by Scholder [71], the Sr and Ba ferrates obtained in this way are always extensively contaminated by oxides of iron and the alkaline earth metals.

Four types of compound of quadrivalent iron are now known: 1) metaferrates(IV) $MFeO_3$‡ (alkali metals, Ba, Sr, Ag, and Pb); 2) orthoferrates(IV) M_2FeO_4 (alkali metals, Sr, and Ba); 3) pentaoxoferrates(IV) M_3FeO_5 (Ba only); and 4) ferrates(IV) of the type $M_3Fe_2O_7$ (Ba and Sr only).

Preparation. The simplest and most widely encountered method for preparing ferrates(IV) is by the thermal oxidation of a mechanical mixture of two solid phases with an M:Fe ratio corresponding to that in the ferrate(IV). In a study of the oxidation of mixtures of two solid phases, Wahl [72] established that for complex compounds§ in which the central atom is in a high oxidation state, neglecting the temperature and the pressure of the gas, the following stabilisation methods are possible: 1) selection of complex-forming ligands; 2) selection of cation; 3) change in the ratio of the number of cations to the number of central atoms.

It can readily be appreciated that the choice of ligand has a significant influence on the degree of oxidation. When it is necessary to stabilise a low or intermediate oxidation state, ligands with a low electronegativity are chosen; on the other hand, the formation of complexes in which the central atom is in a high oxidation state requires ligands with a high electronegativity, such as fluorine and oxygen. Oxygen is preferred, however; there are then extensive possibilities for the stabilisation of higher oxidation states, since oxygen can carry a negative charge greater than unity, and can form π-bonds.

A not unimportant factor in the production of highly oxidised complexes is the choice of cation. Chemical experiments have shown that the formation of these complexes is most favoured by large cations.

The influence of change in the ratio of the number of cations to the assumed central atom on the degree of oxidation is small. For example, it is observed for the oxidation of an $Fe_2O_3 + K_2O$ mixture: $KFeO_2$ is formed at K : Fe = 1 : 1, K_2FeO_4 at 2 : 1, and K_3FeO_4 at 3 : 1. It is not observed, however, for an $Fe_2O_3 + BaO$ mixture: $BaFeO_3$ is formed at Ba : Fe = 1 : 1, Ba_2FeO_4 at 2 : 1, and Ba_3FeO_5 at 3 : 1. Here, the iron in all the products is quadrivalent.

In the preparation of ferrates(IV), combinations of iron oxides, hydroxide, or nitrate with the oxide, hydroxide, carbonate, nitrate, or other compound of the alkali, alkaline earth, or other metal can be used in the mixture being oxidised. A large number of experiments on the preparation of ferrates(IV) by the oxidation of mixtures of two solid phases under different conditions (400–1000°, stream of dry or moist O_2) showed that the Fe^{IV} concentration in the products does not exceed 90%. [32,71,74–77] An Fe^{IV} concentration of 100% was observed in only one instance, in the preparation of Na_4FeO_4 by the oxidation of a stoichiometric $Fe_2O_3 + Na_2O$ mixture in a stream of dry O_2 at 450°. [75] The study of the kinetics of the oxidation of a mechanical $Fe_2O_3 + 2BaCO_3$ mixture in a stream of O_2 at 700–900° showed that the reaction between the components is incomplete at the temperatures of the experiment, leading to the presence of Ba and Fe oxides in the reaction products [73]. Similar results can evidently be expected in the oxidation of other mechanical mixtures.

Recent experiments [77–80] have shown that it is more appropriate to prepare ferrates(IV) by the oxidation of a single solid phase, that is ferrate(III), previously prepared by sintering the above mixtures in air or in an atmosphere of an inert gas at high temperatures (1100 to 1400°). Subsequent saturation of ferrates(III) with oxygen under high pressure increases the degree of oxidation of iron, raising the Fe^{IV} concentration to even 100% (see Table). In most instances, however, Fe^{III} cannot be oxidised completely to Fe^{IV} even by carrying out the preparation at super-high O_2 pressures.

Because of the incomplete oxidation of Fe^{III} to Fe^{IV}, which is evidently due to the insufficient thermal stability of ferrates(IV), non-stoichiometric compounds containing oxygen vacancies in the crystal lattice are obtained. The loss of each oxygen anion is compensated by the conversion of two Fe^{IV} ions into two Fe^{III} ions. Thus the empirical formulae of the oxygen-deficient compounds are: for the metaferrates(IV) $M(Fe^{IV}_{1-2x}Fe^{III}_{2x})O_{3-x}$, for the orthoferrates(IV) $M_2(Fe^{IV}_{1-2x}Fe^{III}_{2x})O_{4-x}$, and for ferrates(IV) of the type $M_3Fe_2O_7$ $M_3(Fe^{IV}_{2-4x}Fe^{III}_{4x})O_{7-2x}$, where $0 \leq x \leq 0.5$.

Van Hook [82,83] established that the degree of oxidation of iron in ferrates depends to some extent on the area of the surface being oxidised. In the study of the influence of the surface area, three $BaFeO_{2.5}$ specimens—a fine powder with an average particle size of ~ 5 μm, a ceramic

‡M represents a bivalent metal atom or two univalent metal atoms.

§Metallates formed on the oxidation of mixtures of two solid phases.

tablet with a porosity of ~ 25%, and a piece of a single crystal grown in air by cooling from the melting point 1370°—were oxidised under identical conditions until their weight showed no further change with time. It was found that the degree of oxidation of iron was greater in the first specimen than in the second, and greater in the second than in the third. It was noted that although adsorption of oxygen took place, it was clearly a secondary factor, since only small differences in the degree of oxidation were observed for specimens for which the surface areas differed considerably from one another.

Preparation of ferrates(IV) by the thermal oxidation of ferrates(III) by oxygen under pressure.

Sr and Ba ferrates(IV) can be obtained by the decomposition, in an oxidising atmosphere, of complex compounds containing iron and the alkaline earth metal, for example $M_3[Fe(OH)_6]_2.xH_2O$ and $M_2[Fe(C_2O_4)_3]_2.xH_2O$ (M = Sr or Ba). Here, the formation of the ferrates involves the reaction between the decomposition products of the complexes and the subsequent oxidation of Fe^{III} to Fe^{IV}. Thus when the hydroxoferrates(III) $M_3[Fe(OH)_6]_2$ are heated in a stream of O_2 at 300–450°, products with the composition $MFeO_3 + \frac{1}{2}M(OH)_2$, containing only quadrivalent iron, are formed [32,71]. Attempts to remove the component $M(OH)_2$ by extraction with anhydrous methanol led to appreciable decomposition of the metaferrates(IV) (to 56% Fe^{IV}).

Sr_2FeO_4, Ba_2FeO_4, and Ba_3FeO_5 with an Fe^{IV} concentration of 100% are formed when $M_3[Fe(OH)_6]_2 + xM(OH)_2$ mixtures ($x = 1$ for M_2FeO_4, $x = 3$ for M_3FeO_5) are heated in a stream of O_2 at 800°. [75]

In the products obtained by heating tris(oxalato)-ferrates(III) $M_3[Fe(C_2O_4)_3]_2$ in a stream of O_2, the Fe^{IV} concentration does not exceed 75%. [84,85]

For the preparation of Sr and Ba metaferrates(IV) from the corresponding ferrates(VI), the most suitable starting materials are Ba and Sr ferrates(VI). As already noted, when $BaFeO_4.aq$ specimens are kept, their colour changes from cherry-red to dense black, accompanied by the quantitative conversion of barium ferrate(VI) into barium metaferrate(IV). The liberation of oxygen is complete in several weeks (sometimes days) even in a sealed glass vessel; when the latter is opened, the oxygen volatilises with a loud crack. An important feature is that the oxidation coefficient does not fall below 0.97 even when the experiment is continued for a long time (240 days). Strontium ferrates(VI) do not undergo this transformation.

The conversion of $BaFeO_4$ into $BaFeO_3$ takes place much more rapidly, in 7–20 min, when freshly prepared $BaFeO_4$ is heated to 90–100° in 50% KOH or NaOH solution [32,38]. In concentrated alkali solutions, $SrFeO_4$ decomposes immediately to $Fe_2O_3.aq$, $Sr(OH)_2$, and O_2, and in hot saturated $Sr(OH)_2$ solution it is converted into Sr metaferrate(IV), extensively contaminated by Fe^{III}. [32] Ba and Sr metaferrates(IV) containing not more than 85 to 92% Fe^{IV} can be obtained by the thermal decomposition of Ba and Sr ferrates(VI) in a stream of O_2 at 700 to 1000°.

Only lithium and silver ferrates(IV) have been prepared by double decomposition. Li_2FeO_3 (94–98% Fe^{IV}) was obtained by the reaction of solid K_2FeO_4 and LiOH (Li : Fe = 8) at 300° and subsequent removal of the excess of LiOH by extraction with absolute methanol at −30°. Ag_2FeO_3 (100% Fe^{IV}) was obtained by adding $AgNO_3$ to K_2FeO_4 solution at 0° (Ag : Fe = 2) and washing the resulting precipitate with ethanol and ether at 0°. [32]

Analyses. The compositions of ferrates(IV, V, VI) are usually determined by analysis for the component elements, and expressed as atomic ratios M : Fe : O$_{act}$. The concentration of active oxygen is determined iodometrically (Fe^{IV}, V, VI $\xrightarrow{I+H^+}$ Fe^{II}) or gas-volumetrically (Fe^{IV}, V, VI $\xrightarrow{H^+}$ Fe^{III}). The gas-volumetric method can be used as an independent method for the determination of the Fe^{IV} concentration [61]. An original method for the determination of Fe^{IV} was proposed by Mori [86]. The ferrate(IV) specimen is dissolved in hydrochloric acid containing an excess of Fe^{2+} ions, which reduce Fe^{IV} to Fe^{III}. The quantities of Fe^{IV} and Fe^{III} in the specimen are determined from the total quantity of Fe^{3+} ions and the quantity of unreacted Fe^{2+} ions in the solution. The analysis is carried out in a stream of CO_2 to avoid the oxidation of Fe^{2+} by atmospheric oxygen.

Some authors have used the Mössbauer spectra for analytical studies; the ratio of the intensities of the characteristic peaks of Fe^{III} and Fe^{IV} was taken as equal to the ratio of the concentrations of the corresponding ions [85,87]. Chemical analysis confirmed that the results were correct.

Chemical properties. All the alkali metal ferrates(IV) form loose black powders without a definite crystal structure, stable at room temperature in the absence of moisture. In aqueous solutions or dilute alkali solutions they disproportionate with the formation of the corresponding ferrates(VI) and $Fe(OH)_3$. An exception is Li_2FeO_3, which decomposes in water to $Fe(OH)_3$ with the liberation of O_2. [32] The alkali metal ferrates(IV) are used as oxidising agents for organic substances and for water purification [88].

All the alkaline earth metal ferrates(IV) form black or dark-grey powders, stable in air, with the exception of Ba_3FeO_5. In moist air, the latter disproportionates in a few minutes with the formation of chiefly $BaFeO_4$, with a colour change from black to cherry-red. In a stream of O_2, all Sr and Ba ferrates(IV) are stable as far as 700–1000°; they are insoluble in water, but gradually (very slowly for $BaFeO_3$) decompose to alkaline earth metal salts, Fe^{III} salts, and O_2. On treatment with hydrochloric acid, Cl_2 and O_2 are liberated simultaneously.

Ba and Sr metaferrates(IV) begin to decompose in air at 320°. The decomposition has the characteristics of reversible thermal dissociation. With increase in temperature the dissociation pressure, equal to the atmospheric pressure of oxygen, is reached by $M(Fe^{IV}_{1-2x}Fe^{III}_{2x})O_{3-x}$ with increasing oxygen deficiency.

Structure and physical properties. The series of ferrates(IV) $SrFeO_3$, Sr_2FeO_4, and $Sr_3Fe_2O_7$ are the structural analogues of the corresponding titanates $SrTiO_3$, Sr_2TiO_4, and $Sr_3Ti_2O_7$.[77] These three structural types of ferrate(IV) are related to one another: the compounds with higher alkaline earth metal contents are derived from the perovskite structure by the introduction of layers of Sr and O ions between single or double perovskite layers.

Studies by a number of authors[85,86,90-92] has shown that the compounds with the composition $M(Fe^{IV}_{1-2x}Fe^{III}_{2x})O_{3-x}$ and $M_3(Fe^{IV}_{2-4x}Fe^{III}_{4x})O_{7-2x}$ are characterised by a constant crystal structure over a fairly wide range of values of x. Thus according to Brisi[91], compounds with the composition $Sr(Fe^{IV}_{1-2x}Fe^{III}_{2x})O_{3-x}$ crystallise in a single phase with the ideal perovskite structure, like $SrTiO_3$. No significant displacement of the lines in the X-ray diffraction patterns of specimens with different degrees of oxidation (40, 50, or 75% Fe^{IV}) was observed, and the values of the lattice parameter remained almost unchanged at 3.853 Å. In this instance the contraction which it might appear should have taken place with decrease in the quantity of oxygen ions and the formation of vacancies in the lattice is almost completely compensated by the increase in the ionic radius of iron on going from the quadrivalent to the tervalent state. The observed fact that the lattice parameter remains constant suggested that any compound $SrFeO_{3-x}$, including the stoichiometric compound, can be assigned a lattice parameter within the range 3.85 Å. On this basis it is possible to calculate the minimal distance between the ions in the cubic lattice:

O—O 2.70Å, Sr—O 2.73Å, Fe—O 1.93Å

The value 0.58 Å was obtained empirically for the Fe^{IV} radius by subtracting from the last of the above quantities the radius of the oxygen ion (1.35 Å). The value of 0.58 Å is only approximate, however. In fact we have close packing of the Sr and O ions, and the Fe ions merely occupy the free space in the centre of the octahedron formed by the oxygen ions.

The lattice parameter of recently prepared stoichiometric $SrFeO_3$ was in fact found to be equal to 3.850 Å. Detailed X-ray diffraction studies[80], however, established, in contrast to Brisi's results[91], that in the compounds $SrFeO_{3-x}$, increase in the oxygen deficit is accompanied by a gradual, albeit slight, increase in the parameter of the cubic cell. As oxygen is lost, tetragonal distortion of the cubic perovskite cell is observed, beginning at the composition $SrFeO_{2.84}$¶. As the composition approaches $SrFeO_{2.5}$, the tetragonal cell gradually changes into the monoclinic perovskite cell[93]. Thus as Fe^{IV} is reduced to Fe^{III} in the $SrFeO_3$–$SrFeO_{2.5}$ system there is a decrease in the symmetry of the perovskite cell, related to the change in the oxidation state of iron.

The first studies of the structure of the metaferrates $BaFeO_{3-x}$[74,94,95] showed that the cubic (a = 3.995 Å), tetragonal (a = 3.981 Å, c = 4.005 Å), and hexagonal (a = 5.69 Å, c = 13.89 Å) phases formed by these compounds have structures analogous to that of the corresponding phases of the familiar ferroelectric $BaTiO_3$.

¶ The tetragonal distortion is very small ($c : a \simeq 1.005$). The specimens are "almost cubic". It was probably for this reason that the distortion of the cell was not observed for Brisi's specimens[91].

This feature aroused particular interest in the compounds $BaFeO_{3-x}$ and stimulated further study of their structure[78,84-86,91,96-98].

Some workers considered that the structures found for the ferrates $BaFeO_{3-x}$ should also be shown by stoichiometric $BaFeO_3$, and some, without determining the compositions of the specimens, assigned their structure directly to $BaFeO_3$. If $BaFeO_3$ specimens with known compositions, prepared by different methods, are arranged in order of increasing Fe^{IV} concentration, the following change in structure can be observed. Highly oxidised specimens generally have a hexagonal structure[78,86,91], which may be preserved as far as the composition $BaFeO_{2.70}$,[86] and with decrease in the concentration of Fe^{IV} in the specimens the unit cell parameter gradually increases. When oxygen is lost, beginning from the composition $BaFeO_{2.88}$ (76% Fe^{IV}), the products have the cubic perovskite structure and its distorted forms—tetragonal, orthorhombic, monoclinic, and triclinic[84-86,96]. The dynamics of their interconversion is such that with decrease in the Fe^{IV} concentration there is a gradual decrease in the symmetry of the perovskite cell. Thus analysis of published data indicates that the structural changes in $BaFeO_{3-x}$ are related to the change in the oxidation state of the iron present.

The fundamental importance of this conclusion lies in the fact that the barium metaferrate phases, with structures analogous to those of the polymorphic modifications of $BaTiO_3$, correspond not to $BaFeO_3$, but to different compounds in the $BaFeO_3$–$BaFeO_{2.5}$ system.

The conclusion that $BaFeO_3$ is not a complete structural analogue of $BaTiO_3$, since the metaferrate(IV) corresponds to a single hexagonal structure, was confirmed by recent X-ray diffraction studies of $M(Fe^{IV}_{1-2x}Fe^{III}_{2x})O_{3-x}$ with Fe^{IV} concentrations from 0 to 100%, for which the starting material was $BaFeO_4$.[99]

It was established experimentally that the thermal stability of the hexagonal phase $BaFeO_{3-x}$ increases with increase in the oxygen pressure. The compound exists as far as 915° in air and as far as 1250° at 10 atm O_2, and at 50 atm O_2 it melts without decomposition at 1412°.[82]

The existence of Fe^{IV} in ferrates(IV) and the appreciably covalent character of the bond between Fe and the oxygen ions coordinated to it were confirmed by the Mössbauer spectra[77,79,87,96,100]. The nature of the covalent bond is similar to that observed in compounds containing Fe^{VI}. The Mössbauer spectra show isomer shifts due to the quadrivalent state of iron. The theoretically calculated isomer shift for the free Fe^{4+} ion[101], equal to -1.30 mm s^{-1}, is more negative than the experimental values observed for the compounds containing Fe^{IV}. Thus the isomer shift had the values -0.17 mm s^{-1} for $SrFeO_3$ and -0.29 mm s^{-1} for $BaFeO_{2.95}$ at 298°K. These more positive values are interpreted as resulting from a considerable covalent contribution to the 3d orbitals of the Fe^{4+} ion from the oxygen ligands. Comparison of the values of the isomer shifts for $BaFeO_{2.95}$ and $SrFeO_3$ showed that the covalent contribution to the Fe–O bond is smaller for $BaFeO_3$ than for $SrFeO_3$. Comparison of the isomer shifts for $Sr_3Fe_2O_{6.9}$ and $SrFeO_3$ showed that the introduction of the layers of Sr and O ions between the double perovskite layers has little influence on the bonding. The spectra of the ferrates with an oxygen deficit show quadrupole splitting, indicating the presence of Fe^{III} in addition to Fe^{IV}.

It is suggested[78] that $BaFeO_3$ has an interesting future, primarily because of its unusual magnetic properties.

When $BaFeO_{2.95}$ is cooled, a sharp change from ferrimagnetism to antiferromagnetism is observed at 164°K. The maximal value of the specific magnetisation $\sigma g = 13.8$ electromagnetic units at 164°K. The change in the magnetic ordering is accompanied by a sudden change in the temperature dependence of the conductance. The plot of $\lg\rho$ against $1/T$ shows a peak at the temperature of the transition. No departure from hexagonal symmetry was observed below the temperature of the transition.

Stoichiometric $SrFeO_3$ is antiferromagnetic with a Neel temperature of 130°K. It exhibits anomalous electrical properties. Ceramic discs of this material are good conductors ($\rho \simeq 10^{-3}\ \Omega\,cm^{-1}$) with the same temperature coefficient as metallic conductors [80].

$SrFeO_3$ forms unrestricted solid solutions with $SrTiO_3$, [102] with a linear increase in the lattice parameter a as Fe^{IV} is replaced by Ti^{IV}.

Perovskite series of solid solutions $La_{1-x}Sr_xFeO_{3-y}$ were obtained in an atmosphere of oxygen by replacing the tervalent La by the bivalent Sr. [79,103] With increase in the oxygen pressure during preparation, the oxygen deficit in the solid solutions decreases to almost zero. The stoichiometric compositions $La_{1-x}Sr_xFeO_3$ have distorted perovskite structures.

The system of solid solutions $SrFeO_3$–$BiFeO_3$ shows the structural transformation: cubic → tetragonal → cubic, with increase in the degree of replacement of Sr by Bi. [104]

Tauber [105], from a melt with Ba : Bi : Fe = 1 : 2 : 3, obtained dendritic cubic crystals $(Ba_{0.33}Bi_{0.67})(Fe^{III}_{0.67}Fe^{IV}_{0.33})O_3$ with lattice parameters very close to those of cubic $BaFeO_{3-x}$.

$BaFeO_3$ forms solid solutions with $BaTiO_3$. The conclusion [106] that the addition of small quantities of $BaFeO_3$ (3–5%) to the titanate produces a sharp change in its structure from tetragonal to hexagonal cannot be regarded as correct with respect to Fe^{IV}, since the solid solution specimens were prepared by a method which excluded the formation of Fe^{IV} (heating at 1380°). In this instance the observed sharp change in the structure and ferroelectric properties are due to the introduction of Fe^{III} ions into the $BaTiO_3$ lattice.

III. FERRATES(V)

The only known quinquevalent iron compounds are potassium, sodium, and rubidium ferrates(V). K_3FeO_4 was first prepared in 1956, by the oxidation of an $Fe_2O_3 + 6KO_X$ mixture in a stream of O_2 at 400–500°. [7] The K_3FeO_4 obtained in this way always contains small quantities of $KFeO_2$ and KO_X. Potassium ferrate(V) mixed with $KFeO_2$ is also formed by the thermal decomposition of K_2FeO_4 at 700° in a stream of O_2 [17] (see Russian page 1979). Pure K_3FeO_4 is obtained by the reaction of Fe_2O_3, $KFeO_2$, or K_2FeO_4 with anhydrous KOH (Fe : K = 1 : 3) in a stream of O_2 at 600–700°. [107]

The oxidation of mixtures of RbO_X or RbOH with Fe_2O_3 at 600° in a stream of O_2 gives rubidium ferrate(V) with the composition $Rb_3FeO_{4.4-4.7}$, containing peroxide. When heated for a short time at 350° in a stream of N_2, these products are converted into Rb_3FeO_4. [107]

Sodium ferrate(V) could not be obtained by the corresponding reactions. Na_3FeO_3, prepared from Fe_2O_3 and Na_2O_2 in a stream of N_2 at 600°, reacts with O_2 with the formation of Na_3FeO_4, the degree of conversion being proportional to the pressure of oxygen. Thus the product contains 40 mole % Na_3FeO_4 at 20 atm O_2, and 80 mole % Na_3FeO_4 at 120 atm O_2, and the conversion of Na_3FeO_3 into Na_3FeO_4 is probably quantitative at 200 atm O_2. [107]

In dilute H_2SO_4 and HNO_3, ferrates(V) decompose to Fe^{III} with the liberation of O_2, and in the reaction with HCl, Cl_2 and O_2 are liberated simultaneously. In water or dilute alkali solutions, disproportionation takes place:

$$6K_3FeO_4 + 8H_2O = 4K_2FeO_4 + 2Fe(OH)_3 + 10\ KOH$$

The concentration of active oxygen can be determined iodometrically only in very pure ferrates(V); when $MFeO_2$ or MO_X are present, correct results are obtained only in the gas-volumetric method. The quantity of Fe^V in the specimens can be determined by analysis of the products of disproportionation, in which 66.6% of the Fe^V is converted into Fe^{VI}.

K_3FeO_4 begins to decompose in a stream of O_2 above 700° according to the equation $K_3FeO_4 = KFeO_2 + K_2O + \frac{1}{2}O_2$. At 250–500° in a stream of O_2, K_3FeO_4 is slowly converted into $KFeO_2 + 2KO_X$, and in this instance the decomposition products are formed not by the simple decomposition of K_3FeO_4 but by its reaction with molecular oxygen. This was established from comparative experiments in which K_3FeO_4 was heated in a stream of O_2 or N_2. In the latter, potassium ferrate(V) remains unchanged at these temperatures. Analysis of the products of the decomposition of K_3FeO_4 in O_2 at a pressure of 100 atm and temperatures up to 400° indicates that the following reaction takes place: $K_3FeO_4 + 0.75O_2 = KFeO_2 + 2KO_{1.75}$. [107]

Unlike potassium ferrate(V), Na_3FeO_4 in a stream of O_2 at 200–250° gives up active oxygen with the conversion of Fe^V into Fe^{IV}.

The X-ray diffraction patterns of K_3FeO_4 show that it is amorphous towards X-rays. Magnetic measurements gave an effective magnetic moment of 3.6–3.7 μ_B. [7] These values are close to the spin magnetic moment for three unpaired electrons (3.87 μ_B), expected for Fe^V.

Compounds of octavalent iron have not been prepared. The electron affinities calculated by Ionova and Dyatkina [108] for the isoelectronic oxo-anions of the first transition series, of which the last member is the FeO_4 molecule, change in the following order: TiO_4^{4-} 2.4 eV, VO_4^{3-} 3.8 eV, CrO_4^{2-} 5.5 eV, MnO_4^- 7 eV, and FeO_4 10.7 eV. It can be seen that the FeO_4 molecule should have a very high electron affinity, and this explains the difficulty of obtaining iron tetroxide and the perferrate ion.

Organosilicon Derivatives of Monoazaheterocycles

E. Lukevics and A. E. Pestunovich

The literature data and studies in the field of organosilicon derivatives of heterocycles containing one nitrogen atom in the ring have been reviewed. The methods of preparation, physical, chemical, and biological properties, and practical applications of organosilicon nitrogen-containing heterocycles in which the silicon atom is linked directly to a ring carbon or nitrogen atom and also via an oxygen atom or a carbon chain have been examined.
The bibliography includes 350 references.

III. Compounds containing the Si-N bond 944
IV. Compounds containing the Si-O bond 947

I. INTRODUCTION

During recent years, the organosilicon derivatives of nitrogen-containing heterocycles have gained an important place in the chemistry of both organosilicon and heterocyclic compounds. It is sufficient to mention their successful applications in the chromatographic analysis of natural products, their ever increasing use in the syntheses of pyridine, pyrimidine, pteridine, and purine derivatives otherwise difficult to obtain, and also new methods of synthesis of nucleosides and penicillins developed on their basis to demonstrate the important role which organosilicon derivatives of nitrogen-containing heterocycles play in preparative organic chemistry. On the other hand, the study of reactions of organosilicon derivatives with derivatives of nitrogen-containing heterocycles and of the chemical, physical, and physicochemical properties of the products yields valuable information about the structures and reactivities of these heterocycles.

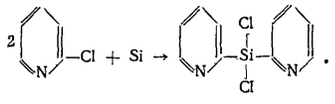
A systematic account of the first data on organosilicon derivatives of nitrogen-containing heterocycles was given in a review[1] which included information about studies published up to 1965. The number of investigations in this field and the wide variety of their subjects have now increased so much that it is desirable to describe them in separate reviews. We felt it necessary to consider in the first place the results of studies on organosilicon derivatives of nitrogen-containing heterocycles with one nitrogen atom in the ring published up to November, 1970.

II. COMPOUNDS CONTAINING THE Si – C_n – HETEROCYCLE GROUP

A. METHODS OF PREPARATION

1. Direct Synthesis

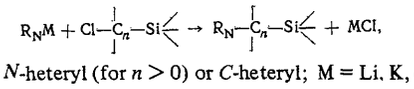
The possibilities of direct synthesis, which is the main industrial method for the preparation of alkyl- and arylchlorosilanes, in the series of nitrogen-containing heterocycles have been hardly investigated. Only two patents indicate that, when 2-chloropyridine is passed over silicon or over a silicon – copper alloy at 350 – 380°C, dichlorobis-(2-pyridyl)silane is formed[2,3]:



2-Bromopyridine reacts similarly. The halogeno-derivatives of other heterocycles have not been used in this reaction.

2. Organometallic Synthesis

The general method for the synthesis of organosilicon derivatives of nitrogen-containing heterocycles in which the silicon atom is linked directly to a ring carbon atom and also to the ring carbon and nitrogen atoms via a carbon chain is based on the interaction of organo-lithium, -potassium, or -magnesium derivatives of heterocycles with R-chlorosilanes ($n = 0$) or R-(chloroalkyl)silanes ($n > 0$)†:



[R_N = *N*-heteryl (for $n > 0$) or *C*-heteryl; M = Li, K, or MgBr]

Using *C*-organolithium derivatives, *N*-methyl-2-pyrrolylsilanes[4], *N*-benzyl-5-indolinylsilanes[5], *N*-alkyl-1-carbazolyl- and *N*-alkyl-3-carbazolylsilanes[6,7], 2-benzothiazolylsilanes[7], 2-pyridylsilanes[8-10], 3-pyridylsilanes[11,12], β-(2-pyridyl)- and β-(4-pyridyl)-ethylsilanes[13,14], 2,3,5,6-tetrachloro-4-pyridylsilanes[15], and 9,10-dihydro-10-methyl-9-acridylsilanes[16] were synthesised in this way. The yields of the trisubstituted pyridylsilanes[8-11] varied from 16 to 50%. (*N*-Alkyl-3-carbazolyl)triphenylsilanes are formed in higher yields than the 1-isomers. For example, whereas 9-ethyl-3-carbazolyl-lithium gives rise to (9-ethyl-3-carbazolyl)triphenylsilane in 64% yield, the yield of the 1-isomer is only 8%. The yield of the latter increases somewhat when bromotriphenylsilane is employed instead

† Unless otherwise stated, R is an organic substituent (Translator).

of the chlorotriphenylsilane[7]. The substitution of the chlorosilane by the bromosilane increases the yield of (2-benzothiazolyl)triphenylsilane from 5 to 19%.[7]

Organic *N*-lithio-derivatives have been used to prepare the piperidides of tri-R-silylacetic acid from their esters[17].

N-Potassio-derivatives of nitrogen-containing heterocycles have been used to synthesise organosilicon phthalimides[18-21] and also tri-R-(*N*-pyrrolylmethyl)silanes[4].

When picolinylpotassium reacts with halogenosilanes, pyridylmethylsilanes are formed[22]. If the initial picolinylpotassium was obtained from potassamide, after its reaction with chlorotrimethylsilane it is possible to isolate from the reaction mixture 2-bis(trimethylsilyl)-methylpyridine in addition to trimethyl-(2-pyridylmethyl)-silane.

Organic *C*-methyl magnesio-derivatives have been used to prepare trialkyl-(2-pyridyl)silanes[11,23], di-R-(2,3,5,6-tetrachloro-4-pyridyl)silanes[15], and tri-R-(8-alkoxy-5-quinolinyl)silanes[24].

Organometallic silyl derivatives, in particular triphenylsilyl-lithium and (tri-R-silyl)-R-lithium, can also be used to prepare *C*-silylated derivatives of nitrogen-containing heterocycles. With halogen-substituted heterocycles, the halogen atom is replaced by the tri-R-silyl-group:

$$R_N{-}Cl + LiSi(C_6H_5)_3 \rightarrow R_N{-}Si(C_6H_5)_3 + LiCl$$

and with unsubstituted heterocycles an addition reaction takes place, for example:

Thus, when triphenylsilyl-lithium reacts with pentachloropyridine in tetrahydrofuran (THF) solution at −70°C, (2,3,5,6-tetrachloro-4-pyridyl)triphenylsilane is formed[25] (together with hexaphenyldisilane and 4,4′-octachlorobipyridyl); (9-alkylcarbazolyl)triphenylsilanes[7,26] and the corresponding (10-ethylphenothiazinyl)triphenylsilane[26] are formed in the reactions with 9-alkyl-2-bromo- and 9-alkyl-3-bromo-carbazoles and with 2-, 3-, and 4-chloro-10-ethylphenothiazines respectively. Triphenylsilyl-lithium cleaves the C–O bond in *N*-alkoxymethylpiperidines with formation of (*N*-piperidinylmethyl)triphenylsilane[27].

Triphenylsilyl-lithium adds to pyridine[28] in the 1,4-positions and to acridine[16,29] in the 9,10-positions. The reaction of acridine with *p*-trimethylsilylphenylmagnesium bromide takes place similarly[30]. On the other hand, in the case of quinoline the addition of *p*-trimethylsilylphenyl-lithium[31] and 2-triphenylsilyl-5-thienyl-lithium[32] takes place in the 1,2-positions.

The addition of trimethylsilylphenyl-lithium to the carbonyl group of phenyl 2-pyridyl ketone leads to the formation of trimethylsilylphenyl-(2-pyridyl)phenylmethanol[33].

3. Amination of Alkenylsilanes

Aziridine[34-42], pyrrolidine[36,37], piperidine[36,37,39,43], and perhydroazepine[44] add to vinylsilanes in the presence of lithium, sodium, potassium, or their amides:

$$\equiv SiCH{=}CH_2 + HN(CH_2)_n \rightarrow \equiv SiCH_2CH_2N(CH_2)_n.$$

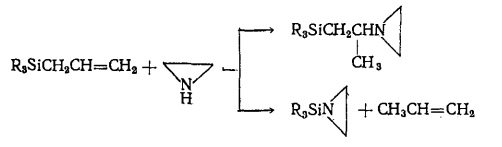
The addition of pyrrolidine and piperidine to triethylvinylsilane in the presence of metallic lithium begins at room temperature and takes place with a spontaneous temperature rise[36,37]. The yields of reaction products after 2 h amount to 70 – 72%. The rate of addition of aziridine is much lower (yield 39%) and pyrrole does not add to triethylvinylsilane under these conditions even after 25 h.[37]

When triethylvinylsilane was heated with aziridine in the presence of sodium for 7 h at 100°C, [2-(*N*-aziridinyl)ethyl]triethylsilane was formed in 90% yield. In the presence of sodamide, the reaction terminates after only 2 h at 50°C. Methyldiphenylvinylsilane readily combines with aziridine even at room temperature.

The rate of addition of piperidine to tri-R-vinylsilanes in the presence of lithium piperidide increases in the following sequence in terms of the organic substituent linked to the silicon atom: ethoxy- < triethyl < trimethyl < dimethylphenyl < methyldiphenyl[39], probably due to the increase in the same sequence of the double bond polarity, which promotes nucleophilic attack. The decrease of the rate of reaction for ethoxy-derivatives can be caused by part of the catalyst being consumed in the cleavage of the $Si-OC_2H_5$ bond[39]. The rate of addition of piperidine to the tri-R-vinylsilanes in THF solution is approximately twice as high as when the reaction is carried out in benzene or heptane[39]. The use of THF also makes it possible sometimes to lower the temperature of the amination reaction and to increase the yield of the reaction products[38].

When R-vinylsilanes with unsubstituted hydrogen atoms react with aziridine in the presence of lithium, dehydrocondensation and addition reactions take place simultaneously, the relative rate of the latter increasing from diethylvinylsilane to diphenylvinylsilane. The introduction of the aziridine group at the silicon atom also increases the rate of the addition reaction[40].

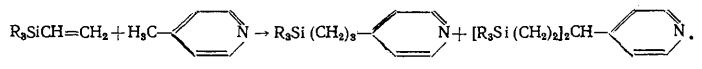
As the double bond is removed further away from the silicon atom in the compounds $R_3Si(CH_2)_nCH{=}CH_2$ (n = 0, 1, or 2), the rate of addition of aziridine decreases. With allylsilanes, addition is frequently accompanied by β-decomposition[34,45]:



(γ-Butenyl)trimethylsilane does not react with aziridine in the presence of $NaNH_2$ even on heating to 100°C. In contrast, *p*-trimethylsilylstyrene readily combines with aziridine[34] even at 50°C.

The addition of piperidine to 1-triethylsilylbuta-1,3-diene in the presence of sodium gives a mixture of 1,4- and 3,4-addition products[46] and the reaction of 1-trimethylsilylbut-3-en-1-yne with piperidyl-lithium gives, apart from the normal product of the addition to the double bond, the corresponding allenic amine[47].

When trimethylvinylsilane is heated with 4-methylpyridine at 55°C in the presence of sodium for 3 – 6 h, mono- (43%) and di-addition (49%) products are formed[48]:

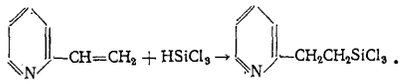


When metallic potassium is employed as a catalyst, the ratio of the products is altered in favour of a higher yield of the disilyl derivative (30 : 60).

4. Hydrosilylation of Heterylalkenes and Heterylalkynes

Trichlorosilane adds to 2-vinylpyridine in the presence of triethylamine and tributylamine giving a high yield

(91% with triethylamine) of trichloro-[β-(2-pyridyl)ethyl]-silane[49]. However, the reaction takes place smoothly also in the presence of other catalysts[49-53]:



High yields of hydrosilylation products are also found in the reaction of trichlorosilane with 4-vinylpyridine and 2,6-dimethyl-4-vinylpyridine[54]. The first stage in this reaction is the formation of a complex $HSiCl_3.nB$ (B = vinylpyridine; n = 3 for 4-vinylpyridine and n = 4 for 2-vinylpyridine)[55]. The complex of trichlorosilane with 2-vinylpyridine decomposes even at room temperature with evolution of heat and a hydrosilylation product is formed[55].

Alkylchlorosilanes and alkylarylchlorosilanes (both with unsubstituted hydrogen atoms) add to 2-vinylpyridine, 4-vinylpyridine, and 2,6-dimethyl-4-vinylpyridine in the presence of a catalyst (*NNNN'*-tetramethylenediamine and Cu_2Cl_2) with formation of β-adducts[56].

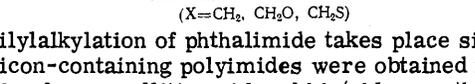
When 2- and 4-vinylpyridines are hydrosilylated with trialkylsilanes in the presence of chloroplatinic acid, a mixture of α- and β- adducts is produced, with the former predominating[51]. Pentamethyldisiloxane[57-59] and *sym*-tetramethyldisiloxane[57] produce α-adducts by this reaction, while heptamethylcyclotetrasiloxane gives a mixture of α- and β-isomers[57].

In the presence of chloroplatinic acid, the hydrosilylation of 2-allyloxypyridine[60,61], *N*-vinyl-lactams[62,63], *N*-vinylsuccinimide[64], and *N*-allyloxymethylphthalimide[65] was achieved.

The hydrosilylation of *N*-propargylpyrrolidine[66], *N*-propargylpiperidine[66,67], and *N*-propargylmorpholine[66] with triethylsilane in the presence of $H_2PtCl_6.6H_2O$ yields γ-adducts with a *trans*-structure. On going from triethylsilane to dibutylmethylsilane and from heptamethyltrisiloxane with three unsubstituted hydrogen atoms to triethoxysilane, there is a gradual increase of the content of the β-adduct in the reaction products and for the last compound the amounts of the γ- and β-adducts are almost equal[67].

5. Amination of Halogenosilanes with Organic Substituents

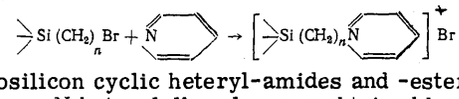
Tri-R-halogenoalkylsilanes silylate the amino-groups of aziridine[42], pyrrolidine[66,68], piperidine[43,68-70], morpholine[44,68,71], thiamorpholine[44], and perhydroazepine[44,72] in the presence of hydrogen halide acceptors (potassium carbonate, triethylamine, excess of heterocyclic base):



(X=CH_2, CH_2O, CH_2S)

N-Silylalkylation of phthalimide takes place similarly[18] and silicon-containing polyimides were obtained from the di-imide of pyromellitic acid and bis(chloromethyl)tetramethyldisiloxane[73].

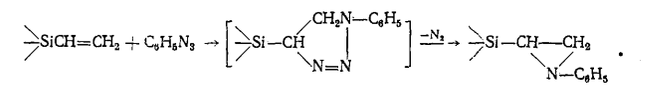
Prolonged heating of halogenoalkylsiloxanes with pyridine gives the corresponding organosilicon pyridinium salts[74-77]:



Organosilicon cyclic heteryl-amides and -esters derived from *N*-heterylalkanols were obtained by the reaction of trimethylsilylbenzoyl and trimethylsilylphenylacetyl chlorides with heterocyclic bases[78,79] and *N*-heterylalkanols[80].

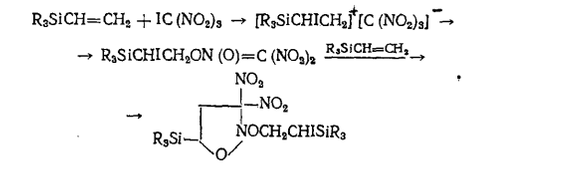
6. Cyclisation Reactions

Organosilicon derivatives of aziridine have been obtained by the reaction of vinylsiloxones with phenyl azide[58,81] at room temperature or with benzyl azide[82] at 60 — 80°C. The first stage of this reaction may be the addition of phenyl azide to the vinyl group with formation of a five-membered ring, which splits off a nitrogen molecule and is converted into an *N*-phenylaziridinyl derivative:



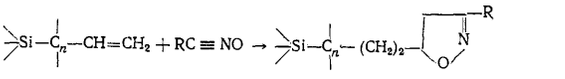
After a 40 day reaction of heptamethylvinylcyclotetrasiloxane and heptamethyl-3-vinyltrisiloxane with phenyl azide, the yields of *C*-aziridinyl derivatives did not exceed 11%. The reaction of allylsiloxanes with phenyl azide is even more difficult[81]. Benzyl azide adds to heptamethyl-3-vinyltrisiloxane somewhat more readily[82]. When the reaction is performed in petroleum ether solution at 30 — 40°C, the yield of product after 10 days was 40.5%.

The addition of iodotrinitromethane to trimethylvinylsilane in carbon tetrachloride solution leads to the formation of an isoxazolidine derivative[83,84]:



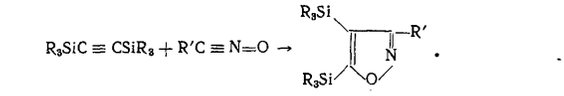
The product of the reaction of allyltrimethylsilane with iodotrinitromethane is *N*-trimethylsiloxy-5-trimethylsilylmethyl-3,3-dinitroisoxazolidine[83].

Organosilicon derivatives of isoxazolidine have been synthesised by the addition of nitrile oxides to vinyl-[85], allyl-[85], and vinylethynyltri-R-silanes[86,87]:

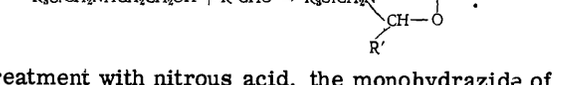


and also by the condensation of vinylsiloxanes with 1,4-dinitrobutane in the presence of phenylene di-isocyanate and triethylamine and by the reaction of alkenylsiloxanes with 1,2-dichloroglyoxime in the presence of triethylamine[88].

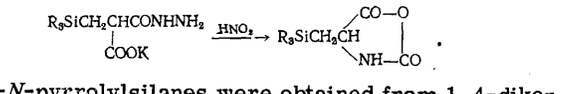
The reaction of ethynylsilanes with nitrile oxides yields isoxazolylsilanes[85]:



Alkyl-*N*-oxazolidinylsilanes were obtained by the condensation of silylaminoalcohols with aldehydes[89]:

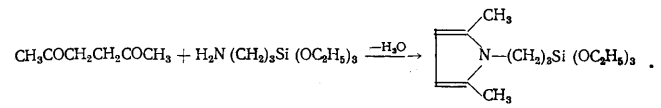


On treatment with nitrous acid, the monohydrazide of trimethylsilylmethylmalonic acid cyclises into an oxazolidinedione derivative[90]:

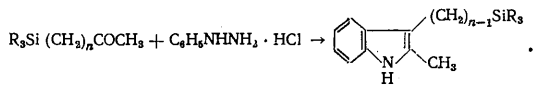


Alkyl-*N*-pyrrolylsilanes were obtained from 1,4-diketones and aminoalkylsilanes[91,92]. Thus triethoxy-γ-(2,5-dimethylpyrrolyl)propylsilane is formed when

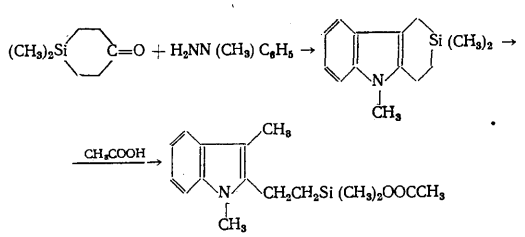
hexane-2,5-dione is heated with γ-aminopropyltriethoxysilane for 1 h at 140—150°C:



The condensation of γ-, δ-, and ε-silylketones with phenylhydrazine hydrochloride at 170—200°C in the presence of copper(I) chloride yielded silyl derivatives of indole[93-95]:

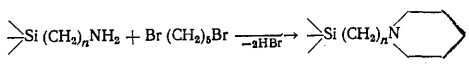


When 4,4-dimethyl-4-silacyclohexanone is refluxed with 1-methyl-1-phenylhydrazine in glacial acetic acid, dimethyltetrahydrosilacarbazole is formed and then converted into indole derivatives[96]:



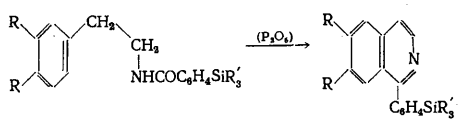
When a solution of *p*-trimethylsilylbenzylamine and itaconic acid is heated to boiling in pyridine, 4-carboxy-*N*-(*p*-trimethylsilylbenzyl)-2-pyrrolidinone is produced[20].

Tri-R-(2-piperidinoethyl)silanes and tri-R-(3-piperidinopropyl)-silanes were synthesised by the reaction of 2- and 3-aminoalkylsilanes with 1,5-dibromopentane[97]:



2,2,4,4-Tetranitropiperidinoalkylsilanes were obtained similarly by the condensation of aminoalkylsilanes with 2,2,4,4-tetranitropentane-1,5-diol[98,99].

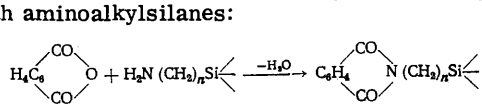
1-Trimethylsilylphenyl- and 1-trimethylsilylbenzyl-derivatives of isoquinoline were synthesised by the cyclisation of β-arylethylamides of the corresponding trimethylsilylarylcarboxylic acids in toluene when acted upon by phosphorus pentoxide or phosphoryl chloride[78]:



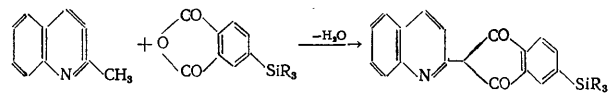
7. Other Methods

The Mannich reaction with piperidine and morpholine has been used for the aminomethylation of tri-R-ethynylsilanes[100] and trimethylsilylmethylacetophenone[101].

Silyl derivatives of succinimide[102,103] and phthalimide[102-105] are formed when dicarboxylic acid anhydrides react with aminoalkylsilanes:



If one employs alkoxyaminoalkylsilanes in this reaction, the hydrolysis of the alkoxy-groups with water liberated on condensation and further polycondensation of phthalimidoalkylsilanols gives rise to polymeric products. Trialkylsilylphthalimides were also obtained by heating the anhydrides of 3- and 4-trimethylsilylphthalic acids with urea at 170°C. The condensation of these anhydrides with quinaldine leads to the formation of the corresponding quinolinophthalones[106]:



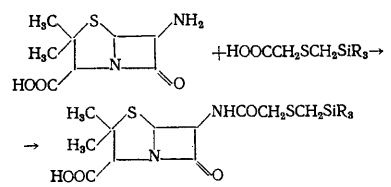
N-Heterylsilylalkanols were obtained by the opening of the oxiran ring of alkyloxiranylsilanes with aziridine[107] or phthalimide[104].

Silylaldimines were obtained by the reaction of heterocyclic aldehydes with aminoalkylsilanes:

The reaction has been used to prepare indole[108], oxazole[108], benzoisoxazole[108,109], thiazole[109], benzoisothiazole[109], pyridine[108], and acridine[108] derivatives.

Organosilicon derivatives of carbazole have been obtained by the reaction of carbazole with trimethylsilylacetyl chloride in the presence of stannic chloride[110]; organosilicon esters of nicotinic acid were obtained by heating alkylchlorosilanes with sodium nicotinate[111]; polymeric alkylsilylpyridylalkylenes were obtained by the copolymerisation of 4-vinylpyridine with methylallylsilacyclobutane[112].

A silicon-containing penicillin was synthesised by the reaction of 6-aminopenicillanic acid with trimethylsilylmethylmercaptoacetic acid in acetone using *NN'*-dicyclohexylcarbodiimide as the condensing agent[113]:



B. PHYSICAL PROPERTIES

Electronic[8,11,114], vibrational[4,15,17,55,66,67,83,86,106,115-118], and ^{1}H NMR[9,10,15,25,46,48,51,57,65,66,86,96,115,119] spectra of organosilicon derivatives of nitrogen-containing heterocycles have been used mainly to confirm the structures of the compounds synthesised.

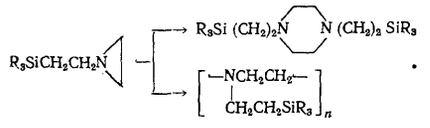
By comparing the calculated and experimental electronic spectra of trimethyl-(2-pyridyl)silane it was suggested that the π electrons of the heterocycle interact with the vacant orbitals of silicon[114]. However, trimethyl-(2-pyridyl)silane is a stronger base than 2-t-butylpyridine (according to potentiometric titration data, the pK_a values are 6.63 and 5.76 respectively). Trimethyl-(4-pyridyl)-silane is a weaker base than 4-t-butylpyridine, the basicity of which is higher than that of the 2-isomer[119].

The changes in the ultraviolet spectra of trialkylpyridylsilanes have been used to investigate the kinetics of their solvolysis[11]. The stereochemistry of this reaction was studied by determining the optical activities of methyl-1-naphthylphenyl-(2-pyridyl)silane and its methanolysis and hydrolysis products[8].

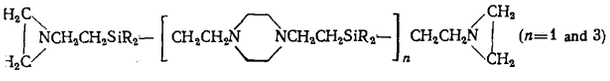
:. CHEMICAL PROPERTIES

. Thermal Reactions

Tri-R-[2-(*N*-aziridinyl)ethyl]silanes remain unchanged fter heating for 5 h at 200°C. An increase of temperaıre to 250 — 300°C leads to the formation of considerable mounts of thermal conversion products among which roducts with a high molecular weight are formed ›gether with products of cyclodimerisation to piperazine ›rivatives owing to the opening of the aziridine ng[117,118,120]:

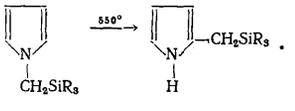


When [2-(*N*-aziridinyl)ethyl]triethylsilane is heated in ə presence of sodium iodide, the only product is the rresponding piperazine derivative, the yield of which ›reases from 22% for a molar reactant ratio of 1 : 0.2 50% for the equimolar ratio[120]. The yield of the poly›r and the degree of polymerisation depend to a conlerable degree on the nature of the groups linked to the icon atom. For example, when R = C_2H_5, heating at ›°C leads to the formation of a tetramer in about 7% ld. On the other hand, dimethylphenyl and ethoxyıethyl derivatives give 70 — 80% of compounds with 5 — 9.[117] Complexes of alkylaziridinylsilanes with c chloride polymerise at a temperature as low as l°C to form polymers with n = 80 — 300°C.[117] Dialkyldi-[2-(*N*-aziridinyl)ethyl]silanes form linear di- tetra-mers on heating to 250 — 300°C:[118]



ırther increase of temperature leads to the formation ross-linked insoluble polymers[118].

When trimethyl-(*N*-pyrrolylmethyl)silane is heated at °C, it isomerises to trimethyl-(2-pyrrolylmethyl)ne[4]:



Reduction

he reduction of organosilicon derivatives of nitrogenıining heterocycles has been used to prepare derivawith hydrogenated rings and also to modify the funcl groups in the side chain of the heterocycle or ›s linked to the silicon atom.

ıus pyridylsilanes[33] and alkylpyridylsiloxanes[121] were ›rted by catalytic reduction (H_2/PtO_2) into the correling piperidinylsilanes and alkylpiperidinylsiloxanes)-acridinyl)triphenylsilane (reduction with Zn/HCl) ›onverted into (9,10-dihydro-9-acridinyl)triphenyl›16].

e cyano- and ethoxycarbonyl functional groups of rlsilanes[5], the amide groups of substituted piperi- and morpholinyl-R-silanes[78], and the alkoxy-groups ylalkoxyaziridinylsilanes[38] were reduced with lithium niumhydride.

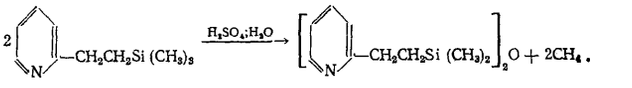
Aldimines obtained from heterocyclic aldehydes and silylamines were hydrogenated catalytically to amines:

Derivatives of indole[122], oxazole[122], benzoisoxazole[122], pyridine[122], and acridine[122] were obtained in this way.

In the presence of Raney nickel, trimethylsilylmethylphenyl piperidinoalkyl ketones were reduced to the corresponding carbinols[101].

3. The Formation of Siloxanes

When acted upon by concentrated sulphuric acid, trimethyl-[β-(2-pyridyl)ethyl]silane splits off a methyl group. Subsequent hydrolysis yields tetramethyl-1,3-bis-[β-(2-pyridyl)ethyl]disiloxane which forms copolymers with alkyl- and aryl-polysiloxanes in the presence of KOH:[13,14]



Alkylpiperidyl-[97,121] and alkylcarbazolyl-polysiloxanes[110] were obtained similarly.

Alkaline hydrolysis of dialkylethoxy-(*N*-heterylalkyl)-silanes yields 1,3-bis-(*N*-heterylalkyl)tetramethyldisiloxanes:

where R_N = aziridinyl[116], pyrrolidinyl[68], piperidinyl[68], and morpholinyl[68].

Acetoxydimethyl-[β-(3-methyl-2-carbazolyl)ethyl]silane is hydrolysed similarly[96].

Alkaline hydrolysis of [2-(*N*-aziridinyl)ethyl]diethoxymethylsilane results in the formation of a cyclic trimer, while hydrolysis with 95% ethanol leads to a linear trisiloxane with terminal ethoxy-groups. Hydrolysis with an excess of water yields a polysiloxane oil which solidifies on standing[116].

Polysiloxanes were obtained by the hydrolysis of dichloromethyl-(2-succinimidoethyl)silane[64], triethoxy-(3-succinimidopropyl)silane[102,103], triethoxy-(3-phthalimidopropyl)silane[102,103], and diethoxymethyl-[γ-(2-pyridyloxy)propyl]silane[61]. Polysiloxane resins obtained by the hydrolysis of trichloro-[β-(2-pyridyl)ethyl]silane and its 4-analogue do not lose their solubility in inert solvents even after heating to 105°C for 24 h.[49,50,54]

4. Desilylation

The Si — C bond between the silicon atom and the heterocycle in (9-ethyl-3-carbazolyl)triphenylsilane and (9-ethyl-1-carbazolyl)triphenylsilane is readily cleaved by hydrogen chloride in glacial acetic acid[7]. The process also involves a partial cleavage of the Si — C_6H_5 bond.

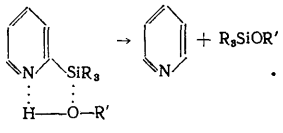
In the combined protonation and desilylation by perchloric acid in aqueous methanol, (9-ethyl-3-carbazolyl)trimethylsilane is more reactive than the corresponding dibenzofuran and dibenzothiophen derivatives[6].

(9-Ethyl-1-carbazolyl)triphenylsilane is cleaved by a solution of alkali in aqueous dioxan or ethanol but with appreciably greater difficulty than the corresponding dibenzofuran and dibenzothiophen derivatives. Under the above conditions, (9-ethyl-3-carbazolyl)triphenylsilane is stable[7].

Trimethyl-(2-pyrrolylmethyl)silane is cleaved by alcoholic alkali with much greater difficulty than benzyltrimethylsilane[4].

The Si — CH_2CO bond in the piperidide of diethylmethylsilylacetic acid[17] is cleaved quantitatively by 5% hydrochloric acid even at 0°C.

In contrast to the 3- and 4-isomers, trimethyl-(2-pyridyl)silane readily reacts with water, methanol, or ethanol to form pyridine and trimethylsilanol or alkoxytrimethylsilane[11,123]. The relative rates of desilylation at 50°C in water, methanol, and ethanol are 740 : 120 : 1. Higher alcohols do not enter into this reaction. The desilylation of trimethyl-(2-pyridyl)silane by water is inhibited by acids, while alkalies do not alter its rate. The reaction is of first order with respect to silane, has a high negative entropy of activation, and does not show an isotope effect. On the basis of these data, one may suppose that the desilylation proceeds via a five-membered cyclic complex[11]:

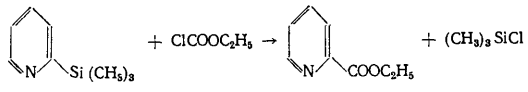


The above mechanism is confirmed by the finding that the hydrolysis and methanolysis of the optically active methyl-1-naphthylphenyl-(2-pyridyl)silane takes place with retention of its configuration[8].

Trimethyl-(2-pyridyl)silane is hydrolysed much faster than trimethyl-(2-pyridyl)germane but more slowly than trimethyl-(2-pyridyl)stannane[124]. The relative rates of hydrolysis of the silicon, germanium, and tin derivatives are $1 : 10^{-4} : 22$.

The rate of methanolysis of trialkyl-(2-pyridyl)silanes as a function of the groups linked to the silicon atom decreases in the following sequence: dimethyl > trimethyl > triphenyl > triethyl[10]. The rate of cleavage of the Si — C bond in methyl-substituted 2-trimethylsilylpyridines, $2\text{-}(CH_3)_3Si(C_5H_3N)R$, by water decreases in the following sequence as a function of the position of the methyl group[9,125] (the positions of the methyl group R and the relative rates of desilylation at 30.2°C are quoted): 4-methyl-(1.70)- > 6-methyl-(1.59) > 3-methyl-(1.58) > H(1) > 5-methyl-(0.71). The same sequence is largely followed also in methanolysis. The only exception is trimethyl-(3-methyl-2-pyridyl)silane which is least reactive in this case[9,125].

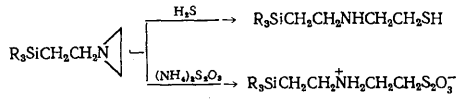
Trimethyl-(2-pyridyl)silane is readily desilylated by carboxylic acid chlorides and chlorocarbonic esters[126]:



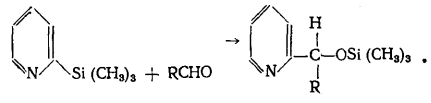
The Si — C bond in trimethyl-(2-pyridylmethyl)silane is cleaved by 95% aqueous ethanol with formation of hexamethyldisiloxane. However, in contrast to trimethyl-(2-pyridyl)silane, this requires prolonged heating and the reaction is catalysed by alkalies and especially by acids[22]. The rate of reaction decreases in the sequence trimethyl-(4-pyridylmethyl)silane > trimethyl-(2-pyridylmethyl)-silane > methyl-2-bis(trimethylsilyl)pyridine. There is a particularly marked difference between the rates of hydrolysis in an acid medium of the last two compounds, probably owing to steric factors which impede the protonation of the nitrogen atom preceding the attack on the silicon atom.

5. Other Reactions

The aziridine ring in [2-(*N*-aziridinyl)ethyl]trimethylsilane and [3-(*N*-aziridinyl)propyl]trimethylsilane is opened by hydrogen sulphide or ammonium thiosulphate with formation of the corresponding silyl derivatives of 2-aminoethanethiol and 2-aminoethanethiosulphuric acid[42]:



Trimethyl-(2-pyridyl)silane adds to aldehydes via the mechanism[127,128]:



A number of the usual reactions involving the functional groups linked to the heterocycle have also been carried out. These include the transformation CN → $CONH_2$ → NH_2 → OH in 2- and 4-substituted trimethyl-(3-pyridyl)-silanes[12], alkylation[96] and vinylation[129,130] of the NH group in trialkylsilylindoles, transamination of 3-dimethylaminomethyl-5-trimethylsilylindole with piperidine[5], the conversion of phthalimidoalkylsilanes into aminoalkylsilanes by treatment with hydrazine hydrate[18,20,21], and the formation of trimethylsilyl-substituted derivatives of indigo[131].

D. BIOLOGICAL PROPERTIES

The toxicity of trialkyl(piperidinylmethyl)silanes to white mice depends little on the nature of the alkyl groups linked to the silicon atom and varies in the range from 45 to 90 mg kg^{-1}.[132,133] Trialkyl-(3-piperidinopropyl)-silanes are somewhat more toxic than 2-piperidinylethyl and piperidinylmethyl derivatives[132-134]. Triethyl-(3-piperidinylpropyn-1-yl)silane (LD_{50} = 195 mg kg^{-1}) is less toxic than the corresponding vinyl and ethyl derivatives[64,132]. The toxicity of diethoxy-[3-(*N*-heteryl)propyl] methylsilanes decreases from the piperidine derivative to morpholine and thiamorpholine derivatives[135,136].

The hydrochlorides of diethylmethyl-(2-piperidinylethyl)silane and triethyl-(3-piperidinylpropyl)silane impair the coordination of the movement of white mice when administered in doses smaller by a factor of 8.2 and 7.3 respectively than the median lethal doses[132].

Trialkyl-(3-piperidinylpropyl)silanes exhibit a fungistatic activity in relation to the pathogenic fungi *Candida albicans*, *Epidermophyton* Kaufmann-Wolf, and *Trychophyton gypseum*. The minimum concentration of the compound inhibiting the growth of *Epidermophyton* Kaufmann-Wolf 41 decreases in the following sequence as a function of the groups linked to the silicon atom: diethylmethyl, methyldipropyl > methyldipentyl > dibutylmethyl, amounting to 12.5 μg ml^{-1} for the last silane.

E. PRACTICAL APPLICATIONS

Alkylpyrrolylsiloxanes and alkylpiperidinylsiloxanes are used as lubricating oils[97,121] and as modifying agents in various oils and resins[121]. Pyridylsiloxanes[121] and (pyridylalkyl)siloxanes[47] are used to synthesise ion-exchange resins.

The products of the joint hydrolysis of diethoxymethyl-[β-(4-pyridyl)ethyl]silane and dichlorodimethylsilane[55] and alkyl-(2-pyridyloxy)polysiloxanes[60] have been used to prepare elastomers. Polysiloxane elastomers based on alkylpyrrolylsiloxanes[92], alkyloxopyrrolidinylsiloxanes[62], and alkylsuccinimidosiloxanes[64] exhibit a high resistance to oils. Alkoxyalkylaziridinylsiloxanes form coatings on the surface of various materials which are resistant to the action of organic solvents[107].

Alkylpyrrolylsilanes have been suggested as antioxidants[137] and the addition of ethoxydimethyl(piperidinylmethyl)silane accelerates the formation of polyurethane foam plastics[68].

Alkylpyridylpolysiloxane salts are used as emulsifying agents[23,76] and also to impart hydrophobic properties to textiles[74,75,79] and to increase their fire resistance[75].

III. COMPOUNDS CONTAINING THE Si—N BOND

A. METHODS OF PREPARATION

1. Reaction of Halogenosilanes with Heterocyclic Bases

A general method for the preparation of organosilicon derivatives of nitrogen-containing heterocycles with an Si—N bond is the reaction of heterocyclic bases with halogenosilanes. Heterocycles with an unsubstituted N—H bond give rise to *N*-silylheterocycles and tertiary heterocyclic bases give rise to complexes or the reaction does not occur at all, depending on the structure of the halogenosilane.

The *N*-silylation of nitrogen-containing heterocycles may be represented by the general mechanism

$$R_NNH + Cl{-}Si\lessgtr \xrightarrow{+B} R_NN{-}Si\lessgtr + B{\cdot}HCl,$$

where R_NNH = aziridine[138-142], pyrrolidine[143-147], succinimide[148], the anhydrides of *N*-carboxy-α-aminoacids[149], phthalimide[65,150], piperidine[43,143,146,151-155], morpholine[152,155-159], perhydroazepine[156], and ε-caprolactam[160,161].

Ammonia[138], triethylamine[138,140,143,149,150,156,160,161], pyridine[65,138], or an excess of the heterocyclic base itself[139,141,146,147,153,154,159] are used as the acceptors (B) of the hydrogen halide liberated. The reaction can be achieved without a solvent[153] or in solution in ethyl ether[151,161], pentane[140,144], benzene[138,139,142,143,154,159], THF,[149] or dimethylformamide (DMF).[150] *N*-Silylpyrrolidine and *N*-silylpiperidine were obtained from iodosilane and the corresponding bases in the gas phase[146].

Tri-R-(*N*-heteryl)silanes and di-R-bis-(*N*-heteryl)-silanes can be obtained in this way readily and rapidly.

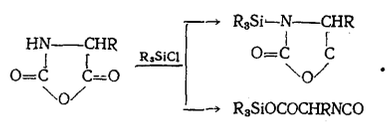
The rate of reaction of di-R-dichlorosilanes with ε-caprolactam decreases in the following sequence as a function of the organic substituent linked to the silicon atom[161]:

$$(CH_3)_2SiCl_2 > CH_3C_2H_5SiCl_2 > CH_3(i\text{—}C_4H_9)SiCl_2 > CH_3C_6H_5SiCl_2 > (C_6H_5)_2SiCl_2.$$

To obtain a high yield of R-tris-(*N*-heteryl)silanes, prolonged heating of the reactants is often necessary[154,156]. Tetrapyrrolidinylsilane was obtained in 50% yield by heating silicon tetrachloride with an excess of pyrrolidine[147]. A similar reaction with piperidine in ethereal solution yielded a mixture of trichloropiperidinylsilane, dichloropiperidinylsilane, and chlorotripiperidinylsilane[151]. To obtain tetrapiperidinylsilane, chlorotripiperidinylsilane must be heated with piperidine for 12 h at 250—270°C.[151] The reaction of morpholine with silicon tetrachloride yielded only chlorotrimorpholinylsilane[159].

A study of the stereochemistry of the reaction of chloromethyl-1-naphthylphenylsilane with pyrrolidine showed that it proceeds with inversion of configuration[144].

In certain cases, when *N*-heterylsilanes are synthesised from chlorosilanes, side reactions reduce their yield. For example, in the reaction of chlorosilanes with aziridine, silylation is accompanied also by the opening of the aziridine ring, which in the absence of hydrogen chloride acceptors becomes the main process[139,146]. Two products are formed in the silylation of the anhydrides of *N*-carboxy-α-aminoacids with chlorotrimethylsilane at 0°C in the presence of triethylamine[149]:



An increase of reaction temperature promotes the formation of an acyclic product polymerisation[149].

Depending on their structure, halogenosilanes react with pyridine to form both ionic and molecular complexes. Bromosilane[162,163], iodosilane[162-164], dibromosilane[162,163], di-iodosilane[162,163], and silicon tetraiodide[163,165,166] form complexes with pyridine which conduct electricity in acetone solutions and to which the following structures have been attributed: $[2C_5H_5N.SiH_3]^+X^-$, $[4C_5H_5N.SiH_2]^{2+}2X^-$, and $[4C_5H_5N.SiI_2]^{2+}2I^-$. In the presence of pyridine, dichlorosilane and chlorosilane form a current-conducting complex $H_2SiCl_2.2C_5H_5N$.[162,163] Fluorosilane and difluorosilane are decomposed by pyridine[163]. Silicon tetrafluoride[162,167-172], silicon tetrachloride[162,165,167,170,172-178], and silicon tetrabromide[162,165,167,170,179] form with pyridine, quinoline, and isoquinoline complexes of the type $SiX_4.2L$ (X = F, Cl, or Br; L = pyridine, quinoline, or isoquinoline). Data concerning the formation of complexes with a different structure[166,177,180-182] were not confirmed[162,168,170,178,183].

The acceptor capacity of tetrahalogenosilanes in relation to pyridine decreases in the sequence $SiCl_4 \sim SiBr_4 > SiF_4$, since the heats of formation $-\Delta H$ of complexes of the type $SiX_4.2C_5H_5N$ also decrease on passing from the chloro- (27.7 kcal mole^{-1}) and bromo- derivatives (26.8 kcal mole^{-1}) to the fluoro-derivative (17.9 kcal mole^{-1})[167,184,185]. The values of $-\Delta H$ quoted in other studies[170,186] are clearly too high.

When mixed silicon tetrahalides were allowed to react with pyridine, the complexes $SiCl_3Br_3.2C_5H_5N$, $SiCl_3Br.2C_5H_5N$, $SiCl_3I.3C_5H_5N$, and $SiCl_2I_2.4C_5H_5N$ were formed[187]. Ionic structures were attributed to the last two compounds[187,188]: $[3C_5H_5N.SiCl_3]^+I^-$ and $[4C_5H_5N.SiCl_2]^{2+}2I^-$.

Trichlorosilane forms a 1 : 2 complex with pyridine[162,167,168], a 1 : 3 complex with 4-vinylpyridine[55], and a 1 : 4 complex with 2-vinylpyridine[55]. Trifluorosilane and tribromosilane form 1 : 4 complexes with pyridine[163]. When bromomethylsilane and iodomethylsilane react with pyridine, 1 : 2 complexes are formed, while chloromethylsilane undergoes quantitative disproportionation under these conditions to methylsilane and dichloromethylsilane[189]. The latter forms with pyridine an extremely unstable complex of unknown composition. The greatest influence of halogenosilanes on the stoichiometry of pyridine complex has been observed with iodosilanes. Thus, whereas iodomethylsilane forms with pyridine a 1 : 2 complex, di-iodomethylsilane forms a 1 : 4 complex and di-iododimethylsilane and iodotrimethylsilane give rise to 1 : 1 complexes[163,189]. Bromotrimethylsilane forms with pyridine an unstable product of unknown

composition[163]. Fluorotrimethylsilane, chlorotrimethylsilane, dichlorodimethylsilane, and trichloromethylsilane do not interact with pyridine[163,167,173,189]. The claims of successful reactions of this type[190,191] were not confirmed in this respect.

Complexes of halogenosilanes with pyridine *N*-oxide[192], picoline[167,168], 2-hexylpyridine[164], 2,4-dimethylpyridine[166], 2,2-bipyridyl[164,165,182,193-204], and phenanthroline[187,196,204] have also been obtained.

Iodotriphenylsilane combines with 2,2′-bipyridyl to form a complex which dissociates in dichloromethane solution into an iodide anion and a triphenyl(bipyridylyl)-siliconium cation in which both nitrogen atoms form coordinate bonds with the silicon atom[193]. The reaction is more difficult with bromotriphenylsilane and does not occur at all with chlorotriphenylsilane.

The reactions of hexachlorodisilane and hexabromodisilane with pyridine involve the cleavage of the Si — Si bond[187]:

$$Cl_3SiSiCl_3 + 3C_5H_5N \rightarrow 2C_5H_5N \cdot SiCl_4 + 1/n\,(C_5H_5N \cdot SiCl_2)_n .$$

Tetrapropylammonium pentafluorosilicate forms an unstable complex with pyridine[205].

Pyridine complexes, similar to those of halogenosilanes, are formed also by a series of other organosilicon compounds: silicon tetraisothiocyanate[206], tetranitrate[207], and oxalate[208], silyltetracarbonylcobalt, and silylpentacarbonylmanganese[209-211]. Poly-(2-vinylpyridine *N*-oxide) (PVPO) forms a complex with silicic acid[212]. Possibly such complex formation is in fact responsible for the increase of the resistance of macrophages to the action of quartz dust under the influence of PVPO.[213,214]

2. Organometallic Synthesis

In the synthesis of Si — N derivatives, *N*-organometallic derivatives of the heterocyclic base are allowed to react with chlorosilanes instead of the base itself:

$$R_NNM + ClSi\lessgtr \rightarrow R_NN{-}Si\lessgtr + MCl$$

M=Li, Na, K, MgBr

Using *N*-lithium-substituted heterocycles, *N*-R-silyl derivatives of pyrrole[215,216] and pyrrolidine[144] were obtained in this way. The reaction of chloromethyl-1-naphthylphenylsilanes with pyrrolidinyl-lithium takes place with inversion of configuration[144].

The reaction of 9-carbazolylsodium with silicon tetrachloride in benzene solution yielded di-(9-carbazolyl)dichlorosilane[217].

N-Pyrrolylsilanes[143,218-220] (and not *C*-pyrrolylsilanes as believed previously), succinimidosilanes[221], phthalimidosilanes[63,221], and *N*-indolylsilanes[143] have been synthesised on the basis of *N*-potassium-substituted heterocycles. The reaction of indolylpotassium with chlorotrimethylsilane is more difficult than the reaction of pyrrolylpotassium[143].

N-Pyrrolylsilanes were also obtained from pyrrolylmagnesium bromide and R-chlorosilanes[215,216,218,222,223]. Pyrrolidinyl-, piperidinyl-, and morpholinyl-silanes were obtained similarly via organomagnesium derivatives[224].

Triphenylsilyl-lithium silylates piperidine with formation of triphenylpiperidinylsilane[225]:

$$(C_6H_5)_3SiLi + HN\bigcirc \rightarrow (C_6H_5)_3SiN\bigcirc + LiH .$$

The reaction of bis(trimethylsilyl)mercury with pyridine leads to the formation of 1,1′-bis(trimethylsilyl)-1,1′,4,4′-tetrahydro-4,4′-bipyridyl[226]:

$$R_3SiHgSiR_3 + 2N\bigcirc \rightarrow R_3SiN\bigcirc\!\!-\!\!\bigcirc NSiR_3 + Hg .$$

2-Methylpyridine and 4-methylpyridine react similarly.

1,4-Bis(trimethylsilyl)-1,4-dihydropyridine was obtained by the reaction of pyridine with chlorotrimethylsilane in the presence of alkali metals[227]:

$$N\bigcirc + 2M + 2ClSiR_3 \xrightarrow{-2MCl} R_3Si{-}\bigcirc NSiR_3 .$$

3. Silylation with Aminosilanes and Silazanes

When aminotriethylsilane is heated to boiling with pyrrolidine over a period of 6 h, triethylpyrrolidinylsilane is formed in 95% yield[143]:

$$(C_2H_5)_3SiNH_2 + HN\square \rightarrow (C_2H_5)_3SiN\square + NH_3 .$$

Piperidine enters into this reaction with somewhat greater difficulty. The yield of triethylpiperidinylsilane reaches 89% only after refluxing the reaction mixture for 10 h.[143] 2-Aminothiazole reacts similarly[228].

Dialkylaminotrimethylsilanes were used instead of aminotrialkylsilanes for the *N*-trimethylsilylation of piperidine[42], perhydroazepine[156], morpholine[156], 2-aminothiazole and 2-aminobenzothiazole[229], δ- and ϵ-caprolactams[160], and also proline and tryptophan esters[230].

Hexamethyldisilazane silylates the NH group of heterocycles with much greater difficulty than do aminotrialkylsilanes. Frequently catalytic amounts of ammonium sulphate[218,231] or chloride[231] are essential for the occurrence of this reaction. Thus after pyrrole has been refluxed for 12 h with hexamethyldisilazane, no reaction was observed. On the other hand, in the presence of ammonium sulphate the yield of trimethyl-(*N*-pyrrolyl)silane reached 50% after only 2 h.[231] Indole was found to be somewhat more reactive than pyrrole[231].

After refluxing for 3 h a mixture of piperidine and hexamethyldisilazane without a catalyst, the yield of trimethylpiperidinosilane reached only 16%, but in the presence of chlorotrimethylsilane it increased to 35%. The addition of ammonium chloride or sulphate increased the yield further to 52 — 55%.[230] The yield of the silylation product depends also on the nature of the solvent and is a maximum when the reaction is carried out in quinoline (61%). Toluene (54%) and decalin (54%) are also satisfactory solvents. In ethyl ether, trimethylpiperidinosilane is not formed at all[230].

The reaction of nitrogen-containing heterocycles with hexamethyldisilazane has also been used to synthesise *N*-trimethylsilylpyrrolidinone[232], *N*-trimethylsilylsuccinimide[221], and *N*-trimethylsilylindoline[231].

4. Silylation with Silanes containing Unsubstituted Hydrogen Atoms

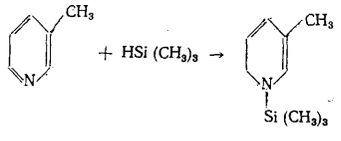
In the presence of alkali metals or Pd/C, silanes with unsubstituted hydrogen atoms enter into dehydrocondensation reactions with heterocyclic compounds containing the N — H bond:

$$R_NNH + H{-}Si\lessgtr \rightarrow R_NN{-}Si\lessgtr + H_2 .$$

Aziridine[35,39,233,234], 2-substituted aziridines[235], pyrrolidine[236], and piperidine[237] were silylated in this way. The reaction with aziridine proceeds more readily than with secondary aliphatic amines and piperidine and may be catalysed by potassium, sodium, and lithium. Aziridine is silylated at the maximum rate by tri-R-silanes containing phenyl and benzyl groups. Trialkylsilanes react more slowly and with alkoxysilanes the rate of dehydrocondensation is lowest. When aziridine reacts with vinylsilanes, the dehydrocondensation process competes with the addition of aziridine to the vinyl group[39]. 2,2-Dimethylaziridine reacts with greater difficulty than 2-methyl- and 2-phenyl-aziridines[235].

The dehydrocondensation of optically active methyl-1-naphthylphenylsilane with pyrrolidine in the presence of palladium and charcoal takes place with inversion of configuration[236].

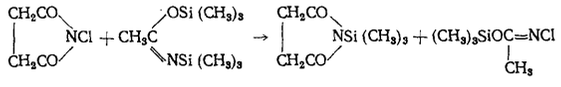
Trimethylsilane reacts with pyrridine in the presence of palladium on charcoal to form *N*-trimethylsilyl-1,2-dihydropyridine (yield about 25% after 25 h at 30°C), *N*-trimethylsilyl-1,4-dihydropyridine (35%), *NN'*-bis(trimethylsilyl)-1,1'-dihydro-4,4'-bipyridyl (25%), *N*-trimethylsilyl-1,2,3,6-tetrahydropyridine (12%), and many other trimethylsilylhydropyridines[238-240]. Pd/C is a more active catalyst than Rd/C, palladium(II) chloride, platinum, and Ru/C. However, Rd/C is more selective, driving the process mainly towards the formation of *N*-trimethylsilyl-1,4-dihydropyridine[239]. With 3-methylpyridine, trimethylsilane adds quantitatively to the 1,4-positions in the presence of Pd/C:[239]



4-Methylpyridine reacts four times as slowly as pyridine and it proved altogether impossible to add trimethylsilane to 2-methylpyridine[239].

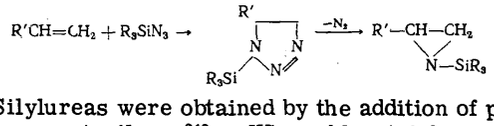
5. Other Methods

N-Trimethylsilylsuccinimide was obtained by the reaction of *N*-chlorosuccinimide with bis(trimethylsilyl)-acetamide[241,242]:



The same compound is formed when *N*-bromosuccinimide reacts with ethyl trimethylsilylacetate[242], bromotrimethylsilane in the presence of styrene[243], and hexa-alkyldisilanes[244,245]. Phthalimide and homodihydrocarbostyril are silylated by bis(trimethylsilyl)acetamide like succinimide[246,247].

Trimethyl-(2-R-*N*-aziridinyl)silanes were obtained by the thermal decomposition of *N*-trimethylsilyl derivatives of dihydro-1,2,3-triazole, which is formed as an intermediate when azidotrimethylsilane adds to alkenes[248]:



N-R-Silylureas were obtained by the addition of piperidine to isocyanatosilanes[249]. When chlorotriphenoxysilane was allowed to react with hexamethylenediamine, the formation of triphenoxy-(*N*-perhydroazepinyl)silane was observed, probably as a result of the cyclisation of (6-aminohexylamino)triphenoxysilane formed initially[250].

B. PHYSICAL PROPERTIES

Electronic[198,222,239], vibration[55,146,147,156,159,161,168,188,196,205,206,209,210,218,234,239,243,251-254], and ^{1}H NMR [140,147,156,239,243,247,255] spectra of *N*-heterylsilanes were not investigated systematically. In both cases spectroscopic data were used only to confirm the structures of the compounds synthesised.

In a number of instances, an attempt was made to assign the bands in the infrared absorption spectra to the corresponding Si — N stretching vibrations. The absorption bands at 695 cm^{-1} for pyrrolidinylsilane[146,253], at 705 cm^{-1} for piperidinylsilane[146], at 910 cm^{-1} for iodopiperidinylsilane[254], at 932 cm^{-1} for chloropiperidinylsilane[254], at 945 — 950 cm^{-1} for R-piperidinylsilanes[156], at 960 cm^{-1} for R-morpholinylsilanes[156], at 975 cm^{-1} for chlorotrimorpholinylsilane[159], and at about 1057 cm^{-1} for trimethyl-(*N*-pyrrolyl)silane[218] were assigned to ν_{as}(S — N).

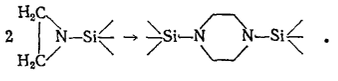
Quantum-chemical calculations have been made for (*N*-pyrrolyl)silanes on the basis of spectroscopic data and it has been concluded that $p_\pi - d_\pi$ interaction takes place in their molecules[222,223]. ^{1}H NMR spectra confirmed the occurrence of such interaction also in the (*N*-aziridinyl)-trimethylsilane molecule[255].

X-Ray diffraction analysis[256] established that the complex $2C_5H_5N.SiF_4$ has a centrosymmetric *trans*-configuration with an Si — N distance of 1.93 Å.

C. CHEMICAL PROPERTIES

1. Thermal Reactions

On heating to 250°C, tri-R-(*N*-aziridinyl)silanes are converted into piperazine derivatives[257]:



When platinised charcoal is introduced into the reaction mixture, the yields of products are unaffected. The addition of azobisisobutyronitrile makes it possible to obtain higher yields even when the reaction temperature is reduced to 200°C.

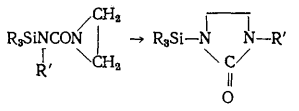
The nature of the organic groups linked to the silicon atom in the tri-R-(*N*-aziridinyl)silane molecule has a considerable influence on its reactivity. Thus, whereas the yield of *NN'*-bis(trimethylsilane)piperazine is only 25% after heating (*N*-aziridinyl)triethylsilane for 5 h at 250°C, in the case of the diethylphenyl derivative the yield of the piperazine derivative reaches 40%, while (*N*-aziridinyl)-diethoxyethylsilane does not undergo any changes under these conditions[257].

On heating in a sealed tube at 260°C, *N*-silylpyrrolidine and *N*-silylpiperidine disproportionate[146]:

In contrast, trialkyl-(*N*-pyrrolyl)silanes remain unchanged on heating to 260°C for 12 h.[218]

Urea derivatives obtained by the reaction of R-(*N*-aziridinyl)silanes with isocyanates rearrange to

2-imidazolidinone derivatives at a temperature as low as 140°C:[140]



2. Desilylation

The Si — N bond in *N*-heterylsilanes dissociates with elimination of the silyl group under the influence of various reagents: hydrogen chloride[144,146,258], sulphur halides[143], phosphorus[229,259], boron[270], acyl halides[155], carboxylic acid *N*-halogenoamides[242], water[144,155,156,159,168,174,216,218], alcohols[168,218,238-240,261], hydrogen sulphide[258], oxygen compounds of sulphur[258], ammonia[218,230,258], *NN'*-dialkylureas[247,262,263], and lithium aluminiumhydride[144,145].

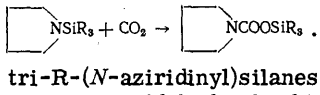
This reaction has been used both for the synthesis of heterocyclic compounds (for example, 1,4-dihydropyridine[238-240]) and their derivatives (for example, *N*-pyrrolylphosphines[259] and di-*N*-piperidinyl sulphide[143]) and for the silylation of compounds containing an active hydrogen atom (for example, *N*-hydroxymethyl-*N*-methylformamide[261] and *NN'*-dialkylureas[247,262,263]).

A study of the stereochemistry of the hydrolysis[144] and cleavage of optically active methyl-(1-naphthyl)phenylpyrrolidinylsilane with boron trifluoride[260] established that these reactions take place with inversion of configuration, while in the cleavage by hydrogen chloride and in the reduction by lithium aluminium hydride the configuration is retained[144].

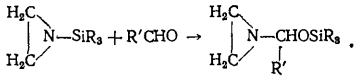
Many reactions which involve the dissociation of the Si — N bond at room temperature can lead to the formation of adducts with retention of this bond at a lower temperature. For example, at −88°C pyrrolidinylsilane and piperidinylsilane form hydrogen chloride complexes of the type $C_5H_{10}NSiH_3 \cdot 2HCl$, which decompose with dissociation of the Si — N bond when the temperature is raised[146]. At −46°C piperidinylsilane and pyrrolidinylsilane form 1:1 adducts with iodosilane[146,254].

3. Addition to Carbonyl Compounds

Tri-R-(*N*-heteryl)silanes add to carbon dioxide and also to carbon disulphide according to the mechanism[264]

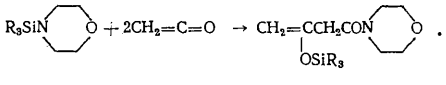


The reactions of tri-R-(*N*-aziridinyl)silanes with aliphatic, aromatic, and heterocyclic aldehydes lead to the formation of tri-R-(*N*-aziridinylalkoxy)silanes[265,266]:

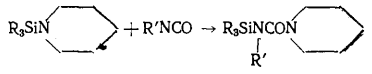


The addition of *N*-trimethylsilylpyrrolidinone[261,267] and *N*-trimethylsilylsuccinimide[261] to benzaldehyde and of trimethylpyrrolidinylsilane and trimethylpiperidinylsilane to chloral[268] takes place similarly.

Trimethylmorpholinylsilane reacts with keten at room temperature to form the morpholide of β-(trimethylsiloxy)vinylacetic acid[269,270]:

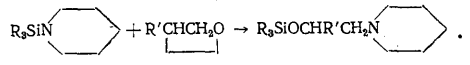


The addition of tri-R-(*N*-aziridinyl)silane[140] and tri-R-piperidinylsilanes[271] to organic isocyanates leads to the formation of *N*-tri-R-silyl-substituted ureas:



4. Reactions with Oxirans and Lactones

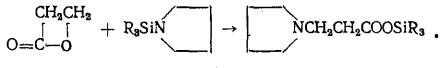
The reaction of trimethylpiperidinylsilane with R'-oxirans at 80°C takes place with the opening of the oxiran ring via the mechanism[272,273]



A necessary condition for the occurrence of this reaction is the presence of powerful electro-accepting substituents in the group R' of the oxiran. For example, when trimethylpiperidinylsilane reacts with trichloromethyloxiran, the yield of (1-trichloromethyl-2-piperidinylethoxy)trimethylsilane is 89% after only 1.3 h, while with chloromethyloxiran the yield of the reaction product does not exceed 45% even after heating for 22 h and methyloxiran and trimethylpiperidinylsilane do not react at all in a sealed tube at 80°C.

The reaction of substituted oxirans with *N*-trimethylsilylpyrrolidinone takes place via a similar mechanism[274,275].

Trimethylpyrrolidinylsilane, trimethylpiperidinylsilane, and trimethylmorpholinylsilane react with β-propiolactone on heating to 80°C with formation of trimethylsilyl esters of β-(*N*-heteryl)propionic acid[224,276,277]:



Trimethylpyrrolidinylsilane reacts faster than the corresponding piperidinyl- and diethylamino-silanes[276].

D. PRACTICAL APPLICATIONS

Trialkylpiperidinylsilanes and trialkylmorpholinylsilanes are used as catalysts for the hydrosilylation of acrylonitrile with trichlorosilane which promote the formation of the β-isomer[152,157,158,278].

Trimethylmorpholinylsilane and methylphenyldipyrrolidinylsilane are used in the preparation of organosilicon polymers[279].

Dihydropyridylsilanes inhibit the oxidation of various polymers and increase their resistance to the action of light[240].

Organosilicon derivatives of aziridine have been used to prepare water- and oil-repellent fabrics[138,142].

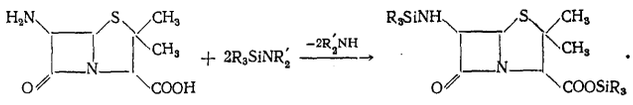
IV. COMPOUNDS CONTAINING THE Si — O BOND

A. METHODS OF PREPARATION

A number of general methods for the silylation of the hydroxy-group have been used to synthesise organosilicon derivatives of nitrogen-containing heterocycles with the Si — O bond. In the presence of tertiary amines, chlorosilanes were used to silylate *N*-hydroxymethylphthalimide[150,280], 2-hydroxypyridine[281-283] (Ismail[283] claims that

the *N*-silylation product was obtained), 2- and 4-pyridylalkanols[284], 4-hydroxy-2,2,6,6-tetramethylpiperidine 1-oxide[285-289], *N*-carboxyanhydrides of hydroxy-α-amino acids[290], proline[291], and picolinic[292], nicotinic[293] and 6-aminopenicillanic[294-296] acids.

The trimethylsilyl ester of 6-trimethylsilylaminopenicillanic acid forms in 29% yield when a suspension of calcium 6-aminopenicillanate is heated with chlorotrimethylsilane in the presence of triethylamine for 3 h to 60°C. When the sodium salt is used instead of the calcium salt, the yield of product falls to 25%.[294] The same compound is formed in 98.5% yield when 6-aminopenicillanic acid reacts with (diethylamino)trimethylsilane at 80 – 150°C with simultaneous distillation of the diethylamine evolved in the process[294]:



The trimethylsilyl ester of 7-trimethylsilylaminocephalosporanic acid is obtained similarly[297].

When 6-aminopenicillanic acid is heated with hexamethyldisilazane in nitrogen at 120°C for 3 h, the trimethylsilyl ester of 6-trimethylsilylaminopenicillanic acid is formed in 64.5% yield[294,298].

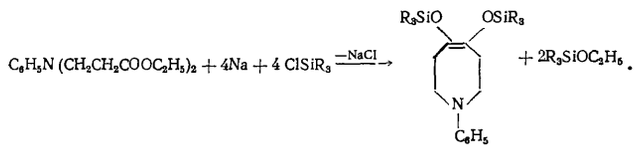
Silazanes have also been used to silylate penicillins[299-301], lincomycin[302,303], hydroxyproline[304,305], tryptophan[304], pyridylalkanols[306,307], piperidinylalkanols[307,308], morpholinylalkanols[309], and 8-hydroxyquinoline[310].

Oxindole and tryptophan have been silylated with bis(trimethylsilyl)acetamide[246,247].

Many reactions leading to the formation of derivatives of nitrogen-containing heterocycles with the Si – O bond were already considered above in the discussion of the chemical properties of compounds with Si – C and Si – N bonds. These include the reactions of trialkyl-(2-pyridyl)silanes with aldehydes[127,128] and the reactions of *N*-heterylsilanes with aldehydes[261,264-268], oxirans[272-275], keten[269,270], and lactones[224,276,277].

Aziridine, azetidine, and pyrrolidine add to the double bonds of trialkylvinyloxysilanes and 3-(trimethylsiloxy)-propyl acrylates with formation of the corresponding 2-(*N*-heteryl)ethoxysilanes and 3-(trimethylsiloxy)propyl β-(*N*-heteryl)propionates[311]:

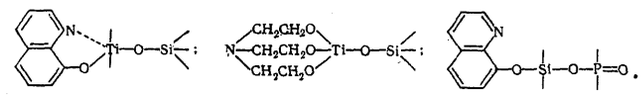
When *NN*-bis-(β-ethoxycarbonylethyl)aniline is heated with sodium and chlorotrimethylsilane in toluene solution, it is cyclised and silylated with formation of 4,5-bis(trimethylsiloxy)-1-phenyl-3,2,6,7-tetrahydroazepine[312]:



Tri-R-silanols[313] and 1,1,3,3-tetra-R-disiloxane-1,3-diols[314-317] form complexes with piperidine, picoline, and quinoline.

When 2-hydroxypyridine *N*-oxide was allowed to react with silicic acid, a complex was formed, which was characterised by conversion into its chloride, hexachlorostannate, and tetrachloroferrate[318] and resolved into optical isomers with the aid of the disodium salt of dibenzoyl-L-tartrate[319].

Oxinatotitanosiloxans[320-341], cyclic nitriloethylene tri-R-siloxytitanates[342], and dioxinatosilicon bisphosphorodichloridate[343] are obtained by the general methods used for the formation of the Ti – O – Si [344] and P – O – Si [345] groups:



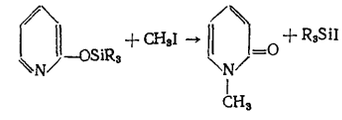
B. PHYSICAL, CHEMICAL, AND BIOLOGICAL PROPERTIES

Studies of the ultraviolet spectra of oxinatosilanes showed that dioxinatodiphenylsilane (λ_{max} = 370 nm) has a chelate structure with a hexacovalent silicon atom, in contrast to trimethyloxinatosilane and dimethyldioxinatosilane[310].

A high inversion frequency of the nitrogen atom in the trialkyl[α-(*N*-aziridinyl)alkoxy]silane molecule was demonstrated by ^{1}H NMR.[346] ^{1}H NMR [272,346,347] and ESR [286,287] spectra were also used to confirm the structures of the compounds synthesised.

The majority of organosilicon derivatives of nitrogen-containing heterocycles with the Si – O bond are readily hydrolysed by water[224,273,283,310,312]. Their Si – O bond is cleaved by methanol[272] and acetic acid[272].

Pyridyloxysilanes readily react with alkyl halides[281,283]. Thus, in contrast to α-pyridone which reacts with methyl iodide only at 100°C under pressure, 2-(trimethylsiloxy)-pyridine reacts with methyl iodide after only brief heating on a water bath with formation of a high yield of *N*-methyl-α-pyridone[281]:



2-(Trimethylsiloxy)pyridine interacts with 2,3,4,6-tetra-acetyl-1-bromoglucose in the presence of $AgClO_4$ even at room temperature, forming *N*-(2,3,4,6-tetra-acetylglucosido)-α-pyridone[281].

Trimethylsilyl esters of 6-trimethylsilylaminopenicillanic acid react with carboxylic acid anhydrides or chlorides and are converted into trimethylsilyl esters of penicillins, which give high yields of the corresponding penicillin on hydrolysis with water[294-296,298,299,348,349]. Cephalosporins are obtained similarly[297].

The complex of benzylpenicillin and potassium methylsiliconate proved to be effective in the treatment of myxomatosis (a virus disease), which is not susceptible to the action of either potassium methylsiliconate or benzylpenicillin separately[350]. Thus it has been shown that the spectrum of the activity of penicillin can be extended by employing its complex with potassium methylsiliconate.

Modern Ideas on the Biosynthesis of Lignin

O.P.Grushnikov and N.N.Shorygina

According to modern ideas, the biosynthesis of lignin consists of two main stages, the first of which includes the formation of aromatic monomeric precursors of lignin synthesised in the plant from carbon dioxide via carbohydrates and the second involves the construction of the lignin macromolecule from the monomeric precursors.
The review deals with studies which led to the determination of the individual stages in the biosynthesis of the aromatic precursors of lignin in plants and also with the main features of the formation of polymeric lignin in its synthesis from coniferyl alcohol *in vitro*. Certain aspects of the biosynthesis of lignin *in vivo* have also been considered.
The bibliography includes 288 references.

CONTENTS

I. Introduction 955

III. Formation of lignin from monomeric precursors 961
IV. Some aspects of the biosynthesis of lignin *in vivo* 969

I. INTRODUCTION

There is no doubt that the study of the formation of lignin in plants is of considerable theoretical and practical interest. As will be shown below, the elucidation of the main aspects of the biosynthesis of lignin yielded much information about its structure. It is also evident that a knowledge of the characteristics of the formation of lignin in plants is necessary for the solution of important problems in the chemistry of lignin such as the relation between various components of plant tissue, the inhomogeneity of lignin, etc. Moreover, information about the formation of lignin in plants may prove valuable also in the development of rational industrial methods for the delignification of vegetable raw materials. Finally, one must emphasise that the study of the biosynthesis of lignin is of interest not only for the chemistry of wood but also for such branches of biology as plant physiology, plant biochemistry, etc.

The problems of the formation of lignin in plants have for a long time attracted the attention of chemists working in the field of the chemistry of lignin but it was not until 1950 to 1960 following the application of new research techniques (the employment of tracer techniques, the method of tissue culture, various biochemical techniques, etc.) that considerable progress has been achieved in this field. The problems of the biosynthesis of lignin in plants have been frequently considered in a number of reviews and monographs [1-13] written mainly by specialists working in this field and therefore dealing primarily with the investigators' own ideas.

The general biosynthesis of lignin in plants can be represented schematically as follows:

$$\text{carbon dioxide} \xrightarrow{\text{photosynthesis}} \text{carbohydrates}$$
$$\xrightarrow{\text{aromatisation}} \text{primary structural elements}$$
$$\xrightarrow{\text{dimerisation}} \text{secondary structural elements}$$
$$\xrightarrow{\text{formation of polymeric molecules}} \text{lignin.}$$

In the biosynthesis of lignin, it is possible to isolate two main stages, the first of which involves the formation of aromatic monomeric precursors of lignin synthesised in the plant from carbon dioxide via carbohydrates and the second involves the formation of lignin macromolecules from the monomeric precursors. Both stages will be examined in detail below.

However, in considering the biosynthesis of lignin in plants one must not forget that the lignification process always takes place in conjunction with other processes involved in the formation of the cell wall. It is known from plant anatomy that wood cells are formed from live cambial tissue which persists throughout the life of dicotyledonous plants and on the activity of which depends the growth of the thickness of the trunk. Owing to the periodic activity of cambium, the wood elements formed from it are deposited during the vegetative period in a certain sequence which results in the formation of annual layers. Secondary wood consists mainly of conducting and mechanical elements which loose their protoplasmic content at an early stage and are converted into physiologically dead tissues. However, wood includes also the live cells of the wood parenchyma and wood rays, the metabolism of these cells characterising the vital properties of secondary wood. On the basis of the foregoing, it is interesting to examine the lignification of plant cell walls within the framework of the metabolism characteristic of cambial and meristematic tissues, since the lignification process is part of the complex biochemical activity of the young cells of the xylem [14-17]. However, examination of this aspect of the biosynthesis of lignin is evidently a task for the future since at present many biochemical processes occurring in the formation of the cell wall have been inadequately investigated. Nevertheless in the discussion below of the chemical aspects of the biosynthesis of lignin, certain problems of the formation of cell walls will be partly elucidated.

Finally the formation of lignin—a phenolic polymer—cannot be treated in isolation from the biosynthesis of many phenolic compounds widely distributed in plants (essential oils, anthocyanins, lignans, tannins, alkaloids, etc.). A definite chemical relation between the elementary structural units of lignin and the above phenolic compounds is evidently a consequence of similar processes involved in the biosynthesis of aromatic substances in plant tissues [18-20]. For a number of reasons, the consideration of these problems is also omitted from this review.

II. FORMATION OF MONOMERIC INTERMEDIATES IN THE BIOSYNTHESIS OF LIGNIN

1. The Role of Carbon Dioxide in the Lignification Process

In 1950 Hartt and Burr [21] reported for the first time that, after sugar cane plants have been exposed to an atmosphere of $^{14}CO_2$ in the dark, the lignin isolated from them is radioactive. Subsequent experiments by Stone, who exposed wheat plants to both prolonged [22] and brief [23] exposure to an atmosphere of $^{14}CO_2$, demonstrated convincingly the involvement of carbon dioxide in the biosynthesis of lignin. After the nitrobenzene oxidation of lignins isolated from the experimental wheat plants, radioactive vanillin, *p*-hydroxybenzaldehyde, and syringaldehyde were obtained. The participation of carbon dioxide in the biosynthesis of lignin was also confirmed by the data of Kreitsberg and coworkers [24,25], who performed experiments with fast growing poplar trees. At the present time the idea that carbon dioxide is the starting material in the biosynthesis of lignin in higher plants is generally accepted.

2. The Role of Carbohydrates in the Lignification Process

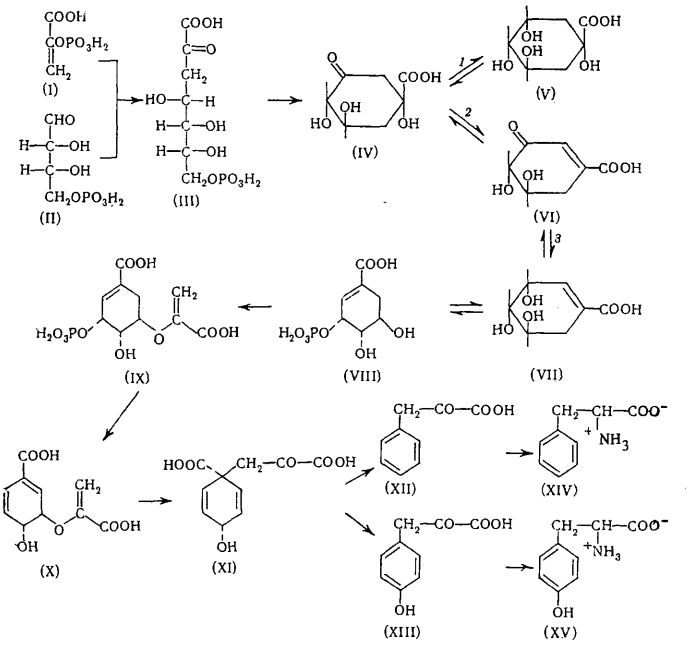
An extensive study on the carbohydrate precursors of lignin was carried out by a group of investigators under the supervision of Nord and Schubert. Schubert and Acerbo [26] demonstrated for the first time an enzymatic mechanism for the conversion of D-glucose into lignin in plants. They introduced labelled D-glucose into the wood of the Norway spruce from the precambial layer of which they isolated radioactive lignin after allowing a period for the metabolism to operate. In a subsequent study by Acerbo et al. [27], a Norway spruce tree was fed [1-^{14}C]-D-glucose and [6-^{14}C]-D-glucose for 28 days, the lignin was oxidised to vanillin, and the latter was decomposed in order to determine the radioactivity of each individual carbon atom. It was shown that in both cases ^{14}C is incorporated preferentially in the 2-, 6-, and 7-positions (carbonyl carbon atoms) and in the 8-position (methyl carbon atom) of the vanillin molecule. These results were confirmed by Kratzl and Faigle [28,29]. Hasegawa and Higuchi also demonstrated the involvement of glucose in the biosynthesis of lignin by introducing labelled glucose into young stems of the eucalyptus [30] and also in tissue culture experiments [31].

However, it has been shown that D-glucose is not the only carbohydrate capable of being converted into lignin. Thus, after injecting radioactive pentoses into the wood of the fast growing poplar, Sergeeva and Kreitsberg [32] isolated radioactive lignin. The involvement of pentoses in the formation of the lignin macromolecule confirmed Klason's hypothesis [33,34] that lignin may be formed from pentosans as a result of intracellular fermentation. Kratzl and Zauner [35] introduced into spruce wood xylitol labelled at all the carbon atoms and observed that the xylitol is incorporated both in polysaccharides and in lignin.

3. The Aromatisation Process

The classical studies by Davis [36-38] and Sprinson [37,39] on mutants of the *Escherichia coli* bacterium established very reliably one of the pathways in the biosynthesis of aromatic aminoacids from carbohydrate precursors. The overall results of these investigations are compiled in Scheme 1.

Scheme 1



According to the sequence presented in Scheme 1, the condensation of phosphoenolpyruvic acid (I), formed in the glycolysis of glucose, and D-erythrose-4-phosphate (II), formed from glucose in the pentose reaction cycle (the "pentose cycle"), leads to the formation of 2-oxo-7-phospho-3-deoxy-D-arabinoheptonic acid (III), which subsequently cyclises into 5-dehydroquinic acid (IV). Subsequent biosynthesis proceeds via the following obligatory intermediates: 5-dehydroshikimic (VI) and shikimic (VII) acids. 5-Phosphoshikimic acid (VIII) combines with a molecule of phosphoenolpyruvic acid (I) to form 3-enol-5-phosphopyruvoylshikimic acid (IX) which is converted into prephenic acid (XI) via the intermediate chorismic acid (X), the presence of which in the reaction cycle was established for the first time by Gibson [40-42]. As shown in Scheme 1, prephenic acid may be decarboxylated with formation of aromatic compounds via two pathways, in only one of which is the ring hydroxyl retained. Thus the first aromatic compounds synthesised by mutants of *E. coli* from carbohydrates are phenylpyruvic acid (XII) and its 4-hydroxy-derivative (XIII), which are converted by transamination into L-phenylalanine (XIV) and L-tyrosine (XV) respectively. Since the above scheme has been considered in detail in all the reviews of the biosynthesis of lignin, we shall not discuss it in depth apart from mentioning that, according to Davis' data [36], shikimic acid (VII) is an obligatory intermediate in the biosynthesis of aromatic compounds in *E. coli*.

At the present time the majority of investigators [3-14] believe that in higher plants the aromatisation of carbohydrate material takes place via shikimic acid (Scheme 1). This hypothesis is based on a number of considerations. Thus Brown and Neish [43] introduced the following ^{14}C-labelled compounds into a solution with wheat and maple cuttings: shikimic acid (VII), L-phenylalanine (XIV), and protocatechuic acid and showed that (VII) and (XIV) were incorporated into the lignin of wheat and maple. Eberhardt

and Schubert[44] converted labelled shikimic acid into the aromatic rings of the lignin macromolecule by implanting the acid in sugar cane plants. The vanillin obtained after the nitrobenzene oxidation of lignin from the experimental plant was decomposed in order to determine the radioactivity of each individual carbon atom. It was found that the vanillin atoms in the 6-, 2-, and 5-positions contained 44, 41, and 0% of the total radioactivity, while the atoms of the initial shikimic acid contained 52, 43, and 0% of the total radioactivity in the same positions. The results of this investigation convincingly demonstrate the conversion of shikimic acid into lignin without any rearrangement of the carbon atoms in its six-membered ring. The studies by Neish and coworkers showed that labelled shikimic acid is incorporated into both phenylalanine (XIV) and tyrosine (XV) by sage[45,46], wheat[47], and buckwheat[47] plants. Since these plants belong to different families, the authors suggested that vascular plants can in general employ shikimic acid for the synthesis of aromatic aminoacids.

Hasegawa and coworkers[48], who studied the distribution of shikimic acid (VII) in plants, established that it is widely distributed in higher plants and particularly in gymnosperms. Among the latter, shikimic acid was detected in greatest amounts in the pine family and the cryptomeria and among angiosperms in the magnolia family. Later the same investigators[49] detected shikimic acid in the leaves of 82 plant species (of the 164 investigated). According to Higuchi's data[50], among 96 woody plant species investigated 70 contained shikimic acid. The wide distribution of shikimic acid in plants is also indicated by Plouvier's results[51-54].

Apart from the data discussed above, the similarity of the biosynthetic pathways to aromatic compounds in micro-organisms and higher plants is also convincingly demonstrated by the observation in plants of enzymes which catalyse some of the reactions shown in Scheme 1. Thus Nandy and Ganguli[55,56] showed that, in the presence of extracts from mung bean seedlings, D-erythrose-4-phosphate (II) and phosphoenolpyruvic acid (I) are converted into 5-dehydroshikimic acid (VI). Mitsuhashi and Davis[57] detected in the pea and in spinach 5-dehydroquinate hydrolyase (5-dehydroquinate dehydratase) (EC 4.2.1.10.)†, which catalyses the (IV) → (VI) conversion (reaction pathway *2*). 5-Dehydroquinate dehydratase was also isolated from the buds of red cabbage[59]. Balinsky and Davis[60,61] isolated shikimate: NADP oxidoreductase‡(shikimate dehydrogenase) (EC 1.1.1.25) from the etiolated epicotyledons of pea seedlings and investigated the effects of various phenolic compounds on them. They found that the enzyme is associated with NADP and does not act on quinic and dehydroquinic acids. Nandy and Ganguli[62] isolated shikimate dehydrogenase from mung bean seedlings and found that in the presence of NADP it determines the position of equilibrium, which is displaced towards the formation of shikimic acid. Higuchi and Shimada[63] investigated the changes in the activity of shikimate: NADP-oxidoreductase in relation to the lignification of bamboo. It is noteworthy that Balinsky and Davis[64] isolated 5-dehydroquinate dehydratase and shikimate dehydrogenase from the extracts of certain higher plants and Gamborg[65] detected these enzymes in suspensions of cell cultures from a number of plants. The above investigators believe that the wide distribution of these enzymes is evidence of their important role in the biosynthesis of aromatic compounds in higher plants.

A few words should be said about the role of quinic acid (V) in the biosynthesis of monomeric lignin precursors. The wide distribution of quinic acid in higher plants[11,48,68,51-54,66-68] evidently indicates that in the biosynthesis of aromatic compounds in plants it can play a more important role than in bacteria. By exposing young rose plants to an atmosphere of $^{14}CO_2$, Weinstein et al.[69] isolated labelled quinic acid, the specific radioactivity of which was higher than that of shikimic acid isolated from the same plants. Subsequent experiments by these investigators[70-72] showed that, when various vascular plants are fed labelled quinic acid, the latter is converted into shikimic acid (VII), phenylalanine (XIV), and tyrosine (XV). Goldschmid and Quimby[73] reported that interconversion of quinic and shikimic acids in hemlock branches. The data obtained by Sergeeva and coworkers[74] in a study of the formation of shikimic and quinic acid in year old poplar shoots fed $^{14}CO_2$ demonstrate that, during the growth of the plant, the acids are genetically related. Gamborg[75] achieved the interconversion of quinic and shikimic acids (reaction pathways *1–3* in Scheme 1) *in vitro* with the aid of three enzymes: 5-dehydroquinate dehydratase, shikimate dehydrogenase, and quinate: NAD oxidoreductase (quinate dehydrogenase) (EC 1.1.1.24) isolated from suspensions of plant cell cultures from mung beans. It is noteworthy that Gamborg was the first to detect quinate dehydrogenase in higher plants[65] and to investigate in detail the properties of this enzyme after isolating it from mung bean cell culture suspension[76].

Among the reactions quoted in Scheme 1, the conversion of shikimic acid (VII) into prephenic acid (XI) has been least thoroughly investigated[77]. So far enzymes catalysing the individual stages of this reaction have not been isolated from micro-organisms in a pure form. In higher plants the enzymes have still not been detected. Therefore there is an evident need for a more detailed study of this reaction at an enzymatic level.

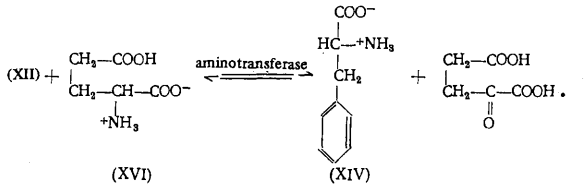
Gamborg and Simpson[78] studied the conversion of prephenic acid (XI) into phenylalanine (XIV) and tyrosine (XV) by enzymes isolated from mung bean plants. They established that mung bean extracts contain aminotransferase (transaminase), prephenate aromatase, and prephenate dehydrogenase, which are responsible for these conversions, and noted that it is impossible to demonstrate the enzymatic formation of phenylpyruvic acid (XII), since it is formed spontaneously when an acid acts upon prephenate. Gamborg and Keeley[79] isolated from the cotyledons of the wax bean prephenate dehydrogenase, which in the presence of NADP catalyses the (XI) → (XIII) conversion. This enzyme was also detected in the cotyledons and shoots of mung bean plants. A study of the changes in the concentration of prephenate dehydrogenase during the development of mung bean plants showed that the maximum concentration is observed in the cotyledons 4–5 days after the start of growth.

The final stage in the formation of phenylalanine and tyrosine, which play significant roles in the biosynthesis not only of lignin but also of other plant phenols[18-20], consists of the transamination of the ketoacids (XII) and (XIII). The transamination reactions were studied in various plants (lupin, maize, barley, pea, oats, and mung beans) by Wilson et al.[80], who detected a number of aminotransferase systems in these plants (α-oxoglutaric

†In these cases where the systematic name of the enzyme is followed by its number (code) in brackets, the name is based on the international nomenclature[58]; in the remaining cases the authors' own designations of the enzymes are retained.

‡ NADP = nicotinamide-adenine dinucleotide phosphate; NAD = nicotinamide-adenine dinucleotide.

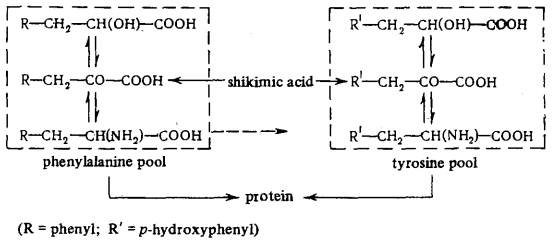
acid–alanine; α-oxoglutaric acid–aspartic acid; α-oxoglutaric acid–glycine; α-oxoglutaric acid–phenylalanine; oxaloacetic acid–alanine; pyruvic acid–methionine). The authors isolated, from etiolated white lupin seedlings and barley seedlings subjected to illumination, aminotransferases which catalyse the transamination of α-oxoglutaric acid with 17 different aminoacids. The authors' experiments with labelled compounds confirmed the presence of aminotransferases in the plants. Kretovich and Uspenskaya [81] investigated the formation of phenylalanine (XIV) as a result of transamination between phenylpyruvic acid (XII) and glutamic (XVI) or aspartic acid in homogenates of pea seedlings:



Gamborg [82,83] isolated from young mung bean plants an aminotransferase catalysing the transamination of a number of cyclic and aromatic aminoacids (including phenylalanine and tyrosine) in the presence of pyruvate or α-oxoglutarate, which behave as amino-acceptors.

In a study of the conversion of labelled shikimic acid into phenylalanine (XIV) and tyrosine (XV) by wheat and buckwheat plants, Gamborg and Neish [47] noted the ease of the interconversion of the α-hydroxy-, α-oxo-, and α-aminophenylpropanoic acids synthesised from shikimic acid and on the basis of their results concluded that there are two different pools of phenyl and *p*-hydroxyphenyl derivatives (the so called "phenylalanine pool" and the "tyrosine pool") (Scheme 2). Within each pool α-hydroxy or α-oxo-acids are readily converted into the corresponding aminoacids. At the same time, no conversion of compounds of the tyrosine pool into those of the phenylalanine pool was observed (the reverse conversion takes place to a significant extent). In addition it was shown that shikimic acid is a better tyrosine precursor than any compound of the phenylalanine pool. The results demonstrate that plants, like bacteria, form tyrosine from prephenic acid as a result of transamination (Scheme 1) but they are also capable of producing it by the hydroxylation of phenylalanine.

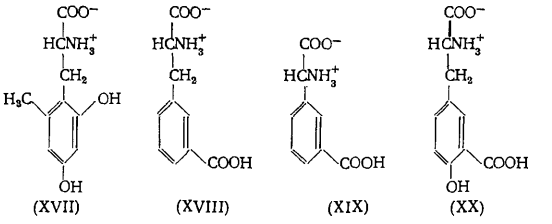
Scheme 2



(R = phenyl; R' = *p*-hydroxyphenyl)

The studies discussed above, which involved both the isolation of plant enzymes and experiments with labelled compounds, suggest that aromatic compounds are formed in plants via a pathway which is identical or very similar to the sequence of reactions presented in Scheme 1. At the same time one should note that many results support the hypothesis that in higher plants there are other synthetic pathways to aromatic lignin precursors than those already discussed. In particular Nandy and Ganguli [55,56] observed that the cell-free extract from mung bean converts glucose-6-phosphate and glucose-1-phosphate into dehydroshikimic acid. Higuchi and Shimada [84] isolated from bamboo shoots D-glucose-6-phosphate: NADP oxidoreductase (EC 1.1.1.49) and 6-phospho-D-gluconate: NADP oxidoreductase (EC 1.1.1.44) and investigated the activities of these enzymes in relation to lignification.

In addition, it is interesting to note that, apart from phenylalanine and tyrosine, certain other aromatic acids have been detected in certain plants. Thus Schneider [85] isolated orcinylalanine (XVII) from the seeds of *Agrostemma githago*. Thompson et al. isolated *m*-carboxy-L-phenylalanine (XVIII) [86] and *m*-carboxy-L-phenylglycine (XIX) [87] from the bulbs of *Iris tingitana*. Larsen and Kjaer [88] detected *m*-carboxy-L-tyrosine (XX) in the seeds of *Reseda odorata*. Unfortunately experiments on the biosynthesis of these aminoacids were not made and it is difficult to say whether they are formed via shikimic acid or in some other way:



According to modern ideas [18–20,89], there exist two main biosynthetic pathways to phenolic compounds: (1) the shikimate pathway, and (2) the acetate–malonate pathway. Studies with labelled compounds, discussed in detail by Neish [90], showed convincingly that the biosynthesis from acetate does not play an appreciable role in the formation of lignin, which is produced from carbohydrates via shikimic acid. It is quite likely that future studies will make it possible to refine and supplement the sequence involved in the formation of aromatic lignin precursors presented in Scheme 1 but there is already no doubt that the scheme correctly reflects the main processes occurring in the biosynthesis of aromatic compounds in plants.

4. Conversion of Aromatic Aminoacids into Monomeric Lignin Precursors

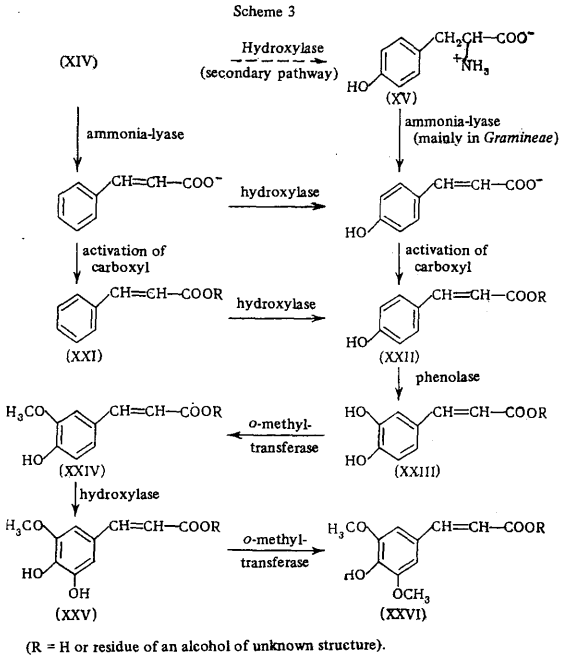
Brown and Neish [91,92] carried out an extensive study on the formation of lignin by introducing into plants labelled phenolic compounds (C_6-C_1 and C_6-C_3), which were regarded as potential intermediates in the biosynthesis of lignin. The results demonstrated that phenylalanine (XIV) is an effective precursor of lignin in many plants, while tyrosine (XV) is used for the biosynthesis of lignin only in a limited number of species. Subsequent studies by Neish [93] and Brown [94], who investigated the formation of lignin from [^{14}C]phenylalanine and [^{14}C]tyrosine in a number of plant species, showed that only species of *Gramineae* employed with equal efficiency both phenylalanine and tyrosine. Although these plant species can incorporate *p*-coumaric acid (XXII, R = H) in lignin, *Gramineae* are distinguished by their capacity to convert tyrosine directly into *p*-coumaric acid, while all other plants form this acid from phenylalanine via cinnamic acid (XXI, R = H).

The above conclusion was confirmed by studies at the enzymatic level. Koukol and Conn [95] demonstrated the presence in six plant species of an enzyme which catalyses the deamination of phenylalanine to cinnamic acid and which was subsequently called phenylalanine ammonia-lyase. At the same time Neish [96] detected in seven grass species an analogous enzyme, tyrosine ammonia-lyase, which deaminates tyrosine to *p*-coumaric acid. Later Young and Neish [97] studied the properties of the above ammonia-lyases which they isolated from wheat plants (*Triticum aestivum*) and bracken (*Pteridium aquilinum*). In addition, Neish and coworkers [98] studied a number of plants belonging to different species and showed that, although tyrosine ammonia-lyase can be detected in other families, only *Gramineae* contain the maximum concentrations of this enzyme.

Thus the results of the above investigations indicate two possible pathways to the formation of *p*-coumaric acid: by direct action of ammonia-lyase on tyrosine, mainly in *Gramineae*, or by the hydroxylation of cinnamic acid formed as a result of the deamination of phenylalanine.

McCalla and Neish [46] studied the sequence of conversions from cinnamic acid (XXI, R = H) to sinapic acid (XXVI, R = H) by feeding labelled phenylalanine to sage cuttings (Scheme 3). They extracted labelled *p*-coumaric (XXII, R = H), caffeic (XXIII, R = H), ferulic (XXIV, R = H), and sinapic (XXVI, R = H) acids, the different rates of incorporation of ^{14}C in each acid agreeing with the sequence shown in Scheme 3. Moreover, the above sequence is confirmed by experiments in which labelled cinnamic and other acids were introduced separately, which led to the observation of rapid conversion of the additive into the final compounds of the sequence and relatively slow conversion into the initial compounds§.

Scheme 3



(R = H or residue of an alcohol of unknown structure).

§ There is convincing evidence for the demethylation of sinapic [99-101] and ferulic [102,103] acids in plants, but the mechanism of this process has not yet been established.

Since it is difficult to suppose that the reactions considered occurred in plants with acids in a free form, the authors suggested that the cinnamic acid derivatives indicated in Scheme 3 are present mainly in alkali-labile bound forms, which are evidently esters. Later El-Basyouni and Neish [104,105], obtained more convincing evidence for the involvement of these bound forms, which they thought to be soluble and insoluble esters, in the formation of lignin. The nature of the bound forms is not entirely clear, but it is believed that they can be bound either to protein fractions [13] or they may be esters of glucose [106-109] or quinic acid [110].

The individual stages of the sequence presented in Scheme 3 have been confirmed by studies at an enzymatic level. Thus Nair and Vining [111] isolated from spinach leaves a phenylalanine hydroxylase, which catalyses the hydroxylation of L-β-phenylalanine to tyrosine at pH 4.2. The same investigators [112] demonstrated the presence in spinach leaves of cinnamic acid 4-hydroxylase, which characterises the hydrolysis of *trans*-cinnamic acid to *p*-coumaric acid. An analogous enzyme was isolated by Russell and Conn [113] from the terminal buds of the pea and Higuchi and coworkers [114] obtained it from bamboo, asparagus, and *Ginkgo biloba* shoots and from Japanese cedar seedlings.

Byerrum et al. [115] showed that in the metabolism of barley and tobacco plants the methyl group of methionine is involved in the formation of the methoxy-groups of lignin. With the aid of labelled compounds, they demonstrated that the reaction consists of the transfer of the methyl group from the sulphur atom of methionine to an oxygen atom in lignin and therefore it can be regarded as an example of transmethylation in higher plants. Later it was shown that in tobacco plants the donors of the methyl group in the formation of methoxy-groups of lignin may be glycine, serine, and formaldehyde [116] and in the poplar glycine may serve this purpose [117]. A number of investigators [118-120] established the presence in grasses and in woody shrubs of enzymes capable of methylating caffeic acid in the presence of *S*-adenosylmethionine. Hess [121,122] detected in petunias and certain other plants an analogous enzyme which methylates 5-hydroxyferulic acid to sinapic acid in the presence of adenosine triphosphate, methionine, or *S*-adenosylmethionine, confirming thereby data obtained earlier with the aid of labelled compounds [101]. Higuchi et al. [123] reported the isolation from bamboo shoots of an *o*-methyltransferase which catalyses the formation of ferulic and sinapic acids. They demonstrated that the activity of the enzyme gradually increases as the bamboo shoots are lignified. Higuchi and coworkers [124] compared the specificities of the *o*-methyltransferases extracted from the bamboo and the poplar (angiosperms) and from *Ginkgo biloba* (gymnosperms). They showed that the methyltransferase from the bamboo and the poplar is *meta*-specific for caffeic, 3,4,5-trihydroxycinnamic, and 5-hydroxyferulic acids. The rate of formation of sinapic acid (XXVI, R = H) from 5-hydroxyferulic acid (XXV, R = H) in the reaction *in vitro* is higher than the rate of formation of ferulic acid (XXIV, R = H) from caffeic acid (XXIII, R = H). On the other hand, the methyltransferase from *Ginkgo biloba* methylates only caffeic acid and not 3,4,5-trihydroxycinnamic and 5-hydroxyferulic acids. The authors suggest that the observed difference between the specificities of the *o*-methyltransferases from gymnosperms and angiosperms is one of the factors responsible for the differences between the metabolism of lignin in these groups of plants. It is noteworthy that, according to the data of Kratzl and Puschmann [125], the methoxylation

of the aromatic ring can occur also in the stage involving the oxidation of coniferyl alcohol.

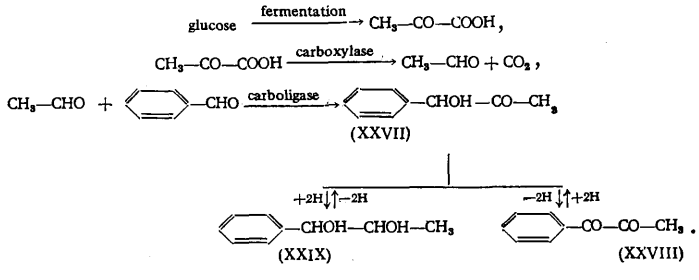
Vaughan and Butt[126-128] isolated from spinach leaves a copper-containing preparation of phenolase which catalysed the hydroxylation of *p*-coumaric acid to caffeic acid. The authors showed that this enzyme behaves like an oxidase with a mixed function (both molecular oxygen and an electron donor, for example ascorbate, NAD.H_2, or 6,7-dimethyl-5,6,7,8-tetrahydropteridine, are essential for the completion of the hydroxylation reaction).

The concluding stage of the biosynthesis of the monomeric precursors of lignin is enzymatic reduction of ring-substituted derivatives of cinnamic acids to the corresponding derivatives of cinnamyl alcohols. A similar conversion of ferulic acid was investigated by Higuchi and Brown[129], who employed a ^{14}C-labelled substrate and showed that ferulic acid is reduced by wheat plants to coniferyl alcohol via the formation of an aldehyde as an intermediate. Gross and Zenk[130-132] confirmed these reactions by studies at an enzymatic level, having isolated the corresponding enzymes from the mycelium of the fungus *Neurospora crassa*. The previously unknown arylaldehyde: NADP oxidoreductase (EC 1.2.1) catalyses the reduction of the carboxy-groups of aromatic acids to the corresponding aldehydes. The second enzyme aryl carbinol: NADP oxidoreductase (EC 1.1.1.2), which catalyses the reversible reduction of aromatic aldehydes to aromatic alcohols, differs from the familiar alcohol dehydrogenases, acting preferentially on primary aromatic alcohols. The authors noted a broad substrate specificity of the enzymes isolated and investigated their properties. Similar enzymes have not so far been isolated from higher plants.

5. The Possibility of Other Biosynthetic Pathways to Monomeric Lignin Precursors

Higuchi[50,133,134] suggested that compounds with the phenylpropane structure, which are monomeric precursors of lignin, may be synthesised in plants via pathways other than those discussed above, namely as a result of a $C_6-C_1 + C_2$ condensation, i.e. by the addition of C_2 compounds to derivatives of phenylmethane formed from 5-dehydroshikimic or shikimic acid.

As early as 1921 Neuberg and Hirsch[135] observed that, in the fermentations of sucrose or pyruvic acid in the presence of benzaldehyde, acetylphenylmethanol (XXVII) is formed. Part of the ketol produced was oxidised to benzoyl methyl ketone (XXVIII), while the remainder was reduced to methylphenylethylene glycol (XXIX). The authors suggested the following sequence of reactions:



The enzyme which catalysed the last reaction was called carboligase. Later Neuberg and coworkers[136,137] reported that, when yeast carboligase acts on aromatic aldehydes (*o*-chlorobenzaldehyde, anisaldehyde, and *o*-toluic aldehyde), the corresponding ketols are formed. Recently the formation of acetylphenylmethanol (XXVII) catalysed by yeast carboligase was noted also by other investigators[138-140].

Since the structures of the side chains of the ketols and diketones thus produced are identical with the products of the ethanolysis of lignin (the so called "Hibbert's ketones"), Higuchi[133,134,141] investigated the possibility of the formation of phenylpropane precursors of lignin as a result of a reaction catalysed by carboligase.

Vanillin, syringaldehyde, and *p*-hydroxybenzaldehyde were separately subjected to fermentation by brewer's yeast in sucrose solution. After fermentation, the resulting solutions were found to contain methyl vanilloyl ketone, methyl syringoyl ketone, and *p*-hydroxybenzoyl methyl ketone, part of these compounds being reduced to the corresponding alcohols and the remainder being oxidised to the corresponding acids. The diketones obtained are identical with certain products of the ethanolysis of lignin. The authors suggested a subsequent formation from the diketones of compounds of the type of acetylphenylmethanol and benzoylmethylmethanol, although the existence of these ketones has not been confirmed experimentally.

The results of a number of investigators[134,141-143] indicate the presence of C_6-C_1 aldehydes in the cambial sap of many woody plants, wheat, and bamboo shoots. Stepanov and Kuzin[144] detected carboligase in the leaves of a number of plants. In addition, Brown and Neish[91,145] reported that, when wheat plants are fed labelled preparations of vanillin and *p*-hydroxybenzoic acid, the latter are incorporated into the wheat lignin. Ishikawa and Takaichi[146] observed that, when adult pea plants are incubated with vanillin and *p*-hydroxybenzaldehyde, their lignin content increases relative to control plants. Freudenberg and coworkers[147,148] showed that labelled [^{14}C]glucovanillin is incorporated into the lignin of young pines. Kratzl[149,150] reported the incorporation of labelled *p*-creosol into lignin.

The results of the above investigations enabled Higuchi[50,133,134] to suggest that C_6-C_1 aldehydes, which may be formed in plants via different pathways[151], are converted into phenylpropanols as a result of a reaction catalysed by carboligase. The phenylpropanols are further transformed by rearrangements and dismutations, as in the mechanism proposed by Hibbert[152,153] and discussed in the next section.

In conclusion of the discussion of questions relating to the formation of monomeric lignin precursors as a result of a $C_6-C_1 + C_2$ condensation, we may note that although such processes may occur in plants, they probably play only a secondary role in the biosynthesis of lignin.

6. The Role of Coniferin in the Lignification Process

As early as 1861, Hartig[154] detected coniferin, which is the β-D-glucoside of coniferyl alcohol, in the cambial sap of conifers. It has now been shown[155] that coniferin is encountered mainly in conifers, comprising six families and 15 species (the syringic analogue of coniferin—syringin—has been detected also in certain deciduous trees). As will be shown below, many investigators regarded coniferin as a precursor of lignin in the wood of conifers

owing to its evident biochemical relation to coniferyl alcohol. Freudenberg and Bittner [156] introduced coniferin synthesised from labelled [^{14}C]coniferyl alcohol under the bark of young spruce stems. Two months after injection, more than 90% of ^{14}C was detected in the lignin fraction. Later Freudenberg and Niedercorn [157] showed that labelled phenylalanine may be converted into both coniferin and into lignin by young spruce stems, and therefore they suggested that coniferin is an intermediate in the formation of lignin. The experiments of Freudenberg and coworkers [147], which are discussed in detail below, showed that coniferin is hydrolysed by β-glucosidase to coniferyl alcohol, from which lignin macromolecules are then constructed. Studies on the role of coniferin by the method of tissue culture [158–165] demonstrated stimulation of lignification by both coniferin and syringin. Kratzl and coworkers [166–168] determined quantitatively the coniferin incorporated in spruce lignin. These studies showed that the aglucone of coniferin is incorporated into lignin without a rearrangement of the side chain.

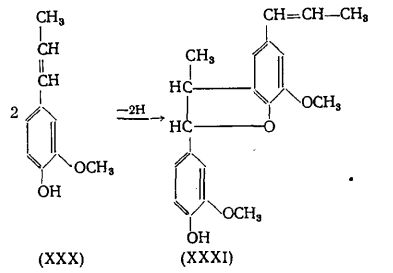
However, despite the above investigations, the question of the role of coniferin in the lignification process still cannot be resolved quite unambiguously. The reason is both the fact that the distribution of coniferin is not universal and the failure to detect β-glucosidase in some lignification processes [150].

III. FORMATION OF LIGNIN FROM MONOMERIC PRECURSORS

The studies discussed in the preceding section concerning the detection in plants of various enzymatic systems catalysing the individual stages of the biosynthesis of monomeric lignin precursors and also experiments with various labelled compounds have been carried mainly *in vivo*, i.e. on plants or tissue cultures. The studies discussed in this section involve mainly experiments *in vitro*. This method has both many advantages and significant disadvantages, which will be discussed below.

1. A Brief Historical Review of Studies on the Biosynthesis of Lignin *in Vitro*

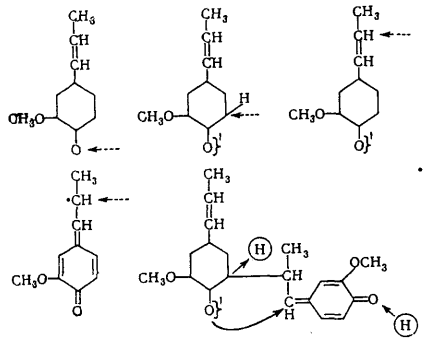
After the determination of the structure of the glucoside coniferin present in the cambial sap of conifers during the vegetative period, Tiemann and Mendelsohn [169] suggested in 1875 that there is a definite genetic relation between coniferin and lignin. In 1897 Klason [170] used this idea in his studies on the chemistry of lignin and suggested that lignin is a product of the condensation polymerisation of coniferyl alcohol formed in the plants on enzymatic hydrolysis of coniferin. Later Klason [171–178] regarded lignin as a condensation product of coniferaldehyde formed by the oxidation of coniferyl alcohol. In 1908 the French chemists Cousin and Hérissey [179,180] observed that, when isoeugenol (XXX) is dehydrogenated, a crystalline product is formed, among others; according to analytical data, it consists of two eugenol molecules. The authors dehydrogenated isoeugenol with an alcoholic solution of $FeCl_3$ or with dehydrogenases from the sap of the fungus *Russula delica* in the presence of oxygen and in both cases obtained the same product. According to the hypothesis of Cousin and Hérissey, the product, which they called dehydrodi-isoeugenol, is a biphenyl derivative. It was not until 1933 that Erdtman [181,182] demonstrated the true structure of dehydrodi-isoeugenol and showed that it is a phenylcoumaran (XXXI):



(XXX) (XXXI)

Erdtman [182] proposed a mechanism for the dehydropolymerisation of isoeugenol to dehydrodi-isoeugenol via the intermediate formation of an oxygen radical¶. The mechanism is presented in Scheme 4 as formulated by the author [182].

Scheme 4



According to Erdtman's hypothesis, the formation of dehydrodi-isoeugenol may be regarded as a model of the biosynthesis of lignin in plants, which is achieved as a result of the dehydropolymerisation of guiacylpropane derivatives containing oxygen in the side chains. Erdtman's hypothesis became the starting point of all subsequent studies on the biosynthesis of lignin, which will be discussed below.

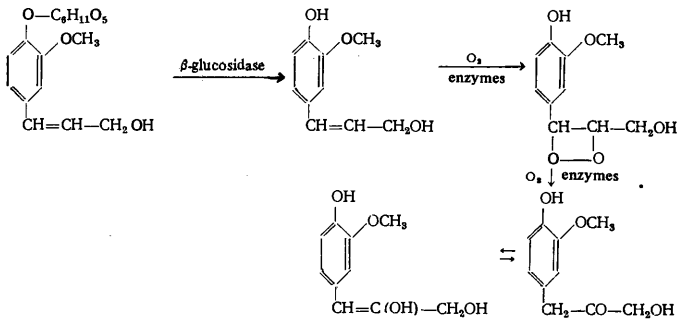
The isolation and identification of various monomeric products of the ethanolysis of wood ("Hibbert ketones") enabled Hibbert to put forward in 1941 the so called dismutation hypothesis [152,153]. According to this hypothesis, the respiration of plant cells is catalysed by substances of the type of coniferyl alcohol, which function as oxygen transferring agents. Hibbert believed that the oxidation-reduction system in plant cells is analogous to the system proposed by Szent-Györgyi [187] for animal cells, which is evident from the Scheme below:

Szent-Györgyi system for animal cells	*Hibert system for plant cells*
HOOC—CO—CH_2—COOH	R—CO—CH_2—CH_2OH
$+2H\downarrow\uparrow-2H$	$+2H\downarrow\uparrow-2H$
HOOC—CH(OH)—CH_2—COOH	R—CH(OH)—CH_2—CH_2OH
$\downarrow-H_2O$	$\downarrow-H_2O$
HOOC—CH=CH—COOH	R—CH=CH—CH_2OH
$+2H\downarrow\uparrow-2H$	$+2H\downarrow\uparrow-2H$
HOOC—CH_2—CH_2—COOH	R—CH_2—CH_2—CH_2OH
	(R = 4-hydroxy-3-methoxyphenyl)

¶ It is noteworthy that the hypothesis of a radical mechanism of the dehydrogenation of phenols, which subsequently became widely accepted in organic chemistry and biochemistry, was first put forward by Pummerer [183–186].

Thus, according to Hibbert's hypothesis, monomeric phenyl compounds are synthesised by plants as respiration catalysts. In higher plants, in the postmortem state of the cells, these compounds are oxidised and readily undergo various reactions (dehydrogenation, condensation, and polymerisation) leading to the formation of lignin. Hibbert's hypothesis was subsequently developed in Manskaya's studies.

In 1947 Manskaya [188,189] investigated the oxidation processes in wood relating to lignin formation. She showed that the cambial tissue and the wood of the new annual layer in the pine contain oxidising enzymes: peroxidase and polyphenol oxidase, whose substrates are coniferin and its derivatives. Manskaya pointed out the equilibrium in the oxidation-reduction processes in the cambial tissue as a result of which phenol oxidation products do not accumulate in the cells. When live cells die during the wood formation process, oxidation processes begin to predominate markedly over reduction processes and polyphenol oxidation products begin to be deposited in the form of lignin. According to Manskaya's hypothesis, the deposition of lignin is related directly to the breakdown of the respiratory apparatus in plant cells. The hypothesis states that the oxidation of coniferyl alcohol in the lignifying cells of the cambium may be represented by the following scheme:



The products obtained as a result of the enzymatic oxidation are converted by further condensation into lignin, which is deposited in the cell walls of the wood. The results of Manskaya's study [190] of the changes in the activity of peroxidase in cambium and the adjacent woody layer and also of the corresponding changes in the coniferin content showed that in the period of maximum enzymatic activity the coniferin content was lowest and conversely. The results of this investigation served as a basis for the conclusion that coniferin is the substrate of the enzymes. Later Manskaya and Bardinskaya [142] oxidised coniferyl alcohol with peroxidase (from the precambial layer of the pine) or by polyphenol oxidase (from the lignified central part of the root of the sugar beet) and obtained polymeric compounds which were close in their elemental composition, the content of functional groups, the molecular weight, and ultraviolet spectroscopic data to Freudenberg's preparations obtained from coniferyl alcohol by the action of enzymes from the field mushroom.

In considering the questions of the biosynthesis of lignin, attention should be concentrated on the work of Freudenberg and his coworkers the aim of which was to prepare and investigate biosynthetic lignin. The studies of these investigators over a period of many years, which involved highly sophisticated experiments, made a considerable contribution to the chemistry of lignin, having provided information not only about the possible pathways of its biosynthesis but also about the structure of this complex polymeric substance.

In 1943 Freudenberg and Richtzenhain [191] and later Richtzenhain alone [192-194] observed the formation of polymeric lignin-like materials when various monomeric phenolic derivatives of the guiacyl and syringyl series were acted upon by the unpurified enzymes of the mushroom *Psalliota campestris*. The results led the authors to the conclusion that lignin is formed by the enzymatic dehydrogenation of substituted phenol derivatives, confirming thereby Erdtman's hypothesis.

In 1949 Freudenberg [195,196] reported the preparation of biosynthetic lignin, which he called dehydropolymer (DHP). The preparation was obtained by the action of enzymes from the sap of the mushroom (*Psalliota campestris*) on coniferyl alcohol at a neutral pH, 20°C and with aeration over a period of three days. The yield of DHP was 93% relative to the initial coniferyl alcohol. The resulting polymer was very close to lignin isolated from spruce wood in terms of important characteristics, such as solubility, elemental composition, the content of functional groups, the yield of formaldehyde on distillation with 28% sulphuric acid, the yield of aromatic acids on methylation, fusion with alkali, remethylation, and oxidation with $KMnO_4$, colour reactions, ultraviolet spectra, etc. This study began a large cycle of investigation on the enzymatic dehydrogenation of coniferyl alcohol. Later Freudenberg and his coworkers studied the principles of the biosynthesis of lignin *in vitro*, investigated the dehydrogenation of coniferyl alcohol by isolating the intermediates, and compared the properties of DHP and spruce wood lignin.

In 1963 Freudenberg and Harkin [197] reported at during the vegetative period the cambial sap contains, together with coniferin, small amount of *p*-glucocoumaryl alcohol and syringin. Accordingly, Freudenberg and coworkers [198-200] dehydrogenated a mixture of *p*-coumaryl, coniferyl, and sinapyl alcohols in molar proportions of 14 : 80 : 6 in order to obtain biosynthetic lignin closest to the lignin from conifers.

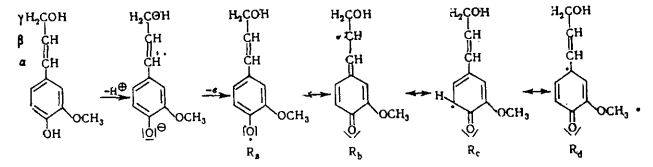
It would hardly be useful to consider the studies of Freudenberg and his coworkers in their historical sequence, which, while giving an idea about the evolution of the authors' views on the structure and biosynthesis of lignin *in vitro*, would make it difficult to describe the present state of this problem. Therefore in subsequent sections we shall consider the main aspects of Freudenbergs investigations and his principal conclusions, which constitute the foundation of present ideas on the biosynthesis of lignin.

2. The Mechanism of the Polymerisation of Coniferyl Alcohol

According to Freudenberg's views [199,201,202]†, coniferyl alcohol is polymerised via a radical mechanism. In the course of the study of the enzymatic dehydrogenation of coniferyl alcohol, Freudenberg and his coworkers [201,203-205] established that, when the action of dehydrogenases from field mushrooms or cambium on an aqueous solution of coniferyl alcohol is terminated as soon as the latter ceases to be detected in the reaction mixture, it is possible to isolate dimeric intermediates in the dehydrogenation reaction. By extracting the reaction mixture with

† Since Freudenberg's studies have served as a basis for his numerous publications dealing with the evolution of his views, in each case the references include both the first publication on the given problem and the latest communications which contain his present views.

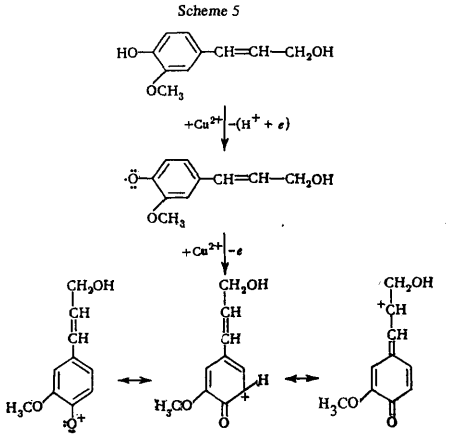
methylene chloride or n-butyl alcohol, dehydrodiconiferyl alcohol [203], DL-pinoresinol [204], and β-coniferyl ether of guiacylglycerol [201] were isolated and then identified. On the basis of these intermediates in the biosynthesis of lignin *in vitro* and also Erdtman's hypothesis that lignin is formed via a radical mechanism, Freudenberg put forward the following scheme for the conversion of coniferyl alcohol in the course of its enzymatic dehydrogenation:



According to this scheme, during enzymatic dehydrogenation, the coniferyl alcohol molecule loses the hydrogen atom from the phenolic hydroxyl to form the aryloxy-radical R_a. This radical can exist in any of the mesomeric forms indicated (R_a–R_d). Freudenberg et al. [206] established that the half-life of these mesomeric forms in a 1 : 1 (by volume) dioxan–water mixture is 45 s. The mesomeric forms of the radical recombine further with one another and undergo various transformations, discussed in detail in the next section, which leads ultimately to the formation of biosynthetic lignin (DHP). One must emphasise that, according to Freudenberg's data [207–209], the dehydrogenation of coniferyl alcohol is not a specific reaction, since it can be initiated by various reactants: laccase isolated from the sap of field mushrooms in the presence of atmospheric oxygen; horseradish peroxidase in the presence of H_2O_2; laccase and peroxidase isolated from the precambial layer of spruce wood; a number of inorganic agents [copper(II) salts, MnO_2, lead peroxide]; radicals such as, for example, 2,4,6-tri-t-butylphenoxyl, etc.

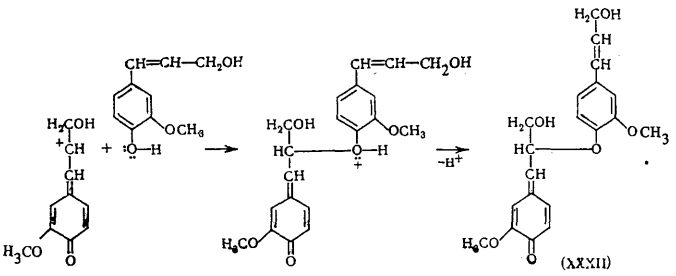
Apart from the radical mechanism of the polymerisation of coniferyl alcohol, discussed above, one should consider the ionic mechanism proposed by Adler [210] (Scheme 5).

Scheme 5



According to Adler's views, the initial reaction has a radical mechanism and takes place without electron transfer. The suggested subsequent "one-electron transfer", as a result of which an unpaired electron is removed from the radicals formed initially, can be achieved either enzymatically or without the involvement of enzymes using Cu^{2+} or Fe^{3+} as catalysts.

The mesomeric cation thus produced can react with coniferyl alcohol which results in the formation of the dimeric quinone methide (XXXII). As will be shown below, the formation of this quinone methide may be represented also as due to the combination of the mesomeric forms R_a and R_b: [201]

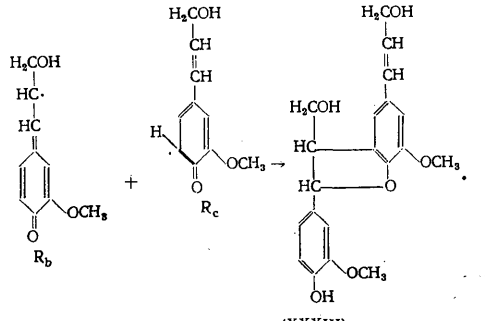


(XXXII)

3. The Principles of the Growth of the DHP Molecule and the Principal Intermediates Isolated in the Course of the Formation of Biosynthetic Lignin

Freudenberg established [211] that the decomposition of the enzymes by NaCN can interrupt the enzymatic dehydrogenation of coniferyl alcohol at any stage with the aim of the subsequent isolation of the intermediate in the biosynthesis of lignin *in vitro*. The best yield of low-molecular-weight intermediates in the dehydrogenation of coniferyl alcohol was obtained after removing approximately one atom of hydrogen from each molecule of the initial carbinol. When large amounts of hydrogen are eliminated, water-insoluble products with a high molecular weight are produced. The intermediates in the biosynthesis of lignin *in vitro* thus produced were separated by paper chromatography. After treating the chromatograms with diazobenzenesulphonic acid, about 40 spots were detected [212]. Freudenberg and coworkers [4,213] succeeded in isolating and then identifying a number of dimeric, trimeric, and oligomeric intermediates. Freudenberg suggested [214] that the intermediates may be referred to as lignols.

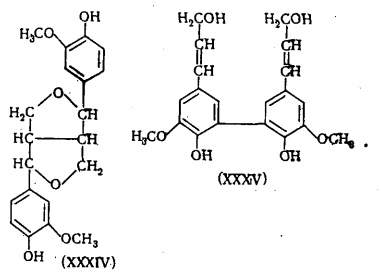
As mentioned in the preceding section, Freudenberg suggested that dilignols are produced as a result of the combination of the mesomeric forms R_a–R_d of the aryloxy-radicals obtained by the enzymatic dehydrogenation of coniferyl alcohol. Thus the combination of the R_b and R_c forms yields dehydrodiconiferyl alcohol (XXXIII): [203]



(XXXIII)

A similar example of the stabilisation of two mesomeric R_b forms owing to dimerisation is provided by the formation of DL-pinoresinol (XXXIV) [204] and also by the formation of dehydrobisconiferyl alcohol (XXXV) [211] as a

result of the combination of two mesomeric forms R_b:

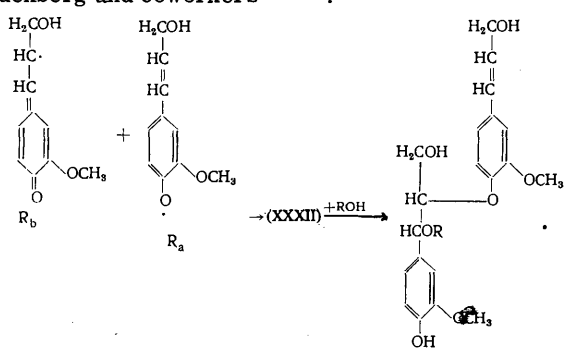


(XXXIV) (XXXV)

According to Freudenberg's views [208,215], the quinone methide (XXXII), formed by the combination of the mesomeric forms R_a and R_b, plays an important role in further biosynthesis of lignin [201]. It is noteworthy that the quinone methide structure proposed initially as hypothetical was subsequently confirmed by ultraviolet spectroscopic measurements [216]. At the same time it was established that the half-life of the quinone methide in a 1 : 1 (by volume) dioxan–water mixture at 20°C is about 60 min. The quinone methide is unstable and cannot be stabilised by an intramolecular rearrangement. Consequently, it is stabilised intramolecularly by combination with the elements of water or other dissociated hydroxyl-containing compounds, provided that steric conditions allow it. The addition of water to quinone methide leads to the formation of the β-coniferyl ether of guiacylglycerol (XXXVI), [201] which constitutes, together with the dilignols (XXXIII) and (XXXIV), the main part of the dimeric intermediates. It is interesting that these three principal dilignols in the biosynthesis of lignin *in vitro* were also detected by Freudenberg and Harkin [197] in the cambial sap of the spruce.

Enzymatic dehydrogenation of coniferyl alcohol in aqueous solution containing 30% of methanol results in the formation of the α-methyl-β-coniferyl ether of guiacylglycerol (XXXVII) [208] and, when the reaction is carried out in an aqueous solution containing 66% of sucrose, the corresponding sugar ester (XXXVIII) is produced [208,217]. Freudenberg regards this benzyl ether linkage as one of the most probable types of lignocarbohydrate linkages in plant tissues.

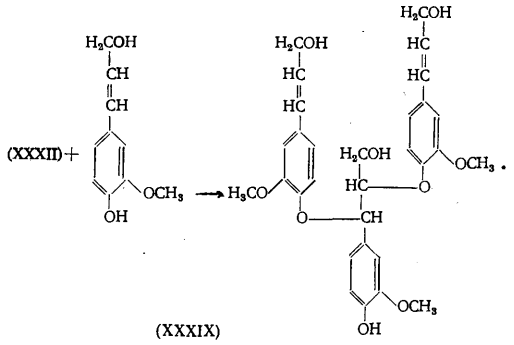
Since the dilignols considered are orthophenols, they can undergo further enzymatic dehydrogenation with reformation of dimeric radicals, which can recombine both with one another and with the mesomeric forms R_a–R_d. Such reactions lead to trilignols, tetralignols, and subsequently oligolignols. A number of the oligomeric compounds were isolated and identified by Freudenberg and coworkers [218–224]:



(XXXVI, R=H)
(XXXVII, R=CH_3)
(XXXVIII, R=$(C_6H_{10}O_5)_nH$)

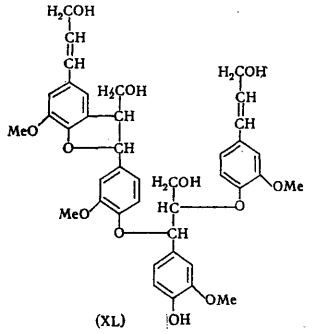
On the basis of the identified intermediates in the biosynthesis of lignin from coniferyl alcohol *in vitro*, Freudenberg [202,212,225,226] formulated the main pathways to the growth of the DHP molecule.

The first pathway consists of continuing dehydrogenation of oligolignols which leads to the formation of new aryloxy-radicals undergoing various recombinations. However, if the growth of the DHP molecule took place exclusively via dehydrogenation, then in this case each structural unit should loose two hydrogen atoms plus a further ~0.4 of a hydrogen atom owing to the formation of the carbonyl groups ($-C\overset{H}{\underset{O}{\diagup\!\diagdown}}$ and $\diagup\!\diagdown C{=}O$), i.e. altogether 2.4 hydrogen atoms. In fact, the maximum loss occurring is approximately two hydrogen atoms [227], which includes the average loss of 1.7–1.8 hydrogen atoms by each DHP structural unit owing to the formation of the bonds and 0.2–0.3 of a hydrogen atom owing to the formation of carbonyl groups. Thus the amount of hydrogen the removal of which leads to condensation corresponds to 1.7–1.8 atoms per structural units, which is insufficient for the formation of large molecules. In other words, a linkage produced as a result of addition or polymerisation and not related to the loss of hydrogen corresponds approximately to each four structural elements associated owing to the loss of hydrogen. This indicates the existence of other pathways to the growth of the lignin macromolecule. In this respect the quinone methide (XXXII), which can combine with phenols without an additional loss of hydrogen, plays a key role. The simplest example of the second pathway to the growth of the DHP macromolecule is the addition of coniferyl alcohol to the dimeric quinone methide (XXXII), which yields a trilignol—the aryl benzyl ether (XXXIX): [218]

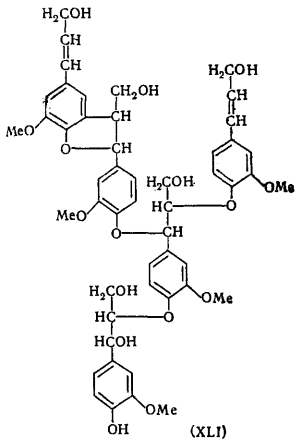


(XXXIX)

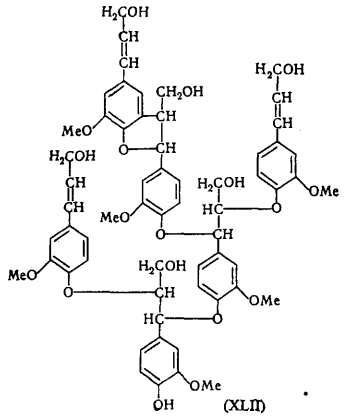
This growth pathway can also be illustrated by the formation of the tetralignol (XL) (the adduct of dehydrodiconiferyl alcohol and the quinone methide [218]), the pentalignol (XLI) (the adduct of the trilignol and the quinomethide) [224], and the hexalignol (XLII) (the adduct of the tetralignol and the quinone methide) [224].



(XL)

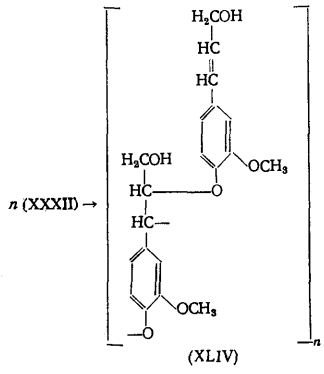


(XLI)



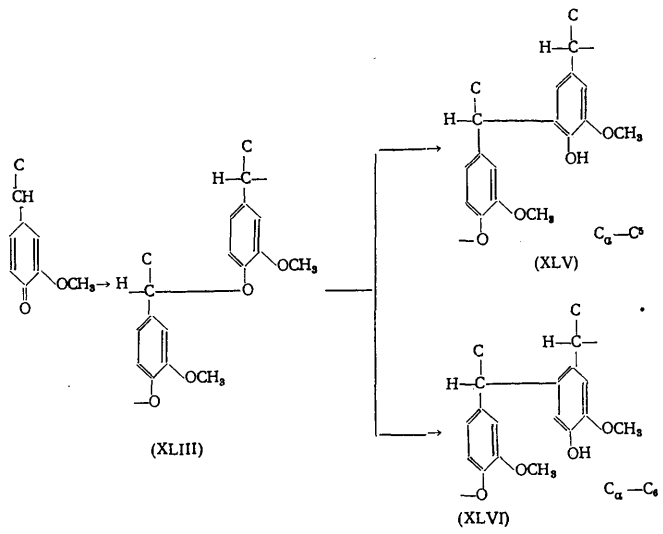
(XLII)

The polymerisation of *p*-quinone methides, leading to the formation of aryl benzyl ethers (XLIII),[228] competes with the addition of phenols to quinone methides. For example, compound (XLIV) is a product of the polymerisation of the quinone methide (XXXII). This process is considered as the third pathway to the growth of the DHP molecule:



(XLIV)

Finally the fourth pathway to the growth to the DHP molecule involves the rearrangement of α-aryl ethers, leading to the formation of diphenylmethane derivatives[222,228]. This process takes place after prolonged treatment with very dilute acids (similar conditions obtain in the cell sap of plants). As a result of the condensation between the α-C atom of the first unit and the fifth carbon atom in the ring of the second unit with simultaneous regeneration of the phenolic hydroxyl of the second unit, the ether (XLIII) is converted into the structure (XLV). A similar condensation of the α-C atom can occur to a lesser extent with the sixth carbon atom of the second unit and even less effectively with the second carbon atom. This rearrangement of α-aryl ethers does not take place solely in polymers but has been observed also with α-aryl guiacylglyceryl ethers (tri- and tetra-lignols)[222,226].



(XLIII)

(XLV)

(XLVI)

The non-enzymatic recombination of various mesomeric forms of the aryloxy-group formed on dehydrogenation of coniferyl alcohol results in a lack of optical activity of the polylignols synthesised both *in vivo* and *in vitro* despite the presence of asymmetric centres[205,215].

4. Chemical and Physical Properties of Dehydropolymers and Their Comparison with Those of Lignin Produced by Mechanical Milling

Table 1 presents semiempirical "formulae" for the $C_{(6)}-C_{(3)}$ structural unit of lignin, various DHP preparations, and lignin produced by mechanical milling [milled-wood lignin (MWL)] and isolated from spruce and beech wood by Björkman's method[229,230]. The data presented are evidence of the similarity of spruce wood MWL and DHP obtained by the enzymatic dehydrogenation of a mixture of coniferyl, *p*-coumaryl, and sinapyl alcohols.

In addition to the data in Table 1, we may mention that, in the MWL from spruce wood and DHP obtained by the enzymatic dehydrogenation of coniferyl alcohol, the total content of hydroxy-groups, determined by Verly's method, is in both cases 1.2–1.4 moles per $C_{(6)}-C_{(3)}$ unit[230,231], of which 0.30–0.35 mole comprises phenolic hydroxyls (determined by potentiometric titration in a non-aqueous medium[227,232]); the content of carbonyl groups, determined by the hydroxylamine method, is 0.20 mole per $C_{(6)}-C_{(3)}$ unit for MWL[230] and 0.15 mole for DHP.[231]

It is interesting to note that the molecular weights of preparations of both biosynthetic lignin and lignin isolated from wood or by mechanical grinding are in the range 6000–10 000.[209,230] The results of spectroscopic studies on these preparations are also similar. The infrared spectra of MWL and DHP are identical except for certain

details due to the fact that the preparations differ somewhat in their contents of carbonyl groups (ν = 1710–1740 cm^{-1}) and ethylene double bonds (ν = 970 cm^{-1}).[233–235] The ultraviolet spectra of both preparations are similar as regards the positions of the maxima and minima. At the same time the extinction coefficient of biosynthetic lignin is higher by a factor of 1.2–1.3%. However, after DHP has been kept in 0.1 *N* inorganic acid at 20°C for one week, the extinction coefficient of biosynthetic lignin becomes the same as that of natural lignin[209,236]. Finally, Freudenberg and Harkin showed[237] that both preparations contain small amounts of free radicals. According to ESR data, their concentration is 2.3×10^{16} spin g^{-1} in MWL from spruce wood and 2.15×10^{16} spin g^{-1} in biosynthetic lignin from coniferyl alcohol.

Table 1. Semiempirical "formulae" of certain preparations of biosynthetic and natural lignins (according to the data of Freudenberg et al.[198]).

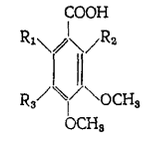
Preparation	Semiempirical "formula"	Loss of hydrogen	Increment of water
DHP from *p*-coumaryl alcohol	$C_9H_{8.75}O_2(H_2O)_{0.30}$	1.25	0.30
DHP from coniferyl alcohol	$C_9H_{7.49}O_2(H_2O)_{0.28}(OCH_3)_{1.01}$	1.51	0.26
DHP from *p*-coumaryl and coniferyl alcohols (1:4)	$C_9H_{7.76}O_2(H_2O)_{0.28}(OCH_3)_{0.83}$	1.44	0.28
DHP from *p*-coumaryl, coniferyl, and sinapyl alcohols (14:80:6)	$C_9H_{7.64}O_2(H_2O)_{0.31}(OCH_3)_{0.92}$	1.44	0.31
MWL from spruce wood	$C_9H_{7.78}O_2(H_2O)_{0.40}(OCH_3)_{0.91}$	1.30	0.40
MWL from beech wood	$C_9H_{6.28}O_2(H_2O)_{0.41}(OCH_3)_{1.36}$	2.36	0.41

*For greater clarity the oxygen content in the "formulae" of the lignins is shown as in the initial alcohol (two atoms per $C_{(6)}$–$C_{(3)}$ unit). The excess oxygen is liberated in the form of water.

The products obtained by the interaction of both DHP and spruce wood lignin with thioglycolic acid had the same elemental composition[196]. This applies also to products of the methylation of DHP and spruce wood lignin with both dimethyl sulphate and alkali and with diazomethane[238], as well as to ammonium lignosulphonates obtained from spruce wood and DHP.[196]

Convincing evidence of the similarity of the compositions of natural and biosynthetic lignins was obtained by cleavage reactions. Thus, when these preparations are treated under identical conditions with hot alkali and then methylated with dimethyl sulphate and the methylated products are oxidised with permanganate. MWL and DHP from a mixture of coniferyl, *p*-coumaryl, and sinapyl alcohols yield more than 20 of the so called degradation acids, mainly methoxybenzoic acids, and the total yield of identified products is about 18% of theoretical[198,214]. The main product of the oxidation of methylated lignins is veratric acid (XLVII), which constitutes about half of the overall yield. The remaining acids were detected in insignificant amounts. Freudenberg and coworkers showed[198,214] that the quantitative ratios and types of acids formed on oxidation of both lignin preparations are identical.

It is interesting to note that in the preparation of biosynthetic lignins from 5-deuterioconiferyl alcohol the loss of deuterium was 45%.[239] On dehydration under the conditions of DHP synthesis, 6-deuterioconiferyl alcohol looses 8–10% of deuterium and 2-deuterioconiferyl alcohol loses 2–4%.[240] These values indicate the relative involvement of various sites in the aromatic ring in the formation of intermolecular C–C bonds of lignin, the reactivity ratios of the 5-, 6-, and 2-positions (45 : 9 : 3) corresponding approximately to the quantitative ratios of the yields of isohemipinic (XLVIII), metahemipinic (XLIX), and hemipinic (L) acids in the products of the oxidative degradation of methylated DHP and MWL:[214]



(XLVII, $R_1=R_2=R_3=H$)
(XLVIII, $R_3=COOH$; $R_1=R_2=H$)
(XLIX, $R_1=COOH$; $R_2=R_3=H$)
(L, $R_2=COOH$; $R_1=R_3=H$)

When biosynthetic lignin obtained from [β-^{14}C]coniferyl alcohol, is cleaved, the isohemipinic acid (XLVIII) formed has 49–52% of the specific radioactivity of the initial alcohol, while metahemipinic acid (XLIX) has 10.5% of the specific radioactivity[241]. The isohemipinic and metahemipinic acids isolated from the oxidative degradation products of lignin, formed in young shoots or after the introduction of similarly labelled phenylalanine[242] or coniferin[206], have the same radioactivities in relation to those of the initial lignins (53 and 12% respectively).

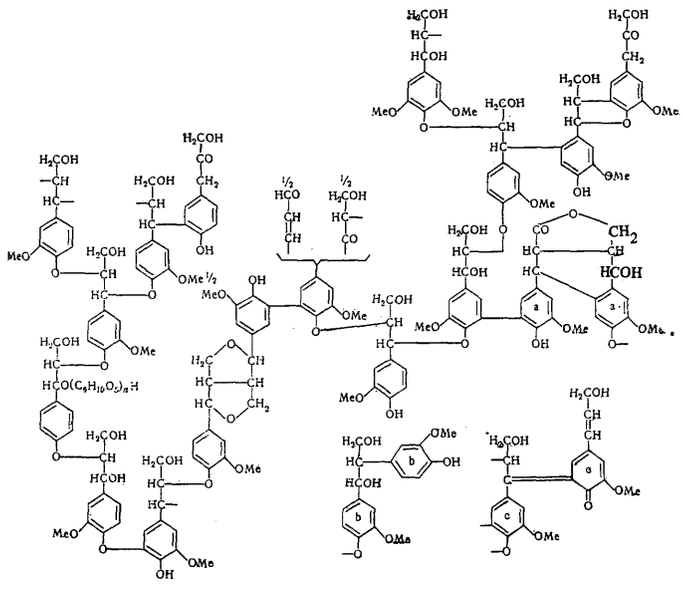
On heating with 28% sulphuric acid, the yield of formaldehyde is 1.1% for MWL and 1.4% for DHP.[209] Finally the yields of vanillin on nitrobenzene oxidation of both preparations are identical and amount to 25% of the initial lignin[209].

Thus the data discussed above demonstrate convincingly the similarity of natural (MWL) and biosynthetic (DHP) lignins as regards many important chemical and physical properties.

5. The Structure of a Lignin Fragment

The data discussed above on the biosynthesis of lignin *in vitro* (intermediates, the ratio of the principal dilignols, the four growth pathways) together with the chemical analyses of spruce wood lignin isolated by Björkman's method (elemental composition, the number and types of hydroxy-groups, the ratio of the three initial monomeric alcohols, the content of carbonyl groups, etc.) and the results of experiments on the polymerisation of labelled [^{14}C]coniferyl alcohol served as a basis of the schematic structural formula of a lignin fragment derived by Freudenberg. The first version[243] proposed in 1961 was subsequently modified several times by the author[220,226,237]. The latest scheme, put forward by Freudenberg at the International Symposium at Grenoble[225], consists of 18 units and corresponds to the composition of the dehydropolymer obtained by the dehydrogenation *in vitro* of a very dilute mixture of 14 moles of *p*-coumaryl alcohol, 80

moles of coniferyl alcohol, and 6 moles of sinapyl alcohol catalysed by laccase.



The detailed characteristics and an assessment of the schematic formula for a lignin molecular fragment as well as its comparison with natural and biosynthetic lignins are given in a number of latest reports by Freudenberg and coworkers [209,215,225,244-247]. In the present review we shall confine ourselves to a Table where certain characteristics of spruce wood lignin are compared with the corresponding data calculated on the basis of the schematic formula of a lignin fragment (Table 2).

Table 2 shows that the characteristics predicted on the basis of Freudenberg's scheme and covering a wide range of the chemical reactions of lignin are satisfactorily consistent with the experimental value. This enabled Freudenberg [225] to assert that at the present time there are no facts in the chemistry of lignin which could not be accounted for by his scheme.

In conclusion of the discussion of Freudenberg's work on the biosynthesis of lignin *in vitro*, we must consider certain methodological questions. Freudenberg [209] correctly suggests that comparison of the biosynthetic and natural lignins is valid only when the following factors are identical in both cases: (1) the initial monomeric products and their ratios; (2) the conditions governing the formation of lignin (enzyme systems, temperature, etc.); (3) the final products.

As shown in the previous sections, in the present stage of the investigation of lignin, all these factors appear to be identical both in the *in vitro* biosynthesis of lignin and in the formation of lignin in the plant. On the basis of the identity of the starting materials and final products in the synthesis of lignin *in vitro* and *in vivo*, Freudenberg [209] concluded that the mechanisms of natural and artificial lignification are the same and that the intermediates formed in both cases are similar. Moreover, Freudenberg [202] postulates that the data obtained in the study of the biosynthesis of DHP from *p*-hydroxycinnamyl alcohols can be used to account for the structure of natural lignin.

The structures of polysaccharides, proteins, and other biopolymers are established by identifying the oligomeric products obtained as a result of their cleavage reactions (mainly by hydrolysis). The determination of the structure of lignin on the basis of those of the oligolignols formed during its biosynthesis *in vitro* constitutes essentially a first attempt to determine by this type of procedure the structure of this complex polymer. One must not forget that the role of lignin in the plant is responsible for a number of the characteristics of its natural synthesis. In contrast to the synthesis of proteins, the molecules of which are constructed with the aid of templets, which ensures their exact reproduction, many stages of the biosynthesis of lignin take place in a random fashion, which is the reason for the wide variety of types of intramolecular bonds in its macromolecule. All this must be taken into account in assessing the structural scheme for a fragment of the lignin molecule devised by Freudenberg.

Table 2. Comparison of certain characteristics of lignin with data calculated on the basis of the schematic representation of a lignin* fragment (according to Freudenberg's data [247]).

Characteristic	Found or calc. for spruce wood lignin	Predicted on the basis of the schematic formula of a lignin fragment
Units capable of reacting with thioglycolic acid (α-ether, α-carbinol, phenylethylene, carbonyl)	0.8	0.8
Formation of lignosulphonic acid**		
Group X } A	0.15	0.17
Group Z } A	0.15	0.20
Group B	0.30	0.28
Total	0.60	0.65
Units capable of splitting off methanol (0.5% HCl, 20°C)	0.62	0.72
Units capable of splitting off methanol after treatment with $NaBH_4$	0.42	0.41
Condensation at 5-C	0.45	0.42
Condensation at 6-C	0.08	0.07
Condensation at 2-C	0.04	
Units capable of involvement in biphenyl linkages	0.25-0.30	0.22
Units capable of forming Hibbert ketones	0.1	0.17
Units capable of forming vanillin and vanillic acid	0.32	0.30-0.35
Aromatic and similar protons } from NMR spectra	2.5	2.4
Aliphatic protons } from NMR spectra	3.8	3.8

*The calculation refers to the average composition of the structural unit.
**Group X = *p*-hydroxybenzyl alcohols and alkyl *p*-hydroxybenzyl ethers; group Z = *p*-alkoxybenzyl alcohol; group B = alkyl *p*-alkoxybenzyl ethers.

On the basis of the foregoing, one must emphasise that the series of Freudenberg's studies on the biosynthesis of lignin has made a major contribution to the chemistry of lignin. Freudenberg's scheme for a lignin macromolecular fragment undoubtedly provides an approximate idea about the structure of lignins. Freudenberg's principal conclusions have been confirmed by the latest studies of Nimz [248-250] on the isolation of dimeric and oligomeric lignin fragments by mild hydrolysis (percolation) of wood. However, Pew's work on the enzymatic dehydrogenation of alkyl-*p*-hydroxyphenylmethanols and *p*-hydroxypropiophenones, discussed in the next section, has revealed a number of new aspects of the biosynthesis of lignin which

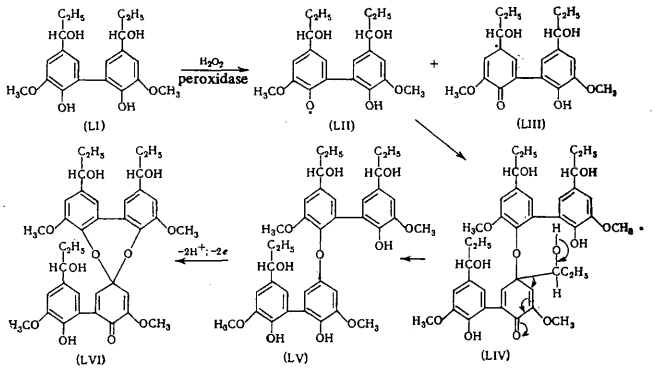
are not accounted for by Freudenberg's theory. Other combinations of groups leading to the formation of hitherto undiscovered structural elements of lignin are quite probable. Thus the question of the formation of lignin in plants and *in vitro* requires further studies.

6. Enzymatic Dehydrogenation of Other Phenylpropane Compounds and "Chemical Synthesis" of Lignin

A considerable number of studies on the preparation of lignin-like polymers by the enzymatic dehydrogenation of phenolic precursors other than coniferyl alcohol have been published. These investigations, which have been quite adequately discussed in the monograph of Brauns and Brauns [2], are of comparatively lesser interest since they deal mainly with the final dehydropolymerisation products. The recently published work of Pew [251-255] on the enzymatic dehydrogenation of a number of phenolic compounds structurally related to lignin is superior in this respect.

The study of the dehydrogenation of model phenols, preferably without C–C bonds in the side chain conjugated with the aromatic ring (eugenol, allylsyringol, isoeugenol, dehydrodieugenol, and others), by the action of peroxidase and hydrogen peroxide, led Pew and coworkers [251] to the conclusion that, apart from the biphenyl linkages, diphenyl ether linkages between monomeric units play a considerable role in the formation of lignin.

In addition, the authors showed that the enzymatic dehydrogenation of the phenols results in the formation of quinone methides of a type different from that described in the literature, which the authors believe can participate in the formation of lignin. Later Pew and Connors [252] published the results of a study of the enzymatic dehydrogenation of a number of alkyl-*p*-hydroxyphenylmethanols. When ethylguiacylmethanol was dehydrogenated in an aqueous solution by peroxidase and hydrogen peroxide, a hitherto unknown dibenzo[*d*,*f*][1,3]dioxepin (LVI) is formed with elimination of the side chain as propionaldehyde:

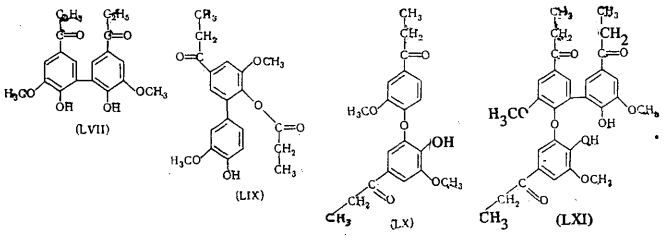


The mechanism of the formation of the dioxepin (VIL) proposed by the authors [252] consists in the initial formation of dehydrobisethylguiacylmethanol (LI) with its subsequent dehydrogenation, which leads to the formation of the biphenylyloxy-radical (LII); this combines with the cyclohexadienone mesomeric form of the same radical (LIII) to yield the dienone tetramer (LIV). The latter is then rearomatised by the elimination of propionaldehyde to form compound (LV), which yields phenoxy- and *p*-cyclohexadienone radicals on further dehydrogenation. The radicals undergo an intramolecular coupling to form the dioxepin (LVI).

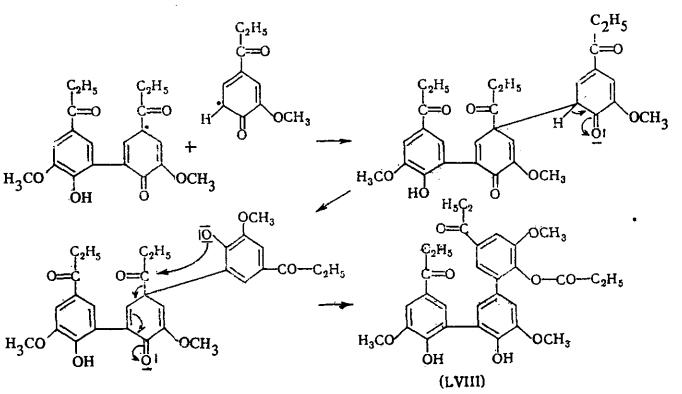
The authors showed [252] that an analogous type of reaction with formation of the corresponding dioxepin is undergone also by β-guaiacyl guaiacylglyceryl ether, the analogue of the extremely important dimeric intermediate in the biosynthesis of lignin *in vitro*. In addition, evidence was obtained showing that other *p*-hydroxybenzyl alcohols and certain ethers reacts similarly.

The results of this investigation enabled Pew and Connors to conclude that cyclohexadienone forms of phenoxy-radicals play an important role in the biosynthesis of lignin. It is particularly true in those cases where the *ortho*-position in relation to the phenolic hydroxyl is blocked, as in the cases where biphenyl and diphenyl ether linkages or a methoxy-group are present in syringic structures. Coupling involving this type of radical is usually accompanied by the removal of the side chain and, when biphenyl groups are present, it leads to the formation of structures of the dioxepin type. The latter can enter into the composition of the lignin macromolecule as such or in the form of quinonoid structures formed by the hydrolysis of the dioxepins.

Pew and Connors [253] also achieved the enzymatic dehydrogenation of a number of *p*-hydroxypropiophenones. When propioguaiacone is dehydrogenated in aqueous solutions by peroxidase and hydrogen peroxide, the product is an *oo'*-dihydroxybiphenyl derivative—dehydrodipropioguaiacone (LVII). In addition to this compound, a triphenyl derivative (LVIII), with an *op'*-biphenyl type of linkage hitherto unknown for lignin and with a propionate ester group, a dimeric ester (LIX), an *o*-diphenyl ether derivative (LX), and a trimer (LXI) containing both the *oo'*-biphenyl and *o*-diphenyl ether linkages were also identified.



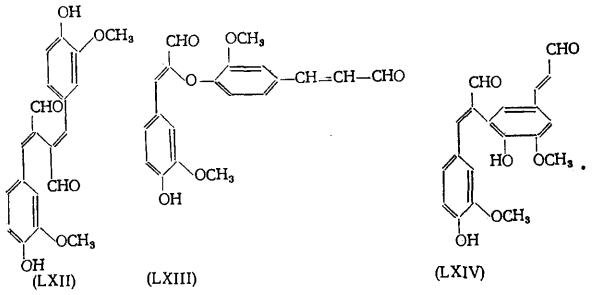
According to Pew and Connors [254], the mechanism of the formation of the trimer (LVIII) consists of the coupling of the cyclohexadienone mesomeric form of the biphenyl radical with the mesomeric *ortho*-radical. The coupling is followed by the rearomatisation of the dienone ring via an intramolecular nucleophilic attack on its carbonyl group in the side chain by the phenoxide ion produced by the deprotonation of the upper unit, which leads to transfer of the side chain and the formation of the ester (LVIII).



The formation of esters via the transfer of the side chain was demonstrated[254] with the aid of spectroscopic methods also on dehydrogenation products of vanillin, acetoguaiacone, and ethyl vanillate and on this basis it was concluded that the reaction is probably general.

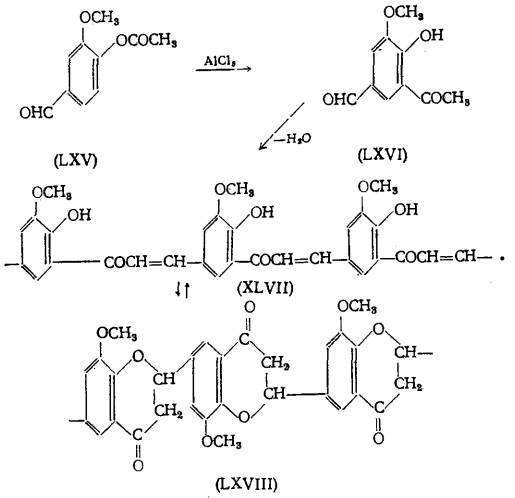
The results led to the hypothesis that lignin contains *op'*-oriented biphenyl linkages—a hitherto unknown type of linkage between monomeric units—and also that aliphatic acid esters are structures characteristic of the lignin macromolecule.

Connors et al.[255] dehydrogenated *trans*-coniferaldehyde in aqueous solution with peroxidase and hydrogen peroxide. They showed that the bulk of the products consists of three hitherto unknown dimers: 2,3-diformyl-1,4-di-(5-guaiacyl)buta-1,3-diene (LXII); α-[4-(β-formylvinyl)-2-methoxyphenoxy]coniferaldehyde (LXIII); α-[5-(β-formylvinyl)-2-hydroxy-3-methoxyphenyl]coniferaldehyde (LXIV):



(LXII) (LXIII) (LXIV)

The results of the above studies on the enzymatic dehydrogenation of various model compounds of lignin, carried out by Pew and coworkers, reveal certain aspects of the biosynthesis of lignin *in vitro* and can be regarded as supplementing Freudenberg's theory. There is no doubt that future studies will broaden current ideas on the biosynthesis of lignin and will lead to the discovery of new structural features of this polymer. Finally, mention should be made of the studies of Russell[256-259] on the chemical synthesis of lignin, which constitutes perhaps the only attempt of this kind. The author employed as the starting material vanillin monoacetate (LXV), which yielded 5-formyl-2-hydroxy-3-methoxyacetophenone (LXVI) as a result of the Fries rearrangement. The acetophenone readily underwent condensation polymerisation to compound (LXVII) which in turn cyclised into poly-8-methoxydihydrobenzopyrone (LXVIII). According to Russell's data, the polymer is in many respects analogous to spruce wood lignin:



(LXV) (LXVI) (XLVII) (LXVIII)

It is noteworthy that, whereas in the biochemical synthesis of lignin the aryloxy-radicals produced react in different forms to yield various recombination products which precludes a strictly defined sequence of linkages between the monomers in the polymer, in the chemical synthesis this type of disorder does not occur. Modern ideas concerning the inhomogeneity of the structure of lignin are inconsistent with Russell's "formula" and therefore his investigations were not continued further and are quoted here only for historical interest.

IV. SOME ASPECTS OF THE BIOSYNTHESIS OF LIGNIN *IN VIVO*

The results of the study of the biosynthesis of lignin *in vitro* led Freudenberg[147,260,261] to a hypothesis concerning the formation of lignin in the plant. During the vegetative period, new cells are actively formed in the cambial layer of wood. Young, still unlignified cells adjoining the cambium are gradually replaced, as they are separated further from the cambial layer, by ripe thick-walled cells, which produce an intense colour on treatment with phloroglucinol and hydrochloric acid. Coniferin has been detected in considerable amounts in the cambial layer and on either side of it. However, the laccase and peroxidase present in the precambial layer are capable of dehydrogenating coniferyl alcohol only. On this basis, one may expect the presence in this part of woody tissue of β-glucosidase which has in fact been detected in cuttings of 2 year old spruce shoots treated with indican (indoxyl glucoside). The β-glucosidase cleaved indican and the free indoxyl formed was rapidly converted in air into indigo, indicating the location of β-glucosidase. It was found that β-glucosidase is absent both from the young cells of the precambial layer and from the ripe lignified cells but is detected in large amounts in an intermediate layer, which is evidently the zone where lignin is formed. On the basis of these results, Freudenberg suggests that the formation of lignin in the plant can be represented as follows. Coniferin diffuses into the tissue where it is cleaved by β-glucosidase to free coniferyl alcohol, which is converted into lignin by the action of peroxidase and laccase. As soon as the tissue, particularly its intracellular parts, is filled by lignin, the cells die and β-glucosidase is no longer detected in them. It is interesting to note that, when the enzyme action continues after the tissue has been filled by lignin, the latter is degraded. Thus, when laccase or peroxidase acts on a suspension of natural or biosynthetic lignin in water, the preparations are degraded in a manner resembling humification and the degradation of phenols in the soil. A similar degradation is observed when wood rot serves as a source of dehydrogenases. Moreover, as mentioned above, the yield of DHP amounts to about 90%, never reaching 100%. According to Freudenberg's views[262], this is because lignin is partly decomposed on dehydrogenation. Thus the same enzymes (laccase and peroxidase) are involved in the formation and degradation of lignin.

As stated in the introduction, the lignification process cannot be regarded in isolation from other processes occurring in the formation of the plant cell. The complete set of these processes includes the biosynthesis of various components of plant tissue, during which different types of chemical linkages may arise between them together with the formation of various morphological components of the cell wall. These problems are undoubtedly of considerable theoretical and practical interest. On the

other hand, the available literature data are very limited, which precludes at the present time the consideration of the problems of the biosynthesis of the complete set of plant cell wall components. Evidently such an attempt is a matter for the future when not only the problems of the biosynthesis of the individual plant components (lignin, celluloses, and hemicelluloses) but also the general relations governing the formation of the plant cells will become adequately elucidated. However, even now many interesting data obtained in the study of the lignification of tissue cultures throw light on certain aspects of the biosynthesis of lignin *in vivo*.

As stated above, the method of tissue culture is widely used [31,99,101,158-165,263-271] in the study of various enzymatic systems involved in the biosynthesis of monomeric precursors of lignin and also in tests on various labelled compounds as lignin precursors. These investigations were considered in individual subsections of section II. Apart from these more of less local problems, experiments on tissue culture permitted an approach to the solution of wider problems of the biochemistry and physiology of plants. These may be formulated as follows: (1) the establishment of the possibility of a local lignification process or of the requirements by this process for compounds entering from the roots or leaves of the plant; (2) the establishment of the identity of the lignin precursors with retention or exclusion of correlations in the plant organism (when the biosynthesis of aromatic lignin precursors is localised, as mentioned above, are obtained); (3) the establishment of the chemical nature of the possible lignin precursors and the discovery on this basis whether the lignification process takes place in isolated tissues via the same pathways as in whole plants; (4) the elucidation of the physiological role of intermediate metabolites of the lignification process in the metabolism of the whole organism.

The studies using the tissue culture method established [264] that the lignin deposited in cell walls of the xylem elements of isolated tissues has a chemical composition similar to that of the lignin of higher plants. Moreover, it has been shown [165] that the biosynthesis of lignin in isolated tissues which have been living for a long time in an *in vitro* culture takes place locally using the carbohydrates of the nutrient medium. Consequently lignification does not require the supply of specific compounds from the roots or plant organs above ground. Since it was observed that inhibition of the growth of tissues does not affect the accumulation of lignin, it has been suggested [162] that the lignification and growth processes are to some extent separate.

The conclusions arrived at as a result of studies on tissue cultures are of great interest and permit an approach to the solution of the problems of the biosynthesis of lignin from a wider standpoint than is allowed by experiments on the biosynthesis of lignin *in vitro*. On the other hand, there is no doubt that these conclusions require certain additions and corrections. Finally a few concluding words may be said concerning the biosynthesis of lignin in connection with the problems of the orthogenesis and phylogenesis of plants.

In 1934 Holmberg [272] studied the lignins isolated from 50 plant species with the aid of thioglycolic acid and observed that the carbon content in the lignins of gymnosperms is higher by 3–4% than in the lignins of angiosperms, while the content of methoxy-groups is higher in the latter than in the former. Later, Hibbert and coworkers [273-275] used Freudenberg's method [276] of nitrobenzene oxidation to investigate plants of different classes and showed that, while the main product of the nitrobenzene oxidation of the lignin of gymnosperms is vanillin, dicotyledonous angiosperms yield a mixture of vanillin and syringaldehyde, while monocotyledonous angiosperms give a mixture of vanillin, syringaldehyde, and *p*-hydroxybenzaldehyde. The results led to the hypothesis that the reaction with alkaline nitrobenzene may be used for a taxonomic classification of plant materials. Subsequent investigations [277,278] by more sophisticated methods for the separation of oxidation products confirmed Hibbert's main conclusion with certain revisions. The results have served as a basis of the concept, generally accepted at the present time, that lignin is made up of phenylpropane derivatives methoxylated to different extents in the aromatic ring. The extensive studies by Manskaya [279-282], Kratzl [283], and others on lignins from different plant groups yielded interesting data concerning the role of lignin in the phylogenesis of plants. Thus Manskaya [279-282] studied living plant forms close to fossil plants in order to establish the formation of lignin in the phylogenesis in various plant groups. The author believes that the distinctive features of the lignins in various plant groups and the nature of the changes in their chemical composition on going from lower to more highly organised plants make it possible to deduce the relative content of lignin and the ratio of its elements methoxylated to different extents in plants existing in the past geological epochs. According to the majority of investigators, lignin which occurred initially in vascular plants of the order *Pteridophyta* (in recent years definite evidence has been obtained for its presence also in mosses [284] and even seaweed [285,286]), probably underwent considerable quantitative as well as qualitative changes during the evolution of plants.

There are many data demonstrating the changes in lignin during the orthogenesis of plants. Thus Stone et al. [287] showed that the ratio of vanillin and syringaldehyde in wheat lignin oxidation products vary with the age of the plants. Higuchi [134] studied the composition of lignin in the upper, middle, and lower parts of the shoots of three bamboo species. He showed [134], that as lignification progresses, there is a considerable increase in the overall content of aldehydes (calculated as the content of Klason's lignin) obtained on nitrobenzene oxidation and also of the ratio of syringaldehyde and vanillin. In the upper part of the bamboo shoots, where the degree of lignification was lowest, the fraction of syringaldehyde in the nitrobenzene oxidation products was also lowest. As lignification proceeded, the fraction of syringaldehyde increased, reaching a maximum in the adult plant. Freudenberg and Torres-Serres [288] showed that the cambial layer of one- and two-year old spruce shoots contains comparatively more *p*-glucocoumaryl alcohol than older spruces. Correspondingly the content of methoxy-groups in LMG from young spruces is 12–13% compared with 15.6% in MWL from the adult spruce [242,288]. These results suggest that the changes in lignin during onthogenesis corresponds to changes which it undergoes during phylogenesis.

The above data are undoubtedly of considerable interest although in the present stage of investigation it is as yet impossible to explain the changes in the degree of methoxylation of lignin during the onthogenesis and phylogenesis of plants.

Acid-Base Equilibria in Amphiprotic Solvents and Potentiometric Titration

L.N.Bykova and S.I.Petrov

Modern ideas about acid-base equilibria in amphiprotic solvents (acetonitrile, dimethylformamide, ketones, and others) are discussed. Data are presented for the homoconjugation constants of phenol and benzoic acid derivatives in these solvents and the calculation of acid-base titration curves is described. The question of the solvent acidity scales and their relative positions on a unique acidity scale are discussed. Factors limiting the solvent acidity scale calculated from its autoprotolysis constant are considered. Data are presented for the measured relative (practical) acidity scales for non-aqueous solvents and their mixtures in potentiometric titration. The optimal conditions chosen for acid-base titration are justified. The bibliography includes 180 references.

1. INTRODUCTION

During recent years considerable advances have been achieved in the physical and analytical chemistry of non-aqueous solutions[1-17]. This has assisted a quantitative assessment of the effect of the properties of the solvent on those of the solute and a further development of the theory of acid — base potentiometric titration in non-aqueous solutions.

The study of acid — base interaction in amphiprotic solvents with weak acid and basic properties showed that the overall scheme of equilibria in electrolyte solutions (acids, bases, and salts) includes a large number of intermediate stages. Therefore a quantitative interpretation of these interactions is very much more complicated than in an aqueous medium or in solvents with properties similar to those of water (lower alcohols, glycols). Progress in this field of science involved measurements by different methods (spectrophotometric, conductimetric, and potentiometric) not only of the dissociation constants of acids and bases in amphiprotic solvents but also of equilibrium constants characterising individual stages of the acid — base interaction. The effect of water and other hydrogen bond donors and acceptors on the conditions governing acid — base interactions in amphiprotic solvents has been characterised quantitatively. The equations derived by Kolthoff make it possible to calculate the pH of buffer solutions and also potentiometric titration curves in solvents such as acetonitrile, dimethylformamide (DMF), and dimethyl sulphoxide.

Since acid — base interaction in any solvent is due primarily to the acid and basic properties of the solvent itself, it is necessary to consider the question of solvent acidity scales. The studies in this field have yielded many new data for autoprotolysis constants and the unique null proton activity coefficients which can be used to construct a unique solvent acidity scale. Factors limiting solvent acidity scales merit special attention, since under real conditions solvents usually contain admixtures of water and other solvents which distort their acid — base properties. This necessitates the study of the physicochemical properties of mixed solvents.

The present review considers the latest data on acid — base interaction in amphiprotic solvents and solvent acidity scales. The large volume of information in this field necessitates continual review and critical assessment of the published work.

In conclusion the choice of the optimal conditions for potentiometric acid — base titration is justified. New studies on the theory and practice of potentiometric acid — base titration have shown that the potentialities of this method are far from being exhausted[18].

2. ACID — BASE EQUILIBRIA AND CALCULATION OF TITRATION CURVES

When an acid HA interacts with a base B in a protolytic solvent SH, a number of reactions take place; the main processes are as follows[8,19-21]:

intrinsic ionisation of the solvent:

$$2SH \rightleftarrows SH_2^+ + S^- ; \quad (1)$$

interaction of the acid with the solvent:

$$HA + SH \rightleftarrows HS \cdots HA \rightleftarrows SH_2^+ \cdot A^- \rightleftarrows SH_2^+ + A^- ; \quad (2)$$

interaction of the base with the solvent:

$$B + SH \rightleftarrows B \cdots SH \rightleftarrows BH^+ \cdot S^- \rightleftarrows BH^+ + S^- ; \quad (3)$$

interaction of the acid with the base:

$$HA + B \rightleftarrows BH^+ \cdot A^- \rightleftarrows BH^+ + A^- . \quad (4)$$

Depending on the properties of the solvent, the acid and the base, a definite relation is established between these equilibria.

When an acid HA is titrated in a solvent SH with a standard solution of a base B, reaction (4) predominates[19]. However, there is the possibility of a simultaneous side reaction (3) in which the solvent interacts as an acid with the titrant. The extent of reaction (4) depends on the relative acid properties of the acid HA and the solvent SH. The stronger the acid HA and the weaker the acid SH, the higher the extent of reaction (4) and the interaction of the HA acid being determined with the titrant B is quantitative. The weaker the acid HA and the stronger the acid SH the less complete is reaction (4).

When a base B is titrated in a solvent SH with a standard solution of an acid HA, the main reaction (4) is accompanied by a side reaction (2). The extent of reaction (4) depends on the relative basic properties of the

base B being determined and the solvent SH. The more basic the properties of the solvent SH and the weaker those of B the less complete is reaction (4) because the side reaction (2) occurs to a considerable degree.

Since in aqueous solutions salts are fully dissociated and strong acid and base solutions may be employed as titrants, for the calculation of titration curves in water it is necessary to know the concentration of the acid HA or the base B being titrated, their dissociation constants K_A or K_B, and the autoprotolysis constant of water K_S.[22,23]

Calculation of acid — base equilibria in water-like solvents such as ethanol and methanol resembles the calculation of titration curves in water, since the formation of ion pairs takes place to only a slight extent and salts behave as strong electrolytes. Compared with water, the activity coefficients in these solvents are appreciably reduced (at the same ionic strength). The Debye — Hückel law may be employed at ionic strengths less than 0.01.[19]

In other alcohols, the dielectric constants of which are less than 24, calculations of titration curves are complicated, since ion pairs are formed. In this case it is also necessary to consider the dissociation constants of the titrant electrolyte and of the salt formed. Such calculations of titration curves have been performed by Kolthoff and Bruckenstein[19] for acetic acid. They studied the acid — base equilibria in acetic acid and measured the dissociation constants of electrolytes and the autoprotolysis constant of the solvent[22]. The titration curves calculated from these data agree satisfactorily with experiment. The lack of data for the dissociation constants of electrolytes and sometimes also the autoprotolysis constants of the solvents precludes the use of the Kolthoff equation for the calculation of titration curves in alcohols with low dielectric constants.

Table 1. The dissociation (K_{HA}) and homoconjugation ($K_{HA_2^-}$) constants of substituted phenols and benzoic acids in acetonitrile.

No.	Compound	pK_{HA}[28,30,32—34]	$\lg K_{HA_2^-}$[27,28,30,32,33]

Considerable advances have been achieved recently in the study and interpretation of the acid — base interaction in aprotic dipolar solvents (acetonitrile, dimethyl sulphoxide, dimethylformamide, and others). In these solvents, the molecules of which are incapable of forming hydrogen bonds with the acid anions and base molecules, hydrogen-bonded complexes of the type HA_2^- and B_2H^+ are formed.

Much credit is due to Kolthoff, Coetzee, and coworkers[24-26] for their investigation of acid — base interactions in acetonitrile. The formation of complexes via hydrogen bonding between the acid (HA or BH^+) and the conjugate base (A^- or B) was called homoconjugation. Homoconjugation in acetonitrile has been studied comprehensively for the dissociation of phenol and benzoic acid derivatives, amines, and other organic bases[21,24-30].

The existence in solution of species of the type HA_2^- was predicted theoretically[31]. In the first place homoconjugation is determined by the relative basicities of the solvent molecule and the acid anion and the amphoteric properties of the solvent molecule. The capacity of the acid molecule HA for the formation of the complex HA_2^- increases as the proton-donating properties of the acid and the proton-accepting properties of its anions become more pronounced. The possibility of forming an intramolecular hydrogen bond lowers the capacity of the acid for interaction with the anion. Thus *ortho*-substituted phenols and benzoic acids are less involved in the homoconjugation process than the *meta*- and *para*-substituted derivatives. Homoconjugation does not occur when acid anions are additionally stabilised by intramolecular hydrogen bonding or by resonance (the anions of picric acid, 2,4-dinitrophenol, and 2,6-dihydroxybenzoic acid) and also as a result of steric blocking of the ionic group (2,6-di-t-butylphenol)[32,33].

Kolthoff[25] showed that, in the calculation of the concentration of hydrogen ions in a solution of a weak acid, it is necessary to begin with the overall constant $K_{2(HA)}$ which includes the acid dissociation constant K_{HA} and the homoconjugation constant $K_{HA_2^-}$:

$$HA \rightleftarrows H^+ + A^-; \quad K_{HA} = \frac{[H^+][A^-]\, f^2}{[HA]},$$

$$HA + A^- \rightleftarrows HA_2^-; \quad K_{HA_2^-} = \frac{[HA_2^-]}{[HA]\,[A^-]},$$

$$2\,HA \rightleftarrows H^+ + HA_2^-; \quad K_{2(HA)} = \frac{[H^+]\,[HA_2^-]\, f^2}{[HA]^2} = K_{HA}\,K_{HA_2^-},$$

The data in Table 1 show that the homoconjugation constants $K_{HA_2^-}$ for phenol and benzoic acid derivatives are usually fairly high. The acid strength of phenol and benzoic acid derivatives in acetonitrile increases on introduction of electron-accepting substituents. It was found that the relations between pK_{HA} and the σ constants for the substituents in phenols and benzoic acids are linear[32,33]. For benzoic acids, the relations between $\lg K_{HA_2^-}$ and σ are also linear[33]. Fig. 1 shows the variation of pK_{HA} and $\lg K_{HA_2^-}$ with the σ constants of the substituents in benzoic acids (lines I and II respectively). The different forms of these relations are due to the fact that the capacity for homoconjugation is less sensitive to changes in the structure of the compound.

To characterise quantitatively the proton-donating capacity of benzoic acid molecules and the proton-accepting capacity of their anions, Kolthoff and Chantooni[33] measured the heteroconjugation constants of acid molecules in relation to the base Cl^- and of acid anions in relation to the acid *p*-bromophenol (HR):

$$HA + Cl^- \rightleftarrows HACl^-; \quad K_{HACl^-} = \frac{[HACl^-]}{[HA]\,[Cl^-]},$$

$$HR + A^- \rightleftarrows HRA^-; \quad K_{HRA^-} = \frac{[HRA^-]}{[HR]\,[A^-]}.$$

Fig. 1 shows (lines III and IV) that the proton-donating capacity of the molecules increases and the proton-accepting capacity of the corresponding anions falls with increase of the σ constants of the substituents. The overall effect of these changes due to the σ constants is reflected in the relation between $\lg K_{HA_2^-}$ and $\Sigma\sigma$ (line II). Similar relations have been found for phenol derivatives[32].

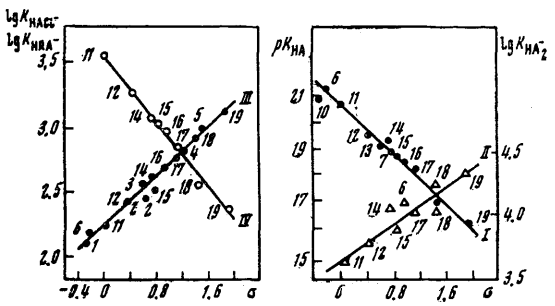

Figure 1. Variation of pK_{HA} (line I), $\lg K_{HA_2^-}$ (line II), $\lg K_{HACl^-}$ (line III), and $\lg K_{HRA^-}$ (line IV) for substituted benzoic acids with the σ constants of the substituents: 1) *p*-methoxy-; 2) *o*-iodo-; 3) *o*-chloro-; 4) 2,6-dichloro-; 5) 5-chloro-2-nitro-; 6) 3,4-dimethyl-; 7) 3,5-dichloro-; numbers 10 — 19 correspond to the ordinal numbers in Table 1.

It has been established that homoconjugation has a significant influence on the shape of the titration curves of acids and bases in acetonitrile. Kolthoff[25] derived an equation relating the activity of hydrogen ions in a solution of a weak acid and its salt, the acid dissociation and homoconjugation constants, and the analytical concentrations of the acid (C_A) and the salt (C_S):

$$a_{H^+}^2 f^2 C_s - a_{H^+} f K_{HA}\{(C_s + C_A) + K_{HA_2^-}(C_s - C_A)^2\} + K_{HA}^2 C_A = 0. \quad (5)$$

In the derivation of Eqn. (5), it was assumed that (1) the salt R_4NA formed in the interaction between the acid HA and the base R_4NOH is fully dissociated, (2) the salt R_4NHA_2 is also a strong electrolyte, and (3) the concentration of hydrogen ions in solution is much lower than the concentration of the salt ($C_{H^+} \ll C_S$). Eqn. (5) is applicable only to a thoroughly purified solvent free from impurities capable of behaving as hydrogen bond donors or acceptors (water, methanol).

Examination of Eqn. (5) shows that, at the instant of half-neutralisation, $a_{H^+} = K_{HA}/f$, i.e. the pH of the solution is determined by the p*K* for the dissociation of the acid. The shape of the titration curve in the buffer region is determined by the product $K_{HA_2^-}(C_S + C_A)$ or $K_{HA_2^-}C_A^0$, where C_A^0 is the initial analytical concentration of the acid titrated. The higher this value the higher the slope of the buffer section of the titration curve, the smaller the pH jump at the end of the titration, and the less satisfactory the conditions for the differential titration of a mixture of acids[35].

Calculation of the pH for the buffer section of the titration curve by Eqn. (5) shows that, when $K_{HA_2^-}C_A^0 \geq 10^2$, an inflection is observed in the titration curve at the half-neutralisation point[25]. Since $K_{HA_2^-}$ for acetonitrile is of the order of $10^3 - 10^4$ (Table 1), the shape of the titration curves is hardly distorted for $C_A^0 \leq 10^{-3}$. In the absence of homoconjugation, the pH in the course of titration from 1% to 99% neutralisation increases by 4 units. In the presence of homoconjugation the pH change is $\Delta pH = -\lg[10^{-4}/(K_{HA_2^-}C_A^0)^2]$. Thus, when $K_{HA_2^-}C_A^0 = 10^3$, ΔpH is as much as 10 units.

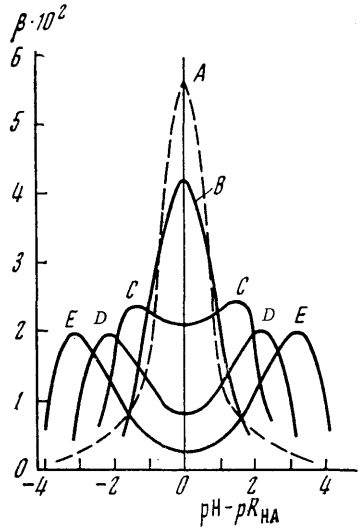

Figure 2. Dependence of the buffer capacity β on the pH of a mixed solution of HA and $(C_2H_5)_4NA$: *A*) dissociation without homoconjugation; *B*) $K_{HA_2^-}C_0 = 1$; *C*) $K_{HA_2^-}C_0 = 10$; *D*) $K_{HA_2^-}C_0 = 100$; *E*) $K_{HA_2^-}C_0 = 1000$.

Kolthoff and Chantooni[25] studied the buffer capacity of solutions of acids and their tetraethylammonium salts as a function of $K_{HA_2^-}C_A^0$. The authors derived from Eqn. (5) an expression for a quantitative characteristic of the buffer capacity of the solution (β):

$$\beta = -2.303\left[\frac{K_{HA}\,K_{HA_2^-}-(C_A^0-2C_s)^2+K_{HA}\,C_A^0-2C_s[H^+]}{[H^+]+4K_{HA}\,K_{HA_2^-}\,(C_A^0-2C_s)-K_{HA}^2/[H^+]}\right], \quad (6)$$

which is applicable to the calculation of β almost over the entire section of the neutralisation curve corresponding to the buffer region. Fig. 2 presents relations between the buffer capacity β and the pH of the solution in mixtures of HA and $(C_2H_5)_4NA$ for different values of $K_{HA_2^-}C_A^0$. Calculation of the buffer capacity by Eqn. (6) at the instant of half-neutralisation when $K_{HA_2^-}C_0 \gg 1$ leads to the expression

$$\beta_{1/2} = -\frac{2.303}{2}\sqrt{\frac{C_0}{2K_{HA_2^-}}},$$

which shows that $\beta_{1/2}$ depends on the ratio $C_0/K_{HA_2^-}$ and is smaller the smaller the value of the ratio.

If homoconjugation takes place to a considerable extent and $K_{HA_2^-}C_0 \geq 10$, the buffer capacity has two maxima which are displaced with increase of $K_{HA_2^-}C_0$ towards more acid and alkaline regions, in accordance with $pH_{1/2}$.

Water and alcohols can behave as hydrogen bond donors and acceptors in aprotic dipolar solvents[32,33,36-41]. Kolthoff and Chantooni[37] made a quantitative study of the effect of these impurities on the acidity of solutions of mixtures of weak acids and their salts in acetonitrile. They showed that, in the presence of a hydrogen bond donor HR, it is necessary to take into account the following equilibria involving the formation of complexes:

$$A^- + HR \rightleftarrows AHR^-; \quad K_{AHR^-} = \frac{[AHR^-]}{[A^-][HR]},$$

$$A^- + 2HR \rightleftarrows A(HR)_2^-; \quad K_{A(HR)_2^-} = \frac{[A(HR)_2^-]}{[A^-][HR]^2}.$$

If the substance is amphoteric, then, owing to its acceptor properties in relation to the hydrogen bond, we have the equilibria (heteroconjugation)

$$HA + B \rightleftarrows AHB; \quad K_{BHA} = \frac{[BHA]}{[B][HA]},$$

$$HA + 2B \rightleftarrows AHB_2; \quad K_{B_2HA} = \frac{[B_2HA]}{[B]^2[HA]}.$$

An equation has been derived for the calculation of a_{H^+} in a buffer solution taking into account heteroconjugation. Apart from the assumptions made in the derivation of Eqn. (5), it was postulated that (1) K_{HA} and $K_{HA_2^-}$ do not change when HR and B are introduced into the solution, (2) HA_2^- is not involved in heteroconjugation, and (3) the $A^-\ldots HR$ and $AH\ldots B$ interactions take place without proton transfer owing to the extremely weak acid and basic properties of HR and B. The equation relating a_{H^+} to the analytical concentrations of the acid and the salt, the equilibrium concentrations of the hydrogen bond donor HR and acceptor B, the acid dissociation constant, and the homoconjugation and heteroconjugation constants is

$$a_{H^+}^2 f^2 W^2 C_s - a_{H^+} f K_{HA} V W \left[(C_s + C_A) + \frac{K_{HA_2^-}}{V W}(C_s - C_A)^2\right] + K_{HA}^2 V^2 C_s = 0, \quad (7)$$

where

$$V = 1 + K_{AHR^-}[HR] + K_{A(HR)_2^-}^2[HR]^2 + \ldots$$
$$W = 1 + K_{BHA}[B] + K_{B_2HA}^2[B]^2 + \ldots$$

The pH values of buffer solutions of methanesulphonic, picric, 3,5-dinitrobenzoic, salicylic, and benzoic acids and their tetraalkylammonium salts in acetonitrile in the presence of added water, calculated by Eqn. (7), agree well with measurements up to a water concentration of 0.7 M. Fig. 3 shows the effect of water and other hydrogen bond donors and acceptors on the pH of a benzoate buffer solution in the presence of an excess of the acid or salt. It demonstrates that, in the presence of excess salt in the buffer solution, the addition of a hydrogen bond acceptor (dimethyl sulphoxide) causes almost no change in the pH of the buffer solution, but the addition of hydrogen bond donors greatly reduces the pH. In the presence of an excess of acid in the buffer solution, water, methanol, and n-butyl alcohol hardly change the pH, while more powerful hydrogen bond donors and acceptors reduce or increase the pH respectively.

It follows from Eqn. (7) that, when the concentrations of the acid and salt are equal, the activity of hydrogen ions is defined by the relation

$$(a_{H^+})_{1/2} = \frac{V}{W} \cdot \frac{K_{HA}}{f}.$$

Consequently $pH_{1/2}$ is in this case smaller by $\lg(V/W)$ than the $pH_{1/2}$ for a buffer solution in which only a homoconjugation process takes place.

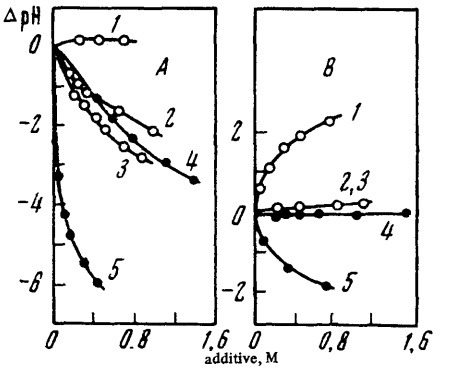

Figure 3. Effect of impurities on the pH of a benzoate buffer solution: *A*) $C_A = 3.6 \times 10^{-3}$ M, $C_S = 3.05 \times 10^{-2}$ M, pH_0 23.40; *B*) $C_A = 6.5 \times 10^{-2}$ M, $C_S = 2.18 \times 10^{-3}$ M, pH_0 16.80; 1) $(CH_3)_2SO$; 2($n\text{-}C_4H_9OH$; 3) CH_3OH; 4) H_2O; 5) $p\text{-}BrC_6H_4OH$;

It follows from the foregoing that heteroconjugation can have a significant influence on the shape of the titration curve in the buffer region[37,42]. According to Eqn. (7) the shape of the curve is determined by the factor[25,37]

$$\frac{C_0 K_{HA_2^-}}{V W}.$$

The study of the effect of methanol added to the solution during the titration is of particular practical interest for acid — base titration in acetonitrile, since standard solutions of quaternary ammonium hydroxides are usually prepared in a benzene — methanol mixture. Fig. 4 presents curves for the potentiometric titration of a 0.02 M solution of 3,5-dinitrobenzoic acid in acetonitrile with tetra-alkyl ammonium hydroxide calculated by Eqns. (5) and (7). The calculations were performed in the range from 0.5% to 99% neutralisation. Fig. 4 shows that methanol has a significant effect only after the point of half-neutralisation. In the presence of *p*-bromophenol, which shows a greater tendency towards heteroconjugation, the titration curve has the shape identical with that for a weak acid in water. The pK_A for 3,5-dinitrobenzoic acid is reduced by 3 units compared with the value in the pure solvent.

Homoconjugation and heteroconjugation in acetonitrile are less characteristic of bases than acids, since acetonitrile has a greater solvating capacity in relation to cations than in relation to anions. These processes have

almost no effect at a base concentration of 10^{-3} M. However, certain hydrogen-bonded complexes B_2H^+ are fairly stable, and their formation must be taken into account in a quantitative interpretation of acid — base equilibria in acetonitrile[12,24,26,29,43]. It has been shown[24] that nitrogenous bases form in acetonitrile not only 1 : 1 hydrogen-bonded complexes B_2H^+ but also more complicated species:

$$B + BH^+ \rightleftarrows BHB^+; \quad K_{BHB^+} = \frac{[BHB^+]}{[B][BH^+]},$$

$$B + BHB^+ \rightleftarrows B_2HB^+; \quad K_{B_2HB^+} = \frac{[B_2HB^+]}{[B][BHB^+]}.$$

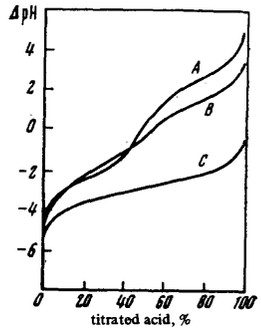

Figure 4. Curves for the potentiometric titration of 0.02 M solution of 3,5-dinitrobenzoic acid calculated by Eqn. (7): *A*) in the absence of impurities; *B*) with 0.1 M R_4NOH solution containing 10% of methanol; *C*) in the presence of 0.5 M solution of *p*-bromophenol.

Table 2. The negative exponents of the dissociation constants (pK_{BH^+}) of the conjugate acids of bases and the logarithms of the homoconjugation constants in acetonitrile[24,29].

Base	pK_{BH^+}	$\lg K_{BHB^+}$	$\lg K_{B_2HB^+}$
Ammonia	16.46	1.04	0.3

Morpholine	16.61	1.00	—
1,3-Diphenylguanidine	17.90	—	—

Homoconjugation increases with the strength of the base and the number of hydrogen atoms at the nitrogen atom of the conjugate acid and depends on steric factors (Table 2).

It follows from the pK_{BH^+} data that in acetonitrile all protonated amines are weaker acids than in water owing to the low basicity of acetonitrile[24]. Although on average ΔpK_{BH^+} for bases in acetonitrile and water is 7.6 units, there is a fairly complex quantitative relation between $pK_{BH^+}(CH_3CN)$ and $pK_{BH^+}(H_2O)$. Thus in acetonitrile steric factors play a more important role than in water[29].

Table 2 shows that the formation constants of the complexes BHB^+ in acetonitrile are approximately 100 times smaller than those of the complexes HA_2^-. The tendency of aliphatic amines towards homoconjugation increases in the sequence $R_3N < R_2NH < RNH_2$. Aromatic amines, which are weaker bases, are less capable of homoconjugation than aliphatic amines. For diamines, the formation of BHB^+ decreases with increase of the number of methylene groups owing to the stabilisation of the cation by an intramolecular hydrogen bond[29].

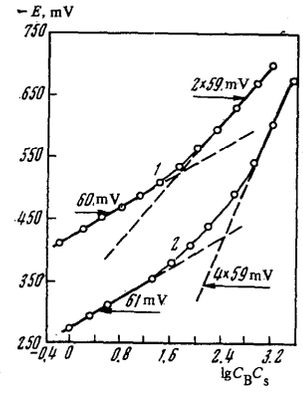

Figure 5. Variation of the glass electrode potential in buffer solutions: 1) piperidine and piperidinium picrate at constant $C_S = 5 \times 10^{-4}$ M; 2) hydrazine and hydrazinium perchlorate at constant $C_S = 5 \times 10^{-4}$ M.

Examination of the effect of homoconjugation on the shape of neutralisation curves for bases showed that, as for acids, the formation of hydrogen-bonded complexes leads to a decrease of the buffer capacity of the solution and a decrease of the pH near the end point of the titration[24]. The main effect of homoconjugation is shown at the beginning of the titration and before the equivalence point where either the base or the salt is present in a large excess. Fig. 5 illustrates the effect of homoconjugation on the change of the glass electrode potential in buffer solutions where the concentration of the salt was kept constant and that of the base was varied. In the absence of homoconjugation, the $E = f(\lg \frac{[B]}{[BH^+]})$ relation is linear with a slope of 59 mV (at 25°C) in accordance with the Nernst equation. When BHB^+ complexes are formed, the equilibrium concentrations [B] and $[BH^+]$ are not equal to the analytical concentrations, because

$$[B] = C_B - [BHB^+] \text{ и } [BH^+] = C_s - [BHB^+]$$

and the relation between E and $\lg(C_B/C_S)$ deviates from linearity. In the presence of a large excess of the base

the relation $E = f(\lg \frac{C_B}{C_{BH^+}})$ is again linear but with a slope of 118 mV (Fig. 5, curve 1). The formation of large complexes leads to a slope $n \times 59$ mV, where n is the number of base molecules bound to the protonated base, i.e. the complex may be represented by B_nHB^+. Fig. 5 (curve 2) illustrates this type of relation for a buffer solution consisting of hydrazine and its perchlorate. It shows that the effect of homoconjugation for bases in acetonitrile occurs for fairly high ratios $C_B/C_{BH^+} \geq 100$.

Table 3. The negative exponents of the dissociation constants (pK_{HA}) and the logarithms of the formation constants ($\lg K_{HA_2^-}$) of the complexes of certain acids in dimethyl sulphoxide[41].

Acid	pK_{HA}	$\lg K_{HA_2^-}$
Picric	—1.0	—
2,6-Dihydroxybenzoic	3.1	—
4-Chloro-2,6-dinitrophenol	3.5	—
2,6-Dinitrophenol	4.9	—
Salicylic	6.8	0.48
3,5-Dinitrobenzoic	7.4	0.36
2,6-Di-t-butyl-4-nitrophenol	7.6	—
3,5-Dinitrophenol	10.6	0.48
p-Nitrophenol	11.0	0.60
o-Nitrophenol	11.0	0.78
Benzoic	11.1	0.78
Acetic	12.6	0.48
5-5-Diethylbarbituric	13.0	—
Phenol	16.4	1.60

In the absence of homoconjugation or when the concentration of the titrated base is less than 10^{-3} M, the neutralisation curves for bases in acetonitrile resemble those in aqueous solution[26].

Table 4. The negative exponents of the acid dissociation constants (pK_{HA}) and the logarithms of the homoconjugation constants ($\lg K_{HA_2^-}$) in dimethylformamide[50].

Acid	pK_{HA}	$\lg K_{HA_2^-}$
Picric	1.4	—
Hydrochloric	3.2	2.2
2,6-Dihydroxybenzoic	3.56	—
4-Chloro-2,6-dinitrophenol	4.7	—
2,6-Dinitrophenol	5.9	—
2,4-Dinitrophenol	6.3	—
Salicylic	8.23	1.7
3,5-Dinitrobenzoic	8.9	3.2
p-Nitrobenzoic	10.6	2.6
3,5-Dinitrophenol	11.3	3.2
p-Nitrophenol	12.5	2.3
Benzoic	12.25	2.4
Acetic	13.4	2.6

Homoconjugation and heteroconjugation phenomena also are observed in other aprotic dipolar solvents such as dimethyl sulphoxide[44,45], dimethylformamide[46-50], sulpholane[51], and acetone[52].

Dimethyl sulphoxide is a more basic solvent than acetonitrile. Therefore dimethyl sulphoxide molecules enter into a reaction with the anion which competes with the homoconjugation process:

$$A^-...HA + SH \rightleftharpoons A^-...HS + HA.$$

As a result, phenols and benzoic acids show a smaller tendency towards the formation of HA complexes in dimethyl sulphoxide (Table 3).

Table 3 shows that the formation constants of the complexes HA_2^- in dimethyl sulphoxide are smaller approximately by a factor of 100 than in acetonitrile (Table 1). In consequence, the potentiometric titration curves in dimethyl sulphoxide have a more pronounced buffer region and a correspondingly sharper change of the pH at the end point of the titration.

Dimethylformamide is somewhat less basic than dimethyl sulphoxide and therefore homoconjugation of acids in this solvent takes place to a greater extent than in dimethyl sulphoxide but to a lesser extent than in acetonitrile[46-50]. The homoconjugation constants in dimethylformamide are approximately ten times smaller than in acetonitrile (Table 4).

The buffer regions on the titration curves of acids and bases in dimethylformamide and dimethyl sulphoxide can be calculated as in acetonitrile. Similar calculations cannot be made for cations because one cannot make the assumptions used in the derivation of Eqn. (5) for the pH in acetonitrile.

3. SOLVENT ACIDITY SCALES

Acid—base equilibria in any solvent are due primarily to the acid—base properties of the solvent itself. Therefore the question of acid—base interaction is closely related to the question of solvent acidity scales. The extent of acidity scale is determined by the autoprotolysis constant of the solvents and their relative positions on the pH scale are determined by the relative trans-solvation energies of the protons in the different solvents (see Izmailov[8], Chapter X, and Bates[53], Chapters VII and VIII).

Izmailov[54,55] proposed unique zero-concentration proton activity coefficients γ_{0H^+} which are determined by the change in the solvation energy of protons when they are transferred from an infinitely dilute non-aqueous solution to an infinitely dilute aqueous solution. The activity coefficient γ_{0H^+} enabled Izmailov[54,56] to establish a unique solvent acidity scale:

$$pA = pH_s - \lg \gamma_{0_{H^+}},$$

where pH_S assumes values ranging from 0 to pK_S for the solvent and $\lg \gamma_{0H^+}$ indicates the shift of the acid limit of the scale in the non-aqueous solvent relative to the acid limit of the scale in water.

A rigorous thermodynamic approach to the determination of the activity coefficients of individual ions is difficult to achieve, since the accuracy of the theoretical calculations of solvation energy is less than that of the differences between the solvation energies in different solvents; experimental methods do not yield an unambiguous answer in those cases where the diffusion potential is high. Therefore several methods have been proposed for the determination of $\lg \gamma_0$ for ions, each of which involves certain non-thermodynamic assumptions[14,53-64]. The problem of the estimation of the γ_0 for ions has engaged the attention of many investigators. They were called "degenerate activity coefficients" by Grunwald,

"medium effects" by Bates, "solvent activity coefficients" by Parker, and "partition coefficients" by Kolthoff.

Izmailov, Aleksandrov, and other investigators of the Kharkov school of physical chemistry have made a major contribution to the theory of unique zero-concentration ionic activity coefficients, in the first place those of hydrogen ions, and their experimental determination in practice[54-56,65-68]. Studies in recent years showed that interest in unique zero-concentration activity coefficients of protons has increased in connection with the further development of methods for the measurements of pH in non-aqueous solutions and the development of the theory of acid – base interaction[69-76]. However, there are few $\lg \gamma_{0H^+}$ data for solvents employed in acid – base titrations and they are contradictory[44,56,73,74].

On the basis of the pK_s and $\lg \gamma_{0H^+}$ data then available, Izmailov[56] included only five solvents in his unique acidity scale (pA). At the present time the unique acidity scale already includes thirteen solvents[77]. The solvent autoprotolysis constants have been determined by various methods[78-89]. A critical assessment of the pK_s values available in the literature for amphiprotic solvents has been made by the authors of the review[77]. Table 5 lists the pK_s and $\lg \gamma_{0H^+}$ values for certain solvents widely employed in analytical practice.

Table 5. The negative exponents of the autoprotolysis constants (pK_s) of certain solvents at 25°C and the values of $\lg \gamma_{0H^+}$.

Solvent	pK_s [77–85]	$\lg \gamma_{0H^+}$ [44,56,67]
Formic acid	6.2	10.0
Acetic acid	14.5	—
Ethylene glycol	15.6	—
Water	14.0	0
Methyl alcohol	16.7	3.1
Ethyl alcohol	19.5	3.9
Isopropyl alcohol	22.0	4.2
t-Butyl alcohol	26.8	—
Acetone	32.5	4.7
Ethyl methyl ketone	31.0	—
Acetonitrile	33.3	7.9
Dimethylformamide	29.4	—
Dimethyl sulphoxide	33.3	—1.5

Acidity in non-aqueous solvents is measured and acidity scales are established also on the basis of the H_0, H_-, and $R(H)$ functions[90-98]. Izmailov (see Ref. 8, Chapter X) showed that the H_0 and H_- functions cannot reflect the activity of hydrogen ions in a non-aqueous solution owing to the different effects of the medium on the activity coefficients of indicator ions and molecules. Other acidity functions (H_R, H_0, H_+, H_{2+}) proposed subsequently suffer from the same disadvantages[99,100].

Cells with transport are mainly used in potentiometric titration in non-aqueous solutions[1,2,4]. The glass electrode, the advantages of which are well known, is employed as the indicator electrode and the reference electrodes are calomel or silver|silver chloride half-cells. The behaviour of the glass electrode in non-aqueous and mixed solvents has been described in a number of studies[101-116]. It has been shown that in many non-aqueous media the glass electrode retains its response to hydrogen ions. However, the applicability of the glass electrode in non-aqueous solutions may be limited in highly acid and highly basic media. The use of reference electrodes in non-aqueous solutions has been described[117-122].

In cells with transport, there is a liquid junction between two solutions where a diffusion potential arises, which leads to an indeterminacy in the measurement of proton activities (see Izmailov[8], Chapter X, and Bates[53], Chapters VII and VIII). However, it has been suggested that the error due to the liquid junction in cells with transport is constant in a given solvent and depends little on the nature of the electrolyte and the activity of protons (see Bates[53], Chapter VIII). Experimental studies have confirmed this hypothesis[67,68,123,124].

A direct measurement of the diffusion potential E_j is impossible and its estimation is extremely difficult. E_j may be determined only when the proton activity coefficients are known (see Bates[53], Chapter VIII). However, since the $\lg \gamma_{0H^+}$ are contradictory, the values of E_j cannot always be estimated unambiguously either[60-62,67,69]. The values of E_j for measurements with an aqueous calomel electrode have been quoted in a number of studies for methyl, ethyl, and isopropyl alcohols, acetonitrile, dimethylformamide, and dimethyl sulphoxide and it has been shown that the E_j can reach several pH units[57,69,125-127]. There are data showing that when the aqueous potassium chloride solutions in the reference electrode is replaced by a methanol solution, E_j decreases[60,112]. When a liquid junction is formed between two aprotic dipolar solvents, E_j does not exceed 20 mV.[60]

The problem of the estimation of the E_j and $\lg \gamma_{0H^+}$ has been recently solved successfully with the aid of the quantity δ proposed by Bates (see Ref. 53, Chapter VIII and Ref. 124), which is defined as the difference

$$\delta = \bar{E}_j - \lg \gamma_{0H^+},$$

where $\bar{E}_j$ is the diffusion potential in pH units.

Measurements of δ in aqueous alcoholic media have shown that in mixed solvents δ is small up to 80 wt.% of the alcohol (see Izmailov[54], Chapter VIII). It is suggested that in this composition range there is a mutual cancellation of E_j and $\lg \gamma_{0H^+}$. A further increase of the content of alcohol in the mixture leads to a sharp increase of δ to 2 – 2.5 pH units. The values of δ have been measured for mixtures of water with alcohols, acetone, dioxan, dimethylformamide, dimethyl sulphoxide, and other solvents[67,68,128-130]. The variation of δ with mixture compositions is explained by changes in the structure and acid – base properties of the mixed solvent.

Together with the question of the extent of solvent acidity scales and their relative positions, the question relating to factors which limit the solvent acidity scale is very important for acid – base titration. The pH range corresponding to the theoretical pK_s solvent acidity scale calculated from the autoprotolysis constant can be by no means always fully employed in acid – base titration in the given solvent. The theoretical solvent acidity scale is limited by the influence of the following factors. In the first place the alkaline titrants employed are usually solutions of bases without the solvent lyate ions, since it is often impossible to obtain the latter. Many solvents have low dielectric constants and therefore acids and bases with strengths equal to those of the lyonium and lyate ions of the solvent cannot exist in them. The concentrations of the compounds titrated and of the titrants are as a rule 0.01 – 0.1 M, which also reduces the pH jump in the titration. Finally the employment of the entire solvent acidity scale in the titration is hindered

also by the loss of sensitivity of the indicator and particularly glass electrodes in highly acid or highly basic regions.

A particularly marked limitation of acidity scales for solvents with weak acid or basic properties is caused by the presence in them of admixtures of water, alcohols, glycols and other solvents with fairly pronounced acid or basic properties[131,132]. The available literature data for the autoprotolysis constants of mixed solvents show that the addition of the first portions of water to isopropyl alcohol, acetone or dimethyl sulphoxide leads to a sharp increase of the autoprotolysis constant and a corresponding contraction of the solvent acidity scale[96,97,114,133–135].

In a mixture of two protolytic solvents SH and MH there are four main inter-related equilibria which determine protolysis in the mixed solvent[132,136–141]:

$$SH + SH \rightleftarrows SH_2^+ + S^-, \quad (I)$$

$$MH + MH \rightleftarrows MH_2^+ + M^-, \quad (II)$$

$$MH + SH \rightleftarrows MH_2^+ + S^-, \quad (III)$$

$$SH + MH \rightleftarrows SH_2^+ + M^-. \quad (IV)$$

To a first approximation, the autoprotolysis constant for the mixed solvent can be regarded as the product of the equilibrium concentrations of the lyonium and lyate ions of the mixed solvent:

$$K_s = (C_{SH_2^+} + C_{MH_2^+})(C_{S^-} + C_{M^-}).$$

Depending on the acid and basic properties of the components of the mixed solvent and its composition, definite relations are established in each specific case between the activities of the individual ions in solution. If the acidities and basicities of the mixture components are similar, then protolysis in the mixed solvent is determined by all four equilibria. Only for mixture compositions close to those of the pure solvents does protolysis correspond mainly to the autoprotolysis of the pure solvents. Examples of mixtures of this kind are those of water and ethylene glycol.

When the acidity and basicity of the solvent MH are higher than those of the solvent SH, the autoprotolysis of SH may be neglected in the mixed solvent (acetone — water mixtures):

$$K_s = C_{MH_2^+} C_{M^-}.$$

For mixtures of two solvents one of which has more pronounced acid properties (SH) and the other more pronounced basic properties (MH), protolysis is determined mainly by equilibrium (III) (mixtures of water and amines):

$$K_s = C_{MH_2^+} C_{S^-}.$$

If the basicities of the solvents constituting the mixture are similar and the acidity of the solvent MH is higher than that of SH (dimethylformamide — water mixtures), the autoprotolysis constant of the mixed solvent may be represented by the following expression [equilibria (II) and (IV)]:

$$K_s = (C_{MH_2^+} + C_{SH_2^+})\, C_{M^-}.$$

If the acid properties of the mixture components are similar and the basic properties of the solvent MH are more pronounced than those of SH (water — methanol mixtures), the expression for the autoprotolysis constant of the mixed solvent is [equilibria (II) and (III)]:

$$K_s = C_{MH_2^+}(C_{M^-} + C_{S^-}).$$

The addition of a solvent MH with a basicity higher than that of the solvent SH leads to a decrease of the acid limit of the acidity scale for the mixed solvent owing to the reaction

$$SH_2^+ + MH \rightleftarrows MH_2^+ + SH.$$

If the acidity of the solvent MH is higher than that of SH, the addition of MH to SH leads to a decrease of the basic limit of the acidity scale for the mixed solvent; this involves the following reaction:

$$S^- + MH \rightleftarrows M^- + SH.$$

Fig. 6 presents as an example three cases of the decrease of the limits of the acidity scales for non-aqueous solvents with weak acid or basic properties in the presence of added water.

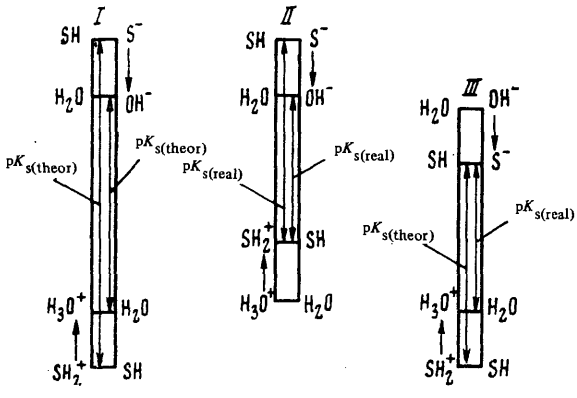

Figure 6. Effect of water on the acidity scales for non-aqueous solvents: I) acidity and basicity of water higher than the corresponding properties of the solvent; II) acidity of water higher and its basicity lower than the corresponding properties of the solvent; III) basicity of water higher and its acidity lower than the corresponding properties of the solvent.

In choosing the conditions for acid — base titration, it is necessary to know the effect of added solvents on each limit of the solvent acidity scale. Since, as stated above, the determination of individual ionic activities involves considerable difficulties, the determination of the variation of the acidity scale limits for mixed solvents on the basis of a rigorous thermodynamic approach is difficult to achieve. There are literature data for $\lg \gamma_{OH^+}$, which determine the variation of the acid limit of the acidity scale for mixtures of water with methyl, ethyl, and isopropyl alcohols and with acetone[57,67,68,74]. These results demonstrate that the addition of water leads to a decrease of the acid limit of the acidity scale for alcohols and acetone since these solvents are less basic than water. The data described above, referring to the acidity scales of non-aqueous solvents and their relative positions on the unique acidity scale, show that at present the physicochemical data necessary for the construction of practical (real) acidity scales for the majority of solvents and their mixtures, which might be used in potentiometric acid — base titration, are not available. It is therefore of interest to obtain practical solvent acidity scales taking into account all the factors which determine the titration conditions.

Real (empirical) solvent acidity scales were first obtained by van der Heijde and Dahmen[142,143]. However, these workers did not give a physicochemical interpretation of their acidity scales. Probably this is why van der Heijde and Dahmen's studies were not developed further in the following decade.

Later a simple and rapid method was proposed for the measurement of real acidity solvent scales, which were called relative acidity scales (E_S).[144] The method of measurement of the relative acidity scales was used successfully to investigate real acid base titration conditions[145-148]. The relative acidity scale is the range of values in millivolts (E_S) or in pH units (E'_S) which may be used in acid — base titration in the given solvent under specified conditions (titrant system, presence of other solvents, etc.). The limits of the E_S scale are measured as the half-neutralisation potentials of $HClO_4$ and R_4NOH solutions which are widely used as the strongest titrants in non-aqueous media[4]. The relation between the negative exponent of the autoprotolysis constant of the solvent and the extent of the relative acidity scale may be represented by the equation

$$pK_s \geqslant E'_s - \lg(a_{H^+}\, a_{OH^-}). \qquad (8)$$

The sign of equality refers to the case where K_S is the autoprotolysis constant of the solvent containing water and the "greater than" sign refers to the case where K_S is the autoprotolysis constant of the pure solvent. It follows from Eqn. (8) that the relative (real or practical) solvent acidity scale in terms of pH units is part of the pK_S acidity scale and depends on the system of titrants employed. Fig. 7 presents the relative acidity scales for water and non-aqueous solvents. Evidently the E_S scales for non-aqueous solvents have different lengths and occupy different positions relative to the acidity scale for water.

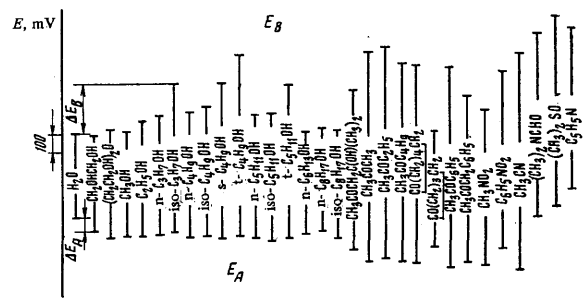

Figure 7. Relative acidity scales for certain solvents.

It has been shown that one of the main factors determining the position of the limits of the relative solvent acidity scale relative to the limits of the scale for water is the acid and basic properties of the solvent[149]. Comparison of the limits of the relative acidity scales with parameters characterising the basic and acid properties of solvents showed that, with decrease of the basic properties of the solvent, the acid limit E_A of the scale shift towards the region of higher proton activities, and with decrease of the acid properties of the solvent, there is a shift of the basic limit E_B of the scale towards the region of lower proton acitivities. Thus, the highest values of the acid limits of relative acidity scales obtain in ketones, acetonitrile, nitrobenzene, and nitromethane, which are least basic; the highest values of the basic limits of relative acidity scales are in ketones, acetonitrile, dimethylformamide, dimethyl sulphoxide, and pyridine, which are characterised by the smallest acidity.

The lengths of the E'_S and pK_S solvent acidity scales are compared in Fig. 8.[83] The values of E'_S and pK_S were taken from the literature[80,81,84,85,88,112,144,150-153]. With the exception of the points referring to acetonitrile and dimethyl sulphoxide, there is a linear relation between E'_S and pK_S. The points lying below the straight line drawn according to the equation

$$E'_s = pK_s + \lg(C_{HClO_4}\, C_{R_4NOH}) \qquad (9)$$

(C_{HClO_4} and C_{R_4NOH} are the $HClO_4$ and R_4NOH concentrations employed in the measurement of the limits of the E'_S scale) are readily explained by the incomplete dissociation of $HClO_4$ and R_4NOH in certain solvents and also by the presence of water and methanol impurities in the solvents, since the R_4NOH solutions were prepared in a benzene — methanol mixture and those of $HClO_4$ were obtained from 70% aqueous solution.

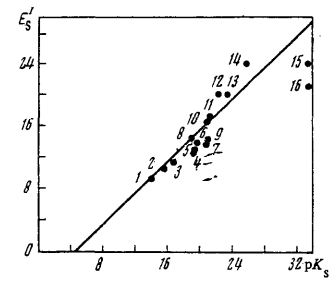

Figure 8. Comparison of the negative exponents of the autoprotolysis constants (pK_S) and the E'_S parameters of relative acidity scales: 1) water; 2) ethylene glycol; 3) methyl alcohol; 4) ethyl alcohol; 5) n-propyl alcohol; 6) n-butyl alcohol; 7) n-pentyl alcohol; 8) isobutyl alcohol; 9) isopentyl alcohol; 10) isopropyl alcohol; 11) s-butyl alcohol; 12) t-butyl alcohol; 13) dimethylformamide; 14) ethyl methyl ketone; 15) acetonitrile; 16) dimethyl sulphoxide.

Since the method of measurement of relative solvent acidity scales and Eqn. (9) yields values of pK_S which are lower than the true values, the points above the straight lines can only be due to incorrect autoprotolysis constants for a number of solvents (t-butyl alcohol, ethyl methyl ketone, dimethylformamide) in the literature. Consequently, comparison of the E'_S and pK_S solvent acidity scales yields information about the reliability of the experimental K_S for solvents, as shown by the authors of the review[83].

The relative positions of the E'_S and pK_S relative solvent acidity scales on Izmailov's pA unique acidity scale are compared in Fig. 9.[83] The filled regions correspond to those parts of the pK_S scale which for one reason or another cannot be used in titration. As already stated, one of such reasons is the incomplete dissociation of $HClO_4$ and R_4NOH in certain solvents. The filled regions can also reflect the

effect of the diffusion potential of the cell used to measure the limits of the E'_S scale.

In the measurement of the limits of the E'_S scale, R_4NOH solutions were prepared in a 1 : 5 benzene — methanol mixture and therefore the solvents investigated contained a certain amount of methanol and benzene and also water. Water and methanol have more pronounced acid or basic properties than many amphiprotic and aprotic dipolar solvents (ketones, acetonitrile, dimethyl sulphoxide, etc.). Therefore one of the factors restricting the limits of the acidity scales for solvents with weak acid or basic properties is of course the presence of water, methanol, and similar solvent impurities.

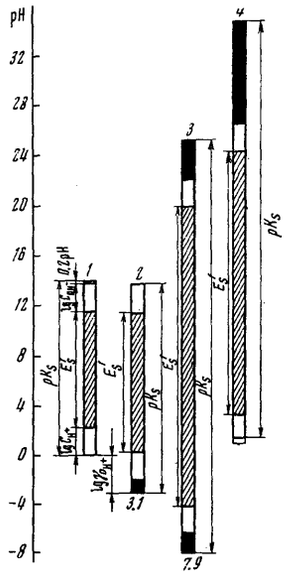

Figure 9. Comparison of the E'_S and pK_S acidity scales in terms of the pA unique acidity scale: 1) water; 2) methyl alcohol; 3) acetonitrile; 4) dimethyl sulphoxide.

The method of measurement of relative acidity scales proved to be effective not only in the study of the chemical-analytical properties of individual solvents but also in the study of the properties of their various mixtures widely used in titration[154-158]. The general laws governing the variation of the limits of the relative acidity scales for mixed solvents have been established. It has been shown that the length and position of the acidity scale for a mixed solvent depend mainly on the lengths and positions of the scales for the mixture components (Fig. 10). If the limits of the acidity scales for the individual solvents differ greatly, the limits of the acidity scale for the mixed solvent vary with composition non-additively. The most marked change in the limits of the acidity scale is observed following the addition of the initial portions of a second solvent with lower values of acidity scale limits. The variation of the limits of the E_S scales for mixed solvents can be explained by the variation of the acid and basic properties of the mixture in relation to those of the individual components, since the acid and basic properties of the mixed solvent vary non-additively with composition (see Izmailov[8], Chapter VII).

Measurements of relative acidity scales for mixtures of protolytic and aprotic solvents showed that the addition of 40 — 50% of the aprotic solvent has almost no influence on the limits of the acidity scale for the protolytic solvent[150]. The variation of the limits of the acidity scales for mixtures is not related to changes in the dielectric constant provided that the latter is not too low ($\epsilon > 10 - 15$).[156]

Comparison of the extents of the E_S scales and solvent polarities on the E_T scale reveals a definite relation between these quantities[151]. For protolytic solvents a decrease of polarity corresponds as a rule to an increase of the extent of the relative acidity scale. If one of the solvents has a higher acid limit and the other a higher basic limit of the E_S scale, then, on passing from solvent to solvent, the change in acid or basic properties may not correspond to the change in the polarity of the mixtures. Under these conditions, the curve relating the limit to mixture composition shows a minimum (mixtures of pyridine with water, methanol, and ethylene glycol and mixtures of nitromethane with alcohols) (Fig. 10).

Comparison of the extents of relative acidity scales for mixed solvents in terms of pH units with published negative exponents of the autoprotolysis constants (pK_S) showed that the variation of these quantities is the same. Consequently the variation of the extents of E'_S scales for mixed solvents reflects correctly the variation of the pK_S for the mixed solvents, as shown for a mixture of water and dimethyl sulphoxide (Fig. 11).

Comparison of the changes in the acid limits ΔE_A of E_S acidity scales for mixture of water with methyl, ethyl, and isopropyl alcohols and actone with the δ values[67,68,128,129] showed that the variation of ΔE_A for the mixtures parallels that of δ (Fig. 12). This confirms the conclusion that the position of the acid limit of the E_S scale on the unique acidity scale is determined mainly by the change in the

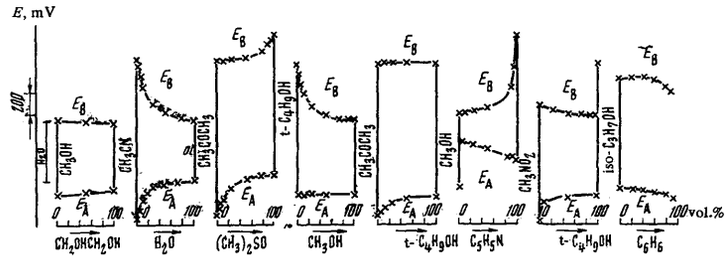

Figure 10. Relative acidity scales for mixed solvents corresponding to different component ratios.

basicity of the solvent and the diffusion potential of the cell used to measure the limits of the E_S scale.

The similarity in the variation of the limits of the E_S scales for mixed solvents made it possible to derive empirical equations for the calculation of the acid and basic limits of the acidity scales for mixtures as a function of mixture composition. With the aid of these equations, the limits and extents of the acidity scales were extrapolated and their values for pure solvents evaluated. This is particularly important for solvents with weak acid and basic properties[159]. On the basis of the E_S scales for pure solvents, it is possible to determine their pK_S values[77].

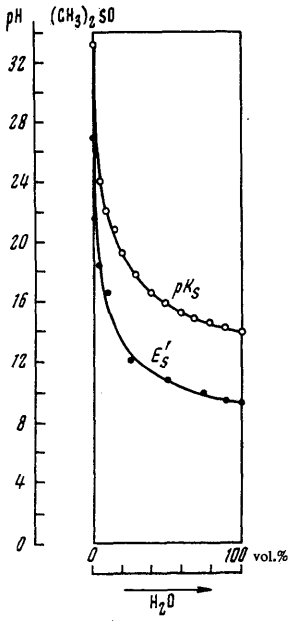

Figure 11. Comparison of the pK_S and E'_S acidity scales for a mixture of dimethyl sulphoxide and water.

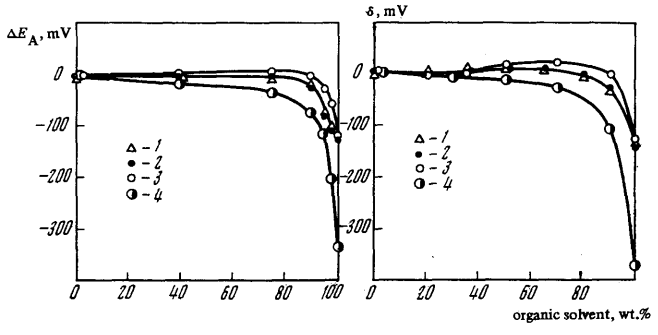

Figure 12. Comparison with δ of the differences ΔE_A between the acid limits of the acidity scales for water and its mixtures with different solvents: 1) methyl alcohol; 2) ethyl alcohol; 3) isopropyl alcohol; 4) actone.

It follows from the foregoing that study of the chemical-analytical properties of mixed solvents by measuring their relative acidity scales has made it possible (a) to establish the main factors determining the practical solvent acidity scale in potentiometric titration, (b) to establish the general characteristics of the variation of the limits of the acidity scales for mixed solvents, (c) to elucidate the role of water and similar added solvents (alcohols, glycols) in acid – base titration, and (d) to propose a simple method for the estimation of the autoprotolysis constants of solvents with insignificant acid or basic properties.

4. CHOICE OF OPTIMAL CONDITIONS FOR POTENTIOMETRIC ACID – BASE TITRATION

In connection with the extensive development of methods for acid – base titration, the problem of a soundly based choice of optimal titration conditions is becoming increasingly urgent. The scientific principles for the employment of non-aqueous solvents in acid – base titration have been developed by Izmailov (see Ref. 8, Chapter XI, and Refs. 160 and 161). Starting with the theory of titration errors developed by Roller, Izmailov specified the principal ways for the improvement of acid – base titration conditions. The choice of conditions for the titration of acids, bases, mixtures of acids, or mixtures of bases is made by comparing the solvent autoprotolysis constants K_S and the acid (K_A) or basic (K_B) dissociation constants. On the assumption of complete dissociation of the titrant and of the salt formed and of the absence of a salt effect, the titration conditions are characterised by the titration constant K_T (C_A and C_B are the concentrations of the acid and base):

$$\text{for acids } K_T = \frac{K_S}{K_A C_A}; \qquad \text{for bases } K_T = \frac{K_S}{K_B C_B},$$

$$\text{for mixtures of bases } K_T = \frac{K_{A_1} C_{A_1}}{K_{A_2} C_{A_2}} (K_{A_1} < K_{A_2}), \text{ and}$$

$$\text{for mixtures of bases } K_T = \frac{K_{B_1} C_{B_1}}{K_{B_2} C_{B_2}} (K_{B_1} < K_{B_2}).$$

On passing from water to non-aqueous solvents, an improvement in the conditions for the titration of weak acids and bases and also of mixtures of acids and mixtures of bases is achieved when the titration constant is appreciably reduced.

When he considered methods for the improvement of titration conditions, Izmailov had at his disposal the autoprotolysis constant of solvents such as alcohols, acetic and formic acids, liquid ammonia and hydrazine. Calculation of the pK_T values for acids and bases from these data led to general agreement between theory and experiment. However, the use of later data for the autoprotolysis constants of acetonitrile, dimethylformamide, and dimethyl sulphoxide to estimate pK_T for phenol and its mononitro-derivatives failed to reflect the improvement in the conditions governing the titration of weak acids which is known to occur on passing from water to these solvents[150]. The apparent conflict between theory and experimental acid – base titration can be resolved if the literature values of the autoprotolysis constants of the solvents are incorrect. The use of the latest K_S data for acetonitrile and dimethyl sulphoxide in the calculation of pK_T indicates a much greater improvement in the conditions for the titration of phenols in these solvents compared with water.

A critical examination of the published data for the solvent autoprotolysis constants and the dissociation constants of the compounds titrated shows that the choice of titration conditions on the basis of the known values of K_S and K_{diss} is impossible for the majority of solvents important in practice. Firstly, few values of K_S for solvents and K_{diss} for electrolytes are available and their reliability is in many cases poor[77]. Secondly, titrations are not usually performed in pure solvents and there are almost no K_S and K_{diss} data for mixed solvents. Thirdly, the choice of titration conditions on the basis of K_S and K_{diss} includes a number of assumptions which are inapplicable to solvents with a low ionising capacity. Fourthly, for aprotic dipolar solvents, where acid — base interaction involves a large number of intermediate stages, the titration conditions cannot be determined by comparing the autoprotolysis constants of the solvents and the dissociation constants of the electrolytes.

In his paper, Charlot[162] states the principles of acid — base titration in non-aqueous media and begins with the same basic postulates as Izmailov. The titration curve is predicted by comparing the pK_S solvent acidity scales with the pH values for various acid — base pairs corresponding to the instant of half neutralisation of the acid (pH = pK). However, the author points out that, owing to the lack of data for the relative positions of the non-aqueous solvent acidity scales, this method is applicable to the assessment of titration conditions in a single solvent only.

The half-neutralisation potential $E_{1/2}$ is frequently used as a chemical-analytical characteristic of the compound determined in a non-aqueous solution[1,2,4,163-179]. Owing to the complete dissociation of the salt formed and its high solubility, the pH of an aqueous solution at the half-neutralisation point is equal to pK_{diss} and therefore the half-neutralisation potential is a function of the dissociation constants only. In most cases $E_{1/2}$ in a non-aqueous solution, employed as a measure of the relative acidity of electrolytes, reflects correctly the variation of their dissociation constants, which is confirmed by the linear relation between $E_{1/2}$ and $pK_{A(ns)}$.[112] Therefore the half-neutralisation potential for the electrolyte in a non-aqueous solvent is largely determined by the same factors as the dissociation constant.

If the electrolyte is a stronger acid than the solvent lyonium ions, the half-neutralisation potential of the electrolyte is reduced to the level of the half-neutralisation potential of SH_2^+; the half-neutralisation potential of a base stronger than the solvent lyate ions is reduced to the level of the half-neutralisation potential of S^-. If the acid or base is a weaker electrolyte than the solvent (considered as an acid or base respectively), its half-neutralisation potential is outside the limits of the acidity scale for the solvent and such electrolytes cannot be titrated as acids or bases in the solvent.

The position of $E_{1/2}$ for the electrolyte on the unique solvent acidity scale depends mainly on the strength of the electrolyte in the given solvent and on the activity of protons in the form of lyonium ions. The half-neutralisation potential for the electrolyte in a non-aqueous solvent depends not only on factors determining the dissociation constant of the electrolyte but also on those which determine the shape of the titration curve in the buffer region. Thus the half-neutralisation potential of the electrolyte has a number of advantages over the dissociation constant in the selection of conditions for potentiometric titration. On the other hand, it is necessary in many cases to know not only the half-neutralisation potential but also the shape of the titration curve for the electrolyte in the buffer region[35].

Van der Heijde and Dahmen[143] attempted to find a theoretical basis for the choice of titration conditions. However, they compared for this purpose the half-neutralisation potentials of acids with the acid limits of empirical solvent acidity scales, which depend on the basicity of the solvents, while the titration conditions for acids are determined by the acid properties of the solvent. This led them to the incorrect conclusion that there is no definite relation between the change in the half-neutralisation potentials of acids on passing from solvent to solvent and the limits of the acidity scales. As a result, the solvent — titrant combinations proposed by van der Heijde for acids and bases of different groups lack a rigorous theoretical basis and the method of selection of titration conditions involving them is complicated and inefficient.

Further studies in this field showed that the basic limit E_B of the relative solvent acidity scale determines the possibility of the titration in the solvent of weak acids and the acid limit E_A determines the possibility of the titration of weak bases, since the half-neutralisation potentials of weak acids are located close to the basic limit and those of weak bases are close to the acid limit of the E_S solvent scale. The higher the basic and acid limits of the E_S scale compared with the limits of the water scale the greater the possibility of titrating in the given solvent weak acids and bases which cannot be titrated in an aqueous solution[144,150,156]. The potential jumps in the titration of electrolytes in the given solvent can be determined approximately as the differences between the basic (for acids) or acid (for bases) limits of the solvent scale on the one hand and the half-neutralisation potential of the electrolyte on the other.

The length of the relative solvent acidity scale characterises the possibility of differential titration of acids or bases in the solvent. A shift of the relative solvent acidity scale to the basic region creates favourable conditions for the differential titration of mixtures of weak and moderately strong acids. A shift of the acidity scale to the acid region improves the conditions for the separate titration of mixtures of strong acids.

In considering the conditions for differential titration of mixtures of bases, one should bear in mind that the position of the acid limit of the scale determines the conditions for the titration of mixtures of weak bases and that of the basic limit determines the conditions for the titration of mixtures of strong bases.

The differentiating effect of solvents is shown to varying extents for acids and bases of different strengths and types. The use of relations between half-neutralisation potentials for acids and bases on the one hand and their pK values in water and Hammett's σ constants on the other makes it possible to predict the half-neutralisation potentials for electrolytes in non-aqueous solvents on the basis of $pK_A(H_2O)$ and σ:[165-179]

$$\Delta E_{1/2} = A\ pK_A\ (H_2O) + B, \qquad (10)$$

$$\Delta E_{1/2} = A'\ \Sigma\sigma + B', \qquad (11)$$

where $\Delta E_{1/2}$ is the half-neutralisation potential of the electrolyte in relation to a standard.

To assess the possibility of the differential titration of a mixture of electrolytes on the basis of $pK_A(H_2O)$ or the σ constants and Eqns. (10) and (11), the values of their half-neutralisation potentials in non-aqueous solutions are found and their differences are determined. For a fairly distinct buffer region on the titration curves for the

individual compounds, a difference between the $E_{1/2}$ for two electrolytes of 150 — 200 mV is usually enough to ensure their separate titration in the mixture[163]. When the potential changes more markedly in the buffer region, the required difference may increase to 300 mV.

On passing from water to non-aqueous solvents, electrolytes belonging to a different reaction series give rise to individual relations between $\Delta E_{1/2}$ on the one hand and $pK_A(H_2O)$ or σ constants on the other[150]. As a result, in some cases there is an improvement in non-aqueous solvents (relative to water) of the conditions for the separate titration of mixtures of electrolytes with similar values of $pK_A(H_2O)$ and in others there is a worsening of the conditions for the separate titration of mixtures of electrolytes with different values of $pK_A(H_2O)$.

Measurements of the relative acidity scales for mixed solvents yield conclusions as to the influence of added solvents on the titration conditions in the given solvent and the use of mixed solvents to improve the conditions for the titration of individual compounds and their mixtures. It was established that the addition of water, methanol, glycols, and similar solvents impairs the titration conditions for weak acids and bases and also for mixtures of electrolytes in solvents with weak acid or basic properties, since it restricts the acidity scales for such solvents[156].

As for individual solvents, the choice of titration conditions in mixed solvents is made by comparing the half-neutralisation potentials of electrolytes with the limits of the acidity scale for the mixtures. If another solvent is added to improve the solvent power of the medium and an attempt is made at the same time to preserve the properties of the main solvent, the permissible content of the added solvent is determined from the dependence of ΔE_A and ΔE_B on mixture composition (Fig. 10). If the second solvent is added to improve the titration conditions, one should bear in mind that a significant improvement of such conditions can be achieved only after adding more than 90 vol. % of the second solvent.

When the use of solvents for acid — base titration is considered, one must take into account the effect of the solvent added together with the titrant to the solution analysed[180]. This applies particularly to R_4NOH solutions, which are usually prepared in alcohol — benzene mixtures. The permissible contents of various alcohols in mixtures used to prepare titrant solutions have been established. However, the choice of the alcohol and its content in the mixture are frequently limited also by the solubility of R_4NOH, the stability of solutions, and the method of their preparation.

The above method of choosing the optimal conditions for acid — base potentiometric titration based on E_S solvent acidity scales and half-neutralisation potentials $E_{1/2}$ of the compounds being titrated has the following advantages. Firstly, account is taken of the effect of many factors determining the titration conditions (the amount and properties of added solvents, the strength and concentration of titrants, the formation of salt precipitates during their titration, etc.) and secondly it is possible to select the conditions for titration in mixed solvents.

---o0o---

The above discussion of the acid — base equilibria in amphiprotic solvents showed that Izmailov's scheme for acid — base interaction (Ref. 8, Chapter VIII), which includes a number of related processes involving the formation of products of the addition of solvent molecules to those of the electrolyte and the formation of solvated ions and ion pairs, must be supplemented by new equilibria. Kolthoff demonstrated convincingly in the case of acetonitrile, dimethyl sulphoxide, and dimethylformamide that for solvents with weak acid properties these additional equilibria involve homo- and hetero-conjugation processes. Factors determining the degree of homo- and hetero-conjugation have been established and it has been shown that, for a quantitative interpretation of acid — base interaction and the calculation of the pH of electrolyte solutions, it is necessary to take into account the constants characterising these equilibria.

The latest determinations of the autoprotolysis constant of solvents have shown that many amphiprotic solvents (acetonitrile, dimethylformamide, dimethyl sulphoxide, and ketones) have extensive acidity scales. Factors which reduce the limits of solvent acidity scales have been discovered and relations governing the variation of the limits of the acidity scales for mixed protolytic solvents have been established. The importance of water (and similar solvents) for the explanation of protolysis in mixed solvents has been demonstrated.

Studies on acid — base interaction in amphiprotic solvents have promoted the development of the theory of potentiometric acid — base titration. The use of electrolyte dissociation constants and homo- and hetero-conjugation constants permits the calculation of titration curves in the buffer region. The conversion from theoretical solvent acidity scales, calculated from the autoprotolysis constants, into real scales is possible on the basis of the δ values taking into account the overall effect of the zero-concentration proton activity coefficient and the diffusion potential in measurements in cells with transport. The effect of numerous factors which determine the conditions governing acid — base titration is reflected in the extent of the relative (real) E_S solvent acidity scale and the electrolyte half-neutralisation potential $E_{1/2}$. The knowledge of these chemical-analytical characteristics permits a choice of the optimal titration conditions.

Analytical Chemistry of Metal Complexes with Nitrogen-containing Ligands of the 2,2′-bipyridyl Type

A.T.Pilipenko and E.R.Falendysh

A brief account is given of the analytical properties of complexes formed by metals with derivatives of 1,10-phenanthroline and 2,2′-bipyridyl, compounds that are widely used in chemical technology, biochemistry, and especially analysis. Detailed consideration is given to the possibilities and limitations of analytical methods based on various properties of these complexes (light absorption, luminescence, solubility, redox properties, etc). A list of 249 references is included.

I. INTRODUCTION

The ability of the heterocyclic amines—1,10-phenanthroline and 2,2′-bipyridyl—to form complex compounds with various metals is widely used in many branches of chemistry and technology. The employment of these complexes in analysis is governed by their specific analytical properties.

The complexes formed with iron, copper, nickel, cobalt, and other metals tend to have high thermal and thermodynamic stability because of strong ligand fields and the formation of π-back bonding with the metals. The presence of a system of conjugated double bonds in these amines is responsible for the deep colour of the complexes, which enables them to be used in spectrophotometric analysis.

The present Review surveys the principal analytical properties of the metal complexes of 1,10-phenanthroline, 2,2′-bipyridyl, and their derivatives, which are widely used in analysis and several other fields of chemistry.

II. SPECTROPHOTOMETRIC METHODS

1. Effect of Substituents on Complex Formation with 1,10-Phenanthroline, 2,2′-Bipyridyl, and their Derivatives

The well known formation of a triphenanthrolineiron complex has long been used for the spectrophotometric determination of bivalent iron. The great stability of this complex is due to delocalisation of charge from the t_{2g} orbital of iron to the π-orbital of the ligand[1]. Iron(II) is known to form stable complexes with ligands having sufficiently strong fields to produce pairing of electrons in $3d$ orbitals. 1,10-Phenanthroline (phen) and 2,2′-bipyridyl (bipy), which form low-spin complexes with iron(II) contrasting with the high-spin ethylenediamine complexes[2], fall into this category of ligands. The lowest unoccupied levels in $[Fe\,phen_3]^{2+}$ and $[Fe\,bipy_3]^{2+}$ are antibonding molecular orbitals located between the ligands and the e_g orbitals of the metal, which explains the possibility of the formation of dative π-bonds. Oxygen-containing ligands (ethylenediaminetetra-acetic, citric, oxalic, tartaric acids), which form high-spin complexes with iron(II), bind it less firmly, and can therefore be used to mask other elements (aluminium, lead, bismuth, calcium, etc.) in the determination of iron with 1,10-phenanthroline[3,4].

On the other hand, manganese(II), zinc(II), cadmium(II), cobalt(II), nickel(II), and copper(I) form more stable complexes with phenanthroline than do aluminium, thorium, lead, bismuth, and calcium, which are characterised rather by bonding with oxygen- and sulphur-containing ligands. This property is exploited to mask the above metals in the complexonometric determination of aluminium, lead, bismuth, and other ions[5-7].

Complexes formed by metals with phenanthroline are usually more stable and more intensely coloured than are those with bipyridyl. The extension of conjugation by the incorporation of a further aromatic ring in the case of phenanthroline probably creates energetically more favourable orbitals for the establishment of π-back-bonding.

The stabilities of complexes of bivalent metals with phenanthroline and its methylated derivatives show that methyl groups in positions 2 and 5 have different effects on the properties of the ligands. The monocomplexes $[ML]^{2+}$ formed by phenanthroline, bipyridyl, and 5-methylphenanthroline have the stability sequence

$$Mn<Cd<Fe<Zn<Co<Ni$$

but the tricomplexes $[ML_3]^{2+}$ have the different sequence[8,9]

$$Mn<Cd<Zn<Co<Cu<Fe<Ni.$$

The variation in the position of iron in these series is due to the abnormally high stepwise stability constant K_3, which exceeds considerably the preceding two constants and the corresponding constant for nickel (Table 1).

The markedly higher stability of triphenanthrolineiron than of the diligand complex is due to the transition from a high-spin to a low-spin configuration.

A similar effect is not observed with the 2-methylphenanthroline complexes, where di- and tri-ligand complexes have the same stability sequence

$$Mn<Fe<Zn<Cd<Co<Ni<Cu$$

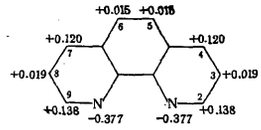
with the exception of univalent copper, which does not form a triligand complex. The position of copper in this

sequence is responsible for the use of 2,9-substituted phenanthroline derivatives for its analytical determination. In some cases the wavelengths and the molar absorption coefficients at band maxima for the iron and copper complexes of methylated phenanthrolines are additive functions [10-12] (see Table 2).

Table 1.

	Ni	Fe
lg K_1	8.6	5.8
lg K_2	8.1	5.2
lg K_3	7.6	10.0

The absorption of light by the iron complexes is most intense with the 4,7-substituted phenanthroline complexes. According to the diagram of the distribution of electron density [13]



(I)

positions 4 and 7, 2 and 9 in the phenanthroline molecule have a high positive charge (I), so that replacing the hydrogen atom at these positions by various donor groups produces a marked change in the properties of the complexes of metals with these ligands. Thus in the case of 4,7-diphenylphenanthroline (bathophenanthroline) the introduction at these positions of phenyl groups, possessing a greater donor power than methyl groups, doubles the sensitivity of the reaction with iron(II) ($\epsilon = 2.22 \times 10^4$) in comparison with phenanthroline. Bathophenanthroline is one of the most sensitive reagents for bivalent iron [14-16] (Table 3).

Table 2. Absorption of light by iron(II) complexes of methylated 1,10-phenanthrolines [10-12].

Positions of CH_3	λ, nm	$10^{-3}\epsilon$	Positions of CH_3	λ, nm	$10^{-3}\epsilon$
—	510	11.1	4,5	516	12.7
3	502	11.5	5,6	520	12.6
4	511	13.5	4,7	512	14.0
5	515	12.2	3,4,7	504	14.0
3,4	505	13.7	4,5,7	517	14.5
3,8	496	11.5	3,4,7,8	500	13.8
3,5	506	12.5	3,4,6,7	510	14.0

In 2,9-substituted phenanthrolines complex formation is influenced mainly by steric factors, owing to the nearness of the substituents to the nitrogen atoms. Thus 2,9-dimethylphenanthroline forms a stable, intensely yellow ($\epsilon = 7950$) dicomplex with copper(I) and the corresponding 2 : 1 iron complex (slightly coloured and unstable), but an iron tricomplex is not formed at all. This enables 2,9-dimethylphenanthroline (neocuproin) to be used as a highly sensitive reagent for copper(I) in the presence of iron(II), [11,17,18] titanium [19], tellurium [20], and plutonium [21].

The phenyl groups in 2,9-diphenylphenanthroline not only prevent the formation of tricomplexes of iron but also probably impede significantly the formation of a tetrahedral dicomplex of copper [13]. This is indicated by the halving of the molar absorption coefficient ($\epsilon = 3620$) in comparison with neocuproin.

Bipyridyl derivatives exhibit similar complexing properties. Positions 3,3′ (or 6,6′) in 2,2′-bipyridyl correspond to positions 2,9 in phenanthroline. Complex formation by bipyridyl with iron or copper leads to stabilisation of the rings in the same plane, and the optical density of such compounds, as a consequence of resonance conjugation, is little inferior to those of the phenanthrolinate complexes [22]. Thus, although 4,4′- and 5,5′-dimethyl derivatives of bipyridyl form tricomplexes with iron having the same absorption intensity [22] ($\epsilon = 8700$) as that of $[Fe\,bipy_3]^{2+}$, the absorption intensity of the iron complex with 3,3′-dimethylbipyridyl is only one-fifth of this value, owing to destruction of the planarity of the structure, which impairs the conditions of conjugation [23]. As in the case of neocuproin, the methyl groups do not prevent formation of a 2 : 1 copper(I) complex, but on the contrary they increase its stability, perhaps owing to enhanced basicity of the nitrogen atoms [22]. Probably for the same reason copper forms complexes [24-26] with bipyridyl-3,3′-diamine and 4,4′,6,6′-tetramethylbipyridyl, whereas iron does not yield complexes with these ligands. These reagents are highly specific for the determination of copper, but are little used owing to the difficulty of preparing them [27].

The presence of aromatic rings fused *ortho* to the nitrogen atoms produces the same effects as do methyl and phenyl groups, without yielding any analytical advantages (Table 3). Somewhat greater selectivity (for copper) in the case of 2-isoquinol-1′-ylquinoline is accompanied by a loss of reagent sensitivity ($\epsilon = 2550$). It is interesting that the introduction of a methyl group at position 3 of the quinoline ring in 2-pyrid-2′-ylquinoline and in 2,2′-biquinolyl diminishes only the sensitivity of the reagent, without affecting the stability or other properties of the complex [27]. Yet the copper complex of 3-phenyl-2,2′-biquinolyl even absorbs rather more strongly than does the corresponding biquinolyl complex, which probably indicates that steric hindrance is balanced by the high donor power of the aromatic ring [13]. In the case of 4,4′-diphenyl-2,2′-biquinolyl the donor properties of the phenyl groups are still more evident ($\epsilon = 9020$ in comparison with 5490 for the biquinolyl complex) [13,26,27]. A highly specific reagent for copper(I) is cuprotest—a derivative of bathophenanthroline containing aromatic groups *ortho* to the nitrogen atoms [28]: no anion (up to 1 M concentration) interferes with the determination of copper(I) with the exception of cyanide, thiosulphate, ethylenediaminetetra-acetate, and sulphide; the determination of microgram quantities of copper is not affected by 10 μg of any other metal. One of the most sensitive and selective reagents for copper(I) is 2,9-dimethyl-4,7-diphenylphenanthroline (bathocuproin), in which the selectivity of neocuproin is combined with the sensitivity of bathophenanthroline [29] and which can be used to determine copper in iron. While about half as sensitive as dithizone, this reagent is far superior in selectivity.

Very little investigation has been made of the effect of various acceptor substituents on the complexing properties

Table 3. Derivatives of 1,10-phenanthroline and 2,2′-bipyridyl in spectrophotometric analysis.

Reagent	Ion to be determined	λ, nm	$10^{-3}\epsilon$	Optimum pH	Solvents and extractants	Foreign ions and possible elimination of their effect	Ref.

of phenanthroline and bipyridyl. The latter ligand is made unreactive towards iron(II) by carboxyls at positions 3,3′ and 5,5′.[22] Phenanthroline-2-carboxylic acid forms a series of mixed complexes with copper and cadmium as well as dicomplexes with iron, cobalt, nickel, manganese, zinc, and cadmium in which it acts as a terdentate electronegative ligand. Iron forms either a dinuclear complex or a six-coordinate complex, a chloroform solution of the latter exhibiting weak absorption ($\epsilon = 2500$).[30,31]

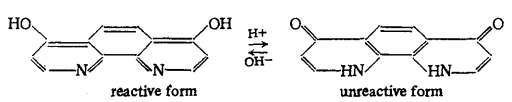
5-Nitrophenanthroline can be used to determine iron at pH 0; the sensitivity of the reaction depends on the nature of the acid, but is unaffected by the nitro-group. Conditions for the determination of iron are best in nitric acid. Phenanthroline behaves as a monobasic acid $phenH^+$ with $K_{diss,25^\circ} = 1.1 \times 10^{-5}$. Because of the high equilibrium constant

$$K_{eq:25^\circ} = \frac{[Fe\ phen_3^{2+}][H^+]^3}{[Fe^{2+}][phen.H^+]^3} = 2{,}5 \cdot 10^6,$$

the phenanthrolinate complex is formed quantitatively at pH 3–9; the complex already begins to be decolorised at pH < 2.[32,33] Probably the nitro-group in nitroferroin, by diminishing the basicity of the nitrogen in phenanthroline, increases the stability of the complex, which makes possible the determination of iron in more acid media.

Similarly, copper(I) can be determined at a lower pH with nitroneocuproin than with neocuproin[17].

In acid and neutral medium phenanthroline-4,7-diol exhibits very little complexing power for iron(II), but in strongly alkaline solutions it becomes an extremely sensitive reagent for iron ($\epsilon = 1.5 \times 10^4$)—as a consequence of the equilibrium



reactive form unreactive form

postulated[22] by analogy with 4-hydroxyquinoline[34].

2. Kinetics of Reactions Involving Metal Complexes of 1,10-Phenanthroline and 2,2′-Bipyridyl

In the analytical application of various phenanthroline derivatives and in the assessment of the stability of complexes formed by various metals, the pH of the medium must be taken into account not only in connection with the acid–base properties of the ligands but also in relation to hydrolysis and aquation, reactions which affect complex formation and the stability of complexes in solution.

Kinetic investigations of the aquation and hydrolysis of various substituted ferroins[35–39] have shown that donor substituents—methyl, phenyl, and amino—in positions 4,7 and 5,6 confer the greatest stability towards these reactions. Acceptor groups—nitro and chloro—in contrast, by diminishing the electron density on iron atoms in tricomplexes, facilitate attack by hydroxide ions on the central atom during hydrolysis, and promote the replacement of ligands by water molecules. Therefore both aquation and hydrolysis occur most rapidly in 5-nitro-, 5-chloro-, and 5-methyl-6-nitro-ferroins, and with greatest difficulty in 4,7- and 5,6-dimethylferroins, as well as in 5-aminoferroin. The kinetic characteristics of ferroin itself are intermediate between those of the two kinds of derivatives. The only exception is the 4,7-dihydroxyphenanthrolinate complex of iron, which readily undergoes aquation in acid medium, while being very stable in alkaline medium.

Solutions in aqueous organic solvents and also various masking ions are very often used in analytical practice to improve the solubility of reagents and enhance the stability of complexes. Therefore planned kinetic investigations of aquation, dissociation, and other reactions involving complex ions will give extremely valuable information on the influence of the ionic strength, the polarising properties of the medium, and the chemical nature of the solvent on the state of these ions in solution.

Thus polarographic studies have revealed a specific effect of methanol on the stability of various bipyridyl complexes of copper[40]. Complex formation between platinum(II) and phenanthroline or bipyridyl is considerably more rapid in the presence of alcohols[41-43]. In this connection it is noteworthy that $\lg(k_w/k_b)$ (where k_w and k_b are the rate constants for the aquation of 5-nitroferroin in aqueous solution and in aqueous butanol respectively) is an extremal function of the mole fraction of the alcohol[44]. This may be due to changes in the structure of the solution, so that structural factors must be considered when organic additives are used.

Study of the racemisation of triphenanthroline-iron and -nickel complexes yields interesting results enabling the stability of complexes to be assessed[45]. Whereas the rates of racemisation and dissociation are the same for $[Ni\,phen_3]^{2+}$ (which is consistent with several known facts), the rate of racemisation of ferroin far exceeds the rate of dissociation, which can be explained by postulating a complicated mechanism of intramolecular rearrangement occurring in a solution of the complex.

The reactivity of such complexes undergoes great changes in the presence of electrolytes[46]. Thus the large cations of strychnine, quinine, and brucine accelerate the dissociation and the racemisation of $[Fe\,phen_3]^{2+}$ and $[Ni\,phen_3]^{2+}$ (probably by diminishing the electron density in the bond between the central metal atom and a ligand nitrogen atom). On the addition of acids, on the other hand, the rate of dissociation decreases, to a far greater extent for $[Fe\,phen_3]^{3+}$ than for ferroin.

Kinetic differences in the rates of formation of complexes with phenanthroline can be used for the simultaneous determination of iron(II) and iron(III).[47] In determinations with phenanthroline iron(III) is usually reduced to the bivalent state by means of ascorbic acid, hydroxylamine, or sodium sulphite[48]. This method can be used to determine iron in vanadium (in weakly acid medium vanadium(IV) gives a colourless complex with phenanthroline[49]).

Tervalent iron gives the most stable complexes with oxygen- and sulphur-containing ligands, in which it is present in a high-spin state owing to the energetic advantage of the d^5 configuration. For this reason the dark blue triphenanthroline complex $[Fe\,phen_3]^{3+}$ is less stable than ferroin, and is obtained by oxidising the latter[13]. Many studies indicate[50-55] that direct reaction between iron(III) and a solution of phenanthroline produces polynuclear complexes of presumed structure[54]

$$[phen_2(X)Fe-O-Fe(X)phen_2]^{2+},\ \text{where } X = Cl^-,\ SCN^-\ \text{etc.}$$

Polynuclear complexes are formed with phenanthroline not only by iron but also by copper[56-60], chromium[61], rhodium[62], molybdenum[63], and palladium[64], but inadequate study has been made of their complicated structure, conditions of formation, and analytical properties.

3. Enhancement of Selectivity of Determination by Extraction

The sensitivity to metals of many phenanthroline reagents, especially those containing phenyl substituents, is limited by the sparing solubility of the reagents themselves in water. The solubility of triphenanthrolineiron in perchlorate media is increased by introducing a sulphogroup at position 3 or 5. The spectral characteristics of the complex remain almost unchanged[65]. The solubility of complexes of copper with bathocuproin has been increased in this way[64].

However, a decrease in the solubility of reagents and complexes in water is usually accompanied by an improvement in their solubility in organic solvents. The application of extraction methods greatly enhances the selectivity and the sensitivity of reactions. Whereas long-chain alkyl sulphates and alkanesulphonates (Teepol) are required for the extraction of ferroin[67], bathophenanthrolineiron is extracted very well by chloroform and by pentanol[16], which enables 0.25 μg of iron to be determined in the presence of $H_2PO_4^-$. However, the kinetic stability of the iron complex in chloroform [with an iron(III) content of 25 mg and above] is debatable[68].

More often a more polar extractant (nitrobenzene[69,70]) or a less toxic one (propylene carbonate[15]) is used. When isopentanol is used to extract the iron complex, the presence of cobalt, whose complex is not extracted at pH 2–9, does not interfere with the determination[11]. Iron has been determined in tin, molybdenum, tungsten, niobium, and tantalum of high purity by an extraction–photometric method using isopentyl alcohol[71]. Such methods for determining anions are based on the ability of ferroin and $[Fe\,bipy_3]^{2+}$ to form insoluble precipitates with many anions. The most stable and insoluble adducts are usually given by large anions—both organic[72,73] (salicylate, picrate, pentachlorophenoxide) and inorganic[74-76] (SCN^-, ClO_4^-, CrO_4^{2-}, $PtCl_6^{2-}$, $HgBr_4^{2-}$, etc.) (Table 3)—which is consistent with the low hydration energies calculated for large ions by means of Born's equation. Thus the use of nitrobenzene to extract adducts of ferroin with chloride, bromide, iodide, thiocyanate, and perchlorate ions showed that the difference ΔH between energies of solvation in water and in the solvent was most negative with the last three anions, zero for bromide, and positive for the chloride ion, which agrees with their stability and extractability[75,77].

Very sensitive methods for determining iron have been based on the formation of adducts of ferroin with dioctyl sulphosuccinate[78] and with cyanides[79]. The latter method enables iron to be determined in the presence of copper, since the colourless copper complex $Cu(CN)_3^{2-}$ is more stable than the corresponding complex with phenanthroline, and on extraction with chloroform in the narrow pH range 9.2–9.7 most anions do not interfere with the determination of iron.

Like ferroin, nickel(II), cobalt(II), zinc(II), copper(I), and cadmium(II) form[80,81] the compounds $M\,phen_3X_2$ ($X = I^-$, SCN^-, ClO_4^-), which can be used for the extractive spectrophotometric determination of the metals, but these methods are insufficiently specific. Several such compounds are suitable for gravimetric determination.

A rapid method for determining nickel in the presence of iron and cobalt is based on formation of the complex of nickel(II) with phenanthroline and trichloroacetic acid, which is extracted with dichloroethane. In the presence of cerium(IV) as oxidant iron and cobalt are not extracted[82].

Ruthenium(II)—an electronic analogue of iron—forms when heated with phenanthroline a yellow tricomplex, which is suitable for its spectrophotometric determination[83]. However, a more sensitive method is to extract tribathophenanthrolineruthenium with hexanol ($\epsilon = 2.7 \times 10^4$), which is inferior in sensitivity only to the 4-phenylthiocarbazide method[84].

4. Luminescent and Catalytic Properties of Metal Complexes of 1,10-Phenanthroline and 2,2′-Bipyridyl

Since preliminary separation of ruthenium from osmium and other platinum metals is required by most—including catalytic—methods, a certain advantage attaches to those based on the specific fluorescence of the bipyridyl [85], 4,4′-dimethylbipyridyl, and 5,6-dimethylphenanthrolinate complexes of ruthenium [86-88]. None of the platinum metals (up to 50 μg—osmium up to 20 μg) interferes with the determination of 0.02–0.07 μg of ruthenium. The strength of emission by the osmium complex is one-sixtieth of that due to the ruthenium complex.

Luminescence has been discovered in triphenanthroline-iridium(III) complexes in dimethylformamide solution [89].

Since transition metals usually quench luminescence by the ease of $d-d$ transitions, ruthenium(II) and iridium(III) are evidently exceptional in having a sufficiently large energy difference between filled and vacant orbitals in their tricomplexes.

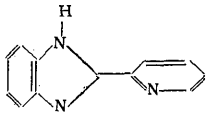
The fluorescent properties of mixed phenanthroline complexes of samarium, europium, terbium, dysprosium, etc. are very important for the development of methods for the analysis of rare-earth metals.

Many complex compounds of transition metals with phenanthroline and bipyridyl exhibit catalytic properties. Thus $[Fe\,bipy_3]^{3+}$ catalyses the chain decomposition of hydrogen peroxide [46]. Bipyridyl complexes of copper(II) actively influence the luminol–hydrogen peroxide system, widely used in luminescent analysis, the catalytic activity increasing in the sequence [90]

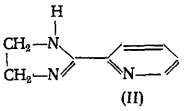
$$Cubipy_3^{2+} < Cubipy_2^{2+} < Cubipy^{2+}.$$

5. Photometric Reactions Involving Ligands Containing One or More N.C:C.N Groups

2-Pyrid-2′-ylbenzimidazole (I) and 2-pyrid-2′-ylimidazoline (II)

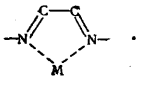


(I)

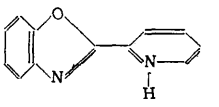


(II)

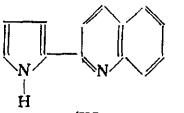
have been used [91] as reagents containing the ferroin grouping N.C:C.N. The tricomplex of iron(II) with (II) absorbs considerably more strongly than does that with (I) (ϵ = 3800 and 7800 respectively), probably owing to the unfavourable steric influence of the aromatic ring in (I), as with reagents of the type 2,2′-biquinolyl and 2-pyrid-2′-ylquinoline [11,92]. Although possessing no advantages over other reagents, (I) and (II) have found wide application in the pharmaceutical industry for the production of various derivatives substituted at the NH group, whose acidic properties are greatly dependent on the nature of the metal—iron, cobalt, nickel, zinc, copper, or manganese—coordinated into the ring



It is interesting that iron(II) does not form complexes with 2-pyrid-2′-ylbenzoxazole (III) and 2-pyrrol-2′-ylquinoline (IV)



(III)



(IV)

perhaps owing to diminished basicity of the nitrogen atom in the five-membered ring [93]. Furthermore, formation of a complex with (IV) is sterically hindered, as with copper and cobalt.

Bipyridyl *NN′*-dioxide forms seven-membered cyclic complexes, resembling complexes of pyridine *N*-oxide in the character of the bond with the metal [94]. However, they are relatively unsuitable for spectrophotometry owing to insufficient intensity of absorption.

Comparison of the structure of reagents for iron and for copper indicates the presence of two specific groups [13]—for iron(II) the N:C.C:N group, and for copper(I) R.CH.N:C.C:N.CH.R, where R = CH_3, C_6H_5, NH_2.

Table 4. Spectral characteristics of complexes of iron(II) with ligands containing a ferroin group [95,96].

No.	Ligand	λ, nm	$10^{-3}\epsilon$
1	 2-Phenyliminoethylpyridine	578	—
2	 Butane-2,3-bismethylimine	568	10.7
3	 2-Methyliminomethylpyridine	551	11.15
4	2,2′-Bipyridyl	522	8.7
5	1,10-Phenanthroline	510	11.5
6	 Butane-2,3-dione dihydrazone	444	7.0
7	 2-Benzoylpyridine oxime	560	15.6

The character of complex formation between the ligand and iron(II) may vary depending on the nature of the groups directly adjacent to the nitrogen atoms of the ferroin grouping. This is evident from the spectral characteristics of complexes of iron with ligands containing different groups directly attached to the nitrogen atoms [95,96] (Table 4). Thus the tricomplex of iron with butane-2,3-dione dihydrazone is sharply distinguished in its visible and ultraviolet spectra from the remaining complexes, which probably indicates that the nature of the ligand changes

under the influence of complex formation. The charcter of complex formation between different metals and 2-benzoylpyridine oxime is determined, as with all oxime and dioxime reagents, by the ability of the hydroxyl hydrogen to be replaced by the metal [97].

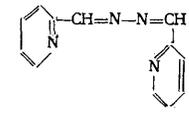
Table 5. Spectral characteristics of dicomplexes of iron(II) with ligands containing a terpyridine grouping N : C.C : N.C.C : N. [98]

No.	Ligand	λ, nm	$10^{-4}\varepsilon$
1	 2,2′,2″-Terpyridine	552	—
2	 2,6-Bismethyliminomethylpyridine	585	—
3	 2-Pyrid-2′-ylmethyliminomethylpyridine	568	1.1—1.2
4	 2-Pyrid-2′-ylmethylenaminoethylamine	592	—
5	 2-Pyrid-2′-yliminomethylpyridine	667	0.75
6	 8-Pyrid-2′-ylmethylenaminoquinoline	659	0.65

The most crucial sites for selectivity towards iron and copper are the 2,9-positions in phenanthroline and the 3,3′-positions in bipyridyl. A 2-carboxyl converts phenanthroline into a terdentate ligand, while bipyridyl and phenanthroline completely lose their ability to form complexes with iron(II) when methyl, phenyl, and amino-substituents are present in these positions. This is explained by steric hindrance to the coordination of iron, which does not develop on complex formation with copper(I); this may be connected with the size of the cations. Replacement of methylimino by ethylimino deprives both substituted phenanthrolines and aliphatic imines (e.g. No. 2 in Table 4) of their ability to yield tricomplexes [96] with iron(II). The appearance of aromatic rings and the increase in their number on passing from butane-2,3-bismethylimine to phenanthroline are accompanied by a shift in the absorption maxima of the iron(II) complexes to shorter wavelengths, but the lengthening of the chain of conjugated double bonds in 2-phenyliminomethylpyridine produces a bathochromic shift owing to the delocalisation of π-bonds. A similar bathochromic displacement is observed in a series of iron(II) dicomplexes with Schiff bases containing a terpyridine grouping N:C.C:N.C.C:N (Table 5). [98] The replacement of aliphatic double bonds (2, 3) by single bonds (4) or double bonds in an aromatic ring (5, 6) leads to a bathochromic shift in the spectrum of the iron(II) complexes, which is especially marked in the last case.

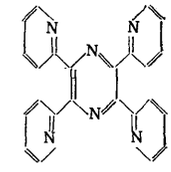
2,2′,2″-Terpyridine, like 2,2′-bipyridyl, is a planar ligand, as is confirmed both by X-ray examination and by the absence of optically active bisterpyridine complexes, e.g. with ruthenium(II) and nickel(II). [46] The formation of octahedral complexes produces some strain in the terpyridine molecule owing to the inevitable distortion of the angles between the pyridine rings. Since such deformation should be still greater with quaterpyridine, four coordination cannot be achieved with this compound. As a reagent, terpyridine has no advantages over bipyridyl, but its derivatives are widely used in analysis, and compounds containing terpyridine and bipyridyl groupings find application in biology. Their complexes with metals—iron, cobalt, nickel, ruthenium, osmium—are intensely coloured and possess biological activity.

Certain difficulties in studying complex formation are created by multidentate ligands [99]. Thus terdentate pyridine-2-carbaldehyde azine forms strongly coloured octahedral complexes with iron(II) and nickel(II). However, dinuclear compounds of the type $[M_2A_3]^{4+}$ are also known, where A represents



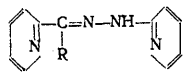
and is a bisbidentate ligand. This reagent forms also the iron complex $[FeA_3]^{2+}$. As with phenanthroline and bipyridyl, the presence of any substituent in position 2 of the pyridine ring strongly affects the coordinating properties of such ligands.

It is interesting that 2,3,5,6-tetrakispyrid-2′-ylpyrazine



is a terdentate ligand like terpyridine, since simultaneous coordination of all six nitrogen atoms is impossible without destroying the planarity of the structure. Furthermore, the coordination of one nitrogen atom of the pyrazine ring causes a marked diminution in the donor properties of the other, which is confirmed by the fact that pyrazine does not form diquaternary ammonium bases. However, unsubstituted pyrazine forms compounds with copper(I), nickel(II), and cobalt(II), in which both nitrogen atoms of the pyrazine ring are coordinated with the metal [100].

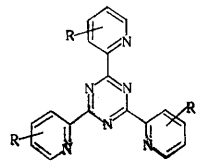
In the terdentate hydrazine derivatives of general formula



either three donor nitrogen atoms may be coordinated depending on the pH (to form the complex cations $[MA_2]^{2+}$) or (in alkaline medium) all four nitrogen atoms may be coordinated to form neutral dicomplexes [101]. The reversibility of such transformations can be utilised for the technical purification of metals, since in alkaline solution these neutral complexes are readily extracted.

Terpyridine forms complexes not only with iron(II) and cobalt(II) but also with quadrivalent platinum [$PtCl_3$terpy].Cl, as well as five-coordinated complexes of the type [MX_2terpy] (M = Co, Cu, Cd), the mechanism of whose formation has not been adequately clarified [45].

One of the most sensitive reagents for iron(II) is 4,4′,4″-triphenyl-2,2′,2″-terpyridine (terrosite) [102] ($\epsilon_{583} = 3.02 \times 10^4$), but the sparing solubility and poor extractability of the complexes obtained restricts its analytical application. The search for highly sensitive reagents whose complexes could be readily extracted has involved the study of numerous hydrazine and triazine derivatives, data on which are briefly summarised in Tables 3 and 4. The most sensitive reagents for the determination of iron(II) were 2,4,6-derivatives of 1,3,5-triazine of general formula

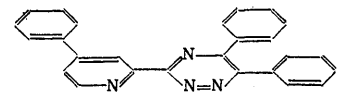


the complexes of which have values of $10^{-4}\epsilon$ of 2.26, 2.44, and 2.52 respectively depending on whether R = H, 4-C_2H_5, 4-C_6H_5. The comparative availability of 2,4,6-tripyrid-2′-yl-1,3,5-triazine has been responsible for its widespread use to determine iron in various materials [104].

The presence of amino-groups in the triazine ring strongly diminishes the complexing power of the ligand, the decrease being an additive function of the number of such groups. Whereas the extinction coefficient for the iron complex of 4,6-dipyrid-2′-yl-1,3,5-triazin-2-amine is more than halved ($\epsilon_{497} = 8000$) in comparison with tripyrid-2′-yl-1,3,5-triazine, we have $\epsilon_{455} = 300$ for 6-pyrid-2′-yl-1,3,5-triazine-2,4-diamine, and 1,3,5-triazinetriamine (melamine) does not form an iron(II) complex at all. The introduction of ethyl and phenyl substituents into the pyridine ring slightly increases the extinction coefficients of the complexes, as was to be expected. Use of the polar extractant nitrobenzene also enables the intensity of absorption of the complexes to be raised [105]. Values calculated for the extinction coefficients from refractometric data were then rather higher than the observed values, which was shown to be due to the involvement of water in formation and extraction of the complex.

Calculation of the most important sites of association in the complexing molecule will probably permit the planned introduction of substituents to obtain extractable complexes having specified properties [106,107].

Among other triazine derivatives the most effective was found to be the bidentate ligand 5,6-diphenyl-3,4′-phenylpyrid-2′-yl-1,2,4-triazine



which is inferior in the sensitivity of its reaction with iron(II) ($\epsilon_{561} = 2.87 \times 10^4$) only to terrosite, but possesses considerably better solubility in organic solvents [102,108].

Complexes of *N*-heterocyclic amidrazones, containing the ferroin grouping, are usually unstable even with a large excess of the reagent. In several cases, however, they can be used as acid–base indicators, since they contain a hydrogen atom which can be detached in alkaline medium [101].

A combined method has been worked out for the simultaneous determination of copper and iron by means of 5,6-diphenyl-3-pyrid-2′-yl-1,2,4-triazine and the ability of copper to form a stable complex with cyanide ions in the presence of this reagent [109]. The concentration of copper was found from the decrease in optical density at the wavelength of absorption by its complex with the reagent ($\epsilon_{488} = 7900$), and that of iron(II) from the optical density of the solution after the addition of sodium cyanide ($\epsilon_{555} = 2.35 \times 10^4$). Use of the above reagents to determine cobalt(II) was relatively ineffective, because of inadequate sensitivity.

Isomeric phenanthrolines and bipyridyls used in spectrophotometric methods are 6-hydroxy-1,7-phenanthroline (an analogue of 8-hydroxyquinoline) to determine iron and vanadium [110,111] and 2,3′-bipyridyl to determine niobium and titanium as mixed complexes with salicylic acid and catechol [112], germanium [113], and uranyl [114].

4,4′-Bipyridyl, in contrast to the 2,2′-isomer, forms with metals of the platinum group microcrystalline precipitates suitable for their microcrystalline detection [115]. The arrangement of the nitrogen atoms in 4,4′-bipyridyl favours the formation of polynuclear compounds with many metals [116].

6. Physicochemical Properties of Mixed Complexes and Their Application to Extractive Photometric Analysis

The sensitivity and the specificity of the extractive photometric analysis of metals can in many cases be considerably increased by the use of phenanthroline (or bipyridyl) mixed with various oxygen-, sulphur-, and nitrogen-containing ligands, since the stability and the light absorption of the mixed complexes are frequently far greater than those of the simple complexes. Thus the adduct of ferroin with a sulphophthalein dye molecule (bromophenol Blue) is intensely coloured [117] ($\epsilon_{630} = 5.9 \times 10^4$) and is readily extracted by a mixture of chloroform and isopentanol (4 : 1) within a narrow pH range (8.7–8.9). Traces of iron in hypophosphite ($\sim 10^{-8}$%) are determined in this way. Dithizone (Dz) is an extremely sensitive but relatively unspecific reagent. Nickel, like many other metals, gives an intensely coloured dithizonate ($\epsilon = 3.4 \times 10^4$), but in the presence of phenanthroline a chloroform-extractable blue complex $NiDz_2$phen is formed, which is more intensely coloured ($\epsilon = 4.91 \times 10^4$) than is the dithizonate [118].

Whereas Cu^+, as a consequence of stereochemical uniformity is characterised by simple complexes with polarised ligands such as phenanthroline and bipyridyl, the easily deformable Cu^{2+} ions readily form mixed complexes by establishing stable covalent bonds with different ligands. Examples are complexes of copper(II) with bipyridyl and glycine, pyridine-2-carboxylic acid, 8-hydroxyquinolinesulphonic acid, pentane-2,4-dione,[119-123] biguanidine, and diacid Schiff bases[124,125]. These are of especial interest, since they are readily soluble in such organic solvents as dimethyl sulphoxide, pyridine, dimethylformamide, and ethanol, and possess high molar absorption coefficients—$\epsilon = (5-12) \times 10^3$.

One of the most sensitive photometric methods for determining copper is based on the fluorescence of the mixed complex CuRBE$phen_2$ (where RBE represents the xanthen acid dye Rose Bengal—tetrachlorotetraiodofluorescein), which can be extracted by chloroform and by ethyl acetate ($\epsilon_{570} = 7.8 \times 10^4$). This method enables 1 μg of copper to be determined in 500 ml of solution on extraction with 25 ml of chloroform. Iron is masked by excees of phenanthroline, since it forms a more stable complex with the latter. Sometimes copper is first extracted as its neocuproin complex in the presence of ethylenediaminetetra-acetic acid in order to improve the selectivity[126]. Since many metals form complexes of this type with phenanthroline and Rose Bengal[127,128] (Table 6), masking agents must be used to enhance the selectivity of this method.

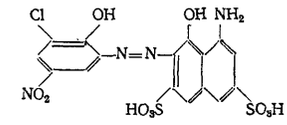
Table 6. Comparative absorption intensities by metal dithizonates by their mixed complexes [M$phen_2$RBE].[127]

Cation	Absorption $10^{-4}\epsilon$		Extractant
	dithizonate	mixed complex	
Cd^{2+}	8.8	9.2	ethyl acetate
Co^{2+}	5.9	9.2	ethyl acetate
Cu^{2+}	4.5	7.8	ethyl acetate
		6.25	chloroform
Mn^{2+}	3.2	6.5	ethyl acetate
Ni^{2+}	3.4	5.0	chloroform
Ag^+	—	4.0	chloroform
Pb^{2+}	7.2	7.0	nitrobenzene
Zn^{2+}	9.4	9.5	ethyl acetate

A highly sensitive method has been developed for determining silver(I) by means of other fluorescein derivatives: the intensity of absorption of the mixed complex Ag$phen_2$BPR is fivefold that of the simple Bromopyrogallol Red complex AgBPR ($\epsilon_{635} = 5.1 \times 10^4$ and $\epsilon_{390} = 1.0 \times 10^4$ respectively). In the presence of excess of phenanthroline iron(II) does not interfere with the determination[129].

Stable cyanide complexes of silver are easily formed in the presence of phenanthroline and either dye (Bromopyrogallol Red or Rose Bengal), a fact which is utilised to determine cyanide ions at concentrations of 0.1–0.00001 M. The end-point of the titration is determined either photometrically or visually from the fluorescence of the mixed complex Ag$phen_2$BPR or Ag$phen_2$RBE.[130] Silver concentrations of 0.2–15 μg ml^{-1} are determined as a mixed complex with bipyridyl and sulpharsazen (the sodium salt of 2-arsono-4′-*p*-nitrophenyltriazenoazobenzene-4-sulphonic acid), which is tribasic[131]. Preliminary extraction with dithizone eliminates the effects of the cations Hg^{2+}, Cu^+, and Pd^{2+}, and of the anions SO_4^{2-}, Cl^-, NO_2^-, and CH_3COO^-.

Galloin, a hydroxylated aromatic sulphonic acid



(H_3R), has also been suggested as a third component for the mixed complex. The formation of $(Ag\,phen_2)_3R$ can be used to determine silver[132] ($\epsilon_{630} = 4.0 \times 10^4$). Pyridine and ammonia are stated not to form analogous ternary compounds with galloin. The stepwise complex formation, depending on the pH of the solution, rather complicates the choice of optimum conditions.

Since most of the above methods for determining copper and silver have approximately the same sensitivity, the choice of reagent must obviously depend on the presence of intefering ions in the specimen[133] (brief data on the effect of foreign ions are given in Table 3).

The widespread use of mixed complexes in chemistry led to a series of studies on the influence of the electronic structure of metals, the nature of ligands, and the interaction of coordinated groups on the stability, solubility, redox behaviour, and other analytical properties of these complexes. The combined application of physicochemical and physical methods to solve these problems enables laws of complex formation to be established, which stimulates the further development of analytical methods using mixed complexes.

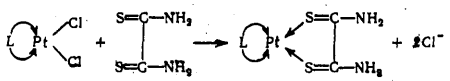
The effect of the nature of the amines on the stability of the mixed compounds has been studied with nickel(II) as example. Thus the replacement of pyridine by ammonia occurs more easily in complexes of this metal with ethylenediamine and pyridine than in those with phenanthroline and pyridine. Complexes in which the ligands are both heterocyclic or both aliphatic are more stable than mixed complexes, in which the π-bonds are regarded as destroying the symmetry of the complexes[134], which diminishes their stability. These results are consistent also with the fact[135] that complexes with 8-hydroxyquinoline or with bipyridyl are more stable than the mixed compounds with these ligands[136]. Nevertheless, the stability of the mixed compounds of cobalt(II) and zinc(II) is the same, while with copper the mixed complexes are the more stable.

Whereas the character of the bond in the copper complexes changes little on passing from bipyridyl to biquinolyl (biqu), while steric factors play the main part with iron, favourable conditions for increasing covalency of the bond are created in gold(III) complexes with biquinolyl. This is apparent, for example, in the fact that the complexes $[AuX_2bipy]^+$ are electrolytes[136], whereas $[AuX_3biqu]$ are non-electrolytes[137]. Study of complex formation between monocomplexes of nickel with phenanthroline and its derivatives on the one hand, and with diethylenediamine and nitrilotriacetic acid on the other, showed[138] that, although the rate of formation of the mixed complex is affected by the nature of the substituent in the phenanthroline, the rate-determining stage of the process is dehydration of the cation $[Ni\,phen]^{2+}$. The infrared spectra of the complexes $Fe(CN)_2(5\text{-}Xphen)_2$ (where X = Cl, NO_2, CH_3, C_6H_5) indicate that the presence of acceptor substituents strengthens the Fe–NC bond and diminishes the electron density on the nitrogen atoms in the phenanthroline molecule[139]; donor groups have the opposite effect. The degree of π-bonding of cyano-groups with the

central metal atom in this series of compounds intensifies from iron(II) through ruthenium(II) to osmium(II).[140] Increase in covalency of the metal–ligand bond and in the stability of the bivalent state in the same sequence is characteristic also of compounds[141] of the type MCl_2bipy_2, and in the sequence $Ni^{2+} < Pd^{2+} < Pt^{2+}$ of the compounds $[MX_2amin]$, where amin = phen, bipy.[42,142,143]

In most cases substitution of a ligand in platinum complexes takes place according to the equation[144,145] $k = k_1 + k_2[Y]$, where k_1 is the aquation [rate] constant and k_2 a constant depending on the nature and the three-dimensional structure of the ligands, while Y is the attacking ligand.

Kinetic study of the exchange interaction between dithio-oxamide and dichlorodiamineplatinum complexes with bipyridyl, pyridine, and ethylenediamine (L)



has shown[146] that the bipyridyl complex is the most reactive, although infrared spectroscopy indicates the most stable platinum–chlorine bond in this particular complex[147]. Obviously, the peculiarities of the metal–ligand (L) bond develop in this case only at the instant of attack on the complex by the second ligand (i.e. at the instant of the transition state).

Salt isomerism has been found among mixed complexes[148] of palladium(II) and platinum(II) of the type $[MX_2bipy]$, where $X = SCN^-$, $SeCN^-$. In aqueous solution thiocyanates in which the metal is coordinated with the nitrogen atom are the more stable, and selenocyanates in which coordination is effected between the metal and the selenium atom.

Mixed complexes with phenanthroline and bipyridyl are used for the analytical determination of scandium, rare-earth metals, and uranyl. Many eight-coordinate compounds of scandium and rare-earth metals with phenanthroline and 4,4,4-trifluoro-1-thienylbutane-1,3-dione[149], pentane-2,4-dione[150], cupferron, and 5,7-dibromo-8-hydroxyquinoline[151] are readily extracted by benzene and other solvents in acid media. These complexes are usually slightly coloured, but differences in extractability associated with the ionic radii of rare-earth metals can probably be used for extractive determinations with the application of isotopes. Several mixed complexes of europium, samarium, terbium, and dysprosium with bipyridyl and 4,4,4-trifluoro-1-thienylbutane-1,3-dione, dibenzoylmethane, etc. fluoresce, generally more strongly than do the simple complexes[152,153]. The bipyridyl molecules probably create asymmetric fields that favour f–f transitions[154]. The complex of uranyl with phenanthroline and 4,4,4-trifluoro-1-thienylbutane-1,3-dione is also extracted well by benzene, and its solutions fluoresce in long-wavelength ultraviolet radiation[155].

Highly charged cations generally form unstable complexes with ligands such as phenanthroline, which usually stabilise the lowest oxidation states—iron(II), copper(I), ruthenium(II), and titanium(III). The stabilisation of tervalent titanium, which is extremely unstable under normal conditions, enables it to be determined in the presence of titanium(IV) and a hundredfold excess of phenanthroline or bipyridyl as the tricomplex. In the presence of oxalic acid, quadrivalent titanium bound into an anionic complex is not extracted by bis-2-ethylhexyl hydrogen phosphate, but the complex of tervalent titanium is readily extracted[156] ($K_{distrib} \simeq 1000$). A metal indicator method has also been used to study the stability of phenanthroline complexes of titanium and zirconium[157,158].

Mixed complexes of highly charged cations are more stable. An alcoholic solution of bipyridyl is used with iron(III) chloride to detect phenols in paper chromatography[159]. Many complexes are known[160–163] of vanadyl with phenanthroline and anionic ligands (4,4,4-trifluoro-1-thienylbutane-1,3-dione, chromotropic acid, collidinic acid, tiron, etc.), which are of interest in connection with their extractability and their electrical conductivity.

Niobium(V) and titanium(IV) form anionic complexes which, with aliphatic and aromatic bases in weakly acid solution, yield precipitates extractable by chloroform[164]. Fairly sensitive methods have been developed for determining niobium as mixed complexes with phenanthroline and catechol or thiocyanate ions[165]. No definite relations could be detected between the pK values of the bases and the stability and extractability of the mixed adducts, since these properties are subject to the simultaneous influence of many factors (the basicity of the ligands, the polarising properties of the medium, the dipole moments of the molecules, etc.), which cannot be allowed for because of the absence of systematic investigations on the combined effect of these factors on the properties of complexes of this type.

Study of the mechanism of complex formation is considerably complicated by the tendency of multivalent cations to undergo hydrolysis in solution and form polynuclear compounds, by their enhanced affinity for oxygen. Therefore an empirical method must frequently be used to standardise the reaction conditions.

For example, the addition of phenanthroline and a solution of tin(II) chloride in 3–5 N hydrochloric acid to a solution containing molybdate ions produces a fairly intense coloration ($\epsilon_{508} = 6290$). However, although this reaction is quite sensitive, its application is extremely restricted owing to the instability of the coloration (~0.5 min). The reaction mechanism has not been elucidated, but it has been established that the most intense colour is observed with the ratio $[Mo^{VI}]/[Mo^{V}] = 1:5$ and the use of phenanthroline. Derivatives of phenanthroline cause the absorption to diminish; with terpyridine $\epsilon_{508} \simeq 880$; and bathophenanthroline forms an insoluble white precipitate. The same reaction is used as a spot test for the detection of 0.2 μg of molybdenum in 0.5 ml of solution, from the colour of a benzene extract[166,167].

Chromium(III) forms complex dinuclear compounds with phenanthroline[61,168], but the mechanism of these processes has also remained univestigated.

III. GRAVIMETRIC AND TURBIDIMETRIC METHODS

In the presence of alkali and alkaline-earth metals, ammonium, aluminium, chromium, beryllium, and scandium, the bivalent metals—cobalt, zinc, nickel, copper—and also bismuth(III) form insoluble mixed complexes with phenanthroline and thiocyanate ions, which are suitable for the gravimetric determination of these metals[169–171].

Milligram quantities of phosphorus are determined by means of the reaction of dodecamolybdophosphoric acid with phenanthroline, which yields an insoluble yellow crystalline precipitate $phen_4H_3PMo_{12}O_{40}$, of high molecular mass and therefore an ideal form for weighing[172]. Uranyl is determined by a combined method involving preliminary precipitation of a mixed complex with phenanthroline and m-aminobenzoic acid $UO_2(m\text{-}NH_2C_6H_4COO)_2phen_4$ and subsequent titration of the complex with nitrite[173]. Mixed complexes, but more soluble, are formed also by p- and o-amino-acids.

The heterometric titration of tungstophosphoric acid with phenanthroline[174] enables 0.0025 M heteropoly-acid or 0.001 M phenanthroline to be determined. The structure of the resulting complex has not been studied. Methods have been worked out also for the heterometric titration of palladium, platinum, and gold as mixed complexes with phenanthroline and thiocyanate or chloride ions[175]. A gravimetric method for determining lead is based on the formation of an insoluble precipitate by the interaction of the bulky quadruply charged anion $[Pb(S_2O_3)_3]^{4-}$ with ferroin[176]. The insolubility of the mixed complexes of scandium and vanadyl with phenanthroline and 4,4,4-trifluoro-1-thienylbutane-1,3-dione forms the basis of turbidimetric methods[149,163] for their determination in aqueous solution. Mercury(I) forms with phenanthroline the insoluble compound[177] $Hg_2(NO_3)_2$phen (solubility product 10^{-24}).

Table 7. Gravimetric methods using 1,10-phenanthroline and 2,2′-bipyridyl

Reagent	Species estimated	Quantity	Error, %	Ref.
Ferroin	$[Pb(S_2O_3)_3]^{4-}$	0.007—0.024 g	0.7	176
1,10-Phenanthroline (or 2,2′-bipyridyl) and thiocyanate	Cu^{2+}	0.0005—0.003 g	0.1—0.6	169
	Zn^{2+}	0.0005—0.003 g	0.1—0.6	169
	Ni^{2+}	0.0005—0.003 g	0.1—0.6	169
	Co^{2+}	0.0001 g	—	170
	Bi^{3+}	0.005—0.020 g	1.5	171
1,10-Phenanthroline and *m*-aminobenzoic acid	UO_2^{2+}	0.01 g	0.2	173
1,10-Phenanthroline and Na molybdate	$H_2PO_4^-$	0.001—0.01 g	—	172
1,10-Phenanthroline	tungstophosphoric acid	$2.5 \cdot 10^{-3}$ M	—	174
K_2[FePhen $(CN)_4$]	Zn^{2+}	10^{-5} M	0.4	249

The sparing solubility of certain compounds of metals with phenanthroline is utilised for their preliminary concentration, after which the metals are determined by spectrophotometric or redox methods. For example, this procedure is used to determine iron with Bromophenol Blue[146]. Since the adduct of ferroin with this dye is extracted over the narrow pH range 8.7—8.9, the iron is first precipitated as ferroin iodide. An indirect method[80] for determining lithium involves precipitation of $KLiFeIO_6$ followed by decomposition and the determination of iron with phenanthroline.

A method[178] for recovering phenanthroline (up to 86%) from ferroin complexes is based on precipitating $CuSO_4$. .phen, decomposing it with ammonia, and extracting the phenanthroline with chloroform.

A turbidimetric method[179] for determining cadmium(II) is based on the insolubility of CdI_2phen. Gravimetric methods have been proposed also for determining cadmium(II) and uranyl with 2,3′-bipyridyl.[143]

Differences in the solubility of ruthenium and osmium complexes in different oxidation states are of industrial interest[180,181]. The optical *D*- and *L*-isomers of osmium(II), ruthenium(II), and nickel(II) triphenanthrolinates not only differ in biological activity but also give compounds with antimonyl *d*-tartrate differing very markedly in solubility, a property which is used for their separation[182].

While considerably less sensitive than other methods, gravimetric methods using various complexes of phenanthroline and bipyridyl derivatives can be applied in combined procedures to enhance the selectivity of reagents. Table 7 gives examples of the most widely used gravimetric methods involving complexes with phenanthroline.

IV. ANALYTICAL METHODS BASED ON THE REDOX PROPERTIES OF METAL COMPLEXES OF 1,10-PHENANTHROLINE AND 2,2′-BIPYRIDYL

The use of solvents varying in donor power—dioxan, alcohols, oxolan, formamide, dimethylformamide, sulpholan, etc.—in preparations and in electrochemical investigations[183–186] enables several compounds of phenanthroline and its derivatives with transition metals to be obtained in different oxidation states. Besides their theoretical interest these complexes are of great practical interest as catalysts. All this leads to the development of methods for determining the different valency forms of metals and use of the redox properties of such complexes for analytical purposes. Among well known examples is the ability of phenanthroline and bipyridyl to stabilise the lower states of oxidation of metals, which has enabled titanium(III) to be determined in the presence of titanium(IV)[156] and various anions to be estimated by means of ferroin $[Fe\,phen_3]^{2+}$, whose redox potential is $E_0 = -1.06$ V, whereas

$$E_{0Fe(H_2O)_6^{2+}/Fe(H_2O)_6^{3+}} = -0.77 \text{ V}.$$

2,3,4-Substituted phenanthrolinates of iron and copper(II) exhibit a linear relation between the redox potential and the dissociation constant of the ligand[187]. Use of substituted phenanthroline complexes has enabled a series of oxidimetric indicators (Table 8) to be produced[22].

Table 8.

Indicator	E_0 in 1 M H_2SO_4, V
$[(5\text{-}NO_2phen)_3Fe]^{2+}$	1.25
$[(5\text{-}SO_4phen)_3Fe]^{2+}$	1.20
$[Fe\,phen_3]^{2+}$	1.06
$[(5\text{-}CH_3phen)_3Fe]^{2+}$	1.02
$[\{5,6\text{-}(CH_3)_2phen\}_3Fe]^{2+}$	0.97
$[\{4,7\text{-}(CH_3)_2phen\}_3Fe]^{2+}$	0.88
$[\{3,4,7,8\text{-}(CH_3)_4phen\}_3Fe]^{2+}$	0.81

The stable vanadium complex $[V\,phen_3]^{2+}$ is also used as a redox indicator[188] in the titration of iron trichloride with bivalent chromium. The corresponding bipyridyl complex is not suitable for this purpose, since its rate of dissociation depends on the acidity of the medium.

Many compounds of tervalent titanium with bipyridyl have been prepared. In view of their low electrical conductivity in non-aqueous solutions, they are assumed to have a bridged structure[189].

The rhenium compound $Na_2[Re(CN)_4bipy]$ is extremely stable in aqueous solution, although the metal is present in the uncharacteristic bivalent state. The acid $H_2[Re(CN)_4bipy]$ is very strong ($pK_2 = 2.23$); it gives

insoluble precipitates with many cations [190]—iron(II), iron(III), copper(II), silver(I), cobalt(II), nickel(II), zinc(II), cadmium(II), mercury(II), etc. Compounds of rhenium with bipyridyl in which the metal is present in its lower oxidation states have typically a dinuclear structure [191]. The number of compounds with phenanthroline and bipyridyl in which the metals—manganese, technetium, rhenium—are present in higher states of oxidation increases in this sequence, which is consistent with the known tendency for the stability of such compounds to increase in the same sequence.

Manganese can be determined by a combined method [192], involving preliminary extraction as $Mn(SCN)_2phen_2$ followed by titration of this complex in acid medium with potassium permanganate. Although the Mn^{2+} ion is very stable in acid solution as a consequence of its d^5 configuration, in the presence of phenanthroline this titrant [193,194] oxidises it in concentrated hydrochloric acid to Mn^{3+}. In ammonium acetate buffer manganese(II) is more firmly bound by ethylenediaminetetra-acetic acid than by phenanthroline, a property that is used to mask manganese [5] in the determination of nickel and cobalt.

Redox systems often catalyse reactions between two other systems if they have an intermediate redox potential. Thus the system $[Co\,bipy_3]^{2+} \rightleftharpoons [Co\,bipy_3]^{3+} + e$ ($E_0 = -0.91$ and -1.2 V in 50% alcohol and in water respectively) is a catalyst for the reduction of aromatic nitro-compounds by sodium tetrahedroborate [195]. The trisbipyridyliron complex catalyses the chain decomposition of hydrogen peroxide [46], and copper complexes act as catalysts of chemiluminescence [90].

The complex $[Fe(C_2H_5)_2bipy_2]^{3+}$ has been prepared by the interaction of iron acetylacetonate and diethylaluminium ethoxide in ether. This is a very active catalyst of the cyclopolymerisation of butadiene, acetylene, and acrylonitrile [196]. Polymerisation has been shown to involve the intermediate formation of a bond between the substrate and the iron atom.

Establishment of the mechanism of the oxidation–reduction reactions of these compounds may be of great value for elucidating the nature of their catalytic action [197]. Thus it has been shown by an isotope method that hydrogen peroxide is formed when the cation $[Cu\,bipy_2]^+$ undergoes oxidation by oxygen: water molecules play no part in the reaction [198]. This fact is very important for understanding the role of this complex cation in chemiluminescence.

In the presence of phenanthroline, cobalt(II) chloride acts as an oxygen carrier [199]. The high rate of electron transfer in complexes of metals with ligands of this type is responsible also for the high rates of redox reactions involving such complexes. This is evidently due to the small difference in size between reduced and oxidised cations, which requires no considerable reorientation of the solvate structure; furthermore, the π-character of the metal–ligand bond also facilitates electron transfer [22,200]. The rates of electron transfer in such complexes far exceed those of complex formation [46].

Study of the optical properties of the D-$[Os\,bipy_3]^{2+}$–L-$[Os\,bipy_3]^{3+}$ system showed that loss of optical activity and electron transfer take place simultaneously and at the same rate [201,202].

The large difference in potential between the Co^{2+}/Co^{3+} and Fe^{3+}/Fe^{2+} systems in the presence of phenanthroline and also the stabilisation of the cobalt(III) and iron(II) states by this ligand, so that a clear end-point is obtained (Δv = 600 mV), are exploited in the potentiometric titration of cobalt(II) with tervalent iron [203]. Cobalt can be determined in metallic nickel by this method. The ferroin that is formed is determined spectrophotometrically or by back-titration with cerium(IV). [204] It is possible also to titrate a bivalent cobalt salt directly with a quadrivalent cerium salt in the presence of ferroin as redox indicator [205]. Similar indirect methods using iron(III) chloride in the presence of phenanthroline have been employed also in determining uranium(IV), [206] niobium [207], vanadium [208], and vitamin E. [209]

A sensitive method [210] for determining traces of hydrogen peroxide is based on its reactions with ferroin or with iron bathophenanthrolinate.

The low potentials of the transition $Cu^{2+} \rightleftharpoons Cu^{+} \rightleftharpoons Cu^{0}$ are responsible for the use of complexes of copper with biquinolyl and 2,9-disubstituted phenanthrolines for the determination of oxidants and reductants (glucose, creatine, ascorbic and uric acids [211]).

Table 9. Combined methods of analysis based on photometric and redox properties of complexes with 1,10-phenanthroline

Reagent	Species determined	λ, nm	$10^{-3}\varepsilon$	pH	Sensitivity	Ref.
Ferroin	H_2O_2	510	11.1	2—9	10^{-5} M	210
Fe bathophenanthrolinate	H_2O_2	533	22.4	4	10^{-6} M	210
	Reductants				μg/100 ml	
$H[Fe(CN)_4Phen]$	quinol	462	—	2	60—300	212
	ascorbic acid				100—500	
	tannin				16—190	
	hydroxylamine				30—300	
	hydrazine				4—50	
	$Na_2S_2O_3$				130—550	
	$K_4[Fe(CN)_6]$				400—1800	
	Oxidants				μg/100 ml	
$K_2[Fe(CN)_4Phen]$	Ce^{IV}	462	—	2	60—560	212
	Cr^{VI}				10—70	
	MnO_4^-				30-120	
	IO_4^-				110 - 460	206
1,10-Phenanthroline and $FeCl_3$	U^{IV}	510	11.1	1.5—5	—	

The pair of complexes—$K_2[Fe(CN)_4phen].4H_2O$ (I) and $H[Fe(CN)_4phen].H_2O$ (II)—is most suitable for the determination of oxidising and reducing agents. The potential of this system ($E_{0,I/II}$ = 0.656 V) is almost independent of pH. The first complex has a sharp absorption maximum at 462 nm; the second hardly absorbs in this region. Many substances can be determined (Table 9) by measuring the optical density at this wavelength in solutions of complex (I) or (II) in the presence of oxidants or reductants respectively. The only limitation of this method is that the rate of redox processes may not be high enough in the determination of a particular substance [212]. The nature of a substituent has an appreciable influence on the kinetics of the oxidation of ferroins by quadrivalent cerium [46]: 5-nitroferroin is oxidised more slowly than ferroin itself by several orders of magnitude.

The rate of oxidation of ruthenium(II) by tervalent thallium is considerably lower in deuterium oxide than in water, which probably indicates that the proton plays a part in the oxidation [213].

Phenanthroline and bipyridyl accelerate the oxidation of malic and lactic acids [214] by chromic acid. It is important to study the mechanism of this reaction in order to elucidate the part played by these acids in biochemical processes.

A kinetic study of the reduction of platinum(IV) by the trisbipyridyl complex of bivalent chromium has established [215] that in aqueous solution stable platinum(IV) compounds usually contain two hydroxy-groups.

We may note in conclusion that redox processes involving complexes of metals with ligands such as phenanthroline and bipyridyl cannot be adequately characterised because of the lack of sufficient quantitative data.

V. VALUE OF 1,10-PHENANTHROLINE AND 2,2′-BIPYRIDYL DERIVATIVES IN ANALYSIS AND IN APPLIED CHEMISTRY

Analysis and technology make widespread use of the ability of 1,10-phenanthroline and 2,2′-bipyridyl to stabilise various oxidation states of metals and also of the catalytic properties of the complexes formed by these ligands with metals [3,4,90,156,188,216–218].

The use of non-aqueous solutions for inorganic preparations has yielded several complexes of metals with these ligands possessing valuable catalytic properties. Thus $[Fe(C_2H_5)_2bipy_2]^{3+}$ effectively catalyses the cyclopolymerisation of butadiene and acetylene [196]. Many complexes of Group VIII metals with ligands containing bipyridyl and imino-groups are also effective biological catalysts. The biological activity of these compounds depends on the nature of the coordinated metal, which is utilised in the production of pharmaceutical preparations [219]. The ability of the imino-hydrogen atom in such ligands to be replaced reversibly by a metal can be used for the technical purification of metals and in analysis [219].

The analytical possibilities are considerably extended by the use of phenanthroline and bipyridyl derivatives containing various donor and acceptor substituents, which have an active influence on the sensitivity and the selectivity of these reagents. The application of non-aqueous solvents and extractants also assists the controlled variation of the analytical properties of the metal complexes [44].

Metal complexes are becoming increasingly widely used in analysis as a consequence of the growing application of non-aqueous solutions in chemistry and technology. Thus dicyanodiphenanthrolineiron(II) (ferrocyphen) and the corresponding ruthenium(II) complex, because of their rapid and reversible protonation accompanied by a sharp change in spectral properties, serve as indicators for acid–base titration in non-aqueous media (acetic acid, chloroform, chlorobenzene, etc.) [220,221]. It is interesting that diethylzinc can be determined selectively (in the presence of its hydrolysis products) with phenanthroline in toluene (spectrophotometrically or thermometrically) [222].

The simultaneous application of different methods using various properties of complexes is acquiring increasing importance in analysis. In iodometric titration, for example, a complex of ruthenium with phenanthroline or a methyl derivative is used as fluorescent indicator, since at the equivalence point the red–orange fluorescence of the initial complex disappears owing to formation of an insoluble iodide complex [223].

Traces (10^{-7}%) of iron have been separated from nickel, chromium, manganese, tin by adsorption of an iron complex on silica gel, and then determined spectrophotometrically [224].

The determination of organic compounds is a separate problem in analysis, for which various methods are used. Thus microgram quantities of phenol are determined in alcoholic solution with bipyridyl and iron trichloride by paper chromatography [159]. Phenanthroline and bipyridyl derivatives themselves are most often determined by gravimetric or spectrophotometric methods using various metal cations [221].

Phthalic acid (10^{-5} M) can be determined by an indirect atomic adsorption method with preliminary extraction of the complex neocuproincopper(I) phthalate with 4-methylpentan-2-one. [225]

The brown dinuclear complex of iron(III) with phenanthroline has found practical application in radiodosimetry. Under the influence of γ-rays it decomposes with the formation of a definite quantity of ferroin proportional to the radiation dose [226].

The number of investigations involving new physical methods has grown considerably during recent years [227–230]. In several cases the use of the results of nuclear magnetic and electron spin resonance, mass spectroscopy, and quantum-chemical calculations enables the effects to be elucidated of electronic and structural factors, the nature of the solvent, the temperature, and the pressure on the analytical properties of the systems formed by metals with these ligands [231–234]. The establishment of relations between the kinetic and thermodynamic parameters of these systems and their analytical properties will make it possible to elucidate the mechanisms of many analytical reactions, to find correlations between the structure of the ligands and the state of the complex ions in solution, and to predict the physicochemical properties of novel complexes as functions of the nature of the ligands and the solvent.

High-temperature Exciton Superconductivity : Synthetic Aspects

E.B.Yagubskii and M.L.Khidekel'

The present review examines for the first time the state of chemical synthetic studies directed towards the production of compounds and systems in which, in accordance with the proposed theoretical models, we may expect to realise the exciton mechanism of superconductivity and hence an increase in the critical temperature of the superconductivity transition. The bibliography contains 197 references.

V. Approaches to the synthesis	1013
VI. Model of a two-dimensional exciton superconductor	1022

I. INTRODUCTION

The phenomenon of superconductivity is manifested in the disappearance of the electrical resistance of a substance when it is cooled below a definite so-called critical temperature (T_c). Superconductivity was first detected in mercury 60 years ago. It has now been established that most metals and several hundred alloys are superconductors[1].

The extensive utilisation of superconductors in technology is prevented by the fact that the critical temperatures of all known superconductors lie at very low temperatures. The highest value of T_c attained is $\sim 21°$ K [for the pseudo-binary compound Nb $(Al_{0.75}Ge_{0.25})$][2]. This is the first superconductor for which T_c lies above the boiling point of liquid hydrogen ($T_h = 20.3°$ K). All other superconductors have $T_c < 21°$ K (helium temperatures). Despite the large number of published papers, little progress have been made in this field: in the last 16 years, the maximal value of T_c has been raised by only 3 deg.

Theoretical calculations show that the critical temperatures of the known types of superconductor apparently cannot exceed 40° K.[3] This is related to the characteristic features of the phonon mechanism, which is responsible for superconductivity in metals, alloys, and a number of inorganic compounds.

At the present time, an extremely attractive approach to the production of high-temperature superconductors with $T_c \geqslant 80°$ K is provided by the preparation of compounds and systems in which it might be possible to realise a fundamentally different mechanism—the exciton mechanism—of superconductivity[3]. This mechanism and the related problem of the preparation of high-temperature superconductors has been discussed extremely intensively in recent years[3–5]. The extreme scientific and technical importance of the problem has been emphasised: in its possible importance for technology, the problem of the production of high-temperature superconductors takes second place only to the problem of producing controllable thermonuclear reactors[4, 6]. The possible existence of high-temperature superconductors has not yet been strictly proved theoretically, but it has not been refuted. Exciton superconductors have not been obtained even at low temperatures. Some authors have been extremely sceptical regarding the possibility of preparing high-temperature superconductors[2, 7], but the importance of the problem has recently been leading an increasing number of research workers to take up its experimental study.

The present review will deal chiefly with the state of chemical synthetic studies directed towards the production of compounds and systems in which, in accordance with the proposed theoretical models, we might expect to realise the exciton mechanism of superconductivity.

II. MECHANISMS OF SUPERCONDUCTIVITY

1. Phonon Mechanism

In 1957, Bardeen, Cooper, and Schrieffer[8, 9] developed the microscopic theory of superconductivity (the BCS theory). According to the BCS theory, the realisation of the superconducting state requires that two basic conditions be satisfied[5]. In the first place, between the conductivity electrons close to the Fermi surface there should be produced an attractive interaction exceeding their direct Coulombic repulsion. The attraction must be sufficiently strong for the formation of combined pairs of electrons. In the second place, all the pairs of electrons must be in the same quantum-mechanical state. Superconductivity is a collective effect: the pairing of two electrons takes place only when a large number of other pairs of electrons are in the same state.

The attraction between electrons in metals arises as a consequence of the interaction of the conductivity electrons with lattice vibrations—phonons. A "free" electron, moving through the ionic metallic lattice, attracts the positively charged metal ions and hence brings about deformation of the lattice close to itself. This leads to the appearance, in the lattice, of a region of excess positive charge, produced by the higher density of ions at the point where the lattice has been deformed. Since the ions move much more slowly than electrons, this region follows at a considerable distance behind the first electron. A second electron attracts the excess of positive charge, and hence interacts indirectly with the first electron

(attracting it). In other words, the interaction of the electrons with the positively charged ions creates vibrations in the lattice (phonons). The exchange of phonons between two electrons leads to their attraction to one another.

The binding energy of the paired electrons determines the critical temperature of the superconductivity transition. Theoretical estimates of T_c show that for the phonon mechanism of superconductivity, the critical temperatures apparently cannot exceed 40° K.[3] This conclusion is confirmed experimentally: in 60 years of research on superconductivity, all metals and a large number of metallic and semiconducting alloys have been studied, but values of $T_c > 21°$ K have not been detected. It should of course be noted that these theoretical estimates are somewhat arbitrary[3], since they are based on an examination of metals with known properties. The development of the technology of high and superhigh pressures has led to the possibility of creating new superconducting phases and compounds which are not formed under "ordinary" conditions[10]. Particularly promising in this connection is the production of metallic hydrogen[11], for which calculations give values of $T_c \sim 30-300°$K. In this connection, the preparation and study of heavy metal hydrides, which can be regarded as alloys based on metallic hydrogen, are of considerable interest[12]. It may be noted that superconductivity was recently detected in polyhydrides and polydeuterides of thorium (T_c = 8.05–8.35° K)[12].

2. Exciton Mechanism

In 1964, Little suggested the possibility of an electron-electron (exciton) mechanism of superconductivity[13–16], in which the attraction between the conductivity electrons arises not as a consequence of phonon exchange, but as a consequence of exciton exchange (electronic excitation). According to some estimates, the realisation of the exciton mechanism should lead to much higher values of T_c (~300° K or more)[14,15].

In contrast to the situation for the phonon mechanism, which is universal in character, the manifestation of the exciton mechanism of superconductivity requires a definite combination of two sub-systems, one conducting, and the other dielectric with a corresponding exciton spectrum. At the present time several models, in which an exciton mechanism may be established in principle, have been proposed[3].

III. MODELS OF ONE-DIMENSIONAL EXCITON SUPERCONDUCTORS

Little examined the chief characteristic features of the exciton mechanism of superconductivity and the possibility of its realisation for the example of a model organic macromolecule (Fig. 1)[5,13–16]. This macromolecule consists of a polyene chain, which plays the role of a one-dimensional metal or semiconductor, and readily polarised substituents, which ensure effective attraction between the conductivity electrons. The "free" electron of the conducting polyene chain ("core"), moving close to one of the substituents, polarises it in such a way that a positive charge is induced at the end of the substituent nearest the conducting chain. This charge attracts another electron of the "core", so that there is effective attraction of this electron to the electron which produced the initial polarisation of the substituent. The attraction may be greater than the direct Coulombic repulsion between the conducting electrons, so that the overall interaction between the electrons of the "core" will be an attraction, and this should bring the system into the superconducting state.

The idea of an exciton mechanism of superconductivity, and Little's quasi-one-dimensional model itself, attracted considerable attention and led to lively discussion[3–5,17–19].

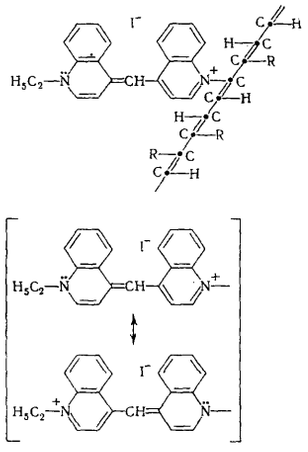

Figure 1. Little's hypothetical superconducting macromolecule.

The main objections are related to the one-dimensional nature of the model[5]. At the present time the question of which states can actually exist in the one-dimensional case with allowance for electron-electron and electron-phonon interactions is far from clear[18,20]. Thus Dzyaloshinskii and Larkin[20] have shown that, depending on the nature of the interaction between the electrons, a quasi-one-dimensional system may exist in different states: metallic, dielectric, antiferromagnetic, or superconducting.

One of the chief objections to Little's model is that in the one-dimensional system the fluctuations of electron density are large and should break down the superconducting state or at least lower T_c considerably. The fluctuations will be much smaller in fibrous structures[21], consisting of accumulations of conducting fibres in a three-dimensional non-conducting medium (the conductivity along the fibres being much greater than that in the perpendicular direction). In these structures, the advantages of the one-dimensional systems proposed by Little will be preserved, since the conducting fibre can be surrounded on all sides by molecules with appropriate electronic polarisability. The fluctuations of electron density, however, will in this instance be three-dimensional in character, and should not break down the superconducting state[4,21]. Structures of this kind are apparently more realistic for experimental realisation than Little's model.

IV. CHIEF REQUIREMENTS TO BE SATISFIED BY THE ELEMENTS OF LITTLE'S MODEL

It can be seen from Figs. 1 and 2 that Little's model consists of two interconnected parts: the quasi-one-dimensional conducting "core" and the readily polarised substituents. In principle, it is possible to use as "core" conjugated polymer chains of different types[16, 22–24]; chains of atoms[25, 26] of molecules [27–29] formed by appropriate arrangement of these units in a molecular crystal; quasi-metallic chains of iodine atoms[16]; etc. In its conducting properties, the "core" should be a metal or a semiconductor with a small gap[26]. For polymer systems, in Little's opinion, highly ordered stereoregular structures are not essential[26]. The length of the macromolecule may be of the order of 100 Å. Superconductivity in the entire specimen will possibly be produced as a consequence of the Josephson effect[26] (tunnelling of electron pairs between individual superconducting molecules through a non-superconducting phase[9]). The fundamental problem of the manifestation of superconductivity in a specimen consisting of superconducting macromolecules has not in fact been examined.

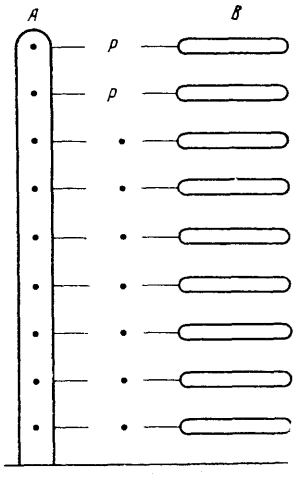

Figure 2. Model of a "one-dimensional exciton superconductor". A) Conducting "core", B) readily polarised substituents, P) connection between the elements of the model.

The substituents must satisfy certain requirements. They must be readily polarised, so that electronic excitations (excitons) which are not readily quenched can arise in them[3, 4]. This means that the substituents should have at least one low-lying excited level exhibiting a high dipole moment[17]. As substituents of this kind it is possible to use molecules (of the cyanine dye type) with a narrow absorption band in the region of ~ 1200 nm and an extinction coefficient of ~ 10^5.[18] It should, however, be noted that although dyes with intramolecular electronic transitions in the region of 1000 nm and above are known, they are generally sparingly soluble and insufficiently stable, so that it is extremely difficult to use them for preparative purposes. Other suggested possible substituents are nitroso-compounds, zwitter-ions, and dithiolene complexes of metals[30]. The latter have absorption bands in the near infrared range[31, 32]. In our opinion, it is also possible to use for the same purpose various organic and organometallic complexes of the semiconductor type, exhibiting a high polarisability (for example radical-ion salts of 7, 7, 8, 8-tetracyanoquinodimethane, and various complexes of iridium and platinum)[33, 34].

The problem of the spatial arrangement of the substituents in Little's model is important. For steric reasons, they cannot be placed on every carbon atom of the core. It is important, however, that the substituents be as close to one another as possible[16]. Moreover, the exciton system should be sufficiently close to the conducting core, since the effect of the induced charge decreases rapidly with separation[16]. There is however a limit to the distance between the polarised substituents and the conducting core, since at sufficiently small separations, exchange interaction between the conductivity electrons and the polarisation is possible, and this decreases the attraction between the conductivity electrons[16]. In Little's model, a decrease in exchange is achieved by having the lateral substituents arranged in a plane perpendicular to the core; there is then no conjugation between the core and the lateral substituents.

V. APPROACHES TO THE SYNTHESIS

At the present time there have been three general approaches to a synthesis based on Little's model. The first of these involves: 1) the creation of a one-dimensional conducting system (core); 2) the selection or synthesis of suitable readily polarised substituents; and 3) the synthetic combination of the two elements. This approach is not yet fully practical, even if only because linear conducting polymer chains are generally non-uniform and sparingly soluble. It is therefore unlikely that they could be subsequently used in a synthesis. In another approach, the aim is first to obtain a conducting chain containing relatively stable dye precursors, and then to convert these into the desired dyes. The third approach involves: 1) the synthesis of certain molecules containing readily polarised groups of substituents, and 2) the controlled polymerisation or crystallisation of these molecules.

We can now examine specific chemical approaches to the synthesis of Little's model. We shall also examine various types of quasi-one-dimensional systems which may prove to be suitable candidates for the role of the core in Little's model.

1. Polymers with a System of Conjugated Bonds

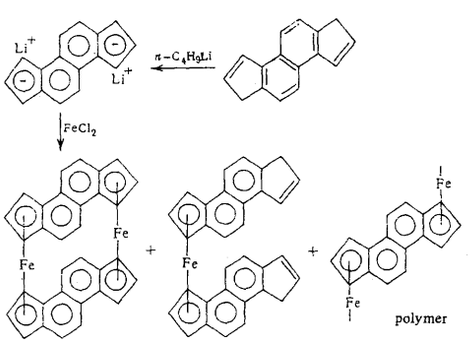
A large number of linear polymers with conjugated bonds, exhibiting semiconducting properties, have been described[35–38]. These properties are determined by two factors: the structure of the polymeric molecule (the system of conjugated π-bonds) and the supermolecular structure of the substance[37]. In most instances it is impossible to obtain polymers with a molecular weight $>$ 3000; the degree of polymerisation usually does not exceed 10.[37] The average extent of the effective intramolecular conjugation is usually less than the average degree of polymerisation, because the arrangement of the structural elements is frequently not coplanar[39]. Existing methods for the synthesis of polymers with conjugated bonds do not make it possible to obtain homogeneous

polymers with a given structure, a high molecular weight, and a narrow molecular-weight distribution. The problem of creating organic superconducting polymeric molecules probably requires fundamentally new approaches to the synthesis of polymers with conjugated bonds, which would make it possible to control closely the actual polymerisation process and to obtain conducting polymers with a rigorously defined structure.

We shall not examine in detail the various linear polymers with conjugated bonds, which formally can lay claim to the role of core in Little's model (polyacetylenes, polyynes, polyphenylenes, polyacenes). These polymers, in our opinion, are unsuitable for this purpose, since for the most part they have a high resistance ($\rho \simeq 10^5 - 10^{12}$ Ω.cm, $E \simeq 0.4-1.0$ eV)[38] and are amorphous, sparingly soluble, and somewhat unstable substances (particularly the polyacenes).

One of the most highly conducting linear polymers is polymeric sulphur nitride $(SN)_x$.[40] The polymer forms fibrous crystals with a metallic lustre, and is diamagnetic. Unfortunately, conductivity measurements have up to the present been carried out only with compressed tablets ($\rho_{0°C} \simeq 0.040-6$ Ω.cm, $E < 0.02$ eV)[40]. The study of the conducting properties of individual oriented fibres or crystals of polymeric sulphur nitride would be of considerable interest in view of its fairly high conductivity, which approaches that of metals.

Schneider[22] has discussed the advantages and disadvantages of various types of polymer with conjugated bonds, capable of laying claim to the role of core. In his opinion, alicyclic systems with a large number of possible degrees of freedom are undesirable, since in these compounds the maximal conjugation cannot be realised, because the polymer chain is insufficiently rigid. Aromatic cyclic systems exhibiting a high rigidity are suitable. Polyacenes are attracting attention in this connection, but these compounds have a low resistance to oxidation and low thermal and photochemical stability. Polyphenylenes are more stable, but in this instance loss of coplanarity is possible, and this influences the degree of conjugation. Another possibility is provided by metallocene polymers, in which polyconjugated groups are joined by metal atoms (Fig. 3). In an attempt to realise Little's model by synthesis, Schneider[22] prepared a metallocene polymer by the following scheme:



The main product was an insoluble amorphous polymer with high molecular weight. Because of its extremely low solubility, it could not be purified and was not well characterised. The disadvantages of this approach are immediately apparent: a conducting polymer core can probably be obtained in this way, but it is difficult to characterise and, which is more important, it is not clear how readily polarised substituents can be attached to it.

Another type of polymer is exemplified by polychelates, in which the metal atom is in the main polymer chain, forming a chelate unit in the conjugation chain.

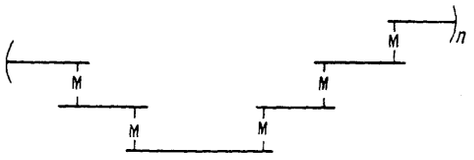


Figure 3. Polymeric metallocene: alternating planar aromatic hydrocarbon rings and metal atoms.

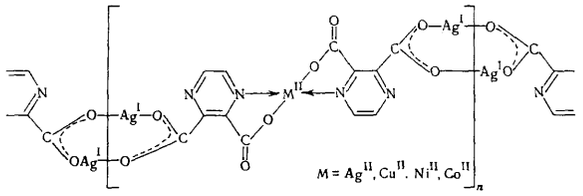
Dewar and Talati[41, 42] suggested that it is possible to prepare chelate polymers with a high conductivity from a suitable transition metal and an aromatic ligand capable of binding two metal atoms. To create conjugation in this system, each metal must form $d\pi - p\pi$ bonds with two neighbouring ligands, using the same d orbital. The conditions are satisfied if the ligands are coplanar and are situated in the *trans*-position relative to one another in an octahedral or square-planar complex. On this basis, the authors cited prepared polymeric chelate complexes of Cu^{II}, Ni^{II}, and Pd^{II} with 1,5-diformyl- and 1,5-diacetyl- 2,6-dihydroxynaphthalene dioximes[41, 42]. Some of the complexes obtained showed a relatively high conductivity ($\sim 10^{-4} - 10^{-5}$ Ω^{-1} cm^{-1}, $E = 0.23$ eV). The molecular weights of the polymers were low, and their degree of polymerisation did not exceed 10. Polymeric complexes of analogous type were also prepared by Kanda and Kawaguchi[43].

Electron transfer in these systems can probably be intensified by introducing suitable metals in different oxidation states into the chain. In particular, Bolto and Weiss[44] suggested that the higher conductivity of the Fe-containing polymer compared with the polymers of other metals obtained by the reaction of chloranil with *o*-phenylenediamine in the presence of the metal salts is due to the presence of two different oxidation states of iron in this polymer.

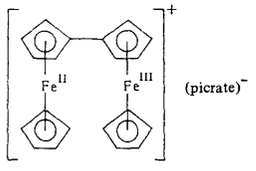
It may be noted that a large number of inorganic compounds containing ions of the same element in different oxidation states are now known[45, 46]. Many of these mixed-valency compounds exhibit characteristic chemical and physical properties (colour, magnetism, conductivity, and reactivity). Thus the metal–metal distances in the crystal lattices of Fe_2O_3 and Fe_3O_4 are almost the same (3 Å), but the conductivity of Fe_3O_4 (a compound with mixed valencies Fe^{II} and Fe^{III}) is greater by six orders of magnitude than that of Fe_2O_3.[47] The high conductivity (2.5×10^2 Ω^{-1} cm^{-1}) of Fe_3O_4 is attributed to rapid valency charge exchanges between iron atoms in different oxidation states[48].

Chelate polymers containing metal ions in different oxidation states were recently prepared[49, 50]. Pyrazine-2, 3-dicarboxylic acid was used as model ligand:



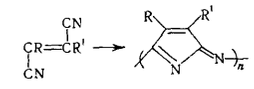
Study of these polymeric complexes by static magnetic susceptibility and NMR methods at helium temperatures showed, however, that the unpaired electrons of the paramagnetic metals interact weakly with one another[51]. The probable reason is that in these complexes the conjugation chain is broken at the ends of the individual fragments. Despite this result, chelate polymers containing ligands with conjugated chains and metal ions in different oxidation states are extremely promising materials for the preparation of highly conducting linear compounds. In fact, in complexes of the type M–L–M′, where M and M′ are ions of the same element in different oxidation states, and L is a ligand with conjugated bonds, it has been possible to detect electron transfer between the metal ions. Creutz and Taube[52] made this observation for the ruthenium complex:

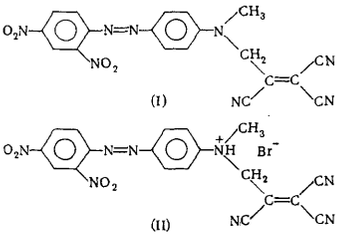
Analogous electron transfer between iron atoms in different oxidation states was observed by Kaufman and Cowan[47] in bis (ferrocinium) picrate:

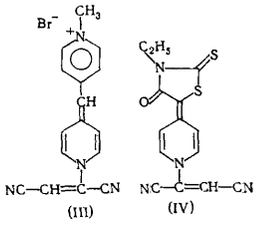


The conductivity of the latter was greater by 5–6 orders of magnitude than that of ferrocene or ferrocinium picrate. Also noteworthy is the existence of electrically conducting complexes containing linear chains of metal ions with different valencies, joined by bridging groups[53] (Cl, Br) (for example, $Pd^{II}(NH_3)_2.Cl_2Pd^{IV}(NH_3)_2Cl_4$). Some of these complexes exhibit anisotropic conductivity, the greatest conductivity being observed along the linear M^{II}–Cl–M^{IV} chains.

An interesting attempt to obtain possible superconductors was made by Liepins and coworkers[23], who prepared nitrile monomers (I–IV) containing dyes as substituents, and then carried out the polymerisation of these monomers at the nitrile groups:

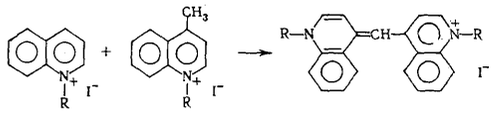




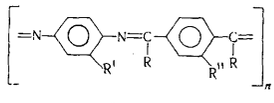


The polymers obtained had a low conductivity ($\sim 10^{-8} - 10^{-12}\ \Omega^{-1}\ cm^{-1}$), however, and superconductivity was not detected. These polymers are apparently non-uniform and disordered; their structure is not known exactly. This is the chief disadvantage of the "polymer" approach: it is impossible to obtain conjugated polymers with a strictly defined structure.

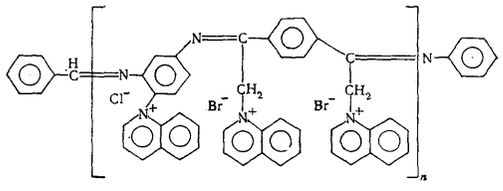
Hodgkin and Heller[24] suggested the initial preparation of a conjugated polymer chain containing relatively stable dye precursors, followed by their conversion into the desired dyes. Cyanine dyes were chosen, since they are readily obtained by the reaction of two quaternary heterocyclic bases, one of which contains an active methyl group:



Thus the first stage of the problem reduced to the preparation of polymers with a system of conjugated bonds, having as substituents quaternary heterocyclic bases, in particular quinoline bases. Polymers based on aromatic Schiff's bases were selected. The aim of the work was primarily to prepare polymers with a high molecular weight and the introduction of substituents to increase the degree of conjugation. The authors cited prepared a number of model Schiff's bases and their polymers, including a polymer containing quaternary quinoline nuclei as substituents:



(R, R′, R″ = H or dye)



In this polymer, one of the quinoline nuclei is joined directly to the aromatic ring, and this is undesirable, since exchange is then possible between the conducting system and the readily polarised system. Subsequently, Hodgkin and Heller proposed the preparation of monomers in which the quaternary quinoline nuclei are separated from the aromatic rings of the main conjugation chain by a methylene group[24]. An analogous approach has been used for the preparation of polymeric polymethine dyes[54].

In the systems examined above, the conducting core is polymeric; we shall now describe compounds in which the conducting chains are formed from atoms or molecules as a consequence of their appropriate arrangement in a molecular crystal. In our opinion, these compounds exhibit definite advantages over polymers, since they can be obtained in the form of single crystals and with a high degree of purity.

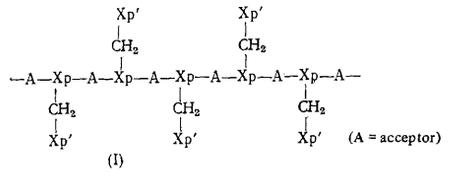
2. Charge-transfer Complexes

Charge-transfer complexes (CTC) are extremely varied[55–57], and many exhibit semiconducting properties[35, 36]. A characteristic feature of the structure of electrically

conducting CTC is the presence, in the crystal, of stacks consisting of alternating molecules of a donor and an acceptor, the distances between which are usually slightly less than the normal van der Waals' distances[35, 36, 58–61]. Thus in the ferrocene–tetracyanoethylene (TCE) complex the distance between the parallel planes of the TCE molecules and the cyclopentadienyl rings is 3.14 ± 0.1 Å[61]. The "stack" structure of the CTC should lead to anisotropy of the electrical conductivity of their single crystals, and this has been observed experimentally[62, 63]. For example, the maximal value of the conductivity ($\sigma = 10^{-5}\ \Omega^{-1}\,cm^{-1}$, $E = 0.23$ eV) in single crystals of the complex of perylene with bis [1, 2-di (trifluoromethyl) ethylene-1, 2-dithiolato]-nickel is observed along stacks consisting of alternating molecules of perylene and the complex acceptor[63].

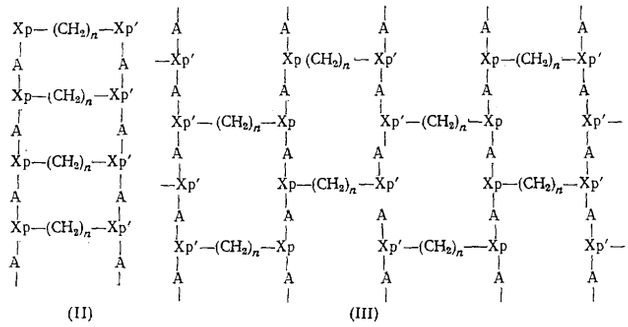
The ability of CTC to form electrically conducting stacks of alternating molecules of a donor and an acceptor in a crystal can apparently be used as a basis for the preparation of various compounds which are models of Little's molecule.

It is to be expected, for example, that in CTC containing bis-dyes with isolated chromophores as the donor component[14], one chromophoric system (Xp) will take part in the formation of the CTC, forming the electrically conducting stack in the crystal, while the other (Xp′) will act as the readily polarised substituent (structure of type I):



(I)

Since the chromophores are isolated, electron exchange between the conducting and polarised electrons in this system is unlikely; at the same time, exciton interaction is possible between two electronic systems at distances of the order of 3 Å. When bis-dyes with bridges longer than $-CH_2-$ between the chromophores are used, other types of structure (II and III) are not excluded:



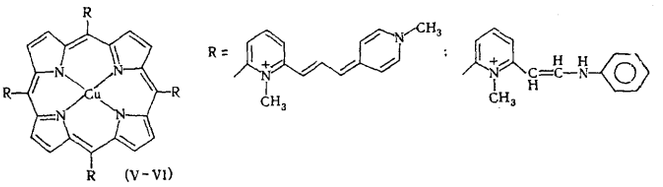
(II) (III)

For bis-dyes with one CH_2 bridge, CTC structures of types (II) and (III) are unlikely, because of the steric hindrance created by the acceptor molecules. Structure (II) is of interest, since of the two stacks connected to one another, one can be regarded as conducting, and the other as polarised. As analogous situation is observed in the double spiral of DNA. In the opinion of some authors[65, 66], the production of increased conductivity of the superconductivity type is possible in certain regions of one DNA spiral as a consequence of the excitation of electrons of another spiral.

The network structure (III) consists of conducting filaments (stacks) joined to one another; the conductivity along the filaments is greater than that in the perpendicular direction (fibrous structures)[21].

The chief difficulties are apparently associated with the preparation of highly conducting donor-acceptor stacks and the production of a structural correspondence between the components of the CTC. Very few charge-transfer complexes based on dyes have yet been described[67, 68], and almost no studies have been made of the conducting properties of this type of CTC.

The preparation of CTC using not bis-dyes but porphyrin molecules (V–VI) containing dyes as substituents[69] is of interest:



R (V-VI)

Porphyrin CTCs, in particular with nitro-compounds as acceptors, have been described[70, 71]. Complexes of etioporphyrin and its copper and nickel derivatives with 7, 7, 8, 8-tetracyanoquinodimethane (TCQM) were recently prepared[25]. The use of porphyrin molecules (V, VI) as CTC components is of particular interest, since exciton interaction between the electronic systems of the dyes and the porphyrin has apparently been detected in these complexes[69]. The position of the so-called Soret band in the absorption spectra of porphyrins usually remains unchanged when electron-accepting or electron-donating substituents are introduced into the ring at the methine bridge. In the spectra of compounds (V, VI), however, the Soret band was displaced appreciably towards longer wavelengths[69]. These shifts were attributed to exciton interaction between the electronic systems of the dye and the porphyrin ring: an electron in the ring generates an exciton in the dye, which can then interact with another electron of the ring. This should lead to a decrease or increase in the Coulombic repulsion between the electrons of the porphyrin ring, and hence to a change in the position of the energy levels in the molecule. The experimentally determined directions and magnitudes of the shifts corresponded to the calculated values[69].

3. Radical-ion Salts

Radical-ion salts represent a limiting case among CTC, where complete separation of the charges between the components of the complexes takes place even in the ground state[35, 55–57].

A characteristic feature of the crystal structure of a number of radical-ion salts is the presence, in the crystal, of stacks consisting of only radical-cations in the case of radical-cation salts[72–74] or only radical-anions in the case of radical-anion salts[75–84]. In contrast to the situation for a CTC, the stacks are formed in this instance from the same molecules (radical-ions of a given sign), the distances between which are usually slightly shorter than the normal van der Waals' distances. Strong interactions may arise within the stacks, and these are responsible, in particular, for the conductivity[85, 86], magnetic properties[86–90], and spectroscopic properties[91–95] of compounds of this type. In those instances where both components of the radical-ion salts are paramagnetic, the stacks

usually consist of alternating radical-cations and radical-anions[96–98].

Information is now available on a number of conducting radical-ion salts, based on strong π-donors: tetrathiotetracene[99], dibenzophenothiazine[100], and derivatives of N,N′-diphenyl-p-phenylenediamine[101], or based on strong π-acceptors: 7,7,8,8-tetracyanoquinodimethane (TCQM)[102], 11,11,12,12-tetracyano-2,6-naphthoquinodimethane[103], 9-dicyanomethylenepolynitrofluorenes[104], etc.[105]. Many of these compounds have a fairly high conductivity ($\sigma \geqslant 10^{-2}\ \Omega^{-1}\ cm^{-1}$, $E \leqslant 0.1$ eV). Radical-ion salts based on TCQM have attracted particular attention[85,86,106–114]. Organic salts of TCQM include compounds for which the conductivity approaches that of metals ($\sigma = 10^{2}\ \Omega^{-1}\ cm^{-1}$, $E = 0.02–0.05$ eV)[85,86].

7,7,8,8-Tetracyanoquinodimethane forms three types of conducting compound: π-complexes and simple and complex radical-ion salts[102]. TCQM forms π-complexes (charge-transfer complexes) with aromatic hydrocarbons, amines, phenols, and various other compounds. These compounds are for the most part poor conductors[102]. ($\rho = 10^{7} - 10^{10}\ \Omega.cm$), and their crystal structure is the same as that of most CTC: it consists of stacks formed by alternating molecules of a donor and an acceptor[58]. The second type of compound formed by TCQM consists of simple radical-anion salts with the general formula $K^{+}(TCQM)^{\cdot}$, where K^{+} may be a metallic, organometallic, or organic cation.

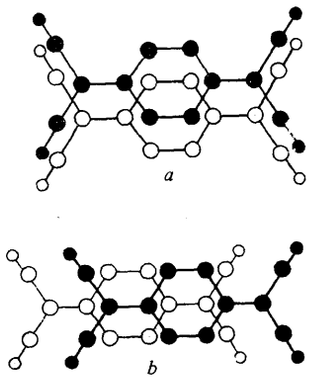


Figure 4. Two basic types of overlap between molecules of TCQM and its salts.

Most simple salts have a relatively high resistance[102] ($10^{4} - 10^{11}\ \Omega.cm$), but they also include some good conductors ($\sigma \leqslant 10^{-1}\ \Omega^{-1}\ cm^{-1}$)[85,108,113,115].

X-ray diffraction study[78,80,84] of the salt [bis (toluene) chromium]$^{+}(TCQM)^{\cdot}$ ($\rho = 3.5 \times 10^{8}\ \Omega.cm$)[110] showed that the TCQM radical-anions form stacks within which it is possible to distinguish pairs formed by TCQM molecules with an interplanar spacing equal to 3.37 Å. The distance between the pairs is 3.43 Å. The overlap of two neighbouring TCQM molecules in the stack is of type a in Fig. 4. The conductivity of this salt along the direction of the stacks is about two orders of magnitude greater than that of a compressed tablet. The TCQM spin system is here diamagnetic[88] at room temperature, indicating strong magnetic interaction in the $TCQM^{\cdot}$ chain (paired interaction).

In general, most poorly conducting simple salts of TCQM containing diamagnetic cations either are diamagnetic at room temperature or exhibit weak paramagnetism, which increases with increase in temperature (singlet-triplet behaviour)[87]. It should be noted that stacks are not always present in crystals of simple salts of TCQM[84,116]. In those instances where they are not formed, the radical-anions are still arranged in individual pairs[84,116].

The tendency for TCQM radical-anions to undergo dimerisation both in the solid state and in solution[117] is apparently a fairly general property of organic radical-ions[118]. An interesting feature is that the organometallic radical-anions of the chelate dithiolene complexes of metals also form stacks in crystals of salts with organic cations. Pairs of these radical-anions can be distinguished within the stacks[119]. The magnetic behaviour of these salts is effectively described by paired interaction[119].

The TCQM salts examined above are the poorly conducting simple salts, but, as we have already noted, some simple salts of TCQM are good conductors. Thus $(N\text{-methylphenazinium})^{+}(TCQM)^{\cdot}$ is one of the most strongly conducting organic compounds ($\sigma \simeq 10^{2}\ \Omega^{-1}\ cm^{-1}$)[86,108,113]; this salt is similar to the conducting complexes of TCQM[86].

Complex salts with the general formula $K^{+}(TCQM)^{\cdot}(TCQM)$ form the most interesting type of conducting compounds of TCQM. In addition to the TCQM radical-anion, they contain the formally neutral TCQM molecule[102]. K^{+} may be an organic or organometallic cation (metal cations, with the exception of Cs^{+}, do not form complex salts)[102]. A characteristic feature of these TCQM salts is their conductivity, which is unusually high for organic compounds ($10^{2} - 10^{3}\ \Omega^{-1}\ cm^{-1}$)[102].

The complex salts can be regarded as compounds of TCQM with mixed valency (-1 and 0), in which one electron is delocalised over two TCQM molecules $[(TCQM)_{2}^{-}]$.

The ability of the TCQM radical-anion to form complex salts is not apparently a specific property of TCQM molecules alone. Complex salts based on other radical-anions are now known[103,105].

A characteristic feature of the crystal structure of most complex salts of TCQM is the presence, in the crystal, of stacks consisting of TCQM molecules arranged one above the other, with a slight displacement[76,77,79–84]. The conductivity of the salts is generally strongly anisotropic and has a maximal value along the direction of the stacks[85,86]. The dimensions and geometry of the cation have a significant influence on the mutual arrangement of the TCQM molecules in the stack and on the distance between them, and hence on the conductivity and magnetic properties of the salts[120]. The highest conductivity ($\sigma \simeq 10 - 100\ \Omega^{-1}\ cm^{-1}$, $E = 0.025 - 0.050$ eV)[85,86,114] is shown by complex salts of TCQM, containing as cations planar aromatic heterocyclic bases with H- or CH_3- (but not $-C_2H_5$) substituents attached to the nitrogen atom[106,107]. The paramagnetic susceptibility of the highly conducting salts of TCQM depends little on temperature in the range above 30°K[86,87].

In the crystals of these salts, the distances between the TCQM molecules in the stack are equalised, and are much shorter than the normal van der Waals' distances, and the TCQM molecules overlap one another in characteristic fashion: the centre of one molecule is

situated above the centre of the double quinodimethane bond of another molecule[75, 79, 82, 84] (overlap of type *b* in Fig. 4). Thus in the complex salt (quinolinium)$^+$-(TCQM)$_2^-$, which is one of the most strongly conducting organic compounds (σ = 100 Ω^{-1} cm^{-1}, E = 0.03 eV)[85, 86, 114], the TCQM molecules are equivalent (each can be assigned a charge of $-\frac{1}{2}$), the interplanar spacings in the stack are equal (3.22 Å)[82], and the overlap is of type *b*. Analogous packing of the TCQM molecules is observed in the stacks in the complex salt [bis(toluene)chromium]$^+$(TCQM)$_2^-$ (Fig. 5)[79, 80], but the distance between the TCQM molecules is here greater than 3.29 Å, and the molecules are crystallographically non-equivalent. The conductivity of this salt is lower by almost two orders of magnitude than that of (quinolinium)$^+$(TCQM)$_2^-$ [110]. On going from the simple salt of bis(toluene) chromium to the complex salt, the interplanar spacings in the stack are equalised, and become slightly shorter; at the same time there is a change in the nature of the overlap, which becomes more effective. The conductivity increases by five orders of magnitude, and the activation energy decreases by a factor of four[110]. Packing analogous to that in (quinolinium)$^+$(TCQM)$_2^-$ is shown by the highly conducting simple salt (N-methylphenazinium)$^+$(TCQM)$^-$ [75], and also by (N, N, N′, N′-tetramethyl-*p*-phenylenediamine)$^+$ - (TCQM)$_2^-$ [77]. The conducting properties of the last compound have not yet been studied, but it may be assumed that the compound has a high conductivity.

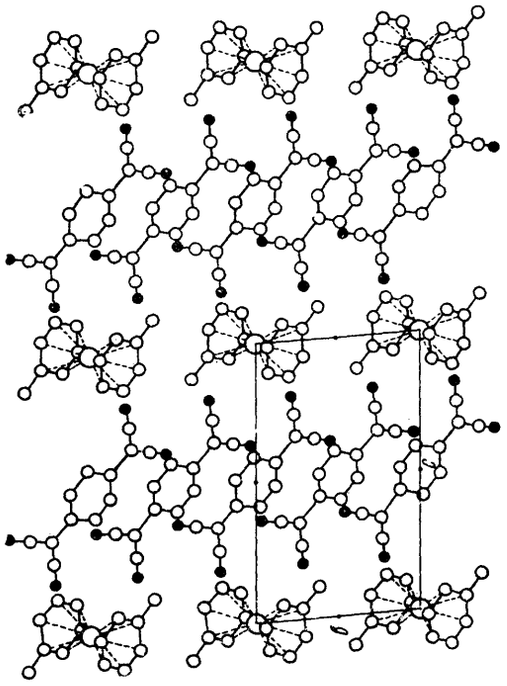

Figure 5. Projection of the structure of the complex salt [bis (toluene) chromium]$^+$ (TCQM)$_2^-$ on the [100] plane [79, 80].

Unlike the complex salts of TCQM with heterocyclic bases containing H- or CH_3-substituents attached to the nitrogen atom, complex salts of TCQM in which the cations are formed by metals, aliphatic bases, or various other non-planar systems generally exhibit a lower conductivity[85, 86], and their paramagnetism is singlet-triplet in character[86, 87, 121]. In these complex salts there is an alternation of spacings between the TCQM molecules in the stack, and these molecules in the stack form structurally repeating groups of two[84, 122, 123], three[76], or four[81, 83]; there is strong overlap within the pairs, but there may be no overlap at all between the pairs[122, 123].

The ability of the TCQM radical-anion to form quasi-one-dimensional conducting stacks in crystals can be used to prepare compounds which provide models of Little's molecule. In 1967, Khidekel' and coworkers[27, 28] and Lupinskii and coworkers[29] suggested that the radical-ion salts of TCQM with dyes may exhibit superconducting properties, since they formally satisfy the necessary conditions for the production of superconductivity: the presence of a linear conducting system (stacks of TCQM molecules) and readily polarised groups (dye cations). The compounds prepared, however, did not exhibit superconducting properties[27–29, 114], although some of them had a high conductivity ($\rho \simeq 10$ Ω. cm, $E \simeq 0.04-0.05$ eV)[27, 28, 124]. The problem of why the compounds obtained do not exhibit superconducting properties is extremely complex: here we shall restrict ourselves to an examination of some possible factors. In the first place, the dyes used[27–29, 124] are not highly polarisable ($\lambda \simeq 500-600$ nm). According to the latest calculations[16], it is necessary to have dyes with absorption bands in the region of 1200 nm. Unfortunately, complex salts of TCQM with cyanine dyes, which absorb light in the region of 700 nm and above, cannot be prepared. This is due to the fact that with increase in the length of the conjugation chain there is an increase in the basic nature of the dye, that is in its ability to undergo oxidation, so that these dyes are oxidised in their reaction with TCQM.

In contrast to Little's model, in which the bond between the conducting chain and the dye is covalent, with length ~ 1.5 Å, the bond in the compounds being considered is predominantly ionic, with length greater than 3 Å. It should however be noted that distances of the order of 3 Å may not be a significant obstacle for exciton interaction. A cardinal problem is the mechanism of conductivity in the highly conducting ($\sigma = 10^1-10^2$ Ω^{-1} cm^{-1}) radical-ion salts of TCQM. If these compounds exhibited conductivity of the metallic type, as suggested earlier[85], they would be almost ideal starting materials for the preparation of organic superconductors. Recent studies[33, 86, 113, 114] of the conducting properties of single crystals of these complexes over a wide range of temperature (4 – 300° K), however, showed that these compounds are semiconductors with a low conductivity activation energy (0.022–0.05 eV) in the range below 200 – 150° K (there is no activation energy of conductivity in the region of room temperature) (Fig. 6). In these compounds the conductivity apparently involves a jump mechanism[86, 114], and not a zone mechanism, that is there is a system of localised current carriers, the movement of which at each stage must necessarily include a thermally activated jump. It should however be noted that in the opinion of some authors[125], the simple salt (N-methylphenazinium)$^+$(TCQM)$^-$ is a "metal", which at temperatures below 200° K is gradually converted into a semiconductor. The problem of the mechanism of conductivity is fundamental, since in a system of localised current carriers the transition to the superconducting state is impossible.

On the whole, the class of compounds based on TCQM and its analogues are extremely interesting materials for

further study. There exist considerable synthetic possibilities for the preparation of new radical-ion salts. Of the greatest interest are TCQM salts containing cations with a high polarisability. Highly conducting complexes of TCQM with tetrathiotetracene (TTT) have now been prepared[126]. The TTT radical-cation introduced into the complexes has absorption bands in the near infrared range (λ = 1000–1300 nm)[99]. The compounds obtained are also of interest in connection with the fact that each of the ionic components of the complex is individually capable of forming highly conducting radical salts.

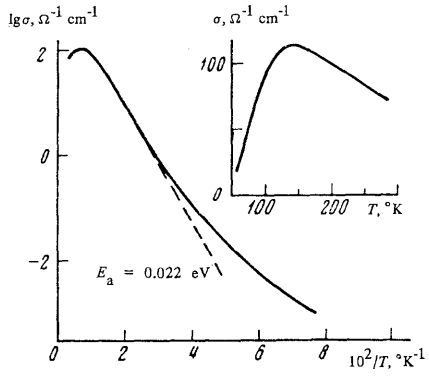

Figure 6. Temperature dependence of the conductivity of single crystals of the complex salt $(acridinium)^+ (TCQM)_2^-$ (constant current). The dependence is typical of that for highly conducting ($\sigma_{293°K} \sim 10^2\ \Omega^{-1}cm^{-1}$) TCQM salts.

An increase in the exciton interaction between the stacks of cations and the stacks of radical-anions in TCQM salts can apparently be achieved by the introduction, for example into the cation, of substituents capable of forming hydrogen bonds[127].

It is also not excluded that with the appropriate choice of cation it will be possible to prepare conducting stacks of TCQM with distances of less than 3.22 Å between the planes of the TCQM molecules (the distance of 3.20 Å is apparently not limiting: shorter intermolecular distances are known, for example 3.10 Å[72]). A decrease in the distances should lead to even stronger exchange interaction between the TCQM molecules in the stacks, and hence possibly to new effects related to the electrical and magnetic properties of these compounds (possibly the production of actual metallic conductivity). The production of an "organic metal" would be a great step forward on the road to the production of organic superconductors (this is particularly interesting in that the question of the possibility that a one-dimensional metal can exist has not yet been finally resolved). Moreover, organic compounds exhibiting a high conductivity may reveal new and previously unknown properties. In this connection, mention may be made of an unusual property detected in highly conducting radical-ion salts of TCQM: the anomalously high value of the dielectric constant (ϵ) at a frequency of 10^{10} Hz at low temperatures [for $(acridinium)^+(TCQM)_2^-$, $\epsilon_{4.2°K}$ = 800 ± 100, and for $(N\text{-methylphenazinium})^+ (TCQM)^-$, $\epsilon_{4.2°K}$ = 350 ± 50], so that these compounds can be called superdielectrics[33].

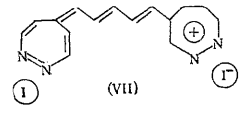
4. Poly-iodine Chains

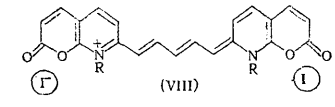
Linear chains of iodine atoms provide another possibility for the production of a conducting core[16]. It is well known that iodine can react with starch and other polysaccharides to form coloured complexes (so-called inclusion compounds)[128]. The macromolecules of amylose (a component of starch) apparently have a structure consisting of a screw or spiral with approximately six glycoside residues in each loop. Inside this loop there is a vacant cavity (or channel) with diameter 5 Å, into which the iodine is introduced. The iodine atoms are arranged linearly inside the amylose spiral with an interatomic distance of 3.1 Å[126]; all the I–I bonds are equalised[126]. In the opinion of some authors, this poly-iodine chain can be regarded as a quasi-one-dimensional metal[16, 128, 129]. The amylose–triiodide complex has been found to give an EPR signal assigned to Pauli paramagnetism, characteristic of metals[129] but these observations were subsequently not confirmed[130].

The question of the possible existence of the metallic state in poly-iodine chains is very important in connection with the problem of exciton superconductivity. To answer this question it would be necessary to study the electrical and magnetic properties of these compounds over a wide range of temperatures.

Although the metallic state has not been observed experimentally in poly-iodides, the semiconducting properties of poly-iodine compounds are familiar[131]. A complex of iodine with pyridazine, with a high conductivity ($\rho \leqslant 50\ \Omega$. cm, $E \leqslant 0.15$ eV) was recently described[132]. The study of the highly conducting ($\sigma = 3.4 \times 10^{-1}\ \Omega^{-1}\ cm^{-1}$, E = 0.07 eV) complex of iodine with N,N′-diphenyl-p-phenylenediamine showed that the electronic conductivity of this complex in the range between +50° and −50° is determined by the poly-iodine chains, in which the distances between the iodine atoms are non-equivalent: 2.99 Å and 3.77 Å[133].

Iodine can form inclusion compounds not only with polysaccharides, but also with other macromolecules: nylon, polyvinyl alcohol, and polyvinyl borate[128]. X-ray diffraction study of the polyvinyl alcohol–iodine complex showed poly-iodine chains with I–I distance equal to 3.1 Å[128]. Many relatively simple organic molecules also form complexes of this kind with iodine. Thus the compounds formed by iodine with diphenylpyrone and coumarin contain linear chains of iodine atoms with I–I distance equal to 3.06 Å[128]. For the diphenylpyrone complex it is suggested that the iodine is situated between the four phenyl groups of two pyrone molecules. These iodine atoms form a chain in the crystal[16]. A similar structure was recently proposed for the complex of bis (diphenylglyoximato) palladium(II) with iodine[134]. In Little's opinion, exciton interaction between the conductivity electrons and the polarisation electrons is possible in iodine complexes of this type, and this should lead to attraction between the conductivity electrons of the quasi-metallic poly-iodine chain, and hence to conversion of the system into the superconducting state[16]. Kagan[135] recently suggested the possibility of preparing superconductors from the starting materials (VII) and (VIII):





These compounds are extremely interesting, since they combine a high polarisability with the ability to stabilise quasimetallic poly-iodine chains.

5. Chains of Metal Ions

A number of complex compounds contain linear chains of metal ions[136–144]. Some of these compounds exhibit a high conductivity ($\sim 10^2\ \Omega^{-1}\ cm^{-1}$) along the metallic chain[34, 145–147]. A number of authors have therefore suggested that the polyene core in Little's model be replaced by a system of stacks of metal ions[25, 148–150].

Electrically conducting organometallic complexes containing chains of directly interacting metal ions can be divided into two groups: 1) complexes in which all the metal ions in the linear chain are in the same oxidation state[151–159] (Table 1), and 2) complexes containing metal ions in a linear chain in formally different oxidation states[34, 86, 145–147, 160–162].

Table 1. Electrical conductivity (σ), activation energy (E), and metal–metal distance in various complexes containing linear chains of metal ions in the same oxidation state.

[a] Activation energy of the conductivity generally isotropic[152, 156]; [b] (dimethylglyoximate)$^-$; [c] (acetylacetonate)$^-$; [d] $\sigma_{\parallel} : \sigma_{\perp} > 500$; [e] $\sigma_{\parallel} : \sigma_{\perp} > 100$; [f] (8-quinolinolate)$^-$.

Complexes of the first group (with square-planar structure) (Table 1) have a characteristic crystal structure[136, 138, 171, 142, 151, 152, 157]: the molecules are arranged one above the other, forming chains of metal ions along the C axis of the crystal with a relatively short metal–metal distance (3.1–3.4 Å). In Magnus' salt $[Pt(NH_3)_4]^{2+}[PtCl_4]^{2-}$ and its analogues, the stacks consist of alternating planar anions and cations[137, 139, 140]. In salts of the $K_2[Pt(CN)_4]$ type, the stacks are made up of identical anions[144].

Complexes of this type exhibit anisotropy of their conductivity (Table 1), the conductivity being a maximum along the chain of metal ions ($\sigma_{\parallel}$). The mechanism of conductivity in Magnus' salt, and also in the dicarbonylacetylacetonato-compounds of Ir^{I} and Rh^{I} has been treated by a number of authors within the framework of the zone theories[152, 157, 159], as follows. The d_{z^2} orbitals of the metal atoms overlap and form a valency zone[139], which in square planar complexes of metals with the d^8 electronic configuration is completely filled. The valency zone is separated by a large gap (ΔE) from the conductivity zone formed by the overlapping p_z orbitals; the doubled value of the activation energy for conduction corresponds to the magnitude of the gap between the valency zone and the conductivity zone. For Magnus' salt, ΔE = 0.6 eV (4840 cm^{-1})[157]. The absorption spectrum[139, 163] of the complex along the *c* axis shows a band with a maximum of 6400 cm^{-1} (the start of the absorption lies at 4500 cm^{-1}), which is close to the magnitude of the energy gap obtained from the temperature dependence of the conductivity. Moreover, Magnus' salt shows photoconductivity with a threshold at 4500 cm^{-1}.[152]. All this provides evidence in support of the zone mechanism, but the overall problem of the mechanism of conductivity in these complexes has not been finally elucidated, and requires further study[152, 156].

It can be seen from Table 1 that the conductivity of the complexes depends markedly on two factors: the characteristic features of the electronic structure of the metal and the magnitude of the metal–metal distance in the linear conducting chain. Although the dicarbonylacetylacetonato-compounds of iridium and rhodium are isostructural[152] and have identical ligand environments, the conductivity increases by five orders of magnitude on going from the rhodium complex to the iridium complex[151, 152]. This is apparently due to the fact that the outer $5d_{z^2}$ orbitals of iridium overlap more effectively than the outer $4d_{z^2}$ orbitals of rhodium[152] (the overlap in this instance is determined by the size of the *d* orbitals). A similar increase in conductivity is observed on going from palladium complexes to platinum complexes in Magnus' salt and its analogues, and this can also be attributed to the better overlap of the $5d_{z^2}$ orbitals of Pt compared with the $4d_{z^2}$ orbitals of Pd[152, 157]. This correlation is not observed, however, for the dimethylglyoximato-complexes of Ni, Pd, and Pt^{II}; the platinum complex has a lower conductivity than the nickel complex[157]. This may be due to defects in the linear conducting chain; these should have a greater influence on the conductivity in one-dimensional systems than in two- or three-dimensional systems[157].

The influence of the magnitude of the metal–metal distance on the conducting properties is clearly shown by a study of the structure and conductivity of complexes at high pressures (up to 170 kbar)[159]. With increase in pressure to 100–120 kbar, the conductivity of Magnus' green salt and the dicarbonylacetylacetonato-compound of iridium(I) increases sharply (by about 3–5 orders of magnitude)[159]. This is due to a decrease in the distance between the metal ions (by $\sim$ 8–10%) and the corresponding increase in the interaction between them[159, 164]. The p_z and d_{z^2} levels approach one another, the magnitude of the gap decreases, and the conductivity increases. At very high pressures, changes in the metal–ligand distances, which are less sensitive to pressure, begin to have a significant influence on the electronic structure of the complexes. Decrease in these distances has the opposite influence[164]: the p_z and d_{z^2} levels move apart, the magnitude of the gap increases, so that the conductivity should decrease, as is in fact observed experimentally at pressures above 100–120 kbar.

A fairly large number of complexes in which interaction between metal ions with the same valency in a linear chain is assumed have now been prepared[165, 166]. These are chiefly square-planar d^8 complexes of iridium and rhodium with various ligands. Up to the present, however, complexes with a metal–metal distance less than 3.1 Å have not been obtained in this series of compounds.

A second group of electrically conducting complexes containing the complex-forming metal in formally different oxidation states[144] is of considerable interest (Table 2). In these compounds the linear conducting chains are made up of squares with Pt or Ir metal ions at the centres, and

the ligands (CN, CO, etc.) at the corners (Fig. 7). Crystallographically, all the metal atoms in the chain are equivalent, although formally, for example, in the $K_2[Pt(CN)_4]Br_{0.3}\cdot 2.3H_2O$ complex, approximately five out of six platinum atoms are in the bivalent state (Pt^{II}), and one is in the quadrivalent state (Pt^{IV})[144].

Table 2. Electrical conductivity (σ), activation energy (E), and metal–metal distance in various complexes containing linear chains of metal ions in formally different oxidation states.

$Ir(CO)_{2.9}Cl_{1.1}$[e]	+1.1	2.85	161, 167	0.2	0.064	146

[a] Measured by the four-contact method. [b] $\sigma_{\parallel} : \sigma_{\perp} \sim 200$ (measured by the two-contact method)[147, 162]. [c] $E_{\parallel} \simeq E_{\perp}$. [d] Depending on the water content. [e] $0.95[Ir(CO)_3Cl]\cdot 0.05[Ir(CO)Cl_3]$.

The distances between neighbouring metal atoms are shortened considerably (2.8–2.9 Å), due to the appreciable overlap of the d_{z^2} orbitals (strong metal–metal interaction)[144]. A zone is formed in which the upper levels are only partly filled. Examination of the electronic structure of the complexes has shown that they can be regarded as one-dimensional metals [144, 161].

It was recently shown[34, 86, 146, 147] that compounds of this class have a high conductivity ($\sim 10^2\ \Omega^{-1}cm^{-1}$) along the chain of metal ions ($\sigma_{\parallel}$) (Table 2) and have an activation energy for conduction[34, 86, 146], indicating that these compounds are semiconducting in character[34, 146]. On the other hand, Kuse and Zeller[147], who studied the optical properties of single crystals of the complex $K_2[Pt(CN)_4]Br_{0.3}\cdot 2.3H_2O$ at a frequency of the order of 10^{14} Hz, concluded that the complex is a one-dimensional metal. These authors[147] attributed the activation energy of the conductivity to defects in the linear chain.

An interesting feature is that platinum complexes with mixed valencies are similar in many respects to the highly conducting radical-ion salts of TCQM[34, 86]. They are also characterised by anomalously dielectric constants at a frequency of 10^{10} Hz at liquid helium temperatures[34, 86]. This apparently indicates that highly conducting linear chains exhibit various common features, which are due to the presence of the quasi-one-dimensional electronic system.

Yet another type of highly conducting complex with mixed valencies was discovered recently[168]. Compounds with the compositions $K[Ir_2(CO)_4Cl_4]$ (IX) and $K_2[Ir_2(CO)_4Cl_5]$ (X), in which the iridium atoms are in oxidation states 1 and 2, have been studied[169]. For polycrystalline specimens at room temperature, the conductivity has the values 1.5–5 $\Omega^{-1}cm^{-1}$ and 0.2–0.3 $\Omega^{-1}\,cm^{-1}$ for complexes (IX) and (X) respectively[168]. The activation energy of the conductivity is the same for the two compounds ($\sim$ 0.035 eV). The crystal structure of the complexes is unknown, but it may be expected that the metal ions form a linear chain. The true conductivity of these compounds in a single crystal should be much greater than that found for the polycrystalline specimens.

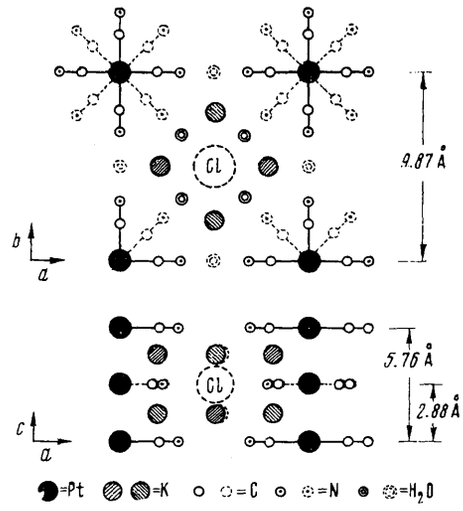

Figure 7. Crystal structure of $K_2[Pt(CN)_4]\ Cl_{0.32}\cdot 2.6H_2O$. Projections along the c and b axes.

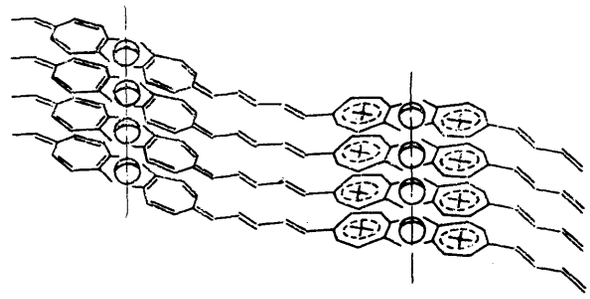

Figure 8. Suggested structure of an exciton superconductor based on metal complexes with readily polarised dyes, containing substituents of the chelate type.

The existence of highly conducting complexes containing linear metallic chains suggests that it may be possible to prepare compounds, based on metal complexes, satisfying the requirements of Little's model[149, 150].

In particular, it is proposed to prepare platinum complexes with mixed valencies, containing a chain of platinum ions and highly polarised ligands[149].

The approaches to the preparation of high-temperature superconductors based on metal complexes have been examined[135]. Various dyes containing substituents of the chelate type have been suggested as starting materials for the preparation of proposed exciton superconductors (Fig. 8). It can be seen from Fig. 8 that the metal ions form linear conducting chains, joining the highly polarised dyes. The preparation of compounds of this type will undoubtedly encounter considerable difficulties associated with solubility, purification, and crystallisation of the products. The intended products may not exhibit the required properties, because of steric complications: non-coplanarity of the dye molecules, non-coplanarity of the carbon atoms of the ring and the ligand atoms, and, which is most important, lack of correspondence between the interplanar spacings for the dyes and the dimensions of the metal atoms.

VI. MODEL OF A TWO-DIMENSIONAL EXCITON SEMICONDUCTOR

In addition to Little's model, the model of a two-dimensional exciton superconductor of the "sandwich" type[3, 4] (Fig. 9), first put forward by Ginzburgh and Kirzhnits[170], is widely known. The conductivity of the "sandwich" is due to a thin metal film ($d \simeq 10-15$ Å), and the attraction between the electrons is increased by the exchange of excitons propagated in the coatings of the "sandwich".

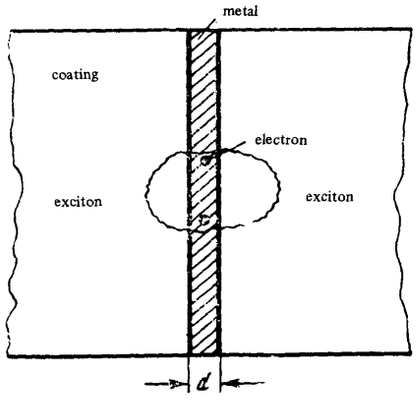

Figure 9. Model of a two-dimensional exciton superconductor of the "sandwich" type: a thin metal film between two coating layers.

The latter may consist of a dielectric, a semiconductor, or even a "poor" metal[3]. The important feature is that electronic excitations (excitons) which are not readily quenched be produced in them. The two-dimensional model of an exciton superconductor has certain advantages over Little's one-dimensional model: the fluctuations of electron density are smaller, and the Coulombic repulsion of the electrons is screened[3]. The interaction between the polarisation and conductivity electrons in the "sandwich" will possibly be weaker[3], however, than that in Little's model. To increase the interaction, the coatings must be very closely joined to the thin metal film (Fig. 9). It seems appropriate to ensure this by chemical interaction between the coating and the film[3]. The existence of chemical binding on the surface of metals has been shown, in particular, in the study of the catalytic properties of metals[171].

The possibility of obtaining high values of T_c in models of the "sandwich" type has stimulated interest in the study of the influence of organic molecules on the critical temperatures of superconducting metal films[176, 177]. The unambiguous interpretation of the changes in T_c observed in studies of this kind[172–177] is fairly complicated, since the critical temperatures of metal films depend markedly on a large number of factors (thickness, nature of the surface, particle size)[177–179]. It should be emphasised that the authors cited were dealing with fairly thick films. In addition to the selection of suitable coatings, the preparation of metal films with thicknesses of several atomic dimensions ($d \simeq 10-15$ Å) presents the main difficulty in the experimental realisation of a superconducting model of the "sandwich" type. Of considerable interest in this connection are granulated superconductors[180], in which fine metal particles are situated in a suitable dielectric matrix. In this instance there is no need to produce a continuous extremely thin metal film.

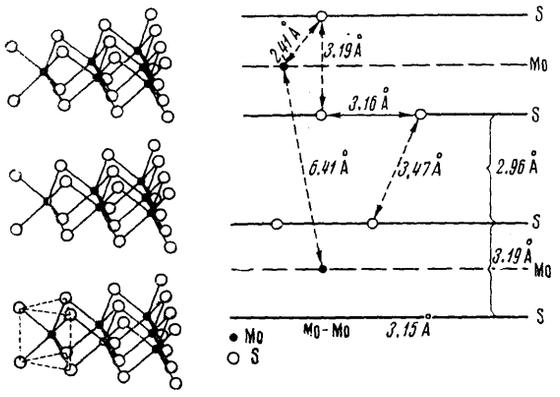

Figure 10. Structure of MoS_2.

In connection with the problem of producing a two-dimensional exciton superconductor, there has recently been an increase in interest in the study of layer compounds. A layer structure is characteristic of many dihalides and dichalcogenides of the transition metals. These include semiconductors, semimetals, metals, and superconductors[181]. Layer compounds of this type can be regarded as consisting of stacks of "sandwiches"[3]. Fig. 10 shows the structure of MoS_2, which is typical of layer dichalcogenides of the transition metals. The layer of molybdenum is situated between two layers of sulphur, and the bonding within this sandwich is strong; the Mo–S distance is equal to 2.4 Å. At the same time, the bonding between the "sandwiches" in the lattice is weak and is determined chiefly by van der Waals' forces; the distance between the sulphur atoms of neighbouring layers is 3.47 Å. The absence of continuous chemical bonding along the c axis

makes it possible to introduce into the transition metal dichalcogenides molecular or atomic layers of various substances: alkali and alkaline earth metals [182], organic bases[183–185], and amides[186]. The introduction takes place between the weakly connected "sandwiches"; the lattice expands along the c axis, with an increase in the distance between the metal layers[182–186]. Graphite, in which the bonding between the carbon layers is weak, is also capable of forming layer compounds of similar type with alkali[186, 187] and transition[188, 189] metals, acids[186], halogens[186], and metal chlorides[186, 189].

Table 3. Superconducting intercalation compounds of TaS_2 with Lewis bases[183, 185].

Bases[a]	pK_a of base	Distance between metal planes	T_c, °K
Pure TaS_2	—	6.04	0.8
$(Pyridine)_{0.5}$	5.3	11.85[b] 12.02	3.55
$(2\text{-Aminopyridine})_{0.53}$	5.2	12.09	3.25
$(2\text{-Dimethylaminopyridine})_{0.32}$		11.94	3.15
$(4\text{-Dimethylaminopyridine})_{0.34}$	9.7	12.25	2.30
$(2\text{-Ethylpyridine})_{0.29}$	6.0	9.64[b] 11.58	3.0
$(3\text{-Ethylpyridine})_{0.29}$	5.7	11.34	4.5
$(4\text{-Ethylpyridine})_{0.33}$	6.0	11.98	2.95
$(2\text{-Isopropylpyridine})_{0.25}$	5.8	11.45	3.80
$(4\text{-Isopropylpyridine})_{0.28}$	6.0	11.98	2.82
$(2\text{-Methylpyridine})_{0.34}$	6.0	11.79	2.95
$(3\text{-Methylpyridine})_{0.33}$	5.7	11.83	2.95
$(4\text{-Methylpyridine})_{0.33}$	6.1	11.76	2.70
$(2,6\text{-Dimethylpyridine})_{0.2}$	6.7	9.59	2.15
$(2,4,6\text{-Trimethylpyridine})_{0.165}$	9.6	9.67	1.95
$(2\text{-Phenylpyridine})_{0.255}$	5.1	11.92	3.15
$(4\text{-Phenylpyridine})_{0.26}$	5.2	12.31	1.6
$(2\text{-Propylpyridine})_{0.245}$	—	11.46	2.85
$(4\text{-Propylpyridine})_{0.25}$	6.1	11.85	2.75
$(Aniline)_{0.75}$	—	18.12	3.06[c]
$(Octadecylamine)_{0.58}$	—	35.02[b] 51.02	3.05[c]

[a]Number of molecules of base per molecule of TaS_2. [b]Two phases. [c]Temperature corresponding to the start of the heat capacity anomalies[185] associated with the conversion into the superconducting state.

Intercalation compounds exhibit interesting properties, particularly electrical[186, 190–195] and magnetic[186, 196, 197] properties. Thus the studies of compounds of graphite with K, Rb, and Cs has shown that these compounds (with the composition C_8M) are converted into the superconducting state at temperatures of 0.55, 0.155, and 0.135° K respectively[191, 192]. Neither the alkali metals nor graphite are superconductors. MoS_2 is a semiconductor[181], but its intercalation compounds with sodium and potassium are "metals"[193], which are converted into the superconducting state at temperatures of ~1.3° K and ~4.5° K respectively[194].

Work on the penetration of strong organic Lewis bases (of the pyridine type) into the superconducting dichalcogenides of Nb, Ta, and Pd is of considerable interest[183–185, 196]. The superconductivity did not disappear, and even a slight increase in T_c was observed (see for example Table 3). By varying the base, it is possible to alter considerably the distances between the metal layers, increasing them to 30 Å or more (Table 3). The ability to form intercalation compounds is here determined chiefly by two factors: 1) the nature of the electronic structure of the original transition metal dichalcogenides, and 2) the characteristic features of the organic Lewis bases, in particular their basic strength and dimensions[183]. Unlike the "metallic" dichalcogenides of Ta and Nb, the "semiconducting" dichalcogenides of Mo and W do not form intercalation compounds with pyridine and its derivatives[183]. TaS_2 forms stable compounds only with bases for which pK_a is greater than 4.[183]

The intercalation compounds obtained show marked anisotropy of the conducting and superconducting properties[185]. The interaction between the layers is weak, and it possibly does not have a decisive influence on the conversion into the superconducting state. There is no correlation between T_c and the magnitude of the distance between the metal planes[184, 185] (Table 3). It is not excluded that the superconductivity in these systems is a property of the two-dimensional metallic layers[187] (two-dimensional superconductivity). These materials are of considerable interest, since their study may provide an answer to the fundamental question of the possible existence of two-dimensional superconductivity. The preparation of intercalation compounds with highly polarised organic molecules appears attractive, and would be of particular interest in connection with the exciton mechanism of superconductivity, which might be produced in systems of this kind.

---o0o---

The indefinite nature of the theory of the possible existence of high-temperature superconductivity of the exciton type makes it difficult to choose specific chemical routs to the preparation of possible superconducting compounds. The realisation of the models by synthesis in most instances required the development of new approaches and methods.

The results obtained up to the present, however, suggest that it may be possible to obtain compounds with structures corresponding to the existing requirements of theory. In any event, studies of this kind carried out in the field adjoining solid state physics and chemical synthesis will undoubtedly lead to interesting results.

New Organic Ligands in Complexes of Transition Metals

I.I.Kritskaya

Results obtained for complexes of transition metals with unusual organic ligands—trimethylenemethane, tetramethylene-ethane, pentadienyl, and benzyl—are summarised. The chief structural and chemical features of these compounds are discussed. A list of 169 references is included.

I. INTRODUCTION

The development of the chemistry of organic derivatives of transition metals, the vigour of which strikes the imagination, has not weakened even after twenty years have elapsed. Since the discovery of ferrocene it has become evident that any organic molecule can be in some way bound to a transition metal. Alkyl, aryl, and mixed radicals, as well as an acetylene residue, are able to combine with the metal by a simple σ-bond. Mono-, di-, and poly-enes—acyclic and cyclic, conjugated, unconjugated, and cumulated—aromatic and non-aromatic hydrocarbons and heteroatomic compounds form the most diverse π-complexes, frequently of unexpected structure. Besides such types of complex formation, which have already become usual, fresh possibilities have been revealed during recent years in this apparently exhausted field. It was demonstrated theoretically and confirmed experimentally that unstable organic species are stabilised significantly by complex formation. This provided a means of fixing and investigating such molecules as cyclobutadiene, such biradicals as trimethylenemethane and tetramethylene-ethane, and ions of the benzenonium type, which are extraordinarily difficult or quite impossible to study in the free state.

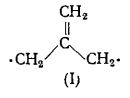
Complexes of various carbenes have been obtained. Furthermore, new possibilities have been revealed for the coordination of stable molecules. For example, an aromatic molecule is able to combine with a metal by an individual link, besides the "normal" type of bonding (as in π-arene complexes). This raises the problem of the stability of aromatic systems in the presence of transition metals.

The present Review discusses complexes with relatively new organic ligands—trimethylenemethane, tetramethylene-ethane, π-benzyl, and pentadienyl—surveying the conditions of formation as well as their physical and chemical features. Together with the π-benzyl complexes an attempt has been made to examine also the available factual information on the fragmentary coordination of aromatic molecules with metals. Work published up to December 1971 is covered.

II. π-COMPLEXES WITH TRIMETHYLENEMETHANE AND TETRAMETHYLENE-ETHANE

1. Trimethylenemethane—Structural Characteristics of the Free Biradical and of the Trimethylenemethane Ligand

The unstable reactive species trimethylenemethane (I) should theoretically have a triplet ground state (i.e. be a biradical) with a strongly delocalised system of four π-electrons[1] (delocalisation energy 1.46 β). Trimethylenemethane is important for theoretical chemistry because its central carbon atom forms a bond of maximum order ($N = 1.732$) and has the minimum free valency ($F = 0$). These are the extreme values possible for unsaturated carbon[2].

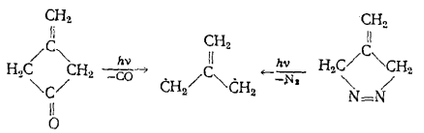


(I)

The molecule (I) has been examined as a model in various theoretical calculations[3-7] and has been assumed as an intermediate species in the thermal decomposition of 4-methylene-Δ^1-pyrazoline[8] and esters of 2-methylene-propane-1,3-diols[9], the thermal isomerisation of methylenecyclopropanes[10], the action of alkali metals on 3-halogeno-2-halogenomethylpropenes[11,12], and other reactions[13,14]. The chemical processes involving trimethylenemethane and its closest homologues and heteroanalogues have been reviewed[15].

The calculated carbon — carbon bond lengths of ~1.42 Å [6,16] and the first ionisation potential of 8.62 eV [16] have been confirmed experimentally in investigations of complexes of trimethylenemethane with the tricarbonyl-iron group[16-20]. The singlet form of trimethylenemethane is probably generated in thermal processes[16-22]. The triplet character of trimethylmethane and the equivalence of all six hydrogen atoms have been confirmed experimentally. By means of the electron spin resonance spectra Dowd observed this species among the products of

the low-temperature photolysis of 4-methylene-Δ^1-pyrazoline and 3-methylenecyclobutanone (at about −200°C):[23-25]



At this temperature the spectrum of trimethylenemethane remains for a month, but even at −150°C it changes instantly and irreversibly.

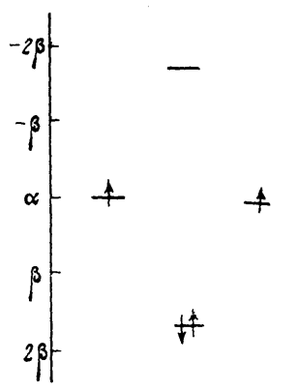


Figure 1. Energy-level diagram of the π-system of trimethylenemethane obtained by the Hückel molecular-orbital method.

Fig. 1 shows the energy levels of the π-system of trimethylenemethane.

As in other cases, this biradical is stabilised by forming a complex with a transition metal. It can reasonably be assumed that bonding occurs by interaction of the lowest filled molecular orbital with the sd_{z^2} hybrid orbital of the metal and of the doubly degenerate molecular orbital of symmetry E with the d_{xy} and d_{yz} orbitals of the metal. Probably no significant use is made of the highest molecular orbital $A_2(2)$, which is strongly antibonding, although no calculations have been made of the overlap integrals.

Existing experimental information shows that trimethylenemethane combines especially readily with the tricarbonyliron group, and its complexes are comparable with those of cyclobutadiene with respect to choice of metal and other partners. On the other hand, as will be shown below, direct transitions are possible from allylic complexes to trimethylenemethane, and *vice versa*. Thus the chemistry of compounds of this new ligand is also closely similar to that of π-allylic derivatives.

X-Ray[17,18,26,27] and electron[19,20] diffraction investigations of trimethylenemethane complexes indicate the equivalence of the bonds in the ligand, which is uniformly bound to the iron atom located exactly above the central carbon atom (Fig. 2). The $Fe-C_{(4)}$ distance is 1.93 Å both in the crystal and in the gaseous state; it is rather smaller than the distance (2.06 Å) from iron to the plane of the ligand in tricarbonyl(cyclobutadiene)iron. However, the distance from iron to the terminal carbon atoms (2.09 − 2.16 Å) is rather longer. The C − C bond lengths in coordinated trimethylenemethane are ~1.40 Å. Both methods show that $C_4H_6Fe(CO)_3$ has C_{3v} molecular symmetry with a crossed relative arrangement of the ligands (a trigonal antiprism). The central carbon atom of the trimethylenemethane system emerges to between 0.31 [18] and 0.22 [26] Å from the plane of the other three carbon atoms, on the side opposite to the metal. The phenyl-substituted complex exhibits[18] non-coplanarity of the substituent and the adjacent carbon atom (angle of deflection 59°), which should diminish the degree of $p_\pi - p_\pi$ interaction between the fragments. Possibly for this reason the introduction of a phenyl substituent into the trimethylenemethane system does not affect the positions of the absorption bands due to carbonyl groups[28].

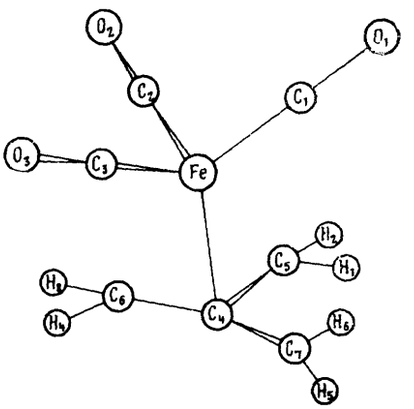

Figure 2. Structure of tricarbonyl(trimethylenemethane)-iron[20].

The nuclear magnetic resonance spectra of ^1H- and ^{13}C-tricarbonyl(trimethylenemethane)iron show that all six protons are magnetically equivalent and have a chemical shift of ~2 ppm,[29] which is in the region of absorption by the terminal protons of π-allylic and π-butadiene derivatives of iron. The spin − spin interaction constant $I_{^{13}C,H} = 162$ c/s, which is also typical of ethylenic π-complexes.

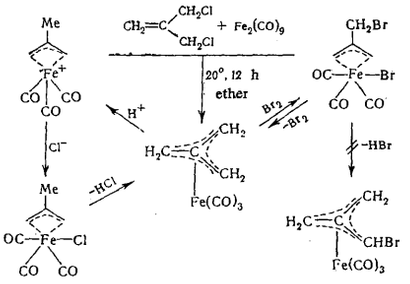
The complexes reported at the present time have in the infrared spectrum two or three carbonyl-stretching absorption bands according to the local symmetry of the carbonylmetal group $M(CO)_n$.[28-30]

2. Condition of Formation and Chemical Reactions of Trimethylenemethane Complexes

The trimethylenemethane complex was first obtained by Emerson and his coworkers[29] by the reaction of 3-chloro-2-chloromethylpropene with iron nonacarbonyl (Scheme 1). They also found that the new complex easily adds hydrogen chloride with conversion into a known allyl derivative of iron. Subsequently these workers developed this observation and found the conditions for the reverse transformation from substituted allyl complexes to trimethylenemethane derivatives[31]. This reaction occurs simply on

fractional distillation of the mixture formed by interaction between an allyl halide and iron nonacarbonyl. The first stage yields an allyl complex, which need not be isolated. The yields of trimethylenemethane derivatives obtained by this method reach 30%. Propenes and sometimes diene complexes of iron are obtained as side-products.

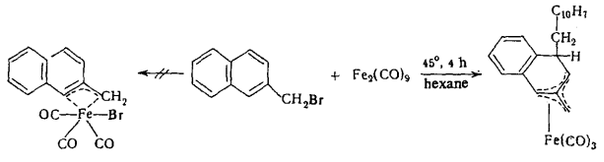
Scheme 1



Scheme 1 shows that tricarbonyl(trimethylenemethane)-iron is able also to add bromine reversibly. The resulting tricarbonyl(2-bromomethylallyl)iron bromide could be degraded in two ways—elimination of hydrogen bromide with formation of a complex containing a brominated trimethylenemethane ligand or elimination of bromine to return to the original complex—the latter of which actually occurs.

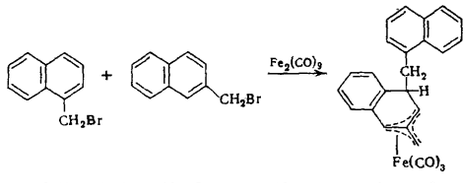
The salt $NaFe(CO)_4$ can be used instead of iron nonacarbonyl in the above reaction[30], which somewhat increases the yield of the complex.

Unusual conditions for obtaining the trimethylenemethane system have been found by Nesmeyanov and his coworkers[26,27,32,33]. This system is formed from 2-bromomethylnaphthalene, which under the conditions indicated adds the naphthylmethylene radical to one of the double bonds of the substituted ring:



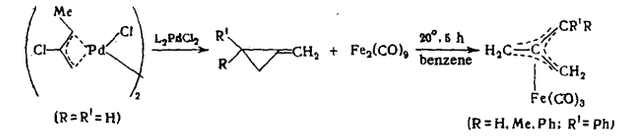
The extremely mild conditions of this transformation and the accompanying breakdown of the aromatic structure of the naphthalene molecule indicate that the nature of the trimethylenemethane ligand conforms well to the electronic and steric requirements of iron and that it is preferred to allyl.

The naphth-1-ylmethyl radical is able to take part in this reaction only as an adduct:



Formation of the trimethylenemethane system from 1-methylnaphthalene would have entailed breakdown of the aromatic structure of the second ring as well, and obviously this cannot be compensated even by formation of a bond with a metal. Several extremely stable compounds have been obtained under the above conditions, including the first complex of trimethylenemethane containing halogen in the ligand (Table 1). X-Ray diffraction examination of one of these compounds[26,27] enabled the structure of the complexes obtained to be understood correctly, and showed that the chief molecular parameters are general both for higher analogues and for the simplest complexes of trimethylenemethane.

Ring-substituted methylenecyclopropanes undergo ring-opening in the presence of iron carbonyl, and then coordinate with the iron as the trimethylenemethane form[28]:



The yields of the complexes reach 40 — 60%, but in the absence of substituents in the three-membered ring only tricarbonyl(butadiene)iron is obtained.

Table 1. Summary of data on complexes with trimethylenemethane and tetramethylene-ethane*.

Metal	Compound	Colour	M.p., °C	Ref.
Cr	$(CH_2)_3CCr(CO)_4$	yellow	83	30

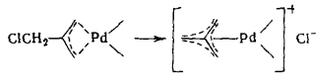
		brown	cryst.	54
Pd		white	cryst.	55

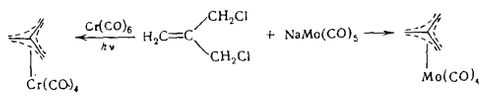
*In this and subsequent tables a dash in a column means that the characteristic is not given in the original paper.

A quite different result—formation of complexes with a π-allylic ligand—ensues when methylenecyclopropane undergoes ring-opening under the influence of palladium salts[34]. On the other hand, n.m.r. data confirm the formation of a fairly stable intermediate species, probably of the trimethylenemethane type, in the solvolysis of 2-chloromethylallyl complexes of palladium[35]:



Thus methylenecyclopropane obviously behaves differently in the presence of iron and of palladium, perhaps because of different states of the trimethylenemethane formed when the ring is opened.

A few complexes of trimethylenemethane with Group VI metals have been prepared[30]:



The conditions of their formation are clear from the above scheme. However, the yields are very low.

The list of compounds containing a trimethylenemethane ligand is not yet very long (Table 1). It is evident that they are all quite stable substances, melting at fairly high temperatures (often with decomposition). The thermal stability of the complexes is greatly improved by the introduction of phenyl substituents. The naphthalene derivatives melt without decomposition at 140 – 170°C, and are the most stable. The stability of the trimethylenemethane complexes also governs their behaviour in the mass spectrometer. All the compounds studied give molecular ions[29,33]. These compounds are considerably less stable in solution than in the solid state.

As with most other types of π-complexes, structural investigations predominate over chemical studies in this case. This is obviously due to the relative inaccessibility of these compounds and their comparative instability in solution. Besides the above addition of bromine and hydrogen chloride, the oxidation of tricarbonyl(trimethylenemethane)iron by a quadrivalent cerium salt has been studied[30], which obviously results in the liberation of trimethylenemethane. In any case, an adduct of the latter compound is obtained in the presence of tetracyanoethylene. Thus complexes of trimethylenemethane may give the free compound. Photochemical degradation of the complex with iron tricarbonyl[36] yields a complicated mixture, containing the dimer *p*-xylene, paracyclophane, and several other products. In the presence of cyclopentene 2-methylenepentalene is formed by addition of the biradical to an isolated double bond. This type of addition has hitherto been regarded as impossible.

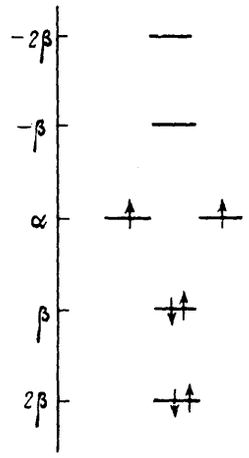


Figure 3. Energy-level diagram of the π-system of tetramethylene-ethane obtained by the Hückel molecular-orbital method.

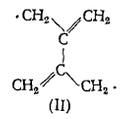
3. Tetramethylene-ethane and its Complexes

Like trimethylenemethane, tetramethylene-ethane (II)



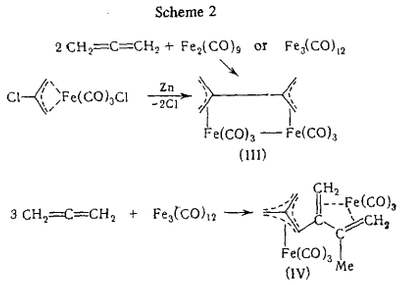
(II)

also has the triplet ground state predicted theoretically[1] and confirmed experimentally[37]. Calculation by the Hückel method gives the energy-level diagram for the π-system[38] illustrated in Fig. 3. The delocalisation energy is respectively ~2 β and 0.35 β relative to the system with two double bonds and two localised electrons and relative to two allyl radicals. This species is comparatively

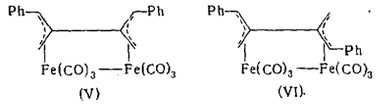
unstable in the free state, its lifetime at −196°C being about 20 min[37]. The formation of tetramethylene-ethane was suggested in a study of the degenerate thermal rearrangement of 1,2-dimethylenecyclobutane[39,40]. Tetramethylene-ethane is the central fragment of the stable bisgalvinoxyl biradical[41]. Electron spin resonance spectra have been obtained for the radical anion[42] and the radical cation[41] of tetramethylene-ethane.

The hypothesis that tetramethylene-ethane is an intermediate species in the di- and tri-merisation of allene was confirmed by isolation of the binuclear complexes (III) [43-46] and (IV) [47] in the reaction of allene with iron carbonyl (Scheme 2). The latter contains a ligand which is a kind of combination of trimethylenemethane and a tetramethylene-ethane derivative. The complex (III) can be obtained independently by eliminating the two halogen atoms from tricarbonyl-2-chloroallyliron chloride.

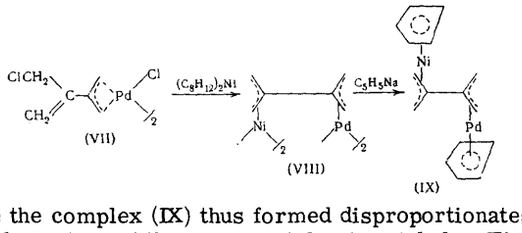
Scheme 2



Analogous complexes (V) and (VI) are obtained from phenylallene and iron carbonyl[48]. They are assumed to be isomeric, with different relative orientations of the substituents in the allyl groups

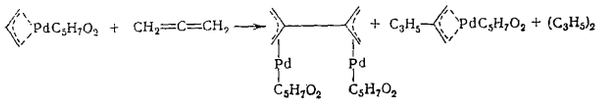


In the presence of palladium salts allene yields the complex (VII) together with other products[49-53]. If the reaction is conducted in a polar medium with excess of allene present, (VII) is the main product. The substituent in the allyl ligand of (VII) is itself a potential ligand. In fact it combines with an additional metal atom to give the tetramethylene-ethane complex (VIII),[54] which is capable of the usual reactions, e.g. rupture of the bridge by the action of C_5H_5Na:

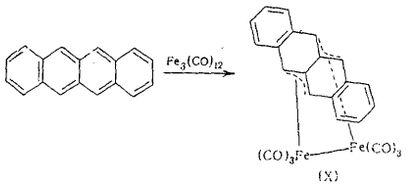


In time the complex (IX) thus formed disproportionates to give a derivative of the same metal, viz. nickel. The transoid configuration of (IX) was supported by preliminary X-ray diffraction results[54].

An analogue of (VIII) can be obtained by the incorporation of allene into an existing π-allylic type of palladium complex with an acetylacetonate group[55]:



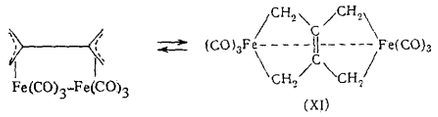
Finally, another surprising change to a tetramethylene-ethane derivative was discovered by Fischer et al.[56] When tetracene was heated with $Fe_3(CO)_{12}$, an extraordinarily stable compound containing two tricarbonyliron groups was formed, whose infrared and n.m.r. spectra suggested the structure (X):



Most complexes of tetramethylene-ethane are solids having surprising thermal stability. Their mass spectra contain peaks due to molecular ions[48].

Unfortunately there is as yet no single completed X-ray structural investigation of tetramethylene-ethane complexes. All the latter that have been described are binuclear compounds. This ligand probably cannot be coordinated other than with a few metal atoms without strong disruption of coplanarity and delocalisation. It would therefore be interesting to ascertain in what measure its fragments bound to different metal atoms are autonomous and whether the system preserves its planarity. Existing spectroscopic data seem to indicate that the two allylic systems are autonomous when the molecule contains two different metals. The n.m.r. spectrum of (IX) contains two sets of signals for each moiety of the molecule, as if each were independent. The *syn*- and *anti*-protons of each allylic group and the protons of the cyclopentadienyl rings absorb at different magnetic field intensities, and all signals for the nickel-containing moiety are displaced to a higher range than those for the moiety containing palladium.

The complex (III) possesses the properties of flexible systems. This is apparent in the variation of its spectrum with temperature and is explained[45] by a valency-tautomeric equilibrium of the type



The introduction of phenyl substituents raises the barrier to the dynamic process, and the spectra of (V) and (VI) show no dependence on temperature[47]. A third product was isolated in the preparation of complexes (V) and (VI); its spectral properties were compatible with structure (XI), and it underwent thermal rearrangement to (VI). Thus the possibility of valency tautomerism seems to be confirmed by isolation of a second equilibrium form. However, the molecules are quite complicated, and X-ray examination is very necessary to confirm these conclusions.

Complex (X) would also be interesting to examine by X-ray diffraction. The central portion of this molecule is quite analogous to (III), and the changes in the n.m.r. spectrum of tetracene after coordination are consistent with such a form of bonding. Further confirmation of the structure can be found in the infrared spectra, for carbonyl-containing complexes of iron have entirely analogous spectra in the region of carbonyl-stretching vibrations[48,56]. These workers give three bands for each of the two tricarbonyliron groups in (III), (V), and (VI)—e.g. at 2062, 2030, 1996, 1983, 1970, and 1940 cm^{-1} in the case of

(VI)—but the lower three bands are significantly less intense and are poorly resolved. The spectrum of complex (X) contains five bands, situated close to the first five bands enumerated above.

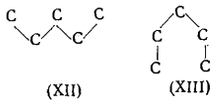
Chemical investigations of tetramethylene-ethane complexes are very sparse. These complexes are decomposed by bromine with the formation of 1,4-dibromo-2,3-bisbromomethylbut-2-ene[44,45].

III. COMPLEXES OF PENTADIENYL

A considerable number of complexes have now been prepared in which the transition metal is bound to an open chain of five unsaturated carbon atoms. These complexes can be combined under the name *pentadienyl*, although they can probably include structural variants. They have been known for about a decade, but only recently have they begun to be investigated systematically as a class.

1. Structural Characteristics of the Cation and Anion of Pentadienyl and the Pentadienyl Ligand

The simplest acyclic pentadienyl species (anion, cation, and radical) probably have the form (XII) of carbon skeleton. However, when this system is part of a ring of moderate size, (XIII) will be the more probable form of skeleton.

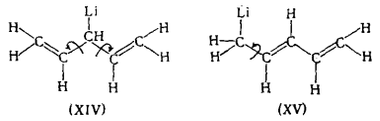


(XII) (XIII)

Fig. 4 shows the energy-level diagram of the π-system of pentadienyl. The delocalisation energy for all three species is 1.464 β.[2]

Acyclic dienyl cations are quite stable in strongly acid media, and can be observed directly by nuclear magnetic resonance[58]. At room temperature the molecules studied do not exhibit the properties of flexible systems.

The temperature variation of the n.m.r. spectrum of the pentadienyl anion (as the lithium derivative) indicates that the terminal protons become equivalent above 30°C.[59] This was explained by equilibrium between ionic and covalent forms of the lithium derivative, for which the two structures



(XIV) (XV)

were possible. Rotation about the single bond leads to interchange of the positions of the terminal protons. The spectral data show that rotation occurs more readily about inner than outer carbon — carbon bonds.

The chemical shifts for the various protons in the pentadienyl system suggest that the charge is distributed non-uniformly along the chain. In the anion the greatest electron density is concentrated on the odd carbon atoms, as predicted by theory[2,60].

Pentadienyl anions are capable of [1, 6] sigmatropic rearrangements, which conform to the Woodward — Hoffman rules. These changes are slowed down by the presence of alkyl substituents[61].

The large majority of pentadienyl complexes known at the present time contain the ligand in the form (XIII), which is probably geometrically more favourable for coordination with a single metal atom. The only example in which form (XII) of pentadienyl is fixed on a transition metal is a bis-π-allylic type of nickel complex containing two metal atoms (see below).

Benzenonium ions are stabilised as pentadienyl complexes of transition metals. Almost all known complexes with this ligand in either form (around 150 individuals have been isolated) are quite stable compounds. The following experimental results enable the relative stability of the pentadienyl cation and its complexes to be compared with other cations and complexes of other ligands.

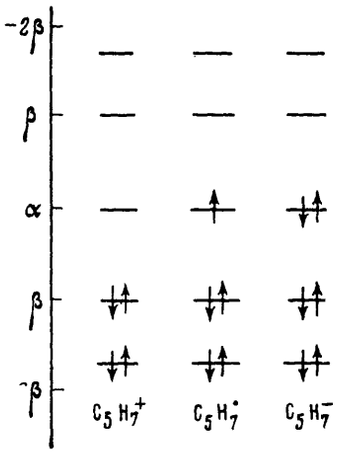


Figure 4. Energy-level diagram of the π-system of pentadienyl obtained by the Hückel molecular-orbital method.

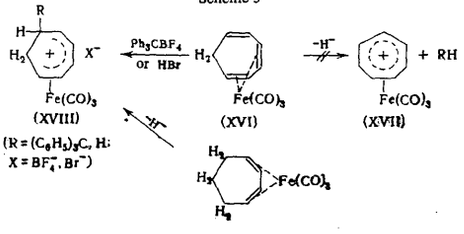
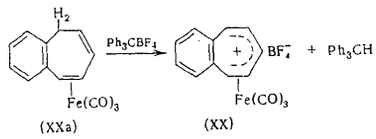
The cycloheptatriene derivative of iron (XVI) has one free double bond and an α-methylene group relative to the coordinated system (Scheme 3). However, it exhibits no tendency to change into the tropylium complex (XVII) under conditions such that a hydride ion is usually easily detached from an α-methylene group[62-64].

Scheme 3



Scheme 3 shows that (XVI) develops acceptor properties towards electophiles: it adds a proton or a triphenylmethyl cation to give the complex (XVIII) with a pentadienyl ligand[62,65]. On the other hand, the same cation and its analogue (XX) [66] can be obtained in the usual way—by

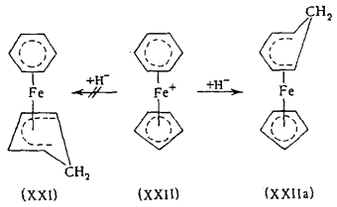
detachment of a hydride ion from (XIX) and (XXa) respectively:



(XXa) (XX)

The n.m.r. spectrum of (XX) shows that the positive charge is mainly localised in the pentadienyl system, and is not transmitted to the benzene ring: i.e. the coordinated form (XX) is probably correct, not the alternative benzotropylium form. The formation of pentadienyl complexes by the detachment of a hydride or a hydroxide[67] ion under the influence of a triphenylmethyl salt suggests that the resulting complex cations are more stable (less electrophilic) than the triphenylmethyl cation, whereas the reverse order of stability is observed for the free species. Thus the diminution in electrophilicity on passing from $C_6H_7^+$ to $C_6H_7Fe(CO)_3^+$ obviously results from the transmission of electron density from the tricarbonylmethyl group. The pentadienyl cation is preferable to the tropylium cation for iron, primarily because it is a four-electron donor. A vast quantity of experimental results confirm the special affinity of iron for organic ligands, contributing four electrons to the common electron shell. Furthermore, the pentadienyl cation contains a vacant non-bonding π-orbital, more capable than the antibonding orbital of the tropylium cation of taking part in dative bonding[2,38].

Having studied the reduction of a large number of arene-ironcyclopentadienyl (XXII) salts by hydride reductants[68-70], and also the addition to them of other nucleophilic reagents[71], Pauson and his coworkers showed convincingly that only the six-membered ligand changes, and of the two possible products (XXI) and (XXIIa) only the latter is obtained:



(XXI) (XXII) (XXIIa)

This probably applies also to the cathodic reduction of these salts[72].

Similarly, six- and seven-membered (but not four-membered) ligands add a hydride ion on the reduction of $C_7H_8CoC_4R_4^+$ and $C_6H_6CoC_4R_4^+$:[73,74] in other words, the pentadienyl ligand is preferred to the butadiene and allyl ligand respectively.

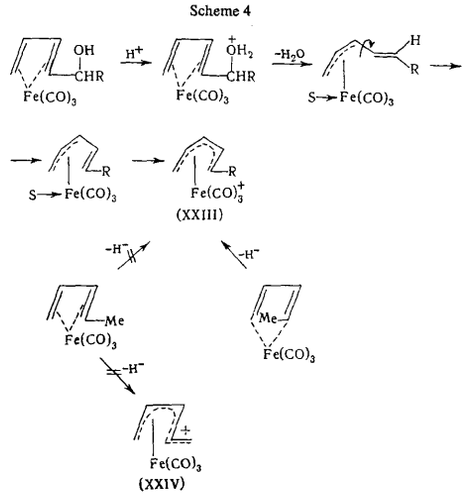
The structural problems discussed below are being studied in connection with pentadienyl complexes.

(*a*) *cis*- and *trans*-Forms of the ligand

When this ligand does not form part of a ring, it may be expected (in view of the geometry of the initial diene complexes) that *cis*- and *trans*-forms—(XXIII) and (XXIV)—will be produced. Pentadienyl derivatives of this kind are usually obtained from substituted diene complexes by the detachment of an anion from a side-chain[75-77] (Scheme 4).

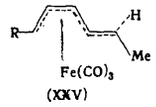
An immense quantity of experimental results shows that, independently of the initial configuration, either the *cis*-form of the complex is obtained or else the reaction does not take place at all (Scheme 4). The mechanism of inversion[76] is clear from the scheme, and involves complexes of allylic type at intermediate stages.

Scheme 4



(XXIII) (XXIV)

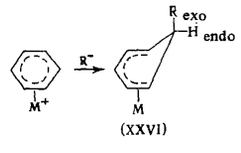
Recent spectral[78-80] and chemical[81,82] results indicate that a complex can be obtained with a ligand in the *trans*-configuration. The temperature dependence of the n.m.r. spectrum of acid solutions of tricarbonyl(2-methylhepta-3,5-dien-2-ol)iron and analogous compounds[79] shows that the *trans*-isomer exists in solution at temperatures below −50°C. The activation energy of conversion to the *cis*-form is ~13 kcal mole^{-1}. Preservation of the *trans*-configuration of the cation at low temperatures was attributed[80] to vertical stabilisation of the ionic centre by iron:



(XXV)

(*b*) Steric configuration of the ligand

The next problem, whose solution required considerable effort, involved the stereochemistry of the addition of nucleophiles (and thus the three-dimensional structure of the complexes) in the conversion of arene-containing complex cations into neutral cyclohexadienyl complexes:



(XXVI)

Spectral[68-71] and X-ray diffraction[83] results suggest that nucleophilic species (H^-, $C_6H_5^-$, CH_3^-) add on the outside of the ligand, and the ingoing substituent occupies an *exo*-position. This destroys the coplanarity of the ring, and the cyclohexadienyl ligands assume the form (XXVI). It

will be shown below that seven-membered rings buckle similarly.

The infrared spectra of cyclohexadienyl complexes have one extremely interesting feature: they contain an unusually low carbon — hydrogen stretching band (2730 — 2830 cm^{-1}),[71] which seems to be independent of the nature of the metal. Recent structural investigations show that this band is undoubtedly due to the *exo*-proton of the methylene group. The lowering of the frequency is no doubt caused by complex formation, since the free hydrocarbons do not exhibit anomalous bands. Because of the geometry of cyclohexadienyl complexes, illustrated above and to be discussed in detail later, it can hardly be supposed that the methylene *exo*-proton will interact through a tetrahedral carbon atom with the electron system of the metal[84]. Hyperconjugation is assumed to be possible in a molecule of the complex[71], as a consequence of overlapping of the σ-bonding *exo*-hydrogen — carbon orbital and neighbouring π-orbitals of the ligand directly involved in combining with the metal. The displacement of electrons from the carbon — hydrogen bond resulting from such interaction lowers the frequency of the stretching vibration. Experimental and calculated results[71] show that this phenomenon is general in character for ligands formed from five- and seven-membered rings. The cation $C_6H_7Fe(CO)_3^+$ is an exception to the general rule: its spectrum contains no anomalous band[84,85].

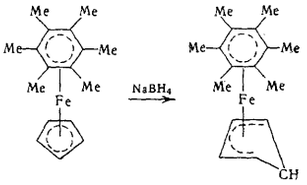
The nuclear magnetic resonance data[71] indicate that atoms and groups (hydrogen, methyl, phenyl) occupying an *exo*-position with respect to the metal are more strongly shielded than the corresponding *endo*-substituents: i.e. *endo*- and *exo*-substituents differ in their n.m.r. spectra. Protons and substituents situated in the coordinated moiety also exhibit non-equivalence, and the order of variation in shielding is opposite to that for benzenonium ions[68]. We shall return to this fact later.

Stereospecificity of addition to a complex cation may be due to spatial requirements or to an unsymmetrical distribution of electron density with respect to the plane of the ligand in the initial molecule, involving concentration on the *endo*-side, i.e. closer to the metal. Hence the approach of an anion will occur preferentially on the *exo*-side.

The direction of attack by a nucleophile on substituted arene complexes is determined to some extent by the nature of the substituents. A hydride ion usually goes towards an unsubstituted carbon atom in the benzene ring; when the number of such sites is small ($n < 3$), addition occurs also at a substituted carbon atom. When R = CH_3 ($n = 1 - 3$), the reaction involves almost exclusively unsaturated positions with a random probability distribution[68]. If methoxyl is the substituent, reduction occurs predominantly *meta* thereto. In the reduction of $CH_3OC_6H_5FeC_5H_5$, for example, the relative reactivities of the positions were found to be $o:m:p = 1:5:3$.[69] This may be due to a decrease in the local positive charge at the *ortho* and *para* positions owing to $p_\pi - p_\pi$ overlapping of the π-system of the ring and a lone pair on the oxygen.

When the nuclear substituent is a halogen, reduction occurs mainly in the *ortho* position, probably owing to the electron-accepting inductive effect of the halogen.

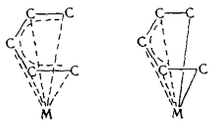
The addition of anions—$C_6H_5^-$, CH_3^-,[71,86] etc.—is in general controlled by the same rules. For example, the reaction between $CH_3C_6H_5FeC_5H_5^+$ and methyl-lithium involves unsubstituted carbon atoms, and *ortho*, *meta*, and *para* positions are equally reactive[71]. Only when all hydrogen atoms of the six-membered ring have been substituted does the behaviour of the cation on reduction change significantly: hexamethylbenzeneironcyclopentadienyl is reduced by adding a hydride ion to the five-membered ring[71]:



Similarly, only $C_6H_7MnC_6(CH_3)_6$ is obtained[87] of the two possible reduction products of the cation $C_6H_6MnC_6(CH_3)_6^+$.

(c) Possible forms of bonding with metal

The distribution of electron density in the pentadienyl ligand is of great interest. It is important to elucidate whether there is equivalent bonding of all five carbon atoms with the metal as in (XXVII) or whether the terminal carbon atoms are bound to the metal by σ-bonds, while the central portion acts as a π-allyl (structure XXVIII):



(XXVII) (XXVIII)

The latter suggestion is based on the above mentioned non-coplanarity of the rings, which may be due to rehybridisation at the terminal atoms of the coordinated portion.

Several structural investigations have been made on pentadienyl complexes, but all on derivatives in which this ligand forms part of a ring. Thus more or less complete investigations have been made on $C_6H_7Mn(CO)_3$,[84] azulene — $Mn_2(CO)_6$,[89,90] $(CH_3)_6C_6HRe(CO)_3$,[83] two azulene complexes of molybdenum carbonyl[91-93], and μ-(ππ-1, 6-dihydroheptalenebistricarbonylmolybdenum)[94]. Figs. 5 and 6 illustrate results obtained by Churchill and his coworkers for $C_6H_7Mn(CO)_3$ and guaiazulene — $Mo_2(CO)_6$ [84,93] derivatives of cyclohexadienyl and cycloheptadienyl respectively. The main features of these structures are easily seen. As already noted, the tetrahedral carbon atom in the cyclohexadienyl complexes is deflected substantially (by 42°) from the plane formed by the remaining five carbon atoms, which are arranged almost in the same plane and form an open pentagon. In $(CH_3)_6C_6HRe(CO)_3$ the deflection of the methylene group reaches 50°.[83] The deflection in structures analogous to Fig. 6 is considerably smaller (10 — 18°), which may be due to the presence of a direct metal — metal bond or of a second carbonylmetal group[90].

Like the other examples studied, the structures also show some lack of symmetry in the situation of the metal relative to the pentadienyl fragment, although the carbon — carbon bonds remain the same (~1.40 Å). As in the π-allylic complexes the metal is located closest to the central carbon atom of the system; the distances to the terminal and intermediate carbon atoms are 0.2 — 0.07 Å longer. The distances to the remaining carbon atoms, not directly bound to the metal, increase still more (difference up to 0.5 Å). The carbon — carbon distances are rather shorter in the pentadienyl than in the cyclopentadienyl ligand, while the mean metal — carbon distances are longer. This indicates stronger bonding of the metal

to the cyclopentadienyl than to the pentadienyl ligand, or else stronger bonding inside the pentadienyl than in the cyclopentadienyl fragment.

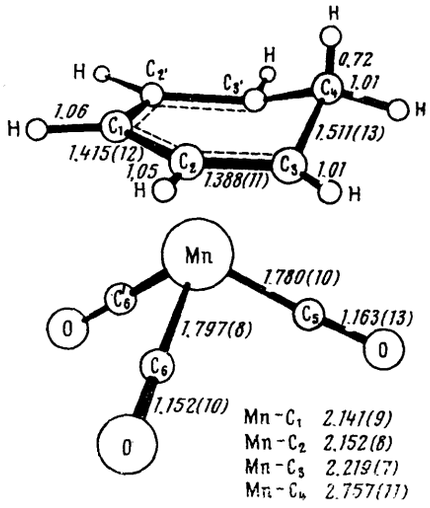


Figure 5. Structure of tricarbonyl(cyclohexadienyl)manganese[84].

The $C_{(4)}-C_{(3)}$ and $C_{(4)}-C_{(3')}$ bonds (Fig. 5) and the $C_{(4)}-C_{(10)}$ and $C_{(8)}-C_{(9)}$ bonds (Fig. 6) are elongated, and approach values corresponding $C_{sp^2}-C_{sp^3}$ bonds.

The angles in the cyclopentadienyl ring are rather smaller than the ideal angles for sp^2- and sp^3-hybridised carbon. All the azulene complexes studied exhibit shortening of the $C_{(9)}-C_{(10)}$ distances and lengthening of the $C_{(4)}-C_{(10)}$ and $C_{(8)}-C_{(9)}$ distances relative to uncoordinated hydrocarbon, which indicates that the two systems of π-electrons in the coordinated hydrocarbon are largely autonomous.

Thus the metal – carbon distances show rather weaker bonding between the terminal atoms of the pentadienyl system and the metal than with the central part of this ligand. However, no significant alternation in carbon – carbon bond lengths is observed, so that there are at present no grounds for discussing the limiting structure (XXVIII). On the other hand, the n.m.r. spectra also indicate an unsymmetrical distribution of electron density along this fragment. In fact, signals from protons attached to the terminal carbon atoms are observed at significantly higher fields than those from protons attached to the central carbon atoms of the system. With $C_6H_7MnC_6(CH_3)_6$, for example, we have the values (in ppm)—*exo*-H 1.05, *endo*-H and $H_{(3,3')}$ 1.4, $H_{(2,2')}$ 3.5, and $H_{(1)}$ 5.0 [87]—and a similar rule is observed for cycloheptadienyl complexes[88]. Furthermore, the chemical shifts depend on the nature of the solvent[95], which may be due to differences in electron density at different positions in the ligand. A final conclusion on the degree of asymmetry of bonding will obviously become possible after further structural investigations by both spectral and X-ray methods.

The first indications have been obtained that certain π-cyclohexadienyl systems are flexible[86]. However, the nature of the dynamic processes underlying such behaviour remains obscure.

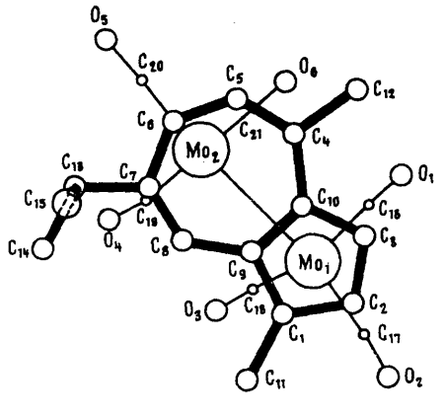

Figure 6. Structure of complex of guaiazulene with $Mo_2(CO)_6$.[93]

2. Methods of Preparation of Pentadienyl Complexes

We shall mention some general methods of preparation of pentadienyl complexes, in addition to those considered above.

1. Direct reaction between alkali-metal pentadienyl derivatives and salts of transition metals. Such a reaction has as yet been accomplished only in a single example with chromium(II) chloride[96]:

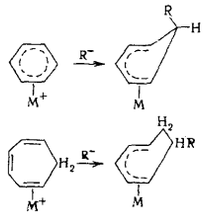
$$CrCl_2 + 2\,NaC_5H_7 \xrightarrow[-30^\circ C]{\text{oxolan}} Cr(C_5H_7)_2 + 2\,NaCl$$

The product of this reaction is very interesting. It exists as a monomer containing two pentadienyl groups and one chromium atom, is thermally stable (m.p. 122°C), and has two unpaired electrons. It resembles triallylchromium in its chemical properties: it is extremely sensitive to air, easily eliminates pentadiene on appropriate treatment, and is converted by carbon monoxide into $(C_5H_7)_2Cr(CO)_2$. No structural data are available, so that nothing definite can yet be said on the character of the bond.

Another complex of acyclic pentadienyl $(C_5H_7)_2Ni_2$ is now known, which contains two pentadienyl ligands and two metal atoms. This complex is obtained from nickel dichloride and penta-1,4-diene in the presence of triethylaluminium[97]. X-Ray results[98] show a di-π-allylic type of structure (Fig. 7). The nickel acquires its characteristic sixteen-electron shell, while the ligand is fixed in its most usual form.

2. Reduction of complex cations containing six- and seven-membered cyclic ligands. This method is used considerably more frequently[68-70,73,87,95,99-103]. Since the behaviour of the hydride anion and other nucleophilic agents is similar[71,86,88,99,104-107], this method may have even wider

application. It is suitable for the preparation of neutral cyclohexadienyl and cycloheptadienyl derivatives of all those metals for which the initial arene and cycloheptatriene complexes have been obtained:



(R = H, Alk, Ar, AlkO, CN, NR_2)

The reductants most often used are sodium tetrahydroborate, lithium tetrahydroaluminate, and sodium in liquid ammonia[102].

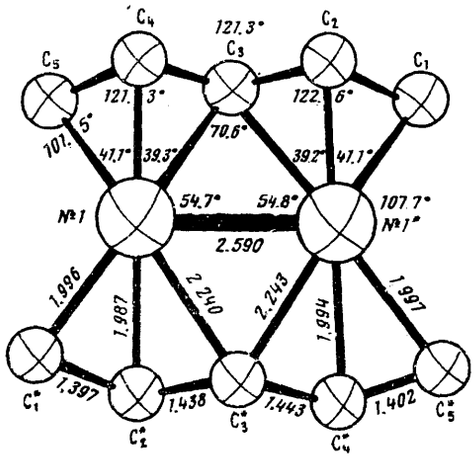


Figure 7. Structure of bispentadienyldinickel[98].

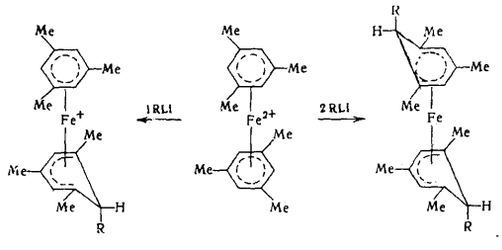
Several aspects of these reactions have been considered above. It should be added that the electronic requirements of the central atom also affect the course of these reactions. For example, reduction of the dibenzenerhenium and dibenzenetechnetium cations leads to the formation of benzenecyclohexadienyl complexes, whereas the doubly charged dibenzeneruthenium cation is reduced predominantly to benzeneruthenium cyclohexadiene[99]:

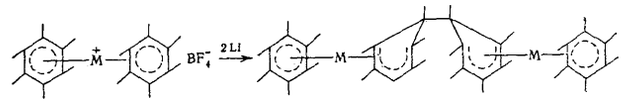
$$(C_6H_6)_2Ru^{2+} + NaBH_4 \rightarrow \underset{\text{main product}}{(C_6H_7)_2Ru} + C_6H_6RuC_6H_8$$

$$(C_6H_6)_2Re^{1+} + NaBH_4 \rightarrow C_6H_8ReC_6H_7$$

The corresponding cation of iron adds one or two moles of RLi:[86]

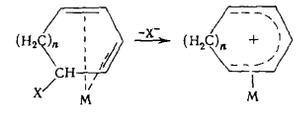


In isolated cases reduction is accomplished by an alkali metal alone, e.g. by fusing with metallic lithium[102,103]:



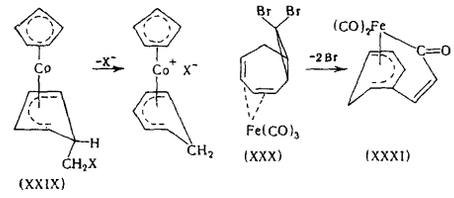
Reduction has been used to obtain all the known types of cyclohexadienyl complexes—$C_6H_7M(CO)_n$, $C_6H_7MC_5H_5$, $C_6H_7MC_6H_8$, $(C_6H_7)_2M$, $C_6H_7MC_4H_4$—in which this ligand is accompanied by carbonyl, cyclopentadienyl, arene, and cyclobutadiene ligands.

3. Detachment of an anion from an α-methylene of a diene complex. This method is suitable for obtaining cyclohexadienyl, cycloheptadienyl, and acyclic pentadienyl derivatives as cations[62,64,66,67,75–77,81,108]. The outgoing species may be hydride, methoxide, hydroxide, or halide ions. In contrast to the previous reactions, complex salts are formed here:



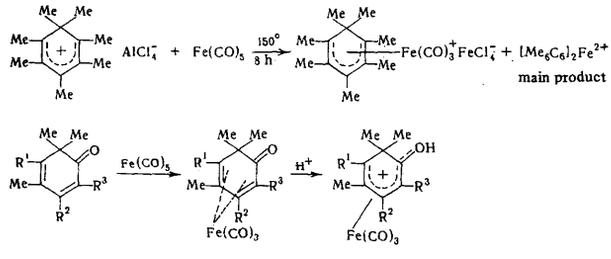
($n = 0, 1, 2$)

This method yields predominantly pentadienylcarbonyl complexes of general formula $C_5H_5[CH_2]_nM(CO)^+_m$. A proton or a triphenylmethyl cation may act as acceptor for the outgoing anions. These reactions are sometimes accompanied by enlargement[67,109–111] or contraction[112–114] of the rings. Solvolysis of (XXIX), for example, yields a cyclohexadienylcyclopentadienylcobalt cation (a cobalticinium analogue), and (XXXI) is obtained from (XXX) by treatment with methyl-lithium:

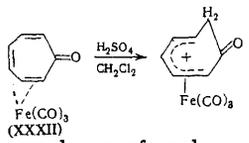


4. Addition of cations to free ethylenic group in polyalkene complexes. Salts of complex cations are obtained by the protonation of uncharged derivatives of diene type containing at least one free unsaturated group in the ligand[65,115–121] or by adding to it a carbonium ion[62,122], which has also received brief mention above. For example, complexes of bezenonium ions can be obtained by direct reaction with iron carbonyl[122] or by protonating a cyclohexadienone complex[120] (Scheme 5).

Scheme 5

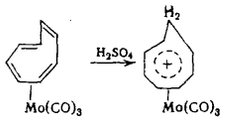


The cycloheptatrienone derivative (XXXII) is protonated at a carbon – carbon double bond[121]:

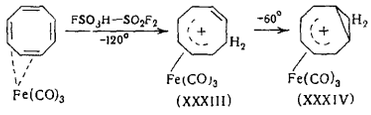


(XXXIII)

The protonation of complexes of cyclo-octatriene[119] and cyclo-octatetraene[115,117] provides a vivid example of how the electronic requirements of the metal determine the form of coordination of the organic cation. Thus the protonation of $C_8H_8Mo(CO)_3$ yields a homotropylium complex in which all six π-electrons of the ligand are involved in bonds with the metal[123]:



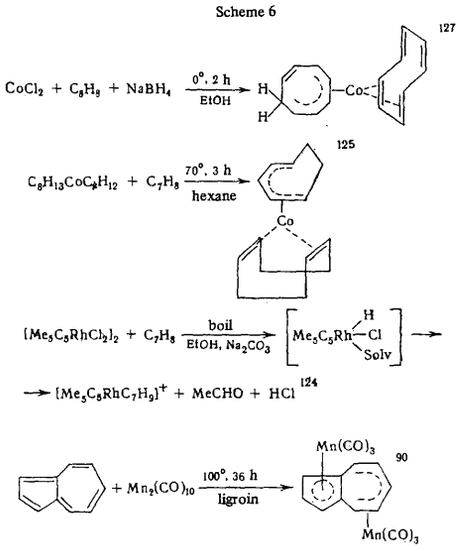
The protonation of $C_8H_8Fe(CO)_3$ [115,117] ultimately gives tricarbonyl(bicyclo[5,1,0]octadienyl)iron (XXXIV), where only four π-electrons of the pentadienyl system are used in bonding with iron:



The formation of (XXXIV) results[117] from electrocyclic ring closure in the coordinated organic ligand (XXXIII). The form of bonding in (XXXIII) is analogous to that for tricarbonyl(tropylium)iron[116].

5. Other modes of formation of pentadienyl derivatives. Pentadienyl complexes are formed in several cases of reaction between unsubstituted alkenes and various metal derivatives[90,124-128]. A few examples of such reactions are given below. The conversion of an alkene to a pentadienyl ligand requires the presence of metal hydrides, which may be introduced either directly[127] or may be formed in an intermediate stage of the process[124], the source of hydrogen being either the solvent or one of the components[125] (Scheme 6).

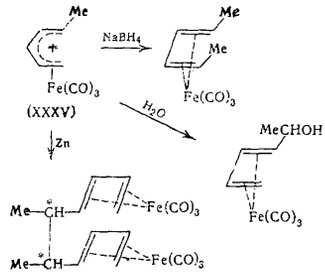
Scheme 6



3. Chemical Properties of Pentadienyl Complexes

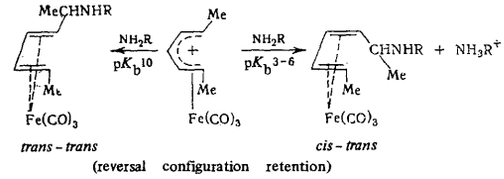
The above experimental results show that in most cases the formation of pentadienyl complexes is reversible. This does not mean that an equilibrium is established between the initial compound and the reaction product. Under suitable conditions, however, it is possible to effect the reverse change, and convert pentadienyl complexes into the diene complexes. Thus the complex (XXXV), obtained by detachment of a hydride ion from the corresponding diene complex, can be reduced by sodium tetrahydroborate[77], and also undergoes other reactions yielding diene complexes[129] (Scheme 7).

Scheme 7



The mechanisms of the reactions of complex cations with nucleophilic agents show specific differences, while conforming to general rules. For example, the reaction between $C_6H_7Ru(CO)_3^+$ and the methoxide anion begins with attack by the latter on the carbonyl group[130]. An intermediate product—the complex $C_6H_7Ru(CO)_2COOCH_3$ containing an ester group—was isolated, which gives the substituted diene complex $CH_3OC_6H_7Ru(CO)_3$ by rearrangement. However, in none of the other cases studied, those already mentioned and reported in Refs. 131 – 134, when the attacking species were nucleophiles from the hydride ion to amines, alkoxides, and β-diketones, was it possible to find any indication that the reaction followed a similar course or that the metal atom was attacked initially.

If the pentadienyl ligand does not form part of a ring, interaction with a nucleophile may involve either reversal or partial retention of the geometrical configuration of the ligand[76,77,133,134]. The geometrical form of the products obtained with amines depends on the basicity of the amine[133,134]:



(reversal configuration retention)

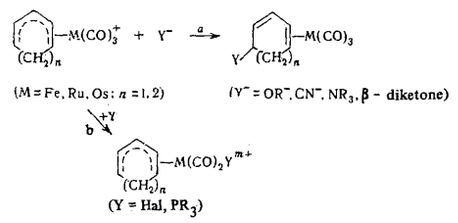
Addition is much slower when ligands possessing weaker acceptor properties than the carbonyl group are introduced into the initial complex. Increasing the size of the ring acts in the same direction: seven-membered ligands react more slowly than do six-membered ligands. The following sequence of reactivity has been found towards pentane-2,4-dione[132]:

$$C_6H_7Os(CO)_3^+ \simeq C_6H_7Fe(CO)_3^+ > C_6H_7Fe(CO)_2PPh_3^+ > C_7H_9Fe(CO)_3^+ > MeOC_6H_6Fe(CO)_3^+ \gg C_7H_9Fe(CO)_2I > C_7H_9Fe(CO)_2CN, MeOC_6H_6Fe(CO)_2I.$$

Neither β-diketones nor amines react with the later members of the series. All this suggests the probable occurrence of direct attack on the pentadienyl ligand.

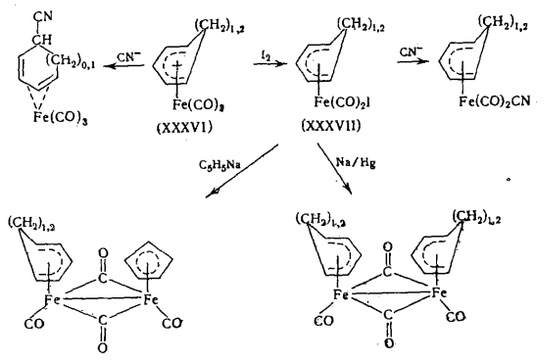
These reaction yield neutral complexes of substituted dienes (Scheme 8*a*). However, there are examples of a quite different course of reaction with nucleophiles, involving retention of the pentadienyl ligand and substitution of other groups present in the molecule (*b*).

Scheme 8

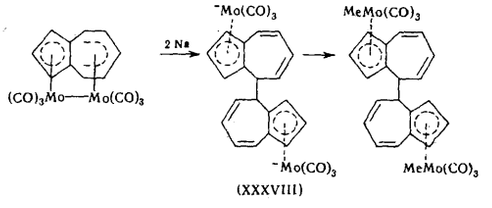


Pauson et al.[135] investigated the chemical reactions of pentadienyl derivatives of iron and compared them with those of aromatic cyclopentadienyl complexes. The cations (XXXVI: $n = 1, 2$) react with iodine, with replacement of one of the carbonyl groups and conversion into neutral compounds (XXXVII) having very similar properties to $C_5H_5Fe(CO)_2I$. These iodides are in fact able to exchange covalently bound halogen, and dimerise when reduced with sodium amalgam or treated with C_5H_5Na. This sometimes involves substitution of the pentadienyl ligand (Scheme 9). However, the above addition reactions with conversion into a diene system—quite uncharacteristic of aromatic complexes—are more characteristic of pentadienyl complexes. This constitutes their main chemical difference.

Scheme 9



When discussing the X-ray results we noted that a metal is more weakly bound to a pentadienyl than to a cyclopentadienyl ligand. This is suggested also by the formation of (XXXVIII) when the azulene complex of molybdenum carbonyl is treated with metallic sodium[93,136]:



Rupture of the molybdenum — molybdenum bond is accompanied also by cleavage of the bond with the seven-membered ring, i.e. with pentadienyl, whereas the bond with the five-membered ring is preserved.

Table 2 lists data for the complexes of pentadienyl with various metals.

Table 2. Summary of data on complexes with pentadienyl.

Metal	Compound	Colour	M.p., °C	Ref.

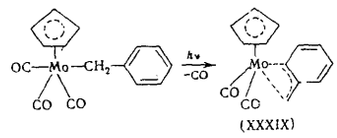
IV. THE BENZYL LIGAND IN TRANSITION-METAL COMPLEXES

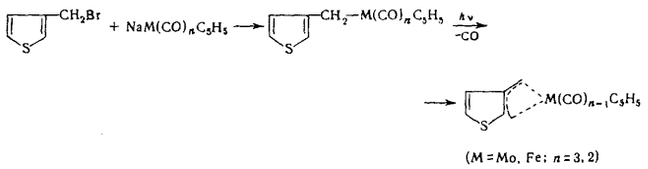
Comparatively recently a new form of coordination of aromatic molecules with transition metals—a π-allylic type of bonding involving one double bond of the benzene ring—has been discovered experimentally, and the products have been termed π-benzyl complexes.

King and Fronzaglia found that the products of prolonged ultraviolet irradiation of the σ-benzyl derivative of tricarbonyl(cyclopentadienyl)molybdenum included a small quantity of a substance containing one fewer carbonyl group than the starting material[140]:



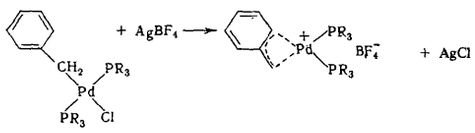
(XXXIX)

The structure (XXXIX) was suggested, and subsequently confirmed by X-ray diffraction. The same method has been used to obtain a few molybdenum and tungsten complexes substituted in the ligand[141,142] and also π-thienyl derivatives of molybdenum and iron[143]:



(M = Mo, Fe; n = 3, 2)

Complex cations in which a π-benzyl ligand is attached to palladium are obtained by a similar method[144]:



Thus in all these reactions an ethylenic group of the benzene ring occupies the coordination site vacated by the outgoing ligand. Compounds of this type that have been reported are quite stable, as indicated by their thermal constants (Table 3) and also the conditions of their preparation. In solution these complexes are unstable.

Table 3. Summary of data on complexes of π-benzyl type.

Metal	Compound	Colour	M.p., °C	Ref.

	2-Cl-$C_6H_4CH_2CHPd(PEt_3)_2^+BF_4^-$	yellow-orange	cryst.	144

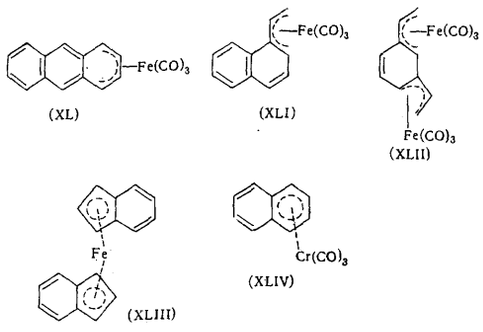
π-Benzyl complexes are easily obtained with molybdenum and tungsten, but not so well with iron. The yields of (XXXIX) and its analogues reach 25%, but the photochemical reaction of $C_5H_5Fe(CO)_2CH_2C_6H_5$ [145] involves elimination of the benzyl radical (not carbonyl) and dimerisation of the residue. The yields of thienyl derivatives of molybdenum amount to 30 — 50%, and of iron about 2% with poor reproducibility. However, the mass spectrum of $C_6F_5CF_2Fe(CO)_2C_5H_5$ includes a fragment corresponding to a π-benzyl derivative[146].

It is of considerable interest that the benzyl group can act as a bidentate ligand in complex formation. With such

coordination disturbance of the usual state of the molecule may be expected from that of delocalisation and the appearance of non-equivalence in the ethylenic groups of the ring. Therefore coordination of individual portions of an aromatic molecule would probably be determined by the donor — acceptor properties of such fragments and the metal-containing group of the complex. The very possibility of this type of interaction is being ascertained at the present time, and the first structural investigations have started.

Complexes of fused aromatic hydrocarbons have been reported, in which only part of the initial molecule is directly bound to the metal. They are represented (Scheme 10) by the structures (XL),[147] (XLI),[147] (XLII),[148] (XLIII),[149] (XLIV),[150,151] and also tricarbonyl(acenaphthylene)chromium, acenaphthylenebistricarbonyliron[152], and others.

Scheme 10



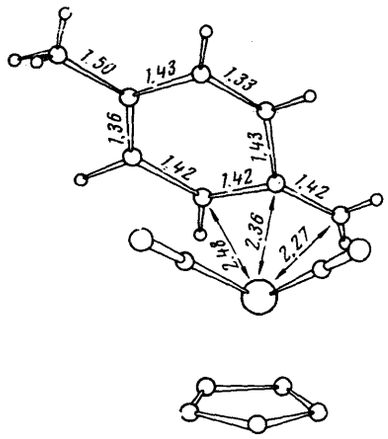


Figure 8. Structure of dicarbonyl(π-*p*-isopropylbenzyl)-cyclopentadienylmolybdenum[141].

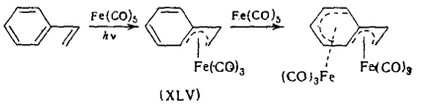
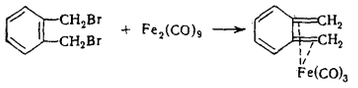
After the structure of the π-benzyl derivatives had been established, and confirmed the breakdown in the aromatic character of this ligand, interest in such compounds grew. New examples of fragmentary coordination were found, sometimes involving fundamental reconstruction of the whole system. It was shown in particular that under severe conditions even styrene could be dismembered (formally) into two butadiene units, each of which combined with a tricarbonyliron group[153-155]:



(XLV)

If the aromatic molecule contains substituents capable of interacting with the metal, the rearrangement of the ligand may become more fundamental, as shown above in the reactions of 2-bromomethylnaphthalene and of brominated xylene with iron carbonyl[156]:



Thus an aromatic molecule is undoubtedly able to yield π-complexes involving not only the whole system of delocalised π-electrons but even part of this system.

If the π-systems of the fragments thereby become completely independent, a significant loss of delocalisation energy should occur. Calculation shows e.g. that in the formation of (XXXIX) and (XLV) such loss would exceed 1.4 β, and will be 1.23 β and 1.91 β in the formation of (XLI) and (XLII) respectively. Nevertheless, in individual cases complexes are obtained under comparatively mild conditions. This may mean that the state of the aromatic molecule does not change so strongly, or else that it changes considerably but this loss is balanced by the formation of new bonds.

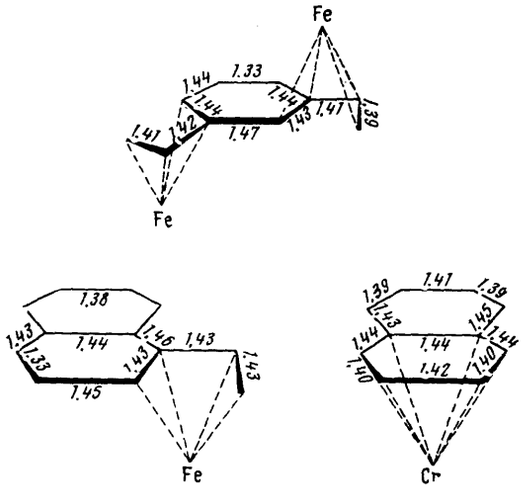


Figure 9. Some structural parameters of complexes of *m*-divinylbenzene with $Fe_2(CO)_6$, vinylnaphthalene with $Fe(CO)_3$, and naphthalene with $Cr(CO)_3$.[158]

Spectral and X-ray investigations of complexes of the benzyl type[141,157] and also of several derivatives mentioned above[158] show that fragmentary coordination may cause some localisation of π-electrons in the remaining free portion of the ring. The parameters involved are given in Figs. 8 and 9. The shortest bonds are 1.33 — 1.36 Å: i.e. they are typically ethylenic.

Comparison of data for tricarbonyl-iron and -chromium derivatives (Fig. 9) shows that the former grouping produces the more significant localisation of bonds. The short-range and long-range spin — spin interaction constants (proton n.m.r.) for these complexes[159,160] also indicate different degrees of localisation of the π-electron system under the influence of tricarbonyliron and tricarbonylchromium groups.

The carbon — carbon distances in the coordinated fragments are typical of each class of derivative. The metal atom in a π-benzyl complex is located somewhat unsymmetrically with respect to the allyl group and closer to the exocyclic atom.

It cannot at present be stated definitely whether the alternation of bonds found for these systems affects their chemical behaviour. An attempt to subject the butadiene portion of the π-benzyl ligand to the Diels — Alder reaction[142] did not give a clear result. This question merits further study; it is extremely important in connection both with the chemistry of aromatic compounds and with the role of the metal.

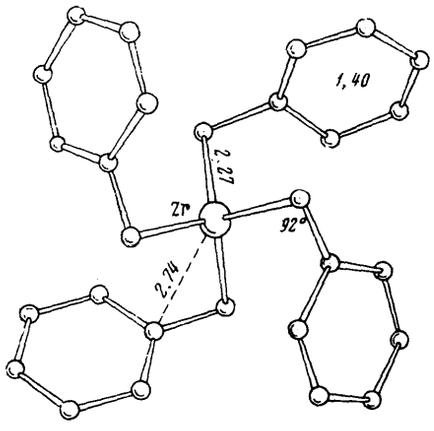

Figure 10. Structure of tetrabenzylzirconium[166].

The n.m.r. spectra of π-benzyl complexes of molybdenum and tungsten depend on the temperature, which indicates that the molecules are flexible[140,142]. At low temperatures (below −30°C) the spectrum is consistent with the suggested structure. With rise in temperature, however, it simplifies as a result of the averaging out of three pairs of protons—the two methylene protons and the ring *oo'*- and *mm'*-protons—by an intramolecular dynamic process assumed[142] to involve production of a σ-form. Quite rapid rotations about CH_2 — Mo and CH_2 — C bonds are possible in such an intermediate compound, which may be responsible for the observed averaging. The process is independent of the nature of the solvent: i.e. decrease in coordination number on passing to the σ-form is not balanced by interaction with the solvent. However, this transition restores the resonance stabilisation, so that energetically a σ-state is entirely probable. Thus the tendency to pass into a dynamic state, which is well known with allylic derivatives of metals, is characteristic also of the π-benzyl type of complexes.

π-Thienyl complexes do not exhibit the properties of flexible systems, but the existence of rotational isomers is not excluded[143].

After the discovery of π-benzyl complexes further investigation became necessary of the nature of the bond in several other benzyl derivatives of metals. The reason for this was their considerably greater stability compared with alkyl and aryl derivatives. For example, the tetrabenzyl derivatives of vanadium[161], titanium[162-164], and zirconium[165,166] have been prepared. The latter two compounds are stable, and have been studied by X-ray diffraction. Although a π-benzyl form was not confirmed in this case, the structure has noteworthy features (Fig. 10). In both cases the molecule is a distorted tetrahedron. All seven atoms within the benzyl groups are coplanar, their plane being almost perpendicular to the M — CH_2 bonds. All the M — CH_2 — C angles are significantly smaller than tetrahedral, while the distance (2.74 Å) from the metal to the first carbon atom of the ring is shorter than would be expected for a true σ-structure. The electron system of this atom is probably able to interact with vacant orbitals of the metal. According to the n.m.r. results this interaction is maintained even in solution[164].

Great interest attaches also to the extraordinarily stable triphenylmethyl derivatives of nickel—$[(C_6H_5)_3C]_2Ni$ [167] and $(C_6H_5)_3CNiCl$ [168]—on which no structural investigations have been made.

In concluding this Section mention must be made of the surprising lithium complex $C_6H_5CH_2Li.2N(CH_2CH_2)_3N$† containing a benzyl ligand and two amine molecules. Its structure[169] is analogous to the π-complex of molybdenum: i.e. it contains a π-bonded ligand. π-Complexes are not characteristic of non-transition metals; π-complexes involving separate fragments of an aromatic system are still less characteristic .

The main aim of this Review is to direct the attention of chemists of various kinds, including theoreticians, to the new opportunities and new problems which are opening up in the organic chemistry of the transition metals. The problems raised cannot be solved without combining many endeavours. The Reviewer will have achieved her aim if interest in these problems is aroused and maintained.

The Ullmann Reaction

M.Goshaev, O.S.Otroshchenko, and A.S.Sadykov

The review describes data obtained in recent years on the synthesis of biaryls by treating aryl halides with powdered copper at an elevated temperature (the Ullmann reaction). The conditions governing the reaction, the limits of its applications at the present time, and its mechanism are discussed.
The bibliography includes 200 references.

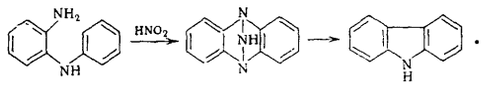
CONTENTS

1. Introduction 1046
2. Reaction conditions 1046
3. Reaction mechanism 1051

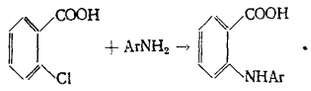
I. INTRODUCTION

There are three reactions associated with Ullmann's name[1].

1. The Graebe–Ullmann synthesis of carbazole[2]:



2. The Ullmann condensation[3,4] which consists of the interaction of *o*-chlorobenzoic acid with phenols, thiophenols, arenesulphonic acids, and aromatic amines in the presence of catalytic amounts of copper with formation of diarylamines:



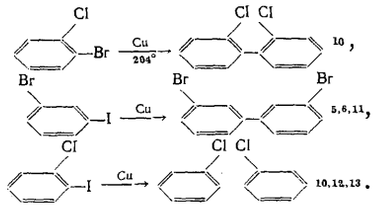
3. The Ullmann synthesis[5,6] of biaryls by the reaction of aryl halides with powdered copper at an elevated temperature:

The last reaction is widely employed in organic chemistry and the number of studies dealing with it is continuously increasing. This review describes data for this reaction obtained from 1963, after the publication of Fanta's reviews[7,8], until 1971. The present limits of the applications of the Ullmann reaction (see, for example Nilsson[9]), the conditions governing its occurrence, and its mechanism are discussed.

2. REACTION CONDITIONS

a. Synthesis of Symmetrical Biaryls

Depending on the nature of the halogen atom, aromatic halides behave differently under the conditions of the Ullmann reaction. The reactivity of the halides increases in the series Cl < Br < I. Aromatic fluoro-compounds do not enter into this reaction at all[10]:



In halogenonitrobenzenes, the activating effect of the nitro-group increases in the series *m* < *p* < *o*.[8,14]

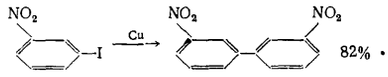
Table 1. Dependence of the yield of biaryls on the halogen and on the position of the nitro-group in the initial halogenonitrobenzene.

Halogen	Yield of dinitrobiphenyl, %		
	ortho-	*para-*	*meta-*
I	65	54	36
Br	64	36	15
Cl	40	0	0

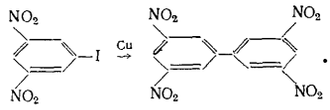
A defect of the results listed in Table 1 is that all the experiments carried out to establish the reactivity of the halogeno-derivatives were performed under severe conditions. To obtain valid data, experiments at a lower temperature using solvents are necessary. At any rate, in the synthesis of asymmetric biaryls exceptions from the rule formulated above are encountered[8]. Moreover, 2-iodopyridine is less reactive in the Ullmann reaction than 2-bromopyridine[15]. This problem will be discussed in greater detail in connection with the mechanism of the Ullmann reaction.

Highly electronegative groups such as the nitro-, carboxy-, and other groups have an activating effect when they are in the *ortho*-position relative to the halogen atom.

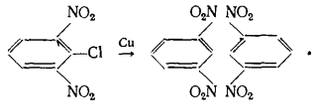
For the nitro-group, this effect decreases in the series $o > p > m$. For example, *o*-iodonitrobenzene is most reactive in the Ullmann reaction, while the *p*- and *m*-isomers are less reactive [16,17]. It has been found recently [11] that *m*-iodonitrobenzene forms under these conditions 3,3′-dinitrobiphenyl in 82% yield:



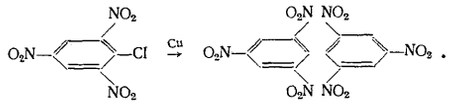
However, the presence of a further nitro-group in the *m*-position relative to the halogen greatly hinders the formation of the biaryl. Thus the yield of 3,3′,5,5′-tetranitrobiphenyl from 1-iodo-3,5-dinitrobenzene is only 15%:[18]



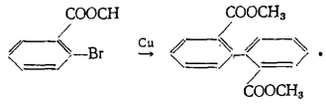
The nitro-group in the *o*-position relative to chlorine in the aromatic ring strongly activates it in this reaction; the yield of 2,2′-dinitrobiphenyl from *o*-chloronitrobenzene is 66%;[19–24] chlorobenzene is less reactive [8]. The introduction of a second nitro-group in the *o*-position relative to the halogen atom in *o*-chloronitrobenzene also reduces the yield of the biaryl; the yield of 2,2′,6,6′-tetranitrobiphenyl from 1-chloro-2,6-dinitrobenzene is 61%:[25,26]



On the other hand, the yield of the biaryl from picryl chloride is 55–58%:[19,27–29]

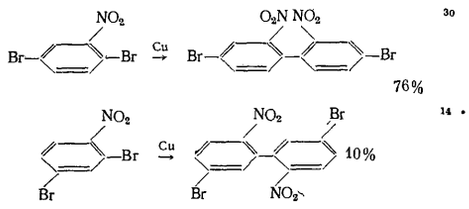


The effect of the alkoxy carbonyl group is approximately the same. Thus methyl *o*-bromobenzoate gives rise to 2,2′-dimethoxycarbonylbiphenyl in 80% yield [14]:



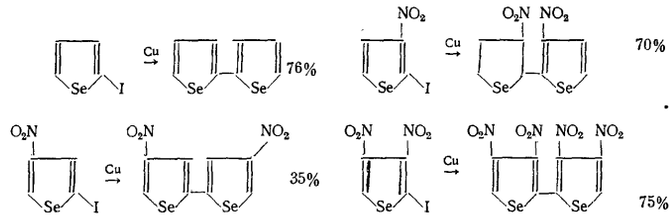
On the other hand, 3,3′- and 4,4′-dimethoxycarbonylbiphenyls are obtained from *m*- and *p*-iodobenzoate esters in yields of only 15 and 25% respectively [14].

The higher reactivity of the halogen in the *o*-position relative to the nitro-group compared with those in the *m*- and *p*-positions can be illustrated by the following examples:

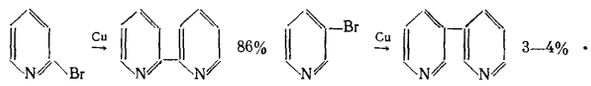


The phenyl substituent in the *p*-position relative to the halogen atom has a highly activating effect, while the same substituent in the *o*- and *m*-positions hinders the reaction. Thus, in the presence of copper at 225–260°C, *p*-, *o*-, and *m*-iodobiphenyls give rise to isomeric terphenyls in yields of 97, 50, and 16% respectively [31].

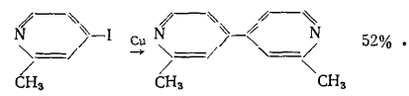
Interesting results were obtained for isomeric 2-iodoselenoles [32]:



An effect similar to that of the nitro-group is also shown by the nitrogen atom in the pyridine ring. It activates the halogen atom in the 2-position, as shown by the formation of 2,2′-bipyridyl from 2-bromopyridine (yield 87%).[33,34] 3-Halogenopyridines enter into this reaction with greater difficulty [35–37]:



A halogen in the 4-position of the pyridine ring is somewhat more reactive than in the 3-position [38]:

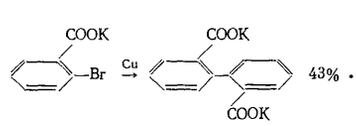


On the basis of literature data, Fanta [7] predicted that electropositive groups should deactivate the halogen in the Ullmann reaction. However, this hypothesis was disproved by later studies (see Table 2c in Ref. 8), in particular the work of Forrest [14].

The activating effect of the substituent depends both on its nature and its position relative to the halogen atom involved in the reaction.

A decrease of the yield of the biaryl is usually observed when the aromatic ring contains groups such as NH_2, $NHCOCH_3$, $NHCH_3$, SO_2NH_2, $SO_2NHC_6H_5$, COOH, and OH.[6,39] To obtain the required yields of products, the influence of the amino-group must be weakened by acylation and that of the hydroxy- and carboxy-groups by esterification (see Table 2c in Ref. 8).

Although *o*-bromobenzoic acid reacts with copper at 160°C with formation of copper benzoate and copper(I) bromide only, when the Ullmann reaction is performed with the potassium salt of this acid, it is possible to obtain a 43% yield of biphenyl-2,2′-dicarboxylic acid [40]:

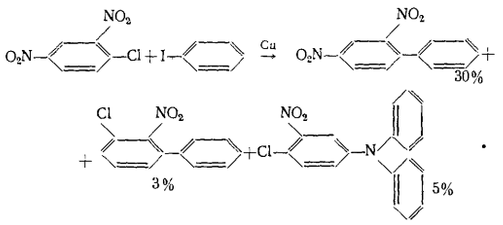


The methyl ester of this acid gives rise to the dimethyl ester of biphenyl-2,2′-dicarboxylic acid in 82% yield [6].

The yield of biaryls from aromatic compounds containing 2 or more halogen atoms is always lower than the yield from monohalogeno-derivatives [7,8].

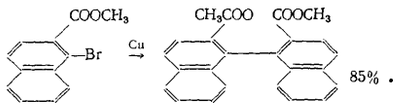
Certain halogenonitrobenzenes undergo side reactions, namely the reduction of the nitro-group. Thus when

1-chloro-2,4-dinitrobenzene reacts with iodobenzene, the following products are formed[14]:

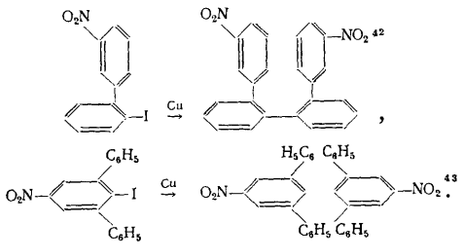


Steric factors have a definite influence on the course of the Ullmann reaction. Bulky substituents such as the nitro-, alkyl-, halogeno-, alkoxy-, and carboxy-groups do not hinder the Ullmann reaction. This is confirmed by the high yield of biaryls from 2,6-disubstituted halogenobenzene (Table 3, see also Table IIc in Ref. 8).

On the other hand, 1-bromo-2-methylnaphthalene[41] is completely inert, which is probably not caused solely by the steric influence of the methyl group. Alkyl and other electropositive groups in any position relative to the halogen atom in the naphthalene ring are known to deactivate the halogen, while electronegative (electrophilic) groups (NO_2, COOR) activate it[41]. This is also confirmed by the high yield of the dimethyl ester of 1,1′-binaphthyl-2,2′-dicarboxylic acid from the methyl ester of 1-bromo-2-naphthoic acid[41]:



Steric hindrance becomes appreciable when substituents such as the phenyl and naphthyl groups are introduced in the 2,6-positions relative to the halogen atom in the benzene ring:

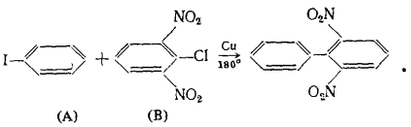


The yields of biaryls in such cases are very low.

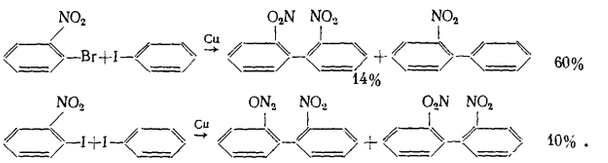
b. Synthesis of Asymmetric Biaryls

Examples of the use of the Ullmann reaction for the synthesis of symmetrical biaryls were described above (Table 4 on p. 1053; see also Table IIc in Ref. 8 and Table 1c in Ref. 7). At the same time, the reaction has been successfully used also for the synthesis of asymmetric biaryls. The results of latest syntheses of asymmetric biaryls by the Ullmann reaction are presented in Table 5 on p. 1055. For earlier results, see Table IIIc in Ref. 8 and Table 2c in Ref. 7.

Forrest[14] showed that optimal yields of asymmetric biaryls are obtained when one of the aryl halides (A) is more reactive than the other (B):



Component (B) should contain at least one electronegative group (NO_2, COOR) in the 2-position and better still two such groups in the 2- and 6-positions relative to the halogen atom. Best yields of asymmetric biaryls are obtained when component (A) contains iodine and component (B) contains bromine or chlorine, as can be seen from the following examples:

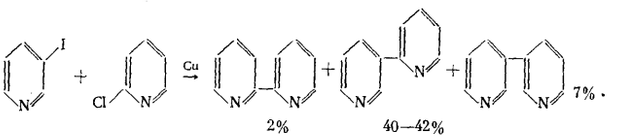


As was to be expected, the reaction of aryl halides with similar reactivities gives a mixture of three biaryls in approximately equal proportions[44-47].

When mixtures of aryl halides (A) and (B) are used, the reaction can be carried out at a much lower temperature than with component (B) alone.

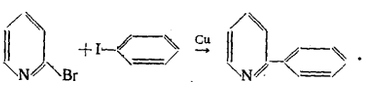
The degree of reaction increases when the reaction is performed in the presence of an excess of component (A) with simultaneous increase of the amount of asymmetric biaryls[14].

It has been established[48] that, when an inactive component (A) is heated with copper for a specific time with subsequent addition of an active component (B) in portions, the yield of the asymmetric biaryl increases sharply. In such cases component (B) is taken in an excess:



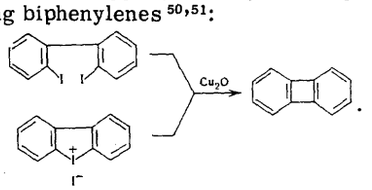
Under the usual conditions, i.e. on simultaneous heating of a mixture of components (A) and (B) in the presence of copper, 2,3′-bipyridyl is formed in a yield of only 7%.[48]

2-Bromopyridine reacts with iodobenzene, forming 2-phenylpyridine in a yield of 50–55%:[49]



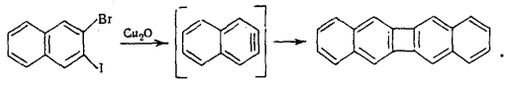
c. Synthesis of Biphenylenes

By heating 2,2′-dihalogenobiphenyls or 2,2′-biphenyliodonium iodide with copper(I) oxide, Lothrop succeeded in synthesising biphenylenes[50,51]:

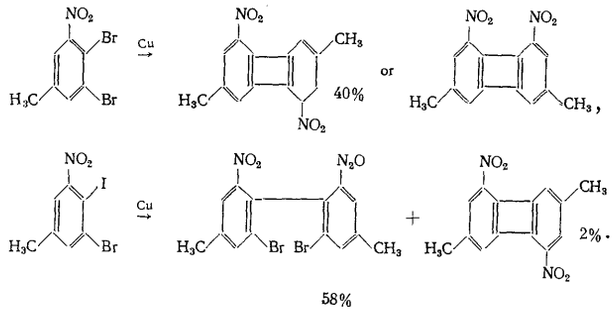


Subsequently this method was used to synthesise also many other biphenylenes [8]. In most cases the reaction is carried out in the presence of copper(I) oxide, the yields of biphenylenes depending significantly on its quality [52-54].

In view of the formation of dibenzobiphenylene on heating 2-bromo-3-iodonaphthalene with copper bronze in dimethylformamide, it was suggested that the reaction proceeds via the formation of dehydronaphthalene with its subsequent dimerisation [56]:



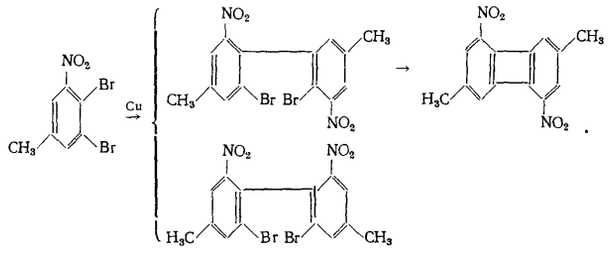
On the other hand, dihalogenonitrotoluenes yield the following products [57]:



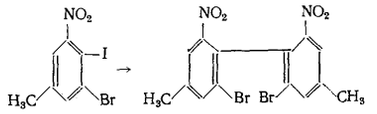
58%

According to Corbett and Holt [57], biaryls cannot serve as intermediates in the formation of biphenylenes. A more detailed examination of these investigations and the studies of recent years [58-60] reveals certain other features of the reaction. Thus contrary to Lothrop's data [50,51], Salfeld and Baume [58] established that metallic copper can also be employed in the synthesis of biphenylenes instead of copper(I) oxide. The yield of biphenylenes is then considerably higher.

The structure of biphenylenes synthesised by the method of Corbett and Holt [57] was investigated by Harrison et al. [59], who found that the product obtained under these conditions is 3,7-dimethyl-1,5-dinitrobiphenylene. Together with the main product, 2,2′-dibromo-4,4′-dimethyl-6,6′-dinitrobiphenyl is also formed in this reaction with a yield of 20%. Probably the process proceeds via the following mechanism:

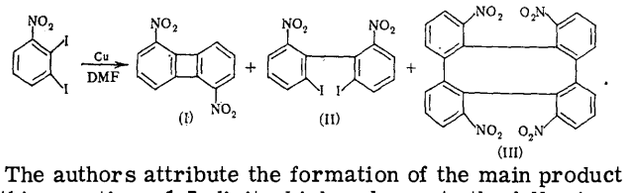


The above scheme shows that the formation of biphenylene involves the formation of a biaryl as an intermediate. Therefore it is easy to account for the formation of a biaryl and not a biphenylene from 3-bromo-4-iodo-5-nitrotoluene:

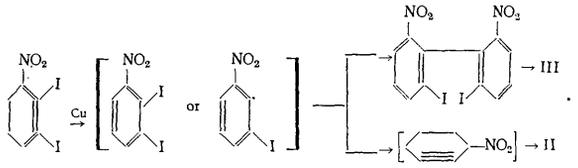


The 2,2′-dibromo-6,6′-bitolyl obtained does not enter into subsequent reactions owing to the presence of the nitro-group in the *m*-position relative to the halogen.

The reaction of 2,3-di-iodo-1-nitrobenzene with copper yielded 1,5-dinitrobiphenylene, 2,2′-di-iodo-6,6′-dinitrobiphenyl, and 4,5,12,13-tetranitroquaterphenylene [60]:

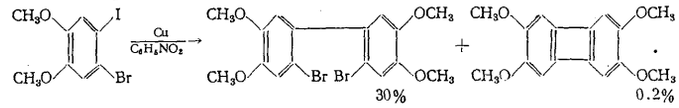


The authors attribute the formation of the main product of this reaction—1,5-dinitrobiphenylene—to the following sequence of steps:



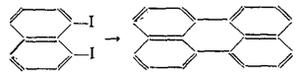
According to this scheme, biphenyl is obtained from dehydrobenzene. However, the absence of 1,2-dinitrobiphenylene (II) from the mixture is evidence against the formation of dehydrobenzene, since in this case the formation of both 1,2- and 1,5-dinitrobiphenylene (I) would be equally probable.

In addition, it has been shown [61] that, when 4-bromo-5-iodoveratrol reacts with copper bronze in nitrobenzene, biphenylene is formed in an insignificant yield (0.2%) and the main product is a biaryl:

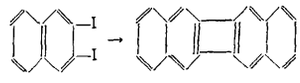


Thus a more detailed examination of the available literature data reveals a similarity of the Ullmann and Lothrop reactions. It is likely that an intermediate aryne is not in fact formed in the Lothrop reaction. The formation of intermediates of this type is usually coupled [62] with an increase in the complexity of the mixture of products obtained. Under the conditions described, this did not occur.

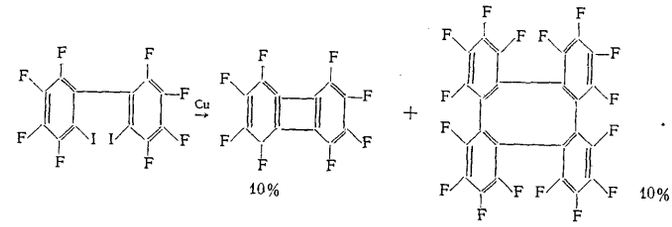
Apart from biphenylenes, other cyclic polyaryls were obtained from aryl dihalides. Thus perylene was synthesised from 1,8-di-iodonaphthalene [63]:



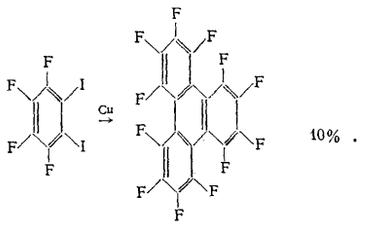
and 2,3-di-iodonaphthalene yielded dibenzobiphenylene [64]:



Octafluorobiphenylene and polyfluoroquaterphenylene were obtained from octafluoro-2,2′-di-iodophenylene [65]:

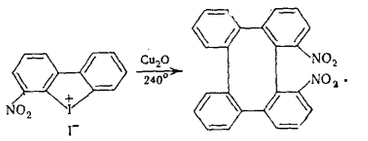


3,4,5,6-Tetrafluoro-1,2-di-iodobenzene forms a trimer:

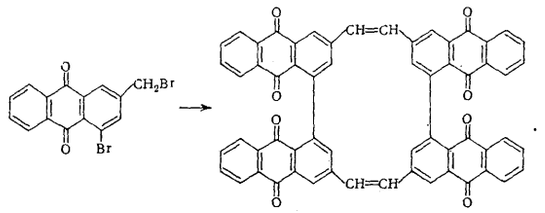


10%.

Pyrolysis of 3-nitrobiphenylene-2,2′-iodonium iodide at 340°C in the presence of copper(I) oxide yields dinitroquaterphenylene; biphenylene was not detected in the reaction products [66]:



Another interesting product was obtained from 4-bromo-2-bromomethylanthraquinone [67]:



Numerous other studies on biphenylenes have been made [68–78].

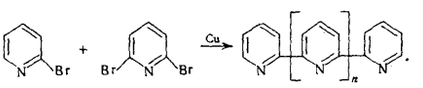
Reactions of aryl dihalides with aryl monohalides yield various polyaromatic compounds.

d. Reactions of Bifunctional Aryl Halides

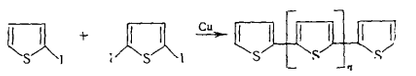
The reactions of bifunctional aryl halides can be divided into two groups: (1) synthesis of cyclic condensation products from two aryl dihalide molecules and (2) synthesis of linear products from a mixture of an aryl dihalide and an aryl monohalide.

The reactions of the first group were largely considered in the discussion of the synthesis of biphenylenes. Those of the second group give rise to a mixture of ter-, quater-, and poly-phenyls; this is best regarded as a special case of the synthesis of asymmetric biaryls. The results obtained are compiled in Table 6 (see also Table IVc in Ref. 8).

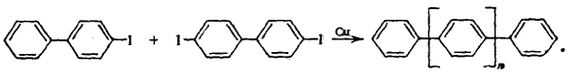
The reaction of 2-bromopyridine with 2,6-dibromopyridine yields bi-, ter-, quater-, quinque-, and sexipyridyls [79]:



Polythienyls have also been synthesised [80,81]:



as well as polyphenyls [82]:



Arylation products are formed in high yields when one of the aryl halides is reactive and the reactivity of the other is somewhat lower [83,84].

e. Experimental Conditions

In most cases copper powder is gradually added to the aryl halide at a specified temperature. An excess of copper, usually a threefold excess, is almost always employed. Sometimes a tenfold excess of copper is used [14,17]. With the exception of certain cases [41], special purification of the aryl halide is not required for the Ullmann reaction. The yield of the biaryl very often depends on the quality of the copper employed. The question of the effect of the quality of the copper used in the reaction still remains controversial. Frequently commercial copper powder, known as copper bronze, is employed [14]. A special form of copper bronze, "Naturcupfer-C", is also used [6,85].

Commercial copper bronze contains traces of oil but these impurities are readily removed by washing with alcohol or ether. According to Ullmann and Bielecki [19], preliminary treatment of the copper is not needed for the synthesis of biaryls. However, the use of commercial copper powder precludes reproducible yields of 2,2′-dinitrobiphenyl [16] and 2,2′-bipyridyl [86,87]. In such cases freshly prepared copper has been used for a long time [88].

Kleiderer and Adams [89] and Vogel [90] suggest that activated copper be used in the Ullmann reaction. The activation involves treatment of the copper bronze with iodine in acetone and subsequent washing with a mixture of acetone and hydrochloric acid and then pure acetone. When a tenfold excess of copper bronze activated in this way was used, 2,2′-dinitrobiphenyl was obtained from *o*-iodonitrobenzene in almost quantitative yield [17].

In some studies [19,91], it was stated that sometimes mechanically contaminated copper gives better results than freshly precipitated copper. Thus "lithographic copper", containing 0.2–0.5% of long-chain fatty acids (mainly stearic, palmitic, oleic, etc. [13]) is effective. Electrolytic copper treated with stearic acid has also been used [92].

Lothrop [50,51] found that in the synthesis of biphenylenes from 2,2′-dihalogenobiphenyls or from biphenylene-2,2′-iodonium iodide, copper(I) oxide gives very satisfactory results, while copper powder is completely inactive. Contrary to these results, it has been established [93,94] that freshly precipitated copper gives entirely satisfactory yields of biphenylenes. "Gatterman's precipitated copper powder" gives even better results [95].

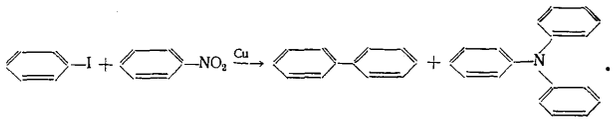
The study of the synthesis of biphenylenes in the presence of copper(I) oxide, commercial copper powder, and copper prepared by the method of Brady and McHugh [88] showed [58] that in the last case best results are obtained.

Apart from those mentioned above, one of the decisive factors governing the success of the Ullmann reaction is reaction temperature. The Ullmann reaction is carried out over a very wide range of temperatures, between 60° [17] and 360°. [96] In most cases the range is between 150° and 280°C (see Tables 4 and 5 on pp.1053 and 1055 and also the Tables in Refs. 7 and 8). Sometimes high temperature may cause the formation of side products. For example, for compounds containing the nitro-groups, the reaction temperature should not be raised above 200°C, since this promotes oxidation-reduction processes [13,14].

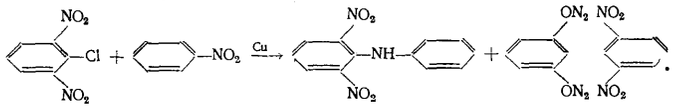
The Ullmann reaction is frequently carried out in solution. Under these conditions, side reactions, which

may occur in the case of labile aryl halides, are to some extent suppressed. The solvents employed are nitrobenzene, toluene, naphthalene, *p*-cymene, biphenyl, anthracene, dimethylformamide (DMF), and others.

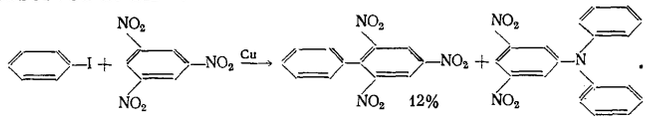
Forrest[14], who used nitrobenzene as a solvent, found that in the presence of copper iodobenzene enters into the following reaction:



When 1-chloro-2,6-dinitrobenzene was allowed to react in boiling nitrobenzene, a product corresponding to the reduction of the nitro-group and a biaryl were obtained in a very low yield[96]:



When a mixture of iodobenzene and 1,3,5-trinitrobenzene was treated with copper, the formation of a biaryl was not observed at all[14]:



Thus nitrobenzene cannot be regarded as an inert solvent in the Ullmann reaction. More suitable solvents are high-boiling hydrocarbons—biphenyl, *p*-cymene, naphthalene, and others.

Recently DMF has been employed with increasing frequency[97]. One of its advantages is its miscibility with water, which facilitates the isolation of reaction products. Moreover, certain aryl halides, which are relatively unreactive in other solvents, give high yields of biaryls in DMF.[11,33,34,41,97] For example, 3,3′-dinitrobiphenyl was obtained in a yield of 82% from the relatively unreactive *m*-iodonitrobenzene[11] (see p. 1046). 3,3′-Dimethyl-5,5′-dinitrobiphenyl was prepared in 71% yield from 3-iodo-5-nitrotoluene[98]. Bipyrrolyls[99-102], bifuryls[103], and bithienyls[104,105] have been obtained in satisfactory yields. Aryl halides containing the formyl[106], keto-[107,108], and carbamoyl[109] groups give satisfactory yields of biaryls in DMF.

Only a few studies in which DMF was used to synthesise asymmetric biaryls have been published[30,37,110,111] and the yields were relatively low. The disadvantages of DMF include its capacity to promote dehalogenation reactions[26,108,112] and halogen exchange reactions[13].

Apart from these solvents, toluene[28], benzene[102,113,114], decane, decalin, pseudocumene, tetralin[33,115-118], xylene[32,118], phenyl ether[119], bitolyl[73], pyridine[120], quinoline[121], etc. have been used in the Ullmann reaction. Sand[19,20,23] has also been employed as an inert diluent and heat exchanger. In some cases common salt has been used instead of sand, which facilitates the isolation of the product from the sintered mass[87].

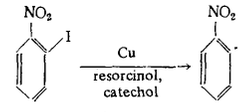
The Ullmann reaction is usually performed in air and in some cases a stream of hydrogen or nitrogen is employed[122]. Some investigators claim[123] that these precautions are superfluous when the initial and final reaction products are not sensitive to atmospheric oxygen. However, it is very likely that an inert atmosphere promotes a satisfactory yield of products, protecting the copper powder, particularly the activated powder, from oxidation[89,90].

3. REACTION MECHANISM

The mechanism of the Ullmann reaction, like those of certain other organic reactions, is still the subject of controversy and discussion[8,14]. There are several views concerning the mechanism but none is entirely convincing.

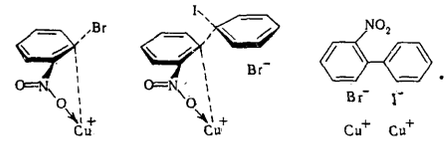
By treating halogenobenzenes with copper or sodium, Rapson and Shuttleworth[124,125] obtained the corresponding dehalogenated products. They suggested that these products are formed owing to the abstraction of hydrogen atoms from the solvent by the free radical produced in the reaction. To confirm this hypothesis, halogenobenzenes were treated with copper bronze in an excess of ethyl benzoate in a sealed tube; 2-carboxybiphenyl and 4-carboxybiphenyl were isolated from the reaction mixture. The authors concluded that a biaryl is formed in the Ullmann reaction as a result of the coupling of free phenyl radicals. Bell and Morgan[126] also believe that the Ullmann reaction has a free-radical mechanism.

To solve the problem of the intermediate in the Ullmann reaction (the aryl radical or aryl anion), the behaviour of *o*- and *p*-iodonitrobenzenes and of *o*-bromonitrobenzenes in an excess of resorcinol and catechol was examined[127]. It was shown that the yield of the dehalogenated product (nitrobenzene) in the experiments with catechol is higher than with resorcinol, although the critical oxidation constant for resorcinol (1.043) is higher than for catechol (0.742). The authors believe[127] that these results confirm a free-radical mechanism of the Ullmann reaction:



Despite these conclusions, Fanta[7,8] concluded on the basis of literature data (he examined about 500 studies) that this reaction has a clearly ionic mechanism. He believes that the reaction consists mainly of two stages, the first of which includes nucleophilic attack by metallic copper on the carbon–halogen bond as a result of which an arylcopper complex is formed on the surface of the metal. He also believes that the success of this stage depends strongly on the sensitivity of aromatic halides to nucleophilic attack in general.

The second stage involves the reaction of the arylcopper complex with a second molecule of the initial aryl halide to form the biaryl and copper halide. This stage depends mainly on steric factors.

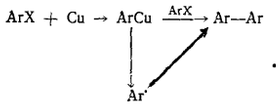


Thus Fanta rules out the formation of free radicals in the Ullmann reaction.

On the basis of a vast number of experimental data and literature results, Forrest[14] also postulates an ionic mechanism for the Ullmann reaction.

Other workers[128] formulate the mechanism of the Ullmann reaction in a somewhat different way. They believe that the reaction consists of two stages: the first involves the formation of an organocopper compound and the second, involving the formation of a biaryl, can occur in two ways, i.e. the biaryl can be formed either as a result of the attack by the initial aryl halide on the organocopper compound or as a result of the coupling of

two free radicals formed owing to the disproportionation of the organocopper compound. They believe that more than half of the biaryl is formed due to the attack by the initial aryl halide on the organocopper compound.



The foregoing statements clearly show that the question of the mechanism of the Ullmann reaction remains controversial.

The formation of anomalous products such as biphenyl-2-carboxylic and biphenyl-4-carboxylic acids from iodobenzene and methyl benzoate [125], 2,6-dinitrobiphenyl from iodobenzene and *m*-dinitrobenzene, and 2,4,6-trinitrobiphenyl from iodobenzene and *sym*-trinitrobenzene [11] is quoted as an argument in support of the free-radical reaction mechanism. In view of the formation of carbon dioxide in 2.6% yield on heating a mixture of benzoic acid and copper in *o*-iodonitrobenzene at 201–208 °C, Nursten concluded [127] that the dehalogenation observed in previous studies [129–131] involves the formation of intermediate free radicals. However, Forrest showed [14] that the formation of such side products is observed for highly hindered aryl halides and is virtually absent for simple halides.

Fanta [8] showed that the interaction of iodobenzene with *m*-dinitrobenzene under the conditions of the Ullmann reaction yields somewhat different proportions of products than on treatment of *m*-dinitrobenzene with benzoyl peroxide at 100 °C (a free-radical reaction) or on decomposition of diazonium chloride in *m*-dinitrobenzene (a Gomberg–Bachmann free-radical reaction) (Table 2).

Table 2.

	2,4-	2,6-
	0	8
	8	1
	2	0.2

Supporters of the ionic mechanism believe that the Ullmann reaction involves the formation of an organocopper complex or compound as an intermediate stage. Therefore their attention was attracted to the question of the synthesis and reactivity of arylcopper derivatives.

Organocopper compounds of this type were synthesised for the first time by Reich [132] and then Gilmann and Straley [133], Starkey and coworkers [134], and Costa et al. [135] In the last study, the optimal conditions for the formation of phenylcopper were established. Recently Lewin and Cohen [128,136,137] and other investigators [138–147] carried out several studies on the synthesis and properties of organocopper compounds.

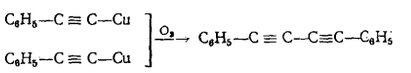
Diphenylcopper and dimethyl copper were also obtained [148] and it was shown that they are stable at the boiling point of tetrahydrofuran (THF) (64 °C).

On hydrolysis, diphenylcopper yields benzene and not biphenyl. It has been shown that phenylcopper reacts with aldehydes as a typical Grignard reagent: for example, it reacts with benzaldehyde to form diphenylmethanol in 24% yield [133]. Forrest showed [14] that the addition of nitrocompounds, aldehydes, and ketones to the reaction mixture suppresses the main Ullmann reaction. The formation of triphenylamine when the reaction of iodobenzene and copper is carried out in nitrobenzene may be attributed to typical reactions of organometallic compounds with nitrobenzenes, although phenylmagnesium bromide reacts with nitrobenzene to form only diphenylamine and not triphenylamine [149]:

The thermal decomposition of phenylcopper, *p*-tolylcopper, phenylsilver, and *p*-tolylsilver has been investigated [150,151] and it has been established that the process proceeds via the formation of free radicals, since biaryls and benzenes are the products of this reaction. When a free-radical acceptor (*p*-benzoquinone) is added to the mixture, the yield of products falls sharply. The formation of free radicals is observed also when methylcopper is decomposed [150]. Other workers claim that the thermal decomposition involves a bimolecular mechanism in which a dimer is formed via an organocopper compound [151].

The thermal decomposition of *cis*- and *trans*-ethylenecopper compounds has been studied and the possibility of their dimerisation has been demonstrated [151].

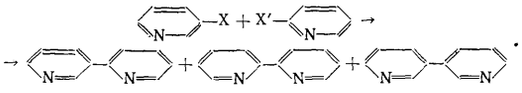
A necessary condition for the synthesis of biaryls from arylcopper is the presence of oxidising agents in the mixture. Gilmann and Straley [133] showed that phenylcopper is oxidised in air over a period of 2 h with formation of biphenyl. On the other hand, in an inert atmosphere phenylcopper is stable over a period of 36 h but the product is again biphenyl. This is also consistent with the following synthesis of diacetylenes [152]:



which has been known for a long time. Furthermore the presence of free radicals in the reaction mixture leads to the formation of side products. Lewin and Cohen [128] claim that, when the reaction of *p*-iodotoluene with copper is performed in quinoline, 8-methylquinoline, or 1-methylnaphthalene, about half of the biaryl is formed from free radicals which are generated owing to the disproportionation of phenylcopper. They did not observe the formation of side products. However, the free radicals produced in the decomposition of benzoyl peroxide in quinoline [153] and in 2-methylnaphthalene [154] gave various phenyl-substituted quinolines and 2-methylnaphthalenes. The decomposition of benzoyl peroxide in chloro- and bromo-benzenes [155] results in the formation of 2-, 3-, and 4-chloro- and 2-, 3-, and 4-bromo-biphenyls, dihydrobiphenyls, diphenyl-, chloro-, and bromo-benzoic acids, dichloro- and dibromotetrahydroquarterphenyls, etc. On the other hand, the decomposition of phenyldiazonium chloride in pyridine gives an almost 80% yield of 2-, 3-, and 4-phenylpyridines [156].

The absence of these products in the experiments of Lewin and Cohen [128] casts doubt on the hypothesis of a radical mechanism of the Ullmann reaction.

The studies by the authors of this review are useful for the estimation of the reactivities of halogen atoms [37,48,49,157-159]. Using the synthesis of 2,3′-bipyridyl as an example, a new method of synthesising asymmetric biaryls was proposed. When 3-iodopyridine was heated with copper in boiling DMF and 2-chloropyridine was added dropwise, 2,3′-bipyridyl was formed in 40–42% yield. On the other hand, when the mixture of all the reactants was heated simultaneously, 2,3′-bipyridyl was formed in a yield of only 7%: [157]



When 3-iodopyridine was replaced by 3-chloropyridine and 2-chloropyridine was replaced by 2-iodopyridine in this reaction, 2,3′-bipyridyl was not obtained. Other halogenopyridines were also employed (Table 3).

*The condensation of 5,5-dibromo-10,11-dihydro-5*H*-dibenzo[*a*, *d*]cycloheptene to 5,5′-bi-(10,11-dihydro-5*H*-dibenzo[*a*, *d*]cycloheptenylidene) in the presence of alkyllithium [113] is apparently meant here (Ed. of Translation).

Thus the reactivity of halogens in the first stage, involving the formation of an arylcopper compound, increases from chlorine to iodine and that in the second stage, involving the decomposition of the arylcopper compound, increases from iodine to chlorine. The arylcopper compound is evidently formed via a free radical.

The following mechanism was proposed for the Ullmann reaction as the most probable:

$$\begin{array}{l} ArX + Cu \rightarrow Ar^{\cdot} + CuX \\ \qquad\quad \downarrow Cu \\ \qquad\quad ArCu \\ ArX + ArCu \rightarrow Ar{-}Ar + CuX \end{array} .$$

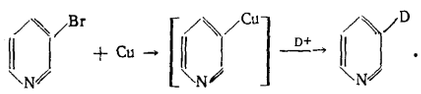
According to this mechanism, the first reaction stage involves the cleavage of the carbon–halogen bond with formation of a free aryl radical. The latter then forms an organocopper compound. This is followed by the second reaction stage—the formation of a biaryl as a result of nucleophilic attack by the organocopper compound on the initial aryl halide.

The formation of an organocopper compound in the Ullmann reaction is consistent with the observed dehalogenation of the starting material [129,130,160–162] and also with the formation of pyridine from 3-bromopyridine in the presence of copper at a high temperature [35–37]. In the last case pyridine is formed owing to the decomposition by acid agents of the organocopper compound formed in the course of the reaction. When the reaction mixture obtained in the Ullmann reaction with 3-bromopyridine was decomposed with a solution of DCl in D_2O, [3-D]pyridine was obtained [163]:



The reactivities of aryl halides can also be estimated from the yields of dehalogenation products. Such dehalogenation was first observed by Ullmann [160] in the reaction of 2-chloro-3,5-dinitrobenzoic acid with copper; the main product was 3,5-dinitrobenzoic acid. Dehalogenation is observed also when the reaction is carried out in the presence of tetrahydronaphthalene [161], alcohol [162], and benzoic acid [129,130]. The last method has been used to debrominate various bromonitronaphthalenes [131]. The dehalogenation process proceeds via the mechanism

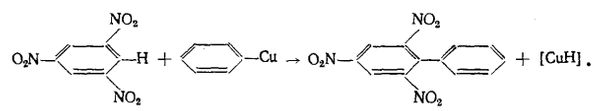
$$ArX + Cu \rightarrow ArCu \xrightarrow{H^+} ArH + Cu^+.$$

Smidt established [129] that the interaction of picryl chloride with copper in the presence of benzoic acid results in the formation of 1,3,5-trinitrobenzene in a yield of only 20%, while the reaction of 1-chloro-2,4-dinitrobenzene and *o*-chloronitrobenzene gives 1,3-dinitro- and nitro-benzenes in yields of 52 and 59% respectively. Consequently an increase of the number of electronegative constituents (in the present case nitro-groups) in the *ortho*-position relative to the halogen atom deactivates the aryl halide in the first stage of the Ullmann reaction. However, this should promote the second reaction stage, since electronegative groups in the *ortho*-position relative to the halogen should activate the carbon–halogen bond in relation to nucleophilic attack.

Indeed the interaction of iodobenzene, picryl chloride, and copper at 135°C is explosive and leads to an asymmetric biaryl [164,165].

The formation of 2,6-dinitrobiphenyl and 2,4,6-trinitrobiphenyl in the reaction of iodobenzene with *m*-dinitrobenzene and *sym*-trinitrobenzene [14] can be accounted for by the following processes:

$$C_6H_5I + Cu \rightarrow C_6H_5Cu,$$



A number of 2,6-dinitrobiphenyls have been synthesised according to this scheme [167].

The reaction of *o*-bromonitrobenzene with α-iodonaphthalene gave α-bromonaphthalene (yield 40%). [14,168]

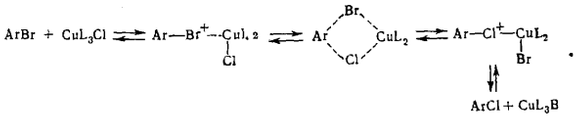
Thus there is an exchange of halogen atoms. This process can be accounted for by the following mechanism [169]:



We may note that, according to this mechanism, halogen exchange involves an organocopper halide formed in the Ullmann reaction.

The mechanism proposed above for the Ullmann reaction, involving the intermediate formation of organocopper compounds, accounts for the following typical features: (1) the Ullmann reaction takes place only with aromatic halogeno-derivatives; (2) dehalogenated products may be formed in the course of the reaction [124,125]; (3) asymmetric biaryls may be formed in high yields by the reaction of activated and non-activated aryl halides below the temperature required for the synthesis of the symmetrical biaryl from the non-activated aryl halide [14,165]; (4) the Ullmann reaction may be suppressed by the addition of proton donors [14,129–131,160]; (5) exchange of halogen atoms between the starting materials is possible in the course of the Ullmann reaction [168].

The mechanism discussed above is also consistent with the following findings: electronegative groups in the *ortho*-position relative to the halogen atom in aryl halides activate it in relation to the Ullmann reaction; the reaction of iodobenzene with copper in the presence of nitrobenzene results in the formation of triphenylamine [14]; when iodobenzene reacts with copper in the presence of *m*-dinitrobenzene and *sym*-trinitrobenzene, 1,3-dinitrobiphenyl and 1,3,5-trinitrobiphenyl are formed [14].

It is noteworthy that certain aspects of this reaction, for example the effect of solvents on the yield of product, the influence of the amount and quality of the copper on the main and side reactions, and the nature of the stabilisation of the intermediate arylcopper compound, still remain obscure. The use of new effective methods for the analysis and separation of reaction products (ultraviolet, infrared, NMR, and mass spectroscopy, gas–liquid chromatography, etc.) may and should extend significantly our knowledge in this field.

Molecular Structures of Cyclic Organophosphorus Compounds

L.S.Khaikin and L.V.Vilkov

The structural data for various classes of cyclic organophosphorus compounds published up to 1972 are systematically reviewed. The geometrical parameters are classified in accordance with the concepts of the valence states of atoms in the molecule and the types of chemical bonds. The dependence of bond lengths and valence angles in various cyclic systems on the number of atoms in the latter is discussed. Endocyclic parameters are compared with exocyclic parameters and also with the corresponding parameters of acyclic structures. Such comparison makes it possible, in particular, to characterise the influence of exocyclic substituents on cyclic systems which is sometimes reflected in a considerable change of the geometrical parameters. The results of studies on the conformational relations in cyclic phosphorus-containing structures are described.
The bibliography includes 274 references.

I. INTRODUCTION

Among organophosphorus compounds, cyclic derivatives are fairly common. Much information concerning the geometrical parameters and conformational characteristics of these compounds has now accumulated and a systematic account of such data is a timely and important task. We attempted to carry this out using as a theoretical basis for the classification of the geometrical parameters the concepts of the valence state of atoms in the molecule and the types of chemical bonds (in the sense of the classical theory of structure) [1-3]. The review gives a compilation of experimental spectroscopic and diffraction data employed to determine molecular geometry and published up to 1972.

The vast majority of these data appeared after the publication of fundamental reviews on the stereochemistry of phosphorus compounds in the compilations "Topics in Phosphorus Chemistry" [4] and "Topics in Stereochemistry" [5] and also reviews on the stereochemistry of phosphorus sulphides [6], compounds with a PP bond [7], phosphonitriles [8,9], and cyclophosphazanes [10].

Data quoted in our earlier review [11] are used for comparison with the geometrical parameters of cyclic structures. Owing to lack of space, the geometrical isomerism determined by the orientation of exocyclic substituents around the phosphorus atom and other ring atoms is not discussed, although this problem is undoubtedly closely related to that of the conformation of cyclic structures.

II. PHOSPHINOBORINES [(I)-(III)]

The phosphinoborine cyclic systems consist of PB bonds, both atoms being tetracoordinate (Table 1). The comparatively scanty information concerning the structure of phosphinoborines at present available precludes a sufficiently far-reaching analysis of their chemical structure. The lengths of the PB bonds in the rings are the same in each structure within the limits of experimental error. Exocyclic PC bonds have the usual length for single bonds formed by tetracoordinate phosphorus. However, regardless of the complexity of the ring, the length of the PB bond in phosphinoborines is greater than the sum of Pauling's covalent radii (1.91 Å) [12] and also somewhat greater than the length of the analogous bond in acyclic structures (1.83-1.95 Å). Although the phosphorus atom in phosphinoborines is formally pentacovalent, the way this property is reflected in the length of the PB bonds, which cannot be regarded as single bonds, is at least unusual.

The endocyclic valence angles are determined to a considerable degree by the dimensions of the ring system. It is striking that, with increase of the number of PB units in the ring, the endocyclic BPB phosphorus valence angle increases apparently to a greater extent than the PBP boron valence angle.

The structures of phosphinoborines have been investigated only in the crystalline state and the conformations of their ring systems have been found to be non-planar under these conditions.

Table 1. Phosphinoborines*.

Compound	Ring conformation	Endocyclic bonds		Exocyclic bonds		Endocyclic valence angles		Exocyclic valence angles		Research technique	References
		bond type	bond length, Å	bond type	bond length, Å	angle	magnitude, deg	angle	magnitude, deg

III. PHOSPHABENZENES [(IV)–(VIII)]

Compounds of this class are derivatives of benzene in which a phosphorus atom replaces one of the carbon atoms of the benzene ring (Table 2). The planar six-membered phosphabenzene ring is one of the first structures where the phosphorus atom was obtained in a dicoordinate state†.

† The existence of dicoordinate phosphorus in the perchlorates of phosphamethinecyanine derivatives was known previously [17–19]. In the cations $[(C_9H_9NS)_2P]^+$ [18] and $[(C_{11}H_{10}N)_2P]^+$, [19] the phosphorus atom forms two PC bonds in each case. In the first case, the cation is almost planar and has a symmetrical structure [r(PC) = 1.76 ± 0.01 Å, ∠CPC = 104.6°]. In the second case, the cation was found to be asymmetric, which is shown by a difference between the angles of rotation of the $C_{11}H_{10}N$ residues about the PC bonds and by the non-equivalence of the bonds themselves [r(PC) = 1.77 ± 0.01 and 1.81 ± 0.01 Å; ∠CPC = 100.4°].

According to X-ray diffraction data, both endocyclic PC bonds in (IV) and (V) have the same length, which is intermediate between the average lengths of $-\overset{|}{\underset{|}{P}}=C\diagup\diagdown$ bonds (1.65–1.78 Å) of single PC bonds (1.74–1.94 Å) in acyclic structures [11]. The four CC bonds in the ring also have the same length (1.388 ± 0.009 Å). The planarity of the six-membered cyclic system is achieved by an increase of the PCC and CCC angles to 122–126°, while the CPC angle is relatively small (102–103°).

In compound (IV), the displacement of the atoms in the heterocycle from the optimum mean-square plane does not exceed 0.005 Å. The displacement of the exocyclic $C_{(7)}$, $C_{(8)}$, and $C_{(9)}$ atoms from the plane of the ring is not more than 0.024 Å. All these data suggest that the phosphabenzene ring system is aromatic. The NMR and ultraviolet spectroscopic data are consistent with this conclusion [25]. With increase of the coordination number of phosphorus to four, the equivalence of the endocyclic PC (as well as

Table 3. Phospholes and phospholenes.

CC) bonds in phosphabenzene remains unaffected. Within the limits of experimental error, their length remains the same as for dicoordinate phosphorus and the endocyclic CPC angle increases only by 2–4°. However, the ring conformation deviates a little from planarity. Thus in compound (VI) the maximum displacement of a ring atom from the optimum plane reaches 0.055 Å. In compounds (VII) and (VIII), the displacement of the ring C atoms from the $C_{(3)}PC_{(5)}$ plane reaches up to 0.11 and 0.055 Å respectively. Although on passing from di- to tetra-coordinate phosphorus, the geometry of the phosphabenzene ring changes little, the problem of the aromaticity of the ring system in the latter case is more complex. This is particularly due to the ill-defined role of the *d* orbitals of phosphorus [26].

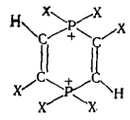
IV. PHOSPHOLES [(IX)–(X)] AND PHOSPHOLENES [(XI)–(XIII)]

According to microwave studies, the ring system of pyrrole, the nitrogen analogue of phosphole, is planar [27,28]. However, the first determinations of the structure of phosphole derivatives (Table 3) by X-ray diffraction showed that their five-membered ring with tricoordinate phosphorus and two C=C double bonds (1.350 Å) is non-planar. In particular, in compound (IX) the phosphorus atom deviates from the plane of the remaining ring atoms by 0.21 Å (the "envelope" conformation). The exocyclic $C_{(6)}$ atom is displaced relative to this plane in the direction opposite to that of the displacement of the phosphorus atom, i.e. it is, as it were, located in an equatorial position. According to one view [29], based on thermochemical data and semiempirical quantum-chemical calculations, the phosphole ring system may be aromatic. However, the barrier to the inversion of the phosphorus atom (16 kcal mole^{-1}), obtained from the NMR spectra of 1-isopropyl-2-methyl-5-phenylphosphole [35], is fairly high. The experimental structural parameters of phospholes do not indicate any significant delocalisation of electrons over the five-membered ring, although the $>P_c-C_c<$ bond in the ring is probably somewhat shorter and approaches the

length of the $=P_c-C_c\langle$ bond involving tetracoordinate phosphorus in phospholenes‡.

Phospholenes—phosphorus–carbon heterocycles with one double bond—also have non-planar conformations, the characteristics of which are determined, in particular, by the position of the double bond relative to the phosphorus atom. According to electron diffraction data, compound (XI) has the envelope conformation with displacement of the phosphorus atom from the plane of the ring. The $C_{(2)}PC_{(5)}/CCC$ dihedral angle in this structure is 13°. In compound (XII), the methylene group closest to the phosphorus atom is displaced from the P–C=C–C plane (dihedral angle 27°). In the condensed system (XIII), studied in the crystalline phase, the $C_{(4)}$, $C_{(5)}$, $C_{(6)}$, and P atoms are coplanar to within 0.05 Å, while the $C_{(2)}$ and $C_{(3)}$ atoms are 0.6 Å and 0.2 Å above and below this plane.

‡ On the basis of a combined spectroscopic study (infrared, ultraviolet, and NMR spectra)[36,37], it has been suggested that π electrons are delocalised in the six-membered PC system of the hexaphenyldiphosphoninocyclohexadiene cation.



However, X-ray diffraction data do not agree with the delocalisation hypothesis, at any rate in the analogous system with alkyl substituents[38]: $r(C=C)_c = 1.340(0.009)$ Å, $r(PC)_c = 1.788(0.008)$ Å, and $r(PC) = 1.793(0.003)$ Å, and the average valence angle of the phosphorus atom is 109.5 ± 0.5°; the average valence angle of the $\rangle C=$ atoms is 120.0 ± 2.2°. The ring was found to be planar to within 0.003 Å.

V. SATURATED PHOSPHORUS–CARBON HETEROCYCLES [(XIV)–(XXIV)]

One of the most interesting saturated PC ring systems is ethylenephosphine (XIV)—a three-membered ring with tricoordinate phosphorus (Table 4). According to microwave data, the CPC endocyclic angle in this compound is only 47.4° ± 0.5°. This is the smallest valence angle of the phosphorus atom ever found. The length of the $\rangle P_c-C_c-$ bonds is geater by 0.017 Å than in the open-chain analogue $HP(CH_3)_2$ (1.850 Å).[11]

According to X-ray diffraction data, in six-membered rings with tricoordinate phosphorus [compounds (XV) and (XVI)], the CPC endocyclic angle increases to about 98° and the $\rangle P_c-C_c-$ bonds are shortened to the usual value of 1.84–1.85 Å. Both these rings have a non-planar conformation of the chair type with an axial location of the exocyclic phenyl substituent at the phosphorus atom despite the difference between the crystal fields in their macrostructures. The deviation of the ring atoms from the average plane diminishes somewhat at its phosphorus end.

Table 4. Saturated phosphorus–carbon heterocycles.

The distribution of torsion angles is as follows (in degrees):

	$PC_{(2)}C_{(3)}C_{(4)}$	$C_{(2)}C_{(3)}C_{(4)}C_{(5)}$	$C_{(3)}C_{(4)}C_{(5)}C_{(6)}$
in (XV)	−49.8	+53.0	−56.1
in (XVI)	−58.0	+62.4	−60.5

	$C_{(4)}C_{(5)}C_{(6)}P$	$C_{(5)}C_{(6)}PC_{(2)}$	$C_{(6)}PC_{(2)}C_{(3)}$
in (XV)	+56.3	−47.6	+44.3
in (XVI)	+56.1	−44.7	+45.5

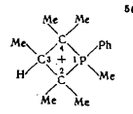
According to the NMR spectrum, in a solution of compound (XVI), one conformation also predominates, as has been suggested for the solid phase [41].

In saturated four-, five-, and six-membered rings with tetracoordinate phosphorus, the length of the $=P_c-C_c-$ bonds does not differ, within the limits of experimental error, from the values found for open-chain compounds. At the same time, the endocyclic CPC angles are determined by the ring size and increase from 82–86° in compounds (XVII)–(XXI) to 94.5–96.5° in compounds (XXII) and (XXIII) and to 102° in compound (XXIV). However, the last value is still less than the analogous angle in open-chain compounds (104–109°). [11] The ring conformations in these compounds are also non-planar. The displacement of the atoms from the optimal mean-square plane in the four-membered rings of (XVII)–(XXI) is 0.10–0.15 Å. The dihedral angles and other characteristics of the conformations of the rings§ are given in Table 5.

In compounds (XVIII)–(XX), the single methyl group at the $C_{(3)}$ atom is fixed in the equatorial position. Thus in these structures there is geometrical isomerism determined by the position of the exocyclic substituent at the P atom.

In the five-membered ring of (XXII), the P, $C_{(2)}$, $C_{(4)}$, and $C_{(5)}$ atoms are approximately in the same plane (the angle between the normals to the $PC_{(2)}C_{(5)}$ and $PC_{(5)}C_{(4)}$

§ In the cyclic cation



the $C_{(2)}PC_{(4)}/C_{(2)}C_{(3)}C_{(4)}$ dihedral angle is 24°. The remaining structural parameters have the following values: $r(PC)_c = 1.93(0.02)$ Å, $\angle(CPC)_c = 82.6°$, and $\angle(PCC)_c = 84.7°$. The methyl group at the $C_{(3)}$ atom is in the *cis*-position relative to the phenyl group.

planes is only 5°), from which only the $C_{(3)}$ atom deviates significantly. The torsion angles relative to the bonds in the ring have the following values starting from $PC_{(2)}$: 5°, 24°, 36°, 30°, and 14°¶.

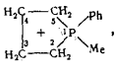
VI. PHOSPHADIAZOLES [(XXV)–(XXVIII)], PHOSPHAOXADIAZOLES (XXIX), AND PHOSPHAOXAZOLES (XXX)

After phosphabenzenes, phosphadiazoles are the second class of compounds in which the existence of dicoordinate phosphorus was demonstrated (Table 6). The planarity of the five-membered ring system with dicoordinate phosphorus was studied by electron diffraction. The experimental geometrical parameters and the vibration, ultraviolet, and NMR spectroscopic data for compounds of this class [52,53,58] suggest that electrons are delocalised in the phosphadiazole rings of (XXV) and (XXVI) as in phosphabenzene derivatives.

The conformation of the five-membered rings with tricoordinate phosphorus in compounds (XXVII), (XXIX), and (XXX) is non-planar: the phosphorus atom is markedly displaced from the plane of the remaining four atoms (envelope conformation). According to electron diffraction data, the dihedral angles characterising the displacement of the phosphorus atom from the plane are respectively 28.8°, 20.0°, and 23.0°. The lengths of the endocyclic PO and PN bonds are normal for tricoordinate phosphorus [11]†. At the same time, it is striking that the endocyclic valence angle at the tricoordinate phosphorus atom is appreciably greater (by about 5°) than that at the dicoordinate phosphorus atom. The exocyclic PCl bonds in (XXVII), (XXIX), and (XXX) occupy axial positions. Their lengths (2.17–2.19 Å) are unusual for covalent bonds of tricoordinate phosphorus. They are significantly longer than in all the cases known previously (2.04–2.08 Å). [11]

¶ A fundamentally identical ring conformation was found in the cation [51]



where the torsion angles have the following values (also starting from $PC_{(2)}$): 5°, 26°, 40°, 36°, and 17°. The remaining parameters of this structure are as follows: $r(PC)_C$ = 1.765(0.02) Å, $r(PC_{Me})$ = 1.80(0.02) Å, $r(PC_{Ph})$ = 1.76(0.02) Å, $\angle(CPC)_C$ = 94.8(1.1)°, $\angle(PCC)_C$ = 101.1(1.7)°.

† Anomalous PN bond lengths were found by X-ray diffraction in the structure of the cation $Cl_4P(NCH_3)_2C^+Cl$—a planar four-membered ring system with hexacoordinate phosphorus [59]. The lengths of both PN bonds—axial (1.91 ± 0.04 Å) and equatorial (1.85 ± 0.06 Å)—are significantly greater than the sum of the covalent radii after correction for heteropolarity (1.75 Å). This can also be said of the exocyclic PCl bonds (2.15 ± 0.02 Å and 2.09 ± 0.02 Å) found in this structure.

VII. PHOSPHONITRILES [(XXXI)–(LXI)]

Phosphonitriles are cyclic structures comprising a variable number of formally unsaturated $-\overset{|}{\underset{|}{P}}{=}N-$ units formed by tetracoordinate quinquevalent phosphorus and dicoordinate tervalent nitrogen. Nevertheless there is no alternation of single and multiple bonds in phosphonitriles (Table 7).

1. Phosphonitriles with Identical Substituents at the Phosphorus Atoms [(XXXI)–(L)]‡

When the substituents at all the phosphorus atoms are the same, the PN bonds in the ring have the same length, which however is much smaller, particularly in more complex rings, when the number of ring units $n > 4$, than the $=\overset{|}{\underset{|}{P}}-N\langle$ (1.60–1.71 Å) and even $-\overset{|}{\underset{|}{P}}{=}N-$ (up to 1.64 Å) bond lengths in acyclic structures [11]. The length of the PN endocyclic bonds is significantly influenced by the substituents at the phosphorus atom. Whereas in the trimers this effect is relatively small [the average r(PN) remains within the limits 1.58 ± 0.02 Å], in the octafluorotetramer (XLIII) r(PN) = 1.507 Å and in the decachloropentamer (XLVII) r(PN) = 1.521 Å, which is far outside the range of the other values. Although the endocyclic valence angles of the phosphorus atom vary in these structures comparatively little (117–123°), these changes are also related to the properties of the substituents. A large NPN angle is obtained when the substituents are halogen atoms. The range of variation of the PNP angles is much greater (120–149°). A gradual increase in the PNP angles takes place with increase of ring size up to hexamers, but subsequently the angles appear to decrease. A systematic effect of the properties of exocyclic substituents on the PNP angles could not be discovered.

It is interesting that the ratio of the ranges of variation of the NPN and PNP angles in phosphonitriles is the reverse of the ratio of the ranges of variation of the BPB and PBP angles in phosphinoborines (see above).

The conformations of the phosphonitrile ring systems bear a definite relation to the number of PN units. The trimers (XXXI)–(XXXVIII) have planar or almost planar ring conformations, the average endocyclic angle being always close to 120°. As a rule, the deviations from the ideal symmetry D_{3h} are minimal: the displacement of the ring atoms from the plane usually does not exceed 0.07 Å. More pronounced distortions were found in only two cases. In compound (XXXII), five ring atoms lie in one plane, while one of the N atoms is displaced from it by 0.15 Å. In (XXXIII), two nitrogen atoms are displaced from the plane of the remaining ring atoms in opposite directions

‡ Symmetrical phosphonitriles with non-geminal substituents [compounds (XLI), (XLV), and (XLVI)] are also included here.

*Each ring phosphorus atom has two different substituents.

by 0.13 and 0.17 Å. Since most of the investigations were made by X-ray diffraction on crystalline materials, the deviations from the planar conformation are frequently accounted for by intermolecular interactions. This view appears to be confirmed by the vibration spectra of solutions of (XXXII) [60] and also the spectra of the tetrafluoro- and hexachloro-compounds in solutions and in liquid and gaseous phases [61,62], which agree with the D_{3h} symmetry. When the substituents at the phosphorus atoms are very bulky, the distortion of the planar conformation can also be a consequence of intramolecular steric interactions. The almost planar ring conformation in trimers and also the equivalence of the endocyclic PN bonds are sometimes quoted as evidence in support of the aromaticity of the $(R_2PN)_3$ system [63].

In the crystalline phase, the tetrameric phosphonitriles (XXXIX)–(XLVI) have significantly non-planar rings with the exception of the octafluoro-compound (XLIII), the conformation of which in the crystalline phase shows only a slight deviation from the D_{4h} symmetry. The displacement of the phosphorus atoms from the mean plane [83] varies as a function of substituents up to 0.35 Å and that of the nitrogen atom is almost constant (0.47–0.54 Å) in such structures, with the exception of (XLIII).

One should note that the vibration spectra of the octafluoro-compound in the gaseous and liquid phases [62] were interpreted on the basis of a lower symmetry (probably C_{2h}) than those of the crystalline phase ($\sim D_{4h}$). The authors [62] believe that this is an indication of a high flexibility of the phosphonitrile ring.

The importance of the role of steric interactions in the determination of the conformations of the tetrameric rings is confirmed by the existence of configurational isomers in the crystalline phase. The first known example (the octachloro-compound) has two polymorphic forms (XLIVa) and (XLIVb) with similar bond lengths and valence angles: the K-form (boat, symmetry close to S_4) and the T-form (chair, symmetry close to C_{2h}). The conformation of the

ring of (XLIV) is evidently different in the liquid and gaseous phases. The vibration spectra of the octachloro-compound in the vapour and liquid phases and in two solid modifications are interpreted according to latest data on the basis of the molecular symmetries D_{4h}, D_{2h}, S_4, and C_{2h} respectively[64], although previously the spectra of the gaseous phase were interpreted on the basis of a lower symmetry[62].

Yet another example of configurational isomerism is provided by a structure with symmetrical non-geminal substituents at the phosphorus atoms: $N_4P_4(C_6H_5)_4Cl_4$. Two crystalline modifications, (XLV) and (XLVI), are known; their molecules differ not only by the ring from (chair, close to C_{2h} symmetry, and crown with distortions resulting in a lowering to C_{2v} symmetry instead of C_{4v} symmetry) but also by the mutual orientation of the substituents at the phosphorus atoms. Whereas in (XLV) the chlorine atoms as well as the C_6H_5 groups are located alternately above and below the ring (the *trans*-isomer), in (XLVI) all the chlorine atoms lie on one side of the ring (the *cis*-isomer). Since (XLV) and (XLVI) are geometrical isomers, the differences between their ring forms are most probably due to steric factors.

Despite the fact that the ring conformations of the tetramers are mainly non-planar, a common feature of phosphonitriles is believed to be a tendency to assume a planar ring conformation. This tendency competes with steric influences of different types.

Analysis of the vibration spectra of solutions and of the liquid and gaseous phases[61,62] suggested a planar ring conformation (symmetry close to D_{5h}) of the decafluoro-pentamer and a lower, probably C_{5v}, symmetry (crown conformation) for the decachloro-pentamer. X-Ray diffraction showed that in the decachloro-pentamer (XLVII) the ring conformation is also very nearly planar: the displacement of the atoms from the plane are not more than 0.2 Å). In the case of D_{5h} symmetry, a planar ten-membered ring would require an increase of the nitrogen valence angles to about 170° (since the endocyclic phosphorus angles usually differ little from 120°). The actual planar conformation (symmetry C_{2v}) is achieved owing to the formation by two nitrogen atoms of angles directed inwards into the ring ("re-entrant" angles). As a result, the average angle of the nitrogen atom decreases to 148°. The vibration spectra of the decabromo-pentamer[65] indicate a distortion of the ring conformation with a consequent change from D_{5h} symmetry probably to a C_{2v} structure, of the type observed for the chloro-derivative. The ring system of the octamer (XLIX) consists of two symmetrical six-membered segments located in parallel planes and joined to one another via PN units. The planarity of each segment (the average deviation of the atoms from the plane is about 0.12 Å) is ensured, as in compound (XLVII), by re-entrant nitrogen atoms. The deviation of the ring atoms from the common plane is also small (0.26 Å).

A nearly planar distribution of PN bonds was found by X-ray diffraction in the structure of the high-polymer (L). This is not inconsistent with infrared spectroscopic data[66]. According to X-ray diffraction, the $[NPF_2]_\infty$ fibres also have a planar chain structure[67]. In this case two molecular conformers were found.

However, the hexamer (XLVIII) has a highly puckered ring. The displacement of the phosphorus atoms from the average plane is 0.56 Å and that of the nitrogen atoms is 0.39 Å. This is regarded as a consequence of the steric interactions of the substituents at the phosphorus atoms—$N(CH_3)_2$ groups.

2. Phosphonitriles with Different Substituents at the Nitrogen Atoms [(LI)–(LVI)]

The different exocyclic substituents at the phosphorus atoms result in the inequality of the PN bond lengths and the analogous angles in the ring. The length of the PN bond in each PNP segment depends in general on substituents at the two extreme phosphorus atoms. For example, r(PN) on the side of halogen atoms is somewhat shorter than on the side of hydrocarbon groups. This is clearly illustrated by the results of an X-ray diffraction study of trimers (in Å): (LI) (1.558 for $=PF_2-N=PF_2$; 1.539 and 1.618 for $=PF_2-N=PPh_2=$); (LII) (1.578 for $=PCl_2-N=PCl_2=$; 1.555 and 1.615 for $=PCl_2-N=PPh_2=$); (LIII) (1.556 and 1.609 for $=PPh_2-N=PPh_2=$; 1.578 for $=PCl_2-N=PPh_2=$). Similar relations were found also for the tetramers (LV) and (LVI).

An increase of the relative number of halogen substituents leads to a systematic decrease of the average PN bond length in the ring, although in the chloro-derivatives these changes are in general within the limits of experimental error; we have (in Å):

1.597 in $N_3P_3Ph_6$ (XXXI) → 1.581 in $N_3P_3Cl_2Ph_4$ (LIII) → 1.583 in $N_3P_3Cl_4Ph_2$ (LII) → 1.581 in $N_3P_3Cl_6$. (XXXVII)

However, in the fluoro-derivatives the changes are fairly explicit:

1.597 in $N_3P_3Ph_6$ (XXXI) → 1.572 in $N_3P_3F_4Ph_2$ (LI) → 1.560 in $N_3P_3F_6$; (XXXVI)

1.596 in $N_4P_4Me_8$ (XXXIX) → 1.560 in $N_4P_4F_4Me_4$ (LVI) → 1.518 in $N_4P_4F_6Me_2$ (LV) → 1.507 in $N_4P_4F_8$. (XLIII)

The conformations of the trimeric rings are nearly planar, as in the case discussed above. In compound (LII) the maximum deviation of the ring atoms from the average plane does not exceed 0.078 Å. In (LI) five P and N atoms are located approximately in one plane and the sixth atom (phosphorus), linked to two phenyl groups, is displaced from this plane by 0.20 Å. The opposite N atom is displaced from the plane of the remaining four atoms by 0.06 Å. This form of the ring may be regarded as a weak boat type of conformation. A similar conformation was found in compound (LIII).

The six-membered ring is closest to planarity in compound (LIV), where the maximum deviation of the P and N atoms from the plane is only 0.011 Å.

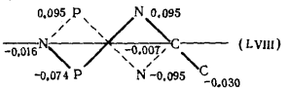
In the tetramer (LVI), the N atoms deviate from the plane of the phosphorus atoms by 0.48 Å. In (LV) the deviation is much less (0.15 Å). In this case, there is a correlation between the increase of the number of F atoms and the tendency towards the formation of a planar ring.

3. Diphosphatriazines and Phosphatriazines [(LVII)–(LIX)]

The six-membered diphosphatriazine rings N_3P_2C are intermediate between the planar triazine structures N_3C_3 and the trimeric phosphonitriles, which, apart from the hexafluoro-compounds, have incompletely planar ring conformations.

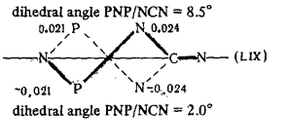
The replacement of one of the phosphorus atoms in the trimer by a carbon atom $=C\langle$ results, according to X-ray diffraction data, in a lengthening of the PN(C) bonds in the ring compared with the PN(P) bonds, to 1.620 Å in (LVIII) and to 1.608 Å in (LIX). Moreover, the endocyclic NPN and PNP angles are smaller than the corresponding angles

in the trimeric phosphonitriles. The ring conformations in both molecules were found to be non-planar, although X-ray diffraction study of the $(NPMe_2)_2NCNMe_2$ structure led to the opposite conclusion[68]. In the methyl derivative (LVIII), the displacement of the ring atoms from the average plane reaches 0.1 Å. In the amino-derivative (LIX), the degree of puckering of the ring is significantly smaller (the displacement of the atoms from the average plane is up to 0.024 Å). However, this difference has little influence on the geometrical ring parameters.



(LVIII)

dihedral angle PNP/NCN = 8.5°



(LIX)

dihedral angle PNP/NCN = 2.0°

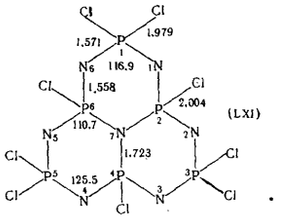
The ring in compound (LVII) also has a non-planar conformation of the chair type which is somewhat distorted owing, it is believed, to intermolecular interactions in the crystalline phase.

4. Structures Complicated by Additional Covalent Bonds at the N Atoms [(LX) and (LXI)]

In compound (LX), the proton and the $CuCl_3$ group are linked covalently to the N atoms at the opposite ends of the eight-membered ring which thus become tricoordinate§. This causes a significant increase in the length of the nearest PN endocyclic bonds. PN bonds of different lengths are located in the ring symmetrically in pairs, the effect of the proton on their length being more pronounced than that of the $CuCl_3$ group: the respective lengths are 1.67, 1.56, 1.60, and 1.63 Å. The valence angles of the P atoms differ significantly from those in the initial compound (XXXIX): the average NPN angle is 114° against 119.8° in the initial compound and the exocyclic CPC angle is 106.6° against 104°. In the absence of factors distorting their symmetry, the endocyclic NPN angles do not differ significantly from 120° in any of the phosphonitrile structures and the exocyclic XPX angles as a rule do not exceed 104°.

The conformation of the ring in compound (LX) is non-planar boat. As in other tetrameric structures (see above), the displacement of the N atoms from the average plane is somewhat greater than that of the P atoms (0.55 and 0.48 Å).

In the condensed cyclic structure of (LXI), the geometrical parameters of the central fragment with a tricoordinate central N atom are of special interest. The average length of the three PN bonds formed by this atom is 1.723 Å, i.e. greater than the average length of the exocyclic PN bonds in phosphonitriles and also of the endocyclic bonds in cyclophosphazanes with tetracoordinate phosphorus (see below). The central N atom is almost coplanar with the neighbouring P atoms (its deviation from their plane amounts to only 0.04 Å), while in the last two cases the N atoms have less planar bond configurations. The increase of the PN bond length with retention of a nearly planar configuration of the N bonds was noted also in the review of the molecular structures of acyclic phosphorus compounds[11].



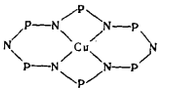
(LXI)

The three penta-atomic segments in compound (LXI) (without the $N_{(7)}$ atom) are almost planar (the average deviation is 0.06 Å) but on the whole the molecule is non-planar; the average dihedral angle of the type $N_{(1)}P_{(2)}N_{(2)}/P_{(2)}P_{(4)}P_{(6)}$ is 49°.

§ In contrast to compound (LX), the complex $[(NPMe_2)_4H^+]_2CoCl_4^{2-}$ has an ionic structure[69]. In each of the two cyclic cations, the only perturbing factor is the proton linked to one of the N atoms. It is interesting to note that the rings have different conformations. One of them has the same boat conformation as (LX), the displacement of the N atoms from the average plane being greater than that of the P atoms (0.59 and 0.40 Å). The other has a conformation of the saddle type, where the P atoms are in one plane to within 0.02 Å and the N atoms are located alternately above and below this plane at a distance of about 0.61 Å. Despite this, the variation of the PN bond length in the two rings is the same: the average length of each pair of bonds is independent of the conformation. Starting with the protonated N atom, the longest of the PN bonds is followed by the shortest bond, after which a long bond is followed by a shorter bond: 1.695, 1.538, 1.614, and 1.582 (±0.015) Å. The remaining parameters are close to those found for compound (LX).

In the trimeric cation $N_3P_3Cl_2(iso\text{-}C_3H_7NH)_4H^+$,[70] the protonation of the ring also has an appreciable influence on the endocyclic bonds and angles. The variation of the PN bond in the ring, starting with the protonated N atom, is as follows: 1.666, 1.583, and 1.558 (±0.005) Å. The shortest bond is near the PCl_2 group, i.e. the differences between the substituents at the P atoms also affect the ring parameters. The lengths of the exocyclic bonds are $r(PN) = 1.609(5)$ and $r(PCl) = 2.000(3)$ Å. The ring has a distorted boat conformation with deviations of the N and P atoms from the average plane up to 0.09 Å.

In the hexameric cyclic cation $[N_6P_6(NMe)_2]_{12}CuCl^+$,[71] the copper atom is linked covalently to four ring N atoms as well as to the Cl atom (overall symmetry $\sim C_2$). As a result there are two types of PN bonds in the ring system



with di- and tri-coordinate N atoms: bond lengths of 1.55 and 1.62 (±0.02) Å. The average endocyclic N and P angles are reduced, compared with those found in the initial structure of (XLVIII), to 133.6(1.3)° and 107.5(1.1)° against 147.5° and 120.0°.

VIII. CYCLOPHOSPHAZANES [(LXII)–(LXVII)]

In contrast to phosphonitriles, the phosphazane ring systems contain tricoordinate nitrogen and are saturated. Among compounds of this class, the structures with tetra- and penta-coordinate phosphorus have been investigated (Table 8).

In the first case, there are X-ray diffraction data for the dimer (LXII) and the trimer (LXIII)¶. The endocyclic PN bonds in each molecule are equivalent. Their average length (1.67 Å) is greater by about 0.1 Å than in phosphonitriles, where the terminal PN bonds have the same length only in structures complicated by additional bonds formed by the N atoms (see above). This length is comparable to that of single PN bonds formed by tetracoordinate phosphorus in acyclic structures (1.60–1.71 Å).[11] The configuration of the bonds involving the nitrogen atom is planar.

It is also striking that the endocyclic angles of the phosphorus atom in compound (LXIII) (105.2°) are significantly

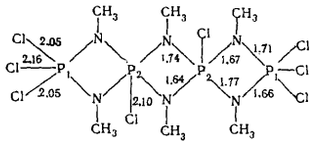
¶ In addition there are data for the structures of the cyclic phosphazane anions $(HNPO_2)_n^{n-}$, where $n = 3$ or 4. These structures differ from those of the non-ionised phosphazanes by the fact that their exocyclic PO bonds are equivalent. It has been shown by X-ray diffraction[105–107] that the endocyclic PN bonds in phosphazane anions are also equivalent (1.66–1.68 Å). The endocyclic angles NPN (104.5° in the trimer[106] and 107–108° in the tetramers[106,107]) are much smaller than in phosphonitriles.

The six-membered ring of the trimer has C_{3v} symmetry (chair conformation), which is confirmed by the vibration spectra of the crystalline structures and solutions[108,109]. The conformational isomerism of eight-membered rings is extremely interesting. X-Ray diffraction data[106,107] and the vibration spectra of the crystalline structures[110,111] showed that the tetrameric anions have conformations of the chair (C_{2h}), boat (S_4), and saddle (D_{2d}) types, the difference between the conformations not affecting the geometrical parameters. The non-planarity of the ring in the tetrameric phosphazane anions is probably greater than in the tetrameric phosphonitriles. In one of the structures with the boat conformation[106], the displacement of the phosphorus atoms from the mean plane[83] is $\Delta P = 0.42$ Å and that of nitrogen atoms $\Delta N = 0.71$ Å, which is greater than in the tetrameric phosphonitriles (see above).

smaller than the exocyclic OP=O angles (116.1°), while in phosphonitriles the opposite relation obtains between the endocyclic NPN angles (115–122°) and the exocyclic XPX angles (97–108°). The ring system of the dimer (LXII) is planar. However, in the molecule of the trimer (LXIII) the ring has a non-planar boat conformation with a symmetry approaching C_s. The N and P atoms located at the opposite ends of the molecule are displaced from the plane of the remaining four ring atoms by about 0.54 Å. Two of the exocyclic MeO groups are located on one side of the ring and the third is on the other. The study of the dipole moments of the dimers with tetracoordinate phosphorus showed that there is a possibility of geometrical (*cis–trans*) isomerism, depending on the relative positions of the exocyclic substituents at the P atom [112].

In dimeric cyclophosphazanes with pentacoordinate phosphorus [compound (LXIV–(LXVII)], the immediate environment of each phosphorus atom gives rise to a distorted trigonal bipyramid. According to X-ray diffraction and electron diffraction data, the endocyclic PN bonds are not equivalent: one of the N atoms is axial and the other is equatorial. The equatorial PN bonds (~1.63 Å) are shorter than the PN bonds in phosphazanes with tetracoordinate phosphorus. The average length of the axial PN bonds (1.74–1.78 Å) is somewhat greater than the sum of the covalent radii corrected for heteropolarity by the Shoemaker–Stevenson method (1.75 Å). The configuration of the bonds involving the N atoms is planar. It is interesting to note that the empirical rule according to which the axial positions in the trigonal bipyramidal structure of substituted fluorophosphoranes should contain F atoms does not hold for the fluoro-derivatives (LXIV) and (LXV). [113,114]

The conformation of the four-membered ring in the dimers with pentacoordinate phosphorus is planar. This is confirmed for (LXIV) by the vibration spectra of solutions [115,116] and also of the liquid and vapour phases [117]. It is striking that the endocyclic NPN angle is smaller than the PNP angle. The condensed structure of (LXVII) contains three planar four-membered rings. The interatomic distances and the angles around $P_{(1)}$ are largely consistent with those found in (LXVI). The trigonal bipyramid around $P_{(2)}$ is distorted much more, since the $P_{(2)}$ atom is involved simultaneously in two rings.



(LXVII)

IX. CYCLIC PHOSPHITES [(LXVIII)–(LXXI)] AND PHOSPHATES [(LXXII)–(LXXXIV)]

In cyclic phosphites, the PO bond length is greater and the OPO bond angles are smaller than the corresponding ring parameters of cyclic phosphates (Table 9), as in the open-chain compounds [11].

However, in the cyclic structures, the geometrical parameters depend on the dimensions of the ring system. In the five-membered rings of (LXVIII)–(LXX) and (LXXII)–(LXXIV), the endocyclic OPO and POC angles

are significantly smaller (by 5–10°) than in the open-chain analogues. Conversely, the magnitude of the exocyclic OPO and POC angles in (LXXII)–(LXXIV) is characteristic also of acyclic esters. The six-membered rings of (LXXI) and (LXXV)–(LXXXIV) are very similar to the acyclic structures as regards the parameters under consideration. It is also noteworthy that the exocyclic PCl bonds in cyclic phosphites are significantly longer than in the PCl_3 or $MeOPCl_2$ molecules (by 0.05–0.08 Å),[11] but not to the same extent as in the oxaphosphadiazole,

etc. structures discussed above. The length of the PBr bond in the six-membered cyclic phosphate is greater by 0.03 Å than in $POBr_3$.[11]

According to electron and X-ray diffraction data, cyclic phosphites and phosphates have as a rule non-planar ring conformations. The only exception is compound (LXXIV), where the five-membered ring with tetracoordinate phosphorus and one multiple bond was found to be planar. Five-membered cyclic phosphites have conformations of the envelope (with an axial exocyclic PCl bond) or twisted envelope (half-chair) types. The OPO/OCCO dihedral angle, characterising in the case of envelope conformation the displacement of the P atom from the plane of the remaining ring atoms, is 26° in (LXVIII) and 24.3° in (LXX). In non-planar five-membered cyclic phosphates, the dihedral angles $O_{(2)}PO_{(5)}/O_{(2)}C_{(3)}O_{(5)}$ and $O_{(2)}PO_{(5)}/O_{(2)}C_{(4)}O_{(5)}$ were found to be respectively 10.9° and 1.8° in (LXXII) (distorted enveloped conformation) and 12.2° and 12.1° in (LXXIII) (half-chair conformation). The only study so far of the six-membered cyclic phosphite (LXXI) showed that in the gas phase its ring has a chair conformation (with an axial exocyclic PCl bond). The chair conformation (with an equatorial P=O phosphoryl bond) is also most characteristic of six-membered cyclic phosphates in the crystalline phase. The phosphorus end of the ring in these compounds is more planar than the carbon end (Table 10).

Table 10.

Compound	Exocyclic substituents at P atom	Dihedral angles, deg		Compound	Exocyclic substituents at P atom	Dihedral angles, deg	
		$O_{(2)}PO_{(6)}/O_{(2)}C_{(3)}C_{(5)}O_{(6)}$	$C_{(3)}C_{(4)}C_{(5)}/O_{(2)}C_{(3)}C_{(5)}O_{(6)}$			$O_{(2)}PO_{(6)}/O_{(2)}C_{(3)}C_{(5)}O_{(6)}$	$C_{(3)}C_{(4)}C_{(5)}/O_{(2)}C_{(3)}C_{(5)}O_{(6)}$
(LXXV)		33.5	54.9	(LXXIX)		41.8	54.7
(LXXVI)		3.7	53.3	(LXXX)		36.5	53.1
(LXXVII)		32.6	51.2	(LXXXII)		36.7	52.5
(LXXVIII)		40.4	54.2	(LXXXIII)		38.3	54.0

The degree of smoothing of the conformation on the side of phosphate group is evidently determined by the nature of the exocyclic substituents at the phosphorus atom, since the $C_{(3)}C_{(4)}C_{(5)}/O_{(2)}C_{(3)}C_{(5)}O_{(6)}$ dihedral angle hardly changes on passing from one structure to the other. Boat conformations occur only in the bicyclic structures of (LXXXI) and (LXXXIV). Numerous studies dealing with the problems of conformational equilibrium and the geometrical isomerism and stereochemistry of cyclic phosphites[143–172] and phosphates[173–193] have been carried out by NMR, by determining the dipole moments, etc. However, as pointed out, in particular, by White et al.[166], the interpretation of the results of these studies is frequently ambiguous and contradictory. Further studies by structural methods are necessary for the solution of the above problems.

X. CYCLIC OXYPHOSPHORANES [(LXXXV)–(LXXXVII)]

1. Characteristics of the Geometrical Structure

Cyclic oxyphosphoranes are a new class of compounds in which a pentacoordinate phosphorus atom is located at the centre of a distorted trigonal bipyramid. The distortion may be due to the presence of a ring system and of different substituents at the phosphorus atom.

In compound (LXXXV), which was investigated by X-ray diffraction, two ester groups in the axial and equatorial positions are linked to a five-membered ring. Two tendencies (Table 11) may be noted: (1) the length of the axial bonds is greater than that of the equatorial bonds, as in other trigonal bipyramidal structures; (2) the PO bonds in the five-membered ring are much longer than the corresponding exocyclic bonds (by 0.05 Å for the equatorial bonds and by 0.1 Å for the axial bonds). The OPO angle in this ring (89.3° ± 0.3°) is smaller than in five-membered cyclic phosphates and phosphites and corresponds to the angle between the axial and equatorial bonds. The POC endocyclic bonds are smaller than the exocyclic bonds and close to the analogous angles in the five-membered cyclic phosphites and phosphates.

In contrast to compound (LXXXV), in compounds (LXXXVI) and (LXXXVII) the phosphorus atom can be regarded as the centre of a trigonal bipyramid only by convention. The endocyclic axial PO bonds in the last two compounds are significantly longer than in (LXXXV) (by 0.25 and 0.6 Å respectively). On the other hand, the endocyclic PC bonds, which are formally equatorial in the trigonal bipyramid, are unusually short. In the four-membered ring of (LXXXVI), this bond (1.76 ± 0.02 Å) is of the same length as the exocyclic P=C bond (1.75 ± 0.02 Å) within the limits of experimental error. The investigators who studied the structure of (LXXXVI) suggest a delocalisation of electrons in the P=C=P system and explain thereby the stability of the ring. It is noteworthy that the CPO angle in the ring is only 71.3° ± 1.0°, which is smaller by 10° than in four-membered phosphorus–carbon heterocycles, while the POC angle is 94.1° ± 1.0°. In the five-membered ring of (LXXXVII), the equatorial PC bond is even shorter (1.70 Å) than in (LXXXVI). The ring conformations in the above structures are planar to within 0.07–0.10 Å.

2. Pseudorotation

The study of the NMR spectra of oxyphosphoranes with four-, five-, and six-membered rings[198–208] showed that, as in acyclic fluorophosphoranes[11], they undergo an intramolecular rearrangement which is usually described as "pseudorotation". This process involves a deformation of the valence angles and as a result two axial groups of the trigonal bipyramid move to the equatorial positions and correspondingly two equatorial groups move to the axial positions. This mechanism was proposed by Berry[209]. However, it is noteworthy that Berry's mechanism does not always provide a sufficiently complete explanation of the characteristics of the spectra[202,207]. The possible mechanisms of pseudorotation are also discussed in other reports[210–215].

It is assumed that in ring structures pseudorotation is hindered by two principal factors characterised by the polarity[216] and strain rules[217,218]. According to the former, alkyl groups occupy preferentially equatorial

Table 11. Cyclo-oxyphosphoranes*.

*The subscripts a and e correspond to axial and equatorial bonds in the trigonal-bipyramidal structure.

positions, while O atoms occupy preferentially axial positions. According to the second rule, the pentacoordinate phosphorus atom is bound to the adjacent ring atoms mainly via one axial and one equatorial bond. This reduces ring strain to a minimum, as a result of which the angle between the axial and the equatorial bonds involving the phosphorus atom is smaller than, for example, that between two equatorial bonds. Pseudorotation requires an energy sufficient to overcome the barrier due to one of these factors or to both at the same time. According to the available data, the potential barrier caused by the polarity rule in alkoxyphosphoranes containing at least one PO bond in a five-membered ring is 10–17 kcal mole^{-1}.[203] The barrier due to the strain rule has been estimated as higher—up to 22 kcal mole^{-1}.[203] In such structures at a temperature ≤140°C, an axial–equatorial arrangement of the ring is greatly preferred[202,203]. In alkoxyphosphoranes with a four-membered phosphetane ring (i.e. having only PC bonds in the ring), an axial–equatorial arrangement of the ring is also preferred, at least at a temperature ≤30°C.[207] The barrier to the transition of the ring to a diequatorial arrangement is estimated in this case as 20 kcal mole^{-1}.[204] Six-membered rings with two oxygen atoms linked to a phosphorus atom can assume a diequatorial arrangement[208]. It is interesting that in the $C_5H_{10}PF_3$ molecule, containing a six-membered phosphorus–carbon ring, there is no pseudorotation at room temperature and the ring assumes a diequatorial arrangement[216].

XI. CYCLIC POLYPHOSPHATES [(LXXXVIII)–(LXXXIX)] AND PHOSPHORUS OXIDES [(XC)–(XCVI)]

The cyclic skeletons of the molecules of these compounds consist of alternating P and O atoms. Among the unionised polyphosphates, only two geometrical isomers of the trimeric diethylamide of metaphosphoric acid, (LXXXVIII) and (LXXXIX), have been investigated. In the first of these, the six-membered ring has the chair conformation, two atoms (phosphorus and oxygen) deviating from the plane of the remaining four by +0.61 and −0.53 Å. Overall, the molecule has the ~C_{3v} symmetry: all three endocyclic P=O bonds lie on one side of the ring (axial bonds) and all three PN bonds are on the other side (equatorial bonds). In the second structure the ring has an unusual conformation: three oxygen atoms and two phosphorus atoms lie approximately in one plane (to within 0.1 Å) and the third phosphorus atom deviates from this plane by 0.54 Å. Two PN bonds are located on one side of the ring and the third on the other. The PO bonds in the ring were found to have the same length (Table 12)†, which however is greater by about 0.05 Å than the length of the analogous bonds in six-membered cyclic phosphates and also in acyclic structures[11]. On the other hand, the OPO endocyclic angles were found to be somewhat smaller than in cyclic phosphates. The configuration of the bonds involving the exocyclic N atoms is almost planar in both structures.

Phosphorus oxides form three-dimensional polycyclic structures. In the simplest of these (the trioxide P_4O_6), tervalent phosphorus atoms are located at the vertices of a tetrahedron and O atoms form bridging bonds along the edges of the tetrahedron. The pentoxide molecules P_4O_{10} consist, as it were, of a P_4O_6 nucleus and four terminal oxygen atoms completing the tetrahedron around each

† Until recently, X-ray diffraction data could not yield an unambiguous answer concerning the identity or non-identity of the PO endocyclic bond lengths in trimeric and tetrameric cyclic polyphosphate anions[4,219]. The identity of the bond lengths has now been demonstrated. In the $Na_3P_3O_9$ crystal structure, the $P_3O_9^{3-}$ anions (the chair conformation) have the following geometrical parameters[220]: $r(P_c-O_c)$ = 1.615(0.004) Å, $r(-P_c=O)$ = 1.484(0.004) Å, ∠POP = 126.9(0.2)°, and ∠OPO = 101.1(0.3)°.

In the $(NH_4)_4P_4O_{12}$ structure, these parameters for the $P_4O_{12}^{4-}$ anion (the chair conformation) have the following values[221]: 1.607(0.004) Å, 1.479(0.004) Å, 131.2(0.0)°, and two different OPO angles—98.7(0.02)° and 104.5(0.2)°.

*The symbols P^{III} and P^{V} denote tervalent and quinquevalent phosphorus respectively.
**Beagley et al.[228] believe that the length 1.556 Å is due to an unusual error in the X-ray diffraction data.

quinquevalent phosphorus atom. The remaining oxides differ from these by the number of terminal oxygen atoms (and correspondingly by the number of tervalent and quinquevalent phosphorus atoms). The replacement of P=O by P=S bonds in $P_4O_6S_4$ leaves the overall structure the same as before.

Table 13, which we took from Stosick[227], lists the bond lengths and the valence angles of all the phosphorus oxides. The $P^{III}-O$ bridging bonds are not the same for both types of oxygen atoms (the difference is 0.029 ± 0.009 Å). This is evidence that the intermediate oxides P_4O_7, P_4O_8, and P_4O_9 cannot be regarded as comprising simply fragments of the terminal members of the series (P_4O_6 and P_4O_{10}).

The $P^{III}-O$ bridging bonds are longer than the $P^{V}-O$ bonds and the corresponding bonds in the acyclic structures (1.60 Å).[11]

XII. CYCLIC POLYPHOSPHINES AND ELEMENTAL PHOSPHORUS

An interesting feature of the PP bond in acyclic structures is the low sensitivity of its length to changes in the valence state of the phosphorus atom and in the nature of the attached groups (2.18–2.22 Å).[11] In the ring systems

considered (Table 14), the length of the $>P-P<$ bond is apparently somewhat greater, although the range of its variation remains fairly narrow (2.21–2.24 Å)‡. Within the limits of each structure the PP bonds are almost equal. The valence angles of the phosphorus atoms vary with the complexity of the ring.

The conformation of the cyclic polyphosphines investigated in the crystal phase is as a rule non-planar. The only exception is compound (CII), where the average torsion angle is only 5° within the limits of the bicyclic ring system. The tetramers (XCVII)–(XCIX) have the molecular symmetry ~D_{2d} with equatorial orientation of the exocyclic substituents. Their PPPP torsion angles are respectively 34°, 31.4°, and 32.2°. The Raman spectra of liquid cyclic polyphosphines $(PR)_4$ have also been interpreted in terms of D_{2d} symmetry [243]. In the pentamers (C) and (CI), the PPPP torsion angles vary in the ranges 18–58° and 2–61° (the envelope conformation), the average in both structures being 38°. In these molecules, the exocyclic substituents at the two adjacent phosphorus atoms lie on one side of the ring, since, in contrast to the tetramers, a regular alternation of the directions in which the substituents are oriented relative to the average plane is in this case impossible. The ring system of the hexamer (CIII) has a chair conformation characterised by an average torsion angle of 84° with equatorial orientation of the exocyclic phenyl groups.

The possibility that the cyclicpolyphosphine ring systems $(PR)_n$ ($n = 4$, 5, or 6) are aromatic was discussed recently [7,29,244]. This hypothesis arose in connection with certain characteristics of the ultraviolet spectra of these compounds [245,246]. One must emphasise that there are no grounds for such a conclusion from the standpointof the structure of cyclic polyphosphines. In particular the absence of electron delocalisation is indicated by the invariance of the PP bond lengths.

The tetrahedral molecules of elemental phosphorus (CIV) in the vapour phase may be regarded as a tricyclic phosphine. The valence angles of the phosphorus atoms are in this case only 60°. It has been suggested that white (crystalline) phosphorus has a similar structure [247,248]. Red phosphorus is formed from white phosphorus when one of the bonds in the tetrahedra is cleaved and the tetrahedra are joined together to form chains or rings [249]. This hypothesis is consistent with the variation spectra of amorphous red phosphorus [250], which agrees best with a polymeric structure consisting of puckered four-membered rings with the D_{2d} (or C_{2v}) symmetry which is the same as (or similar to) the symmetry of the molecules of tetrameric cyclicpolyphosphines (XCVII)–(XCIX). None of the crystalline modifications of red phosphorus, the existence of which has been demonstrated by X-ray diffraction [251], has been subjected to a detailed structural analysis. The different modifications of black phosphorus (CV) and (CVI) contain more complex rings as repeating structural units.

‡ Anomalous $>P-P<$ (2.26–2.33 Å) bond lengths were found in the crystal structures of phosphorus sulphides and selenides (see below).

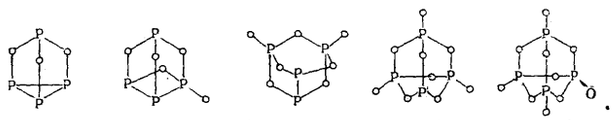
XIII. CYCLIC PHOSPHONOTHIOATES (CVII), PHOSPHOROHALIDOTHIOATES (CVIII), POLYPHOSPHONOTHIOATES (CIX), AND POLYPHOSPHOROHALIDOTHIOATES (CX)

The length of the $=\overset{|}{P}-S-$ endocyclic bonds in five-membered phosphonothioates and phosphorohalidothioates (Table 15) has been shown by the first studies of these structures in the crystalline phase not to differ from that in the acyclic structures (2.07–2.09 Å) within the limits of error [11]. The SPS endocyclic angles are similar to the OPO angles in five-membered cyclic phosphates (98–99°) (see above), but the PSC angles are significantly smaller than the POC angles. The conformations of five-membered rings in phosphonothioates and phosphorohalidothioates are non-planar, as for cyclic phosphates. In structure (CVII), the phosphorus and sulphur atoms deviate from the mean-square plane by 0.15 Å in the opposite directions (the envelope conformation); in structure (CVIII) the deviations of the ring atoms from the best plane are −0.194 Å for P, 0.299 Å for $S_{(2)}$, −0.336 Å for $C_{(3)}$, 0.161 Å for $C_{(4)}$, and 0.071 Å for $S_{(5)}$ (the conformation is close to that of the half-chair form). The conformation of the four-membered ring of the polyphosphonothioate (CIX) is planar (C_{2h} symmetry), like that found for the diphosphazane molecule with tetracoordinate phosphorus [compound (LXII)]. The six-membered ring in compound (CX) has a boat conformation with a PSSP torsion angle of 86°.

XIV. PHOSPHORUS SULPHIDES [(CXI)–(CXVII)] AND SELENIDES [(CXVIII)–(CXX)]

Phosphorus sulphides and selenides (Table 16) consist of large polycyclic molecules P_4S_n or P_4Se_n (n = 3, 5, 7, 9, or 10):



(CXI, CXVIII) (C_{3v}) (CXIV, CXX) (C_1) (CXV *a* and *b*) (C_s) (CXVI) (C_s) (CXVII) (C_{3v})

In contrast to phosphorus oxides, among phosphorus sulphides and selenides there are structures without symmetry elements. The isomeric di-iodo-derivatives resemble closely this series of compounds:

The polycyclic systems contain three-, four-, five-, and six-membered rings. The conformation of the four-membered rings in (CXIV) and (CXX) is close to that of the rings of tetrameric cyclic polyphosphines (see above). The five-membered rings in each of the sulphides [except (CXVI) and (CXVII)] and selenides show a considerable geometrical similarity to the rings of the five-membered polyphosphines (C) and (CI) (the envelope conformation).

*The symbols P^{III} and P^{V} denote tervalent and quinquevalent phosphorus respectively.
**In a tervalent (three-membered?) ring.
***In a quadrivalent (four-membered?) ring.

The six-membered rings in compounds (CXVI) and (CXVII), which include tri- and tetra-coordinate phosphorus, have a chair conformation—the same as in (CIII) and (CV). In the molecules of the di-iodides (CXII), (CXIII), and (CXIX), two five-membered rings are joined by a common PXP fragment.

In turn, the remaining endocyclic bonds form a common six-membered ring in the boat form with the following endocyclic angles:

(CXII)	(CXIII)	(CXIX)
PPS 91° (mean)	PPP 96.5±0.5° SPS 103.2±0.5°	PPP 97.8±1.5° SePSe 103.6±1.3°

It is interesting that the PPP bonds considered are much smaller than in the six-membered rings of black phosphorus (102°). As already noted, the PP bonds in the sulphides and selenides are significantly longer in many cases than the usual bond. The lengths of the PS(PSe) bonds are on average little different from those found in the acyclic compounds[11]. The difference between the bonds of tervalent and quinquevalent phosphorus are not as pronounced as in the oxides. On the other hand, in certain structures [for example, in (CXIV) and (CXX)] the lengths of the single PS and PSe bonds are different, the differences reaching about 0.1 Å.

---o0o---

The above discussion of the molecular structures of cyclic organophosphorus compounds shows that their geometrical structures have certain definitely unusual features.

In small rings with $n = 3-5$ atoms, the valence angles involving the phosphorus atom are apparently largely determined by the dimensions of the ring system. The smallest of the known valence angles of the phosphorus atom—the CPC angle in the  molecule—is only 47.4°. In four- and five-membered rings, the valence angles of the phosphorus atoms are still significantly

smaller than the analogous angles in the acyclic structures. In small rings, the single phosphorus–element bonds are as a rule longer than the bonds in the acyclic structures.

In the case of six-membered rings (excluding, of course, phosphonitriles and similar formally unsaturated structures), there is usually considerable similarity with acyclic structures as regards the above parameters. The main reason for such differences is frequently believed to be the existence of ring strain in small ring systems. However, an appreciable increase in the length of PO bridge bonds occurs also in six-membered rings in the structure of phosphorus oxides.

The effect of exocyclic substituents on the geometrical parameters of the ring system is shown, in particular, in phosphonitriles, where the inhomogeneity of these substituents leads to different lengths of endocyclic bonds and a decrease of the symmetry of the ring system.

It is as a rule impossible to establish significant differences between the parameters of endocyclic bonds and those of acyclic compounds. However, the length of the PCl bonds in phosphadiazoles (2.17–2.19 Å for tricoordinate phosphorus and 2.07 Å for tetracoordinate phosphorus) is much greater (by up to 0.20 Å) than in other phosphorus compounds. In most of the structures investigated, the PCl bonds are shorter than the sum of the covalent radii (2.09 Å). This factor was interpreted as an increase in the multiplicity of the PCl bonds. The greater length of the PCl bond found in phosphadiazoles compared with the sum of the covalent radii gives rise to new theoretical problems.

Ring structures with pentacoordinate phosphorus (cyclophosphazanes) constitute the first case to which the empirical rule of the preferential axial location of fluorine atoms in the trigonal-bipyramidal environment of the phosphorus atom is inapplicable.

The simplest cyclic systems (three-membered systems) do not present any conformational problems, since in such cases only planar structures are possible. Examination of the complete set of the available data shows that in more complex rings the conformation is non-planar when tricoordinate phosphorus is present. The only exception is the five-membered ring in compound (CII), where the average torsion angle is only 5°. Planar conformations are apparently characteristic of ring systems containing di- and penta-coordinate phosphorus. Structures containing tetracoordinate phosphorus can have both planar and non-planar conformations. The non-planarity of the phosphole ring merits particular attention. It implies the non-planarity of ethylene systems, which is difficult to expect in view of the high barrier to rotation about the C=C bond.

It is believed that the ring conformations are due to the operation of forces associated with angular deformations and torsional interactions in relation to bonds. Thus the replacement of hydrogen atoms linked to terminal carbon atoms in five-membered cyclic phosphites and phosphates by methyl groups leads to an increase of torsional interactions and a change in conformation from envelope to half-chair. On the other hand, the envelope conformation is difficult to expect for a ring of this type on the basis of the hypothesis concerning the twisting moments about different bonds, since in this case there is an eclipsed configuration relative to the C–C bond, although it is known that the barrier to rotation relative to this bond is greater than that relative to the C–O and P–O bonds.

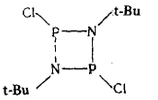
The axial disposition of the P–Cl bonds in the molecules of five- and six-membered ring phosphites and phosphates may be regarded as analogous to the *gauche*-conformation of such bonds about the P–O bonds in the acyclic derivatives.

The valence angles involving the exocyclic N and O atoms are appreciably greater, as in the acyclic compounds, than the values found in trimethylamine and in methyl ether: the nitrogen atom has a planar bond configuration and the POC valence angles are about 120°, exceeding the COC valence angle by 10°.

On the whole, analysis of the structures investigated makes it possible so far to elucidate only the general trends, which require further confirmation and refinement. The inadequacy of the available data is caused not only by the small number of studies but to a greater extent by the insufficient accuracy of their results.

ADDENDUM

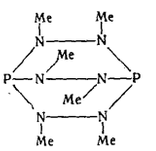
The structure of the dimeric molecule of a cyclophosphazane (CXXI) with tricoordinate phosphorus was investigated for the first time by Muir and Nixon[269]. It was shown by X-ray diffraction that the four-membered ring of this molecule is slightly non-planar: the P and N atoms are alternately 0.045 Å above and below the average plane (a dihedral angle of 6°). Both Cl atoms linked to the P atoms occupy equatorial positions, i.e. they are located on the same side of the ring as the N atoms. However, the substituents at the N atoms are not equivalent in this respect: one of them is in the *cis*-position relative to the Cl atoms and the other in the *trans*-position:



(CXXI).

The molecule of compound (CXXI) has the following geometrical parameters: $r(\rangle P_c-Cl) = 2.105(0.009)$ Å; $r(\rangle P_c-N_c\langle) = 1.689(0.005)$ Å; $\angle NPN = 82.5(0.3)°$; $\angle PNP = 97.3(0.4)°$; $\angle NPCl = 103.3(0.4)°$; $\angle PNC = 129.5°$ (on average). Evidently the bond lengths and valence angles in the ring are very close to the values of the corresponding parameters for the dimeric molecule of a cyclophosphazane with tetracoordinate phosphorus (LXII). However, the PCl bond length in (CXXI) is much greater. A correction for thermal motion increases the length of this bond to 2.149(0.009)Å.

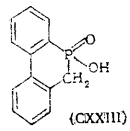
According to an X-ray diffraction study[270], the fundamental geometrical parameters of the bicyclic molecule of (CXXII) have the following values: $r(\rangle P_c-N_c\langle) = 1.68(0.03)$ Å; $\angle NPN = 100(3)°$; $\angle PNN = 117(4)°$; the sum of the valence angles of the nitrogen atom $\alpha_N = 345(2)°$. The PNNP chain in (CXXII) was found to be planar to within 0.06(0.02) Å.



(CXXII).

Two X-ray diffraction studies of cyclic structures with tetracoordinate phosphorus, carried out at the beginning of the 1960's but not mentioned in earlier reviews, are of interest. In one of

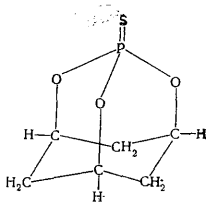
these investigations [271], it was found that in the molecule of compound (CXXIII) the P atom and the C atom of the methylene group are located in the planes of the closest benzene rings, the angle between these planes being 22°.



(CXXIII)

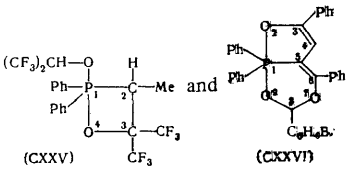
The geometrical parameters of the phosphorus fragment in (CXXIII) are are follows: $r(=P_c-C_c<) = 1.80$ Å; $r(=P_c-C_c-) = 1.79$ Å; $r(-P_c=O)_1 = 1.47$ Å; $r(-P_c=O)_2 = 1.57$ Å; $\angle OP{=}O = 115°$; $\angle CPO = 107°$; $\angle CP{=}O = 114°$; $\angle(CPC)_c = 101°$.

In the second of the above two investigations [272], the following parameters were found for the (CXXIV) molecule: $r(-P_c=S) = 1.90(0.01)$ Å; $r(=P_c-O_c-) = 1.58(0.002)$ Å; $\angle OP{=}S = 113.7(0.9)°$; $\angle OPO = 104.7(1.1)°$; $POC = 113.3(1.7)°$. All three oxygen atoms in the (CXXIV) molecule occupy axial positions in relation to the cyclohexane ring.



(CXXIV)

A further two X-ray diffraction studies have been made on the structure of the cyclicoxyphosphoranes (CXXV) and (CXXVI):



(CXXV) (CXXVI)

In both molecules the oxygen atoms occupy axial positions. In (CXXV), [237] the P atom is in the centre of a distorted trigonal bipyramid with a four-membered ring in the axial-equatorial plane. The ring is non-planar but has a relatively small $C_{(2)}PO_{(4)}/C_{(2)}C_{(3)}O_{(4)} = 11°$ dihedral angle, which corresponds to a displacement of the atoms from the average ring plane by not more than 0.06 Å. The (CXXV) molecule has the following fundamental geometrical parameters: $r(P_cO_c)_a = 1.79(0.01)$ Å; $r(P_cO)_a = 1.71(0.01)$ Å; $r(P_cC_c)_e = 1.83(0.02)$ Å; $r(P_cC)_e = 1.79$ Å (mean); $C_{(2)}PO_{(4)} = 75.5(0.6)°$; $\angle PO_{(4)}C_{(3)} = 94.8(1.0)°$; $\angle PC_{(2)}C_{(3)} = 94.8(1.0)°$.

In the (CXXVI) molecule [274], the P atom is in the centre of an almost regular trigonal bipyramid. Both rings occupy axial-equatorial positions. The five-membered ring is planar, with the parameters $r(P_cO_c)_a = 1.786(0.006)$ Å; $r(P_cC_c)_e = 1.815(0.006)$ Å; $\angle OPC = 87.3(0.2)°$; $\angle POC = 113.8(0.2)°$.

The non-planar six-membered ring has the following parameters: $r(P_cO_c)_a = 1.737(0.006)$ Å; $\angle OPC = 92.7(0.2)°$; $\angle POC = 113.3(0.2)°$.

Thin-layer Electrochemistry

R.S.Tyurin, Yu.S.Lyalikov, and S.I.Zhdanov

This review deals with the theoretical foundations of the methods of thin-layer electrochemistry (chronopotentiometry, voltammetry, and the steady-state current method), and with the application of these methods to the measurement of rate constants of electrochemical reactions, to the study of adsorption, and to the determination of diffusion coefficients, number of electrons involved in the reaction, etc. The scope of the methods of thin-layer electrochemistry, and their advantages in specific cases over alternative methods of studying electrode processes, are discussed. 53 references.

I. INTRODUCTION

The most important recent advances in electrochemistry have been concerned with the development of the theory of electrode processes, which is relevant not only to electrochemistry itself but also to related branches of science and technology. Electrochemical concepts and techniques are used, for example, in studies of biological processes, in studies of the electrochemical and adsorption properties of the semiconductor–electrolyte interface, etc.

Electrochemical processes often need to be studied not only on macroscopic samples but also on small (and even very small) samples. Measurements with small volumes of solution have long been carried out in polarography with the dropping mercury electrode, but the smallest practical volume of solution in cells of conventional design has been 0.2–0.3 ml. The first papers on thin-layer electrochemistry appeared in the early 1960's, and laid the foundations for the solution of the theoretical and the practical problems inherent in studies of the electrolysis of solutions held in a narrow gap between two electrodes. During the last decade there have been significant developments in this area of electrochemistry. Depending on the method used to display the infromation, we can classify this work into thin-layer chronopotentiometry, oscillographic voltammetry, and the steady-state current method. The methods of thin-layer electrochemistry have some definite advantages over the corresponding methods which rely on large volumes of solution. These advantages stem from the fact that the convective transfer of electrochemically active material is practically negligible in thin layers of electrolyte, and therefore the mathematical description of the electrode processes is greatly simplified. Hence, important kinetic parameters such as the rate constants k, the diffusion coefficients D, and the number of electrons n can be evaluated without difficulty. Thin-layer methods using solution volumes as small as 10^{-3} ml are also convenient for the analysis of strongly radioactive solutions which cannot be safely handled in large volumes. Insufficient attention has been paid to thin-layer electrochemistry in the Soviet literature: this review aims to rectify the omission in some measure.

II. THEORY OF THIN-LAYER ELECTROCHEMISTRY

We shall discuss the theory of thin-layer electrochemistry by considering the electrode processes in a thin cylindrical layer of solution of thickness l held between two plane-parallel coaxial electrodes of area A and radius r. The thickness of the layer can be controlled, for example, by using a micrometer as shown in Fig. 1. The volume of solution between the electrodes is $lA \simeq 10^{-3}$ ml. In order to monitor the electrode potential, the experimental solution can be held in contact with a large volume of the same solution through the cylindrical face of the thin layer (of area $2\pi rl$).

Fig. 2 shows the circuit diagram for a thin-layer cell consisting of a pair of plane-parallel electrodes, an auxiliary electrode, and a standard electrode, with suitable connections. Several methods of connection can be used. If the potentials of the working electrodes W_1 and W_2 are controlled independently by means of a standard and an auxiliary electrode, as shown in Fig. 2, we have a coupled thin-layer cell. If the electrode potentials E_1 and E_2 are equal, the cell has effectively one working electrode of total area $2A$ and solution thickness $l/2$. If one of the electrodes is left open-circuited, it acts as an inert plate. Lastly, if the standard and the auxiliary electrode are omitted we have a simple two-electrode thin-layer cell.

As an alternative to the plane-parallel electrodes[1-4], the electrodes for thin-layer electrochemical cells can be in the form of thin wires in a narrow glass or plastic tube[5,6]. A cell of this type is shown in Fig. 3. The thickness of the layer of solution can be varied by suitable choice of wire diameter and channel bore. The electrode

material can be graphite, platinum, mercury, or other metals; for combined electrochemical and spectrophotometric measurements glass plates coated with a conducting layer have been used [1,7-11].

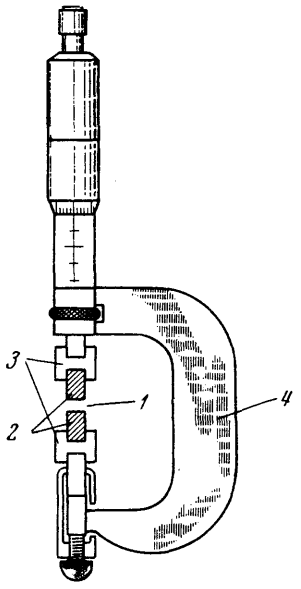

Figure 1. Plane-parallel micrometric electrodes: *1*) gap, *2*) platinum electrodes, *3*) insulating collars, *4*) micrometer.

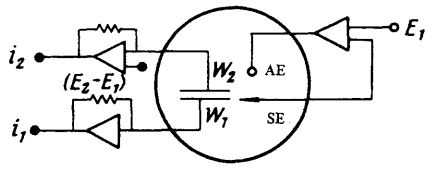

Figure 2. Circuit diagram of a two-electrode thin-layer cell: W_1 and W_2 are the working electrodes, AE is the auxiliary electrode, SE is the standard electrode.

1. Chronopotentiometry

We shall consider a solution containing an electrochemically active material in a thin-layer cell, confined between the boundaries 0 and l, so that $0 < x < l$. Only one of the two close-spaced electrodes is working, and the second electrode behaves as the wall of the cell.

If the material O is reduced at a constant current density i (galvanostatic conditions), and if the edge effect can be neglected†, the concentration of O at the electrode at any instant $c_O(0, t)$ can be calculated by the Laplace transform [12].

†See p. 1098.

Christensen and Anson [2] have shown that

$$c_O(0,t) = c_O^0 - \frac{il}{nFAD}\left[\frac{Dt}{l^2} + \frac{1}{3} - \frac{2}{\pi^2}\sum_{k=1}^{\infty}\frac{1}{k^2}\exp\left(-\frac{\pi^2 k^2 Dt}{l^2}\right)\right] \quad (1)$$

where c_O^0 is the initial concentration of O.

For large l, Eqn. (1) reduces to the familiar chronopotentiometric equation.

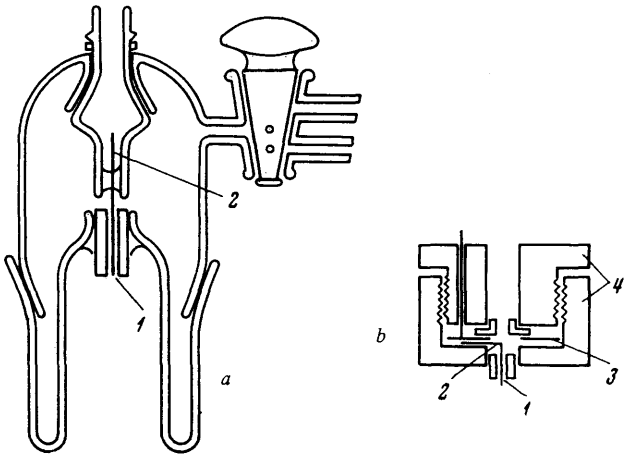

Figure 3. Types of capillary-filament electrode: *1*) gap, *2*) working electrode, *3*) Pt contact disk, *4*) Teflon body.

The time for complete removal of the depolariser from the layer adjacent to the electrode, when $c_O(0, t) = 0$, is called the transient time τ.

If τ is so large that $l^2 < \tau D$, the exponential terms in Eqn. (1) can be ignored, and the following expression for τ is obtained:

$$\tau = \frac{nFAlc_O^0}{i} - \frac{l^2}{3D}. \quad (2)$$

If the Nernst equation applies, the variation of potential with time $[E = f(t)]$ for the reversible redox couple O–R is given by the expression

$$E = E^0 + \frac{RT}{nF}\ln\frac{\tau - t + \frac{2l^2}{\pi^2 D}\sum_{k=1}^{\infty}\frac{1}{k^2}\exp\left(-\frac{\pi^2 k^2 Dt}{l^2}\right)}{t + \frac{l^2}{3D} - \frac{2l^2}{\pi^2 D}\sum_{k=1}^{\infty}\frac{1}{k^2}\exp\left(-\frac{\pi^2 k^2 Dt}{l^2}\right)} \quad (3)$$

where E^0 is the normal potential of the couple O–R. Eqn. (3) assumes equality of the diffusion coefficients of the oxidised and the reduced form of the material. The quantity $l^2/3D$ and the exponential terms of Eqn. (3) can be made small in comparison with t. In this case $E = E^0$ at $t = \tau/2$. The second term in the right-hand side of Eqn. (2) can be ignored when l is small and the concentration of O in solution is large enough. Thus, for $l = 10^{-3}$ cm and $D = 10^{-5}$ cm^2 s^{-1}, we have $l^2/3D \simeq 3 \times 10^{-2}$ s, and the second term in Eqn. (2) can be neglected under these

conditions if $\tau > 3$ s. Eqn. (3) then reduces to Faraday's law in the form used in constant-current coulometry:

$$\tau = \frac{nFAlc_0}{i} \quad (4)$$

or

$$Q = nFAlc_0 . \quad (5)$$

(*a*) Determination of the number of electrons in the reaction

Eqn. (4) can be used to evaluate n when the diffusion coefficients of the species being studied are not known. The cell used for this purpose has very closely spaced electrodes, to make $l^2/3D$ much smaller than the transient time. Thin-layer chronopotentiometry has been used to determine the number of electrons involved in the oxidation of *N,N*-dimethyl-*p*-phenylenediamine. The reaction goes through the steps

$$H_2N{-}C_6H_4{-}N(CH_3)_2 - e \rightleftarrows [H_2N{-}C_6H_4{-}N(CH_3)_2]^+ ,$$

$$[H_2N{-}C_6H_4{-}N(CH_3)_2]^+ - e \rightleftarrows NH{=}C_6H_4{=}N(CH_3)_2^+ + H^+ .$$

Conventional chronopotentiometric measurements[13] on platinum electrodes in acid solutions indicate a two-electron transition, but the interpretation of the results is complicated by subsequent chemical changes of the reaction products. The mean of the experimental values (n = 1.97) obtained in thin-layer experiments is in very good agreement with the value (n = 2) proposed for the oxidation of *N,N*-dimethyl-*p*-phenylenediamine to the di-imine. The thin-layer experiment gives more accurate values than conventional controlled-potential electrolysis[2,14]. Sharper chronopotentiograms are obtained in the thin-layer cell than in a conventional cell, as shown by the curves in Fig. 4 for the oxidation of *p*-phenylenediamine.

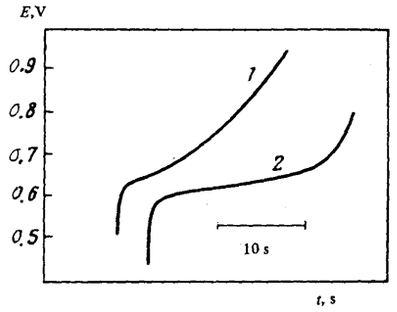

Figure 4. Chronopotentiograms for the oxidation of *p*-phenylenediamine: *1*) diffusion cell (c = 4.72 mM, current density 0.6 μA cm^{-2}); *2*) thin-layer cell (c = 4.99 mM, current density 0.09 μA cm^{-2}). In both cases the supporting electrolyte is 1 M H_2SO_4.

This is because a sharp transition to the next reaction (for example, the oxidation of water) sets in as soon as the whole of the material in the thin layer between the electrodes has been oxidised. In contrast, a significant fraction of the current in diffusion chronopotentiometry is carried by the oxidation of the experimental material which diffuses from the more remote layers of solution when the layer adjacent to the electrode has been depleted: as a result, the potential changes more gradually with time.

(*b*) Determination of diffusion coefficients

Oglesby and coworkers[15] have shown, by analysing Eqn. (2), that the diffusion coefficient of the experimental material can be determined even if the concentration of the solution and the surface area of the working electrode are not known. Thus, a plot of τ against $1/i$ is a straight line whose intercept on the τ axis gives $-l^2/3D$ (Fig. 5).

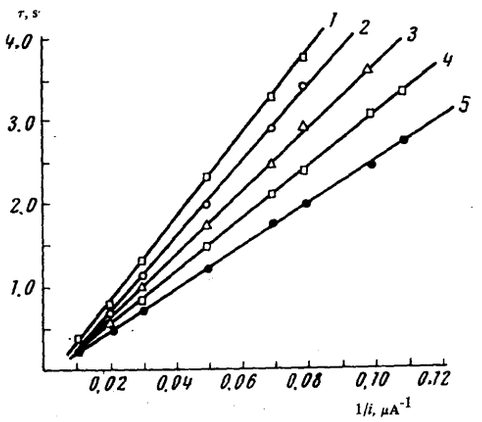

Figure 5. Plots of τ against $1/i$ for different thicknesses of solution: *1*) 1.88×10^{-3}, *2*) 1.62×10^{-3}, *3*) 1.37×10^{-3}, *4*) 1.12×10^{-3}, *5*) 0.864×10^{-3} cm. Area of working electrode 0.27 cm^2. Experimental solution $K_3Fe(CN)_6$ in 0.5 M Na_2SO_4.

Knowing l, the diffusion coefficient of the electrochemically active species can be calculated. Table 1 shows the diffusion coefficients for $Fe(CN)_6^{3-}$ in 0.5 M Na_2SO_4 obtained for different values of the layer thickness l.

Table 1. Diffusion coefficient of $Fe(CN)_6^{3-}$ in 0.5 M Na_2SO_4.

1.88	0.252	0.47

Average $D = 0.45 \times 10^{-5}$ cm^2 s^{-1}

(*c*) Determination of the rate constants of chemical reactions

Thin-layer chronopotentiometry is a very convenient technique for measuring the rate constants of slow chemical reactions involving the electrolysis products. As an

example, we shall consider the hydrolysis of *p*-benzoquinoneimine, formed by the anodic oxidation of *p*-aminophenol on a Pt electrode (Christensen and Anson [16]).

The anodic oxidation of *p*-aminophenol in aqueous solutions proceeds by the following mechanism [17–19]:

$$HO{-}C_6H_4{-}NH_2 - 2e \rightleftarrows O{=}C_6H_4{=}NH + 2H^+ ,$$
$$O{=}C_6H_4{=}NH + H_2O \rightarrow O{=}C_6H_4{=}O + NH_3 .$$

Fig. 6 shows a thin-layer chronopotentiogram of the oxidation of *p*-aminophenol followed by the reduction of *p*-benzoquinoneimine and *p*-benzoquinone.

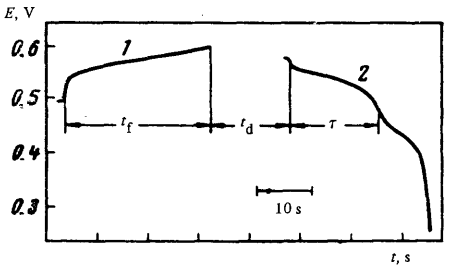

Figure 6. Thin-layer chronopotentiogram: *1*) oxidation of *p*-aminophenol, *2*) reduction of *p*-benzoquinoneimine and *p*-benzoquinone. t_d = 45.4 s.

p-Aminophenol (R) is oxidised during time t_f to *p*-benzoquinoneimine (O), which is then hydrolysed to *p*-benzoquinone (Z) by an irreversible first-order reaction. Since the reduction of *p*-benzoquinone occurs in a different region of potentials, this compound can be treated as electrochemically inert. The current is interrupted during the interval t_d, and the hydrolysis of *p*-benzoquinoneimine is the only possible reaction during this time. The polarity of the current is then reversed, and any unchanged *p*-benzoquinoneimine is reduced back to *p*-aminophenol (R). The hydrolysis reaction continues, in parallel with the reduction of *p*-benzoquinoneimine.

We shall calculate first of all the concentration of O in the thin layer of solution at time t ($0 < t < t_f$). We can write

$$\frac{dc_O}{dt} = \beta - kc_O \qquad (6)$$

where $\beta = i/nFAl$ (see Eqn. (1)). The first term in the right-hand side of Eqn. (6) describes the production of O, the second term describes its removal by the hydrolysis reaction.

Since $c_O = 0$ at $t = 0$, the solution of Eqn. (6) is

$$c_O = \frac{\beta}{k}(1 - e^{-kt}) . \qquad (7)$$

During the period when $i = 0$, i.e. for $t_f < t < t_f + t_d$, we can write

$$\frac{dc_O}{dt} = -kc_O . \qquad (8)$$

Solving Eqn. (8) and substituting for c_O from Eqn. (7), the following expression applies for $t' = t - t_f = 0$ (i.e. at the instant t_f):

$$c_O = \frac{\beta}{k} e^{-kt'}(1 - e^{kt_f}) . \qquad (9)$$

During the period of reduction of O, i.e. for $t_f + t_d < t < t_f + t_d + \tau$, we have

$$\frac{dc_O}{dt} = -\theta\beta - kc_O \qquad (10)$$

where θ is the ratio of cathodic to anodic current.

Solving Eqn. (10) and taking c_O from Eqn. (9) with $t'' = t - (t_f + t_d) = 0$ (i.e. at the instant t_d) we obtain

$$c_O = \frac{\beta}{k}\{e^{-kt''}[\theta + e^{-kt_d}(1 - e^{-kt_f})] - \theta\} . \qquad (11)$$

The transient time is determined by the condition $c_O = 0$, $t'' = \tau$. Hence, from Eqn. (11),

$$\tau = \frac{1}{k}\ln\left[1 + \frac{1}{\theta}e^{-kt_d}(1 - e^{-kt_f})\right] , \qquad (12)$$

and for $\theta = 1$

$$\tau = \frac{1}{k}\ln[1 + e^{-kt_d}(1 - e^{-kt_f})] . \qquad (13)$$

The theory for an analogous electrode process but in the usual chronopotentiometric model is much more complicated. The correctness of Eqn. (13) has been confirmed experimentally: Table 2 shows the results of measurements of the rate constant for the hydrolysis of *p*-benzoquinoneimine in 1.017 M H_2SO_4 at 25°C. The concentration of the starting material, *p*-aminophenol, was 1.01×10^{-2} M.

Table 2. Rate constant for the hydrolysis of *p*-benzoquinoneimine.

t_f, s	t_d, s	τ, s	10^3k, s^{-1}
32.1	9.9	23.9	7.8
41.8	19.9	28.1	7.3
19.0	42.2	12.7	7.0
27.4	45.4	16.6	7.5
36.0	50.4	20.3	7.3
16.6	51.1	10.3	7.4

Average $k = 7.4 \times 10^3$ s^{-1}

The equation for the rate constants of slow chemical reactions is greatly simplified by using the thin-layer cyclic potentiostatic method instead of the chronopotentiometric method. In that method, the unstable form is obtained under potentiostatic conditions, and the current (or the quantity of electricity) is plotted against time. After a certain time the potential is changed to a value at which the unstable product which has not yet reacted is converted back into the original form by the reverse electrochemical reaction. Oglesby and coworkers [20] used this method to study the acid-catalysed rearrangement of hydrazobenzene. The starting compound was the stable azo-form, and the unstable hydrazo-form was produced at the surface of the working electrode. The reaction mechanism is

$$C_6H_5{-}N{=}N{-}C_6H_5 + 2e + 2H^+ \rightleftarrows C_6H_5{-}NH{-}NH{-}C_6H_5 \xrightarrow{k} H_2N{-}C_6H_4{-}C_6H_4{-}NH_2 .$$

Theoretically, the time for complete exhaustion of a layer of solution 2×10^{-3} cm thick is less than one second[21]. If the reaction of interest is sufficiently slow, the unstable product may be formed rapidly in the potentiostatic experiment and allowed to react at the same potential during a much longer time (t_r) than the time required to generate it. The ratio of the quantities of electricity passed in the reverse and the forward electrolysis (h_r/h_b) is equivalent to the ratio of the initial concentration of reactant (e.g. azobenzene) to the final concentration of the product (e.g. hydrazobenzene). The plot of $\ln(h_r/h_b)$ against t_r for a first-order reaction should be a straight line of slope k.

When one-half of the product has reacted, $h_r/h_b = 2$. If we denote the time for half-reaction by $t_{1/2}$, the rate constant can be expressed in the form

$$k=\frac{\ln 2}{t_{1/2}}=\frac{0.693}{t_{1/2}}\ . \qquad (14)$$

The rate constants for the rearrangement of hydrazobenzene obtained by thin-layer methods agree satisfactorily with the values given by other electrochemical methods. Thus, the cyclic galvanostatic method gives 10.2×10^{-3} s^{-1}, the potential jump reversal method gives 10.7×10^{-3} s^{-1}, whereas the thin-layer chronopotentiometric and potentiostatic methods give 18.6×10^{-3} and 11.7×10^{-3} s^{-1} respectively. The concentration of $HClO_4$ was 0.075 M in every case.

(*d*) Study of adsorption

By virtue of its large ratio of electrode surface area to volume of solution, the thin-layer electrochemical cell can be used to study surface phenomena such as adsorption processes. Hubbard and Anson[3] have suggested a simple and convenient method for the quantitative determination of adsorbed materials from theoretical considerations of the behaviour of electrically active substances under the conditions of the thin-layer experiment.

If the compound is adsorbed on the electrode surface, and if the geometry of the cell justifies ignoring the second term in the right-hand side of Eqn. (2), the transient time which characterises the full exhaustion of the depolariser (whether adsorbed or not) can be expressed as

$$\tau=\frac{nFAlc}{i}+\frac{2nFA\Gamma}{i}\ , \qquad (15)$$

where Γ is the amount adsorbed in mole cm^{-2}. The coefficient 2 arises from the fact that adsorption occurs on both electrodes, each of area A. If the adsorbate does not take part in the electrode reaction under conditions leading to reaction by non-adsorbed species, the amount of adsorbate is found from the difference between the experimentally measured quantity of electricity and the quantity of electricity theoretically calculated by Eqn. (5).

The advantages of thin-layer electrochemistry in studies of adsorption phenomena have been demonstrated in a series of papers[22-24] on the adsorption of iodine. It is shown that the adsorption of I_2 and I^- on platinum electrodes can take two forms: an electrochemically active and an inactive state. Initially I_2 is adsorbed in the inactive form (up to $\sim 2\times10^{-9}$ mole cm^{-2}); this is followed by adsorption in the active form (a further 10^{-9} mole cm^{-2}).

Adsorbed, active I^- ($\sim 1.2\times10^{-9}$ mole cm^{-2}) blocks the adsorption of the inactive forms of I_2 and I^-. Adsorbed, inactive I_2 prevents further adsorption of I^-.

The adsorption of active I_2 is unaffected by whether the electrode is covered with I^- ions or by free iodine. The adsorption of inactive I^- can be estimated from the equations for the anodic transient time of the oxidation of I^- to I_2.

The presence of inactive, adsorbed I_2 can be confirmed by oxidative desorption ($n = 5$), followed by estimation of the resulting iodate.

In a study of the behaviour of the I_2/I^- couple it was found that the adsorbed iodide ion is not oxidised at potentials sufficient to oxidise non-adsorbed iodide.

These results suggest that adsorbed I^- and I_2 are not likely to be the species responsible for the electron transfer reactions giving rise to the exchange current at Pt electrodes in I^-/I_2 solutions. Workers who reached the opposite conclusion[25,26] from their kinetic studies must have argued incorrectly.

The conclusions made from the study of the electrochemical behaviour of the I_2/I^- couple on Pt electrodes in thin layers of solution are somewhat inconsistent with conclusions based on other methods[27-33]. However, some aspects of the thin-layer work[22-24] are not entirely convincing, and should be re-examined.

2. Voltammetry

(*a*) Reversible processes

If a depolariser is present in the thin layer of solution, the application of a prescribed potential to the electrode will cause a current to flow through the cell as a result of the electrochemical reaction. The layer of solution immediately adjacent to the electrode surface will be gradually depleted of depolariser; however, a new supply of depolariser is available by diffusion from within the solution. This process produces a thickening of the diffusion layer, which in the thin-layer experiment cannot exceed the value l. On raising the electrode potential the rate of the electrochemical process increases, but at the same time the supply of depolariser is hindered. As a result, the current increases only to a certain value, and then decreases to zero. Anson and Hubbard[34] have derived an equation which describes the current–voltage characteristic of the process, assuming that the electrode potential is varied linearly with time.

For a reversible reaction ($O + ne \rightleftharpoons R$) and a relatively slow rate of change of potential (not more than 20 mV s^{-1}), the following expressions for c_O and c_R can be used:

$$c_O=c_O^0\left\{1/\left[1+\exp\frac{nF}{RT}(E^0-E)\right]\right\}\ , \qquad (16)$$

$$c_R=c_R^0\left\{1/\left[1+\exp\frac{nF}{RT}(E-E^0)\right]\right\}\ . \qquad (17)$$

The current i flowing through the thin-layer cell when the potential is scanned cathodically can be calculated from the expression

$$i=-nFV\frac{dc_O}{dt}\ . \qquad (18)$$

The expression for the cathodic voltammetric curve can be obtained from Eqns. (16) and (18):

$$i=n^2Vrc_O^0\frac{F^2}{RT}\left\{\frac{\exp\frac{nF}{RT}(E^0-E)}{\left[\exp\frac{nF}{RT}(E^0-E)+1\right]^2}\right\}. \qquad (19)$$

The thin-layer voltammetric curve is bell-shaped and symmetrical about the peak potential (see Fig. 7). The current maximum (i_p) is associated with the potential E^0, and is given by the expression

$$i_p = \frac{n^2 c_O^0 r V F^2}{4RT} . \quad (20)$$

The simplicity of the theory of thin-layer voltammetry in comparison with oscillographic polarography is clearly brought out by comparing Eqn. (19) with the Randles–Ševčik equation[35,36].

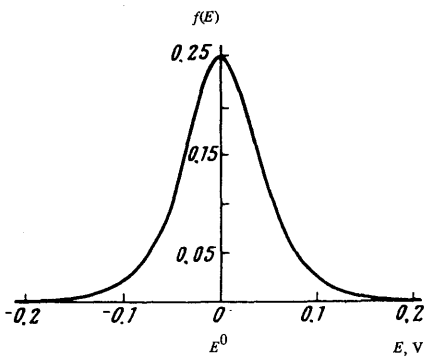

Figure 7. Theoretical i–E voltammetric curve for a reversible process in a thin-layer cell:

$$f(E) = \frac{\exp\left[\frac{F}{RT}(E - E^0)\right]}{\left\{\exp\left[\frac{F}{RT}(E - E^0)\right] + 1\right\}^2} .$$

Comparing the equation for the peak current in normal oscillographic voltammetry,

$$i_p = \frac{0.452 n^{3/2} F^{3/2} c_O^0 D^{1/2} r^{1/2} A}{R^{1/2} T^{3/2}} \quad (21)$$

with Eqn. (20), it can be seen that the current density in thin-layer voltammetry is significantly lower:

$$\frac{i_p}{(i_p)_{tl}} = \left(\frac{RT}{nF}\right)^{1/2} \frac{1.808 D^{1/2}}{r^{1/2} l} = \frac{0.286 D^{1/2}}{n^{1/2} r^{1/2} l} \quad (22)$$

whence $i_p/(i_p)_{tl} = 22$ if $n = 1$, $r = 10^{-3}$ V s^{-1}, $l = 10^{-3}$ cm, and $D = 6 \times 10^{-6}$ cm^2 s^{-1}. However, with small values of r and stationary electrodes these smaller currents can be measured as accurately as the currents encountered in oscillographic polarography, where the large value of r gives rise to substantial capacitive currents.

(*b*) Irreversible processes

Thin-layer voltammetry is very convenient for the study of irreversible reactions[37] ($O + ne \rightarrow R$).

The voltammetric curve for an irreversible system is asymmetric about the peak potential E_p, and the peak potential and its height (peak current) are related to the kinetic parameters k^0 and αn_0 by simple expressions.

We start from the basic equation of electrochemical kinetics, which describes both the forward and the reverse reaction

$$i = nFAk^0 \left\{c_O \exp\left[\frac{-\alpha n_0 F}{RT}(E - E^0)\right] - c_R \exp\left[\frac{(1-\alpha) n_0 F}{RT}(E - E^0)\right]\right\} . \quad (23)$$

If the peak current is at least two orders of magnitude greater than the exchange current the contribution of the reverse reaction to the voltammetric curve is negligible, and we can write

$$i = nFAk^0 c_O \exp\left[(-\alpha n_0 F/RT)(E - E^0)\right] . \quad (24)$$

Combining Eqns. (18) and (24) we obtain

$$\frac{dc_O}{dt} = -\frac{Ak^0 c_O}{V} \exp\left[\frac{-\alpha n_0 F}{RT}(E - E^0)\right] . \quad (25)$$

Integration of Eqn. (25) affords an expression for c_O. Inserting it into Eqn. (24), we arrive at an expression for the cathodic i, E curve in terms of the initial concentration only:

$$i = nFAk^0 c_O^0 \exp\left\{\frac{-\alpha n_0 F}{RT}(E - E^0) - \frac{ARTk^0}{\alpha n_0 FV(-r)} \exp\left[\frac{-\alpha n_0 F}{RT}(E - E^0)\right]\right\} . \quad (26)$$

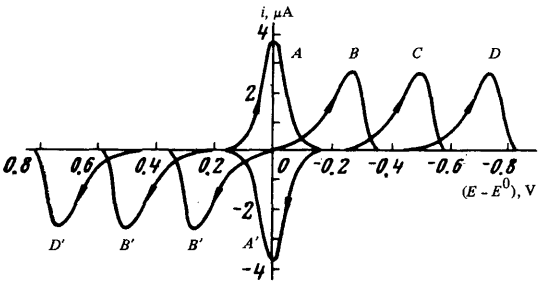

Figure 8. Theoretical voltammetric curves for a reversible reaction and for fully irreversible reactions in a thin layer of solution: *A*) reversible reaction, $k^0 \geq 4 \times 10^{-3}$ cm s^{-1}, *B*)–*D*) fully irreversible reactions, $k^0(B) = 10^{-6}$, $k^0(C) = 10^{-8}$, $k^0(D) = 10^{-10}$ cm s^{-1}. ($\alpha n_0 = 0.5$, $V = 2 \times 10^{-3}$ cm^3, $|r| = 2 \times 10^{-3}$ V s^{-1}, $n = 1$, $A = 0.5$ cm^2, $C^0 = 10^{-6}$ mole cm^{-3}, $T = 298$°K).

Fig. 8 shows plots of Eqn. (26) for several values of k^0 and one value of αn_0. It can be seen that the shape of the curves is independent of k^0, the curves being merely shifted along the potential axis. However, the peaks become broader and flatter if αn_0 decreases (Fig. 9).

The equations for the cathodic peak potential and for the peak current are obtained by equating to zero the differential di/dE from Eqn. (26).

The peak potential depends on αn_0 and on k^0, but is independent of concentration

$${}_cE_p = E^0 - (2.3RT/\alpha n_0 F) \lg\left[\alpha n_0 F(-r)V/ARTk^0\right] \quad (27)$$

whereas the peak current is directly proportional to αn_0 and to concentration

$${}_ci_p = \alpha n_0 n F^2 V(-r) c_O^0/2.718RT . \quad (28)$$

From Eqn. (28) we can calculate αn_0, and hence we can find k^0 from Eqn. (27) if E^0 is known.

Eqns. (27) and (28) can be applied to an anodic reaction by replacing α by $(1-\alpha)$ and c_O^0 by c_R^0.

If a cyclic voltammetric curve is plotted, the same kinetic parameters can be obtained without a knowledge of E^0. In this case we write equations for ${}_cE_p$ and ${}_aE_p$, from which E^0 can be eliminated. The final expression for k^0 is

$$k^0 = \left\{\frac{2.718\,{}_ci_p}{nFAc^0}\left(\frac{-2.718\,{}_ai_p}{nFAc^0}\right)^{{}_ci_p/{}_ai_p}\cdot\exp\left[\frac{-2.718\,{}_ci_p}{nFV|r|c^0}({}_aE_p-{}_cE_p)\right]\right\}^{{}_ai_p/({}_ai_p-{}_ci_p)}. \quad (29)$$

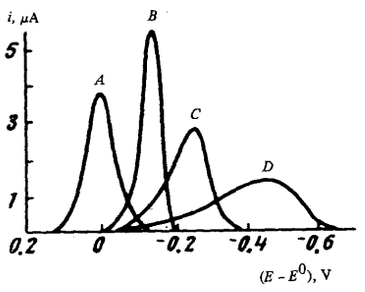

Figure 9. Theoretical voltammetric curves for a reversible reaction and for fully irreversible reactions in a thin layer of solution for different values of αn_0: *A*) reversible reaction, *B*)–*D*) irreversible reactions; $\alpha n_0(B) = 0.75$, $\alpha n_0(C) = 0.50$, $\alpha n_0(D) = 0.25$. ($k^0 = 10^{-6}$ cm s^{-1}, all other parameters as in Fig. 8).

For $\alpha n_0 = 0.5$ and ${}_ci_p = {}_ai_p$, Eqn. (29) simplifies to

$$\lg k^0 \overset{a}{=} -(1260/T)({}_aE_p - {}_cE_p) + \lg(VF|r|/2ART). \quad (30)$$

An equation for α can be obtained by eliminating n_0 from equations for ${}_ci_p$ and ${}_ai_p$ of the type of Eqn. (28). For $c_O^0 = c_R^0$ we have

$$\alpha = {}_ci_p/({}_ci_p - {}_ai_p). \quad (31)$$

Thus, α and n_0 can be evaluated separately in cyclic thin-layer voltammetry, but of course only if n_0 is the same for the cathodic and the anodic process.

Eqn. (26) describes the current–voltage curve of an irreversible reaction with a relative error of 2% if the exchange current does not exceed 2% of the peak current.

Thus, using the equation

$$i_0 = nFAk^0c \quad (32)$$

to calculate the maximum value of the exchange current i_0, and Eqn. (28) to calculate the smallest value of the peak current i_p, we obtain

$$i_0/i_p = 2.718ARTk^0/\alpha n_0FVr > 0.02 \quad (33)$$

or

$$k^0 < (\alpha n_0FV|r|/2.718ART)\cdot 0.02\ . \quad (34)$$

For normal values of the experimental parameters ($\alpha n_0 = 0.5$; $V = 2\times10^{-3}$ cm^3; $|r| = 2$ mV s^{-1}; $T = 298$°K; $A = 0.5$ cm^2) we obtain $k^0 < 1.2\times10^{-6}$ cm s^{-1}.

Hence, Eqn. (26) is applicable to fully irreversible processes, having rate constants of the order of 10^{-6} or less.

Eqn. (19) describes the current–voltage curve for a reversible reaction, with a relative error of 2%, for the condition

$$i_0/i_p = 4ARTk^0/nFV|r| > 50\ . \quad (35)$$

This condition is satisfied if

$$k^0 > (nFVr/4RTA)\cdot 50 \quad (36)$$

With the values of the parameters assumed above, we obtain $k^0 < 4\times10^{-3}$ cm s^{-1}. Hence, a "reversible" reaction is a reaction whose rate constant does not exceed 4×10^{-3} s^{-1}.

(*c*) Effect of double layer structure

All the above equations have been obtained without allowing for the effect of the structure of the electrical double layer. The basic equation of electrochemical kinetics which allows for the effect of the double layer on the surface concentration of the depolariser is

$$i = nFAk^0c_O^0f(\psi_1)\exp[(-\alpha n_0F/RT)(E-E^0)] \quad (37)$$

where $f(\psi_1) = \exp[(\alpha n_0 - z_0)(F/RT)\psi_1]$, and z_0 is the charge on a particle of the substance under study.

The equation for the cathodic i–E curve follows from Eqns. (26) and (37):

$$i = nFAk^0c_O^0f(\psi_1)\exp\left\{\frac{-\alpha n_0F}{RT}(E-E^0) + \frac{Ak^0}{V(-r)}\int_{E_i}^{E} f(\psi_1)\exp\left[-\frac{\alpha n_0F}{RT}(E-E^0)\right]dE\right\} \quad (38)$$

where E_i is the potential at which the scan is started.

Assuming that the electrode potential is divided between two capacitances in series, the fixed (C) and the diffuse (C_d) parts of the double layer, and assuming these capacitances to be independent of potential over the narrow range of potential for which the current is fairly large (about $200/n$ mV), we can write

$$\psi_1 \simeq (C/C_d)(E-\varphi_0) \quad (39)$$

where φ_0 is the zero-charge potential.

Combining Eqns. (38) and (39),

$$i = nFAk^0c_O^0f(\psi_1)\exp\left\{\frac{-\alpha n_0F}{RT}(E-E^0) - \frac{ARTk^0}{FV(-r)}\frac{f(\psi_1)\exp\left[\frac{-\alpha n_0F}{RT}(E-E^0)\right]}{[\alpha n_0 + (z_0-\alpha n_0)C/C_d]}\right\}. \quad (40)$$

The equation for the peak potential is

$${}_cE_p = \frac{\alpha n_0E^0 + (z_0-\alpha n_0)\frac{C}{C_d}\varphi_0 - \frac{RT}{F}\ln\left\{\frac{FV(-r)}{ARTk^0}\left[\alpha n_0 + (z_0-\alpha n_0)\frac{C}{C_d}\right]\right\}}{\alpha n_0 + (z_0-\alpha n_0)C/C_d}. \quad (41)$$

Eqn. (41) reduces to Eqn. (27) when C is much smaller than C_d. (This case is found in the presence of an excess of indifferent electrolyte.) Eqns. (38) and (40) are fully analogous to Eqn. (26) except for the function $f(\psi_1)$ which replaces the factor $\exp[(-\alpha n_0F/RT)\cdot(E-E^0)]$ in Eqn. (40). Taking Eqn. (39) into account, the product $f(\psi_1)\exp[(-\alpha n_0F/RT)\cdot(E-E^0)]$ becomes

$$f(\psi_1)\exp\left[\frac{-\alpha n_0F}{RT}(E-E^0)\right] = \exp\left\{\frac{F}{RT}\left[\frac{C}{C_d}(z_0-\alpha n_0)\cdot\varphi_0 + \alpha n_0E^0\right]\right\}\exp\left[\alpha^*\frac{F}{RT}E\right] \quad (42)$$

where

$$\alpha^* = (z_0-\alpha n_0)C/C_d + \alpha n_0\ . \quad (43)$$

Finally, the peak current with allowance for the effect of double layer structure is given by

$${}_ci_p = \alpha^*nF^2V(-r)c_O^0/2.718RT\ . \quad (44)$$

It follows from Eqns. (43) and (44) that α^* (and therefore also c^i_p) should be smaller for anion reactions than for cation reactions. Thin-layer i–E curves for intermediate and low concentrations of indifferent electrolyte contain information on the ratio C/C_d.

(*d*) Multistage processes

If a compound is reduced in two fully irreversible steps, for example

$$(PtCl_6)^{2-} + 2e \xrightarrow{k_1^0} (PtCl_4)^{2-} + 2Cl^-$$

and

$$(PtCl_4)^{2-} + 2e \xrightarrow{k_2^0} Pt + 4Cl^- \ ,$$

the current–voltage curve (Fig. 10) should have two peaks if the first step is the faster (curve *A*), or one peak if the second step is the faster or if the two steps have comparable rates (curves *B* and *C*).

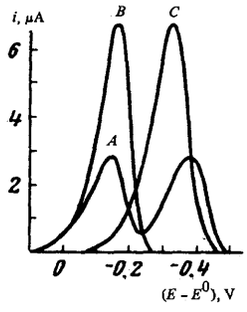

Figure 10. Theoretical thin-layer curves for a two-step fully irreversible reaction: *A*) $k_1^0 = 10^{-5}$, $k_2^0 = 10^{-7}$; *B*) $k_1^0 = k_2^0 = 10^{-5}$; *C*) $k_1^0 = 3 \times 10^{-7}$, $k_2^0 = 10^{-5}$ cm s^{-1} (all other parameters as in Fig. 8).

If $k_1^0 \geq 10^3 k_2^0$ the equations presented in the previous sub-sections can be used to describe both steps.

The basic i–E equation for a fully irreversible, two-step reaction such as

$$O + n_1 e \rightarrow R_1$$
$$R_1 + n_2 e \rightarrow R_2$$

but without allowance for the influence of the double-layer structure is obtained as follows. The contribution to the current from the first step is expressed by Eqn. (26):

$$i_1 = n_1 F A k_1^0 c_1^0 \exp\left\{\frac{-(\alpha n_0)_1 F}{RT}(E - E_1^0)\right\} \frac{-ART k_1^0}{(\alpha n_0)_1 FV(-r)} \cdot \exp\left[\frac{-(\alpha n_0)_1 F}{RT}(E - E_1^0)\right]\Big\} . \quad (45)$$

The current associated with the second step is given by

$$i_2 = -n_2 FV \frac{dc_2}{dt} + i_1 = n_2 F A c_2^0 k_2^0 \exp\left[\frac{-(\alpha n_0)_2 F}{RT}(E - E_0^0)\right] . \quad (46)$$

Eqn. (46) is solved for c_2 and i_2 using the normal methods for linear first-order differential equations

$$c_2 = c_1^0 H^{-1} \int_{E_i}^{E} GH dE \ , \quad (47)$$

$$i_2 = n_2 F A k_2^0 c_1^0 H^{-1} \exp\left[\frac{-(\alpha n_0)_2 F}{RT}(E - E_2^0) \int_{E_i}^{E} GH dE\right] , \quad (48)$$

where

$$G = \frac{n_1 A k_1^0 c_1^0}{n_2 Vr} \exp\left\{\frac{-(\alpha n_0)_1 F}{RT}(E - E_1^0) + \frac{Ak_1^0 RT}{(\alpha n_0)_1 FVr} \exp\left[\frac{-(\alpha n_0)_1 F}{RT}(E - E_1^0)\right]\right\} ,$$

$$H = \exp\{[Ak_2^0 RT/V(-r)(\alpha n_0)_2 F] \exp[(-(\alpha n_0)_2 F/RT)(E - E_2^0)]\} ,$$

c_1^0 is the initial concentration of O and c_2^0 is the initial concentration of R_1. Since the total current is $i = i_1 + i_2$, the expression for the i–E curve becomes

$$i = n_2 FVr c_1^0 G + n_2 F A k_2^0 c_1^0 H^{-1} \exp\left[\frac{-(\alpha n_0)_2 F}{RT}(E - E_2^0) \int_{E_i}^{E} GH dE\right] . \quad (49)$$

The integral term in the right-hand side of Eqn. (49) cannot be solved analytically. Plots obtained by numerical integration for $(\alpha n_0)_1 = (\alpha n_0)_2 = 0.5$ and several pairs of values of k_1^0 and k_2^0 are reproduced in Fig. 10.

(*e*) Partially reversible reactions

The current–voltage curve for fast but not fully reversible reactions, in which the contribution of the reverse reaction cannot be neglected, is described by the equation

$$i = -nFA\left\{k_b c_O^0 - \frac{Ac_O^0}{Vr}(k_f + k_b) X^{-1} \int_{E_i}^{E} X k_b dE\right\} \quad (50)$$

where

$$X = \exp\{[ART/V(-r) n_0 F][k_f/\alpha - k_b/(1-\alpha)]\} ,$$

$$k_f = k^0 \exp[(-\alpha n_0 F/RT)(E - E^0)] ,$$

$$k_b = k^0 \exp\{[(1-\alpha) n_0 F/RT](E - E^0)\} .$$

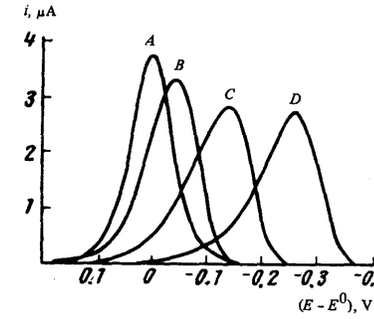

Figure 11. Theoretical voltammetric curves for reactions of intermediate reversibility in a thin layer: $k^0(A) = 4 \times 10^{-3}$, $k^0(B) = 10^{-4}$, $k^0(C) = 10^{-5}$, $k^0(D) = 10^{-6}$ cm s^{-1} (all other parameters as in Fig. 8).

An analogous equation for anodic reactions is obtained from Eqn. (50) by replacing c_O^0 by c_R^0. A plot of Eqn. (50) is shown in Fig. 11. The size of the current peak is intermediate between those given by Eqns. (20) and (28) for reversible ($k^0 > 4 \times 10^{-3}$ cm s^{-1}) and fully irreversible ($k^0 > 1 \times 10^{-6}$ cm s^{-1}) reactions respectively.

(*f*) Competitive reactions

When the starting material can undergo two parallel, fully irreversible reactions, as in

$$O + n_1 e \rightarrow R_1 ,$$
$$O + n_2 e \rightarrow R_2 ,$$

the shape of the current–voltage curve (Fig. 12) differs from that of the corresponding curve for a reaction which takes place by a single path (Fig. 8). In spite of the presence of two reactions, a single peak is obtained. The current–voltage characteristic for an electrode process of this type is derived as follows. The current in this case is given by

$$i = FAc_O(n_1 {}_1k_f + n_2 {}_2k_f) \quad (51)$$

where

$${}_1k_f = {}_1k^0 \exp\{[-(\alpha n_0)_1 F/RT](E - E^0_1)\},$$
$${}_2k_f = {}_2k^0 \exp\{[-(\alpha n_0)_2 F/RT](E - E^0_2)\} .$$

The current must also obey the equation

$$i = -FV\left(\frac{n_{11}k_f + n_2 {}_2k_f}{{}_1k_f + {}_2k_f}\right)\frac{dc_O}{dt} \quad (52)$$

The quantity in brackets in the right-hand side of Eqn. (52) is the instantaneous effective value of n for the mixed reaction. Eqns. (51) and (52) are easily solved:

$$i = FAc^0_O(n_1 {}_1k_f + n_2 {}_2k_f)\exp\left\{\frac{ART}{VFr}\left[\frac{{}_1k_f}{(\alpha n_0)_1} + \frac{{}_2k_f}{(\alpha n_0)_2}\right]\right\} . \quad (53)$$

Plots of Eqn. (53) are given in Fig. 12.

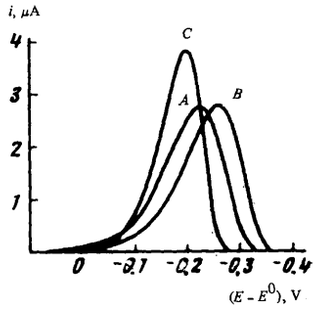

Figure 12. Theoretical voltammetric curves for two parallel reactions: *A*) $E^0_1 = E^0_2 = 0.0$, $(\alpha n_0)_1 = (\alpha n_0)_2 = 0.5$; *B*) $E^0_1 = 0.0$, $E^0_2 = -0.20$, $(\alpha n_0)_1 = (\alpha n_0)_1 = 0.5$; *C*) $E^0_1 = 0.0$, $E^0_2 = 0.20$, $(\alpha n_0)_1 = 0.7$, $(\alpha n_0)_2 = 0.5$. ($n_1 = n_2 = 1$, $k^0 = 10^{-6}$ cm s^{-1}, $c^0_O = 10^{-6}$ mole cm^{-3}, all other parameters as in Fig. 8).

(*g*) Practical applications

The cyclic thin-layer voltammetric method has been used to study the adsorption on platinum of complex ions in the Co^{3+}/Co^{2+}–EDTA‡ and Fe^{3+}/Fe^{2+}–EDTA systems[22]. The Co^{3+}/Co^{2+}–EDTA couple is appreciably irreversible; addition of iodide ions makes the reaction almost reversible (Fig. 13). A probable explanation is that the preferred adsorption of iodide ions causes desorption of the cobalt complexes which inhibit the electrode reaction when they are adsorbed. This property of the iodide ion has been used[22] for the quantitative determination of cobalt complexes, which are readily adsorbed on a smooth platinum surface[38,39]. The full desorption of the cobalt complexes from the platinum surface by the I^- was demonstrated by the following experiment: 0.94 μl of the sample (10^{-3} M CoY^- or CoY^{2-} in 1 M phosphate buffer, pH 7) was introduced into the clean thin-layer cell. The volume of the interelectrode gap was exactly equal to the volume of solution. The distance between the electrodes was first increased to 2–3 mm, and 0.94 μl of 2×10^{-3} M solution of KI was added to the initial solution. The volume of the gap was then decreased to 1.88 μl, and the cobalt complexes were determined. The results are given in Table 3.

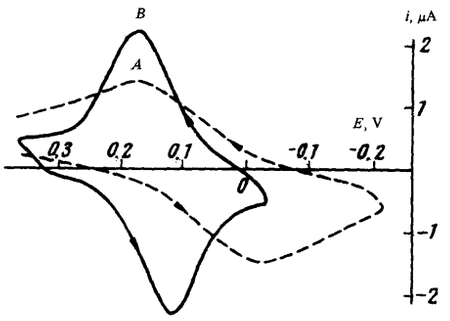

Figure 13. Single-cycle thin-layer voltammetric curve for Co^{3+} and Co^{2+} complexes with EDTA: *A*) without added iodide, 1.77×10^{-3} ml of 1.0 mM Co^{3+}–EDTA in 1 M (pH 7) phosphate buffer; *B*) with added iodide, 1.4×10^{-3} ml of 1.0 mM Co^{3+}–EDTA in 1 M $NaClO_4$ (pH 5) + 1.0×10^{-3} ml 2.0 nM solution of KI. Sweep rate 2 mV s^{-1}.

Table 3. Desorption of CoY^- and CoY^{2-} from a platinum surface by iodide ions.

No. of experiments	total quantity of electricity measured experimentally, Q_{tot} microcoulombs	quantity of electricity in blank experiment, Q_x microcoulombs	$Q_{tot} - Q_x$ microcoulombs	theoretical value of Q microcoulombs
Reduction of CoY^- (Co^{3+}-EDTA)				
6	106±3	14±2	92±5	91
Oxidation of CoY^{2-} (Co^{2+}-EDTA)				
5	115±6	24±2	91±8	91

The scanning range of potential was from 0.25 to −0.05 V (relative to the normal calomel electrode) in the first case, from 0.00 to 0.3 V in the second case. The Q_x values were obtained by repeating the experiment with a solution of phosphate buffer to which no depolariser had been added. The fact that the cobalt complex is completely reduced indicates that the iodide ion itself has no electrochemical activity in this range of potentials.

‡EDTA is ethylenediaminetetra-acetate.

Conversely, the Fe^{3+}/Fe^{2+}–EDTA system is reversible even in the absence of iodide ions. Thus, the displacement of adsorbed ions by more surface-active particles can be used for the quantitative study of the adsorption of ions under thin-layer conditions.

Thin-layer voltammetry has been applied to the study of the stoichiometry of the electrochemical oxidation of $PtCl_4^{2-}$ and $PtBr_4^{2-}$, of the reduction of $PtCl_6^{2-}$ and $PtBr_6^{2-}$, and also of their hydrolysis products[40]. It has been shown that in acid solution the reduction of $PtCl_6^{2-}$ proceeds to the stage of $PtCl_4^{2-}$, and in neutral solutions or solutions free from chloride ions the reduction goes to metallic platinum. The reduction of $PtBr_6^{2-}$ in 1 M bromide solutions goes to $PtBr_4^{2-}$, and in acid solutions or solutions free from bromide ions the reduction goes to Pt. The oxidation of $PtCl_4^{2-}$ in 1 M chloride solutions apparently gives a mixture of $PtCl_6^{2-}$ and $Pt(OH)_2Cl_4^{2-}$, whereas the oxidation of $PtBr_4^{2-}$ in 1 M bromide solutions gives only $PtBr_6^{2-}$. It was also found that the hydrolysis products of $PtCl_6^{2-}$ and $PtBr_6^{2-}$ are reduced with greater ease than their parent complexes.

Thin-layer studies with a very slow voltage scan[34] give valuable information on the mechanism of electrode reactions.

Because of the lower current densities employed, the reversibility of the Cr^{3+}–Cr^{2+} couple under the conditions of thin-layer voltammetry is much better ($E_c = -0.8$, $E_a = -0.6$ V NCE) than under semi-infinite diffusion conditions ($E_c = -0.95$, $E_a = -0.45$ V NCE).[8]

The application of thin-layer voltammetry to the electrolytic oxidation of bivalent platinum complexes of the $Pt(NH_3)_m(NO_2)_{4-m}^{m-2}$ and $Pt(NH_3)_mCl_{4-m}^{m-2}$ type has shown[41,42] that the process is strongly catalysed by free chloride and iodide ions, and that some of the ligands in the reaction product (i.e. the Pt^{IV} complex) are replaced by chloride ions. In the absence of free chloride ions the reactivity of these complexes is strongly reduced.

3. Stead-state Current Method

The existence of a limiting diffusion current depends on the establishment of a steady-state concentration polarisation.

A limiting diffusion current is observed when the thickness of the diffusion layer does not change with time. These conditions are realised at a dropping mercury electrode or at a solid electrode moving relative to the solution. Paired, thin-layer electrolytic cells also enable a constant concentration gradient to be set up; the value of the gradient can be controlled by varying the interelectrode spacing.

Material obtained by reduction at one electrode of a paired cell can diffuse and be oxidised at the other working electrode. Since these processes take place in a closed system, a steady-state current can be obtained.

The formation of the steady-state current i_{ss} is illustrated in Fig. 14.[43] Initially, the potential applied to the working electrodes is made sufficiently negative to ensure that the solution is depleted of the oxidised form O. If the potential of one of the electrodes (the anode) is shifted towards positive values, oxidation of R will begin at some value of the anode potential; the concentration of the oxidised form will increase, and the concentration of the reduced form will decrease. The flow of each form across the thin layer towards the appropriate electrode can be expressed in terms of its surface concentration:

$$\frac{i_{ss}}{nFA} = D_R\frac{(c_R)_{x=0} - (c_R)_{x=l}}{l} = D_O\frac{(c_O)_{x=l}}{l} \quad (54)$$

The total number of moles of O and R contained in the thin layer between the electrodes is constant: $N_O + N_R = N$. Hence

$$\frac{lA\,(c_O)_{x=l}}{2} + \frac{lA\,[(c_R)_{x=0} + (c_R)_{x=l}]}{2} = N. \quad (55)$$

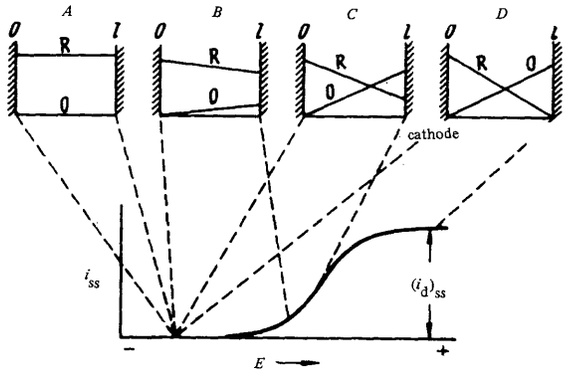

Figure 14. Schematic illustration of the formation of a steady-state current by reference to the concentration profiles of O and R in a thin layer for gradually increasing values of E at one of the electrodes (anode).

Solving Eqns. (54) and (55) simultaneously we obtain

$$(c_O)_{x=l} = \frac{i_{ss}l}{nFAD_O}, \quad (56)$$

$$(c_R)_{x=l} = -\frac{i_{ss}l}{2nFA}\left(\frac{1}{D_R} + \frac{1}{D_O}\right) + \frac{N}{lA}, \quad (57)$$

$$(c_R)_{x=0} = \frac{i_{ss}l}{2nFA}\left(\frac{1}{D_R} - \frac{1}{D_O}\right) + \frac{N}{lA}. \quad (58)$$

When the anode potential becomes sufficiently positive $(c_R)_{x=l}$ vanishes and the current tends to a maximum value $(i_d)_{ss}$. Hence it follows from Eqn. (56) that

$$(i_d)_{ss} = \frac{nFADc}{l}$$
$$\text{where } c = c_O + c_R, \text{ and } D = \frac{2D_OD_R}{D_O + D_R}. \quad (59)$$

Thus, the limiting steady-state current is directly proportional to a function of the diffusion coefficients of the oxidised and the reduced form, the total concentration, and the electrode area, and inversely proportional to the distance between the electrodes.

(*a*) Determination of the kinetic parameters of an electron transfer reaction

Steady-state currents can be used to determine the electron transfer rate constant k_s and the transfer coefficient α. In its most general form, the variation of the current with anode potential is given by

$$i_{ss} = nFAk_s\left\{(c_R)_{x=l}\exp\frac{(1-\alpha)\,nF\,(E-E^0)}{RT} + (c_O)_{x=l}\exp\left[\frac{-\alpha nF\,(E-E^0)}{RT}\right]\right\}. \quad (60)$$

Replacing $\exp[-nF/RT(E-E^0)]$ by θ, and $(cO)_{x=l}$ and $(cR)_{x=l}$ by their values given by Eqns. (56) and (57), we obtain after some simplification

$$\frac{1}{\theta^{\alpha-1}lk_s}+\frac{\theta}{D_O}=\left[\frac{(i_d)_{ss}-i_{ss}}{i_{ss}}\right]\left(\frac{D_O+D_R}{2D_OD_R}\right) \quad (61)$$

This equation describes the variation of the steady-state current with anode potential when the concentration of the oxidised form at the cathode is zero, i.e. $(cO)_{x=0}=0$. Analogous expressions can be obtained for the cathode. If the second term in the left-hand side of Eqn. (61) is much greater than the first (i.e. if k_S is large) this equation reduces to the equation which describes the reversible behaviour of the material:

$$E_{anode}=E^0-\frac{RT}{nF}\ln\left(\frac{1}{2}+\frac{D_O}{2D_R}\right)-\frac{RT}{nF}\ln\left[\frac{(i_d)_{ss}-i_{ss}}{i_{ss}}\right]. \quad (62)$$

If, on the other hand, the first term in the left-hand side of Eqn. (61) is predominant (k_S small), the resulting equation describes the fully irreversible behaviour of the substance under study:

$$E_{anode}=E^0-\frac{RT}{(1-\alpha)nF}\ln\left[\frac{lk_s(D_O+D_R)}{2D_OD_R}\right]-\frac{RT}{(1-\alpha)nF}\ln\left[\frac{(i_d)_{ss}-i_{ss}}{i_{ss}}\right]. \quad (63)$$

The electron transfer rate constant k_S can be evaluated by plotting $\lg\left[\frac{(i_d)_{ss}-i_{ss}}{i_{ss}}\right]$ against E. The plot is a straight line of slope $2.3RT/(1-\alpha)nF$, intersecting the horizontal axis at the potential

$$E^0-[2.3RT/(1-\alpha)nF]\lg\{[lk_s(D_O+D_R)]/2D_OD_R\}.$$

As in other methods, k_S can be found if E^0 is known. To find the rate constant k_S we may use the following approach. If the quantity $\left[\frac{(i_d)_{ss}-i_{ss}}{i_{ss}}\right]$ is plotted against $1/l$ for a series of anodic potentials, we should obtain (according to Eqn. (61)) a family of straight lines of slope $2D_OD_R/[\theta^{\alpha-1}k_S(D_O+D_R)]$, intersecting the vertical axis at the ordinate $2D_R\theta/(D_O+D_R)$. When the intercept is equal to $2D_R/(D_O+D_R)$, and therefore $\theta=1$, the value of k_S can be found from the slope at $E=E^0$. The value of α can then be found from the other curves.

(b) Determination of the diffusion coefficient

Since the steady-state current, according to Eqn. (54), depends on the diffusion coefficients of the oxidised and the reduced form, the equation can be used to evaluate these coefficients. If the concentrations of the oxidised form at $x=0$ and of the reduced form at $x=l$ are zero, Eqn. (54) can be re-written

$$(i_d)_{ss}=nFAD_R\frac{(c_R)_{x=0}}{l}=nFAD_O\frac{(c_O)_{x=l}}{l}. \quad (64)$$

Eqn. (64) can be used to determine the diffusion coefficients from a knowledge of the limiting steady-state current, the concentrations at the electrodes, the electrode area, and the distance between the electrodes. The number of moles of O and R in the thin layer can be measured coulometrically. If one of the electrodes of the thin-layer cell is disconnected (for example, the anode) the current will flow only to the cathode and as long as oxidised material remains in the thin layer. By measuring the quantity of electricity used in the reduction of O, and inserting $Q_c=nFAlc_O$ in Eqn. (64), we obtain

$$D_O=(i_d)_{ss}^2/2Q_c \quad (65)$$

D_R can be expressed in a similar way.

The numerical values of the diffusion coefficients are obtained from the slopes of plots of l against $1/i_{SS}$ and l against Q. The diffusion coefficients for Fe^{2+} and Fe^{3+} in 0.1 M $HClO_4$, measured by this method, are 0.421×10^{-5} and 0.392×10^{-5} cm^2 s^{-1} respectively; those for benzoquinone and hydroquinone in 0.3 M $HClO_4$ are 1.15×10^{-5} and 1.16×10^{-5} cm^2 s^{-1}.

(c) Determination of the rate constants of chemical reactions

The rate constants of chemical reactions can be determined from measurements of steady-state currents.

For slow chemical reactions of the type

$$O+ne\rightleftharpoons R;\ mR+pZ\xrightarrow{k}F$$

we can use the expression

$$i_{ss}=nFAlk(R_{ss})^m(Z)^p \quad (66)$$

where R_{SS} is the steady-state concentration of the reduced form. Under normal conditions ($n=2$, $lA=2\times10^{-3}$, $k(Z)^p=10^{-1}$, $R_{SS}=10^{-6}$) the system will reach steady state in 10 s for a current of 4×10^{-5} A. R_{SS} can be evaluated by anodic scanning and integration of the current associated with the fast oxidation of the substance R. Introducing into Eqn. (66) the quantity of electricity Q_R consumed by the oxidation of R_{SS}, we can write

$$i_{ss}=nFAk\left(\frac{Q_R}{nFA}\right)^m(Z)^p\left(\frac{1}{l^{m-1}}\right). \quad (67)$$

If the reaction is of the first order with respect to R, it follows from Eqn. (67) that the slope of the plot of Q_R against i_{SS} is independent of l. In this case we can determine p from experiments at different concentrations of the component Z, and hence we can arrive at the rate constant.

If the kinetic order of the reaction is 2 or more, the slope of plots of $(Q_R)^m$ against i_{SS} is a function of l, but the dependence is always one order less than in plots of $(R_{SS})^m$ against i_{SS}, as in Eqn. (66). The upper limit of the rate of a pseudo-first order reaction, measured by this method, depends on the rate of diffusion. Assuming that the concentration of R must be constant to within 1% the highest value of k which can be measured by this method is 10^{-1} s^{-1}.

To measure very small reaction rates, we need a high concentration (R_{SS}) and a large interelectrode distance, so as to raise i_{SS} above the level of the background current. For the highest reasonable values ($R_{SS}=10^{-6}$ mole cm^{-3} and $l=2\times10^{-2}$ cm), and assuming that the smallest measurable current is $i_{SS}=10^{-6}$ A, the smallest rate constant which can be determined by this method is 0.5×10^{-3} s^{-1}.

The rates of slow reaction can be studied also by a different method: the method of current decay in the pseudo-stationary state. The electrode potentials of a thin-layer cell are fixed on either side of the equilibrium potential of the redox couple (R–O) in order to establish a limiting steady-state current proportional to the concentration of R.

If the concentration of Z is constant, the current i_{SS} will fall according to the law which describes the rate of

a reaction of the m-th order. Hence, for $m = 1$, the function $i_{SS} = f(t)$ should be of the form

$$\ln \frac{(i_d)_{ss}}{nFAD_R} = -\frac{k(Z)^p t}{(D_R/D_O + 1)} . \quad (68)$$

The upper limit of reaction rate which can be measured by this method is the same as for the previous method. However, there is no lower limit in this case because the steady-state current can be monitored as long as necessary.

Steady-state currents can be used also to measure the rate constants of fast and intermediate bimolecular reactions of the type

$$\begin{aligned} A + ne &\rightarrow B \qquad x = 0 \\ C &\rightarrow D + ne \qquad x = l \\ B + D &\xrightarrow{k} A + C \qquad 0 < x < l . \end{aligned}$$

Measurements of the steady-state current i_{SS} as a function of time offer the possibility of continuous control of chemical reactions leading to changes in the concentration of O and R in the thin layer.

This approach has been used to measure the rate constants of a number of reactions [44,45]. McDuffie and coworkers [44] applied the principle in their work on the rate of the benzidine rearrangement, which occurs by the mechanism

$$O \underset{-ne}{\overset{+ne}{\rightleftharpoons}} R \xrightarrow{k} P .$$

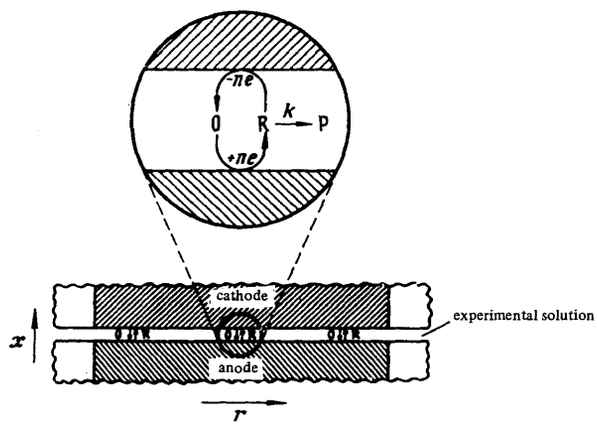

Figure 15. Cross-section of a thin-layer cell with paired electrodes.

A solution of azobenzene of known acidity, ionic strength, and ethanol concentration is added to the thin-layer cell. In order to obtain the limiting steady-state current, the electrode potentials are set so that the concentrations of O and R at the appropriate surface are both zero (Fig. 15). This current falls off exponentially with time, because the species R is consumed in the pseudo-first order irreversible rearrangement. The steady-state current is related to the concentrations of electrically active substances by the expression

$$i_{ss} = \frac{2nFAc}{l}\left(\frac{D_O D_R}{D_O + D_R}\right) \quad (69)$$

where $c = cO + cR$.

The mutual interconversion of O and R takes place at opposite electrodes. It is assumed that mass transfer is much faster than the chemical rearrangement, i.e. $(D/l^2) \gg k$, where $D = DO + DR$.

Under these conditions the distribution of O and R between the electrodes is effectively linear. The rate of a pseudo-first order chemical reaction is

$$\frac{dc_P}{dt} = \frac{dc}{dt} = kc_P . \quad (70)$$

Since the flows to the two electrodes are equal under quasi-steady state conditions, $DOcO = DRcR$. Hence, cR, which is equal to $(c - cO)$, can be expressed as

$$c_R = \frac{c}{1 + D_R/D_O} . \quad (71)$$

Inserting this expression into Eqn. (70), and integrating, we obtain

$$\ln\left(\frac{c}{c^0}\right) = -\frac{kt}{1 + D_R/D_O} \quad (72)$$

where c^0 is the total concentration of O and R at time $t = 0$. Replacing concentrations by currents (see Eqn. (69)) we obtain an expression for the decrease in current:

$$\ln(i_{ss}/i_{ss}^0) = -\frac{kt}{1 + D_R/D_O} . \quad (73)$$

The rate constant for the decay of the steady-state current is

$$k/(1 + D_R/D_O) .$$

If $D_R = D_O$, the rate constant for the current decay is $k/2$, and the plot of $\lg i_{SS}$ against t is a straight line of slope $-k/4.606$ for a pseudo-first order reaction.

Thus, the measurement of rate constants from the decay of the steady-state current i_{SS} is independent of the parameters of the thin-layer cell and of the initial concentration of the material. The experimental values of the rate constant for the acid-catalysed benzidine rearrangement, using the steady-state current decay method, are 0.113 s^{-1} in 0.25 M $HClO_4$, 0.0422 s^{-1} in 0.15 M $HClO_4$, 0.0223 s^{-1} in 0.1 M $HClO_4$, and 9.0×10^{-3} s^{-1} in 0.063 M $HClO_4$. These values are in good agreement with measurements [18] of k for the benzidine rearrangement by the thin-layer potentiostatic method (0.02 s^{-1} in 0.0997 M $HClO_4$ and 0.0086 s^{-1} in 0.063 M $HClO_4$).

The steady-state current decay method can be used also to measure the rate constants of second-order reactions. As an example, McDuffie and Reilley [45] consider the disproportionation of quinquevalent uranium in perchloric acid:

$$\begin{array}{ccc} O & \overset{e}{\rightleftharpoons} & R \\ \uparrow & & \downarrow \\ 2R & \longrightarrow & aO + (2-a)Z \end{array} .$$

Another possible example is dimerisation, when O is not regenerated. These second-order systems are difficult to investigate by the usual electrochemical methods [46–49] because of the need to use non-linear differential equations, for which analytical solutions are not available, in the interpretation of the results.

III. SPECIAL FEATURES AND SCOPE OF THIN-LAYER ELECTROCHEMISTRY

1. Edge Effect

One of the special features of thin-layer electrochemistry is the presence of an edge effect, i.e. the effect of diffusion of electrically active substances from the bulk of the solution into the narrow gap between the working electrodes or between the working electrode and the inert substrate. The edge effect is responsible for an appreciable fraction of the residual current in the thin-layer cell. The error introduced by the edge effect into the observed steady-state current is proportional to the total excess number of moles of O and R (N_{exc}) in the thin layer of solution at time t.

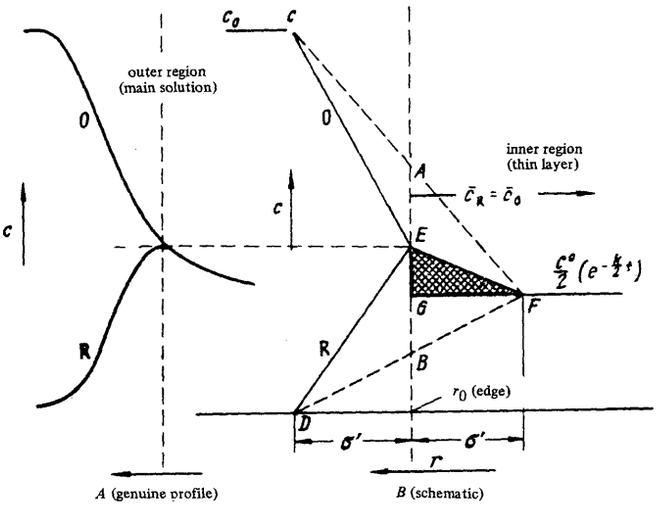

Figure 16. Schematic representation of the concentration profiles of O and R in the thin layer, used in the definition of the edge effect.

The quantity N_{exc} depends on the combined rates of diffusion of both forms of the material from the main bulk of the solution through the cylindrical edge of the thin layer. This rate of diffusion, in turn, depends on the concentration gradients of the electrically active species in the thin-layer region. It is very difficult to allow for all these conditions in a calculation of the contribution of the edge effect to the observed steady-state current. However, an approximate calculation can be made using a simplified model[44]. Immediately after the application of the potential difference ΔE the average concentration of the two forms in the thin layer is $c^0/2$, and there is no nett flow of material into the thin layer. After time t the concentration profile in the region of the edge of a thin-layer element of volume (of radius r_0) can be assumed to be of the type shown in Fig. 16. The concentration distribution is plotted for a point on the x-axis at $l/2$. In the central region of the thin-layer volume ($r/2$) the concentrations of R and O show an exponential decrease which is not distorted by the edge effect. In the schematic diagram the excess of material (N_{exc}) is found mainly in the concentration region within the triangle EGF, which penetrates from the edge into the thin layer to a depth σ^1. The region of excess concentration has the volume $\pi l[r_0^2 - (r_0 - \sigma^1)^2]$ or $\pi l\sigma^1 - (2r_0 - \sigma^1)$. The total excess of O and R, c_{exc}, can be expressed

$$c_{exc} = (c_{edge} - c_{centre})/2 \qquad (74)$$

where c_{edge} and c_{centre} denote the mean combined concentrations (O + R) at $r = r_0$ and $r = 0$ respectively. Point E is taken half-way between points A and B, and from the condition that c_{edge} can be obtained by doubling c_R or c_O at the point E we find

$$c_{edge} = (c^0 + c_{centre})/2 \, . \qquad (75)$$

Using the expression

$$c_{centre} = c^0 e^{-(k/2)t},$$

we obtain

$$c_{exc} = \frac{c^0}{4}[1 - e^{-(k/2)t}] \, . \qquad (76)$$

Multiplying Eqn. (76) by the volume,

$$N_{exc} = \frac{c^0}{4}[1 - e^{-(k/2)t}]\pi l\sigma'(2r_0 - \sigma') \qquad (77)$$

and after dividing by $N^0 = c^0\pi l r_0^2$ we arrive at

$$\frac{N_{exc}}{N^0} = [1 - e^{-(k/2)t}]\left(\frac{\sigma'}{2r_0}\right)\left(1 - \frac{\sigma'}{2r_0}\right). \qquad (78)$$

Since the limiting steady-state current is proportional to the number of moles in the thin layer of solution[43], and since σ' is approximately equal to $2(Dt/\pi)^{1/2}$, we finally obtain the equation for the relative error in the current:

$$\frac{i_{ss\ (error)}}{i^0_{ss}} = \left\{[1 - e^{-(k/2)t}]\left(\frac{Dt}{\pi r_0^2}\right)^{1/2}\left[1 - \left(\frac{Dt}{\pi r_0^2}\right)^{1/2}\right]\right\}. \qquad (79)$$

The edge effect can be minimised by increasing the radius of the working electrode. However, errors due to lack of parallelism between the electrodes become predominant above a certain electrode size. An alternative approach is to fit a plastic ring round the periphery of the thin layer, but in this case it becomes impossible to use an auxiliary and a standard electrode.

2. Influence of Lack of Parallelism and of Surface Roughness of the Working Electrode

A knowledge of the effective thickness l of the layer of solution is essential in all experiments with thin-layer electrolytic cells. The largest steady-state currents are obtained with the smallest layer thicknesses. Furthermore, the electrode separation determines the number of moles of O and R in the thin layer of solution. Both these effects can be perturbed by lack of parallelism and of smoothness in the electrode surfaces. Any roughness protruding into the layer of solution decreases the average thickness of the layer[43], and may decrease i_{ss} by a large amount. The effect of deviations from the ideal plane-parallel geometry of the electrodes can be discussed in terms of the simple model shown in Fig. 17. Using Eqn. (55) we obtain the following equation for the dependence of i_{ss} on $1/l$

$$(i_d)_{ss} = \int_0^a \frac{anFD\,(c_{R_{ss}})_{x=0}}{(l-q) + 2q/ay}\,dy = \frac{a^2nFD\,(c_{R_{ss}})}{2q}\ln\left(\frac{l+q}{l-q}\right). \qquad (80)$$

The equation has been tested, and found to be sufficiently accurate for $l \ll 4q$.

When $l = 4q$ the value of $(id)_{ss}$ calculated by Eqn. (80) is 91% of the ideal value (calculated by Eqn. (64)). These calculations suggest that the effects arising from lack of parallelism can be reduced to an acceptable minimum.

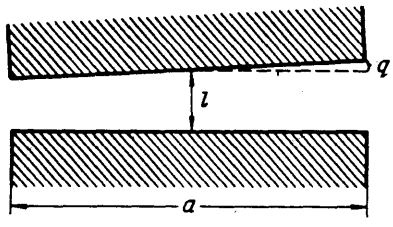

Figure 17. Lack of parallelism between the electrodes of a thin-layer electrolytic cell.

3. Scope and Advantages of the Methods of Thin-layer Electrochemistry

The main advantages of the methods of thin-layer electrochemistry were mentioned in the theoretical discussion given in the previous Sections. The most obvious attractions of thin-layer electrochemistry are the shorter analysis times and the very small volumes of solution needed.

The thin-layer electrochemical cell with a pair of working electrodes can also be used successfully when one of the reactions is hindered by the insoluble product of the other reaction. For example, if I^- and Cl^- ions are present in solution, one of the working electrodes can be used to accommodate a film of Hg_2I_2 (using mercury or an amalgam electrode), and the chloride ion is subsequently deposited on the other electrode.

Like the rotating-disk method with guard ring, the thin-layer methods are particularly useful for studies of chemical reactions preceding or following the electrode reaction, for monitoring short-lived intermediate states of the products of the electrode reaction, and for studying adsorption on the electrode surface.

Thin-layer methods show special promise in the study of adsorption processes, because they offer the possibility of working with such small volumes and concentrations that the total number of moles contained in the interelectrode gap need not be greater than the amount of material adsorbed on the electrode surface.

Thin-layer electrochemistry offers a convenient method of measuring the number n of electrons which take part in the electrode reaction, because the diffusion coefficient need not be known if n is measured by thin-layer chronopotentiometry.

Another potential advantage of thin-layer electrochemistry is the absence of hydrodynamic motion in the solution: as a result, the intermediate products of the reaction are not removed from the sphere of action by convection. The rate of supply of material by diffusion can be varied by varying the distance between the electrodes, and can be made very large. By using optically flat surfaces, the thickness of the diffusion layer can be made as small as 0.1 μm. [50] This is an order of magnitude less than the thickness of the diffusion layer for the rotating electrode (for $D = 10^{-5}$ cm^2 s^{-1}, and with a speed of rotation of 6000 r.p.m., the thickness of the diffusion layer can be reduced only to 5μm).

The use of thin-layer methods in studies of bimolecular reactions also deserves a mention.

When a pair of electrodes of different metals is used, each of the electrodes can be used in the most favourable conditions. Some other advantages of the thin-layer method are mentioned by Andersen and coworkers [51].

IV. PRACTICAL APPLICATIONS OF THIN-LAYER ELECTROCHEMISTRY

In addition to their applications (already mentioned) in the measurement of the rate of chemical reactions [1,16,20,42-45], the study of adsorption processes [3,22-24], the study of irreversibility in electrode reactions [8,24,34,43], the determination of the number of electrons involved in reactions in aqueous and non-aqueous media [2,4,40] and of diffusion coefficients [13,43,44], thin-layer methods can be used to enhance the sensitivity of analytical methods by dissolving weighed amounts of solute in very small volumes of solvent [7,9,52].

Using the equation for the limiting steady-state current $(id)_{ss}$

$$\frac{N}{lA} = \frac{(i_d)_{ss} l}{2nFA}\left(\frac{1}{D_R} + \frac{1}{D_O}\right) \qquad (81)$$

where N is the total number of moles of the oxidised and the reduced form, we can readily calculate the lower concentration limit for a one-electron reaction.

It can be seen from Eqn. (81) that $(id)_{ss}$ is proportional to the total number of moles in the thin layer and inversely proportional to the distance between the electrodes. If the steady-state current is set at 1 μA, and $l = 10^{-3}$ cm, we find that $N/lA = 10^{-9}$ mole cm^{-3} for $D_R = D_O$ (usually $\sim 10^{-5}$ cm^2 s^{-1}).

Thin-layer cells can be used also in combined electrochemical and spectral studies, which offer a powerful means of investigating the nature of electrolysis products [10,11,53].
